Preface

- Organization and Content: What's New in the Ninth Edition
- Part One: Central Concepts of Pathophysiology: Cells and Tissues
- Part Two: Pathophysiologic Alterations: Organs and Systems
- Features to Promote Learning
- Art Program

Ancillaries

Acknowledgments

Part One: Central Concepts of Pathophysiology: Cells and Tissues

Unit I: The Cell

1. Cellular Biology

Chapter Outline

Prokaryotes and Eukaryotes

Cellular Functions

Structure and Function of Cellular Components

Cell-to-Cell Adhesions

Cellular Communication and Signal Transduction

Cellular Metabolism

Membrane Transport: Cellular Intake and Output

Cellular Reproduction: The Cell Cycle

Tissues

Summary Review

References

2. Altered Cellular and Tissue Biology: Environmental Agents

Chapter Outline

Cellular Adaptation

Cellular Injury

Manifestations of Cellular Injury

Cellular Death

Aging and Altered Cellular and Tissue Biology

Somatic Death

Summary Review

References

3. The Cellular Environment: Fluids and Electrolytes, Acids and Bases

Chapter Outline

Distribution of Body Fluids

Aging and Distribution of Body Fluids

Alterations in Water Movement

Alterations in Sodium, Water, and Chloride Balance

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

ACID-Base Balance

Summary Review

References

Unit II: Genes and Gene-Environment Interaction

4. Genes and Genetic Diseases

Chapter Outline

DNA, RNA, and Proteins: Heredity at the Molecular Level

Chromosomes

Elements of Formal Genetics

Transmission of Genetic Diseases

Linkage Analysis and Gene Mapping

Summary Review

References

5. Genes, Environment-Lifestyle, and Common Diseases

Chapter Outline

Factors Influencing Incidence of Disease in Populations

Principles of Multifactorial Inheritance

Nature and Nurture: Disentangling the Effects of Genes and Environment

Genetics of Common Diseases

Summary Review

References

6. Epigenetics and Disease

Chapter Outline

Overview of Epigenetic Mechanisms

Epigenetic Mechanisms

Three Types of Epigenetic Processes

Exploring the Multigenerational Persistence of Epigenetic States

Epigenetic Change Over the Lifespan

Tools for Exploring Epigenetic States

Epigenetics and Cancer

Epigenetics and Covid-19

Epigenetic Modification of mRNA

Future Directions

References

Unit III: Mechanisms of Self-Defense

7. Innate Immunity Inflammation and Wound Healing

Chapter Outline

Innate Immunity

First Line Of Defense: Physical and Biochemical Barriers and the Human Microbiome

Second Line of Defense: Inflammation

Wound Healing

Summary Review

References

8. Adaptive Immunity

Chapter Outline

Overview of Adaptive Immunity

Antigens

Lymphocyte Development

Induction of the Immune Response

Humoral Immunity

Cell-Mediated Immunity

Immunologic Memory

Summary Review

References

9. Alterations in Immunity

Chapter Outline

Hypersensitivity Reactions

Deficiencies in Immunity

Summary Review

References

10. Infection

Chapter Outline

Microorganisms and Humans: A Dynamic Relationship

Infectious Disease

Antibiotic/Antimicrobial Resistance

Vaccines and Protection Against Infection

Summary Review

References

11. Stress and Disease

Chapter Outline

Background and General Concepts of Stress

The Stress Systems

The Impact of Chronic Stress Across the life Span

Coping and Intervention Strategies

Summary Review

References

Unit IV: Cellular Proliferation: Cancer

12. Cancer Biology

Outline

Cancer Terminology and Characteristics

The Biology of Cancer Cells

Activating Invasion and Metastasis

Clinical Manifestations of Cancer

Diagnosis and Staging of Cancer

Treatment of Cancer

Targeted Disruption of Cancer

Summary Review

References

13. Cancer Epidemiology

CHAPTER Outline

Incidence, Mortality Trends, and Race

Genetics, Epigenetics, Tumor Microenvironment, and Cellular Signaling in Cancer

In Utero and Early Life Conditions

Environmental-Lifestyle Factors

Summary Review

References

14. Cancer in Children and Adolescents

Chapter Outline

Incidence and Types of Childhood Cancer

Etiology

Prognosis

Summary Review

References

Part Two: Structure, Function, and Pathophysiologic Alterations: Organs and Systems

Unit V: The Neurologic System

15. Structure and Function of the Neurologic System

Chapter Outline

Overview and Organization of the Nervous System

Cells of the Nervous System

Nerve Impulse

Central Nervous System

Blood Supply

Peripheral Nervous System

Autonomic Nervous System

Tests of Nervous System Structure and Function

Summary Review

References

16. Pain, Temperature Regulation, Sleep, and Sensory Function

Chapter Outline

Pain

Temperature Regulation

Sleep

The Special Senses

Somatosensory Function

Summary Review

References

17. Alterations in Cognitive Systems, Cerebral Hemodynamics, and Motor Function

Chapter Outline

Alterations in Cognitive Systems

Alterations in Cerebral Hemodynamics

Alterations in Neuromotor Function

Chronic Diseases and Disorders Involving Motor Function

Summary Review

References

18. Alterations of the Brain, Spinal Cord, and Peripheral Nerves

Chapter Outline

Central Nervous System Disorders

Infection and Inflammation of the Central Nervous System

Peripheral Nervous System Disorders

Tumors of the Central Nervous System

Summary Review

References

19. Neurobiology of Schizophrenia, Mood Disorders, Anxiety Disorders, Posttraumatic Stress Disorder, and Obsessive-Compulsive Disorder

Chapter Outline

Schizophrenia

Mood Disorders: Depression And Bipolar Disorder

Anxiety Disorders

Posttraumatic Stress Disorder

Obsessive-Compulsive Disorder

Summary Review

References

20. Alterations of Neurologic Function in Children

Chapter Outline

Development of the Nervous System in Children

Structural Malformations

Alterations In Function: Encephalopathies

Cerebrovascular Disease in Children

Epilepsy and Seizure Disorders in Children

Childhood Tumors

Summary Review

References

Unit VI: The Endocrine System

21. Mechanisms of Hormonal Regulation

- Chapter Outline
- Mechanisms of Hormonal Regulation
- Structure and Function of the Endocrine Glands
- Aging and the Endocrine System
- Summary Review
- References

22. Alterations of Hormonal Regulation

- Chapter Outline
- Mechanisms of Hormonal Alterations
- Alterations of the Hypothalamic–Pituitary System
- Alterations of Thyroid Function
- Alterations of Parathyroid Function
- Dysfunction of the Endocrine Pancreas: Diabetes Mellitus
- Alterations of Adrenal Function
- Summary Review
- References

23. Obesity, Starvation, and Anorexia of Aging

Chapter Outline

Adipose Tissue

Obesity

Starvation

Anorexia of Aging

Summary Review

References

Unit VII: The Reproductive Systems

24. Structure and Function of the Reproductive Systems

Chapter Outline

Development of the Reproductive Systems

The Female Reproductive System

Structure and Function of the Breast

The Male Reproductive System

Tests of Reproductive Function

Aging and Reproductive Function

Summary Review

References

25. Alterations of the Female Reproductive System

Chapter Outline

Abnormalities of the Female Reproductive Tract

Alterations of Sexual Maturation

Disorders of the Female Reproductive System

Disorders of the Female Breast

Summary Review

References

26. Alterations of the Male Reproductive System

Chapter Outline

Alterations of Sexual Maturation

Disorders of the Male Reproductive System

Disorders of the Male Breast

Summary Review

References

Online References

27. Sexually Transmitted Infections

Chapter Outline

Sexually Transmitted Urogenital Infections

Sexually Transmitted Infections of other body Systems

Summary Review

References

Unit VIII: The Hematologic System

28. Structure and Function of the Hematologic System

Chapter Outline

Components of the Hematologic System

Development of Blood Cells

Mechanisms of Hemostasis

Clinical Evaluation of the Hematologic System

Pediatrics and the Hematologic System

Aging and the Hematologic System

Summary Review

References

29. Alterations of Hematologic Function

Chapter Outline

Anemia

Myeloproliferative Red Cell Disorders

Alterations of Leukocyte Function

Alterations of Lymphoid Function

Alterations of Splenic Function

Hemorrhagic Disorders and Alterations of Platelets and Coagulation

Summary Review

References

30. Alterations of Hematologic Function in Children

Chapter Outline

Fetal and Neonatal Hematopoiesis

Postnatal Changes in the Blood

Disorders of Erythrocytes

Disorders of Coagulation and Platelets

Neoplastic Disorders

Summary Review

References

Unit IX: The Cardiovascular and Lymphatic Systems

31. Structure and Function of the Cardiovascular and Lymphatic Systems

Chapter Outline

Circulatory System

Heart

Structures that Direct Circulation Through the Heart

Heart Wall

Great Vessels

Chambers of the Heart

Valves of the Heart

Fibrous Skeleton of the Heart

Intracardiac Pressures

Blood Flow during the Cardiac Cycle

Structures that Support Cardiac Metabolism: Coronary Circulation

Structures that Control Heart Action

Factors Affecting Cardiac Output

Systemic Circulation

Lymphatic System

Tests of Cardiovascular Function

Cardiac and Coronary Artery Evaluation

Systemic Vascular Evaluation

Aging and the Cardiovascular System

Summary Review

References

32. Alterations of Cardiovascular Function

Chapter Outline

Diseases of the Veins

Diseases of the Arteries

Disorders of the Heart Wall

Manifestations of Heart Disease

Summary Review

References

33. Alterations of Cardiovascular Function in Children

Chapter Outline

Congenital Heart Disease

Acquired Cardiovascular Disorders

Summary Review

References

Unit X: The Pulmonary System

34. Structure and Function of the Pulmonary System

Chapter Outline

Structures of the Pulmonary System

Function of the Pulmonary System

Tests of Pulmonary Function

Summary Review

References

35. Alterations of Pulmonary Function

Chapter Outline

Clinical Manifestations of Pulmonary Alterations

Disorders of the Chest wall and Pleura

Pulmonary Disorders

Summary Review

References

36. Alterations of Pulmonary Function in Children

Chapter Outline

Disorders of the Upper Airways

Disorders of the Lower Airways

Sudden Infant Death Syndrome

Summary Review

References

Unit XI: The Renal and Urologic Systems

37. Structure and Function of the Renal and Urologic Systems

Chapter Outline

Structures Of The Renal System

Renal Blood Flow and Glomerular Filtration

Kidney Function

Tests of Renal Function

Pediatric Considerations

Geriatric Considerations

Summary Review

References

38. Alterations of Renal and Urinary Tract Function

Chapter Outline

Urinary Tract Obstruction

Urinary Tract Infection

Glomerular Disorders

Acute Kidney Injury

Chronic Kidney Disease

Summary Review

References

39. Alterations of Renal and Urinary Tract Function in Children

Chapter Outline

Structure and Function of the Urinary System in Children

Alterations in Renal and Bladder Function in Children

Glomerular Disorders

Nephroblastoma

Bladder Disorders

Urinary Incontinence

Summary Review

References

Unit XII: The Digestive System

40. Structure and Function of the Digestive System

- Chapter Outline
- The Gastrointestinal Tract
- Accessory Organs of Digestion
- Tests of Digestive Function
- GERIATRIC CONSIDERATIONS
- Summary Review
- References

41. Alterations of Digestive Function

- Chapter Outline
- Disorders of the Gastrointestinal Tract
- Disorders of the accessory Organs of Digestion
- Cancer of the Digestive System
- Summary Review
- References

42. Alterations of Digestive Function in Children

- Chapter Outline

Disorders of the Gastrointestinal Tract

Disorders Of The Liver

Summary Review

References

Unit XIII: The Musculoskeletal System

43. Structure and Function of the Musculoskeletal System

Chapter Outline

Structure and Function of Bones

Structure and Function of Joints

Structure and Function of Skeletal Muscles

Tests of Musculoskeletal Function

Geriatric Considerations

Summary Review

References

44. Alterations of Musculoskeletal Function

Chapter Outline

Musculoskeletal Injuries

Disorders of Bones

Disorders of Joints

Disorders of Skeletal Muscle

Muscle Tumors

Summary Review

References

45. Alterations of Musculoskeletal Function in Children

Chapter Outline

Musculoskeletal Development In Children

Musculoskeletal Alterations In Children

Rheumatologic Disorders

Avascular Disease Of The Bone

Musculoskeletal Tumors In Children

Nonaccidental Trauma

Summary Review

References

Unit XIV: The Integumentary System

46. Structure, Function, and Disorders of the Integument

Chapter Outline

Structure and Function of the Skin

Disorders of the Skin

Disorders of the Hair

Disorders of the Nail

Summary Review

References

47. Alterations of the Integument in Children

Chapter Outline

Acne Vulgaris

Dermatitis

Infections of the Skin

Insect Bites and Parasites

Vascular Anomalies

Other Skin Disorders

Summary Review

References

Unit XV: Multiple Interacting Systems

48. Shock, Multiple Organ Dysfunction Syndrome, and Burns in Adults

Chapter Outline

Shock

Multiple Organ Dysfunction Syndrome

Thermal Injury and Burns

Summary Review

References

49. Shock, Multiple Organ Dysfunction Syndrome, and Burns in Children

Chapter Outline

Shock and Multiple Organ Dysfunction Syndrome

Burns

Summary Review

References

Contents

Part One: Central Concepts of Pathophysiology: Cells and Tissues
Unit I The Cell
1 Cellular Biology, 1
2 Altered Cellular and Tissue Biology: Environmental Agents, 43
3 The Cellular Environment: Fluids and Electrolytes, Acids and Bases, 106
Unit II Genes and Gene-Environment Interaction
4 Genes and Genetic Diseases, 140
5 Genes, Environment-Lifestyle, and Common Diseases, 167
6 Epigenetics and Disease, 187
Unit III Mechanisms of Self-Defense
7 Innate Immunity: Inflammation and Wound Healing, 202
8 Adaptive Immunity, 231
9 Alterations in Immunity, 255
10 Infection, 281
11 Stress and Disease, 310
Unit IV Cellular Proliferation: Cancer
12 Cancer Biology, 331
13 Cancer Epidemiology, 388
14 Cancer in Children and Adolescents, 430
Part Two: Structure, Function, and Pathophysiologic Alterations: Organs and Systems
Unit V The Neurologic System
15 Structure and Function of the Neurologic System, 441

16 Pain, Temperature Regulation, Sleep, and Sensory Function, 474
17 Alterations in Cognitive Systems, Cerebral Hemodynamics, and Motor Function, 509
18 Alterations of the Brain, Spinal Cord, and Peripheral Nerves, 570
19 Neurobiology of Schizophrenia, Mood Disorders, Anxiety Disorders, Posttraumatic Stress Disorder, and Obsessive-Compulsive Disorder, 618
20 Alterations of Neurologic Function in Children, 640
Unit VI The Endocrine System
21 Mechanisms of Hormonal Regulation, 662
22 Alterations of Hormonal Regulation, 688
23 Obesity, Starvation, and Anorexia of Aging, 723
Unit VII The Reproductive Systems
24 Structure and Function of the Reproductive Systems, 738
25 Alterations of the Female Reproductive System, 767
26 Alterations of the Male Reproductive System, 823
27 Sexually Transmitted Infections, 865
Unit VIII The Hematologic System
28 Structure and Function of the Hematologic System, 892
29 Alterations of Hematalogic Function, 925
30 Alterations of Hematologic Function in Children, 987
Unit IX The Cardiovascular and Lymphatic Systems
31 Structure and Function of the Cardiovascular and Lymphatic Systems, 1020
32 Alterations of Cardiovascular Function, 1059
33 Alterations of Cardiovascular Function in Children, 1109
Unit X The Pulmonary System
34 Structure and Function of the Pulmonary System, 1131
35 Alterations of Pulmonary Function, 1153
36 Alterations of Pulmonary Function in Children, 1191
Unit XI The Renal and Urologic Systems
37 Structure and Function of the Renal and Urologic Systems, 1211
38 Alterations of Renal and Urinary Tract Function, 1232

39 Alterations of Renal and Urinary Tract Function in Children, 1270
Unit XII The Digestive System
40 Structure and Function of the Digestive System, 1285
41 Alterations of Digestive Function, 1318
42 Alterations of Digestive Function in Children, 1375
Unit XIII The Musculoskeletal System
43 Structure and Function of the Musculoskeletal System, 1399
44 Alterations of Musculoskeletal Function, 1427
45 Alterations of Musculoskeletal Function in Children, 1476
Unit XIV The Integumentary System
46 Structure, Function, and Disorders of the Integument, 1504
47 Alterations of the Integument in Children, 1541
Unit XV Multiple Interacting Systems
48 Shock, Multiple Organ Dysfunction Syndrome, and Burns in Adults, 1557
49 Shock, Multiple Organ Dysfunction Syndrome, and Burnsin Children, 1591

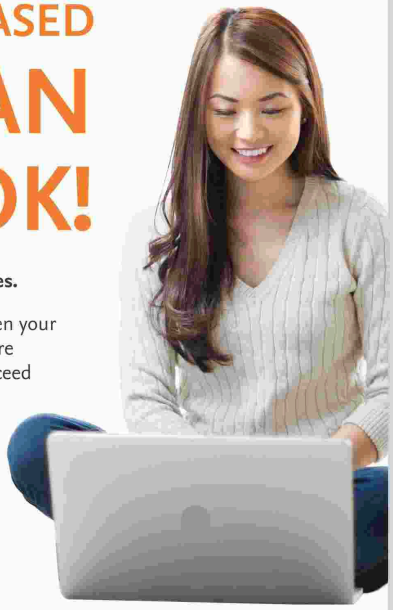
Chronic Posttraumatic Stress Disorder Treatment, 634
In Utero Myelomeningocele Surgery, 645
Gene Therapy for Pediatric Neurologic Conditions, 647
The New Evolving Classification System for Pediatric Brain Tumors, 657
Thyromimetics and Liver Disease, 674
Vitamin D Deficiency, 674
Klotho Protein and Aging, 684
Combination Therapy for the Treatment of Hypothyroidism, 699
Pancreatic β Cell Regeneration as a Plausible Diabetic Therapy, 706
Inflammation and Its Importance to the Pathophysiology of Insulin Resistance in Prediabetes and Diabetes Mellitus Type 2, 707
Smart Pens for Improved Safety and Efficacy of Insulin Therapy, 709
SGLT-2 Use for the Treatment of Obesity, 730
Weight Loss, 730
Gender Reassignment and Gender Affirming Hormone Therapy, 742
Vitamin D and Breast Cancer, 814
Benign Prostatic Hyperplasia, 844
Prostate Cancer, 847
New Therapeutics for Human Immunodeficiency Virus Prevention and Treatment, 876
Treatment Effectiveness for Hepatitis C, 887
Tumor Associated Neutrophils, 896
Red Bloods Cells and Hemostasis, 916
Traumatic Coagulopathy, 928
Immunotherapy, 962
Gene Therapy for Sickle Cell, 998
Molecular Characterization of Childhood Leukemia and Treatment Considerations, 1011

Myocardial Regeneration, 1023
Coronary Lymphatics in Health and Disease, 1028
Hypertension as a Metabolic Disease, 1065
Lipid-Lowering and Antihypertensive Medication Effects on Atherosclerosis-Associated Inflammation, 1072
Takotsubo Syndrome, 1079
Cardioprotection Therapies for Myocardial Infarction and Reperfusion Injury, 1082
Diabetes and Heart Failure, 1096
Stem Cell Therapies for Congenital Heart Disease, 1122
COVID-19 Post-Infective Myocarditis in Children, 1124
The Pulmonary Microbiome, 1136
Silent Hypoxemia in COVID-19, 1140
Future Treatments for Idiopathic Pulmonary Fibrosis, 1164
The Pathogenesis of the Acute Respiratory Distress Syndrome in COVID-19 Infection, 1166
Biological Treatments for Uncontrolled Asthma, 1172
E-Cigarettes and Respiratory Disease, 1173
Molecular and Immune Therapies for Lung Cancer, 1185
COVID-19 Infection in Children, 1201
Obesity and Childhood Asthma, 1203
CFTR Modulators, 1207
Renalase, 1219
Renin–Angiotensin–Aldosterone System Inhibitors in Patients With COVID-19, 1249
Biomarkers for Acute Kidney Injury Risk Stratification, 1257
Promising Biomarkers to Predict Chronic Kidney Disease in Children With Congenital Anomalies of Kidney and Urinary Tract, 1272
The Appendix in Health and Disease, 1302
Digestive Manifestations Related to COVID-19, 1312
Oral Treatments for Ulcerative Colitis, 1338
Portal Hypertension, 1343
Colorectal Cancer, 1362
COVID-19 and the Gastrointestinal System in Children, 1390
The Role of miRNAs as Biomarkers of Obesity, 1394

Factors Affecting Bone Healing, 1408
Progress in Rebuilding Cartilage, 1413
Understanding Tendon and Ligament Repair, 1422
Cartilage Regeneration, 1455
Invasive Therapies to Treat Musculoskeletal Conditions, 1471
Idiopathic Scoliosis, 1485
Serum Interleukin-18 and Systemic Juvenile Idiopathic Arthritis, 1487
Skin Engineering, 1514
COVID-19 and Cutaneous Manifestations, 1514
Coronavirus Rash, 1549
Pro-Inflammatory and Anti-Inflammatory Responses in Sepsis, 1562
Pathophysiology of the Burn Wound, 1580
Therapies for Shock and Sepsis, 1607
Advances in Burn Wound Care, 1615

Evolve®

YOU'VE JUST PURCHASED MORE THAN A TEXTBOOK!



Enhance your learning with Evolve Student Resources.

These online study tools and exercises can help deepen your understanding of textbook content so you can be more prepared for class, perform better on exams, and succeed in your course.

Activate the complete learning experience that comes with each NEW textbook purchase by registering with your scratch-off access code at

http://evolve.elsevier.com/Rogers/pathophysiology/

If your school uses its own Learning Management System, your resources may be delivered on that platform. Consult with your instructor.

If you rented or purchased a used book and the scratch-off code at right has already been revealed, the code may have been used and cannot be re-used for registration. To purchase a new code to access these valuable study resources, simply follow the link above.

Dedication

This book is dedicated to all those who think they can't: guess what —YOU CAN!

To my family, Dwayne, Zachery, and Shane. Your willingness to support this endeavor means more than I can express. I appreciate all the time and space you provided me to work on and complete this project. Your love surrounds me in every aspect of my life and inspires me to be a better human.

Dwayne, thanks for always letting me know that everything will be alright. I guess you were right. You have always been my rock, and I couldn't have made it the last 22 years without you believing in me.

Shane, thanks for never giving up and being the strongest woman I have ever known. Your beautiful smile brightens even the worst of days. You are loved more than you know. P.S. Please call your parents more often.

Last, but not least, my dearest Zachery, the calm in my storm, you have always amazed me with your uncanny ability to see the best in everyone. Never lose your gentle spirit and do not let anyone steal your joy. Believe in yourself and finish writing your own story. You are an inspiration.P.S. Thanks for introducing me to dunking Oreos; life has not been the same since, Oh, and I almost forgot: you have lost the game.

J.L.R.

Preface

The intent of the ninth edition of *Pathophysiology* is to continue the extraordinary work of Kathy McCance and Sue Huether, which started 30 years ago, by illustrating the principles of pathophysiology with clarity and accuracy.

Pathophysiology incorporates basic, translational, and clinical research to advance the understanding of disease and dysfunction. The study of pathophysiology involves many biomedical sciences and a wide range of research activities. Multiple aspects of cellular physiology are progressing rapidly, generating vast amounts of data to understand. This was made ever more present during the writing of this edition, when the world began to see the effects of cellular changes and adaptations from the coronavirus (COVID-19; severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]) pandemic. The information gained provided a greater understanding of the behavior of individual cells, their neighboring microenvironment, and the molecules that not only make up those cells but also communicate with their surroundings. Importantly, the forward movement of biomedical sciences occurs within the context of social, economic, and political processes that determine how disease is defined, experienced, and treated.

Interdisciplinary research has led to significant advancements in genetics, epigenetics, cell signaling and communication, control of cell behavior, metabolism, and cell fate. Knowledge about normal cell structures, function, and signaling pathways is at the forefront of translational science and foundational to the understanding of pathophysiology. Advancements in technology that allow close observation of cells are providing new understanding of cellular processes, including how cells function and prioritize their activities,

monitor their environment, move, differentiate, and regenerate. Advances in the molecular mechanisms of disease, particularly cell signaling, genetic directives, and immune and metabolic modulators, are providing an understanding of individual differences in disease risk, biologic markers, diagnostic strategies, and individualized treatment.

Although these advancements have created an ever-increasing state of excitement, they have also created the problem of how students, professors, and clinicians can cope with the expanding new information. Translating and compressing these data into simplified discussions for students and clinicians is challenging. The approach for this edition of the book was to streamline the content and present the information in an organized, logical sequence of content based on current literature and research reports with understandable explanations and accompanied by illustrations and summary tables. The primary focus is on pathophysiology, and there is less emphasis on the evaluation and treatment that is found in clinical management textbooks.

This edition has been extensively revised with the following specific goals:

- Organize the content in a logical and uniformed format to facilitate learning and teaching.
- Place emphasis on the readability of the material for improved comprehension.
- Focus on updating outdated terminology and use inclusive language.
- Present emerging new data on disease including controversial topics.
- Provide the most current and relevant information on the etiology, epidemiology, pathophysiology, clinical manifestations, and treatment for disease processes.
- Integrate health promotion and disease prevention by updating risk factors, explaining relationships between

nutrition and disease, and referencing screening recommendations.

Organization and Content: What's New in the Ninth Edition

The book is organized into two parts. Part One presents the cellular and tissue responses common to disease. Normal organ system structure and function and the pathophysiology of disease, organized by body systems, are presented in Part Two. All content has been reviewed and updated with extensive new references and revised figures. The previous Chapter 18 in the eighth edition titled *Disorders of the Central and Peripheral Nervous Systems and the Neuromuscular Junction* has been renamed in the ninth edition as *Alterations of the Brain, Spinal Cord, and Peripheral Nerves*. Alterations of the hematologic system, which were previously discussed over two chapters, have been combined into one chapter.

Part One: Central Concepts of Pathophysiology: Cells and Tissues

Part One begins with an in-depth study of the cell and progresses to cover the underlying processes of disease. Concepts covered include cell signaling and cell communication processes; genes and common genetic diseases; epigenetics and disease; fluid, electrolyte, and acid-base balance; inflammation, cytokines and their biologic functions, and normal and altered immunity; infection, stress, coping, and immunity; and tumor biology, epidemiology of cancer, and cancer in children. Revisions and updated additions to Part One include the following:

- Updated content on cellular organelles, the plasma membrane, cell signaling, and communication (Chapter 1)
- Reorganized with extensive updates throughout the chapter with close attention to air pollution and climate change (Chapter 2)
- Updated content on fluids, electrolytes and acids and bases (Chapter 3)
- Updated content on genes and diseases related to genetics, the environment and lifestyle patterns (Chapter 4 and 5)
- Updated content on epigenetics and disease (Chapter 6)
- Updated to content on normal innate and adaptive immunity (Chapters 7 and 8)
- Extensively updated to content on alterations of immunity and inflammation including up-to-date information on coronavirus (COVID-19) and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (Chapter 9)
- Extensively revised with up-to-date information on COVID-19 and SARS-CoV-2 (Chapter 10)
- Updated content on stress and disease (Chapter 11)
- Updated content on tumor biology and invasion and metastases (Chapter 12)

- Updated content on the epidemiology of cancer (Chapter 13)

Part Two: Pathophysiologic Alterations: Organs and Systems

Part Two is a systematic survey of diseases within body systems. Each unit focuses on a specific body system and begins with an anatomy and physiology chapter to provide a basis of comparison for understanding the alterations created by disease. A brief summary of geriatric considerations is included at the end of the section on anatomy and physiology. The discussion of each disease in the alterations chapters is developed in a logical manner that begins with an introductory paragraph on etiology and epidemiology, followed by pathophysiology, clinical manifestations, and evaluation and treatment. Separate chapters are dedicated to pediatric pathophysiology, with a particularly sensitive approach to sex at birth and age. Significant revisions and updated additions to Part Two include the following:

- Updated content on pediatric cancers (Chapter 14)
- Updated content on the anatomy and physiology of the neurologic system (Chapter 15)
- Updated content on pain syndromes and sleep disorders (Chapter 16)
- Rewritten and extensively revised content on Parkinson disease, Huntington disease, amyotrophic lateral sclerosis, multiple sclerosis, and myasthenia gravis with updates to content on consciousness, memory, dementia, and delirium syndromes (Chapter 17)
- Chapter renamed as Alterations of the Brain, Spinal Cord, and Peripheral Nerves. Rewritten and extensively revised content on the manifestations for specific central and peripheral nervous system disorders including brain and spinal cord injury, stroke, seizure, and headache syndromes (Chapter 18)

- Updated content and terminology on schizophrenia, mood disorders, and anxiety (Chapter 19)
- Updated content on cerebral palsy, seizure disorders, and pediatric brain tumors (Chapter 20)
- Updated content on the mechanisms of hormonal regulation (Chapter 21)
- Extensive updates on diabetes mellitus, insulin resistance, and thyroid and adrenal gland disorders (Chapter 22)
- Updated content on obesity and disorders of nutrition (Chapter 23)
- Updated content on anatomy and physiology of the reproductive system (Chapter 24)
- Updated content on female reproductive disorders including cancers, benign breast diseases, and breast cancer (Chapter 25)
- Updated content on male reproductive disorders and cancer with extensive updating and reorganization (Chapter 26)
- Extensive updating of sexually transmitted infections (Chapter 27)
- Updated content on the anatomy and physiology of the hematologic system (Chapter 28)
- Extensively rewritten chapter on the alterations of hematologic function, combining two previous chapters into one with updated content on anemia (Chapter 29)
- Updated content on alterations of hematologic function in children (Chapter 30)
- Updated chapter on the anatomy and physiology of the cardiovascular and lymphatic systems (Chapter 31)
- Updated content on atherosclerosis, endothelial injury and dysfunction, coronary artery disease, myocardial infarction, and heart failure (Chapter 32)
- Updated content on the alterations of cardiovascular function in children (Chapter 33)
- Updated content on the anatomy and physiology of the pulmonary system (Chapter 34)

- New content on COVID-19 and SARS-CoV-2, and updated content on pulmonary embolism asthma, chronic lung disease, respiratory tract infection, pulmonary hypertension, and lung cancers (Chapters 35)
- New content on COVID-19 and SARS-CoV-2 with updated content on childhood asthma, respiratory distress syndrome, cystic fibrosis, lung infections, and sudden infant death syndrome (Chapter 36)
- Updated content on the anatomy and physiology of the renal and urologic system (Chapter 37)
- Updated content on kidney stones, urinary tract infection, glomerulopathies, acute and chronic renal failure, and bladder and kidney tumors (Chapter 38)
- Updated content on urinary tract infection and renal failure in children (Chapter 39)
- Updated content on the anatomy and physiology of the digestive system (Chapter 40)
- Updated content on gastroesophageal reflux disease, peptic ulcer disease, irritable bowel syndrome, inflammatory bowel disease, colon cancer, and hepatitis (Chapter 41)
- Updated content on gluten-sensitive enteropathy, necrotizing enterocolitis, infections of the intestine, and liver disease in children (Chapter 42)
- Updated content on the anatomy and physiology of the musculoskeletal system (Chapter 43)
- Updated content on alterations of the musculoskeletal system (Chapter 44)
- Updated content on alterations of the musculoskeletal system in children (Chapter 45)
- Updated content on integumentary system disorders including pressure ulcers, dermatitis, psoriasis, scleroderma, and melanoma (Chapter 46)
- Updated content on childhood atopic dermatitis, skin infections, and immune drug reactions (Chapter 47)
- Extensively updated content on septic shock, multiple organ dysfunction syndrome, included recent guideline updates,

and burns for adults (Chapters 48)
- Extensively updated content on septic shock, multiple organ dysfunction syndrome, included recent guideline updates, and burns for children (Chapters 49)

Features to Promote Learning

Ease of learning has been enhanced by designing a number of features that guide and support understanding, including:

- *Chapter Outlines* for each chapter
- *Consistent Headings* to underscore the consistent treatment of each disease—Pathophysiology, Clinical Manifestations, and Evaluation and Treatment
- More than 70 *Emerging Science* boxes that review the most current research and clinical developments of disease.
- End-of-chapter *Summary Review* sections that summarize the content in each chapter and serve as built-in content review guides
- Boldface *Key Terms* found within all the chapters
- A comprehensive *Glossary* with approximately 1000 terms to help students with the often-difficult terminology related to pathophysiology

Art Program

The art program is extensive and has received as much attention and revision as the narrative. Nearly 100 new or revised full-color illustrations were created and strategically placed throughout the textbook. Also included are many new high-quality, full-color photographs of clinical manifestations, pathologic specimens, and clinical imaging techniques. The combination of illustrations, algorithms, and photographs and the use of color for tables and boxes allow clarification for complex concepts and the emergence of easily recognized essential information.

Ancillaries

For Students

On **Evolve**, at http://evolve.elsevier.com/Rogers/pathophysiology/, students can access Evolve-only figures, tables, and boxes, 570 review questions, 100 animations to help them master the text content, 26 case studies with questions and answers, and downloadable chapter summaries documents for each chapter.

The **Study Guide** includes a variety of question styles, aiming to help the diverse way students learn. Question types include the following:

- Respond to Clinical Scenarios
- Categorize Clinical Examples
- Match the Definitions
- Order the Steps
- Choose the Correct Words
- Complete These Sentences
- Explain the Pictures
- Teach People About Pathophysiology
- Plus many more…

Answers are found in the back of the Study Guide for easy reference for students.

For Instructors

The **Evolve Instructor Resources** for this textbook provide the following teaching aids:

- Image Collection with all of the approximately 1200 figures from the text
- PowerPoint lecture slides for each chapter (approximately 3300 slides total), including integrated Audience Response Questions in each chapter (218 total), and integrated case studies at the end of each unit (15 total)

- Teach for Nurses Instructor's Manual, broken down by chapter, detailing the resources available to instructors for their lesson planning, and including unique case studies and class activities they can share with students
- Test Bank in ExamView with 1560 questions (in multiple-choice and multiple-response formats) with answers, rationales, and textbook page references

Evolve is an Internet-based learning environment that works in coordination with the text. This resource enables you to publish your class syllabus, outline, and lecture notes; set up "virtual office hours" and e-mail communication; share important dates and information through the online class calendar; and encourage student participation through chat rooms and discussion boards. Free with qualified adoption. Contact your sales representative or visit http://evolve.elsevier.com for more information about integrating **Evolve** into your curriculum.

Acknowledgments

Julia L. Rogers

It is with gratitude that I dedicate this book to the creative pioneers who started it all, Kathy McCance and Sue Huether. Over the last 30 years, you have worked tirelessly to update the textbook to remain relevant using the most current research advancements, and I applaud your dedication. Thanks for having the confidence to pass the torch to me.

To Tamara, thank you for taking a chance on me. You are a sparkle in this world that can light up an entire room. I am forever grateful for your kindness.

To Tina Brashers, a mentor throughout this journey that had several sharp turns. Thank you for your devotion to the book and passion to create. You are brilliant, and I could not have done it without you. I appreciate you more than you will ever know and will forever be slightly envious.

To Melanie, the eagle eyes of the project. Thank you for all the time and commitment you put into this textbook. Words cannot express the gratitude I have for all your hard work.

To the Development and Production teams—Laura, Laurie, Rachel, artists, and editors, thanks for your mastery and caring about this project as much as I do.

To all the contributors—thanks for hanging in there over the last few years. It was a time of change and constraints with COVID, but all of you produced phenomenal work. Thank you!

To my amazing father, who provided me with strength and courage throughout the entire project.

To the WOW women, thanks for helping me pick up the broken pieces and make time for what is most important in life.

To Patti Ludwig-Beymer thank you for taking the time to guide me. You have been a true mentor and reminded me to breathe, believe, and be the very best version of me.

To Dr. Douglas Mazurek, you have been an inspiration to me. You believed in me since the beginning of my nursing career and opened the door to see the possibilities as a nurse practitioner. Thanks for igniting my passion and love for pathophysiology.

To Emily, thanks for making sure everything was in order. You are a gem in the world.

Seek joy. Live your life as your message. Be the change in the world that you wish to see. Most of all……be kind.

Chapter Outline

OUTLINE

Prokaryotes and Eukaryotes, 1

Cellular Functions, 2

Structure and Function of Cellular Components, 2
- Nucleus, 2
- Cytoplasmic Organelles, 2
- Plasma Membranes, 3
- Cellular Receptors, 9

Cell-to-Cell Adhesions, 12
- Extracellular Matrix and Basement Membrane, 12
- Specialized Cell Junctions, 14

Cellular Communication and Signal Transduction, 15

Cellular Metabolism, 17
- Role of Adenosine Triphosphate, 18
- Food and Production of Cellular Energy, 20
- Oxidative Phosphorylation, 20

Membrane Transport: Cellular Intake and Output, 21
- Electrolytes as Solutes, 23
- Transport by Vesicle Formation, 26
- Movement of Electrical Impulses: Membrane Potentials, 27

Cellular Reproduction: The Cell Cycle, 31
- Phases of Mitosis and Cytokinesis, 32
- The Cell Cycle Control System, 33

Control of Cell Division and Cell Growth: Mitogens, Growth Factors, and Survival Factors, 34
DNA Damage Response: Blocks Cell Division, 34
Tissues, 34
Tissue Formation and Differentiation, 34

All body functions are dependent on the integrity of cells. These trillions of complex cells are the basic building blocks of the human body. Therefore an understanding of cellular biology is fundamental to understanding health, wellness, and disease processes. Cells behave as a multicellular "social" organism in that they message between, among, and within one another through cellular communication (cellular "crosstalk"). Cells have the ability to originate, transmit, receive, interpret, and use information to maintain cellular function and specialization. Cells must demonstrate a "chemical fondness" for other cells to maintain the integrity of the entire organism. When they no longer tolerate this fondness, the conversation breaks down, and cells either adapt (e.g., altering function) or become vulnerable to isolation, injury, or disease.

Prokaryotes and Eukaryotes

Living cells generally are divided into eukaryotes and prokaryotes. The cells of animals and plants are eukaryotes, as are the single-celled organisms, fungi, protozoa, and most algae. **Prokaryotes** include bacteria and archaea. Prokaryotes traditionally were studied as core subjects of molecular biology, which generated an abundance of data related to prokaryotic **genomes** (a set of genes carried on molecules of deoxyribonucleic acid [DNA]). Currently, emphasis is on the eukaryotic cell, which contains genomes that are more complex.[1]

Eukaryotes (*eu* = true; *karyon* = nucleus; also spelled "eucaryotes") are larger and have more extensive intracellular anatomy and organization than prokaryotes. Eukaryotic cells have a characteristic set of membrane-bound intracellular compartments, called *organelles*, that includes a well-defined nucleus. The prokaryotes contain no organelles, and their nuclear material is not encased by a nuclear membrane.

Besides having structural differences, prokaryotic and eukaryotic cells differ in chemical composition and biochemical activity. The *nuclei* of prokaryotic cells carry genetic information in a single circular chromosome, and they lack a class of proteins called *histones*, which in eukaryotic cells bind with DNA and are involved in the supercoiling of DNA. Eukaryotic cells have several chromosomes, the number of which is dependent on species. Protein production, or synthesis, in the two classes of cells also differs because of major structural differences in ribonucleic acid (RNA) protein complexes. Other distinctions include differences in mechanisms of transport across the outer cellular membrane and in enzyme content.

Cellular Functions

Cells become specialized through the process of **differentiation**, or maturation, so that some cells eventually perform one function and other cells perform other functions. Cells with a highly developed function, such as movement, often lack some other property, such as hormone production, which is more highly developed in other cells.

The eight chief cellular functions are as follows:

- *Movement*. Muscle cells can generate forces that produce motion. Muscles that attach to bones produce limb movements, whereas muscles that enclose hollow tubes or cavities move or empty contents when they contract (e.g., the colon).
- *Conductivity*. Conduction as a response to a stimulus is manifested by a wave of excitation, an electrical potential that passes along the surface of the cell to reach its other

parts. Conductivity is the chief function of nerve cells. (e.g., the brain or heart).

- *Metabolic absorption*. All cells can take in and use nutrients and other substances from their surroundings. (e.g., cells of the intestines or kidneys).
- *Secretion*. Certain cells, such as mucous gland cells, can synthesize new substances from substances they absorb and then secrete the new substances to serve elsewhere as needed.
- *Excretion*. All cells can rid themselves of waste products resulting from the metabolic breakdown of nutrients. Membrane-bound sacs (lysosomes) within cells contain enzymes that break down, or digest, large molecules, turning them into waste products that are released from the cell (e.g., urine).
- *Respiration*. Cells absorb oxygen, which is used to transform nutrients into energy in the form of adenosine triphosphate (ATP). Carbohydrates, fats, and proteins can be used as fuels. Cellular respiration, or oxidation, occurs in organelles called *mitochondria* (e.g., glucose).
- *Reproduction*. Tissue growth occurs as cells enlarge and reproduce themselves. Even without growth, tissue maintenance requires that new cells be produced to replace cells that are lost normally through cellular death. Not all cells are capable of continuous division (see Chapter 2) (e.g., mitosis and meiosis).
- *Communication*. Communication is vital for cells to survive as a society of cells. Appropriate communication allows the maintenance of a dynamic steady state. Table 1.1

Table 1.1

Principal Cytoplasmic Organelles

Genetic Control	
Organelle	**Characteristics and Description**

Genetic Control	
Organelle	**Characteristics and Description**
 Nucleus (From Patton KT: *Anatomy & Physiology, 10 ed*., Mosby, 2019, Elsevier.)	*(See text for further description of function and structure)*
An illustration shows a three-dimensional cross-sectional view of a nucleus. The following parts in the structure are labeled, clockwise from the top: nuclear pore, nuclear envelope, chromatin, nucleoplasm, and nucleolus.	
Nucleolus	*(See text for further description of*

Genetic Control	
Organelle	**Characteristics and Description**
	function and structure)

Manufacturing, Distributing and Breaking Down Molecules	
Organelle	**Characteristics and Description**
Ribosomes	Ribonucleic acid (RNA)-protein complexes (nucleoproteins) synthesized in nucleolus and secreted into cytoplasm. Provide sites for cellular protein synthesis. Uses the information from deoxyribonucleic acid (DNA), written in messenger RNA (mRNA), to build proteins.

Manufacturing, Distributing and Breaking Down Molecules	
Organelle	**Characteristics and Description**
 Endoplasmic reticulum (rough and smooth) (From McCance KL, Huether S: *Pathophysiology: the biologic basis for disease in adults and children*, St. Louis, 2019, Elsevier.) An unlabeled illustration shows a three-dimensional cutaway view a cell structure. A colored illustration of the cell structure shows and labels the following parts, from the top to the bottom: plasma membrane, secretory vesicles, Golgi apparatus, smooth endoplasmic reticulum or s E R, cisternae, nucleus, nucleolus, nuclear envelope, and r E R.	Network of tubular channels (cisternae) that extend throughout the outer nuclear membrane. **Rough Endoplasmic Reticulum (RER)**—bumpy exterior due to ribosomes and ribonucleoprotein particles attached to it; is responsible for much of a cell's protein synthesis and folding. **Smooth Endoplasmic Reticulum (SER)**—does not contain ribosomes or ribonucleoprotein particles. Rather, membranous surfaces of the SER contain enzymes involved in the synthesis of steroid hormones and are responsible for a variety of reactions required to remove toxic substances from the cell. The SER communicates with the Golgi complex and interacts with other organelles, particularly

Manufacturing, Distributing and Breaking Down Molecules	
Organelle	**Characteristics and Description**
	lysosomes and peroxisomes.
 Golgi complex (From McCance KL, Huether S: *Pathophysiology: the biologic basis for disease in adults and children*, St. Louis, 2019, Elsevier.) An unlabeled illustration shows a three-dimensional cutaway view of a cell structure with a colored section highlighting the Golgi complex. A colored illustration of the Golgi complex shows and labels the cisternae and the secretory vesicles.	Network of flattened, smooth membranes and vesicles located neared the nucleus and the RER. Proteins from the endoplasmic reticulum are processed and packaged into small membrane-bound sacs or vesicles called **secretory vesicles**, which collect at the end of the membranous folds of the Golgi bodies—called **cisternae** (like a stack of pita breads). The secretory vesicles then break off from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane. The vesicles fuse with the plasma membrane, and their contents are released from the cell. The best-known vesicles are those that have coats made largely of the protein **clathrin** and are called *clathrin-coated*

Manufacturing, Distributing and Breaking Down Molecules	
Organelle	**Characteristics and Description**
	vesicles. The Golgi complex is a refining plant and directs cellular traffic (e.g., protein, polynucleotide, polysaccharide molecules) in the cell.
 Lysosomes (From McCance KL, Huether S: *Pathophysiology: the biologic basis for disease in adults and children*, St. Louis, 2019, Elsevier.)	Sac-like, membrane-bound structures containing enzymes for digesting most cellular substances to their basic forms, such as amino acids, fatty acids, and carbohydrates (sugars). The lysosomal membrane acts as a protective shield between the powerful digestive enzymes within the lysosome and the cytoplasm, preventing their leakage into the cytoplasmic matrix. Lysosomes maintain cellular health because of efficient removal of toxic cellular components, removal of useless organelles, termination of signal transduction, and maintenance of metabolic homeostasis. Aging can lead to progressive loss of

Manufacturing, Distributing and Breaking Down Molecules	
Organelle	**Characteristics and Description**
	lysosomal efficiency and decline of the regenerative capacity of organs and tissues. Cellular injury leads to release of lysosomal enzymes that cause cellular self-digestion.
Peroxisomes	Similar to lysosomes in appearance but contain several oxidative enzymes (e.g., catalase, urate oxidase) that can detoxify compounds and fatty acids. Peroxisomes are so named because they usually contain enzymes that use oxygen to remove hydrogen atoms from specific substrates in an oxidative reaction that produces hydrogen peroxide (H_2O_2). Hydrogen peroxide is a powerful oxidant, potentially destructive if it accumulates or escapes from peroxisomes. Peroxisomes also have an important role in the synthesis of specialized phospholipids necessary

Manufacturing, Distributing and Breaking Down Molecules	
Organelle	**Characteristics and Description**
	for nerve cell myelination. Such reactions are important in detoxifying various wastes within the cell or foreign components that enter the cell, such as ethanol. Impairment of peroxisomes can lead to disease (see Fig. 1.1A).

Energy Processing	
Organelle	**Characteristics and Description**
 Mitochondria (From McCance KL, Huether S: *Pathophysiology: the biologic basis for disease in adults and children*, St. Louis, 2019, Elsevier.) An unlabeled illustration shows a three-dimensional cutaway view of a cell structure with colored sections highlighting the mitochondria. A colored cutaway illustration of a mitochondrion shows and labels the following parts, from the top to the bottom: cristae, matrix, inner membrane, and outer membrane.	Organelles, found in large numbers in most cells, are responsible for cellular respiration and energy production. These cytoplasmic organelles appear as spheres, rods, or filamentous bodies that are bound by a double membrane. The **outer membrane** is smooth and surrounds the mitochondrion itself; the inner membrane is convoluted in the mitochondrial matrix to form partitions called **cristae**. The **inner membrane** contains the enzymes of the **respiratory chain**—the name given to the electron transport chain. These enzymes are essential to the process of oxidative phosphorylation that generates most of the cell's adenosine triphosphate. Metabolic pathways involved in the metabolism of carbohydrates, lipids, and amino acids and special

Energy Processing	
Organelle	**Characteristics and Description**
	pathways involving urea and heme synthesis are located in the mitochondrial matrix. Mitochondria contain their own DNA that codes for enzymes needed for oxidative phosphorylation.

Structural Support, Movement, and Communication Between Cells	
Structures	**Characteristics and Description**
 Cytoskeleton (From McCance KL, Huether S: *Pathophysiology: the biologic basis for disease in adults and children*, St. Louis, 2019, Elsevier.)	All eukaryotic cells contain elaborate and specialized internal structures in the cytosol that provide the "bones and muscles" of the cell—the **cytoskeleton**. The cytoskeleton maintains the cell's shape and internal organization, and it permits movement of substances within the cell and movement of external projections (cilia or microvilli; flagella in sperm) outside the plasma membrane. The internal skeleton is composed of a network of protein filaments; the three main

Structural Support, Movement, and Communication Between Cells	
Structures	**Characteristics and Description**
	types of filaments include actin filaments, microtubules, and intermediate filaments. These filaments collectively promote cell strength, shape, and movement. Intermediate filaments bridge the cytoplasm from one cell junction to another, strengthening and supporting the sheet of epithelium.

Structure and Function of Cellular Components

Fig. 1.1A shows a "typical" eukaryotic cell, which consists of three components: an outer membrane called the **plasma membrane**; a fluid "filling" called **cytoplasm** (see Fig. 1.1B); and the "organs" of the cell—the membrane-bound intracellular **organelles**, among them the nucleus.

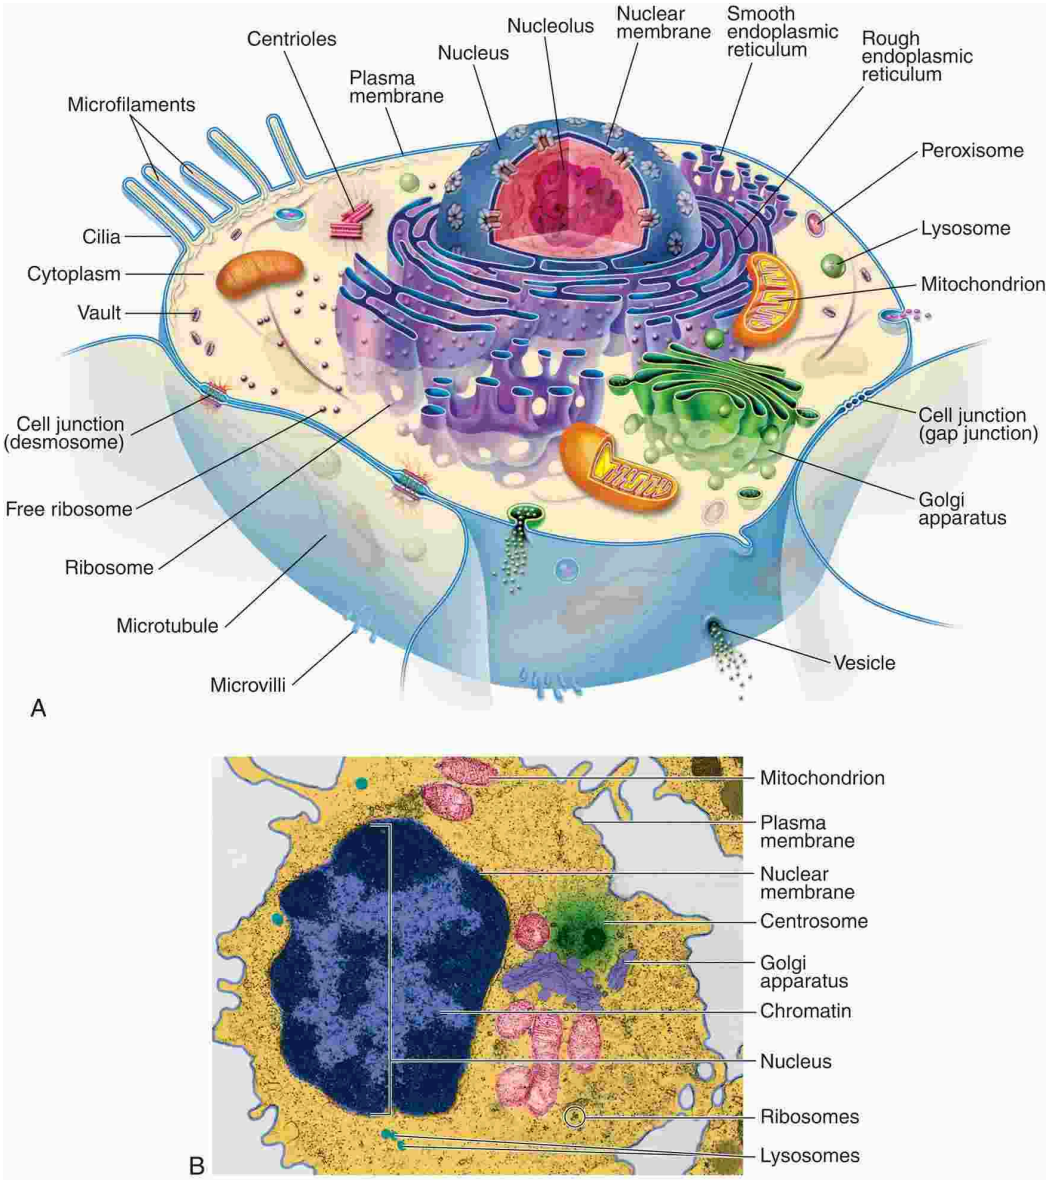

FIG. 1.1 Typical Components of a Eukaryotic Cell and Structure of the Cytoplasm.
(A) Artist's interpretation of cell structure. (B). Color-enhanced electron micrograph of a cell. Both show the many mitochondria known as the "power plants" of the cell. Note, too, the innumerable dots bordering the endoplasmic reticulum. These are ribosomes, the cell's "protein factories." (**B**, From Patton KT, Thibodeau GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

Part A shows a three-dimensional cross-sectional illustration of a cell structure. The following parts in the structure are labeled, clockwise from the top: nucleus, nucleolus, nuclear membrane, smooth endoplasmic reticulum, rough endoplasmic reticulum, peroxisome, lysosome, mitochondrion, cell junction or gap junction, Golgi apparatus, vesicle, microvilli, microtubule, ribosome, free ribosome, cell junction or desmosome, vault, cytoplasm, cilia, microfilaments, centrioles, and plasma membrane. Part B is a color-enhanced electron micrograph of a cell structure. The following parts in the structure are labeled, from the top to the bottom: mitochondrion, plasma membrane, nuclear membrane, centrosome, Golgi apparatus, nucleus, ribosomes, and lysosomes.

Nucleus

The **nucleus**, which is surrounded by the cytoplasm and generally is located in the center of the cell, is the largest membrane-bound organelle. Two pliable membranes compose the **nuclear envelope** (Fig. 1.2A). The nuclear envelope is pockmarked with pits, called **nuclear pores**, which allow chemical messages to exit and enter the nucleus (see Fig. 1.2A, B, and D). The outer membrane is continuous with membranes of the endoplasmic reticulum (see Fig. 1.1). The nucleus contains the **nucleolus** (a small dense structure composed of DNA, RNA, and ribosomal proteins), most of the cellular DNA, and the DNA-binding proteins (i.e., the histones) that regulate its activity. The DNA chain in eukaryotic cells is so long that it is easily broken. Therefore the histones that bind to DNA cause DNA to fold

into chromosomes (see Fig. 1.2C). The wrapping of DNA into tight packages of chromosomes is essential for cell division in eukaryotes. The primary functions of the nucleus are cell division and control of genetic information. These functions include the replication and repair of DNA and the transcription of the information stored in DNA into RNA.

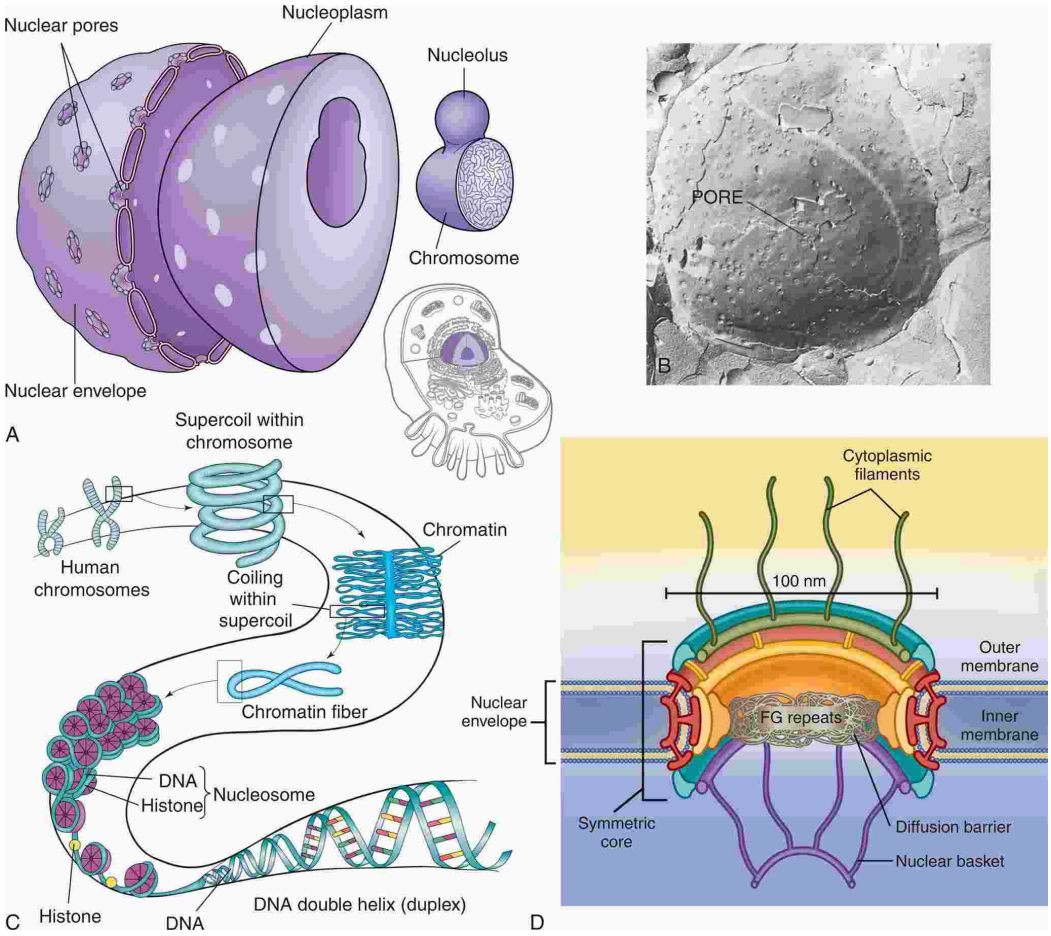

FIG. 1.2 The Nucleus.

The nucleus is composed of a double membrane, called a nuclear envelope, which encloses the fluid-filled interior, called *nucleoplasm*. The chromosomes are suspended in the nucleoplasm (illustrated here much larger than actual size to show the tightly packed deoxyribonucleic acid [DNA] strands). Swelling at one or more points of the chromosome, shown in **(A)** occurs at a nucleolus where genes are being copied into ribonucleic acid. The nuclear envelope is studded with pores. **(B)** The pores are visible as dimples in this freeze-etch of a nuclear envelope. **(C)** Histone-folding DNA in chromosomes. **(D)** Nuclear pore complex. (A, C, From McCance KL, Huether S *Pathophysiology: The biologic basis for disease*

in adults and children. St. Louis: Elsevier; 2019 B, From Raven PH, Johnson GB. *Biology*. St. Louis: Mosby; 1992. D, Adapted from The-scientist infographic: the nuclear pore complex. Available at https://www.The-scientist.com/infographics/infographic-the-nuclear-pore-complex-32456)

Part A comprises three illustrations. The first illustration is a cutaway view of a nucleus. The following parts of the nucleus are labeled, from the outer layer to the inner layer: nuclear envelope, nuclear pores, nucleoplasm. The second illustration is a while nucleus fused with a cutaway rendering of a chromosome. The third illustration is a unlabeled and shows a three-dimensional cutaway view of a cell structure with a colored section for the nucleus. Part B is a micrograph showing freeze-etch of a chromosome with pores labeled. Part C is a decremental iterative illustration of human chromosomes. Human chromosomes comprise supercoils. Chromatins are coiled within the supercoil. A closeup of a chromatin fiber shows and labels the nucleosome, comprising D N A and histone. A closeup of a D N A illustrates its double helical structure. Part D shows a cross-sectional view of a nuclear pore complex. The following parts in the colored illustration are labeled: outer membrane, nuclear envelope, symmetric core, F G repeats, diffusion barrier, nuclear basket, and cytoplasmic

filaments. the systemic core spans 100 nanometers in length.

Cytoplasmic Organelles

Cytoplasm is an aqueous solution (**cytosol**) that fills the **cytoplasmic matrix**—the space between the nuclear envelope and the plasma membrane. The cytosol represents approximately half the volume of a eukaryotic cell. It contains thousands of enzymes involved in intermediate metabolism and is *crowded* with ribosomes making proteins (see Fig. 1.1B). Newly synthesized proteins remain in the cytosol if they lack a signal for transport to a cell organelle.[2]

The organelles suspended in the cytoplasm are enclosed in biologic membranes, so they can simultaneously carry out functions requiring different biochemical environments. Many of these functions are directed by coded messages carried from the nucleus by RNA. Functions of organelles can be divided into four major categories: (1) genetic control; (2) manufacturing, distributing, and breaking down molecules; (3) energy processing; and (4) structural support, movement, and communication between cells. The cytosol is a storage unit for fat, carbohydrates, and secretory vesicles. Table 1.1 lists the principal cytoplasmic organelles.

Plasma Membranes

Membranes define the cell's boundaries. Membranes surround the cell or enclose an intracellular organelle and are exceedingly important to normal physiologic function because they control the composition of the space, or compartment, they enclose. Membranes can allow or exclude various molecules, and because of selective transport systems, they can move molecules in or out of the space (Fig. 1.3). By controlling the movement of substances from one compartment to another, membranes exert a powerful influence on metabolic pathways. Directional transport is facilitated by polarized

domains, distinct apical and basolateral domains. The plasma membrane also has an important role in cell-to-cell recognition, cellular mobility, and the maintenance of cellular shape (Table 1.2).

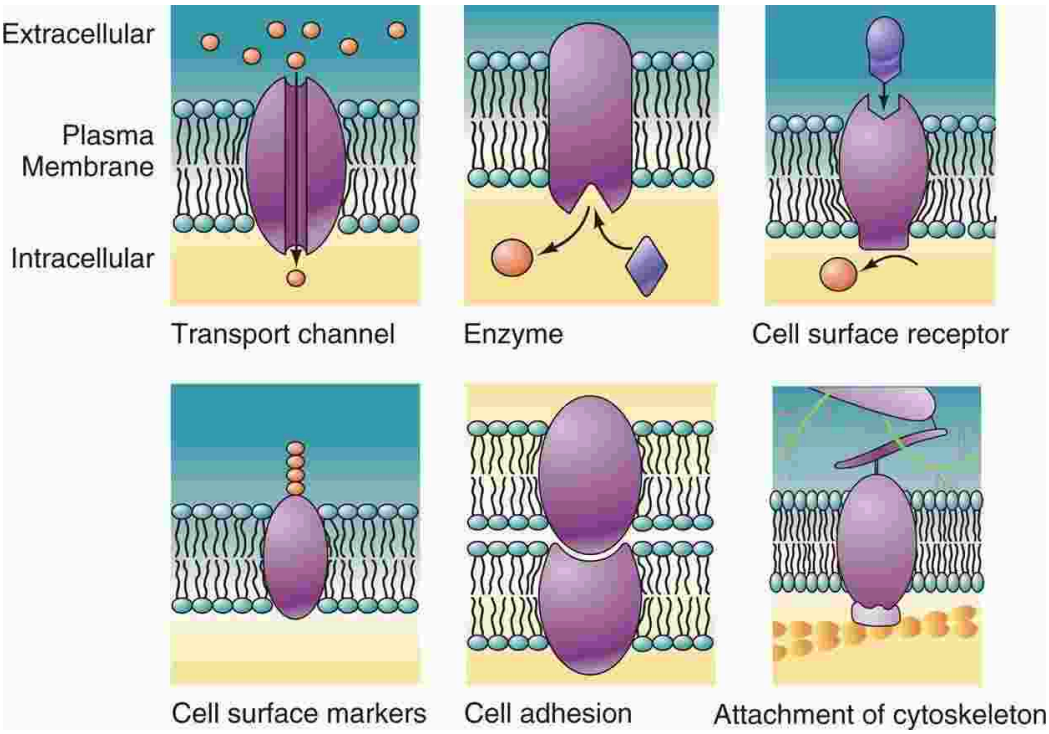

FIG. 1.3 Functions of Plasma Membrane Proteins.
The plasma membrane proteins illustrated here show a variety of functions performed by the different types of plasma membranes. (From Raven PH, Johnson GB. *Understanding biology*, 3rd edition. Dubuque, IA: Brown; 1995.

Six colored illustrations arranged in two rows of three illustrations each show the functions of plasma membrane proteins. Each rendering shows the extracellular environment, the plasma membrane, and the intracellular environment. Top left, transport channel. Ions from the extracellular region pass through an uniport in the plasma membrane and into the intracellular region. Top middle, Enzyme. Ion from the receptor is released into the intracellular

region, while an enzyme in the intracellular region binds itself to the receptor. Top right, cell surface receptor. Enzyme from the extracellular region is attracted to the receptor. Ion moves within the intracellular region. Bottom left, cell surface markers. Ions are stacked on the receptor in the extracellular region. Bottom middle, cell adhesion. Two cells, each with a bilipid layer, bind to each other. Bottom right, attachment of cytoskeleton. Cytoskeleton structures in the extracellular region bind to the receptor as ion move within the intracellular region.

Table 1.2

Plasma Membrane Functions

Cellular Mechanism	Membrane Functions
Structure	Usually thicker than membranes of intracellular organelles
	Containment of cellular organelles
	Maintenance of relationship with cytoskeleton, endoplasmic reticulum, and other organelles
	Maintenance of fluid and electrolyte balance (ion channels)
	Outer surfaces of plasma membranes in many cells are not smooth but are dimpled with cave-like indentations called *caveolae;* they are also studded with cilia or even smaller cylindrical projections called *microvilli;* both are capable of movement
Protection	Barrier to toxic molecules and macromolecules (proteins, nucleic acids, polysaccharides)
	Barrier to foreign organisms and cells
Activation of cell	Hormones (regulation of cellular activity)
	Mitogens (cellular division; see Chapter 2)
	Antigens (antibody synthesis; see Chapter 7)
	Growth factors (proliferation and differentiation; see Chapter 11)
Storage	Storage site for many receptors

Cellular Mechanism	Membrane Functions
	Transport (e.g., sodium [Na^+] pump)
	Diffusion and exchange diffusion
	Endocytosis (pinocytosis, phagocytosis)
	Exocytosis (secretion)
	Active transport
Cell-to-cell interaction	Communication, anchors (integrins), and attachment at junctional complexes
	Symbiotic nutritive relationships
	Release of enzymes and antibodies to extracellular environment
	Relationships with extracellular matrix

Modified from King DW, Fenoglio CM, Lefkowitch JH. *General pathology: Principles and dynamics*. Philadelphia: Lea & Febiger; 1983.

Membrane Composition

The main components of cell membranes are lipids and proteins. The cell membrane is a **lipid bilayer**, composed of two opposing leaflets and proteins that span the bilayer or interact with the lipids on either side of the two leaflets (Fig. 1.4). Historically, the plasma membrane was described as a fluid lipid bilayer *(fluid mosaic model)* composed of a uniform lipid distribution with inserted moving proteins. Although the notion is controversial, it now appears that the lipid bilayer is a much more complex structure where lipids and proteins are not uniformly distributed, but may separate into discrete units called *microdomains*, differing in their protein and lipid compositions. Different membranes have varying percentages of lipids and

proteins. Intracellular membranes may have a higher percentage of proteins than do plasma membranes, presumably because most enzymatic activity occurs within organelles. The membrane organization is achieved through noncovalent bonds that allow different physical states called phases (solid gel, fluid liquid–crystalline, and liquid ordered). These phases can change under physiologic factors, such as temperature and pressure fluctuations. Carbohydrates are mainly associated with plasma membranes, in which they are chemically combined with lipids, forming **glycolipids**, and with proteins, forming **glycoproteins** (Fig. 1.5).

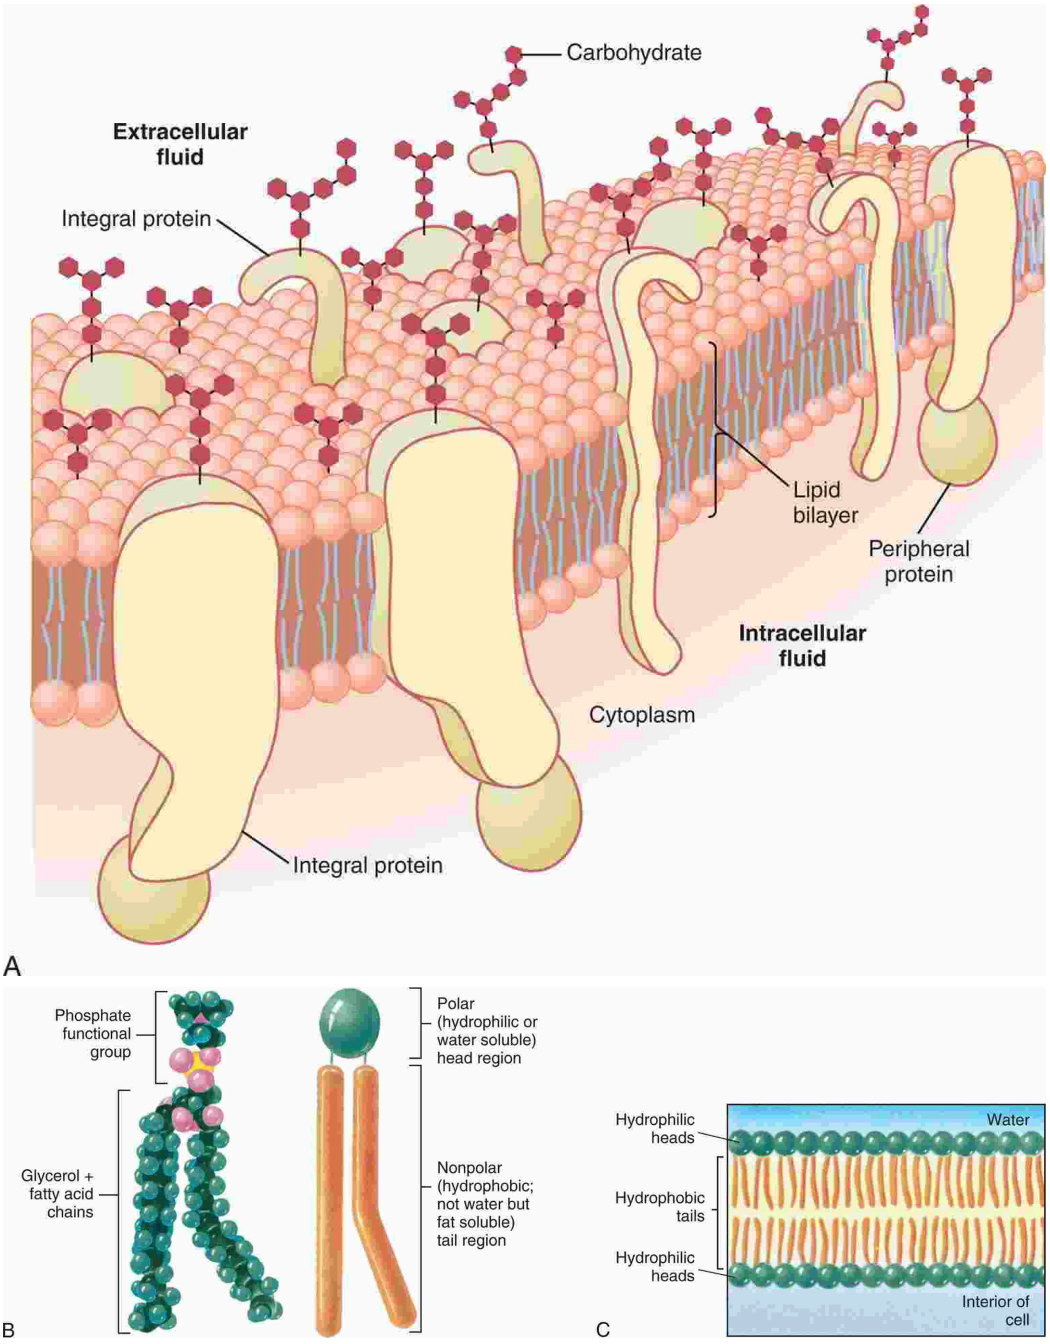

FIG. 1.4 Lipid Bilayer Membranes.
(A) The structure of a cell membrane showing the lipid bilayer, embedded proteins, and attached extracellular carbohydrates. **(B)** Each phospholipid molecule consists of a phosphate functional group and two fatty acid chains attached to a glycerol molecule. **(C)** The fatty acid

chains and glycerol form nonpolar, hydrophobic "tails," and the phosphate functional group forms the polar, hydrophilic "head" of the phospholipid molecule. When placed in water, the hydrophobic tails of the molecule face inward, away from the water, and the hydrophilic head faces outward, toward the water. (A, From Guyton AC, Hall JE. *Textbook of medical physiology*, 11th edition. Amsterdam: Elsevier Saunders; 2006. B and C, From Raven PH, Johnson GB. *Understanding biology*, 3rd edition. Dubuque, IA: Brown; 1995.

Part A is a colored illustration of a plasma membrane. The following parts in the structure are labeled: integral protein, carbohydrate, cytoplasm, lipid bilayer, and peripheral protein. Part B shows an illustration of two phospholipid molecules. Each molecule comprises a polar head region and a nonpolar tail region. The polar head region is hydrophilic or water soluble and comprises a phosphate functional group. The nonpolar tail region is hydrophobic or not water soluble but fat soluble and comprises a glycerol fatty acid chains. Part C shows an illustration of lipid bilayer membranes in water. Each molecule pair has its hydrophilic heads either in the water or in the interior of the cell. The hydrophobic tails are paired away from the water and the interior of cell.

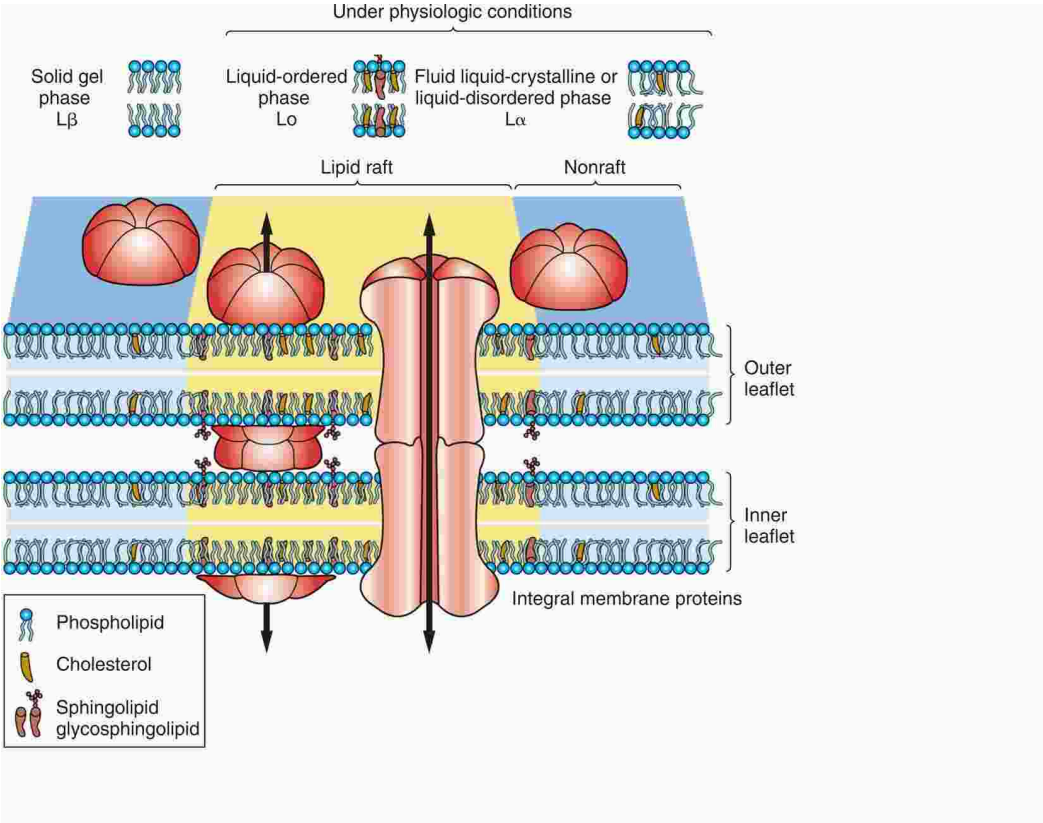

FIG. 1.5 Lipid Bilayer Membranes.
Concepts of biologic membranes have markedly changed in the last two decades, from the classic fluid mosaic model to the current model that lipids and proteins are not evenly distributed but can isolate into microdomains, differing in their protein and lipid composition. The three major phases of lipid bilayer organization include a solid gel phase (e.g., with low temperatures), a liquid-ordered phase (high temperatures), and a fluid liquid-crystalline (or liquid-disordered) phase.

A colored illustration shows the change in a lipid bilayer membrane under physiologic conditions. The changes are illustrated in the following sequence, from the left to the right. 1. Solid gel phase L beta,

comprising phospholipid layer. 2. Liquid-ordered phase L o, comprising cholesterol and sphingolipid glycosphingolipid. 3. Fluid liquid crystalline or liquid-disordered phase L alpha, comprising disordered phospholipids with cholesterols. An accompanying colored illustration shows and labels the lipid raft, nonraft, outer leaflet, inner leaflet, and integral membrane proteins.

The outer surface of the plasma membrane in many types of cells, especially endothelial cells and adipocytes, is not smooth but dimpled with flask-shaped invaginations known as *caveolae* ("tiny caves"). Caveolae, considered to serve as a storage site for many receptors, provide a route for transport into the cell and may act as the initiator for relaying signals from several extracellular chemical messengers into the cell's interior.

Lipids

Each lipid molecule is polar, or **amphipathic**, which means that one part is **hydrophobic** (uncharged, or "repelled by water") and another part is **hydrophilic** (charged, or "attracted to water") (see Fig. 1.4B). The membrane spontaneously organizes itself into two layers because of these two incompatible solubilities. The hydrophobic region (hydrophobic tail) of each lipid molecule is protected from water, whereas the hydrophilic region (hydrophilic head) is immersed in it. The bilayer serves as a barrier to the diffusion of water and hydrophilic substances, while allowing lipid-soluble molecules, such as oxygen (O_2) and carbon dioxide (CO_2), to diffuse through the membrane readily.

Cell membranes may contain many different lipid classes, but in animals, the main ones are phospholipids, cholesterol, and glycolipids. **Phospholipids**, the most abundant lipids, have a phosphate-containing hydrophilic head connected to a hydrophobic

tail. Phospholipids and glycolipids form self-sealing lipid bilayers. Lipids along with protein assemblies act as "molecular glue" for the structural integrity of the membrane. Phospholipids are key for repairing the membrane—they tend to spontaneously rearrange themselves to avoid a tear by folding on themselves and forming a sealed compartment.[2]

Proteins

Proteins perform most of the plasma membrane's tasks and are the major workhorses of the cell. A **protein** is made from a chain of amino acids, known as **polypeptides**. There are 20 types of amino acids in proteins and each type of protein has a unique sequence of amino acids. After translation (the synthesis of protein from RNA, see Chapter 4) of a protein, **posttranslational modifications (PTMs)** are the methods used to diversify the limited numbers of proteins generated. These modifications alter the activity and functions of proteins. PTMs have become very important in understanding disease processes. An emerging field of study in science is **proteomics**, the study of the **proteome**. This molecular approach is used to study an entire set of proteins expressed by a genome from synthesis, translocation, and modification (e.g., folding). Biologists are analyzing and uncovering information related to the roles of proteomes in a staggering number of diseases.

Membrane proteins associate with the lipid bilayer in different ways (Fig. 1.6), including:

1. **Transmembrane proteins** that extend across the bilayer and are exposed to an aqueous environment on both sides of the membrane (see Fig. 1.6A)
2. Proteins located almost entirely in the cytosol and associated with the cytosolic half of the lipid bilayer by an α helix exposed on the surface of the protein (see Fig. 1.6B)
3. Proteins that exist outside the bilayer, on one side or the other, and attached to the membrane by one or more covalently attached lipid groups (see Fig. 1.6C)

4. Proteins bound indirectly to one or the other bilayer membrane face and held in place by their interactions with other proteins (see Fig. 1.6D).[3]

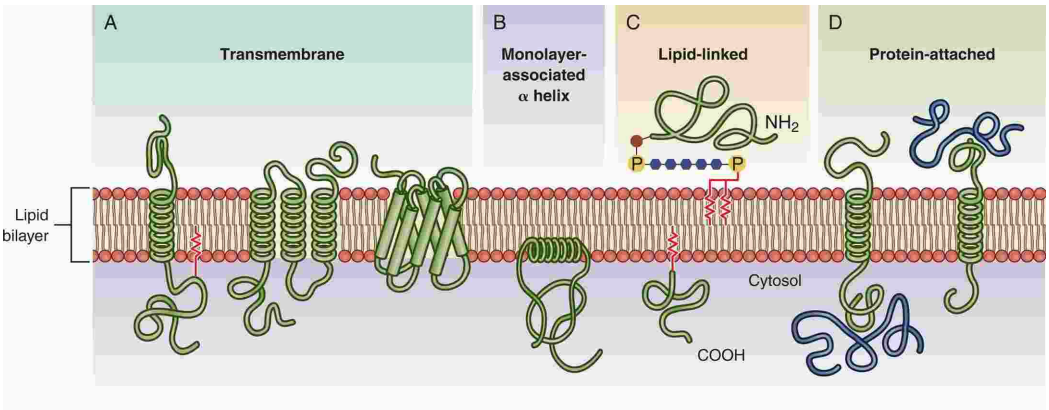

FIG. 1.6 Proteins Attach to the Plasma Membrane in Different Ways.
(A) Transmembrane proteins extend through the membrane as a single α helix, as multiple α helices, or as a rolled-up barrel-like sheet called a β barrel. **(B)** Some membrane proteins are anchored to the cytosolic side of the lipid bilayer by an amphipathic α helix. **(C)** Some proteins are linked on either side of the membrane by a covalently attached lipid molecule. **(D)** Proteins are attached by weak noncovalent interactions with other membrane proteins. (D, Adapted from Alberts B, Bray D, Hopkin K, et al. *Essential cell biology*, 4th edition. New York: Garland; 2014.

A four-part artist's rendering of a Lipid Bilayer Membrane illustrates the different ways proteins attach to the membrane. Part A, Transmembrane. Part B, Monolayer-Associated Alpha Helix. Part C, Lipid-Lined. Part D, Protein-Attached.

Proteins directly attached to the membrane bilayer can be removed by dissolving the bilayer with detergents called **integral membrane proteins**. The remaining proteins that can be removed by gentler procedures, that interfere with protein-protein interactions, but do

not dissolve the bilayer, are known as **peripheral membrane proteins**.

Proteins exist in densely folded molecular configurations rather than straight chains; thus most hydrophilic units are at the surface of the molecule, and most hydrophobic units are inside. Membrane proteins, like other proteins, are synthesized by the ribosome and translocate, called *trafficking*, to different membrane locations of a cell. Trafficking puts unique demands on membrane proteins for folding, translocation, and stability.

Although membrane structure is determined by the lipid bilayer, membrane functions are determined largely by proteins (see Fig. 1.3). Proteins act as:

1. Recognition and binding units (receptors) for substances moving into and out of the cell
2. Pores or transport channels for various electrically charged particles, called **ions** or *electrolytes*, and specific carriers for amino acids and monosaccharides
3. Specific enzymes that drive active pumps to promote concentration of certain ions, particularly potassium (K^+), within the cell while keeping concentrations of other ions (e.g., sodium [Na^+]), less than concentrations found in the extracellular environment
4. Cell surface markers, such as **glycoproteins** (proteins attached to carbohydrates), which identify a cell to its neighbor
5. **Cell adhesion molecules (CAMs)**, or proteins that allow cells to hook together and form attachments of the cytoskeleton for maintaining cellular shape
6. Catalysts of chemical reactions (e.g., conversion of lactose to glucose)

Membrane proteins are key components of energy transduction, converting chemical energy into electrical energy, or electrical energy into either mechanical energy or synthesis of ATP. Investigators are studying ATP enzymes and the changes in shape of

biologic membranes, particularly mitochondrial membranes, and their relationship to aging and disease.[4]

In animal cells, the plasma membrane is stabilized by a meshwork of proteins attached to the underside of the membrane called the **cell cortex**. Human red blood cells have a cell cortex that maintains their flattened biconcave shape.[3]

The cellular protein pool is in constant change or flux. **Proteostasis** is the process that regulates protein synthesis, folding, and degradation within and around a cell. This adaptable system depends on how quickly proteins are made, how long they survive, or when they are broken down. The proteostasis network comprises ribosomes (makers); chaperones (helpers); and two protein breakdown systems or **proteolytic** systems—lysosomes and the ubiquitin-proteasome system (UPS). These systems regulate protein homeostasis under a large variety of conditions, including variations in nutrient supply, the existence of oxidative stress or cellular differentiation, changes in temperature, and the presence of heavy metal ions and other sources of stress. Proteostasis is vital to health, and failure to maintain protein homeostasis is associated with aging and numerous degenerative diseases (Fig. 1.7).

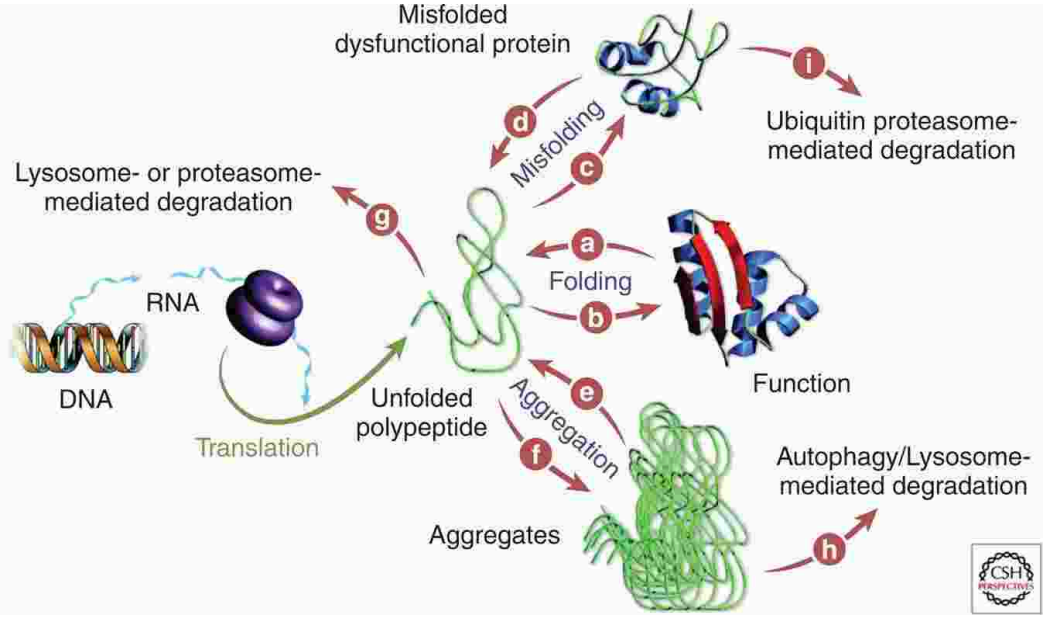

FIG. 1.7 Protein Homeostasis System and Outcomes.
A main role of the protein homeostasis network *(proteostasis)* is to minimize protein misfolding and protein aggregation. The network includes ribosome-mediated protein synthesis, chaperone (folding helpers in the ER) and enzyme mediated folding, breakdown systems of lysosome and proteasome-mediated protein degradation, and vesicular trafficking. The network integrates biologic pathways that balance folding, trafficking, and protein degradation depicted by *arrows a, b*, c*, d, e, f, g, h*, and *i. ER*, Endoplasmic reticulum.
(Adapted from Balch WE, Morimoto RI, Dillin A, et al. Adapting proteostasis for disease intervention. *Science* 2008;319:916 -919.)

An artist's rendering illustrates the Protein Homeostasis System and Outcomes. The illustration is represented as a sequence of networks, a through i.

- D N A and R N A transform into unfolded

polypeptides. • Networks a and b illustrate the folding of unfolded polypeptides into a function. • Networks c and d illustrate the misfolding of unfolded polypeptides into dysfunctional proteins, which leads to network i, ubiquitin proteasome-mediated degradation. • Networks e and f illustrate the aggregation of unfolded polypeptides, which leads to network h, autophagy or lysosome-mediated degradation. • Network g illustrates the transformation of unfolded polypeptide into lysosome- or proteasome- mediated degradation.

Carbohydrates

The short chains of sugars or carbohydrates *(oligosaccharides)* contained within the plasma membrane are mostly bound to membrane proteins (glycoproteins) and lipids (glycolipids). Long polysaccharide chains attached to membrane proteins are called *proteoglycans*. All of the carbohydrate on the glycoproteins, proteoglycans, and glycolipids is located on the outside of the plasma membrane and the carbohydrate coating is called the **glycocalyx**. The glycocalyx helps to protect the cell from mechanical damage.[5] In addition, the layer of carbohydrate gives the cell a slimy surface that assists the mobility of other cells, such as leukocytes, to squeeze through the narrow spaces.[3] Other functions of carbohydrates include specific cell-to-cell recognition and adhesion. Intercellular recognition is an important function of membrane oligosaccharides; for example, the transmembrane proteins called *lectins*, which bind to a particular oligosaccharide, recognize neutrophils at the site of bacterial infection. This recognition allows the neutrophil to adhere to the blood vessel wall and migrate from

blood into the infected tissue to help eliminate the invading bacteria.[3]

Cellular Receptors

Cellular receptors are protein molecules on the plasma membrane, in the cytoplasm, or in the nucleus that can recognize and bind with specific smaller molecules called **ligands** (from the Latin *ligare*, "to bind") (Fig. 1.8). The region of a protein that associates with a ligand is called its **binding site**. For example, hormones are ligands. Numerous receptors are found in most cells. Ligand binding to receptors activates or inhibits the receptor's associated signaling or biochemical pathway (see the Cellular Communication and Signal Transduction section). Recognition and binding depend on the chemical configuration of the receptor and its smaller ligand, which must fit together somewhat like the pieces of a jigsaw puzzle. Binding selectively to a protein receptor with high affinity to a ligand depends on formation of weak, noncovalent interactions—hydrogen bonds, electrostatic attractions, and van der Waals attractions—and favorable hydrophobic forces.[3]

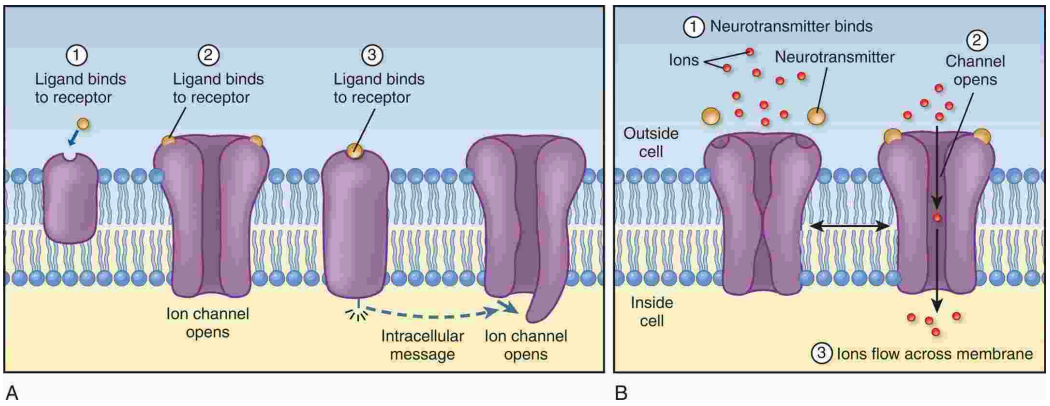

FIG. 1.8 Cellular Receptors.
(A) ***1***, Plasma membrane receptor for a ligand (here, a hormone molecule) on the surface of an integral protein. A neurotransmitter can exert its effect on a postsynaptic cell by means of two fundamentally different types of receptor proteins. ***2***, Channel-linked receptors. ***3***, Non–channel-linked receptors. Channel-linked receptors are also known as *ligand-gated channels*. **(B)** Example of ligand-gated ion channels. The channel structure is changed when, for example, a neurotransmitter binds and ions can now enter.

Two illustrations, A and B, demonstrate the flow of ligands through ion channels in bilipid layers. Illustration A demonstrates three stages. 1. Ligand binds to receptor. 2. Ligand binds to receptor, when the ion channel opens. 3. Ligand binds to receptor. An intracellular message is passed through the open ion channel. Illustration B demonstrates three stages. 1. Neurotransmitter binds ions outside the cell. 2. Ion

Channel opens. 3. Ions flow across the membrane to the inside cell.

Plasma membrane receptors protrude from or are exposed at the external surface of the membrane and are important for cellular uptake of ligands (see Fig. 1.8). The ligands that bind with membrane receptors include hormones, neurotransmitters, antigens, complement components, lipoproteins, infectious agents, drugs, and metabolites. Specific interactions of cellular receptors with their respective ligands have provided a basis for understanding disease.

Although the chemical nature of ligands and their receptors differs, receptors are classified based on their location and function. Cellular type determines overall cellular function, but plasma membrane receptors determine which ligands a cell will bind with and how the cell will respond to the binding. Specific processes also control intracellular mechanisms.

Receptors for different drugs are found on the plasma membrane, in the cytoplasm, and in the nucleus. Membrane receptors have been found for certain anesthetics, opiates, endorphins, enkephalins, antibiotics, cancer chemotherapeutic agents, digitalis, and other drugs. Membrane receptors for endorphins, which are opiate-like peptides isolated from the pituitary gland, are found in large quantities in pain pathways of the nervous system (see Chapters 15 and 16). With binding to the receptor, the endorphins (or drugs, e.g., morphine) change the cell's permeability to ions, increase the concentration of molecules that regulate intracellular protein synthesis, and initiate molecular events that modulate pain perception.

Receptors for infectious microorganisms, or antigen receptors, bind bacteria, viruses, and parasites to the cell membrane. Antigen receptors on white blood cells (lymphocytes, monocytes, macrophages, granulocytes) recognize and bind with antigenic microorganisms and activate the immune and inflammatory responses (see Chapter 7).

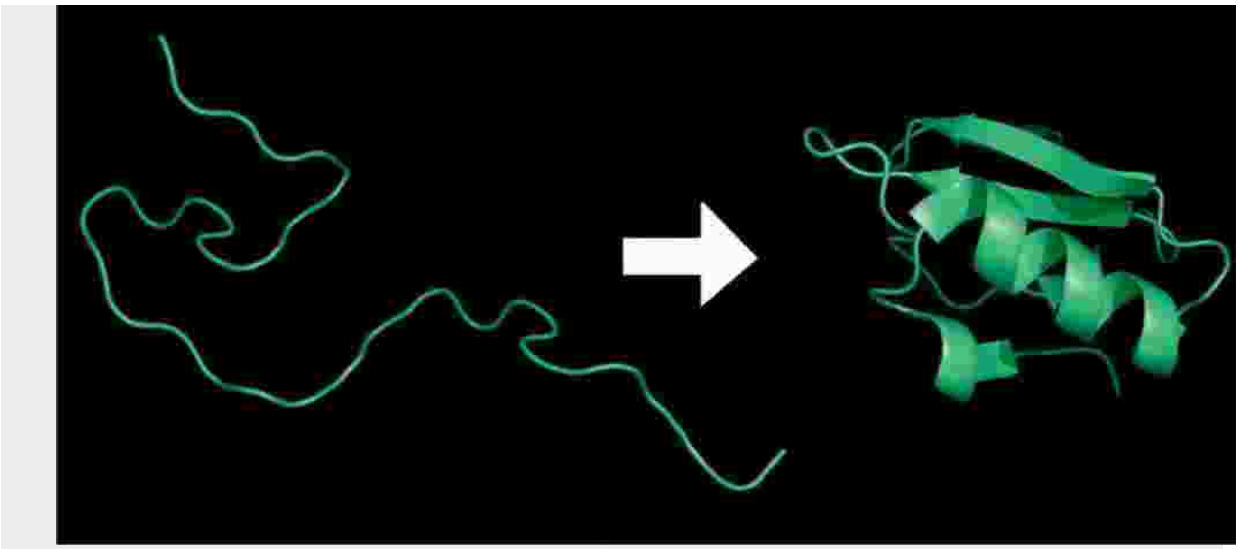
Cell-to-Cell Adhesions

Cells are small and squishy, *not* like bricks. They are enclosed only by a flimsy membrane, yet the cell depends on the integrity of this membrane for its survival. How can cells be connected strongly, with their membranes intact, to form a muscle that can lift this textbook? Plasma membranes not only serve as the outer boundaries of all cells but also allow groups of cells to be held together robustly, in **cell-to-cell adhesions**, to form tissues and organs (Box 1.1). Once arranged, cells are linked by three different means: (1) the extracellular matrix (ECM), (2) CAMs in the cell's plasma membrane, and (3) specialized cell junctions.

Box 1.1

Cell Adhesion Molecules

Cell adhesion molecules (CAMs) are cell surface proteins that bind the cell to an adjacent cell and to components of the extracellular matrix (ECM). CAMs include four protein families: (1) the integrins, (2) the cadherins, (3) the selectins, and (4) the **immunoglobulin superfamily CAMs** (IgSF CAMs). **Integrins** are receptors within the ECM and regulate cell-ECM interactions with collagen. **Cadherins** are calcium (Ca^{2+})-dependent glycoproteins throughout tissue (e.g., epithelial [E-cadherin]). **Selectins** are proteins that bind some carbohydrates (e.g., mucins). The IgSF CAMs bind integrins and other IgSF CAMs.



Extracellular Matrix and Basement Membrane

Cells can be united by attachment to one another or through the ECM (including the basement membrane), which the cells secrete around themselves. The **extracellular matrix (ECM)** is an intricate meshwork of fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates (Fig. 1.9). The **basement membrane (BM)** (also known as **basal lamina**) is a specialized type of ECM. This sheet of matrix is very thin, tough, and flexible; lies beneath epithelial cells; occurs between two cell sheets (kidney glomerulus); and surrounds individual muscle cells, fat cells, and Schwann cells (which wrap around peripheral nerve cell axons) (Fig. 1.10). The ECM is similar to glue; however, it provides a pathway for diffusion of nutrients, wastes, and other water-soluble substances between the blood and tissue cells. Interwoven within the matrix are three groups of large molecules or **macromolecules**: (1) fibrous structural proteins, including collagen and elastin; (2) adhesive glycoproteins, such as fibronectin; and (3) proteoglycans and hyaluronic acid.

1. **Collagen** forms cable-like fibers or sheets that provide tensile strength or resistance to longitudinal stress. Collagen

breakdown, such as occurs in osteoarthritis, destroys the fibrils that give cartilage its tensile strength.

2. **Elastin** is a rubber-like protein fiber most abundant in tissues that must be capable of stretching and recoiling, such as found in the lungs.
3. **Fibronectin**, a large glycoprotein, promotes cell adhesion and cell anchorage. Reduced amounts have been found in certain types of cancerous cells; this allows cancer cells to travel, or metastasize, to other parts of the body. All of these macromolecules occur in intercellular junctions and cell surfaces and may assemble into two different components: interstitial matrix and BM (see Fig. 1.9).

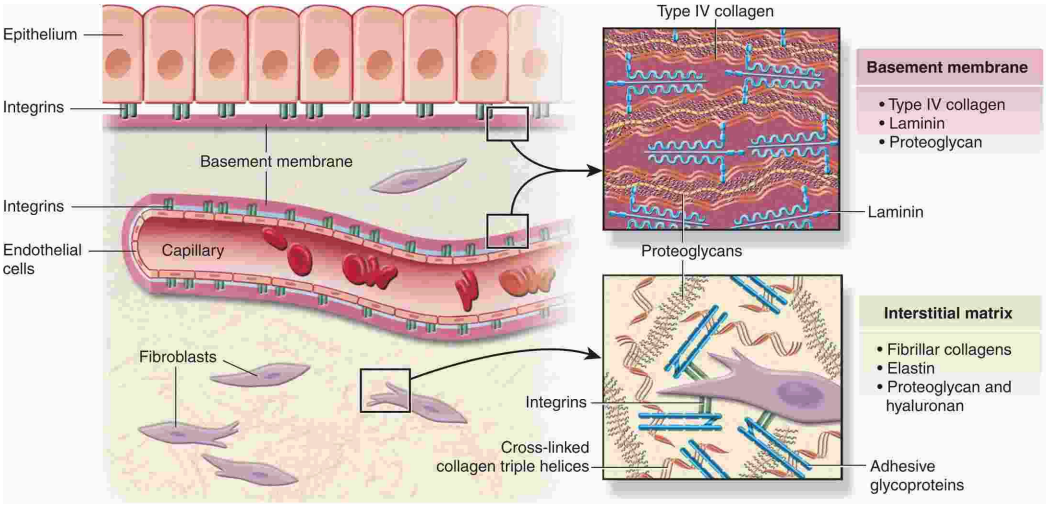


FIG. 1.9 Extracellular Matrix.
Tissues are not just cells but also extracellular space. The extracellular space is an intricate network of macromolecules called the *extracellular matrix (ECM)*. The macromolecules that constitute the ECM are secreted locally (by mostly fibroblasts) and assembled into a meshwork in close association with the surface of the cell that produced them. Two main classes of macromolecules include proteoglycans, which are bound to polysaccharide chains called *glycosaminoglycans;* and fibrous proteins (e.g., collagen, elastin, fibronectin, and laminin), which have structural and adhesive properties. Together the proteoglycan molecules form a gel-like ground substance in which the fibrous proteins are embedded. The gel permits rapid diffusion of nutrients, metabolites, and hormones between blood and the tissue cells. Matrix proteins modulate cell-matrix interactions, including normal tissue remodeling (which can become abnormal, for example, with chronic inflammation). Disruptions of this balance result in serious diseases such as arthritis, tumor growth, and other pathologic conditions. (Adapted from

Kumar A, Abbas K, Jon C. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.

A three-panel illustration shows cross-sectional views of extracellular matrix. Left panel. The illustration shows and labels the following parts, from the top to the bottom, epithelium, integrins, basement membrane, integrins, endothelial cells, capillary, and fibroblasts. Top right panel. The illustration shows a fibroblast and labels the following parts: proteoglycans, integrins, and cross-linked collagen triple helices. The interstitial matrix comprises fibrillar collagens, elastin, proteoglycan and hyaluronan. Bottom right panel. The illustration shows a closeup of proteoglycans. The basement membrane comprises type four collagen, laminin, and proteoglycan.

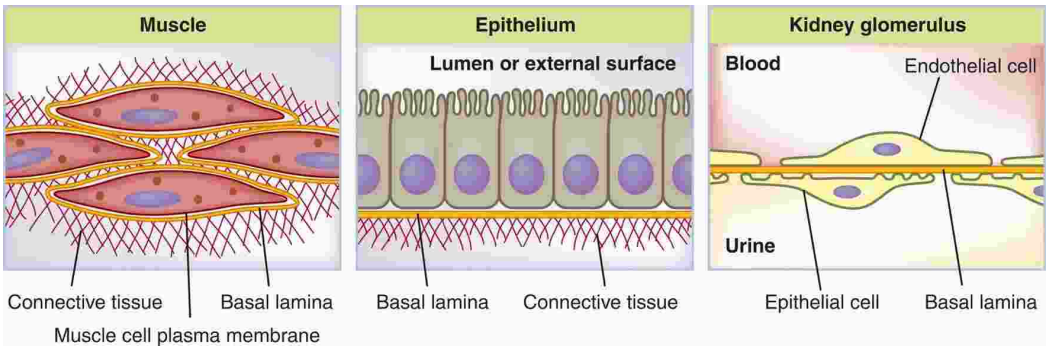

FIG. 1.10 Three Ways Basement Membranes (Basal Laminae) Are Organized.
Basal laminae *(yellow)* surround certain cells like skeletal cells, underlie epithelia, and occur between two cell sheets (kidney glomerulus).
(Adapted from Alberts B, Bray D, Hopkin K, et al. *Essential cell biology*, 4th edition. New York: Garland; 2014.

Three colored illustrations show the organization of basement membranes in Muscle, Epithelium, and Kidney Glomerulus. In Muscle, the Muscle Cell Plasma Membrane is covered by Basal Lamina, which is surrounded by Connective Tissue. In Epithelium, the Lumen or External Surface is aligned on the Basal Lamina with Connective Tissue underneath. In Kidney Glomerulus, the Basal Lamina is surrounded by Endothelial Cells in Blood at the top and Epithelial Cells in Urine at the bottom.

The ECM is secreted by **fibroblasts** ("fiber formers") (Fig. 1.11), local cells that are present in the matrix. The matrix and the cells within it are known collectively as *connective tissue* because they interconnect cells to form tissues and organs. Human connective tissues are enormously varied. They can be hard and dense (e.g., bone), flexible (e.g., tendons or the dermis of the skin), resilient and

shock absorbing (e.g., cartilage), or soft and transparent, similar to the jelly-like substance that fills the eye. In all these examples, the majority of the tissue is composed of ECM, and the cells that produce the matrix are scattered within it like raisins in a pudding (see Fig. 1.11).

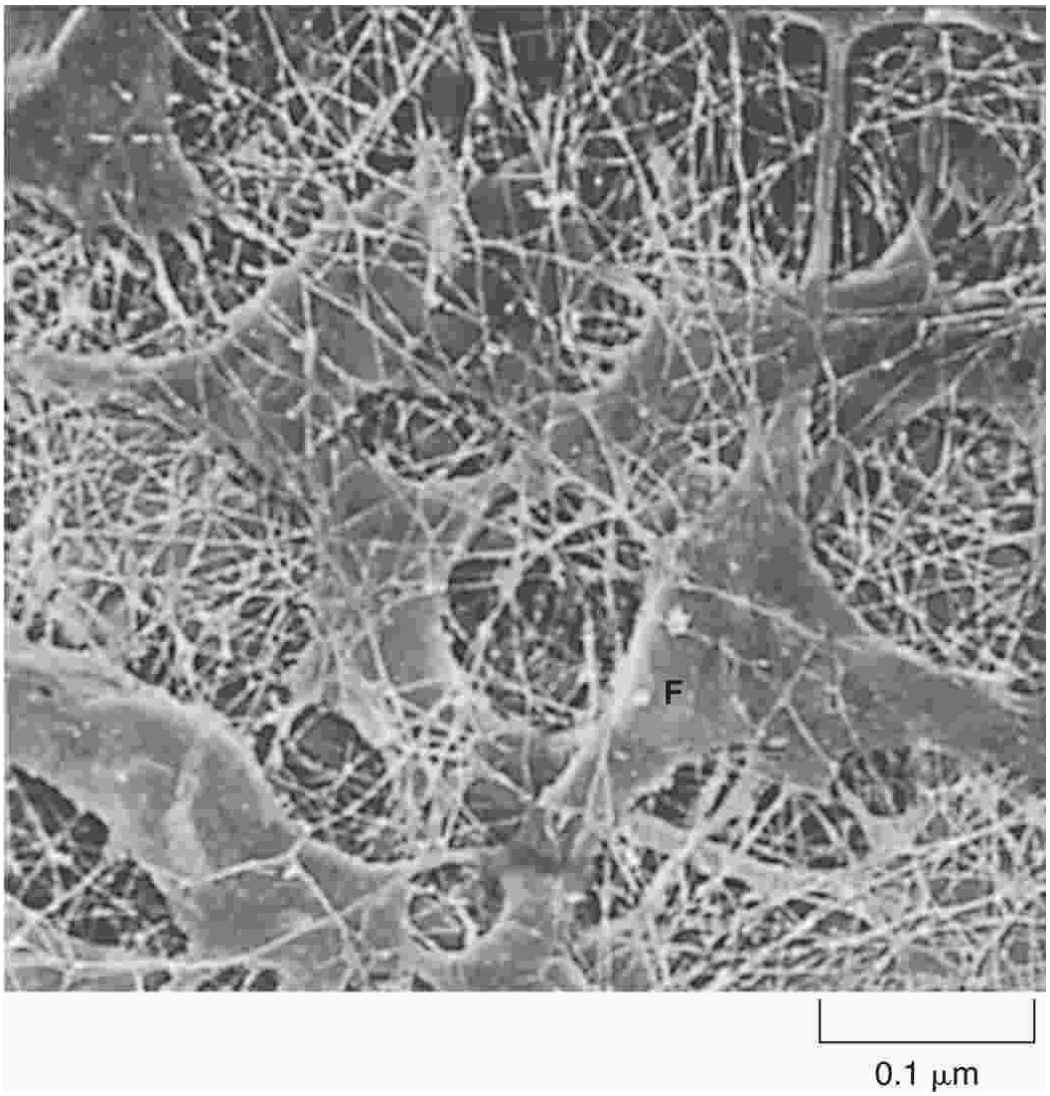

FIG. 1.11 Fibroblasts in Connective Tissue. This micrograph shows tissue from the cornea of a rat. The extracellular matrix surrounds the fibroblasts *(F)*. (Adapted from Nishia T, et al. The extracellular matrix of animal connective tissues. *Invest Ophthalmology Visual Science*, 1998; 29:1887-1880.)

The matrix is not just passive scaffolding for cellular attachment but also helps to regulate the function of the cells with which it interacts. The matrix helps to regulate important functions, such as cell growth and differentiation.

Cell Adhesion Molecules

Cell adhesion molecules (CAMs) are cell surface proteins that bind the cell to adjacent cells and to components of the ECM. CAMs are divided into four protein families: integrins, cadherins, selectins, and the immunoglobulin superfamily (IgSF).[6] **Integrins** are a major class of molecules that typically bind to the ECM, whereas selectins, cadherins, and IgSF are associated with cell-to-cell adhesion. Integrins regulate cell interactions with collagen, fibronectin, vitronectin, and fibrinogen in the ECM. **Cadherins**, an abbreviation of "calcium-dependent adherent proteins," are associated with cell-cell adhesive bonds in solid tissues. They are calcium-dependent glycoproteins that have specific functions and distributions within tissues. For example, epithelial cells express E-cadherin, which cause tight adhesions between cells that interface between the body and the environment to create a protective barrier. Neural and endothelial cells express N-cadherin which helps to maintain the structural integrity of nerve cells and blood vessels.[7] **Selectins** are a family of proteins that bind certain carbohydrates. Selectins are divided into subgroups based on which cell types they are found in: P—platelets, E—endothelial, and L—leukocytes. Their primary function is to allow blood cells to bind to the endothelial surfaces of blood vessels during the inflammatory response (see Chapter 7). The **immunoglobulin superfamily CAMs (IgSF CAMs)** is one of the largest and most diverse protein families. These CAMs include vascular (VCAM), intercellular (ICAM), neural (NCAM), and nectins. Their functions include adhesion between immune and endothelial cells, neural development, and cellular migration and growth.

Specialized Cell Junctions

Cells in direct physical contact with neighboring cells are often interconnected at specialized plasma membrane regions called **cell junctions**. Cell junctions are classified by their function:

1. Tight Junction: To hold cells together and form a tight seal and to maintain apicobasal polarity of individual epithelial cells

(Fig. 1.12)

2. Adherens junctions, desmosomes, hemidesmosomes: To provide strong mechanical attachments
3. Gap junctions: To provide a special type of chemical communication (e.g., inorganic ions and small water-soluble molecules to move from the cytosol of one cell to the cytosol of another cell), such as those causing an electrical wave

(A), Schematic drawing of a belt desmosome between epithelial cells. This junction, also called *zonula adherens*, encircles each interacting cell. The spot desmosomes and hemidesmosomes, like the belt desmosomes, are adhering junctions. The tight junction is an impermeable junction that holds cells together but seals them in such a way that molecules cannot leak between them. The gap junction, as a communicating junction, mediates the passage of small molecules from one interacting cell to the other. **(B)** Electron micrograph of desmosomes. **(C)** Connexons. The connexin gap junction proteins have four transmembrane domains, and they play a vital role in maintaining cell and tissue function and homeostasis. Cells connected by gap junctions are considered ionically (electrically) and

metabolically coupled. Gap junctions coordinate the activities of adjacent cells; for example, they are important for synchronizing contractions of heart muscle cells through ionic coupling and for permitting action potentials to spread rapidly from cell to cell in neural tissues. The reason gap junctions occur in tissues that are not electrically active is unknown. Although most gap junctions are associated with junctional complexes, they sometimes exist as independent structures. **(D)** Cell Polarity of Epithelial Cells. Schematic of cell polarity (cell direction) of epithelial cells. Shown are the directions of the basal side and the apical side. Organelles and cytoskeleton are also arranged directionally to enable, for example, intestinal cell secretion and absorption. (A and B, From Raven PH, Johnson GB. *Biology*. Part A is an illustration of epithelial cells. The following parts in the structure are labeled, from the top to the bottom: belt desmosome, spot desmosomes, and hemidesmosomes. An accompanying illustration shows a top view of the belt desmosome. Another cross-sectional illustration of the belt desmosome shows and labels the following parts from the top to the bottom: junctional complex, tight junction, zonula occludens, belt desmosome, zonula adherents, filamentous material

in intercellular space, spot desmosome, macula adherents, intercellular filaments, and gap junction. The gap junction comprises intercellular channel and intercellular units forming channels for extracellular transport. Part B is an electron micrograph of desmosomes, illustrating cell-to-cell adhesion. Part C is a cross-sectional illustration of connexons. The following parts in the structure are labeled, from the top to the bottom, between cell 1 cytosol and cell 2 cytosol, 2.4 nanometers apart: connexon with diameter of channel equals 1.5 nanometers, gap junction longitudinal section of connexon, passage of ions and small molecules from Cell 1 cytosol to Cell 2 cytosol, no passage of large molecules from Cell 1 cytosol to Cell 2 cytosol, and interacting plasma membranes. Part D is a cross-sectional illustration of a hemidesmosome with three desmosomes. The tight junction is identified between the first and the second desmosomes. The adherents junction is identified between the second and the third desmosomes. The following parts of the structure are labeled from the top to the bottom: apical side, basal side, and basal lamina. The transport pathway of secretion is traced from the hemidesmosome. The transport pathway of absorption is traced toward the hemidesmosome and is identified as the movement of transport vesicles along the cytoskeleton.

In summary, cell junctions make the epithelium leak-proof and mediate mechanical attachment of one cell to another, allowing communicating tunnels and maintaining cell polarity.[8]

Cell junctions can be classified as symmetric and asymmetric. Symmetric junctions include tight junctions (zonula occludens), the belt desmosome (zonula adherens), desmosomes (macula adherens), and gap junctions (also called *intercellular channel* or *communicating junctions*). An asymmetric junction is the hemidesmosome (see Fig. 1.12A). Together they form the **junctional complex**. **Tight junctions** are barriers to diffusion, prevent the movement of substances through transport proteins in the plasma membrane, and prevent the leakage of small molecules between the plasma membranes of adjacent cells.[9]**Desmosomes** unite cells either by forming continuous bands or belts of epithelial sheets or by developing button-like points of contact. Desmosomes also act as a system of braces to maintain structural stability (see Fig. 1.12B). **Gap junctions** are composed of integral membrane proteins called connexins. **Connexins** are hemichannels that extend outward from each of the adjacent plasma membranes (see Fig. 1.12C). Gap junctions facilitate intercellular communication by allowing small ions and signaling molecules to pass directly from the inside of one cell to the inside of another. This process of cell communication is a critical feature for the development, function, and homeostasis of tissues and organs.[10] Multiple factors regulate gap junction intercellular communication, including voltage across the junction, intracellular pH, intracellular calcium (Ca^{2+}) concentration, and protein phosphorylation. **Cell polarity**, the direction of cellular transport, maintains normal cell and tissue structure for numerous functions (e.g., movement of nutrients in and out of the cell) and becomes altered with diseases (see Fig. 1.12D).

The junctional complex is a highly permeable part of the plasma membrane where permeability is controlled by a process called **gating**. Increased levels of cytoplasmic calcium cause decreased permeability at the junctional complex. Gating enables uninjured cells to protect themselves from injured neighbors.

Cellular Communication and Signal Transduction

Cells need to communicate with each other to maintain a stable internal environment, or **homeostasis**; to regulate their growth and division; to oversee their development and organization into tissues; and to coordinate their functions. Cells communicate by using hundreds of signal molecules (e.g., insulin-like growth factor 1). Cells communicate in three main ways:

1. They display plasma membrane–bound signaling molecules (receptors) that affect the cell itself and other cells in direct physical contact (Fig. 1.13A).
2. They affect receptor proteins *inside* the target cell and the signal molecule has to enter the cell to bind to them (see Fig. 1.13B).
3. They form protein channels (gap junctions) that directly coordinate the activities of adjacent cells (see Fig. 1.13C). Alterations in cellular communication affect disease onset and progression. In fact, if a cell cannot perform gap junctional intercellular communication, normal growth control and cell differentiation is compromised, thereby favoring cancerous tumor development (see Chapter 12).

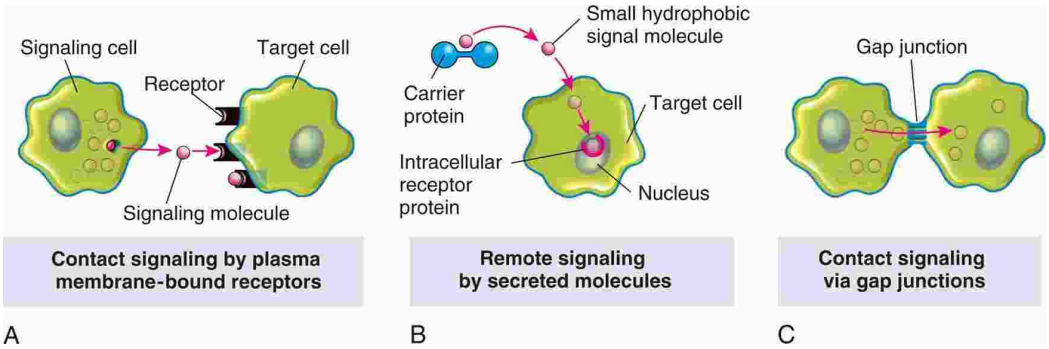

FIG. 1.13 Cellular Communication.
Three primary ways **(A–C)** cells communicate with one another. (B, Adapted from Alberts B, Johnson A, Lewis J, et al. *Molecular biology of the cell*, 5th edition. New York: Garland; 2008.

A three-part illustration shows cellular communication. Part A illustrates contact signaling by plasma membrane-bound receptors. A signaling molecule from the Signaling Cell is accepted at the Receptor site on the Target Cell. Part B illustrates remote signaling by secreted molecules. A Carrier Protein transports a Small Hydrophobic Signal Molecule, which is accepted by the Intracellular Receptor Protein in the Nucleus of the Target Cell. Part C illustrates contact signaling via gap junctions. The Gap Junction between two cells is highlighted and labeled.

Secreted chemical signals involve communication locally and at a distance. Primary modes of intercellular signaling are contact dependent, paracrine, hormonal, neurohormonal, and neurotransmitter. Autocrine stimulation occurs when the secreting cell targets itself (Fig. 1.14).

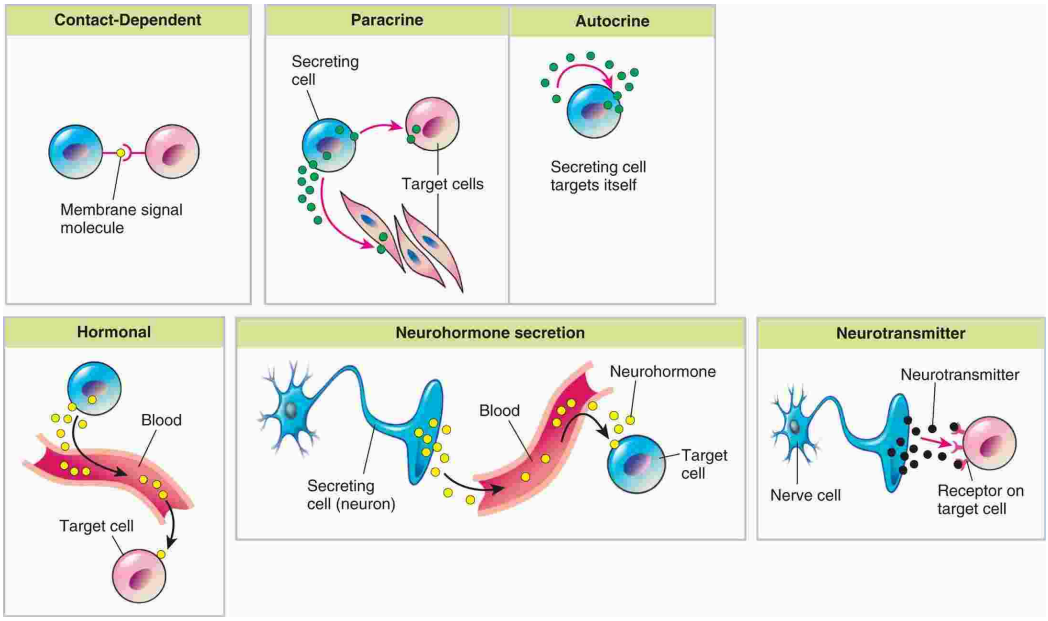

FIG. 1.14 Primary Modes of Chemical Signaling.
Five forms of signaling mediated by secreted molecules. Hormones, paracrines, neurotransmitters, and neurohormones are all intercellular messengers that accomplish communication between cells. Autocrines bind to receptors on the same cell. Not all neurotransmitters act in the strictly synaptic mode shown; some act in a contact-dependent mode as local chemical mediators that influence multiple target cells in the area.

A five-part illustration demonstrates the primary modes of chemical signaling. Contact-dependent. A membrane signal molecule links the source cell and the target cell. Paracrine. The source cell secretes receptors for target cells. Autocrine. The cell secretes receptors that bind to the same cell. Hormonal. The source cell secretes receptors to the target cell,

through the blood stream. Neurohormone secretion. A neuron secretes neurohormones through the blood stream and to the target cell. Neurotransmitter. A nerve cell secretes neurotransmitters that are accepted by the receptors on the target cell.

Contact-dependent signaling requires cells to be in close membrane-to-membrane contact. In **paracrine signaling**, cells secrete local chemical mediators that are quickly taken up, destroyed, or immobilized. Paracrine signaling usually involves different cell types; however, cells also can produce signals to which they alone respond, and this is called **autocrine signaling** (see Fig. 1.14). Cancer cells use this form of signaling to stimulate their survival and proliferation. The mediators act only on nearby cells. **Hormonal signaling** involves specialized endocrine cells that secrete chemicals called *hormones;* hormones are released by one set of cells and travel through the bloodstream to produce a response in other sets of cells. In **neurohormonal signaling** hormones are released into blood by neurosecretory neurons. Like endocrine cells, neurosecretory neurons release blood-borne chemical messengers, whereas ordinary neurons secrete short-range neurotransmitters into a small discrete space (i.e., synapse). Neurons communicate directly with the cells they innervate by releasing chemicals or **neurotransmitters** at specialized junctions called **chemical synapses**; the neurotransmitter diffuses across the synaptic cleft and acts on the postsynaptic target cell (see Fig. 1.14). Many of these same signaling molecules are receptors used in hormonal, neurohormonal, and paracrine signaling. Important differences lie in the speed and selectivity with which the signals are delivered to their targets.[2]

Plasma membrane receptors belong to one of three classes that are defined by the signaling (transduction) mechanism used. Table 1.3 summarizes these classes of receptors. Cells respond to external stimuli by activating a variety of **signal transduction pathways**,

which are communication pathways, or signaling cascades (Fig. 1.15). Signals are passed between cells when a particular type of molecule is produced by one cell—the **signaling cell**—and received by another—the **target cell**—by means of a **receptor protein** that recognizes and responds specifically to the signal molecule (see Fig. 1.15A and B). In turn, the signaling molecules activate a pathway of intracellular protein kinases that results in various responses, such as growing and reproducing, dying, surviving, or differentiating (see Fig. 1.15). If deprived of appropriate signals, most cells undergo a form of cell suicide known as *programmed cell death*, or *apoptosis* (see Chapter 2).

Table 1.3

Classes of Plasma Membrane Receptors

Type of Receptor	Description
Channel linked	Also called *ligand-gated channels;* involve rapid synaptic signaling between electrically excitable cells. Channels open and close briefly in response to neurotransmitters, changing ion permeability of plasma membrane of postsynaptic cell.
Catalytic	Once activated by ligands, function directly as enzymes. Composed of transmembrane proteins that function intracellularly as tyrosine-specific protein kinases.
G-protein linked	Indirectly activate or inactivate plasma membrane enzyme or ion channel; interaction mediated by guanosine triphosphate (GTP)-binding regulatory protein (G protein). When activated, a chain of reactions occurs that alters concentration of intracellular messengers, such as cyclic adenosine monophosphate (cAMP) and calcium, or signaling molecules. Behaviors of other target proteins are also altered. May also interact with inositol phospholipids, which are significant in cell signaling, and molecules involved in the inositol-phospholipid transduction pathway. A G-protein–linked receptor activates the enzyme phosphoinositide-specific phospholipase, which, in turn, generates two intracellular messengers: (1) inositol triphosphate (IP_3) releases calcium (Ca^{2+}), and (2) diacylglycerol remains in the plasma

Type of Receptor	Description
	membrane and activates protein kinase C. Protein kinase C further activates various cell proteins. Several different plasma membrane receptors are known to use the inositol-phospholipid transduction pathway.

Data from Alberts B, Bray D, Hopkin K, et al. *Molecular biology of the cell*, 5th edition. New York: Garland; 2008.

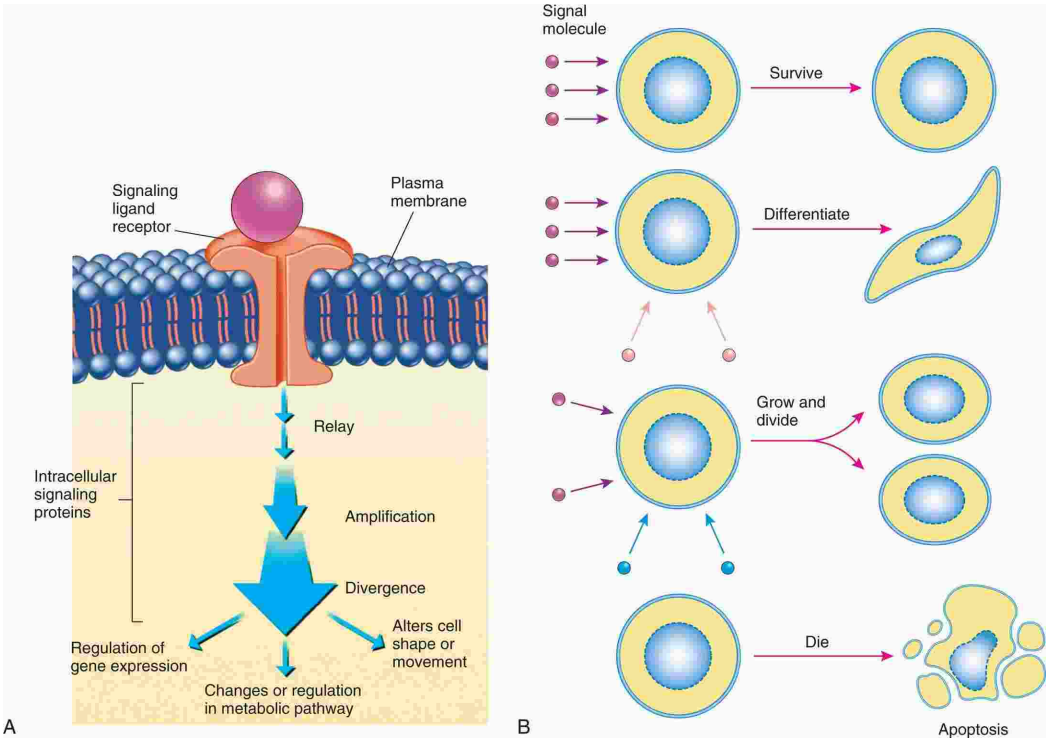

FIG. 1.15 Schematic of a Signal Transduction Pathway.
Like a telephone receiver that converts an electrical signal into a sound signal, a cell converts an extracellular signal. **(A)** An extracellular signal molecule (ligand) binds to a receptor protein located on the plasma membrane, where it is transduced into an intracellular signal. This process initiates a signaling cascade that relays the signal into the cell interior, amplifying and distributing it during transit. Amplification is often achieved by stimulating enzymes. Steps in the cascade can be modulated by other events in the cell. **(B)** Different cell behaviors rely on multiple extracellular signals.

Two schematics, A and B, illustrate signal transduction pathways. Schematic A shows a cross-

section of the transduction pathway. A ligand binds itself to the signaling ligand receptor in the plasma membrane. The ligand is relayed, amplified, and diverged, where divergence includes regulation of gene expression, changes or regulation in metabolic pathway, and alteration of cell shape or movement. Schematic B illustrates cell behaviors: Survive, Differentiate, Grow and Divide, and Die. Survive: The signal molecule retains its shape. Differentiate: The signal molecule changes shape. Grow and divide: The signal molecule separates into two units. Die: The signal molecule disintegrates.

Binding of the extracellular signaling messenger (i.e., ligand), or **first messenger**, to the membrane receptors causes (1) opening or closing of specific channels in the membrane to regulate the movement of ions into or out of the cell; and (2) transfer of the signal to an intracellular messenger or **second messenger**, which triggers a cascade of biochemical events within the cell (Fig. 1.16).

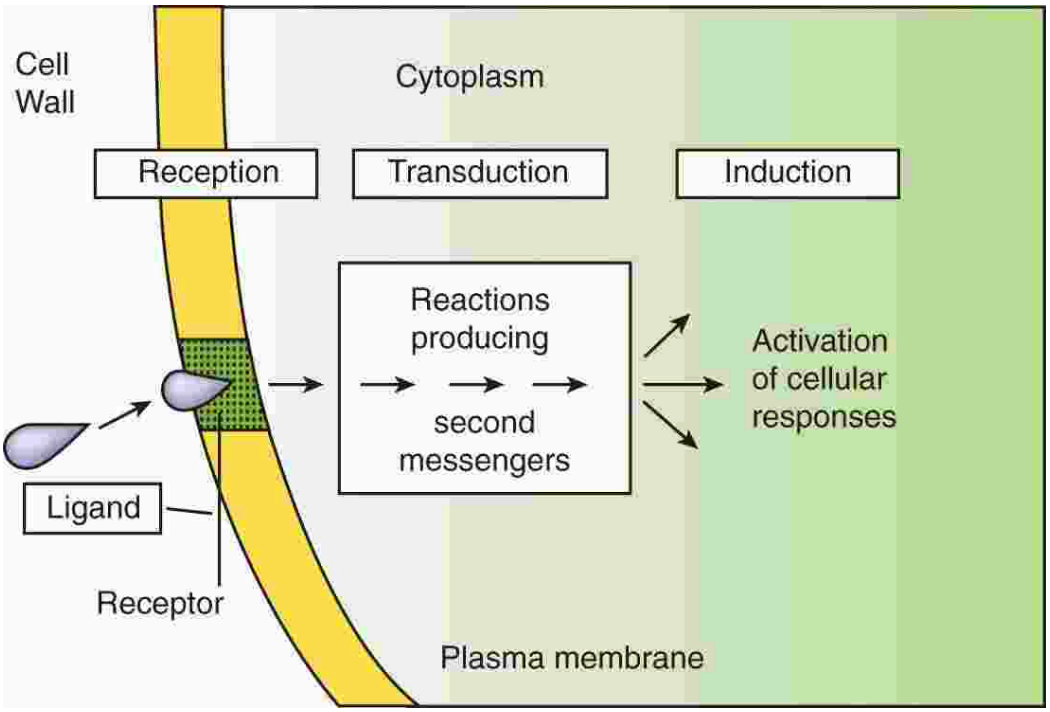

FIG. 1.16 First and Second Messengers.
The first messenger or ligand attaches to the membrane receptor relaying the message across the membrane and intracellular messengers or second messengers trigger the cascade of intracellular events. The two major second-messenger pathways are cyclic adenosine monophosphate and calcium. A large number of human disorders involve problematic signaling.

A cross-sectional illustration shows the reception, transduction, and induction of ligands into the plasma membrane. The schematic shows the cell wall, receptor, cytoplasm, and plasma membrane. The ligand is accepted at the receptor site. Transduction involves reactions producing second

messengers. Induction involves activation of cellular responses.

Cellular Metabolism

All of the chemical tasks of maintaining essential cellular functions are referred to as **cellular metabolism**. The energy-using process of metabolism is called **anabolism** (*ana* = upward), and the energy-releasing process is known as **catabolism** (*kata* = downward). Metabolism provides the cell with the energy it needs to produce cellular structures.

Dietary proteins, fats, and starches (i.e., carbohydrates) are hydrolyzed in the intestinal tract into amino acids, fatty acids, and glucose, respectively. These constituents are then absorbed, circulated, and incorporated into the cell, where they may be used for various vital cellular processes, including the production of ATP. The process by which ATP is produced is one example of a series of reactions called a **metabolic pathway**. A metabolic pathway involves several steps whose end products are not always detectable. A key feature of cellular metabolism is the directing of biochemical reactions by protein catalysts or enzymes. Each enzyme has a high affinity for a **substrate**, a specific substance converted to a product of the reaction.

Role of Adenosine Triphosphate

What is best known about ATP is its role as a universal "fuel" *inside* living cells. This fuel, or energy, drives biologic reactions necessary for cells to function. For a cell to function, it must be able to extract and use the chemical energy in organic molecules. When 1 mole (mol) of glucose metabolically breaks down in the presence of oxygen into CO_2 and water, 686 kilocalories (kcal) of chemical energy are released. The chemical energy lost by one molecule is transferred to the chemical structure of another molecule by an

energy-carrying or energy-transferring molecule, such as ATP. The energy stored in ATP can be used in various energy-requiring reactions and in the process is generally converted to adenosine diphosphate (ADP) and inorganic phosphate (Pi). The energy available as a result of this reaction is approximately 7 kcal/mol of ATP. The cell uses ATP for muscle contraction and active transport of molecules across cellular membranes. ATP not only stores energy but also *transfers* it from one molecule to another. Energy stored by carbohydrate, lipid, and protein is catabolized and transferred to ATP.

ATP can also be found outside of cells. *Extracellular ATP* is released from cells in a variety of conditions and is considered important in inflammation and immunity. High levels of extracellular ATP may contribute to chronic inflammatory responses and to metastasis of cancer cells.[11]

Food and Production of Cellular Energy

Catabolism of the proteins, lipids, and polysaccharides found in food must be broken down into smaller molecules before cells can use them as a fuel source for energy or as building blocks for other molecules. The process can be divided into the following three phases (Fig. 1.17):

Phase 1: **Digestion**. Large molecules are broken down into smaller subunits: proteins into amino acids, polysaccharides into simple sugars (i.e., monosaccharides), and fats into fatty acids and glycerol. These processes occur outside the cell within the intestines or within the specialized lysosome organelle within the cell and are activated by secreted enzymes.

Phase 2: **Glycolysis** and **oxidation**. The most important part of phase 2 is glycolysis, the splitting of one glucose molecule into two molecules of pyruvate. During pyruvate formation, ATP and reduced nicotinamide adenine dinucleotide (NADH) are produced through oxidation, or the removal and transfer of a

pair of electrons. The total process is called *oxidative cellular metabolism* and involves 10 biochemical reactions (see Fig. 1.17).
*Phase 3:***Citric acid cycle (Krebs cycle, tricarboxylic acid cycle)**. Most of the ATP is generated during this final phase, which begins with the citric acid cycle and ends with oxidative phosphorylation. Approximately two-thirds of the total oxidation of carbon compounds in most cells is accomplished during this phase. The major end products are CO_2 and two dinucleotides—NADH and the reduced form of flavin adenine dinucleotide ($FADH_2$)—both of which transfer their electrons into the electron transport chain.

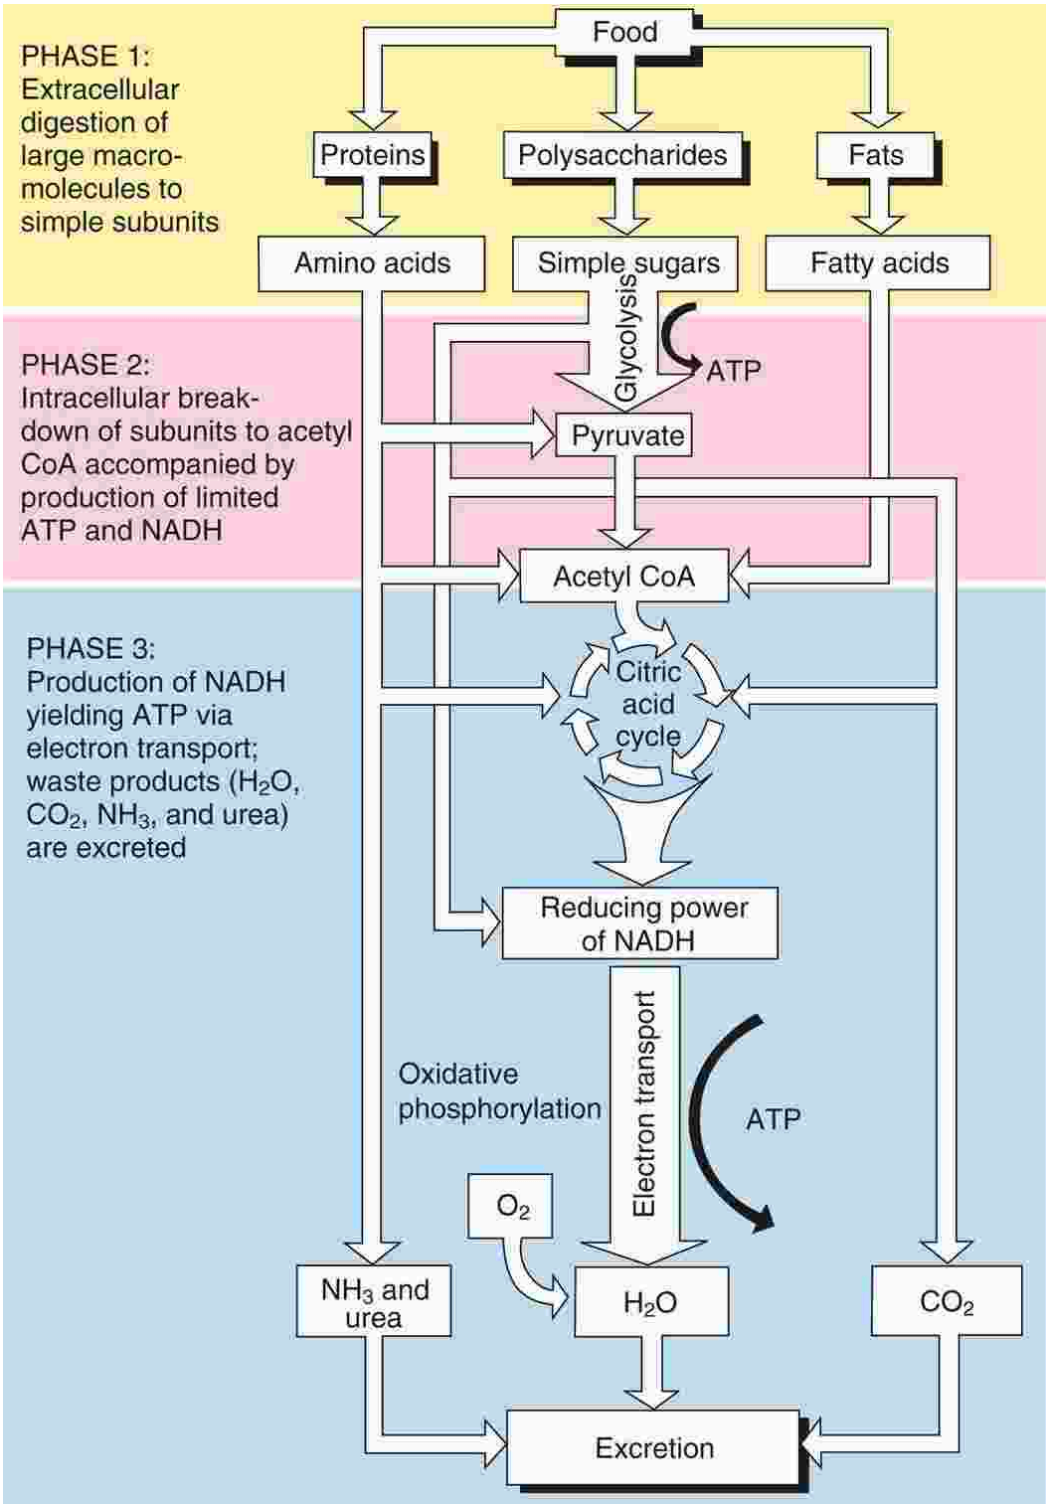

FIG. 1.17 Three Phases of Catabolism, Which Lead From Food to Waste Products.
These reactions produce adenosine triphosphate *(ATP)*, which is used to power other processes in

the cell. *NADH*, Nicotinamide adenine dinucleotide.

A process diagram illustrates three phases of catabolism. Phase 1. Extracellular digestion of large macro-molecules to simple subunits. Food is broken down into Proteins, Polysaccharides, and Fats. Proteins break down into Amino Acids. Polysaccharides break down into Simple Sugars. Fats break down into Fatty Acids. Phase 2. Intracellular breakdown of subunits to acetyl Co A accompanied by production of limited A T P and N A D H. Amino Acids break down into Pyruvates and Acetyl Co A. Simple Sugars are broken down through Glycolysis into Pyruvate. Fatty Acids break down into Acetyl Co A. Phase 3. Production of N A D H yielding A T P via electron transport; waste products (water, carbon dioxide, ammonia, and urea) are excreted. Amino acids are broken down into Citric Acid Cycle and Ammonia and Urea, which are excreted. Simple Sugars are broken down into Citric Acid, Carbon Dioxide, Reducing Power of N A D H and Water through Electron Transport, which are excreted.

Oxidative Phosphorylation

Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP. During the breakdown

(catabolism) of foods, many reactions involve the removal of electrons from various intermediates. These reactions generally require a coenzyme (a nonprotein carrier molecule), such as nicotinamide adenine dinucleotide (NAD), to transfer the electrons and thus are called **transfer reactions**.

Molecules of NAD and flavin adenine dinucleotide (FAD) transfer electrons they have gained from the oxidation of substrates to molecular O_2. The electrons from reduced NAD and FAD, NADH and $FADH_2$, respectively, are transferred to the **electron transport chain** on the inner surfaces of the mitochondria with the release of hydrogen ions. Some carrier molecules are brightly colored, iron-containing proteins known as **cytochromes**, which accept a pair of electrons. These electrons eventually combine with molecular oxygen.

If O_2 is not available to the electron transport chain, ATP will not be formed by the mitochondria. Instead, an anaerobic (without O_2) metabolic pathway synthesizes ATP. This process, called **substrate-level phosphorylation** or **anaerobic glycolysis**, is linked to the breakdown (glycolysis) of carbohydrate (Fig. 1.18). Because glycolysis occurs in the cytoplasm of the cell, it provides energy for cells that lack mitochondria. The reactions in anaerobic glycolysis involve the conversion of glucose to pyruvic acid (pyruvate) with the simultaneous production of ATP. With the glycolysis of one molecule of glucose, two ATP molecules and two molecules of pyruvate are liberated. If O_2 is present, the two molecules of pyruvate move into the mitochondria, where they enter the citric acid cycle (Fig. 1.19).

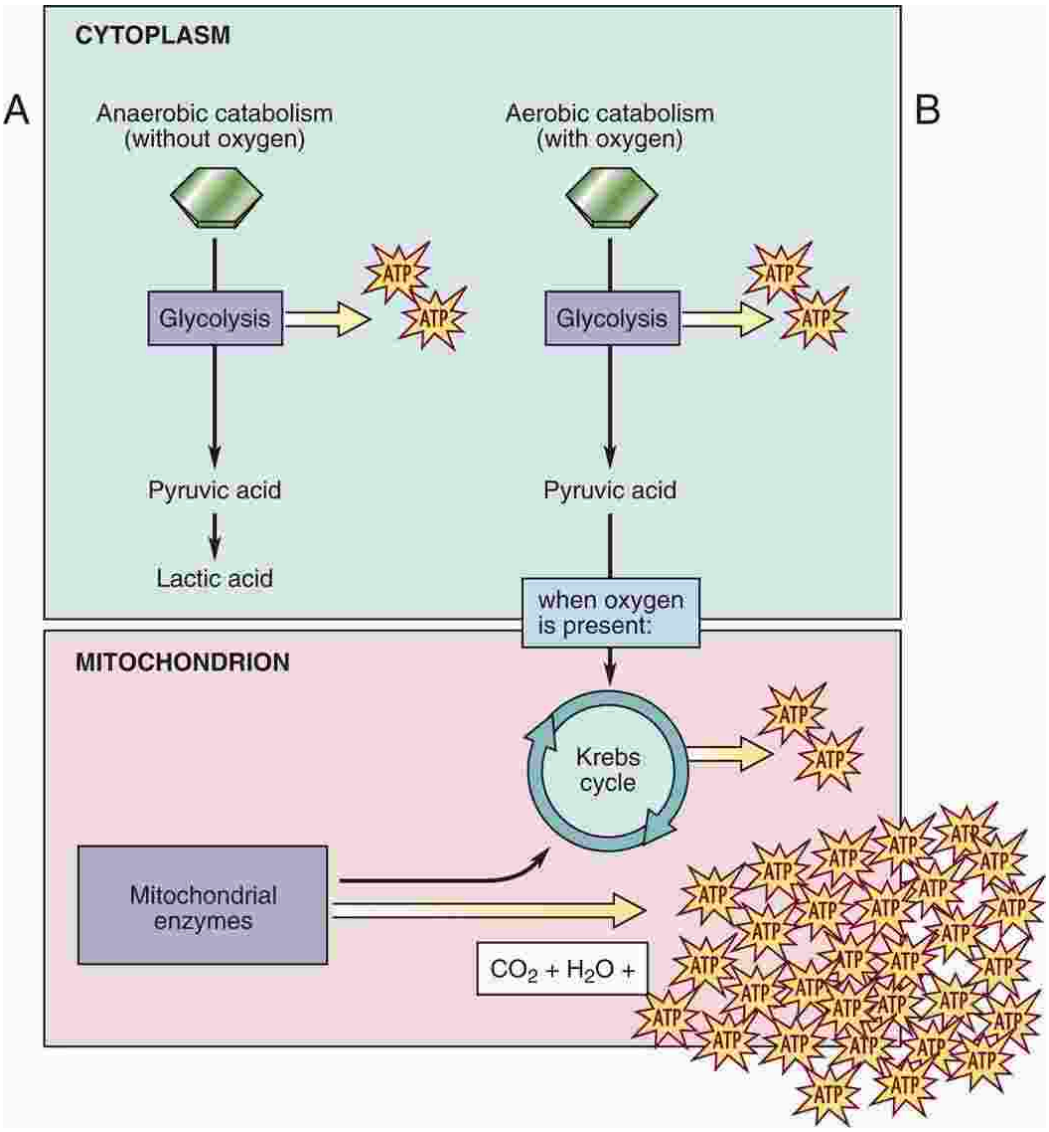

FIG. 1.18 Glycolysis.
Sugars are important for fuel or energy, and they are oxidized in small steps to carbon dioxide and water. Glycolysis is the process for oxidizing sugars or glucose. Breakdown of glucose. **(A)** Anaerobic catabolism, to lactic acid and little adenosine triphosphate (ATP). **(B)** Aerobic catabolism, to carbon dioxide, water, and lots of ATP. (From Herlihy B. *The human body in health and illness*, 5th edition. St. Louis: Saunders; 2015.

A two-part diagram illustrates glycolysis in cytoplasm and mitochondrion. Part A of the illustration shows the following sequence within the Cytoplasm: Anaerobic Catabolism, i.e., without oxygen, to glycolysis to pyruvic acid to lactic acid. Glycolysis produces A T P. Part B of the illustration shows the following sequence within the Cytoplasm: Aerobic Catabolism, i.e., with oxygen, to glycolysis to pyruvic acid. The next part of the sequence occurs within the mitochondrion, when oxygen is present: Krebs Cycle, aided by mitochondrial enzymes. Both glycolysis and Krebs Cycle produce A T P.

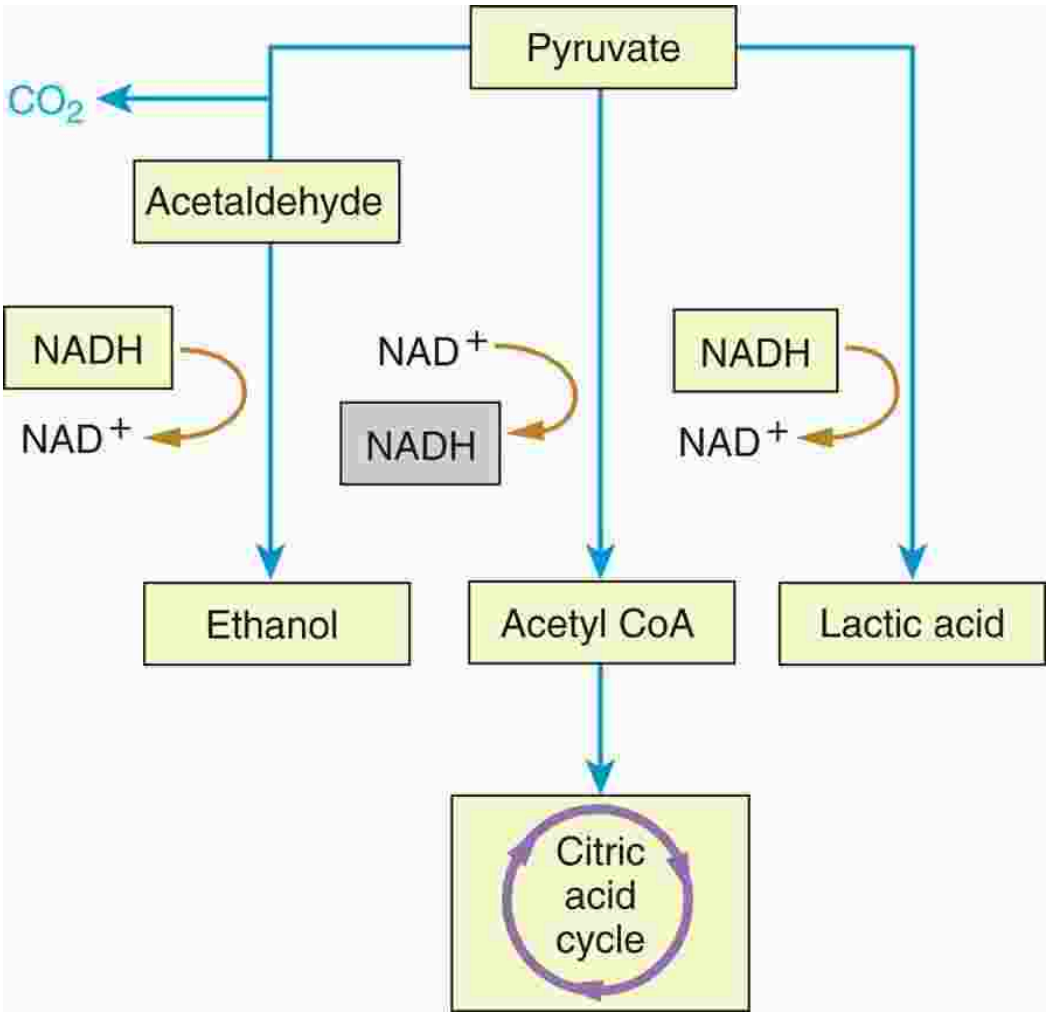

FIG. 1.19 What Happens to Pyruvate, the Product of Glycolysis?

In the presence of oxygen, pyruvate is oxidized to acetyl coenzyme A *(Acetyl CoA)* and enters the citric acid cycle. In the absence of oxygen, pyruvate instead is reduced, accepting the electrons extracted during glycolysis and carried by reduced nicotinamide adenine dinucleotide *(NADH)*. When pyruvate is reduced directly, as it is in muscles, the product is lactic acid. When carbon dioxide *(CO_2)* is first removed from pyruvate and the remainder is reduced, as it is in yeasts, the resulting product is ethanol.

A flow diagram illustrates the breakdown of Pyruvate. Pyruvate releases Carbon Dioxide and reduces into three products: Acetaldehyde, Acetyl Co A, and Lactic Acid, as result of N A D H being reduced to N A D ions in each case. Acetaldehyde further breaks down into Ethanol, and Acetyl Co A breaks down into Citric Acid Cycle.

If O_2 is absent, pyruvate is converted to lactic acid, which is released into the extracellular fluid (ECF). The conversion of pyruvic acid to lactic acid is reversible; therefore, once O_2 is restored, lactic acid is quickly converted back to either pyruvic acid or glucose. The anaerobic generation of ATP from glucose through glycolysis is not as efficient as the aerobic generation process. Adding an oxygen-requiring stage to the catabolic process (phase 3; N see Fig. 1.18) provides cells with a much more powerful method for extracting energy from food molecules. A field of cancer research examines how tumor cells are able to alter their metabolic pathways (metabolic reprogramming) to promote cancer progression (see the Emerging Science Box: Metabolic Reprogramming and Cancer Cells box).[12]

Emerging Science Box Metabolic Reprogramming and Cancer Cells

Proliferating cancer cells require a great deal of cellular energy to support their rapid growth and spread through the body. Cancer cells create more energy by altering their metabolic pathways for all types of fuel sources, including carbohydrates, proteins, and lipids. These alterations are known as metabolic reprogramming. An example of metabolic reprogramming is the ability of tumor cells to greatly increase their uptake of glucose and to use it in multiple alternative pathways for generating energy and the molecules required for rapid growth. Not only do cancer cells use

glucose to generate ATP in mitochondria, they also can convert glucose-derived pyruvate into lactate even in the presence of oxygen (Warburg effect) and can use nonmitochondrial pathways that do not require high levels of oxygen in order to generate energy and important metabolites. These nonmitochondrial pathways are stimulated by mutated genes (oncogenes such as c-MYC) and by growth factors that promote cancer cell proliferation. Glutamate, serine, and amino acid metabolic pathways may also be altered in cancer cells. An increasing understanding of metabolic reprogramming is leading to innovative experimental approaches toward slowing cancer growth.

Data from DeBerardinis RJ, et al. We need to talk about the Warburg effect. *Nature Metabolism*, 2020; 2:127–129; Dong Y, et al. Membrane Transport: Cellular Intake and Output

Cell survival and growth depend on the constant exchange of molecules with their environment. Cells continually import nutrients, fluids, and chemical messengers from the extracellular environment and expel metabolites, or the products of metabolism, and end products of lysosomal digestion. Cells also must regulate ions in their cytosol and organelles. Simple diffusion across the lipid bilayer of the plasma membrane occurs for such important molecules as O_2 and CO_2. However, the majority of molecular transfer depends on specialized **membrane transport proteins** that span the lipid bilayer and provide private conduits for select molecules.[3]

Membrane transport proteins occur in many forms and are present in all cell membranes. Transport by membrane transport proteins is

sometimes called **mediated transport**. Most of these transport proteins allow selective passage (e.g., Na^+ but not K^+, or K^+ but not Na^+). Each type of cell membrane has its own transport proteins that determine which solute can pass into and out of the cell or organelle.[3] The two main classes of membrane transport proteins are *transporters* and *channels*. These transport proteins differ in the type of **solute**—small particles of dissolved substances—they transport. A **transporter** is specific, allowing only those ions that fit the unique binding sites on the protein (Fig. 1.20A). A transporter undergoes conformational changes to enable membrane transport. A **channel**, when open, forms a pore across the lipid bilayer that allows ions and selective polar organic molecules to diffuse across the membrane (see Fig. 1.20B). Transport by a channel depends on the size and electrical charge of the molecule. Some channels are controlled by a gate mechanism that determines which solute can move into it. Ion channels are responsible for the electrical excitability of nerve and muscle cells and play a critical role in the membrane potential.

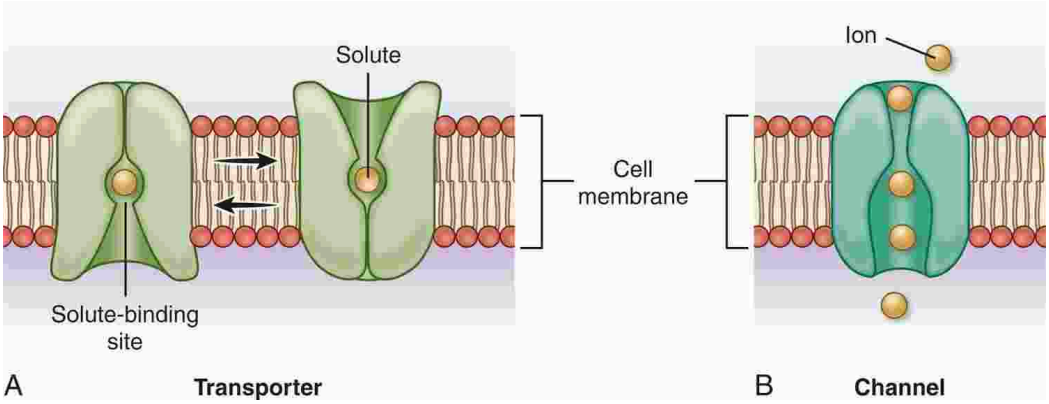

FIG. 1.20 Inorganic Ions and Small, Polar Organic Molecules Can Cross a Cell Membrane Through Either a Transporter or a Channel. (Adapted from Alberts B, Bray D, Hopkin K, et al. *Essential cell biology*, 4th edition. New York: Garland; 2014.

Two illustrations, A and B, show the movement of ions through the cell membrane. Illustration A, transporter, shows and labels the solute-binding site and the solute. Illustration B, channel, shows ions passing through the channel from the external environment into the internal environment.

The mechanisms of membrane transport depend on the characteristics of the substance to be transported. In **passive transport**, water and small electrically uncharged molecules move easily through pores in the plasma membrane's lipid bilayer (Fig. 1.21). This process occurs naturally through any semipermeable barrier. Molecules will easily flow "downhill" from a region of high concentration to a region of low concentration; this movement is called *passive* because it does not require expenditure of energy or a driving force. It is driven by osmosis, hydrostatic pressure, and diffusion, all of which depend on the laws of physics and do not

require life (see the Passive Transport: Diffusion, Filtration, and Osmosis section).

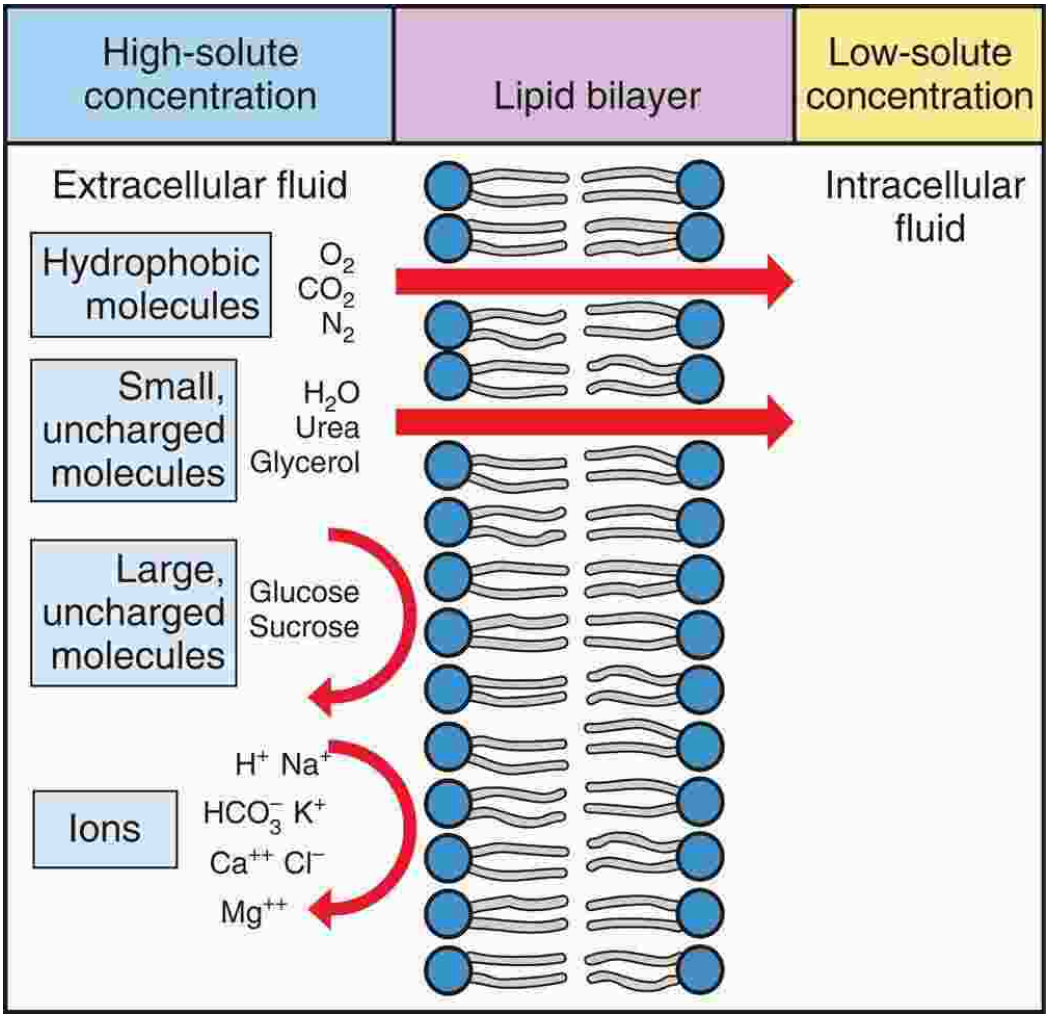

FIG. 1.21 Passive Diffusion of Solute Molecules Across the Plasma Membrane. Oxygen, nitrogen, water, urea, glycerol, and carbon dioxide can diffuse readily down the concentration gradient. Macromolecules are too large to diffuse through the pores in the plasma membrane. Ions may be repelled if the pores contain substances with identical charges. If the pores are lined with cations, for example, other cations will have difficulty diffusing because the positive charges will repel one another; diffusion can still occur, but it occurs more slowly.

A block diagram divided into three sections illustrates the passive diffusion of solutes across the membrane. The three sections, from the left to the right, are as follows: High-Solute Concentration, Lipid Bilayer, and Low-Solute Concentration. The Lipid Bilayer shows an illustration of bilipids. The extracellular fluid from the left, the high-solute concentration, can include hydrophobic molecules, like oxygen, carbon dioxide, and nitrogen dioxide; small uncharged molecules, like water, urea, and glycerol; large uncharged molecules, like glucose and sucrose; and ions, like that of hydrogen, sodium, potassium, bicarbonate, calcium, chlorine, and magnesium. The intracellular fluid, on the right, comprises low-solute concentration. Hydrophobic molecules and small, uncharged molecules are diffused through the lipid bilayer to the intracellular fluid. Large uncharged molecules and ions are recirculated within the extracellular fluid.

Other molecules are too large to pass through pores or are ligands bound to receptors on the cell's plasma membrane. Some of these molecules are moved into and out of the cell by **active transport**, which requires life, biologic activity, and the cell's expenditure of metabolic energy (Fig. 1.22). Unlike passive transport, active transport occurs across only living membranes that have to drive the flow “uphill” by coupling it to an energy source. Movement of a solute against its concentration gradient occurs by special types of transporters called *pumps* (see Fig. 1.22). These transporter pumps must harness an energy source to power the transport process.

Energy can come from ATP hydrolysis, a transmembrane ion gradient, or sunlight (see Fig. 1.22). The best-known energy source is the Na^+-K^+–dependent adenosine triphosphatase (ATPase) pump. It continuously regulates the cell's volume by controlling leaks through pores or protein channels and maintaining the ionic concentration gradients needed for cellular excitation and membrane conductivity (see the Active Transport of Na^+ and K^+ section). The maintenance of intracellular K^+ concentrations is required also for enzyme activity, including enzymes involved in protein synthesis. Large molecules (macromolecules), along with fluids, are transported by endocytosis (taking in) and exocytosis (expelling) (see the Transport by Vesicle Formation section). Receptor-macromolecule complexes enter the cell by means of receptor-mediated endocytosis.

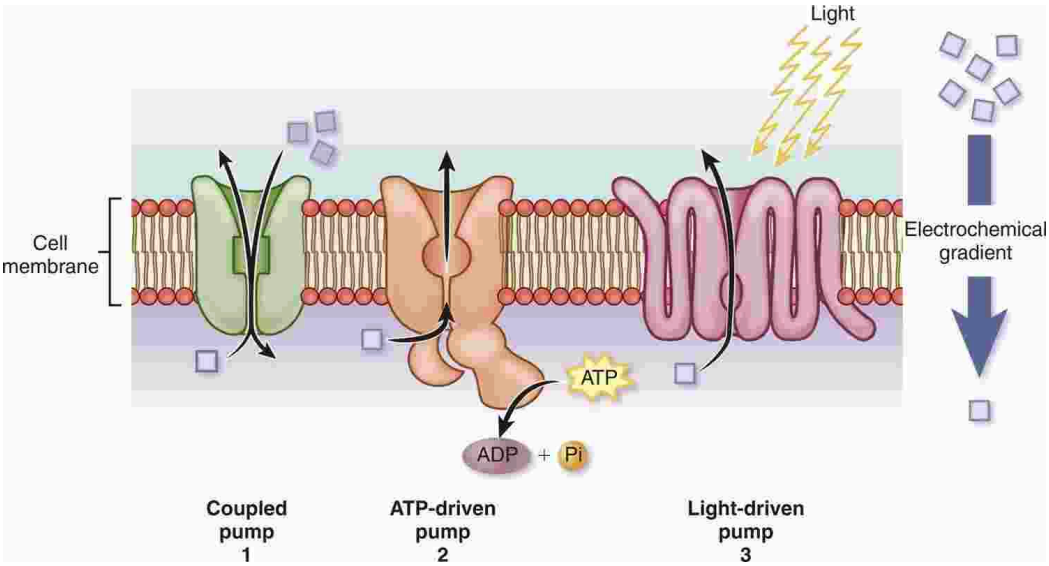

FIG. 1.22 Pumps Carry Out Active Transport in Three Ways.
***1**, Coupled pumps* link the uphill transport of one solute to the downhill transport of another solute. ***2**, Adenosine triphosphate (ATP)-driven pumps* drive uphill transport from hydrolysis of ATP. ***3**, Light-driven pumps* are mostly found in bacteria and use energy from sunlight to drive uphill transport. (Adapted from Alberts B, Bray D, Hopkin K, et al. *Essential cell biology*, 4th edition. New York: Garland; 2014.

An illustration shows a cell membrane with bilipids to illustrate the three ways of active transport. 1. Coupled pump. 2. A T P-driven pump. 3. Light-driven pump. Coupled pump. Solute from extracellular region travels through the antiport and into the intracellular region. Solute from the intracellular region travels through the antiport and into the extracellular region. A T P-driven pump. A T P is broken down to A D P and Pi, which travels

through the uniport from the intracellular region to the extracellular region. Light-driven pump. In the presence of light, solutes from the intracellular region travel through the uniport and into the extracellular region. Electrochemical gradient occurs when solutes are broken down.

Mediated transport systems can move solute molecules singly or two at a time. Two molecules can be moved simultaneously in one direction (a process called **symport**; e.g., sodium-glucose in the digestive tract) or in opposite directions (called **antiport**; e.g., the sodium-potassium pump in all cells), or a single molecule can be moved in one direction (called **uniport**; e.g., glucose) (Fig. 1.23).

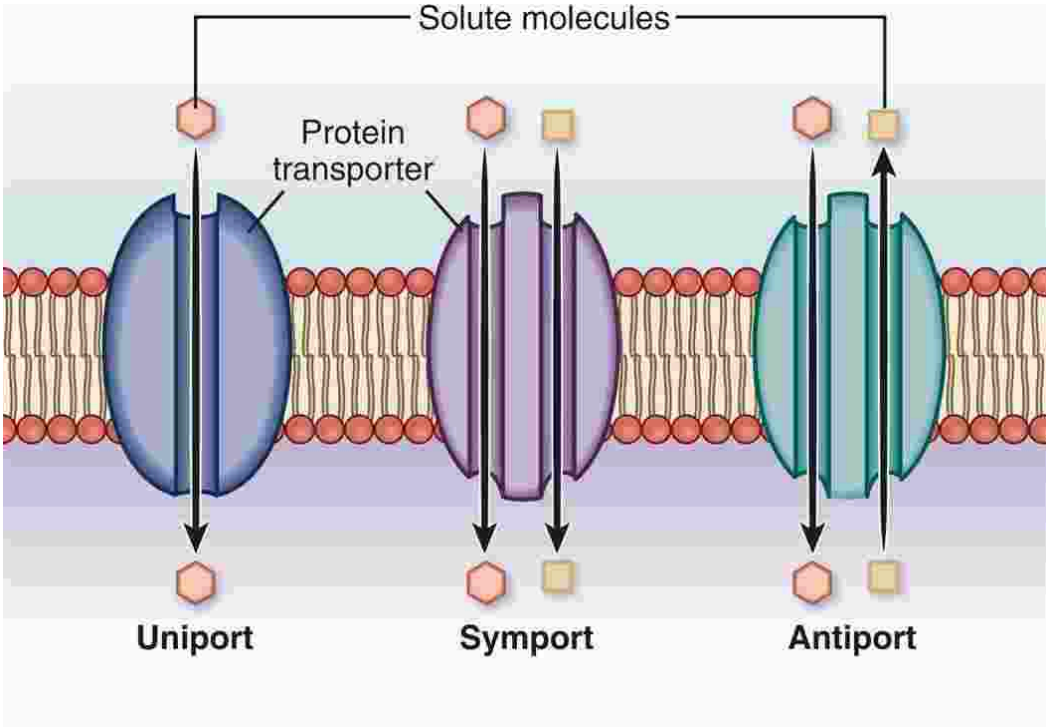

FIG. 1.23 Mediated Transport.
Illustration shows simultaneous movement of a single solute molecule in one direction *(uniport)*, of two different solute molecules in one direction *(symport)*, and of two different solute molecules in opposite directions *(antiport)*.

An illustration of cell membrane with bilipids shows three modes of transport of solutes through channels: uniport, symport, and antiport. Uniport transport involves movement of one solute in one direction. Symport transport involves movement of two different solutes, both in the same direction. Antiport transport involves movement of two different solutes, in opposite directions.

Electrolytes as Solutes

Body fluids are composed of **electrolytes**, which are electrically charged and dissociate into constituent **ions** when placed in solution. Nonelectrolytes, such as glucose, urea, and creatinine, do not dissociate. Electrolytes account for approximately 95% of the solute molecules in body water. Electrolytes exhibit **polarity** by orienting themselves toward the positive or negative pole. Ions with a positive charge are known as **cations** and migrate toward the negative pole, or cathode, if an electrical current is passed through the electrolyte solution. **Anions** carry a negative charge and migrate toward the positive pole, or anode, in the presence of electrical current. Anions and cations are located in both the intracellular fluid (ICF) and the ECF compartments, although their concentration depends on their location. (Fluid and electrolyte balance between body compartments is discussed in Chapter 3). For example, Na^+ is the predominant extracellular cation, and K^+ is the principal intracellular cation. The difference in ICF and ECF concentrations of these ions is important to the transmission of electrical impulses across the plasma membranes of nerve and muscle cells.

Electrolytes are measured in milliequivalents per liter (mEq/L) or milligrams per deciliter (mg/dL). The term *milliequivalent* indicates the chemical-combining activity of an ion, which depends on the electrical charge, or **valence**, of its ions. In abbreviations, valence is indicated by the number of plus or minus signs. Monovalent ions, or ions with one charge, include sodium (Na^+), chloride (Cl^-), and potassium (K^+). Divalent ions, which have two charges, include calcium (Ca^{2+}) and magnesium (Mg^{++}). One milliequivalent (mEq) of any cation can combine chemically with 1 mEq of any anion: one monovalent anion will combine with one monovalent cation. Divalent ions combine more strongly than monovalent ions. To maintain electrochemical balance, one divalent ion will combine with two monovalent ions (e.g., $Ca^{2+} + 2\ Cl^- = CaCl_2$).

Passive Transport: Diffusion, Filtration, and Osmosis

Diffusion

Diffusion is the movement of a solute molecule from an area of greater solute concentration to an area of lesser solute concentration. This difference in concentration is known as a **concentration gradient** (see Fig. 1.21). Although particles in a solution move randomly in any direction, if the concentration of particles in one part of the solution is greater than that in another part, the particles distribute themselves evenly throughout the solution. According to the same principle, if the concentration of particles is greater on one side of a *permeable membrane* than on the other side, the particles diffuse spontaneously from the area of greater concentration to the area of less concentration until equilibrium is reached. Molecules still move back and forth to maintain this equilibrium; however, there is no net change in concentration of the molecules on either side of the permeable membrane. The higher the concentration on one side, the greater is the diffusion rate.

The diffusion rate is influenced by differences of electrical potential across the membrane (see the Movement of Electrical Impulses: Membrane Potentials section). Because the pores in the lipid bilayer are often lined with Ca^{2+}, other cations (e.g., Na^{+} and K^{+}) diffuse slowly because they are repelled by positive charges in the pores.

The rate of diffusion of a substance depends also on its size (diffusion coefficient) and its lipid solubility (Fig. 1.24). Usually, the smaller the molecule and the more soluble it is in oil, the more hydrophobic or nonpolar it is, and the more rapidly it will diffuse across the bilayer. Oxygen, CO_2, and the steroid hormones (e.g., androgens and estrogens) are all nonpolar molecules. Water-soluble substances, such as glucose and inorganic ions, diffuse very slowly, whereas uncharged lipophilic ("lipid-loving") molecules, such as fatty acids and steroids, diffuse rapidly. Ions and other polar molecules generally diffuse across cellular membranes more slowly compared with lipid-soluble substances.

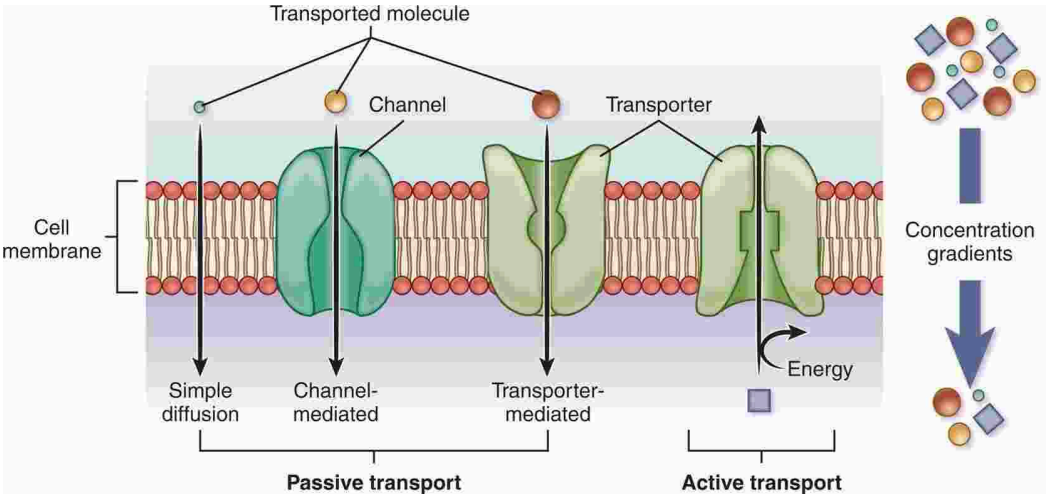

FIG. 1.24 Passive Diffusion of Solute Molecules Across the Plasma Membrane. Oxygen, nitrogen, water, urea, glycerol, and carbon dioxide can diffuse readily down the concentration gradient. Macromolecules are too large to diffuse through pores in the plasma membrane. Ions may be repelled if the pores contain substances with identical charges. If the pores are lined with cations, for example, other cations will have difficulty diffusing because the positive charges will repel one another. Diffusion can still occur, but it occurs more slowly.

An illustration shows a cell membrane with bilipids to illustrate the passive diffusion of solutes across the membrane. The illustration demonstrates passive transport and active transport. Passive transport occurs when the transported molecule undergoes simple diffusion, channel-mediation, and transporter-mediation. Active transport occurs when units pass from the internal environment into the external environment, releasing energy within the

intracellular region. Concentration gradient decreases from extracellular region to intracellular region.

Water readily diffuses through biologic membranes because water molecules are small and uncharged. The dipolar structure of water allows it to rapidly cross the regions of the bilayer containing the polar phosphate head groups. The polar phosphate head groups constitute the two outer regions of the lipid bilayer.

Filtration: hydrostatic pressure

Filtration is the movement of water and solutes through a membrane because of a greater pushing pressure (force) on one side of the membrane than on the other side. **Hydrostatic pressure** is the mechanical force of water pushing against cellular membranes (Fig. 1.25A). In the vascular system, hydrostatic pressure is the *blood pressure* generated in vessels when the heart contracts. Blood reaching the capillary bed has a hydrostatic pressure of 25 to 30 millimeters of mercury (mm Hg), which is sufficient force to push water across the thin capillary membranes into the interstitial space. Hydrostatic pressure is partially balanced by osmotic pressure, whereby water moving *out* of the capillaries is partially balanced by osmotic forces that tend to *pull* water *into* the capillaries (Fig. 1.25B). Water that is not osmotically attracted back into the capillaries moves into the lymph system (see the discussion of Starling forces in Chapter 3).

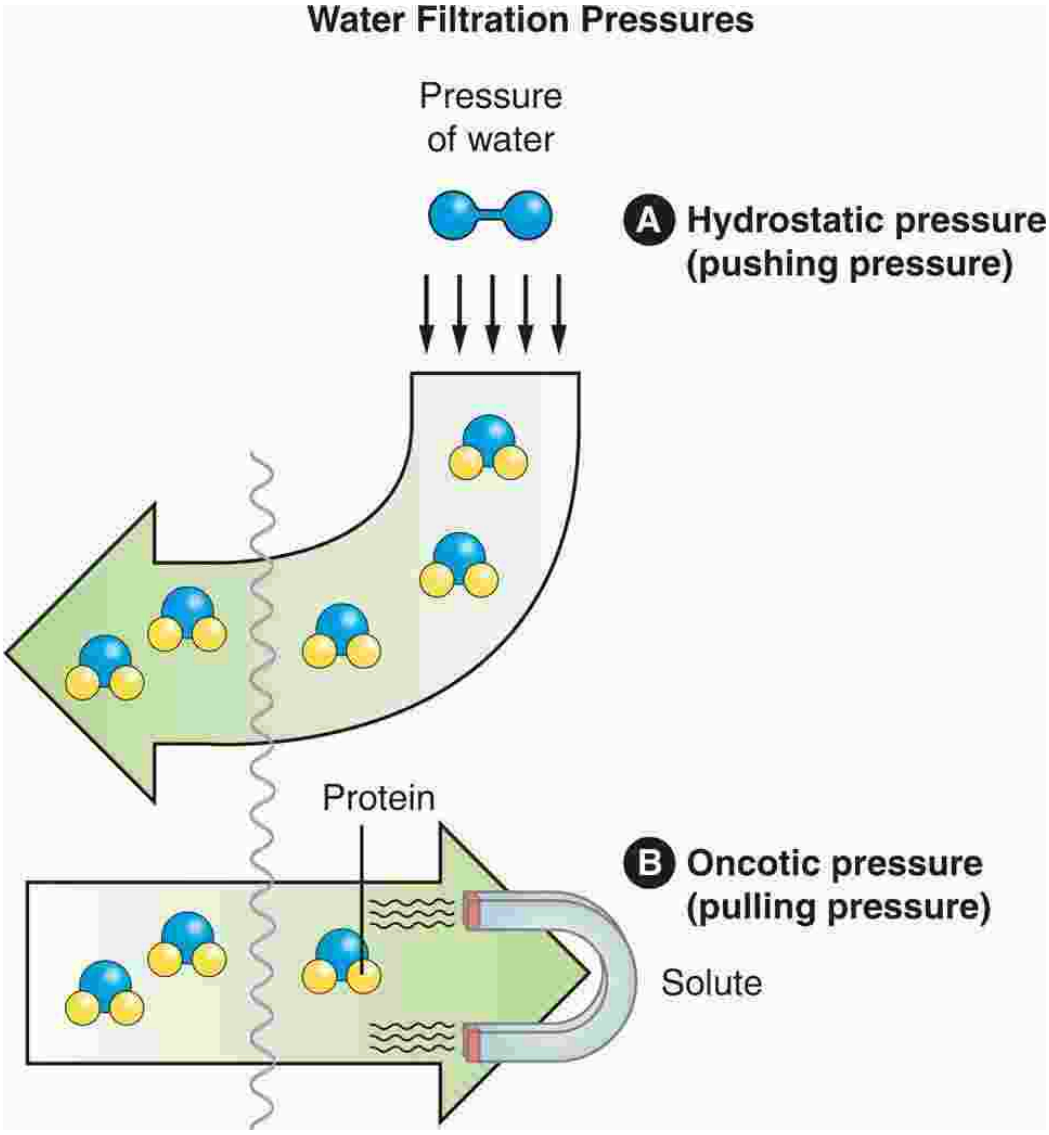

FIG. 1.25 Hydrostatic Pressure and Oncotic Pressure in Plasma.
(A) Hydrostatic pressure in plasma is a pushing pressure in relation to water. **(B)** Oncotic pressure exerted by proteins in the plasma usually tends to *pull* water into the circulatory system. Individuals with low protein levels (e.g., starvation) are unable to maintain a normal oncotic pressure; therefore water is not reabsorbed into the circulation and, instead, causes body edema.

An illustration shows hydrostatic pressure and oncotic pressure. The schematic shows two block arrows: one curving from the top and to the left and the other pointing to the right. Pressure of water in the first schematic pushes the proteins downward. A magnet to the right of the second schematic attracts the proteins.

Osmosis

Osmosis is the movement of water "down" a concentration gradient —that is, across a semipermeable membrane from a region of higher water concentration to one of lower concentration. For osmosis to occur, (1) the membrane must be more permeable to water than to solutes, and (2) the concentration of solutes on one side of the membrane must be greater than that on the other side so that water moves more easily. Osmosis is directly related to both hydrostatic pressure and solute concentration but *not* to particle size or weight. For example, particles of the plasma protein albumin are small but are more concentrated in body fluids compared with the larger and heavier particles of globulin. Therefore albumin exerts a greater osmotic force compared with globulin.

Osmolality controls the distribution and movement of water between body compartments. The terms *osmolality* and *osmolarity* often are used interchangeably in reference to osmotic activity, but they define different measurements. **Osmolality** measures the number of milliosmoles per kilogram (mOsm/kg) of water, or the concentration of molecules per *weight* of water. **Osmolarity** measures the number of milliosmoles per liter (mOsm/L) of solution, or the concentration of molecules per *volume* of solution.

In solutions that contain only dissociable substances, such as Na^+ and Cl^-, the difference between the two measurements is negligible. When considering all the different solutes in plasma (e.g., proteins,

glucose, lipids), the difference between osmolality and osmolarity becomes more significant. Less of plasma's weight is water, and the overall concentration of particles is therefore greater. The osmolality will be greater than the osmolarity because of the smaller proportion of water. Osmolality is thus preferred in human clinical assessment.

The normal osmolality of body fluids ranges from 280 to 294 mOsm/kg. The osmolalities of ICF and ECF tend to equalize, providing a measure of body fluid concentration and thus the body's hydration status. Hydration is affected also by hydrostatic pressure because the movement of water by osmosis can be opposed by an equal amount of hydrostatic pressure. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the **osmotic pressure** of the solution. Factors that determine osmotic pressure are the type and thickness of the plasma membrane, the size of the molecules, the concentration of molecules or the concentration gradient, and the solubility of molecules within the membrane.

Effective osmolality is sustained osmotic activity and depends on the concentration of solutes remaining on one side of a permeable membrane. If the solutes penetrate the membrane and equilibrate with the solution on the other side of the membrane, the osmotic effect will be diminished or lost. For example, urea is a small solute that readily diffuses across cellular membranes. Solutions containing urea quickly lose their effective osmolality because they rapidly equilibrate. Solutes too large to pass through the membrane sustain an effective osmolality, meaning that they enhance osmotic activity. Plasma proteins are examples of molecules that provide effective osmolality because they normally do not cross cellular membranes.

Plasma proteins influence osmolality because they have a negative charge (Fig. 1.25B). The principle involved is known as *Gibbs-Donnan equilibrium;* it occurs when the fluid in one compartment contains small, diffusible ions, such as Na^+ and Cl^-, together with large, nondiffusible, charged particles, such as plasma proteins. Because the body tends to maintain an electrical equilibrium, the nondiffusible protein molecules cause asymmetry in the distribution

of small ions. Anions such as Cl^- are thus driven out of the cell or plasma, and cations, such as Na^+, are attracted to the cell. The protein-containing compartment maintains a state of electroneutrality, but the osmolality is higher. The overall osmotic effect of colloids, such as plasma proteins, is called the **oncotic pressure**, or **colloid osmotic pressure**.

Tonicity describes the effective osmolality of a solution. (The terms *osmolality* and *tonicity* may be used interchangeably.) Solutions have relative degrees of tonicity. An **isotonic solution** (or isosmotic solution) has the same osmolality or concentration of particles (285 mOsm) as ICF or ECF (Fig. 1.26A). Examples of isotonic solutions include 5% dextrose in water and normal (0.9%) saline solution. A **hypotonic solution** has a lower concentration and is thus more dilute than body fluids (Fig. 1.26B). Water is a hypotonic solution. Consequently, water is osmotically pulled into the cells, causing cells to swell or burst. A **hypertonic solution** has a concentration of more than 285 to 294 mOsm/kg (Fig. 1.26C). An example of a hypertonic solution is 3% saline solution. Cells shrink in a hypertonic solution because water is being pulled out of the cells. The concept of tonicity is important when correcting water and solute imbalances by administering different types of replacement solutions (see Chapter 3).

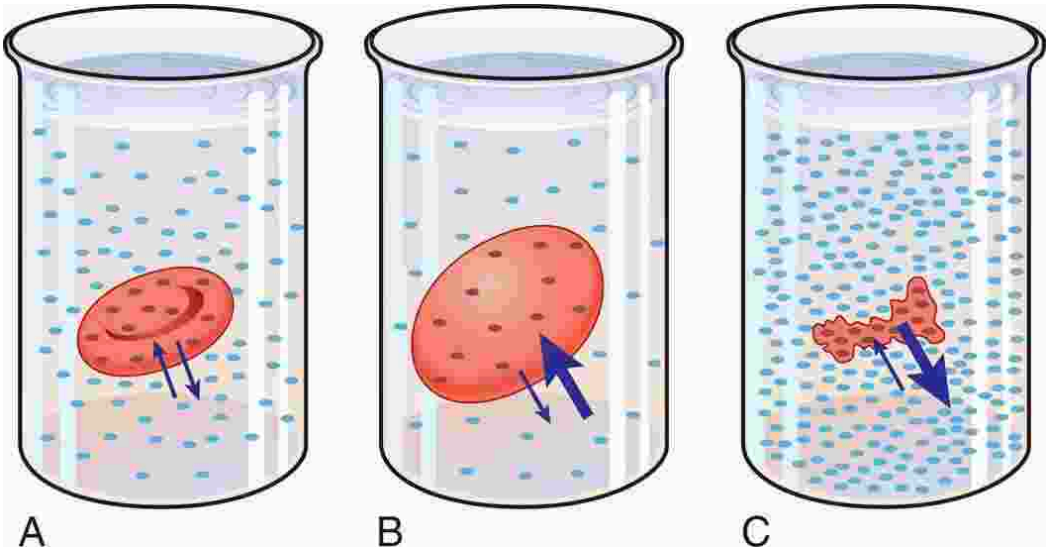

FIG. 1.26 Tonicity.
Tonicity is important, especially for red blood cell function. **(A)** Isotonic solution. **(B)** Hypotonic solution. **(C)** Hypertonic solution. (From Waugh A, Grant A. *Ross and Wilson anatomy and physiology in health and illness*, 12th edition. London: Churchill Livingstone; 2012.

Three schematics, A, B, and C, illustrate tonicity. The schematics show a beaker each. Beaker A shows a protein suspended in an ion solution. Osmality of water to and from the cell is the same. Beaker B shows a larger protein suspended in a solution with lesser concentration of ions. Osmality of water to the cell is greater than osmality of water from the cell. Beaker C shows a distorted protein suspended in a solution in an ion-rich solution. Osmality of water from the cell is greater than osmality of water to the cell.

Active Transport of Na^+ and K^+

The active transport system for Na^+ and K^+ is found in virtually all mammalian cells. The Na^+-K^+–antiport system (i.e., Na^+ moving out of the cell and K^+ moving into the cell) uses the direct energy of ATP to transport these cations. The transporter protein is ATPase, which requires Na^+, K^+, and magnesium (Mg^{++}) ions. The concentration of ATPase in plasma membranes is directly related to Na^+-K^+–transport activity. Approximately 60% to 70% of the ATP synthesized by cells, especially muscle and nerve cells, is used to maintain the Na^+-K^+–transport system. Excitable tissues have a high concentration of Na^+-K^+ ATPase, as do other tissues that transport significant amounts of Na^+ (e.g., kidneys and salivary glands). For every ATP molecule hydrolyzed, three molecules of Na^+ are transported out of the cell, whereas only two molecules of K^+ move into the cell. The process leads to an electrical potential and is called *electrogenic*, with the inside of the cell more negative than the outside. Although the exact mechanism for this transport is uncertain, it is possible that ATPase induces the transporter protein to undergo several conformational changes, causing Na^+ and K^+ to move short distances (Fig. 1.27). The conformational change lowers the affinity for Na^+ and K^+ to the ATPase transporter, resulting in the release of the cations after transport.

FIG. 1.27 Active Transport and the Sodium–Potassium (Na+–K+) Pump.
1, Three sodium (Na^+) ions bind to Na-binding sites on the carrier's inner face. ***2***, At the same time, an energy-containing adenosine triphosphate *(ATP)* molecule produced by the cell's mitochondria binds to the carrier. ATP dissociates, transferring its stored energy to the carrier, and changes shape. ***3*** and ***4***, The ATP releases the three Na^+ ions to the outside of the cell, and attracts two potassium *(K^+)* ions to its potassium-binding sites. *5*, The carrier then returns to its original shape, releasing the two K^+ ions and the remnant of the ATP molecule to the inside of the cell. The carrier is now ready for another pumping cycle.

Five illustrations demonstrate active transport and the sodium-potassium pump. Each illustration shows a bilipid cell membrane. Illustration 1 shows Sodium ions in the intracellular region passing through the channel. A T P molecules also bind to the inner face. Illustration 2 shows A T P and A D P in the intracellular region. A T P reduces to A D P. Illustration 3 shows sodium ions releasing into the extracellular region and potassium ions entering the channel from the extracellular region. Illustration 4 shows potassium ions at the receptor site in the channel. Illustration 5 shows A T P and potassium ions releasing into the intracellular region.

Table 1.4 summarizes the major mechanisms of transport through pores and protein transporters in the plasma membranes. Many disease states are caused or manifested by loss of these membrane transport systems.

Table 1.4

Major Transport Systems in Mammalian Cells

Substance Transported	Mechanism of Transport[a]	Tissues
Carbohydrates		
Glucose	Passive: protein channel Active: symport with Na^+	Most tissues
Fructose	Active: symport with Na^+	Small intestines and renal tubular cells
	Passive	Intestines and liver
Amino Acids		
Amino acid specific transporters	Coupled channels	Intestines, kidney, and liver
All amino acids except proline	Active: symport with Na^+	Liver
Specific amino acids	Active: group translocation	Small intestine
	Passive	
Other Organic Molecules		
Cholic acid, deoxycholic acid,	Active: symport with Na^+	Intestines

Substance Transported	Mechanism of Transport[a]	Tissues
and taurocholic acid		
Organic anions (e.g., malate, α-ketoglutarate, glutamate)	Antiport with counter-organic anion	Mitochondria of liver cells
ATP-ADP	Antiport transport of nucleotides; can be active	Mitochondria of liver cells
Inorganic Ions		
Na^+	Passive	Distal renal tubular cells
Na^+/H^+	Active antiport, proton pump	Proximal renal tubular cells and small intestines
Na^+/K^+	Active: ATP driven, protein channel	Plasma membrane of most cells
Ca^{2+}	Active: ATP driven, antiport with Na^+	All cells, antiporter in red cells
H^+/K^+	Active	Parietal cells of gastric cells secreting H^+
Cl^-/HCO_3 (perhaps other anions)	Mediated: antiport (anion transporter–band 3 protein)	Erythrocytes and many other cells

Substance Transported	Mechanism of Transport[a]	Tissues
Water	Osmosis passive	All tissues

ADP, Adenosine diphosphate; *ATP*, adenosine triphosphate; Ca^{2+}, calcium; Cl^-/HCO_3, chloride/bicarbonate; H^+, hydrogen; K^+, potassium; Na^+, sodium.

[a]Note: The known transport systems are listed here; others have been proposed. Most transport systems have been studied in only a few tissues and their sites of activity may be more limited than indicated.

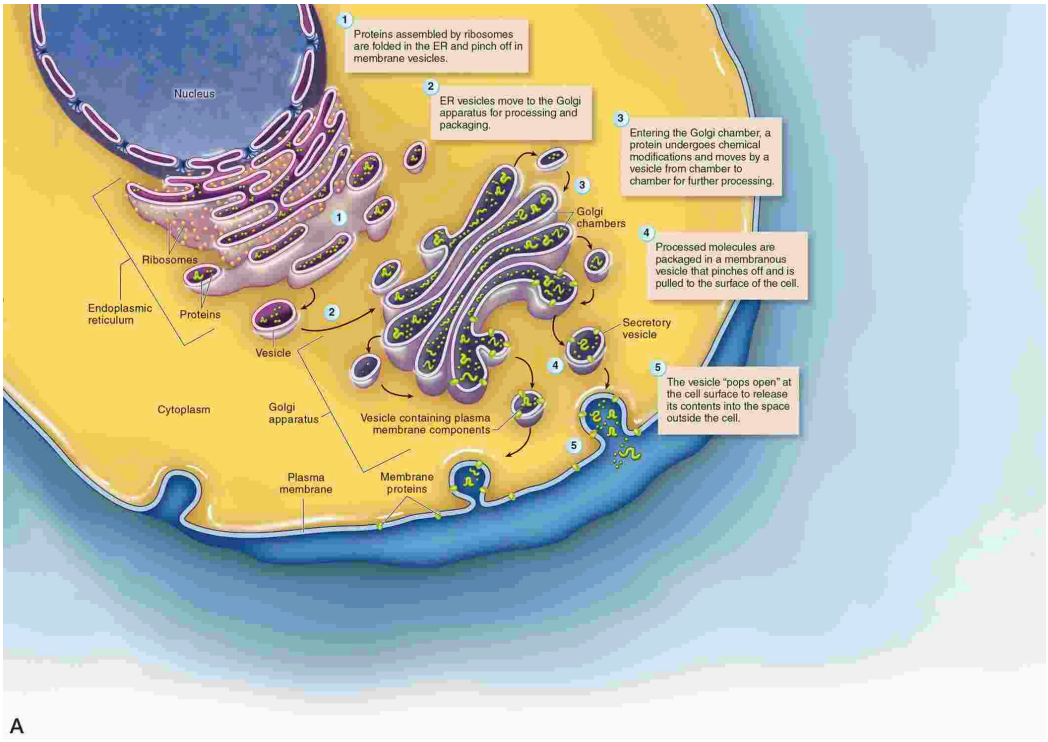
Transport by Vesicle Formation

Endocytosis and Exocytosis

The active transport mechanisms by which the cells move large proteins, polynucleotides, or polysaccharides (macromolecules) across the plasma membrane are very different from those that mediate small solute and ion transport. Transport of macromolecules involves the sequential formation and fusion of membrane-bound vesicles.

In **endocytosis**, a section of the plasma membrane enfolds substances from outside the cell, invaginates (folds inward), and separates from the plasma membrane, forming an **endocytic vesicle** that moves into the cell (Fig. 1.28).



1 Proteins assembled by ribosomes are folded in the ER and pinch off in membrane vesicles.
2 ER vesicles move to the Golgi apparatus for processing and packaging.
3 Entering the Golgi chamber, a protein undergoes chemical modifications and moves by a vesicle from chamber to chamber for further processing.
4 Processed molecules are packaged in a membranous vesicle that pinches off and is pulled to the surface of the cell.
5 The vesicle "pops open" at the cell surface to release its contents into the space outside the cell.

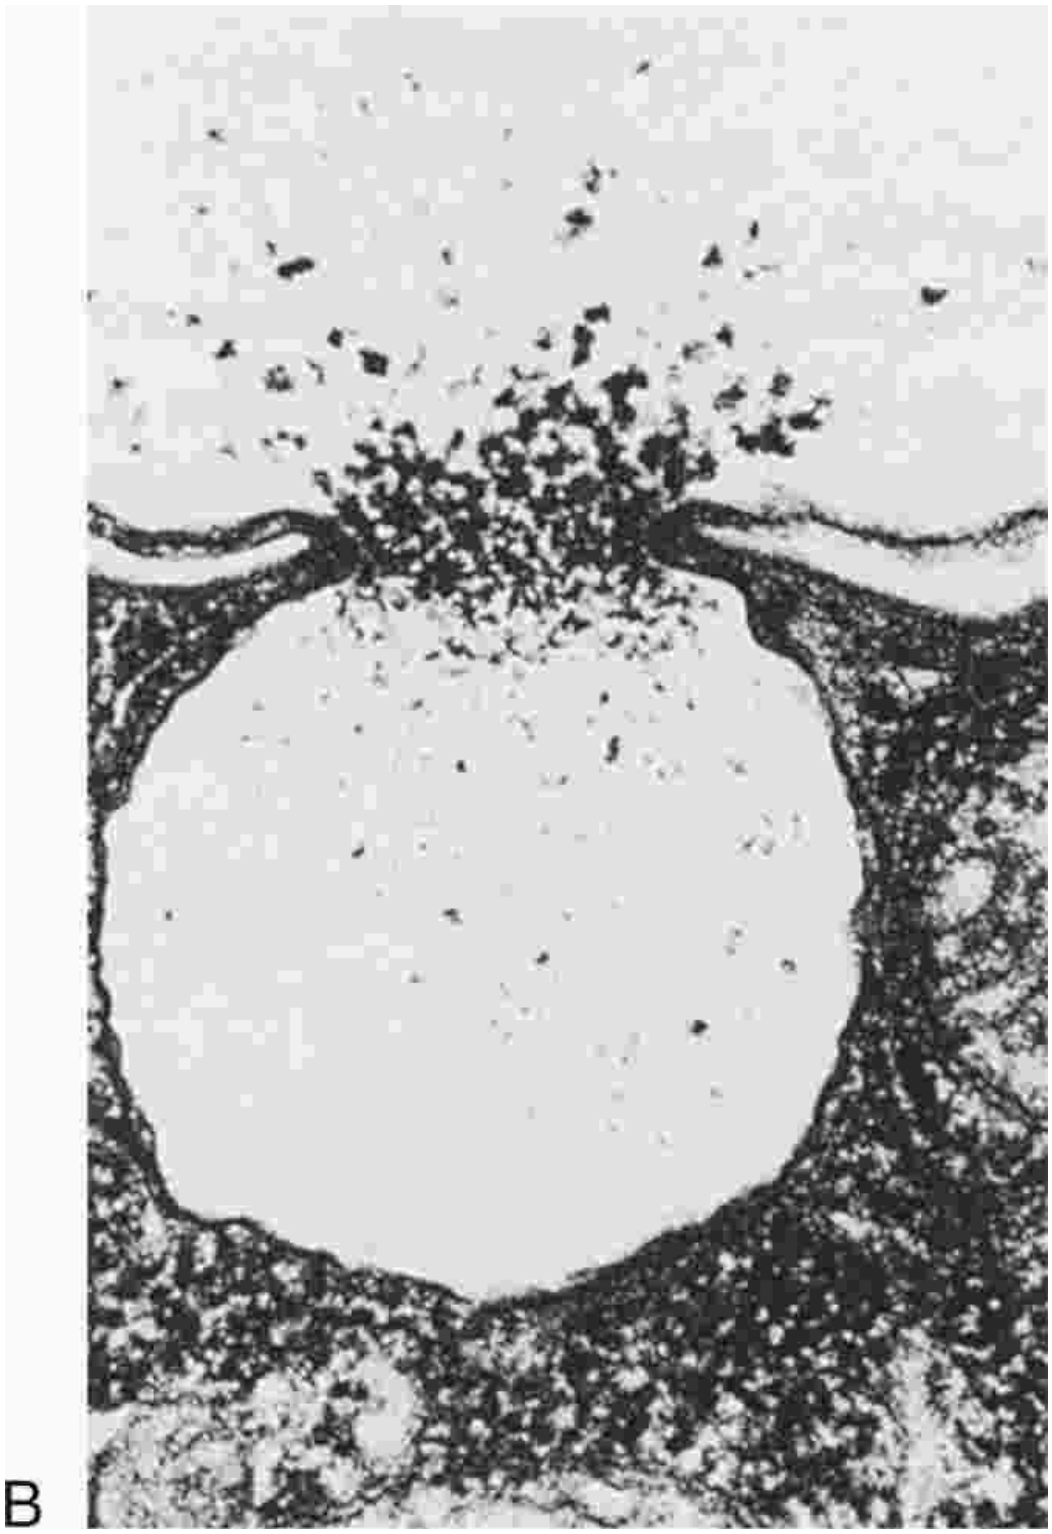

FIG. 1.28 Endocytosis and Exocytosis. **(A)** Endocytosis and fusion with lysosome and exocytosis. **(B)** Electron micrograph of exocytosis. (A, From Patton KT, Thibodeau GA. *The*

human body in health & disease, 7th edition. St Louis: Mosby; 2018. B, From Raven PH, Johnson GB. Biology, 5th edition. New York: McGraw-Hill; 1999.)

Illustration A shows a colored, cross-sectional view of endocytosis and fusion. The steps included are as follows: 1. Proteins assembled by ribosomes are folded in the E R and pinch off in membrane vesicles. 2. E R vesicles move to the Golgi apparatus for processing and packaging. 3. Entering the Golgi chamber, a protein undergoes chemical modifications and moves by a vesicle from chamber to chamber for further processing. 4. Processed molecules are packaged in a membranous vesicle that pinches off and is pulled to the surface of the cell. 5. The vesicle pops open at the cell surface to release its contents into the space outside the cell. Micrograph B shows molecules being released from the cell into the E C M.

Two types of endocytosis are designated based on the size of the vesicle formed. **Pinocytosis** (cell drinking) involves the ingestion of fluids, bits of the plasma membrane, and solute molecules through formation of small vesicles; **phagocytosis** (cell eating) involves the ingestion of large particles, such as bacteria, through formation of large vesicles (vacuoles).

Because most cells continually ingest fluid and solutes by pinocytosis, the terms *pinocytosis* and *endocytosis* often are used interchangeably. In pinocytosis, the vesicle containing fluids, solutes, or both fuses with a lysosome, and lysosomal enzymes digest the vesicle's contents for use by the cell. Vesicles that bud from

membranes have a particular protein coat on their cytosolic surface and are called **coated vesicles**. The best studied are those that have an outer coat of bristle-like structures—the protein **clathrin**. Pinocytosis occurs mainly by the clathrin-coated pits and vesicles (Fig. 1.29). After the coated pits pinch off from the plasma membrane, they quickly shed their coats and fuse with an endosome. An **endosome** is a vesicle pinched off from the plasma membrane from which its contents can be recycled to the plasma membrane or sent to lysosomes for digestion. In phagocytosis, the large molecular substances are engulfed by the plasma membrane and enter the cell so that they can be isolated and destroyed by lysosomal enzymes (see Chapter 7). Substances that are not degraded by lysosomes are isolated in residual bodies and released by exocytosis. Both pinocytosis and phagocytosis require metabolic energy and often involve binding of the substance with plasma membrane receptors before membrane invagination and fusion with lysosomes in the cell. New data are revealing that endocytosis has an even larger and more important role than previously known (Box 1.2). **Exosomes** are small membrane vesicles of endocytic origin containing protein, lipid, and RNA species in a single unit. Exosomes are secreted by many cell types and confer messages between cells as mediators of cell-to-cell communication. Researchers are revealing this communication through exosomes, including those released from cancer cells, taken up by neighboring cells, and capable of inducing pathways involved in cancer initiation and progression (Fig. 1.30).[13] Many new exosome-based therapies are being developed (Emerging Science Box: Exosome-Based Therapies).

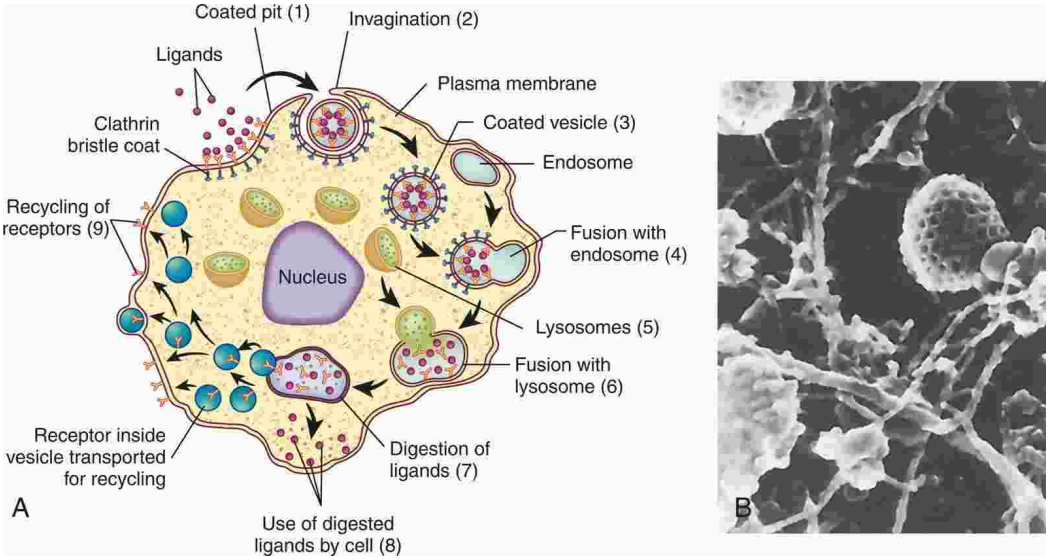

FIG. 1.29 Ligand Internalization by Means of Receptor-Mediated Endocytosis.
(A) The ligand attaches to its surface receptor (through the bristle coat or clathrin coat **(1)** and receptor-mediated endocytosis), invagination **(2)** and coated pit **(3)**, and enters the cell. The ingested material fuses **(4)** with an endosome and lysosomes **(6)** and is processed by hydrolytic lysosomal enzymes **(7)**. Processed molecules can then be transferred to other cellular components **(8 and 9)**. **(B)** Electron micrograph of a coated pit showing different sizes of filaments of the cytoskeleton (×82,000). (B, From Erlandsen SL, Magney JE. Color of histology. St. Louis: Mosby; 1992.)

Illustration A is a colored cross-sectional illustration of a cell structure. The following parts of the structure are labeled, clockwise from the top: ligands, coated pit (1), invagination (2), plasma membrane, coated vesicle (3), endosome, fusion with endosome (4), lysosomes (5), fusion with lysosome (6), digestion

of ligands (7), use of digested ligands by cell (8), receptor inside vesicle transported for recycling, recycling of receptors (9), and clathrin bristle coat. Illustration B is an electron micrograph showing coated pits and cytoskeleton filaments.

Box 1.2

The New Endocytic Matrix

An explosion of new data is disclosing a much more involved role for endocytosis than just a simple way to internalize nutrients and membrane-associated molecules. These new data show that endocytosis not only is a master organizer of signaling pathways but also has a major role in managing signals in time and space. Endocytosis appears to control signaling; therefore it determines the net output of biochemical pathways. This occurs because endocytosis modulates the presence of receptors and their ligands as well as effectors at the plasma membrane or at intermediate stations of the endocytic route. The overall processes and anatomy of these new functions are sometimes called the "endocytic matrix." All of these functions ultimately have a large impact on almost every cellular process, including the nucleus.

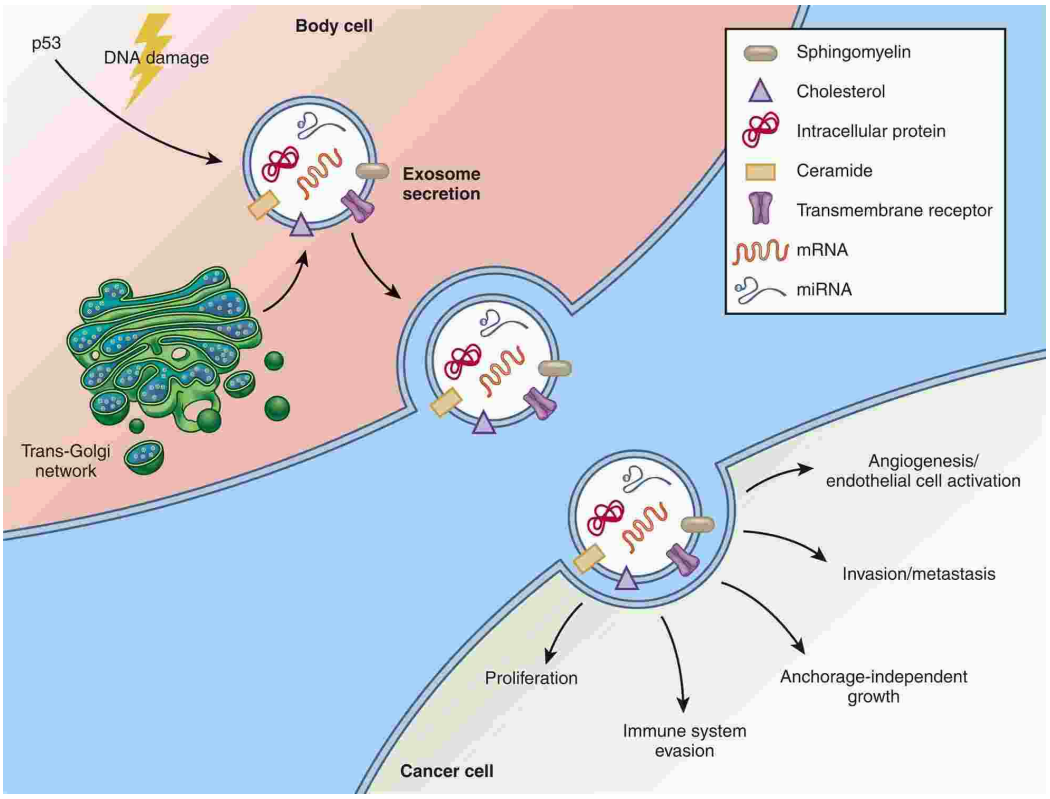

FIG. 1.30 Exosomes and Cell Signaling. Cancer. From a model of cancer cell signaling, exosomes are secreted with characteristic protein and ribonucleic acid (RNA) components. Exosomes that are released from body cells and taken up by neighboring cancer cells and are capable of inducing pathways in cancer initiation and progression. A growing interest in defining the clinical relevance of exosomes in cancers is based partially on their ability to alter tumor microenvironment by regulating immunity, angiogenesis, and metastasis. (From Henderson M, Azorsa D. The genomic and proteomic content of cancer cell-derived exosomes. *Frontiers in Oncology*, 2012; 2:38.)

A colored artist rendering illustrates exosomes and cell signaling. The rendering shows parts of two cell structures. The following parts in the first cell are

labeled: Body Cell, D N A Damage, Exosome Secretion, and Trans-Golgi Network. The Exosome Secretion comprises Sphingomyelin, Cholesterol, Intracellular Protein, Ceramide, Transmembrane Receptor, m R N A, and m i R N A. The Exosome enters the Cancer Cell and undergoes the following: Proliferation, Immune System Evasion, Anchorage-Independent Growth, Invasion or Metastasis, and Angiogenesis or Endothelial Cell Activation.

Emerging Science Box Exosome-Based Therapies

An increased understanding of the role of exosomes in intercellular communication has led to new therapeutic approaches for a number of diseases including cancer. Exosomes are capable of carrying nuclear material (DNA, RNA), lipids, metabolites, proteins, and medications. They can be engineered to deliver therapeutic "payloads" that can promote or constrain a variety of pathophysiologic processes. These payloads may include nucleotides, chemotherapeutic drugs, and immune modulators. They can be administered orally, intranasally, intravenously, or intramuscularly depending on their specific characteristics. The goal is to target and maximize the therapeutic response while reducing adverse reactions. Research areas of particular promise for exosome-based therapies include neurogenerative diseases, cancer, and infection. In addition, exosomes produced by diseased cells can be detected in biologic fluids and be used for early detection. Most recently, a vaccine for coronavirus disease 2019 (COVID-19) that uses exosomes to deliver severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) spike protein messenger RNA is being evaluated in

research trials. Many other new therapeutic uses for exosomes are being explored.

Data from Dai J, et al. Exosomes: Key players in cancer and potential therapeutic strategy. *Signal Transduction and Targeted Therapy*, 2020; 5:145; Kalluri R, et al. The biology, function, and biomedical applications of exosomes. Science, 2020; 367:6478–6977; Patil SM, et al. Exosomes as drug delivery systems: a brief overview and progress update. *European Journal of Pharmaceutics and Biopharmaceutics*, 2020; 154:259-269; Tsai SJ, et al. Exosome-Mediated mRNA Delivery For SARS-CoV-2 Vaccination. bioRxiv, 2020; 11.06.371419.

In eukaryotic cells, secretion of macromolecules almost always occurs by exocytosis (see Fig. 1.28). **Exocytosis** has two main functions: (1) replacement of portions of the plasma membrane that have been removed by endocytosis and (2) release of molecules synthesized by the cells into the ECM.

Receptor-Mediated Endocytosis

The internalization process, called **receptor-mediated endocytosis (ligand internalization)**, is rapid and enables the cell to ingest large amounts of receptor-macromolecule complexes in clathrin-coated vesicles without ingesting large volumes of ECF (see Fig. 1.29). For example, the cellular uptake of cholesterol depends on receptor-mediated endocytosis. In addition, many essential metabolites (e.g., vitamin B_{12} and iron) depend on receptor-mediated endocytosis and, unfortunately, the influenza virus.

Movement of Electrical Impulses: Membrane Potentials

The movement of ions through various channels and transporters results in electrostatic charges across the cell membrane. The electrical potential difference across the plasma membrane when the cell is in a nonexcited state is the **resting membrane potential** and is approximately -70 to -85 millivolts (mV).[14] The difference in voltage across the plasma membrane results from the differences in ionic

composition of ICF and ECF. The positively charged sodium ions are more concentrated in ECF, and positively charged potassium ions are in greater concentration in ICF. Negatively charged intracellular proteins and organic phosphates that cannot cross the cell membrane are also contributory. The concentration difference is maintained by the active transport of Na^+ and K^+ (the sodium-potassium [Na^+-K^+] pump), which transports Na^+ outward and K^+ inward (Fig. 1.31A *and* B). Because the resting plasma membrane is more permeable to K^+ than to Na^+, K^+ diffuses easily from ICF to ECF. The movement of only the cation from the inside of the cell to the outside of the cell leaves behind a negative anion, leaving the inside of the cell more negative and the outside of the cell more positive. The change generates an electrostatic gradient that builds up over time. Because both Na^+ and K^+ are cations, the net result is an excess of anions inside the cell, resulting in the resting membrane potential.

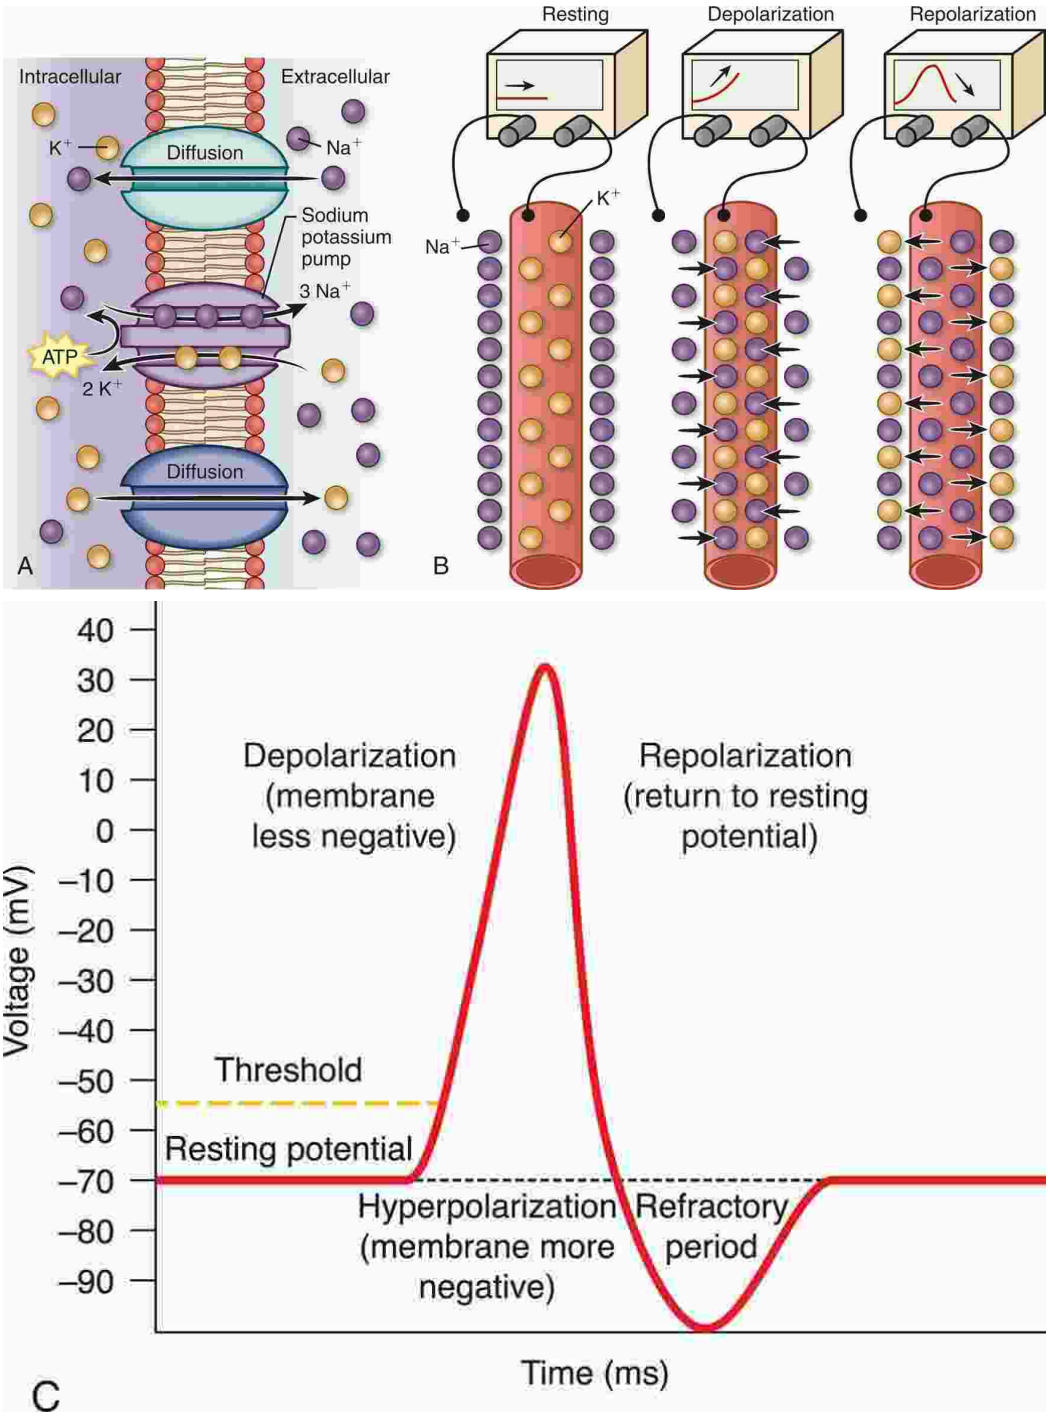

FIG. 1.31 Sodium-Potassium (Na+-K+) Pump and Propagation of an Action Potential.
(A) Concentration difference of sodium *(Na^+)* and potassium *(K^+)* intracellularly and extracellularly. The direction of active transport by the Na^+-K^+ pump is also shown. **(B)** The left diagram

represents the polarized state of a neuronal membrane when at rest. The middle and right diagrams represent changes in sodium and potassium membrane permeabilities with depolarization and repolarization. **(C)** The process for generating an action potential includes depolarization, repolarization, and hyperpolarization. From a recording device, a decrease in potential (i.e., the inside of the cell being less negative than at resting) is represented as an upward deflection, whereas an increase in potential (i.e., the inside being more negative than at resting) is represented by a downward deflection.

Illustration A is a sodium-potassium pump demonstrating diffusion through two uniports and one antiport. Sodium ions diffuse from the extracellular region through the first uniport and into the intracellular region. Two potassium ions from the extracellular region and three sodium ions from the intracellular region diffuse through the antiport. Potassium ions from the intracellular region diffuse through the second uniport and into the extracellular region. Illustration B shows three states of a neuronal membrane: resting, depolarization, and repolarization. At resting state, potassium ions are inside the membrane, and sodium ions outside the membrane. At depolarization state, some sodium ions enter the membrane from the external environment. At repolarization state, all potassium

ions from inside the membrane are released into the external environment. Illustration C is a graph plotting voltage, in milli Volts, against time, in milli seconds. The vertical axis ranges from negative 90 milli Volts to 40 milli Volts. The resting potential is identified as negative 70 milli Volts. The threshold is identified at negative 55 milli Volts. During Depolarization, there is an upward deflection, i.e., a decrease in potential, from negative 70 milli Volts to 30 milli Volts, resulting in a sharp peak. During Repolarization, there is a downward deflection, i.e., an increase in potential, from 30 milli Volts to below negative 90 milli Volts, before returning to the resting potential at negative 70 milli Volts. Hyperpolarization occurs between Depolarization and Repolarization, below the Resting Potential, when the membrane is more negative.

All cells within the body are electrically polarized and have a characteristic resting membrane potential dependent on cell type. The resting membrane potentials of neurons and the three types of muscle cells—smooth, skeletal, and cardiac—are crucial to the proper functioning of the nervous and muscular systems.[14] Nerve and muscle cells are excitable and can change their resting membrane potential in response to electrochemical stimuli. Changes in resting membrane potential convey messages. For neurons, the firing of an action potential allows cell-to-cell communication by the release of various neurotransmitters. In muscle cells, the generation of an action potential causes the muscle to contract. When a nerve or muscle cell receives a stimulus that exceeds the membrane threshold

value, a rapid change occurs in the resting membrane potential, known as the **action potential**. Nerve impulses are described in Chapter 15.

An action potential has three main stages: depolarization, repolarization, and hyperpolarization. Increased levels of K^+ result in depolarization of the membrane of cells. This depolarization inactivates sodium channels, which increases the refractory period.[15] When a resting cell is stimulated through voltage-regulated channels, the cell membranes become more permeable to Na^+, so a net movement of Na^+ into the cell occurs causing the interior of the cell to become more positively charged. The membrane becomes less polarized (less negative) than at resting potential. The membrane potential has *decreased*, moving closer to 0 mV (the potential is less than -70 mV, such as -60 mV). The membrane polarity is neutralized. This decrease is known as **depolarization** (Fig. 1.31C). Initially, depolarization proceeds slowly until it reaches a critical level known as **threshold potential** (usually between -50 and -55 mV). In general, this occurs when the cell has depolarized by 15 to 20 mV. At threshold potential, an explosive depolarization takes place. The sharp upward deflection then reverses itself and the inside of the cell becomes more positive. Just as rapidly, the potential drops back to resting potential as the membrane repolarizes. **Repolarization** is when the membrane returns to resting potential after depolarization. The forces that drive the membrane back to resting potential push it too far, causing a transient **hyperpolarization**. At this stage, the inside of the membrane becomes even more negative (more polarized) than normal. The rapid change in potential from threshold to peak reversal and then back to resting is called the **action potential** (see Fig. 1.31C).

During most of the action potential, the plasma membrane cannot respond to an additional stimulus. This time is known as the **absolute refractory period** (see Fig. 1.31C) and is related to changes in permeability to Na^+. During the latter phase of the action potential, when permeability to K^+ increases, a stronger-than-normal

stimulus can evoke an action potential; this time is known as the **relative refractory period**.

Cellular Reproduction: The Cell Cycle

Humans must make millions of cells every second to just survive.[2] Continuity of life depends on constant rounds of cell growth and division. In most tissues, new cells are created as fast as old cells die. The cycle of repeated rounds of duplication and division is called the **cell cycle**. Reproduction of gametes (sperm and egg cells) occurs through a process called *meiosis*, which is described in Chapter 4. The reproduction, or division, of other body cells (somatic cells) involves two sequential phases—**mitosis**, or nuclear division, and **cytokinesis**, or cytoplasmic division. However, before a cell can divide, it must double its mass and duplicate all its contents. Most of the work preparing for division occurs during the growth phase, called **interphase**. The cell cycle drives the alternation between mitosis and interphase in all tissues with cellular turnover (Fig. 1.32).

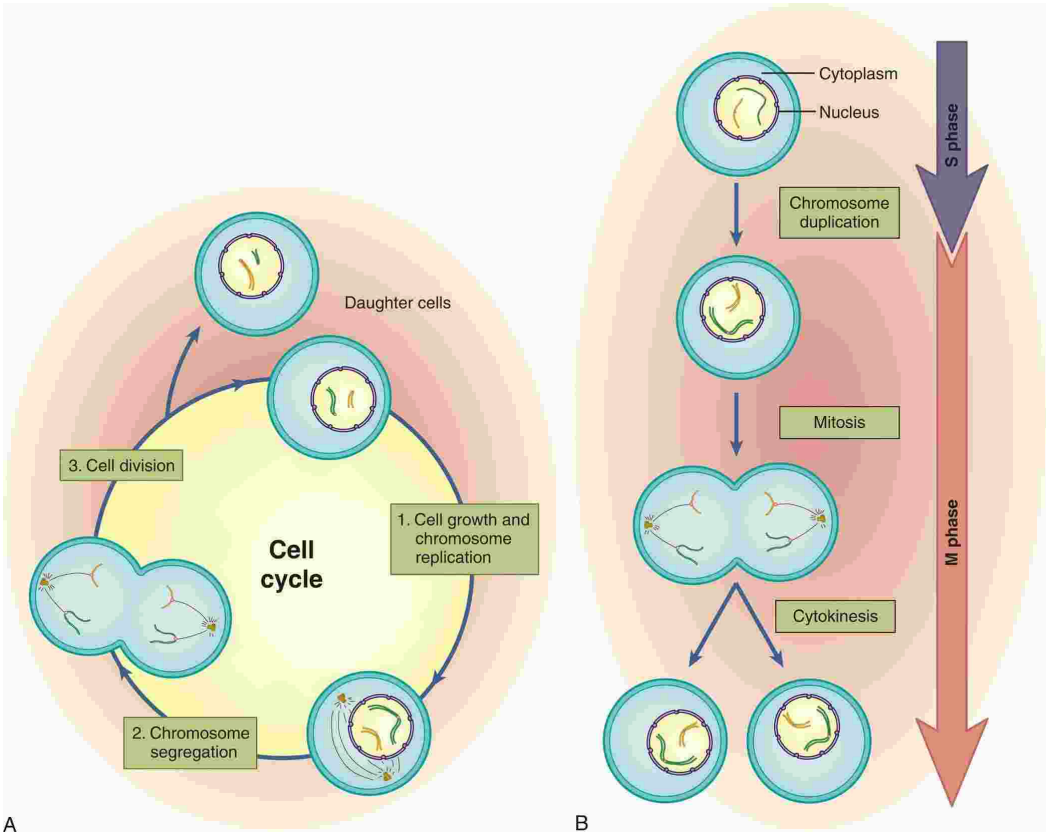

FIG. 1.32 The Cell Cycle.
(A) Simplified figure of schematic cell with one green chromosome and one yellow chromosome to show how two genetically identical daughter cells are produced in each cycle. (B) Cell cycle events: mitosis and cytokinesis. (Adapted from Alberts B, Bray D, Hopkin K, et al. *Molecular biology of the cell*, 6th edition. New York: Garland Science; 2015.)

Two illustrations, A and B, show the cell cycle. Illustration A shows Daughter Cells and a three-step cycle. 1. Cell growth and chromosome replication. 2. Chromosome segregation. 3. Cell division. Illustration B shows the sequence of cell division from the S phase to the M phase. The S phase shows a nucleus inside the cytoplasm. The M phase shows

the following division process: Chromosome Duplication, Mitosis, and Cytokinesis.

The four designated phases of the cell cycle (Fig. 1.33A) are (1) the **G1 phase** (G = gap), which is the period between the M phase and the start of DNA synthesis; (2) the **S phase** (S = synthesis), in which DNA is synthesized in the cell nucleus; (3) the **G2 phase**, in which RNA and protein synthesis occurs, the period between the completion of DNA synthesis and the next phase (M); and (4) the **M phase** (M = mitosis), which includes both nuclear and cytoplasmic division.

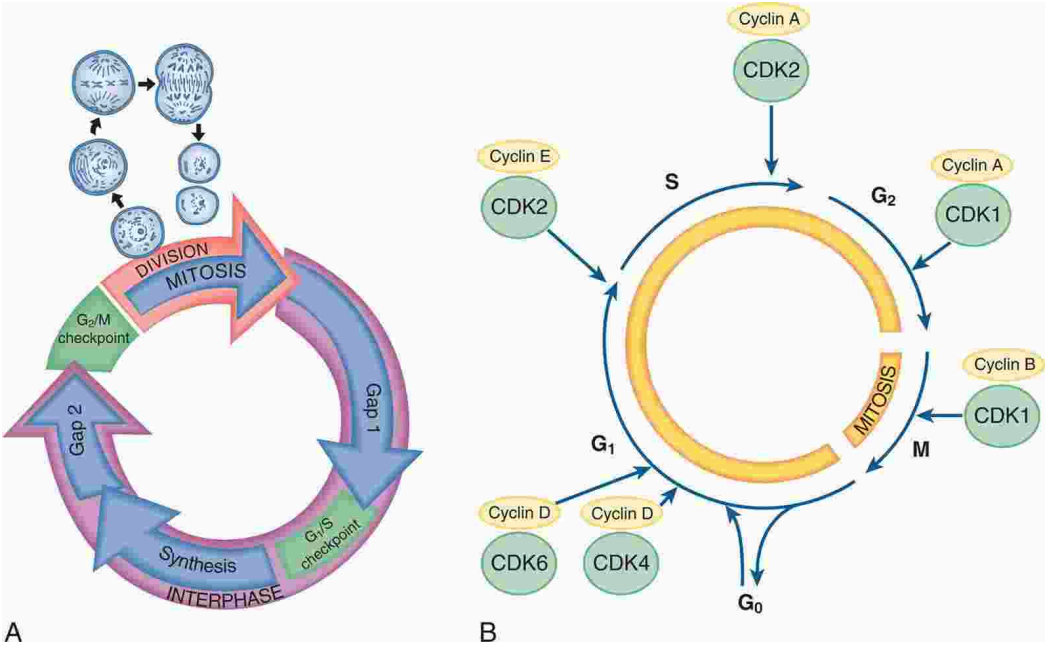

FIG. 1.33 Interphase and the Phases of Mitosis.
(A) The G_1/S checkpoint is to "check" for cell size, nutrients, growth factors, and deoxyribonucleic acid (DNA) damage. See text for resting phases. The G_2/M checkpoint checks for cell size and DNA replication. **(B)** The orderly progression through the phases of the cell cycle is regulated by *cyclins* (so called because levels rise and fall) and *cyclin-dependent protein kinases* (CDKs) and their inhibitors. When cyclins are complexed with CDKs, cell cycle events are triggered.

Two illustrations, A and B, depict the cyclic processes of the interphase and the phases of mitosis. Illustration A depicts Division through Mitosis, Interphase, and G 2 bar M Checkpoint. The Interphase comprises the following stages: Gap 1, G 1 bar S Checkpoint, Synthesis, and Gap 2. This leads

to Gap 2 bar M Checkpoint. Illustration B depicts Cyclin A or C D K 2, Cyclin A or C D K 1 in G 2, Cyclin B or C D K 1 in M, G 0 in and out, Cyclin D or C D K 4, Cyclin D or C D K 6 in G 1, and Cyclin E or C D K 2 in S,

Phases of Mitosis and Cytokinesis

Interphase (the G_1, S, and G_2 phases) is the longest phase of the cell cycle. During interphase, the chromatin consists of very long, slender rods jumbled together in the nucleus. Late in interphase, strands of **chromatin** (the substance that gives the nucleus its granular appearance) begin to coil, causing them to shorten and thicken.

The M phase of the cell cycle, mitosis and cytokinesis, begins with **prophase**, the first appearance of chromosomes. As the phase proceeds, each chromosome is seen as identical halves called **chromatids**, which lie together and are attached by a spindle site called a **centromere**. (The two chromatids of each chromosome, which are genetically identical, are sometimes called *sister chromatids*.) The nuclear membrane, which surrounds the nucleus, disappears. **Spindle fibers** are microtubules formed in the cytoplasm. They radiate from two centrioles located at opposite poles of the cell. The role of the spindle fibers is to pull the chromosomes to opposite sides of the cell by attaching to the chromosome's centromere. The production of the spindle fibers signals the beginning of metaphase.

During **metaphase**, the next phase of mitosis and cytokinesis, the centromeres become aligned in the middle of the spindle, which is called the **equatorial plate** (or **metaphase plate**) of the cell. In this stage, chromosomes are easiest to observe microscopically because they are highly condensed and arranged in a relatively organized fashion in the two-dimensional equatorial plate. The attached spindle fibers begin to pull the centromeres of the chromosomes.

Anaphase begins when the centromeres split and the sister chromatids are pulled apart. The spindle fibers shorten, causing the sister chromatids to be pulled, centromere first, toward opposite sides of the cell. With sister chromatid separation, each is considered to be a chromosome. Thus the cell has 92 chromosomes during this stage. By the end of the anaphase, there are 46 chromosomes lying at each side of the cell. Barring mitotic errors, each of the two groups of 46 chromosomes is identical to the original 46 chromosomes present at the start of the cell cycle.

During the **telophase**, the final stage, a new nuclear membrane is formed around each group of 46 chromosomes, the spindle fibers disappear, and the chromosomes begin to uncoil. Cytokinesis causes the cytoplasm to divide into almost equal parts during this phase. At the end of the telophase, two identical diploid cells, called **daughter cells**, have been formed from the original cell.

The Cell Cycle Control System

Various features of the cell cycle differ from one cell type to another including the length of time to complete certain functions. Most of the variability in cell cycle length in the adult body occurs during the time the cell spends in the G_1 or G_0 phase of the cell cycle. This length of time is different from the brief time a cell takes to progress from the beginning of the S phase through mitosis—typically 12 to 24 hours. Cells are capable of disassembly of their cell cycle control system and can withdraw from the cycle to a nondividing state called **G0**. The reversibility of the G_0 state varies in different types of cells. For example, most of the neurons and skeletal muscle cells are in a *terminally differentiated* G_0 state; with their cell cycle control system disassembled, the molecular regulatory switches (cyclin-dependent kinases [CDKs] and cyclins, see following text) become permanently turned off and cell division rarely occurs.[2]

The **cell cycle control system** triggers the essential events of the cell cycle. The system operates like a timer that triggers the constant sequence of events. Although early embryonic divisions are

independent of feedback controls, in most cells the control system responds to feedback (information) from the processes it controls. For example, if some malfunction occurs with DNA synthesis, signals are sent to the control system to delay progression to the M phase.[2] Such delays allow repair and prevent progression of cellular disasters.

The cell cycle control system works because of a connected series of biochemical switches that either activate or inhibit cell events. Two classes of *switches* or regulatory molecules that determine a cell's progress through the cell cycle are CDKs and cyclins (Fig. 1.33B).

Cyclin-dependent kinases (CDKs) are protein kinases, and their functions rise and fall as the cell moves through the cycle. The rise and fall leads to cyclical changes in phosphorylation of intracellular proteins that start or regulate the events of the cell cycle. Many enzymes and other proteins regulate the different CDKs, and the most important are proteins called **cyclins**.[2] CDK activity is dependent on binding of cyclins *(cyclin-CDK complexes)*. For example, activation of S-phase cyclin-CDK complexes (s-CDKs) initiates the S phase. Without cyclin, CDK is inactive. Binding of *CDK inhibitor proteins (CKIs)* inactivates cyclin-CDK complexes. Two other essential enzyme complexes that regulate the cell cycle control system are the APC/C and SCF ubiquitin ligases, which promote ubiquitylation (process of marking for destruction) and subsequent destruction of various proteins that modulate the cell cycle (Fig. 1.33B).

Control of Cell Division and Cell Growth: Mitogens, Growth Factors, and Survival Factors

Organ size and body size are determined by three main processes: (1) cell growth, (2) cell division, and (3) cell survival.[2] These processes are tightly regulated by intracellular programs and extracellular signal molecules, usually soluble proteins, proteins bound to cells, or molecules of the ECM. The molecules comprise three main classes: (1) mitogens, (2) growth factors, and (3) survival

factors. A **mitogen** is a chemical agent that induces or stimulates mitosis (cell division). Mitogens act as an extracellular signal and they usually come from another neighboring cell. Mitogens can stimulate cell growth, differentiation, migration, and survival.[2]

Growth factors (also called *cytokines*) stimulate an increase in cell mass or cell growth by fostering the synthesis of proteins and other macromolecules and inhibiting their breakdown (Table 1.5), including examples of mitogens and growth factors. Cells starved of growth factors come to a halt after mitosis and enter the arrested, or G_0, state of the cell cycle. Survival factors promote cell survival by inhibiting programmed cell death, or *apoptosis* (see Chapter 2).

Table 1.5

Examples of Mitogens and Growth Factors and Their Actions

Growth Factor	Physiologic Actions
Platelet-derived growth factor (PDGF)	Stimulates proliferation of connective tissue cells and neuroglial cells
Epidermal growth factor (EGF)	Stimulates proliferation of epidermal cells and other cell types
Insulin-like growth factor 1 (IGF-1)	Collaborates with PDGF and EGF; stimulates pro-liferation of fat cells and connective tissue cells
Insulin-like growth factor 2 (IGF-2)	Collaborates with PDGF and EGF; stimulates pro-liferation of fat cells and connective tissue cells
Transforming growth factor-beta (TGF-β)	Stimulates or inhibits response of most cells to other growth factors; regulates differentiation of some cell types (e.g., cartilage)
Fibroblast growth factor (FGF)	Stimulates proliferation of fibroblasts, endothelial cells, myoblasts, and other cell types
Interleukin-2 (IL-2)	Stimulates proliferation of T lymphocytes
Nerve growth factor (NGF)	Promotes axon growth and survival of sympathetic and some sensory and CNS neurons

Growth Factor	Physiologic Actions
Hematopoietic cell growth factors (IL-3, GM-CSF, M-CSF, G-CSF, erythropoietin)	Promotes growth of white and red blood cells

CNS, Central nervous system; *CSF*, colony-stimulating factor; *G*, granulocyte; *GM*, granulocyte-macrophage; *M*, macrophage.

DNA Damage Response: Blocks Cell Division

The **DNA damage response** occurs when DNA is damaged, with recruitment of protein kinases to the site of damage and signaling that promotes a stop to the progression of the cell cycle, called **cell cycle arrest** (Fig. 1.34).

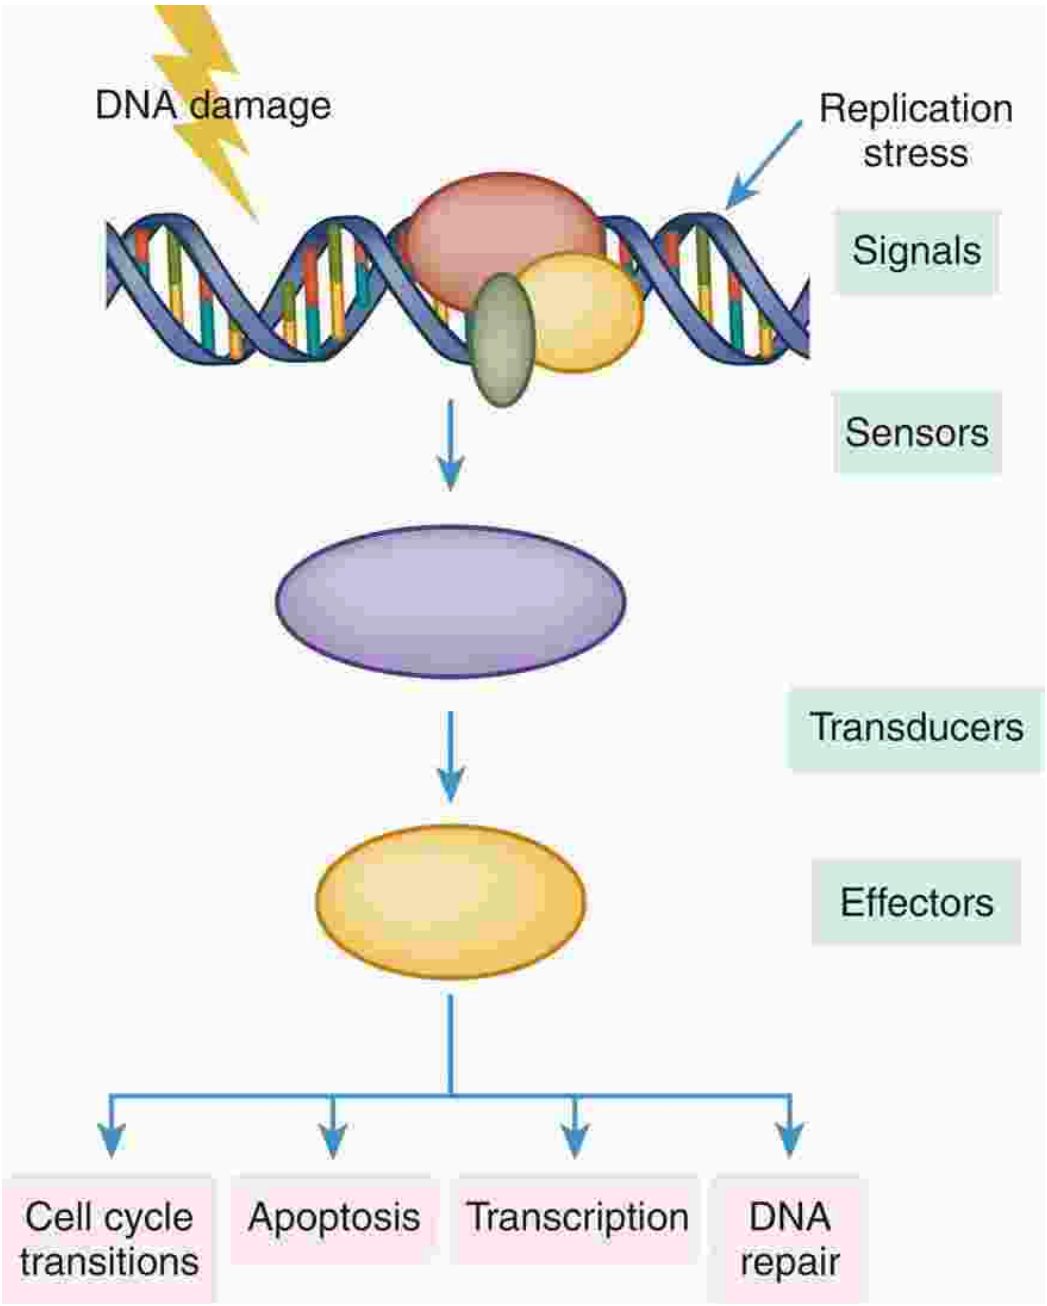

FIG. 1.34 Deoxyribonucleic Acid Damage Response.
Several injurious agents can damage deoxyribonucleic acid (DNA). These include exogenous agents such as ultraviolet light; ionizing radiation; chemicals and endogenous agents; oxidative damage; and replicative stress. Protein kinases are activated and serve as

sensors and transducers causing many effector responses. The cell cycle arrest prevents entry into mitosis and several cell fates occur including DNA repair and apoptosis or cell death.

An illustration shows the D N A damage response. Replication stress in a D N A helical structure comprises signals and sensors, which are separated into transducers and Effectors. Effectors are further reduced to cell cycle transitions, apoptosis, transcription, and D N A repair.

Tissues

Cells of common structure and function are organized into **tissues**, of which there are four primary types: *muscle, neural, epithelial*, and *connective*. Epithelial, connective, and muscle tissues are summarized in Tables 1.6, 1.7, and 1.8, respectively. Different types of neurons have special characteristics that depend on their distribution and function within the nervous system (see Chapter 15). Different types of tissues compose organs. Finally, organs are integrated to perform complex functions as tracts or systems.

Table 1.6

Characteristics of Epithelial Tissues

Simple Squamous Epithelium

Structure

Single layer of cells

Location and Function

Lining of blood vessels leads to diffusion and filtration

Lining of pulmonary alveoli (air sacs) leads to separation of blood from fluids in tissues

Bowman capsule (kidney), where it filters substances from blood, forming urine

Stratified Squamous Epithelium

Structure

Two or more layers, depending on location, with cells closest to basement membrane tending to be cuboidal

Location and Function

Epidermis of skin and linings of mouth, pharynx, esophagus, and anus provide protection and secretion

Transitional Epithelium

Structure

Vary in shape from cuboidal to squamous depending on whether basal cells of bladder are columnar or are composed of many layers; when bladder is full and stretched, the cells flatten and stretch like squamous cells

Location and Function

Linings of urinary bladder and other hollow structures stretch, allowing expansion of the hollow organs

Simple Cuboidal Epithelium

Structure

Simple cuboidal cells; rarely stratified (layered)

Location and Function

Glands (e.g., thyroid, sweat, salivary) and parts of the kidney tubules and outer covering of ovary secrete fluids

Simple Columnar Epithelium

Structure

Large amounts of cytoplasm and cellular organelles

Location and Function

Ducts of many glands and lining of digestive tract allow secretion and absorption from stomach to anus

Ciliated Simple Columnar Epithelium

Structure

Same as simple columnar epithelium but ciliated

Location and Function

Linings of bronchi of lungs, nasal cavity, and oviducts allow secretion, absorption, and propulsion of fluids and particles

Stratified Columnar Epithelium

Structure

Small and rounded basement membrane (columnar cells do not touch basement membrane)

Location and Function

Linings of epiglottis, part of pharynx, anus, and male urethra provide protection

Pseudostratified Ciliated Columnar Epithelium

Structure

All cells in contact with basement membrane

Nuclei found at different levels within cell, giving stratified appearance

Free surface often ciliated

Location and Function

Linings of large ducts of some glands (parotid, salivary), male urethra, respiratory passages, and eustachian tubes of ears transport substances

Table 1.7

Connective Tissues

Loose or Areolar Tissue

Structure

Unorganized; spaces between fibers

Most fibers collagenous, some elastic and reticular

Includes many types of cells (fibroblasts and macrophages most common) and large amount of intercellular fluid

Location and Function

Attaches skin to underlying tissue; holds organs in place by filling spaces between them; supports blood vessels

Intercellular fluid transports nutrients and waste products. Fluid accumulation causes swelling (edema)

Dense Irregular Tissue

Structure

Dense, compact, and areolar tissue, with fewer cells and greater number of closely woven collagenous fibers than in loose tissue

Location and Function

Dermis layer of skin; acts as protective barrier

Dense, Regular (White Fibrous) Tissue

Structure

Collagenous fibers and some elastic fibers, tightly packed into parallel bundles, with only fibroblast cells

Location and Function

Forms strong tendons of muscle, ligaments of joints, some fibrous membranes, and fascia that surrounds organs and muscles

Elastic Tissue

Structure

Elastic fibers, some collagenous fibers, fibroblasts

Location and Function

Lends strength and elasticity to walls of arteries, trachea, vocal cords, and other structures

Adipose Tissue

Structure

Fat cells dispersed in loose tissues; each cell containing a large droplet of fat flattens nucleus and forces cytoplasm into a ring around cell's periphery

Location and Function

Stores fat, which provides padding and protection

Cartilage (Hyaline, Elastic, Fibrous)

Structure

Collagenous fibers embedded in a firm matrix (chondrin); no blood supply

Location and Function

Gives form, support, and flexibility to joints, trachea, nose, ear, vertebral disks, embryonic skeleton, and many internal structures

Bone

Structure

Rigid connective tissue consisting of cells, fibers, ground substances, and minerals

Location and Function

Lends skeleton rigidity and strength

Special Connective Tissues

Plasma

Structure

Fluid

Location and Function

Serves as matrix for blood cells

Macrophages in Tissue, Reticuloendothelial, or Macrophage System

Structure

Scattered macrophages (phagocytes) called *Kupffer cells* (in liver), alveolar macrophages (in lungs), microglia (in central nervous system)

Location and Function

Facilitate inflammatory response and carry out phagocytosis in loose connective, lymphatic, digestive, medullary (bone marrow), splenic, adrenal, and pituitary tissues

---

Table 1.8

Muscle Tissues

Skeletal (Striated) Muscle	
Structure Characteristics of Cells	
Long, cylindrical cells that extend throughout length of muscles	
Striated myofibrils (proteins)	
Many nuclei on periphery	
Location and Function	
Attached to bones directly or by tendons and provide voluntary movement of skeleton and maintenance of posture	 Skeletal (Striated) Muscle. From Thibodeau GA, Patton KT. *Anatomy & physiology*, 6th edition. St. Louis: Mosby; 2007.
Cardiac Muscle	
Structure Characteristics of Cells	
Branching networks throughout muscle tissue	

Striated myofibrils	
Location and Function	
Cells attached end-to-end at intercalated disks with tissue forming walls of heart (myocardium) to provide involuntary pumping action of heart	
Smooth (Visceral) Muscle	
Structure Characteristics of Cells	
Long spindles that taper to a point	
Absence of striated myofibrils	
Location and Function	
Walls of hollow internal structures, such as digestive tract and blood vessels (viscera), provide voluntary and involuntary contractions that move substances through hollow structures	 Smooth (Visceral) Muscle. From Young B, Woodford P. *Wheater's functional histology*, 6th edition. Philadelphia: Churchill Livingstone; 2014.

All cells are in contact with a network of extracellular macromolecules known as the ECM (see the Extracellular Matrix and Basement Membrane section). This matrix results in mechanical strength by holding cells and tissues together.[16] It also provides an

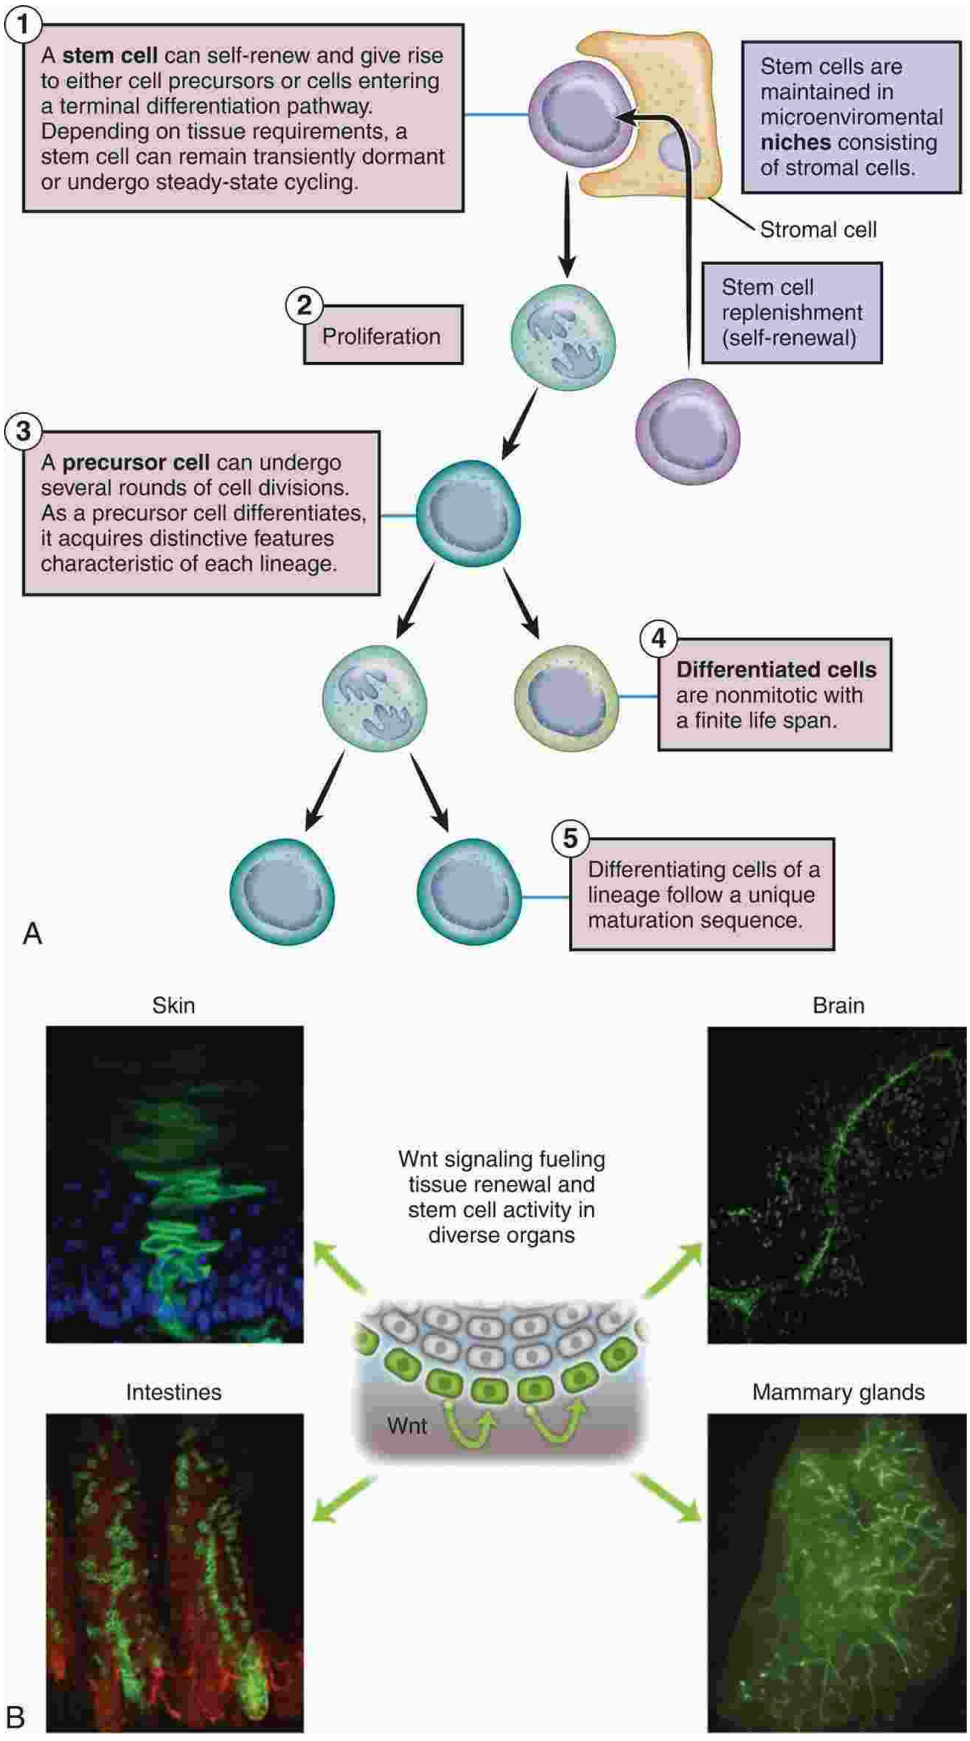
organized latticework in which cells can migrate and interact with one another.

Tissue Formation and Differentiation

To form tissues, cells must exhibit intercellular recognition and communication, adhesion, and memory. Specialized cells sense their environment through signals, such as growth factors, from other cells. This type of communication ensures that new cells are produced only when and where they are required. Different cell types have different adhesion molecules in their plasma membranes, sticking selectively to other cells of the same type. They can also adhere to the ECM components. Because cells are tiny and squishy and enclosed by a flimsy membrane, it is remarkable that they form a strong human being. Strength can occur because of the ECM and the strength of the cytoskeleton with cell-to-cell adhesions to neighboring cells. Cells have memory because of specialized patterns of gene expression evoked by signals that acted during embryonic development. Memory allows cells to autonomously preserve their distinctive character and pass it on to their offspring.[2]

Fully specialized, or **terminally differentiated** cells that are lost, are regenerated from proliferating *precursor cells*. These precursor cells have been derived from a smaller number of stem cells.[2]**Stem cells** are unspecialized cells of the human body and have the ability to differentiate into any type of cell.[17] Stem cells exist in both embryos and adult tissues. In many tissues, stem cells serve as an internal repair and maintenance system, dividing indefinitely. However, in some organs (e.g., pancreas), stem cell division occurs only under special physiologic conditions. These cells can maintain themselves by dividing and perpetuating the stem cell pool over very long periods (throughout life), an ability that is referred to as **self-renewal**. This requires cell control by dividing and developing into multiple specialized cell types in specific tissues or organs, known as **multipotency**, or dividing and developing into the three primary germ cell layers of the early embryo and therefore into all

cells of the adult body, which is known as **pluripotency**.[18] This stem cell–driven tissue renewal is very evident in the epithelial lining of the intestine, stomach, blood cells, and skin, which is continuously exposed to environmental factors. When a stem cell divides, each daughter cell has a choice: It can remain as a stem cell, or it can follow a pathway that results in terminal differentiation (Fig. 1.35).



1
A **stem cell** can self-renew and give rise to either cell precursors or cells entering a terminal differentiation pathway. Depending on tissue requirements, a stem cell can remain transiently dormant or undergo steady-state cycling.
Stem cells are maintained in microenviromental **niches** consisting of stromal cells.
Stromal cell
Stem cell replenishment (self-renewal)
2
Proliferation
3
A **precursor cell** can undergo several rounds of cell divisions. As a precursor cell differentiates, it acquires distinctive features characteristic of each lineage.
4
Differentiated cells are nonmitotic with a finite life span.
5
Differentiating cells of a lineage follow a unique maturation sequence.

B

FIG. 1.35 Properties of Stem Cell Systems. **(A)** Stem cells have three characteristics: *self-renewal, proliferation*, and *differentiation* into mature cells. Stem cells are housed in *niches* consisting of *stromal cells* that provide factors for their maintenance. Stem cells of the embryo can give rise to cell precursors that generate all the tissues of the body. This property defines stem cells as *multipotent*. Stem cells are difficult to identify anatomically. Their identification is based on specific *cell surface markers* (cell surface antigens recognized by specific monoclonal antibodies) and on the lineage they generate following *transplantation*. **(B)** Wnt signaling fuels tissue renewal. (A, From Kierszenbaum A. *Histology and cell biology: An introduction to pathology*, 3rd edition. St. Louis: Elsevier; 2012. B, From Clevers H, Loh KM, Nusse R. Stem cell signaling. An integral program for tissue renewal and regeneration: Wnt signaling and stem cell control. Science, 2014; 346:6205, 1248012.)

Illustration demonstrates the differentiation of stem cells over a sequence of five stages.1. A stem cell can self-renew and give rise to either cell precursors or cells entering a terminal differentiation pathway. Depending on tissue requirements, a stem cell can remain transiently dormant or undergo steady-state cycling. Stem cells are maintained in microenvironmental niches consisting of stromal cells. 2. Proliferation. Stromal cell. Stem cell replenishment (self-renewal). 3. A precursor cell can undergo several rounds of cell divisions. As a

precursor cell differentiates, it acquires distinctive features characteristic of each lineage. 4. Differentiated cells are nonmitotic with a finite life span. 5. Differentiating cells of a lineage follow a unique maturation sequence. Illustration b shows four photomicrographs of tissues in skin, intestines, brain, and mammary glands, all receiving w n t signaling that fuels tissue renewal and stem cell activity in diverse organs.

Summary Review

Prokaryotes and Eukaryotes

1. Eukaryotes are the cells of higher animals and plants, fungi, protozoa, and most algae. These cells are larger and have membrane-bound intracellular compartments (organelles) and a well-defined nucleus. Genetic information is contained in several or many chromosomes.
2. Prokaryotes include bacteria and archaea. They contain no organelles, and their nucleus is not well defined. Genetic information is contained in a single circular chromosome.

Cellular Functions

1. Cells become specialized through the process of differentiation, or maturation, so that they perform one kind of function.
2. The eight specialized cellular functions are movement, conductivity, metabolic absorption, secretion, excretion, respiration, reproduction, and communication.

Structure and Function of Cellular Components

1. The eukaryotic cell consists of three general components: the plasma membrane, cytoplasm, and intracellular organelles.
2. The nucleus is the largest membrane-bound organelle and is found usually in the cell's center. The chief functions of the nucleus are cell division and control of genetic information.
3. Cytoplasm, or the cytoplasmic matrix, is an aqueous solution (cytosol) that fills the space between the nucleus and the plasma membrane. It represents about half of the volume of the cell.
4. The organelles are suspended in the cytoplasm and are enclosed in biologic membranes.
5. Ribosomes are RNA-protein complexes that use the information from DNA, written in messenger RNA (mRNA), to build proteins and provide sites for cellular protein synthesis.
6. The endoplasmic reticulum (rough and smooth) is a network of tubular channels (cisternae) that extend throughout the outer nuclear membrane. The rough endoplasmic reticulum (RER) specializes in the synthesis, folding, and transport of protein components. The smooth endoplasmic reticulum (SER) is involved in the synthesis of steroid hormones and is responsible for a variety of reactions required to remove toxic substances from the cell.
7. The Golgi complex is a network of flattened, smooth membranes and vesicles located near the nucleus. The Golgi complex is responsible for processing and packaging proteins into secretory vesicles that break away from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane.
8. Lysosomes are sac-like structures that contain digestive enzymes. These enzymes are responsible for digesting most cellular substances to their basic form, such as amino acids, fatty acids, and carbohydrates (sugars). Cellular injury leads

to a release of the lysosomal enzymes, causing cellular self-digestion. They also serve as signaling hubs in a network for cellular adaptation.

9. Peroxisomes appear similar to lysosomes but contain several enzymes that either produce or use hydrogen peroxide and their reactions detoxify waste products.
10. Mitochondria contain the metabolic machinery necessary for cellular energy metabolism. The enzymes of the respiratory chain (electron transport chain), found in the inner membrane of the mitochondria, generate most of the cell's adenosine triphosphate (ATP).
11. The cytoskeleton is the “bone and muscle” of the cell. The internal skeleton is composed of a network of protein filaments, including microtubules and actin filaments (microfilaments). They also form cell extensions (microvilli, cilia, flagella).
12. The plasma membrane encloses the cell and, by controlling the movement of substances across it, exerts a powerful influence on metabolic pathways. Other important functions include cell-to-cell recognition, cellular mobility, and maintenance of cellular shape.
13. The basic structure of plasma membrane is the lipid bilayer, which is studded with various proteins. Carbohydrates contained within the plasma membrane are generally bound to membrane proteins (glycoproteins) and lipids (glycolipids).
14. The lipid bilayer determines the structure of the membrane. Each lipid molecule is polar, or amphipathic: the head is hydrophilic (“water loving”) and the tail is hydrophobic (“water hating”). The membrane is organized in two layers, with the tails inward and the heads outward. This provides a barrier to the diffusion of hydrophilic substances, while allowing lipid-soluble molecules to diffuse through readily.
15. Membrane proteins can extend across the bilayer, be in the bilayer but primarily on one side or the other, or can exist outside of the bilayer. Membrane proteins, like other

proteins, are synthesized by the ribosome and then translocate, called trafficking, to different locations in the cell. Trafficking places unique demands on membrane proteins for folding, translocation, and stability. Misfolded proteins are emerging as an important cause of disease.

16. Proteins determine the functions of the membrane. Proteins perform most of the plasma membrane's tasks. Proteins act as recognition and binding units for substances moving in and out of the cell, pores and transport channels, enzymes that drive pumps or maintain ion concentrations, cell surface markers, cell adhesion molecules, and catalysts of chemical reactions. Proteins form cellular receptors that recognize and bind with smaller molecules called ligands.
17. Proteostasis is the state of cell balance of the processes of protein synthesis, folding, and dehydration (protein homeostasis). The proteostasis network is composed of ribosomes (makers), chaperones (helpers), and protein breakdown or proteolytic systems. Malfunction of these systems is associated with disease.
18. The carbohydrates on the outside of the plasma membrane form a coating (glycocalyx) that protects the cell from mechanical damage and creates a slimy surface that assists in mobility. Carbohydrates also function in cell-cell recognition and adhesion.

Cell-to-Cell Adhesions

1. Cell-to-cell adhesions are formed on plasma membranes, thereby allowing the formation of tissues and organs. Cells are held together by three different means: (1) the extracellular membrane, (2) cell adhesion molecules in the cell's plasma membrane, and (3) specialized cell junctions.
2. The extracellular matrix (ECM) is secreted by cells and is a meshwork of fibrous proteins in a gel-like substance. It provides a pathway for diffusion of nutrients, wastes, and

other water-soluble substances. The ECM includes three groups of macromolecules: (1) fibrous structural proteins (collagen and elastin), (2) adhesive glycoproteins, and (3) proteoglycans and hyaluronic acid. The matrix helps regulate cell growth, movement, and differentiation.

3. Basement membrane is a specialized type of ECM that is very thin, tough, and flexible. It lies under the epithelium of many organs and is also called the basal lamina.
4. Cell adhesion molecules (CAMs) are cell surface proteins that bind the cell to an adjacent cell and to components of the ECM. CAMs include four protein families: the integrins, cadherins, selectins, and IgSF.
5. Cell junctions are the contacts between neighboring cells. They can hold cells together with a tight seal, provide strong mechanical attachments, provide a chemical communication, and maintain polarity of cells. Cell junctions can be classified as symmetric and asymmetric. Symmetric junctions include tight junctions, the belt desmosome, desmosomes, and gap junctions. An asymmetric junction is the hemidesmosome.

Cellular Communication and Signal Transduction

1. Cells communicate in three main ways: (1) they form protein channels (gap junctions); (2) they display receptors that affect intracellular processes or other cells in direct physical contact; and (3) they use receptor proteins inside the target cell.
2. Primary modes of intercellular signaling include contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter.
3. Signal transduction involves signals or instructions from extracellular chemical messengers that are conveyed to the cell's interior for execution. If deprived of appropriate signals, cells undergo a form of cell suicide known as programmed cell death or apoptosis.

4. Binding of the extracellular signaling messenger (first messenger) to the membrane receptors causes (1) the opening or closing of channels that regulate ion movement and (2) the transfer of the signal to an intracellular messenger (second messenger) that triggers a cascade of events in the cell.

Cellular Metabolism

1. The chemical tasks of maintaining essential cellular functions are referred to as cellular metabolism. Anabolism is the energy-using process of metabolism, whereas catabolism is the energy-releasing process.
2. ATP functions as an energy-transferring molecule. It is fuel for cell survival. Energy is stored by molecules of carbohydrate, lipid, and protein, which, when catabolized, transfers energy to ATP. The phases of catabolism are digestion, glycolysis and oxidation, and the citric acid cycle.
3. Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP.

Membrane Transport: Cellular Intake and Output

1. Cell survival and growth depend on the constant exchange of molecules with their environment. The majority of molecular transfer depends on specialized membrane transport proteins. The two main classes of membrane transport proteins are transporters and channels.
2. Passive transport does not require the expenditure of energy; rather, it is driven by physical effects. Passive transport mechanisms include diffusion, filtration, and osmosis. Water and small, electrically uncharged molecules move through pores in the plasma membrane's lipid bilayer via passive transport.

3. Diffusion is the passive movement of a solute from an area of greater solute concentration to an area of lesser solute concentration, a difference known as the concentration gradient.
4. Filtration is the movement of water and solutes through a membrane because of a greater pushing pressure on one side. Hydrostatic pressure is the force of water pushing against a cellular membrane.
5. Osmosis is the movement of water across a semipermeable membrane from a region of lower solute concentration to a region of higher solute concentration. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the osmotic pressure of solution. The overall osmotic effect of colloids, such as plasma proteins, is called the oncotic pressure or colloid osmotic pressure.
6. Active transport requires expenditure of metabolic energy by the cell by means of ATP. Larger molecules and molecular complexes are moved into the cell by active transport.
7. The active transport of Na^+ and K^+ is found in virtually all cells. Approximately 60% to 70% of ATP synthesized by cells is used to maintain the transport of Na^+ and K^+.
8. The largest molecules (macromolecules) and fluids are transported by membrane-bound vesicles through the processes of endocytosis (ingestion) and exocytosis (expulsion).
9. Endocytosis, or vesicle formation, occurs when the substance to be transported is engulfed by a segment of the plasma membrane, forming a vesicle that moves into the cell. Pinocytosis is a type of endocytosis in which fluids and solute molecules are ingested through formation of small vesicles. Phagocytosis is a type of endocytosis in which large particles, such as bacteria, are ingested through formation of large vesicles, called vacuoles.

10. In receptor-mediated endocytosis, the plasma membrane receptors are clustered, along with bristle-like structures, in specialized areas called coated pits. Endocytosis occurs when the coated pits invaginate, internalizing ligand-receptor complexes in coated vesicles.
11. Inside the cell, lysosomal enzymes process and digest material ingested by endocytosis.
12. In exocytosis, a membrane-bound vesicle carries macromolecules to the outer cell membrane. It has two main functions: it releases molecules synthesized by the cells into the ECM and replaces portions of the plasma membrane that have been removed by endocytosis.
13. Two types of solutes exist in body fluids: electrolytes and nonelectrolytes. Electrolytes are electrically charged and dissociate into constituent ions when placed in solution. Nonelectrolytes do not dissociate when placed in solution.
14. All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in voltage across the plasma membrane is the resting membrane potential.
15. When an excitable (nerve or muscle) cell receives an electrochemical stimulus, cations enter the cell and cause a rapid change in the resting membrane potential known as the action potential. The action potential “moves” along the cell's plasma membrane and is transmitted to an adjacent cell. This is how electrochemical signals convey information from cell to cell.

Cellular Reproduction: The Cell Cycle

1. Cellular reproduction in body tissues involves mitosis (nuclear division) and cytokinesis (cytoplasmic division).
2. Only mature cells are capable of division. Maturation occurs during a stage of cellular life called interphase (growth phase).

3. The cell cycle is the reproductive process that begins after interphase in all tissues with cellular turnover. There are four phases of the cell cycle: (1) the G_1 phase (G = gap), the period between the M phase and the start of DNA synthesis; (2) the S phase (S = synthesis), during which DNA synthesis takes place in the cell nucleus; (3) the G_2 phase, the period between the completion of DNA synthesis and the next phase in which RNA and protein synthesis occurs; and (4) the M phase (M = mitosis), which involves both nuclear and cytoplasmic division.
4. The M phase (mitosis) involves four stages: prophase, metaphase, anaphase, and telophase.
5. Cellular division and growth are regulated by intracellular programs and several extracellular signal molecules (cell cycle control system). The cell cycle control system works because of a connected series of biochemical switches that either activate or inhibit cell events. Two classes of *switches*, or regulatory molecules that determine a cell's progress through the cell cycle, are CDKs and cyclins.
6. Organ size and body size are determined by three main processes: (1) cell growth, (2) cell division, and (3) cell survival. Mitogens induce or simulate mitosis. Growth factors stimulate an increase in cell mass or cell growth. Survival factors inhibit the programmed cell death called apoptosis.

Tissues

1. Cells of one or more types are organized into tissues, and different types of tissues compose organs. Organs are organized to function as tracts or systems.
2. Three key factors that maintain the cellular organization of tissues are (1) recognition and cell communication, (2) selective cell-to-cell adhesion, and (3) memory.

3. Fully specialized or terminally differentiated cells that are lost are generated from proliferating precursor cells and they, in turn, have been derived from a smaller number of stem cells. Stem cells are cells with the potential to develop into many different cell types during early development and growth. In many tissues, stem cells serve as an internal repair and maintenance system dividing indefinitely. These cells can maintain themselves over very long periods of time, called self-renewal, and can generate all the differentiated cell types of the tissue or multipotency.
4. The four basic types of tissues are epithelial, muscle, nerve, and connective tissues.
5. Neural tissue is composed of highly specialized cells called neurons that receive and transmit electrical impulses rapidly across junctions called synapses.
6. Epithelial tissue covers most internal and external surfaces of the body. The functions of epithelial tissue include protection, absorption, secretion, and excretion.
7. Connective tissue binds various tissues and organs together, supporting them in their locations and serving as storage sites for excess nutrients.
8. Muscle tissue is composed of long, thin, highly contractile cells or fibers. Muscle tissue that is attached to bones enables voluntary movement. Muscle tissue in internal organs enables involuntary movement, such as the heartbeat.

Somatic Death 95

Most diseases are caused by multiple factors acting together *(multifactorial)* or a single factor interacting with a genetically susceptible person. Injury to cells or their surrounding environment, the *extracellular matrix (ECM)*, leads to tissue and organ damage. Although the normal cell is characterized by a narrow range of structural and functional constraints, cells can *adapt* to increased demands and stress to maintain a steady state, called *homeostasis*. Adaptation is a reversible response involving structural or functional modifications to accommodate both physiologic (normal) demands and pathologic (adverse) conditions. For example, the uterus adapts to pregnancy—a normal physiologic state—by enlarging. Pregnancy triggers an increase in the size and number of cells to accommodate a growing fetus. Adaptation to a pathologic condition occurs with high blood pressure or hypertension. Myocardial cells become enlarged, resulting in a larger, thicker left ventricle to accommodate the increased workload of the heart. Cellular adaptations to pathologic conditions are usually only temporarily successful. If the stressor is eliminated, cells can return to normal state without lasting injury; however, severe or long-term stressors can overwhelm the adaptive processes, resulting in cellular injury or death. Common

sources of cell stress include structural damage, neoplasia, fluid/solute accumulations, genetic influences, and aging.

Cellular injury can result from any factor that disrupts cellular structures or deprives the cell of oxygen and essential nutrients. Resultant injury may be *sublethal* (reversible) or *lethal* (irreversible). Common sources of cell injury are classified broadly as ischemic–hypoxic (lack of sufficient oxygen), ischemia–reperfusion, free radical, immunologic, infectious, intentional or unintentional, and inflammatory. Clinical manifestations and alteration to normal physiology will vary with the type of injury. Stress from metabolic derangements is linked to intracellular excessive *accumulations* of carbohydrate, protein, and lipids. Cell death can result in calcium accumulation within surrounding damaged tissue, a condition referred to as *pathologic calcification*. The two main types of cell death are *necrosis* and *apoptosis*. A third process, *autophagy*, occurs during times of cellular stress and is typically triggered by deficiency of nutrients or growth factors. The various forms of cell death are discussed in greater detail later in this chapter.

Cellular aging causes structural and functional changes that may result in decreased capacity to recover from injury and, ultimately, cell death. The exact mechanisms governing cellular aging is unclear; distinguishing pathologic changes from age-associated physiologic changes can be challenging. Aging clearly results in alterations to cellular structure and function, yet *senescence* (growing old) is both inevitable and normal.

Cellular Adaptation

Cells have the remarkable capacity to adapt to their environment to avoid injury. An adapted cell is neither normal nor injured; its status falls somewhere between these two states. Adaptations are reversible changes affecting the size, number, phenotype, metabolic activity, or function of cells.[1]

Adaptive responses have limits; additional stress can compromise essential cell functions leading to cell injury or death. Cell adaptation may be the central component in many disease states. In the early

stages of successful adaptation, cells may have enhanced function, making it difficult to distinguish a pathologic response from vigorous adaptation. Over time, the adaptive response may fail, and pathology will ensue. The most significant adaptive changes in cells include the following:

- Atrophy—decrease in cell size
- Hypertrophy—increase in cell size
- Hyperplasia—increase in cell number
- Metaplasia—reversible replacement of one differentiated cell type by another cell type
- Dysplasia—or deranged cellular growth, is not considered a true cellular adaptation but rather atypical hyperplasia

These changes are shown in Fig. 2.1.

Dysplasia

FIG. 2.1 Adaptive and Dysplastic Alterations in Simple Cuboidal Epithelial Cells.

A series of six illustrations shows the adaptive and dysplastic alterations in simple cuboidal epithelial cells.under Each illustration shows a basement membrane under epithelial cells. The first illustration represents the normal state of cells and shows four simple cuboidal epithelial cells, arranged in a neat row. The second illustration represents the atrophy in cells, where the cells are smaller and distorted. The third illustration represents hypertrophy in cells, where the cells are enlarged. The fourth illustration represents hyperplasia, where the cells are dense and narrower. The fifth illustration represents metaplasia, where the cells are smaller and clustered into a heap. The sixth illustration represent dysplasia, where the cells are much smaller, with broken nuclei, and clustered into a heap.

Atrophy

Atrophy refers to *decrease* in cell *size*. If atrophy affects enough cells, the affected organ decreases in size and is said to be atrophic. Atrophy can affect any organ, but it occurs most commonly in skeletal muscle, heart muscle, secondary sex organs, and the brain. Atrophy is classified as either *physiologic* or *pathologic*, depending on the underlying cause, and regardless of whether atrophy results from normal physiologic or pathologic conditions, identical changes

to cellular structure will occur. Physiologic atrophy occurs with normal development. In early development, embryonic structures (i.e., notochord) undergo atrophy, whereas during early childhood the thymus gland involutes, and in adolescence, the tonsils shrink. In women, the uterus decreases in size shortly after childbirth.

Pathologic atrophy occurs in organs as a result of decreases in workload, pressure, use, blood supply, nutrition, hormonal stimulation, or neural stimulation. *Disuse atrophy* (decreased workload) occurs when a limb is placed in a cast for an extended period with prolonged bed rest or immobilization. Pressure can cause tissue to atrophy and is often seen in pressure ulcers. Chronic ischemia can result in senile atrophy from a decrease in blood supply to the brain (Fig. 2.2). The lack of hormonal stimulation results in atrophic changes that occur more readily with age. In postmenopausal women, the ovaries atrophy secondary to a lack of estrogenic stimulation. In men, the gonads shrink secondary to decreases in hormonal stimulation. Aging also results in atrophic changes to brain cells. *Denervation atrophy* is seen with peripheral neuropathies. Atrophic muscle cells contain less endoplasmic reticulum (ER), fewer mitochondria, and fewer *myofilaments* (the contractile components of the muscle fiber) compared with normal cells. Muscle atrophy, caused by decreased neural stimulation, results in reduced oxygen consumption and decreased amino acid uptake. The mechanisms of atrophy for such changes include a decrease in protein synthesis, an increase in protein degradation, or both. The degradation of proteins occurs mainly by the ubiquitin–proteosome pathway (see Chapter 1).

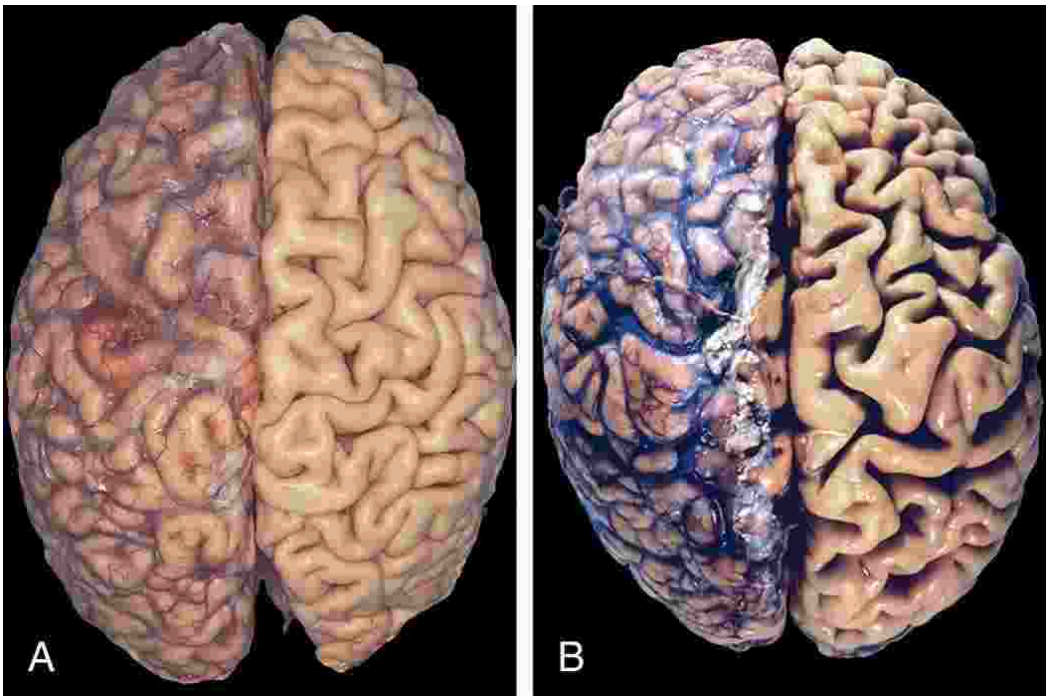

FIG. 2.2 Atrophy.
(A) Normal brain of a young adult. **(B)** Atrophy of the brain in an 82-year-old male with atherosclerotic cerebrovascular disease, resulting in reduced blood supply. Note that loss of brain substance narrows the gyri and widens the sulci. The meninges have been stripped from the right half of each specimen to reveal the surface of the brain. (From Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020:60.)

Atrophy, secondary to chronic malnutrition, is associated with a process called *autophagy* ("self-eating"), where self-destructive autophagic vacuoles are created within the cell. These membrane-bound vesicles contain cellular debris and hydrolytic enzymes that degrade substances into simple units of fat, carbohydrate, or protein. Isolation of these enzymes within autophagic vacuoles prevents uncontrolled cell destruction in neighboring cells and tissue. Some substances contained within autophagic vacuole may resist destruction, persisting as membrane-bound residual bodies within

tissues. Lipofuscin refers to yellow-brown pigmented granules; lipid-containing residue that persists after lysosomal destruction. These granules tend to accumulate in liver, myocardial, renal, retinal, adrenal, and neural tissues as individuals age. When they accumulate in the skin, they are the basis of the so-called age spots appearing in older individuals.

Hypertrophy

Hypertrophy is a compensatory *increase* in the *size* of cells, occurring in response to mechanical load or stress, and results in increased size of the affected organ. Common triggers include repetitive stretching, chronic pressure, and volume overload. The cells of the heart and kidneys are particularly prone to enlargement. Hypertrophy, as an adaptive response, occurs in the striated muscle cells of both the heart and skeletal muscles. It presents clinically as muscle enlargement. In the case of cardiac muscle hypertrophy, typically left ventricular hypertrophy (LVH), an increased synthesis of cardiac muscle proteins follows, allowing muscle fibers to do more work (Fig. 2.3). Hypertrophy may be *physiologic* or *pathologic*. Physiologic hypertrophy results from increased demand, stimulation by hormones, and growth factors. An example of physiologic hypertrophy is enlargement secondary to aerobic exercise or a "runner's heart." In this case, no pathology is present, and normal structure and function are preserved. Pathologic hypertrophy results from chronic hemodynamic overload, such as from hypertension or heart valve dysfunction. When LVH occurs secondary to hypertension, it represents *pathologic hypertrophy*. The initial adaptation, in the form of cardiac enlargement with dilated ventricles, is short lived. Prolonged cardiac hypertrophy progresses to contractile dysfunction and finally heart failure. In contrast to physiologic hypertrophy, where the myocardial matrix is preserved, pathologic hypertrophy is associated with increased interstitial fibrosis, cell death, and abnormal cardiac function (see Fig. 2.3). After a *unilateral nephrectomy* (removal of one kidney), compensatory

hypertrophy occurs in the remaining kidney, which preserves renal structure and function.

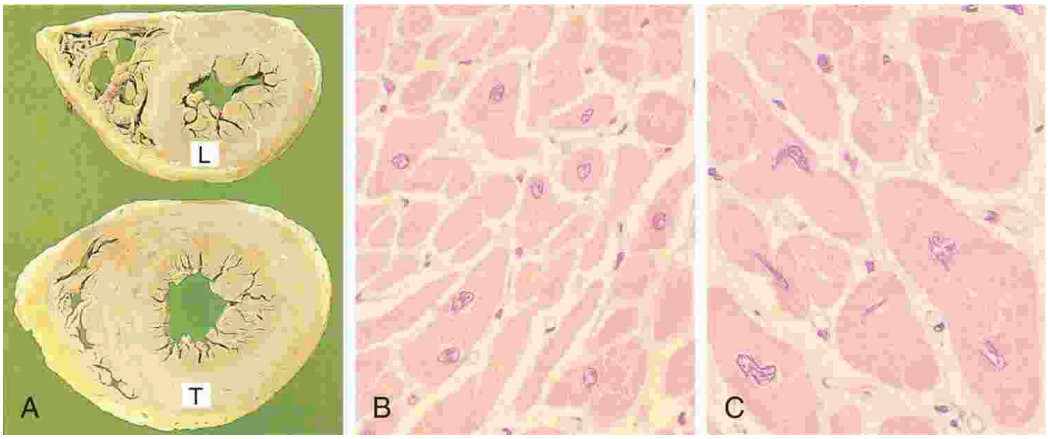

FIG. 2.3 Hypertrophy of Cardiac Muscle in Response to Valve Disease.
(A) Transverse slices of a normal heart and a heart with hypertrophy of the left ventricle (*L*, normal thickness of left ventricular wall; *T*, thickened wall from heart in which severe narrowing of aortic valve caused resistance to systolic ventricular emptying). **(B)** Histology of cardiac muscle from the normal heart. **(C)** Histology of cardiac muscle from a hypertrophied heart. (From Stevens A, Lowe J. *Pathology: Illustrated review in color*, 2nd edition. Edinburgh: Mosby; 2000.)

Close-up A shows transverse slices of a heart, one with normal thickness, labeled L, and the other with thickened walls, labeled T. Micrograph B shows normal tissues in the cardiac muscle of a heart. Micrograph C shows larger and thicker tissues in the cardiac muscle of a heart.

Hyperplasia

Hyperplasia is an *increase* in the *number* of cells, resulting from an increased rate of cellular division. As a response to a stimulus (e.g., injury), hyperplasia occurs when the damage is severe or prolonged or when it results in cell death. Hyperplasia requires that cells undergo mitosis, a process wherein a single cell divides into two identical cells. The main mechanism for hyperplasia is the production of hormones or growth factors, which stimulate the remaining cells after injury or cell loss to synthesize new cell components and, ultimately, to divide. Another mechanism is increased output of new cells from tissue stem cells. For example, if liver cells are injured, new cells can regenerate from intrahepatic stem cells.[1] Mature cells have differing capacity for hyperplastic (mitotic) growth. Although hyperplasia and hypertrophy have distinct processes, they can occur together within the same tissue.

Two types of physiologic (normal) hyperplasia occur: *compensatory hyperplasia* and *hormonal hyperplasia*. Compensatory hyperplasia is an adaptive mechanism that enables organs to regenerate. Removal of part of the liver leads to rapid hyperplasia of the remaining hepatocytes (liver cells). Even with removal of 70% of liver mass, regeneration is complete in about 2 weeks. Significant compensatory hyperplasia readily occurs in epidermal and intestinal epithelia, hepatocytes, bone marrow cells, and fibroblasts. Loss of cells within an organ triggers deoxyribonucleic acid (DNA) synthesis, mitotic division, and hyperplasia. To a lesser extent, hyperplasia occurs in bone, cartilage, and smooth muscle cells. A callus, or thickening of the skin, is an example of compensatory hyperplasia. It occurs in response to injury from a mechanical stimulus. Another example is the response to wound healing secondary to the inflammation process (see Chapters 7 and 9).

Hormonal hyperplasia occurs chiefly in estrogen-dependent organs, such as the uterus and breast. For example, during pregnancy and puberty in the female, proliferation of the glandular epithelium occurs, causing hypertrophy (enlargement) of the female breasts. Similarly, after ovulation, estrogen stimulates the

endometrium to grow and thicken for reception of the fertilized ovum. If pregnancy occurs, hormonal hyperplasia, as well as hypertrophy, enables the uterus to enlarge. (Hormone function is discussed further in Chapters 21, 22, 24–26.)

Pathologic hormonal hyperplasia is the abnormal proliferation of normal cells, usually in response to excessive hormonal stimulation or to the action of growth factors on target cells. Hyperplastic cells are identified by pronounced enlargement of the nucleus, clumping of chromatin, and the presence of one or more enlarged nucleoli. The most common example is pathologic hyperplasia of the endometrium, which is caused by an imbalance between estrogen and progesterone levels with relative increases of estrogen (see Chapter 25). Pathologic endometrial hyperplasia, which causes excessive menstrual bleeding, is under the influence of regular growth-inhibition controls. The resulting endometrial hyperplasia commonly presents as erratic or excessive uterine bleeding, known as *dysfunctional uterine bleeding*. Left unchecked, the regular growth-inhibiting control mechanisms can fail over time, producing malignant transformation or endometrial cancer.[1]

Benign prostatic hyperplasia (BPH) is another example of pathologic hyperplasia and results from changes in hormone balance (Fig. 2.4). The incidence of BPH increases with age, secondary to age-related hormonal imbalances that result in epithelial and stromal proliferation or impaired apoptosis. Similarly, thyroid enlargement, including thyroid goiters, can result from excessive levels of pituitary thyroid-stimulating hormone (TSH). In the absence of malignant transformation, when the predisposing factors are corrected, pathologic hyperplasia will typically regress.

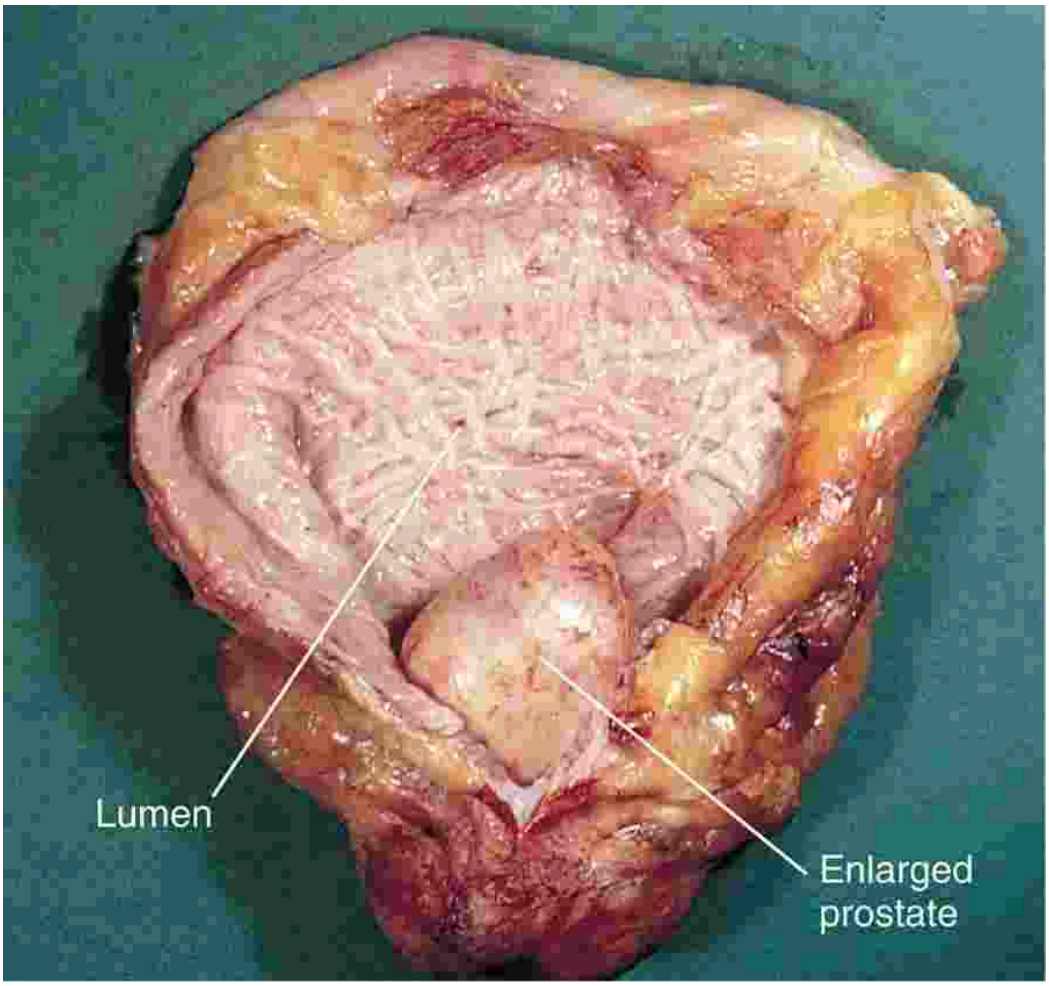

FIG. 2.4 Hyperplasia of the Prostate with Secondary Thickening of the Obstructed Urinary Bladder (Bladder Cross-Section). The enlarged prostate is seen protruding into the lumen of the bladder, which appears trabeculated. These “trabeculae” result from hypertrophy and hyperplasia of smooth muscle cells that occur in response to increased intravesical pressure caused by urinary obstruction. (From Damjanov I. *Pathology for the health professions*, 4th edition. St Louis: Saunders; 2012.)

Dysplasia: Not a True Adaptive Change

Dysplasia refers to abnormal changes in the *size, shape, and organization* of mature cells (Fig. 2.5). Dysplasia is not considered a true adaptive process but is related to hyperplasia and is often referred to as atypical hyperplasia. Although dysplastic tissue appears disorderly, the term *dysplasia* does not refer to cancer. Dysplastic changes are common in the epithelial tissue of the uterine cervix, the endometrium, and the gastrointestinal (GI) and respiratory tract mucosa. Dysplasia that does not involve the entire thickness of epithelium may be completely reversible.[1] When dysplastic changes penetrate the basement membrane, it is considered an invasive neoplasm. Dysplasia is described as "low grade" or "high grade," depending on the degree of variation from normal. If the triggering stimulus is removed—for example, certain hormonal stimuli—dysplastic transformation may be reversible. (Dysplasia is discussed further in Chapter 12.)

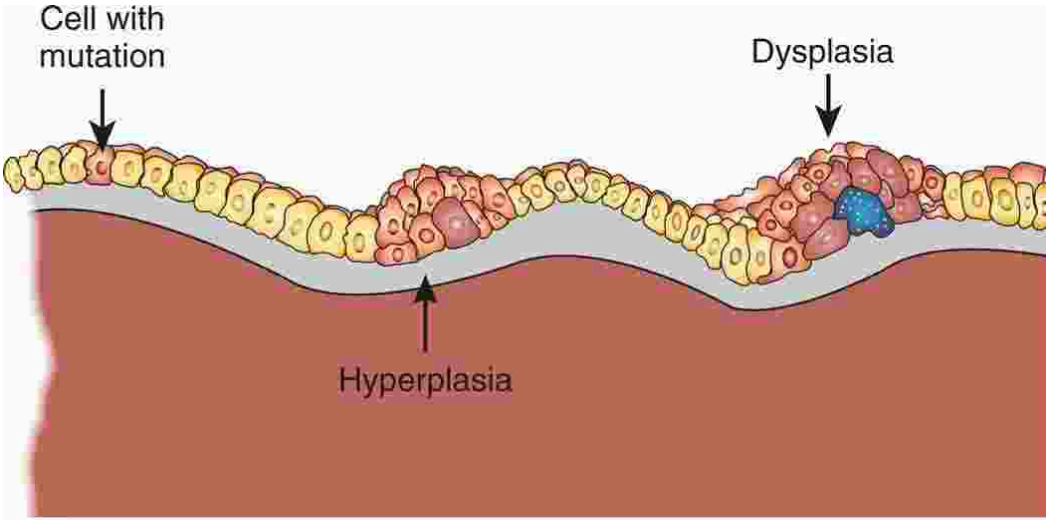

FIG. 2.5 Dysplasia.
Abnormal changes in the size, shape, and organization of cells. Dysplasia is related to hyperplasia and called atypical hyperplasia. (Adapted from http://www.ndhealthfacts.org/wiki/Oncology_%28Cancer%29.)

A diagram shows a series of cells with three distinct sections. The section on the left shows a mutated cell nestled between two normal cells. The section in the middle show a cluster of cells affected by hyperplasia. The section on the right shows a cluster of cells affected by dysplasia.

Metaplasia

Metaplasia is the *reversible* replacement of one mature cell type (epithelial or mesenchymal) by another cell type that can survive in an adverse environment. It is found in association with tissue damage, repair, and regeneration.[1] Usually, however, the change is

not beneficial. For example, in the long-term cigarette smoker, the chronic irritation from smoke causes the normal ciliated columnar epithelial cells of the trachea and bronchi to become replaced by stratified squamous epithelial cells (Fig. 2.6). The newly formed squamous epithelial cells do not secrete mucus or have cilia, causing a loss of a critical protective mechanism. Bronchial metaplasia can be reversed if the inducing stimulus, usually cigarette smoking, is removed. If the inducing stimulus is persistent, it can initiate malignant transformation in the metaplastic epithelium. At certain times, the adaptive replacement cell type may be more suitable to the changed conditions in the surrounding environment. For example, gastroesophageal reflux damages squamous epithelium of the esophagus, and the adapted change or replacement by glandular epithelium may better tolerate the acidic environment.

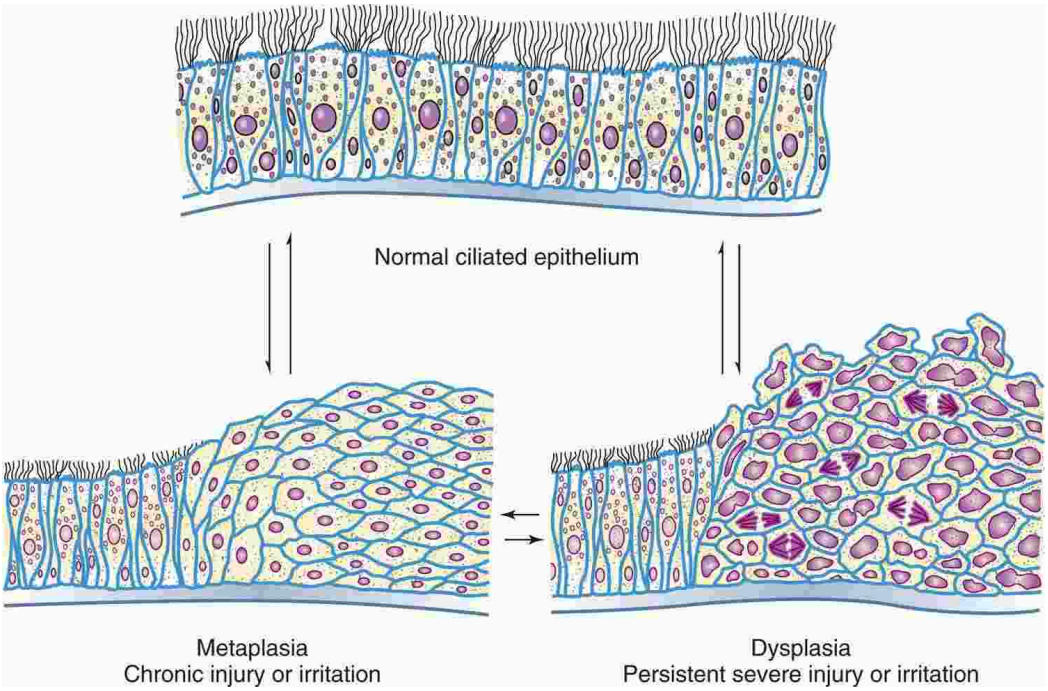

FIG. 2.6 Reversible Changes in Cells Lining the Bronchi.

A three-part diagram illustrates reversible changes in cells along the lining of the bronchi. The part at the top shows a normal ciliated epithelium. The part on the bottom left shows epithelium cells with metaplasia, resulting in chronic injury or irritation. The part on the bottom right shows epithelium cells with dysplasia, resulting persistent severe injury irritation. Each part can experience a reversible process resulting in the other part.

Metaplasia results from a reprogramming of *stem cells* present in most epithelia or colonization by differentiated cell populations from adjacent sites.[1] These precursor cells mature along a different pathway with metaplastic change. Differentiation of stem cells from

a particular cell lineage responds to signals generated by growth factors, cytokines, and ECM components in the cell's environment.

Cellular Injury

Injury to cells and to the ECM leads to injury of tissues and organs and ultimately determines the structural patterns of disease. Cellular injury occurs when the cell is unable to maintain *homeostasis* (a normal or adaptive steady state). The injury may be reversible injury (the cell can recover) or irreversible injury (cellular death). Loss of function is the result of cell and ECM injury and cell death. Cellular injury may occur secondary to a variety of factors: chemical agents, hypoxia, free radicals, infectious agents, physical and mechanical factors, immunologic reactions, genetic factors, and nutritional imbalances. Types of cell injuries and their responses are summarized in Table 2.1 and Fig. 2.7.

Table 2.1

Types of Progressive Cell Injury and Responses

Type	Responses
Adaptation	Atrophy, hypertrophy, hyperplasia, metaplasia
Active cell injury	Immediate response of "entire" cell
Reversible	Loss of ATP, cellular swelling, detachment of ribosomes, autophagy of lysosomes
Irreversible	"Point of no return" structurally when severe vacuolization of mitochondria occurs and Ca^{++} moves into cell
Necrosis	Common type of cell death with severe cell swelling and breakdown of organelles
Apoptosis, or programmed cell death	Cellular self-destruction for elimination of unwanted cell populations
Autophagy	Eating of self, cytoplasmic vesicles engulf cytoplasm and organelles, recycling factory
Chronic cell injury (subcellular alterations)	Persistent stimuli response may involve only specific organelles or cytoskeleton (e.g., phagocytosis of bacteria)
Accumulations, or infiltrations	Water, pigments, lipids, glycogen, proteins
Pathologic calcification	Dystrophic and metastatic calcification

ATP, Adenosine triphosphate; Ca^{++}, calcium.

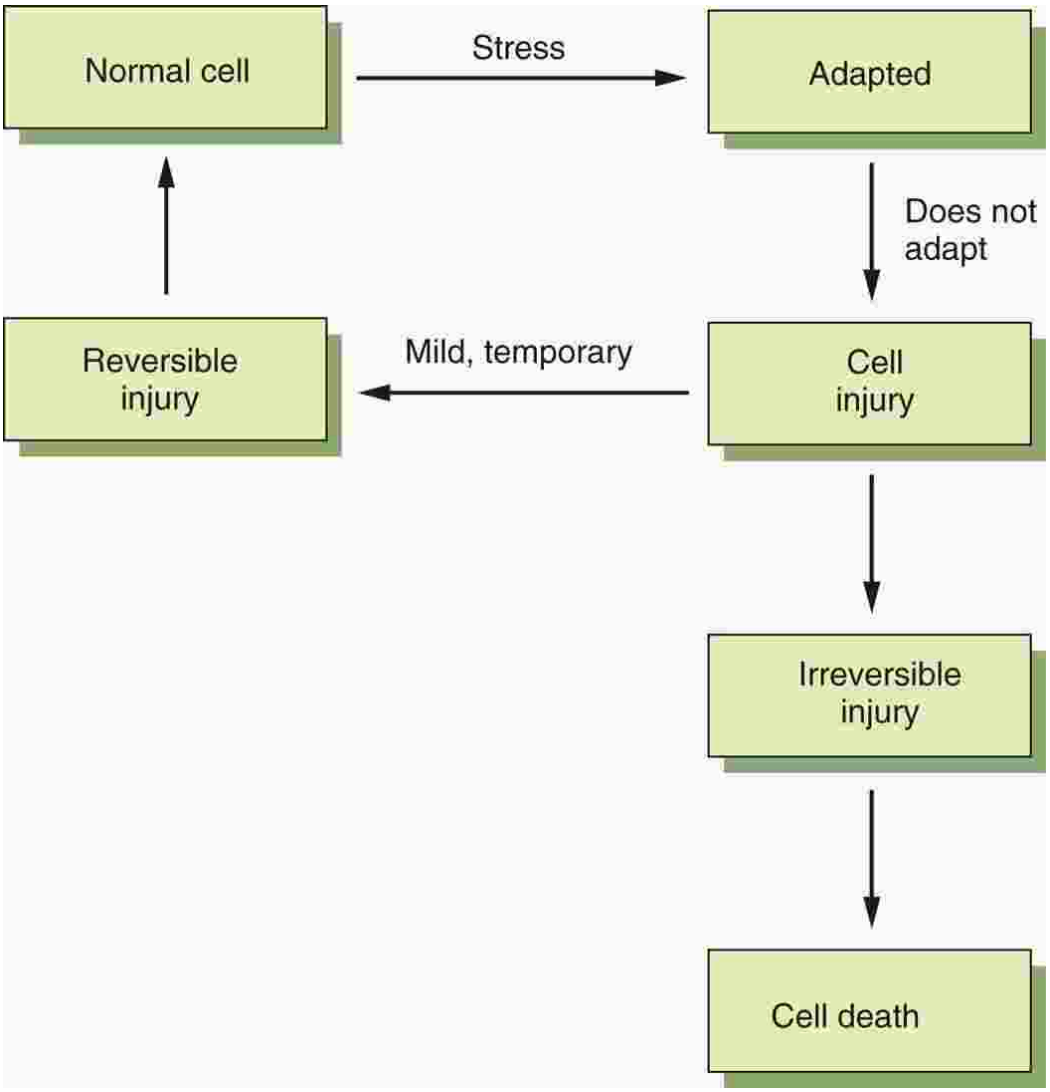

FIG. 2.7 Stages of Cellular Adaptation, Injury, and Death.
The normal cell responds to physiologic and pathologic stresses by adapting (atrophy, hypertrophy, hyperplasia, metaplasia). Cell injury occurs if the adaptive responses are exceeded or compromised by injurious agents, stress, and mutations. The injury is reversible if it is mild or transient, but if the stimulus persists, the cell suffers irreversible injury and eventually death.

A flow diagram shows the various stages of cellular adaptation. The stages are as follows. Normal cell through stress to adapted cell. If cell does not adapt, the cell experiences injury. If the injury is mild and temporary, the cell returns to its normal state. If the injury is irreversible, it leads to cell death.

The extent of cellular injury is a function of cell type, level of differentiation, and adaptive mechanisms of the cell. Also important are the nature, severity, and duration of the injury. Fully differentiated, mature cells are more susceptible to injury than are cell precursors. Two individuals exposed to an identical stimulus may incur varying degrees of cellular injury. Individual differences, including genetics, nutritional status, and immunologic competency, can profoundly influence the extent of cell injury. The precise "point of no return" with respect to cell death remains unclear. Once changes to the nucleus have occurred or cell membranes are disrupted, or both, irreversible injury and cell death are inevitable.

General Mechanisms of Cell Injury

Regardless of the cause of injury, a host of biochemical events results in cell injury and death. Such events include adenosine triphosphate (ATP) depletion, damage from oxygen-derived free radicals, and alterations in calcium level. Injury to cell components includes membrane damage, protein folding defects, mitochondrial compromise, and DNA damage (see Table 2.2). The most common forms of cell injury include (1) ischemic and hypoxic injury, (2) ischemia–reperfusion injury, (3) oxidative stress or accumulation of oxygen-derived free radicals-induced injury, and (4) chemical injury.

Table 2.2

Common Themes in Cell Injury and Cell Death

Theme	Comments
ATP depletion	Loss of mitochondrial ATP and decreased ATP synthesis; results include cellular swelling, decreased protein synthesis, decreased membrane transport, and lipogenesis, all changes that contribute to loss of integrity of plasma membrane
Reactive oxygen species (↑ROS)	Lack of oxygen is key in progression of cell injury in ischemia (reduced blood supply); activated oxygen species (ROS, O_2, H_2O_2, OH^-) cause destruction of cell membranes and cell structure
Ca^{++} entry	Normally intracellular cytosolic calcium concentrations are very low; ischemia and certain chemicals cause an increase in cytosolic Ca^{++} concentrations; sustained levels of Ca^{++} continue to increase with damage to plasma membrane; Ca^{++} causes intracellular damage by activating a number of enzymes
Mitochondrial damage	Can be damaged by increases in cytosolic Ca^{++}, ROS; two outcomes of mitochondrial damage are loss of membrane potential, which causes depletion of ATP and eventual death or necrosis of cell, and activation of another type of cell death (apoptosis) (see p. 7 and p. 46)

Theme	Comments
Membrane damage	Early loss of selective membrane permeability found in all forms of cell injury, lysosomal membrane damage with release of enzymes causing cellular digestion
Protein misfolding, DNA damage	Proteins may misfold, triggering *unfolded protein response* that activates corrective responses; if overwhelmed, response activates cell suicide program or apoptosis; DNA damage (genotoxic stress) also can activate apoptosis (see p. 46)

ATP, Adenosine triphosphate; Ca^{++}, calcium; *DNA*, deoxyribonucleic acid; H_2O_2, hydrogen peroxide; O_2,superoxide radical; OH^-, hydroxyl radical; *ROS*, reactive oxygen species.

Ischemic and Hypoxic Injury

Hypoxia, or the lack of sufficient oxygen within cells, is the single most common cause of cellular injury and is a prominent feature of pathological states encountered in bacterial infection, inflammation, wounds, cardiovascular defects, and cancer (Fig. 2.8).[2] Hypoxia can result from several circumstances, such as reduced oxygen content in the ambient air, loss of hemoglobin, decreased red blood cell (RBC) production, respiratory and cardiovascular diseases, and poisoning of the cellular oxidative enzymes (cytochromes). The most common cause of hypoxia is ischemia, or a reduced supply of blood and therefore oxygen. Hypoxia negatively impacts normal physiologic processes: differentiation, angiogenesis, proliferation, erythropoiesis, and overall cell viability. Mitochondria are the primary consumers of oxygen. Hypoxia triggers the mitochondrial complex to produce reactive oxygen species (ROS). From a physiologic perspective, ROS can be both beneficial and harmful, for example, by promoting *oxidative stress*, which can damage cells (oxidative stress is discussed in the next section). The relationship between hypoxia and

inflammation has been linked to inflammatory bowel disease, certain cancers, and infection. Ongoing research seeks to clarify how tumors adapt to low oxygen levels, including angiogenesis, increasing glucose consumption, and promoting the metabolic state of glycolysis.

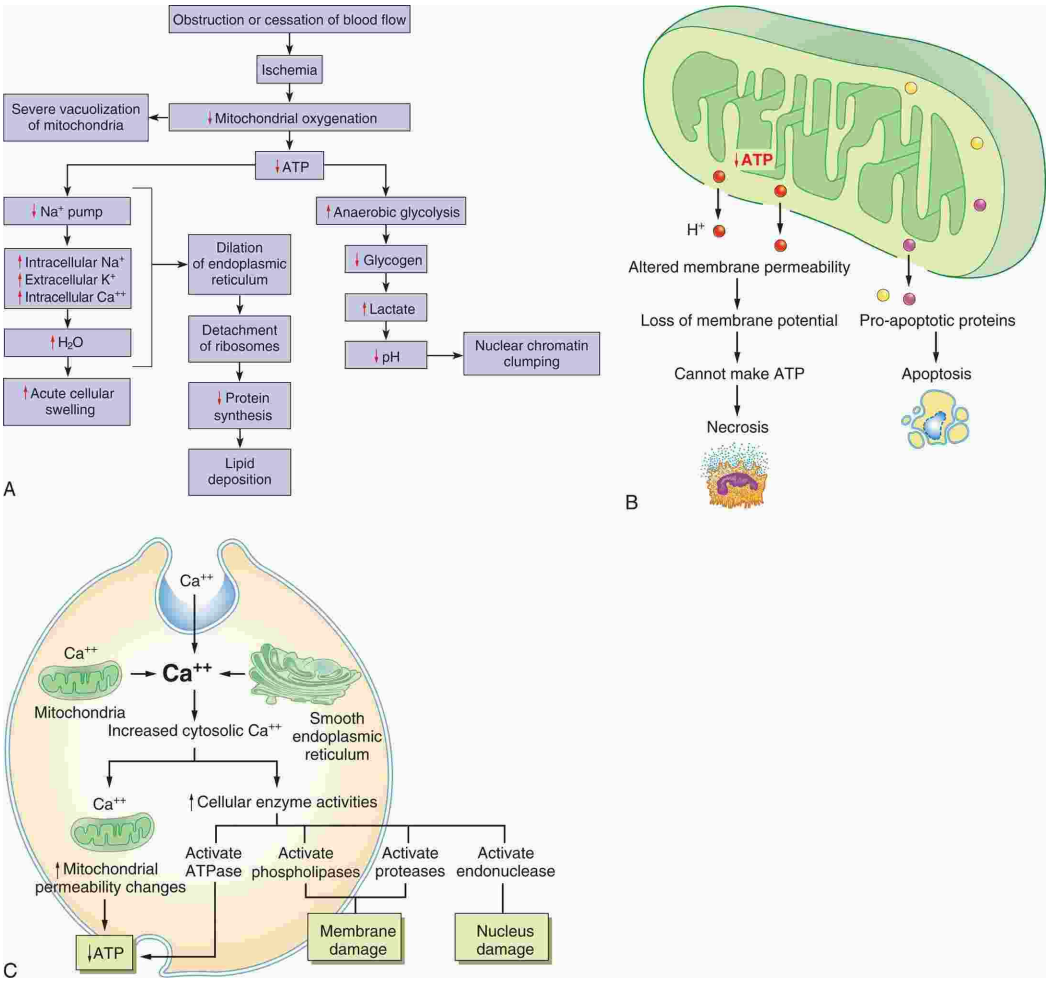

FIG. 2.8 Hypoxic Injury Induced by Ischemia. **(A)** Consequences of decreased oxygen delivery or ischemia with decreased adenosine triphosphate *(ATP)*. The structural and physiologic changes are reversible if oxygen is delivered quickly. Significant decreases in ATP result in cell death, mostly by necrosis. **(B)** Mitochondrial damage can result in changes in membrane permeability, loss of membrane potential, and decrease in ATP concentration. Between the outer and inner membranes of the mitochondria are proteins that can activate the cell's suicide pathways, called *apoptosis*. **(C)** Calcium ions are critical mediators of cell injury. Calcium ions (Ca^{++}) are usually maintained at low

concentrations in the cell's cytoplasm; thus ischemia and certain toxins can initially cause an increase in the release of Ca^{++} from intracellular stores and later an increased movement (influx) across the plasma membrane. (Adapted from Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathophysiologic basis of disease*, 9th edition. St. Louis: Saunders; 2014.)

Part A is a flow diagram. The first stage in the flow is obstruction or cessation of blood flow, which leads to ischemia, which leads to decreased mitochondrial oxygenation, which results in severe vacuolization of mitochondria or decreased A T P. Decreased A T P can result in two sequences. Sequence 1 comprises four stages. Stage 1. Decreased sodium ion pump. Stage 2. Increased intracellular sodium ions, increased extracellular potassium ions, and increased intracellular calcium ions. Stage 3. Water. Stage 4. Acute cellular swelling. The first three stages of sequence 1 can also lead to dilation of endoplasmic reticulum, resulting in detachment of ribosomes, leading to reduced protein synthesis and lipid deposition. Sequence 2 is as follows: increased anaerobic glycolysis, decreased glycogen, increased lactase, decreased p H, and nuclear chromatin clumping. Part B is a cross-sectional illustration of a mitochondrion, with decreased A T P, which releases hydrogen ions, resulting in altered membrane permeability, loss of membrane potential, inability to

make A T P, and necrosis. Pro-apoptotic proteins result in apoptosis. Part C is a cross-sectional illustration of a cell superimposed with a flow diagram. Calcium ions enter the cell and combine with calcium-ion rich mitochondria and smooth endoplasmic reticulum, resulting in increased cytosolic calcium ions. Increased cytosolic calcium ions result in calcium ions and cellular enzyme activities. Cellular enzyme activities activate A T Pase, phospholipases, proteases, and endonuclease. Phospholipases and proteases result in membrane damage. Endonuclease result in nucleus damage. A T Pase and mitochondrial permeability changes result in reduced A T P.

Arteriosclerosis (narrowing of blood vessels) and thrombus (blood clots within vessels) can result in localized tissue ischemia. Progressive hypoxia, caused by gradual arterial narrowing, is better tolerated than the acute anoxia (total lack of oxygen) caused by an acute obstruction, or a thrombus. An acute obstruction in a coronary artery can result in a rapidly evolving *myocardial infarction* ("heart attack") if the blood supply is not restored. Irreversible myocardial cell death, with loss of heart function, will follow. Gradual onset of ischemia, however, usually results in myocardial adaptation. Myocardial infarction and stroke are frequent causes of mortality in the United States and generally result from atherosclerosis and consequent ischemic injury.[3]

Cellular responses to hypoxic injury occur rapidly. Within 1 minute after the blood supply to the myocardium is interrupted, the heart becomes pale and dysfunctional and unable to contract normally. Within 3 to 5 minutes, mitochondrial compromise occurs,

resulting in insufficient ATP production. At this point, the compromised portion of the myocardium ceases to contract. The abrupt lack of contraction is caused by a rapid decrease in mitochondrial phosphorylation, which results in insufficient ATP production. Lack of ATP leads to an increase in anaerobic metabolism, which generates ATP from glycogen when there is insufficient oxygen. When glycogen stores are depleted, even anaerobic metabolism ceases.

Ischemia-induced reduction in ATP levels causes a failure of the plasma membrane's sodium–potassium (Na^+-K^+) pump and sodium–calcium (Na^+-Ca^{++}) exchange mechanisms. Sodium and calcium influx into and accumulate in the cell. Potassium (K^+) diffuses out of the cell. Without the pump mechanism, sodium and water can freely enter the cell resulting in cellular swelling and dilation of the ER. With dilation, ribosomes detach from the rough ER, reducing protein synthesis. If hypoxia persists, the entire cell becomes markedly swollen. These disruptions are reversible if oxygen (O_2) is restored. If oxygen is not restored, vacuolation (formation of vacuoles or cytoplasmic small cavities) occurs within the cytoplasm. The damaged outer membrane causes lysosomes to swell; marked swelling occurs to the mitochondria. With continued hypoxia, cell death rapidly follows as calcium accumulates within the cell, essential metabolic processes cease, and cell membranes become dysfunctional (see Fig. 2.8C). Influx of calcium into the cell activates enzymes that trigger apoptosis. Restoration of blood flow and oxygen can actually result in additional injury known as *ischemia–reperfusion injury*.

Ischemia–Reperfusion Injury

Restoration of blood flow and oxygen to ischemic tissues can increase recovery of cells reversibly injured, but paradoxically result in additional injury known as ischemia–reperfusion injury (reperfusion [reoxygenation] injury) and cause cell death (Fig. 2.9). Reperfusion is a serious complication and an important mechanism

of injury in instances of tissue transplantation and other ischemic syndromes (e.g., hepatic, intestinal, renal). Several mechanisms are proposed for reperfusion injury, including the following:

- *Oxidative stress:* Reoxygenation induces *oxidative stress* by generating ROS and nitrogen species. Reactive oxygen intermediates include hydroxyl radical (OH^-), superoxide radical anion (O_2^-), nitric oxide-derived peroxynitrite ($ONOO^-$), and hydrogen peroxide (H_2O_2), and all have been shown to increase within minutes of reperfusion. They cause damage to the myocytes by altering membrane proteins and phospholipids.[1]
- Nitrogen-based free radicals present mostly in the form of nitric oxide (NO) and are generated by endothelial cells, macrophages, neurons, and other cells. The radicals further damage the already compromised membrane and facilitate calcium overload within the mitochondria. Additionally, reperfusion injury promotes proinflammatory neutrophil adhesion to the endothelium where they release toxic oxidants and harmful proteases. Antioxidant agents, such as vitamin C and vitamin E, reverse neutrophil adhesion. They also reverse neutrophil-mediated reperfusion injury in cardiac muscle.[4,5]
- *Increased intracellular calcium concentration*: Intracellular and mitochondrial calcium accumulate within the cell during acute ischemia. Reperfusion results in even more calcium influx because of damaged cell membranes and ROS-mediated injury to the sarcoplasmic reticulum. The increased calcium enhances mitochondrial permeability; damaged mitochondria have decreased or ceased production of ATP.
- *Inflammation*: Ischemic injury promotes inflammation. Dead cells stimulate immune cells to release cytokine-mediated danger signals, thus initiating an inflammatory response.

- *Complement activation*: Complement activation may exacerbate microvascular damage that has occurred secondary to reperfusion injury.[1]

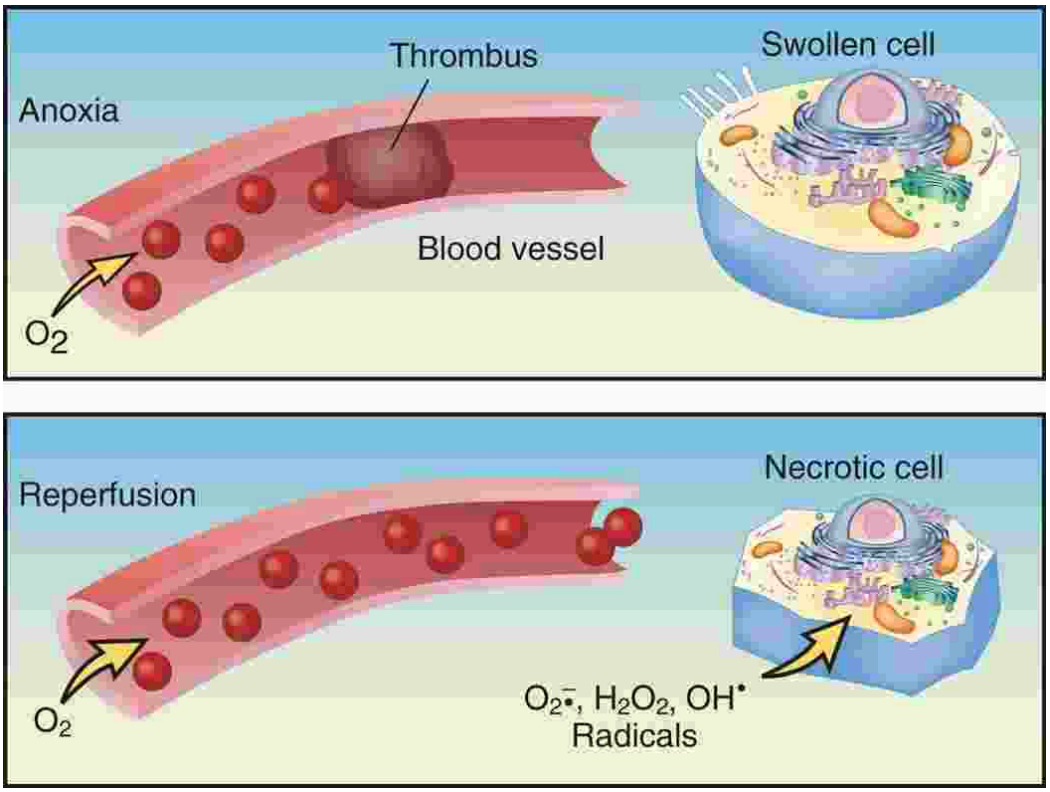

FIG. 2.9 Reperfusion Injury.
Without oxygen, or in anoxia, the cells display hypoxic injury and become swollen. With reoxygenation, risk of reperfusion injury increases because of the formation of reactive oxygen radicals that can cause cell necrosis. (Redrawn from Damjanov I. *Pathology for the health professions*, 3rd edition. St Louis: Saunders; 2006.)

A two-part illustration demonstrates anoxia and reperfusion. The panel for anoxia, at the top, shows a thrombus blocking the passage of oxygen through the blood vessel. An accompanying cutaway diagram shows a swollen cell. The panel for reperfusion, at the bottom, shows oxygen flowing freely through the blood vessel. An accompanying cutaway diagram

shows a necrotic cell with radicals: O 2 anions, H 2 O 2, and O H.

Free Radicals and Reactive Oxygen Species—Oxidative Stress

Free radicals are an important mechanism of cellular injury, especially injury caused by ROS. This form of injury is called oxidative stress. Reactive oxygen species (ROS) are reactive molecules from molecular oxygen formed as a natural oxidant species in cells during mitochondrial respiration and energy generation. The intracellular sources of oxidants are numerous and include (1) cellular organelles with mitochondria (thought to be the largest contributor), ER (particularly during endoplasmic stress), and peroxisomes; (2) nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOX enzymes); and (3) other enzymes (Fig. 2.10). From oxidative phosphorylation, mitochondria utilize oxygen to generate ATP from organic fuel molecules and, in the process, produce ROS. Oxidative stress is caused by an increase in different reactive species, depletion of antioxidant defense, or both. Oxidative stress results in detrimental oxidation of different molecules, including proteins, lipids, nucleic acids, and others. Oxidative stress can activate several intracellular signaling pathways because ROS can regulate enzymes and transcription factors. This process is an important mechanism of cell damage in many conditions, including cell injury, cancer, certain degenerative diseases (e.g., Alzheimer disease), and aging.

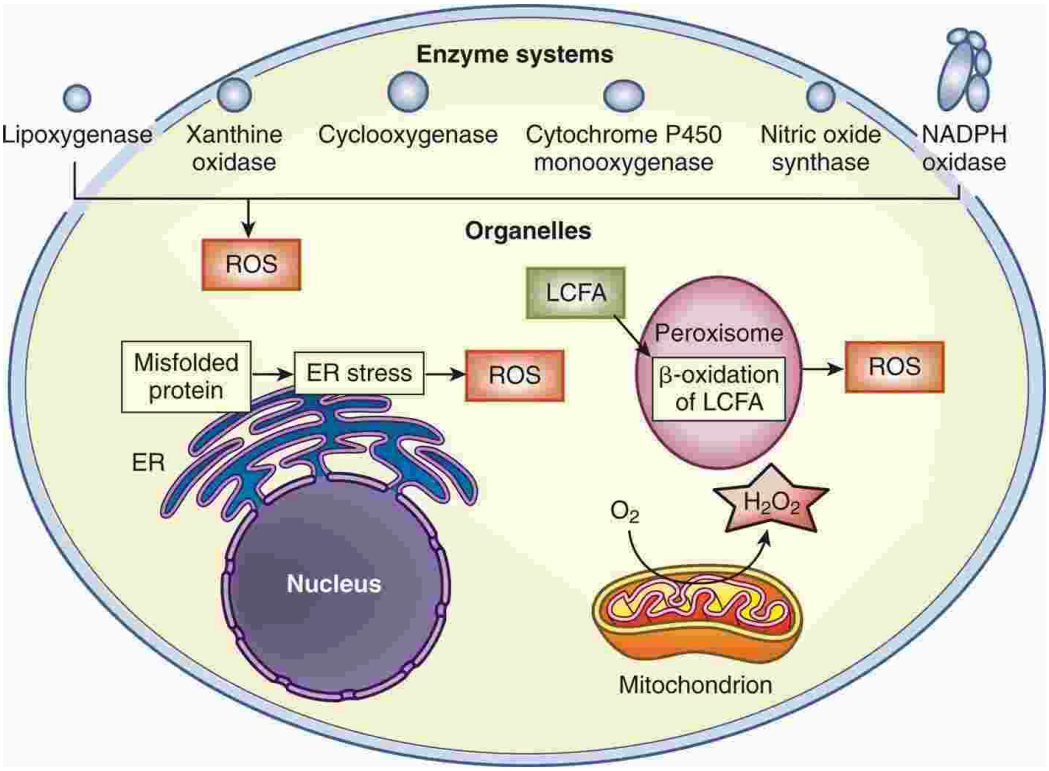

FIG. 2.10 Intracellular Sources of Reactive Oxygen Species and Sites of Generation of Reactive Oxygen Species from Mitochondria. The intracellular sources of reactive oxygen species *(ROS)* include some organelles: mitochondria, endoplasmic reticulum *(ER)* (particularly ER stress), and peroxisomes (metabolizing long-chain fatty acids *[LCFAs]*). As part of the enzymatic reaction cycles, various enzymes generate ROS, including oxidases and oxygenases. H_2O_2, Hydrogen peroxide; *NADPH*, nicotinamide adenine dinucleotide phosphate. (Adapted from Homstrom KM, Finkel T. Cellular mechanisms and physiological consequences of redoxdependent signalling. *Nature Reviews*, 2014;15(6):411–421.)

An illustration of a cell shows enzyme systems, organelles, nucleus, peroxisome, and mitochondrion. Mitochondrion utilizes O 2 to release H 2 O 2. Misfolded protein results in E R stress, which results in R O S. L C F A undergoes beta-oxidation in peroxisome, resulting in R O S. R O S comprises lipoxygenase, xanthine oxidase, cyclooxygenase, cytochrome p 450 monooxygenase, nitric oxide synthase, and N A D P H Oxidase.

A free radical is an electrically uncharged atom, or group of atoms, which has an unpaired electron. Having one unpaired electron makes the molecule unstable; the molecule becomes stabilized either by donating or by accepting an electron from another molecule. The free radical has the potential to form a damaging chemical bond with proteins, lipids, and carbohydrates found within the cell membrane. Free radicals are highly reactive. They have low chemical specificity —that is, they can react with most molecules in their proximity. Reactions involving free radicals are difficult to control, and they initiate chain reactions. Free radicals are generated in a variety of conditions, including chemical and radiation injury, ischemia–reperfusion injury, cellular aging, and microbial destruction by phagocytes.

Free radicals are generated within cells by a number of mechanisms. These mechanisms are as follows:

1. *Reduction–oxidative reactions* (redox reactions): An oxidative-reduction reaction is a type of biochemical reaction involving the transfer of elections between two species (molecule, atom, or ion). A species may either gain or lose an electron. All biologic membranes contain redox systems, which serve to support cellular activity (Fig. 2.11).

2. *Absorption of extreme energy sources* (ultraviolet light, radiation) produces free radicals.
3. *Enzymatic metabolism of exogenous chemicals or drugs:* Many exogenous (outside the body) substances within the environment readily generate free radicals. As an example, CCL_3, a byproduct of carbon tetrachloride [CCl_4]) (Fig. 2.12), forms free radicals known to damage the liver, predisposing this organ to cancer. Accordingly, CCL_4 is classified by the International Agency for Research on Cancer (IARC; Group 2B) as a possible carcinogenic and by the Environmental Protection Agency (EPA) as a probable human carcinogen. Many reported cases of CCL_4 toxicity are associated with drinking alcohol.
4. *Transition metals* (iron and copper) donate or accept free electrons during intracellular reactions, generating free radicals in the process. As an example, the Fenton reaction, involving iron and H_2O_2, produces the potentially damaging hydroxyl radical and higher oxidation states of the iron. It has been implicated in iron accumulation disease.
5. *NO*, a colorless gas, acts as an intermediate in reactions involving endothelial cells, neurons, macrophages, and other cell types. NO can act as a free radical and convert to highly reactive compounds, including peroxynitrite anion ($ONOO^-$), nitrogen dioxide (NO_2), and nitrate (NO_3). Table 2.3 describes the most significant free radicals.

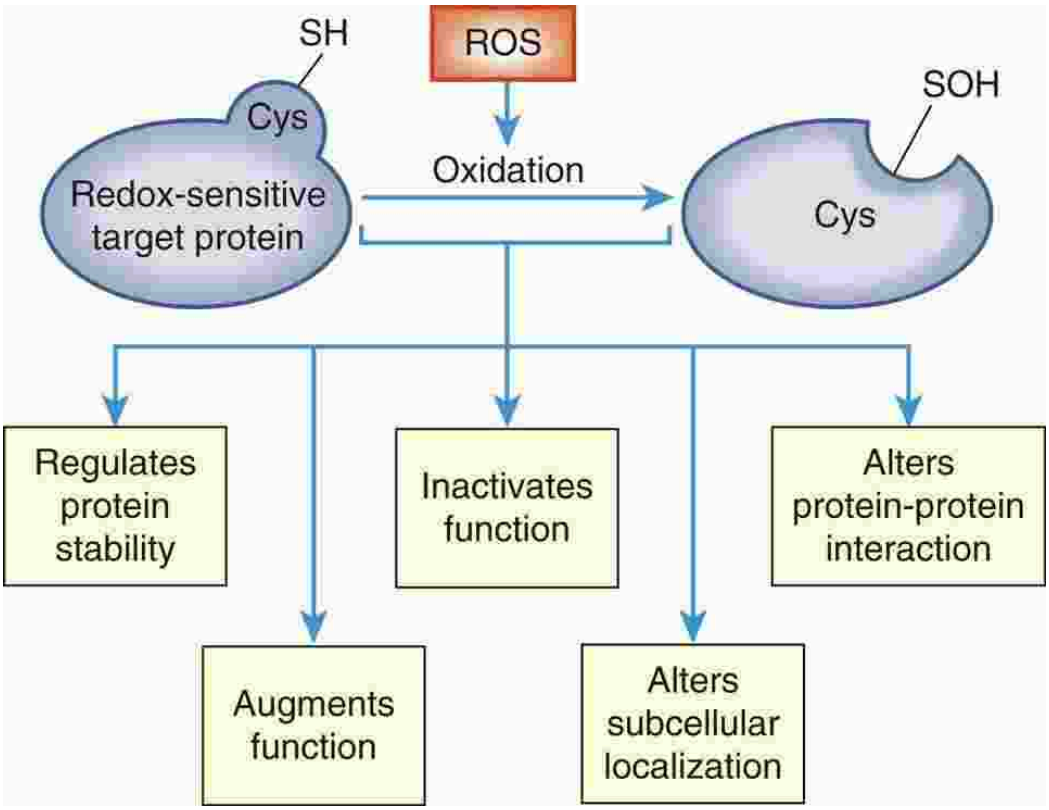

FIG. 2.11 Redox-Dependent Signaling: Biologic Mechanisms and Consequences.
The oxidation and reduction (redox) of sensitive targets or proteins with cysteine *(Cys)* residues provide a mechanism to rapidly and reversibly alter protein function. Cys residues can function as redox-dependent "switches." Oxidation of Cys residues (SH [thiol]) to *SOH* (sulfenic acid) leads to alterations in the redox-sensitive target that result in many effects on protein stability, activity, and protein-protein interaction. (Adapted from Homstrom KM, Finkel T. Cellular mechanisms and physiological consequences of redoxdependent signalling. *Nature Reviews*, 2014;15(6):411–421.)

A flow diagram represents redox-dependent signaling. Redox-sensitive target protein with cys S

H undergoes oxidation from R O S and results in cys S O H. The process regulates protein stability, augments function, inactivates function, alters subcellular localization, and alters protein-protein interaction.

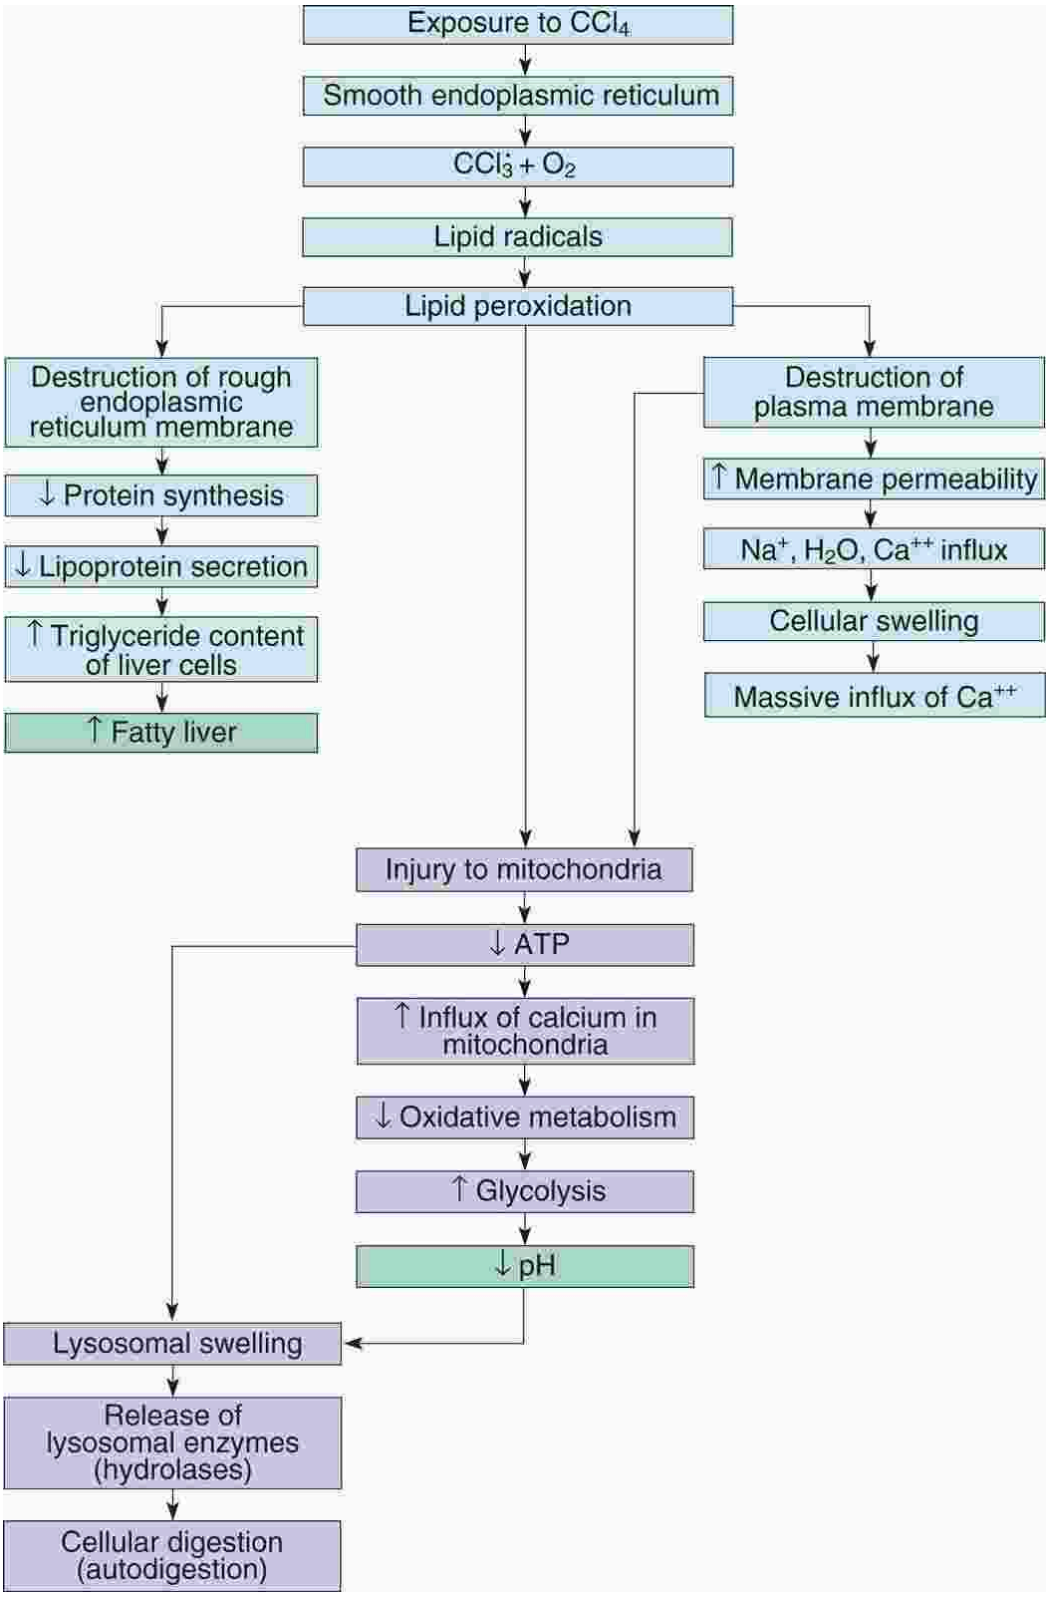

FIG. 2.12 Chemical Injury of Liver Cells Induced by Carbon Tetrachloride (CCl_4)

Poisoning. Light blue boxes are mechanisms unique to chemical injury, purple boxes involve hypoxic injury, and green boxes are clinical manifestations.
ATP, Adenosine triphosphate.

A flow diagram of five connected subparts illustrates the effect of chemical injury induced by carbon tetrachloride in liver cells. Subpart 1. Exposure to C C l 4. Smooth endoplasmic reticulum. C C l 3 plus O 2. Lipid radicals. Lipid peroxidation. Lipid peroxidation can lead to Subparts 2, 3, and 4. Subpart 2. Destruction of rough endoplasmic reticulum membrane. Reduced protein synthesis. Reduced lipoprotein secretion. Increased triglyceride content of liver cells. Increased fatty liver. Subpart 3. Destruction of plasma membrane. Increased membrane permeability. Influx of N a ions, H 2 O, and C a ions. Cellular swelling. Massive influx of C a ions. Destruction of plasma membrane also leads to Subpart 4. Subpart 4. Injury to mitochondria. Reduced A T P. Increased influx of calcium in mitochondria. Reduced oxidative metabolism. Increased glycolysis. Reduced p H. Decreased A T P and decreased p H lead to Subpart 5. Subpart 5. Lysosomal swelling. Release of lysosomal enzymes (hydrolases). Cellular digestion (autodigestion).

Table 2.3

Biologically Relevant Free Radicals

Reactive oxygen species (ROS) Superoxide radical $O_2^- \; O_2 \xrightarrow{\text{Oxidase}} O_2^-$	Generated either (1) directly during autoxidation in mitochondria or (2) enzymatically by enzymes in cytoplasm, such as xanthine oxidase or cytochrome p450; once produced, it can be inactivated spontaneously or more rapidly by enzyme superoxide dismutase (SOD): $O_2^- + O_2^- + -H_2^- \xrightarrow{SOD} H_2O_2 + O_2$
Hydrogen peroxide (H_2O_2) $O_2^- + O_2^- + -H \xrightarrow{SOD} H_2O_2 + O_2$ *Or* Oxidases present in peroxisomes O_2 peroxisome $O_2^- \xrightarrow{SOD} H_2O_2$	Generated by SOD or directly by oxidases in intracellular peroxisomes (NOTE: SOD is considered an antioxidant because it converts superoxide to H_2O_2); catalase [another antioxidant] can then decompose H_2O_2 to $O_2 + H_2O$.)
Hydroxyl radicals (OH^-) $H_2O \rightarrow H\cdot + OH\cdot$ *Or* $Fe^{++} + H_2O_2 \rightarrow Fe^{++} + OH\cdot + OH^-$	Generated by hydrolysis of water caused by ionizing radiation or by interaction with metals—especially iron (Fe) and copper (Cu); iron is important in toxic oxygen injury because it is required for maximal oxidative cell damage

Or $H_2O_2 + O_2^- \rightarrow OH\cdot + OH^- + O_2$	
Nitric oxide (NO) $NO\cdot + O_2^- \rightarrow ONOO^- + H^+$	NO by itself is an important mediator that can act as a free radical; it can be converted to another radical—peroxynitrite anion ($ONOO^-$), as well as nitrogen dioxide (NO_2) and carbonate radical (CO_3^-)

Data from Cotran RS, et al. *Robbins pathologic basis of disease*, 6th edition. Philadelphia: Saunders; 1999.

Free radicals also cause several damaging effects, such as the following:

1. Lipid peroxidation—the destruction of polyunsaturated lipids, which leads to membrane damage and increased permeability. This same process causes fats to become rancid.
2. Protein alteration—a process whereby polypeptide chains become fragmented, leading to protein loss, protein misfolding, and alters protein–protein interaction.
3. DNA damage—results in mutations (Fig. 2.13 and Chapter 4).
4. Mitochondrial effects—mitochondria are organelles that generate ATP. They can become damaged by ROS compromising available energy for the cell. Increases in intracellular calcium also damage mitochondria (see Fig. 2.8A and B). Box 2.1 summarizes the major types of mitochondrial damage. Cell damage from ROS can extend to neighboring cells.

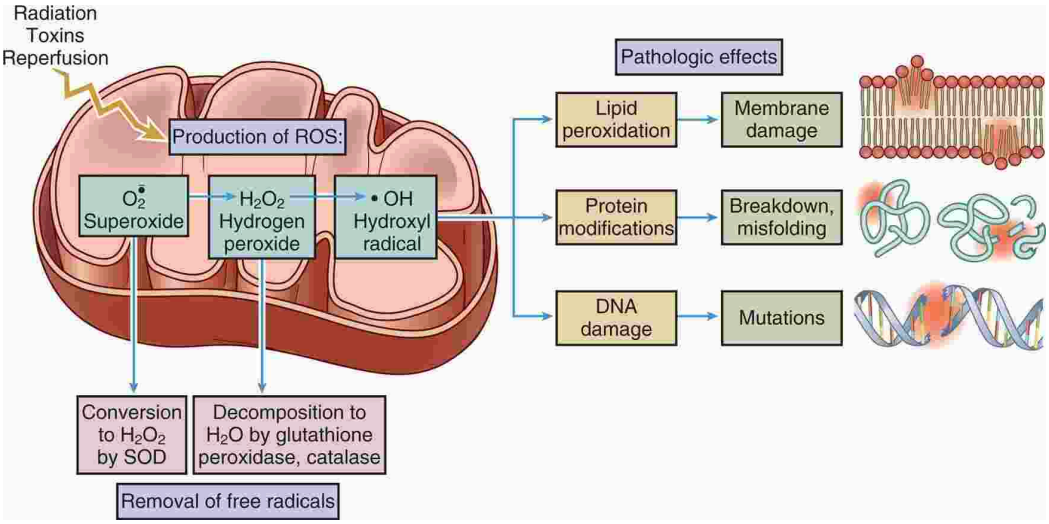

FIG. 2.13 The Role of Reactive Oxygen Species in Cell Injury.
The production of reactive oxygen species *(ROS)* can be initiated by many cell stressors, such as radiation, toxins, and reperfusion of oxygen. Free radicals are removed by normal decay and enzymatic systems. ROS accumulates in cells because of insufficient removal or excess production leading to cell injury, including lipid peroxidation, protein modifications, and DNA damage or mutations. (Adapted from Kumar V, et al., eds. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020.)

A cross-sectional illustration of a mitochondrion and a superimposed flow diagram demonstrate the role of reactive oxygen species in cell injury. Radiation, toxins, and reperfusion occur in the mitochondrion, producing R O S. O 2 superoxide results in conversion to H 2 O 2 by S O D and H 2 O 2, hydrogen peroxide. H 2 O 2, hydrogen peroxide results in decomposition to H 2 O by glutathione

peroxidase, catalase. Conversion to H 2 O 2 by S O D and decomposition to H 2 O by glutathione peroxidase, catalase result in removal of free radicals. H 2 O 2, hydrogen peroxide results in O H, hydroxyl radical. The pathologic effects of hydroxyl radicals include lipid peroxidation, protein modifications, and D N A damage. Lipid peroxidation results in membrane damage. Protein modifications result in breakdown and misfolding. D N A damage results in mutations.

Box 2.1

Three Major Types and Consequences of Mitochondrial Damage

1. Damage to the mitochondria results in the formation of the *mitochondrial permeability transition pore*, a high-conductance channel or pore. The opening of this channel results in the loss of mitochondrial membrane potential, causing failure of oxidative phosphorylation, depletion of adenosine triphosphate (ATP), and damage to **mitochondrial DNA (mtDNA)**, leading to necrosis of the cell.
2. Altered oxidative phosphorylation leads to the formation of reactive oxygen species (ROS) that can damage cellular components.
3. Because mitochondria store several proteins between their membranes, increased permeability of the outer membrane may result in leakage of proapoptotic proteins and cause cell death by apoptosis.

Data from Kumar V, et al, eds. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Elsevier; 2015.

The toxicity of certain drugs and chemicals can be attributed to free radicals. The drug/chemical may be converted to a free radical, or it may generate oxygen-derived metabolites. Free radicals have been either directly or indirectly linked with a growing number of diseases and disorders (see Box 2.2). The body has various mechanisms to eliminate free radicals. As an example, the oxygen free radical *superoxide* may spontaneously decay into oxygen and hydrogen peroxide. Table 2.4 summarizes other methods that contribute to inactivation or termination of free radicals.

Box 2.2

Diseases and Disorders Linked to Oxygen-Derived Free Radicals

- Deterioration in aging
- Atherosclerosis
  - Ischemic brain injury
  - Alzheimer disease
  - Neurotoxins
- Cancer
- Cardiac myopathy
- Chronic granulomatous disease
- Diabetes mellitus
- Eye disorders
- Macular degeneration
- Cataracts
- Inflammatory disorders
- Iron overload
- Lung disorders
- Asbestosis

Oxygen toxicity
Emphysema
Nutritional deficiencies
Radiation injury
Reperfusion injury
Rheumatoid arthritis
Skin disorders
Toxic states
Xenobiotics (tetrachloride [CCl_4], paraquat, cigarette smoke, etc.)
Metal irons (nickel [Ni], copper [Cu], iron [Fe], etc.)

Table 2.4

Methods Contributing to Inactivation or Termination of Free Radicals

Method	Process
Antioxidants	Endogenous or exogenous; either blocks synthesis or inactivates (e.g., scavenges) free radicals; includes vitamin E, vitamin C, cysteine, glutathione, albumin, ceruloplasmin, transferrin, γ-lipoacid, others
Enzymes	Superoxide dismutase,[a] which converts superoxide to hydrogen peroxide (H_2O_2); catalase[a] (in peroxisomes) decomposes H_2O_2; glutathione peroxidase[a] decomposes hydroxyl radical (OH^-) and H_2O_2

[a]These enzymes are important in modulating the cellular destructive effects of free radicals; also released in inflammation.

Chemical or Toxic Injury

Humans are exposed to thousands of chemicals that have insufficient toxicologic data.[6] Time, cost, and an interest in reducing animal testing dictate the need to develop new methods for toxicity testing. To meet public health concerns, many agencies have collaborated to investigate how chemicals interact with biologic systems. Advances in molecular and systems biology, computational toxicology, and bioinformatics have aided investigators' efforts. Mechanisms of cell stress from chemical agents include oxidative stress, ER stress, heat shock response, DNA damage response, mental stress, inflammation, and osmotic stress (sudden change in solute concentration). Chemicals are being classified under these types of cell stress mechanisms.

Xenobiotics (from Greek *xenos*, "foreign"; *bios*, "life") are compounds and chemicals that have toxic, mutagenic, or carcinogenic properties (Fig. 2.14). A few of these compounds include pesticides, antibiotics, steroids, and biomedical waste compounds.[7] Some of these chemicals are found in the human diet, for example, the fungal mycotoxin, aflatoxin B_1. Many xenobiotics are hepatotoxic (toxic to the liver). The liver is the initial site of contact for many ingested compounds—xenobiotics, drugs, and alcohol—predisposing this organ to chemically induced injury. Once absorbed by the GI tract, the liver is the initial site of contact. This dynamic is called *first-pass effect*. A frequent cause for withdrawing medications from the market is hepatotoxicity. Herbal products are less subject to regulation by the U.S. Food and Drug Administration (FDA). There are several classes of dietary, weight reduction, and body building supplements that have compounds that are listed as potentially hepatotoxic. Several marketed herbal medicines, such as ma huang (ephedra), kava Huang, Lipokinetix, and Hydroxycut, have been identified as harmful by the FDA and other health authorities, and subsequently, the FDA has requested these products be removed.[8]

METABOLISM
Excretion

FIG. 2.14 Metabolism of Xenobiotics. Pollutants contained in air, water, and soil are absorbed through the lungs, gastrointestinal tract, and skin.
In the body, the pollutants may act at the site of absorption but are generally transported through the bloodstream to various organs where they can be stored or metabolized. Metabolism of xenobiotics may result in the formation of water-soluble compounds that are excreted, or a toxic metabolite may be created by activation of the agent. (From Kumar V, et al., eds. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020:407.)

A series of diagrams illustrates the metabolism of xenobiotics. Human exposure to air, water, and soil affects skin, lung, and G I tract, leading to absorption into bloodstream and subsequent distribution to tissues. Distribution to tissues results in toxicity, metabolism, and storage. Metabolism leads to toxicity, storage, and excretion. Storage leads to distributions to tissues and excretion.

Many chemical compounds used in household cleaning, insect control, outdoor maintenance, or chemical manufacturing are potential carcinogens. Many such agents are absorbed in the body through the skin or by inhalation; ubiquitous in the environment, some agents have been linked with liver and other organ damage. The extent of chemically induced liver injury varies from minor liver injury to acute liver failure, cirrhosis, and liver cancer.[9,10]

Hepatic detoxification occurs through enzyme-mediated biotransformation and antioxidant systems. Biotransformation is a process whereby enzymatic reactions convert one chemical into a less toxic or nontoxic compound. The liver has the highest supply of biotransformation enzymes of all organs and plays a key role in protecting the host from chemical toxicity. Fig. 2.15 provides a summary of chemically induced liver injury.

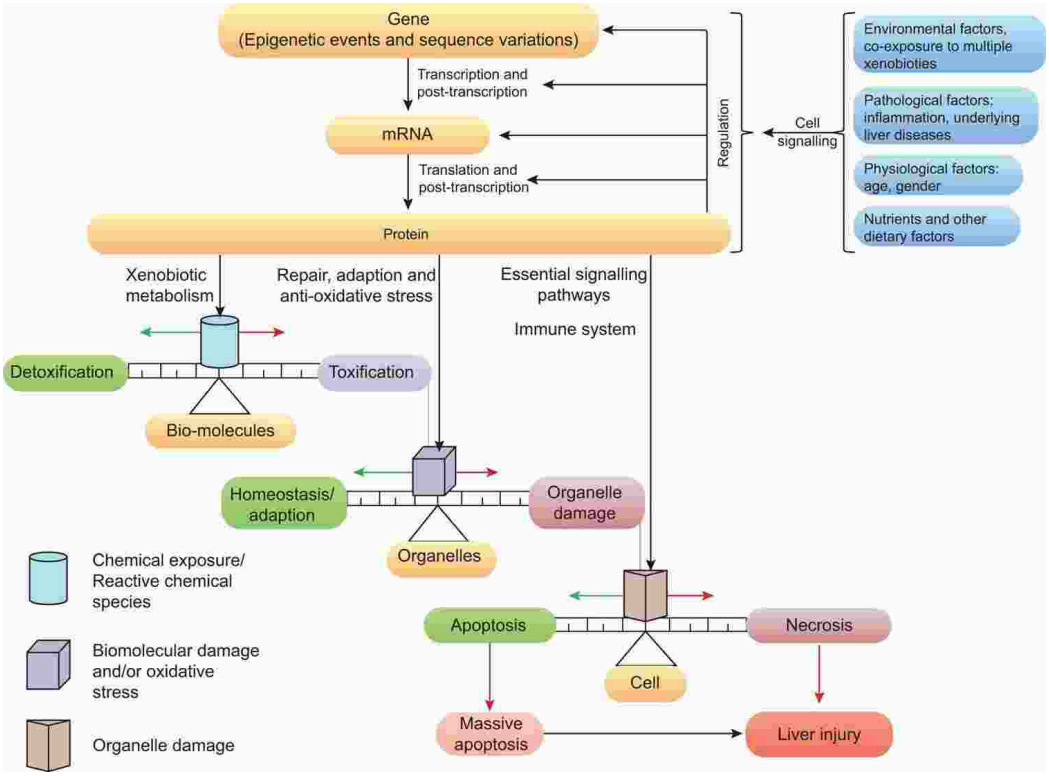

FIG. 2.15 Chemical Liver Injury. Liver injury is a result of genetic, environmental, biologic, and dietary factors.

Certain chemicals can form toxic or chemically reactive metabolites. The risk of liver injury also can increase with increasing doses of a toxicant. Xenobiotic enzyme induction can lead to altered metabolism of chemicals, and drugs can either inhibit or induce drug-metabolizing enzymes. These changes can lead to greater toxicity. The dose at the site of action is controlled by phase I to III xenobiotic metabolites, and metabolizing enzymes are encoded by numerous different genes. Additionally, all aspects of xenobiotic metabolism are regulated by certain transcription factors (cellular mediators of gene regulation). Overall, the extent of cell damage depends on the balance between reactive chemical species and protective responses aimed at decreasing

oxidative stress, repairing macromolecular damage, or preserving cell health by inducing apoptosis or cell death. Significant clinical outcomes of chemical-induced liver injury occur with necrosis and the immune response. Covalent binding of reactive metabolites to cellular proteins can produce new antigens (haptens) that initiate autoantibody production and cytotoxic T-cell responses. Necrosis, a form of cell death (see the Cellular Death section), can result from extensive damage to the plasma membrane with altered ion transport, changes of membrane potential, cell swelling, and eventual dissolution. Green arrows are pathways leading to cell recovery; red arrows indicate pathways to cell damage or death; black arrows are pathways leading to chemically induced liver injury. (Adapted from Gu X, Manautou JE. Molecular mechanisms underlying chemical liver injury. *Expert Reviews in Molecular Medicine*, 2013;14:e4.)

A flow diagram shows the stages in chemical liver injury. Cell signaling is a result of environmental factors, co-exposure to multiple xenobiotics, pathological factors including inflammation, underlying liver diseases, physiological factors: age, gender, and nutrients and other dietary factors. Cell signaling results in regulation of gene, m R N A, and protein in three stages: gene, epigenetic events and sequence variations, through transcription and post-transcription to m R N A, through translation and post-transcription to protein. Protein leads through

xenobiotic metabolism to chemical exposure or reactive chemical species in bio-molecules and can result in detoxification or toxification. Protein can also lead through repair, adaptation, and anti-oxidative stress to biomolecular damage and or oxidative stress in organelles and can result in homeostasis or adaption or organelle damage. Protein can also lead through essential signaling pathways and immune system to organelle damage in cell and can result apoptosis or necrosis. Apoptosis leads to massive apoptosis. Necrosis leads to liver injury. Massive apoptosis also leads to liver injury.

Antioxidants are molecules that inhibit the oxidation of other molecules, thereby preventing the formation of free radicals. Antioxidants often terminate a chain reaction, which would otherwise result in free radical formation. *Endogenous antioxidants* are antioxidants produced by the body. The five most powerful endogenous antioxidants are *superoxide dismutase (SOD), alpha lipoic acid (ALA), catalase, coenzyme Q 10 (CoQ10)*, and *glutathione peroxidase (GPX)*. Exogenous antioxidants are antioxidants that originate from outside the body, typically from dietary sources, such as vitamin C. Foods rich in antioxidants are appropriately encouraged as part of a healthy diet.

Chemical Agents Including Drugs

Numerous chemical agents cause cellular injury. Minute amounts of some, such as arsenic and cyanide, can rapidly destroy cells and cause death of the individual. Chronic exposure to air pollutants, insecticides, and herbicides can cause cell injury (see Fig. 2.14). Carbon tetrachloride, alcohol, and social drugs can significantly alter cellular function and injure cellular structures. Over-the-counter

(OTC) and prescribed drugs are an important cause of cellular injury. The abuse and addiction to opioids, such as heroin, morphine, and fentanyl, and other prescription pain relievers, are a serious global problem that affects all societies. Millions of people abuse opioids worldwide. The issue has become a public health crisis. In the United States, drug overdoses dramatically increased over the last 2 years, with the COVID-19 pandemic as a contributing factor.[11] Over the last two decades, deaths related to opioids more than tripled.[12]

The leading cause of poisoning in children is cosmetics and personal care products in children under 6 years of age, followed by cleaning substances and analgesic medications, including inappropriate administration of OTC preparations containing acetaminophen.[13] Social or street drugs are listed in Table 2.5. The use of e-cigarettes or vaping has become one of the leading causes of lung injury. In 2019, there were 6401 e-cigarette exposures, with nearly 45% involving children less than 5 years of age and another 23% in children 6 to 19 years of age. The exposure rate is up from 2018, when the number of e-cigarette exposures was 3142, causing acute lung injuries disproportionally affecting adolescents, children, and young adults. Hence, the Centers for Disease Control and Prevention (CDC) has classified this injury as e-Cigarette or Vaping Product Use-Associated Lung Injury (EVALI).[14]

Table 2.5

Social or Street Drugs and Their Effects

Type of Drug	Description and Effects
Marijuana (pot)	*Active substance:* Δ9-Tetrahydrocannabinol (THC), found in resin of *Cannabis sativa* plant. With smoking (e.g., "joints"), about 5%–10% is absorbed through lungs; with heavy use, the following adverse effects have been reported: alterations of sensory perception; impairment of cognitive and psychomotor judgments (e.g., inability to judge time, speed, distance); increases in heart rate and blood pressure; increased susceptibility to laryngitis, pharyngitis, bronchitis; cough and hoarseness; possibility of lung cancer (dosages levels not determined); contains large number of carcinogens; data from animal studies only indicate reproductive changes include reduced fertility, decreased sperm motility, and decreased levels of circulatory testosterone; fetal abnormalities include low birth weight; increased frequency of infectious illness is thought to be result of depressed cell-mediated and humoral immunity; beneficial effects include decreased nausea secondary to cancer chemotherapy

Type of Drug	Description and Effects
	and decreased pain in certain chronic conditions.
Methamphetamine ("meth")	An amine derivation of amphetamine ($C_{10}H_{15}N$) used as crystalline hydrochloride CNS stimulant: in large doses causes irritability, aggressive (violent) behavior, anxiety, excitement, auditory hallucinations, and paranoia (delusions and psychosis); mood changes are common, and abuser can swiftly change from being friendly to being hostile; paranoiac swings can result in suspiciousness, hyperactive behavior, and dramatic mood swings. Appeals to abusers because body's metabolism is increased and produces euphoria, alertness, and perception of increased energy Stages: *Low intensity:* User is not psychologically addicted and uses methamphetamine by swallowing or snorting. *Binge and high intensity:* User has psychological addiction and smokes or injects to achieve a faster, stronger high. *Tweaking:* Most dangerous stage; user is continually under the influence, not

Type of Drug	Description and Effects
	sleeping for 3–15 days, extremely irritated, and paranoid.
Cocaine and crack	Extracted from leaves of cocoa plant and sold as a water-soluble powder (cocaine hydrochloride) liberally diluted with talcum powder or other white powders; extraction of pure alkaloid from cocaine hydrochloride is "free-base" called *crack* because it "cracks" when heated. Crack is more potent than cocaine; cocaine is widely used as an anesthetic, usually in procedures involving oral cavity; it is a potent CNS stimulant, blocking reuptake of neurotransmitters norepinephrine, dopamine, and serotonin; also increases synthesis of norepinephrine and dopamine; dopamine induces sense of euphoria, and norepinephrine causes adrenergic potentiation, including hypertension, tachycardia, and vasoconstriction; cocaine can therefore cause severe coronary artery narrowing and ischemia; reason cocaine increases thrombus formation is unclear; other cardiovascular effects include dysrhythmias, sudden death, dilated cardiomyopathy, rupture of descending aorta (i.e., secondary to hypertension); effects on fetus include premature labor, retarded fetal development, stillbirth, hyperirritability.

Type of Drug	Description and Effects
Heroin	Opiate closely related to morphine, methadone, and codeine Highly addictive, and withdrawal causes intense fear ("I'll die without it"); sold "cut" with similar-looking white powder; dissolved in water, it is often highly contaminated; feeling of tranquility and sedation lasts only a few hours and thus encourages repeated intravenous or subcutaneous injections; acts on the receptors enkephalins, endorphins, and dynorphins, which are widely distributed throughout body with high affinity to CNS; effects can include infectious complications, especially *Staphylococcus aureus* infections, granulomas of lung, septic embolism, and pulmonary edema—in addition, viral infections from casual exchange of needles and HIV; sudden death is related to overdosing secondary to respiratory depression, decreased cardiac output, and severe pulmonary edema.
Fentanyl	Synthetic opioid analgesic similar to morphine but is 50–100 times more potent. The synthetic opioid fentanyl and its analogs have risen across the United States in a variety of forms. Currently, it is documented in connection with a growing

Type of Drug	Description and Effects
	number of overdoses and overdose deaths.

CNS, Central nervous system; *HIV*, human immunodeficiency virus.

Data from Kumar V, Abbas A, Aster J. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015; Nahas G, Sutin K, Bennett WM. Review of marihuana and medicine. *New England Journal of Medicine*, 2000;343(7):514..

Snakebite: Envenoming

Snakebite envenoming, poisoning by venom from either the bite of a venomous snake or by spraying venom into the victim's eyes, can have potentially deadly effects.[15] Snakes have hollow fangs in their anterior mouth that they use to inject venom into the subcutaneous tissue of their prey. Snake venom is composed primarily of proteins (e.g., metalloproteinases) and other complex substances with enzymatic activity. Available global data show that 4.5 to 5.4 million people per year are bitten by snakes. The majority (>99%) of snakebites in the United States are from pit vipers, with the majority (56.3%) occurring from rattlesnakes.[16] The chemistry and resulting cellular levels effects of snake venom can vary between species of snakes, but most pit viper envenomation has little neurotoxic effects. Box 2.3 shows the pathophysiology, clinical manifestations, evaluation, and treatment for snakebite envenoming. Fig. 2.16 presents a step-by-step management approach to snake (crotalid) envenomation.

Box 2.3

Snakebite Envenoming

Pathophysiology

Examples of pathophysiological effects from snake envenomation:

- Necrosis of cells due to toxic tissue enzymes
- Increased permeability of cell membranes leading to increased localize spread of venom
- Pit viper venom has both fibrinolytic and protein C activation effects, causing **coagulopathy** (impaired ability to clot blood)
- Mohave rattlesnake envenomation can produce cranial nerve dysfunction, weakness, and paralysis
- Timber rattlesnakes can induce *myokymia*, an involuntary quivering of muscles or localized muscle fibers

Clinical Manifestations

- Fang marks are usually identifiable
- Local symptoms include pain, swelling, and bleeding from the bite site
- With severe presentations, there may be local tissue necrosis and ecchymosis
- Systemic manifestations include angioedema, bleeding from other orifices (hematemesis, hematochezia), nausea, vomiting, diarrhea, dyspnea, and anaphylaxis

Evaluation and Treatment

- Individuals need immediate and rapid transport for evaluation by a qualified medical provider
- Wounds should be cleaned, and severity of envenomation should be assessed
- Persons should be given intravenous fluid and blood drawn for complete laboratory evaluations of snakebite
- Persons who are asymptomatic should be observed for at least 12 hours before safe discharge

- The leading edge of the swelling should be marked, time of observation recorded, and circumference of extremity measured every 30 minutes
- Persons with bites from snakes with neurotoxic venom should be observed for at least 24 hours
- Antivenin should be administered for venomous snakebites within 4 hours of snakebite, but it is still effective for at least the first 24 hours; identification of the snake is helpful in knowing which antivenin to administer

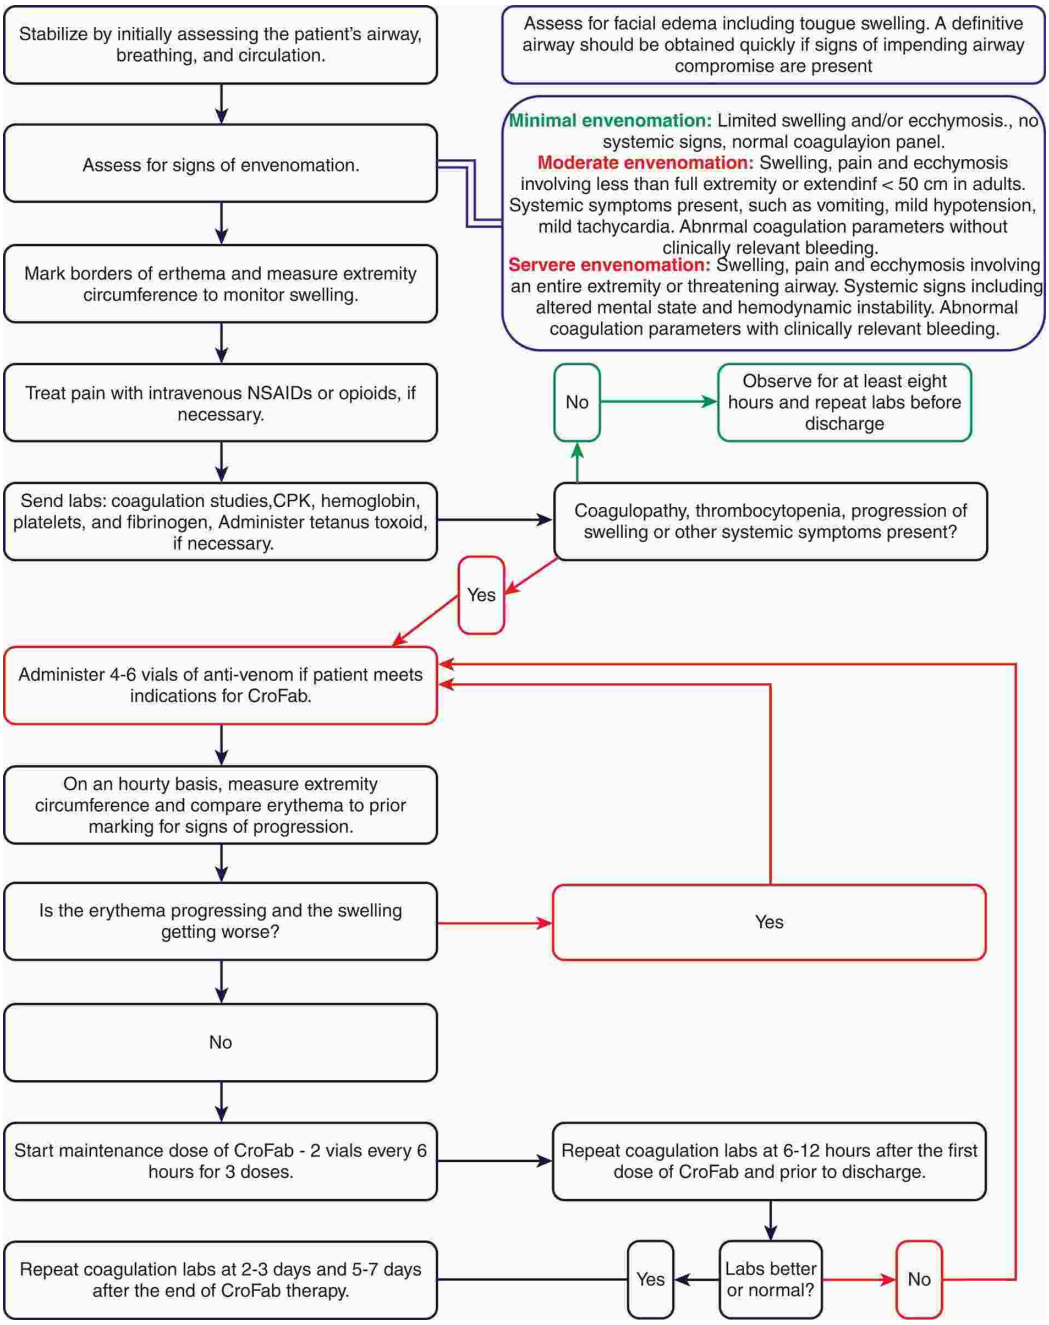

FIG. 2.16 Algorithm Snake (Crotalid) Envenomation Management.
Crotalid venom causes various local, hematologic, neurologic, and system effects requiring a step-by-step approach to treatment. (From Patel V, Kong EL, Hamilton RJ. *Rattle snake toxicity. StatPearls [Internet]*. Treasure Island, FL: StatPearls; 2021.)

A process diagram represents Algorithm Snake or Crotalid Envenomation Management. The process is as follows. Step 1. Assess for facial edema including tongue swelling. A definitive airway should be obtained quickly if signs of impending airway compromise are present. Step 2. Stabilize by initially assessing the patient's airway, breathing, and circulation. Step 3. Assess for signs of envenomation. Minimal envenomation: Limited swelling and or ecchymosis., no systemic signs, normal coagulation panel. Moderate envenomation: Swelling, pain and ecchymosis involving less than full extremity or extending less than 50 centimeters in adults. Systemic symptoms present, such as vomiting, mild hypotension, mild tachycardia. Abnormal coagulation parameters without clinically relevant bleeding. Severe envenomation: Swelling, pain and ecchymosis involving an entire extremity or threatening airway. Systemic signs including altered mental status and hemodynamic instability. Abnormal coagulation parameters with clinically relevant bleeding. Step 4. Mark borders of erythema and measure extremity circumference to monitor swelling. Step 5. Treat pain with intravenous N S A I Ds or opioids, if necessary. Step 6. Send labs: coagulation studies, C P K, hemoglobin, platelets, and fibrinogen, Administer tetanus toxoid, if

necessary. Step 7. Coagulopathy, thrombocytopenia, progression of swelling or other systemic symptoms present? If No, Observe for at least eight hours and repeat labs before discharge. If Yes: Step 8. Administer 4 to 6 vials of anti-venom if patient meets indications for CroFab. Step 9. On an hourly basis, measure extremity circumference and compare erythema to prior marking for signs of progression. Step 10. Is the erythema progressing and the swelling getting worse? If Yes, Step 8. If No: Step 11. Start maintenance dose of CroFab-2 vials every 6 hours for 3 doses. Step 12. Repeat coagulation labs at 6-12 hours after the first dose of CroFab and prior to discharge. Step 13. Labs better or normal? If No, Step 8. If Yes, Repeat coagulation labs at 2 to 3 days and 5 to 7 days after the end of CroFab therapy.

Common Environmental Toxins

Air Pollution

Ambient fine particle air pollution

The world's largest single environmental health risk is air pollution. Air pollution is contamination of the indoor or outdoor environment by any chemical, physical, or biologic agent that modifies natural characteristics of the atmosphere. Air pollution was the fourth leading risk factor for premature death globally, with nearly 12% of all deaths, and more than 6.67 million in 2019 alone (Fig. 2.17). Early deaths from air pollution were surpassed only by high blood

pressure, tobacco use, and poor diet.[17] The percentage of Global Deaths attributed to air pollution in 2019 was:

- 40% of chronic obstructive pulmonary disease (COPD) deaths
- 20% of diabetes deaths
- 20% of ischemic heart disease deaths
- 19% of lung cancer deaths
- 26% of stroke death
- 30% of lower-respiratory deaths
- 20% of neonatal deaths

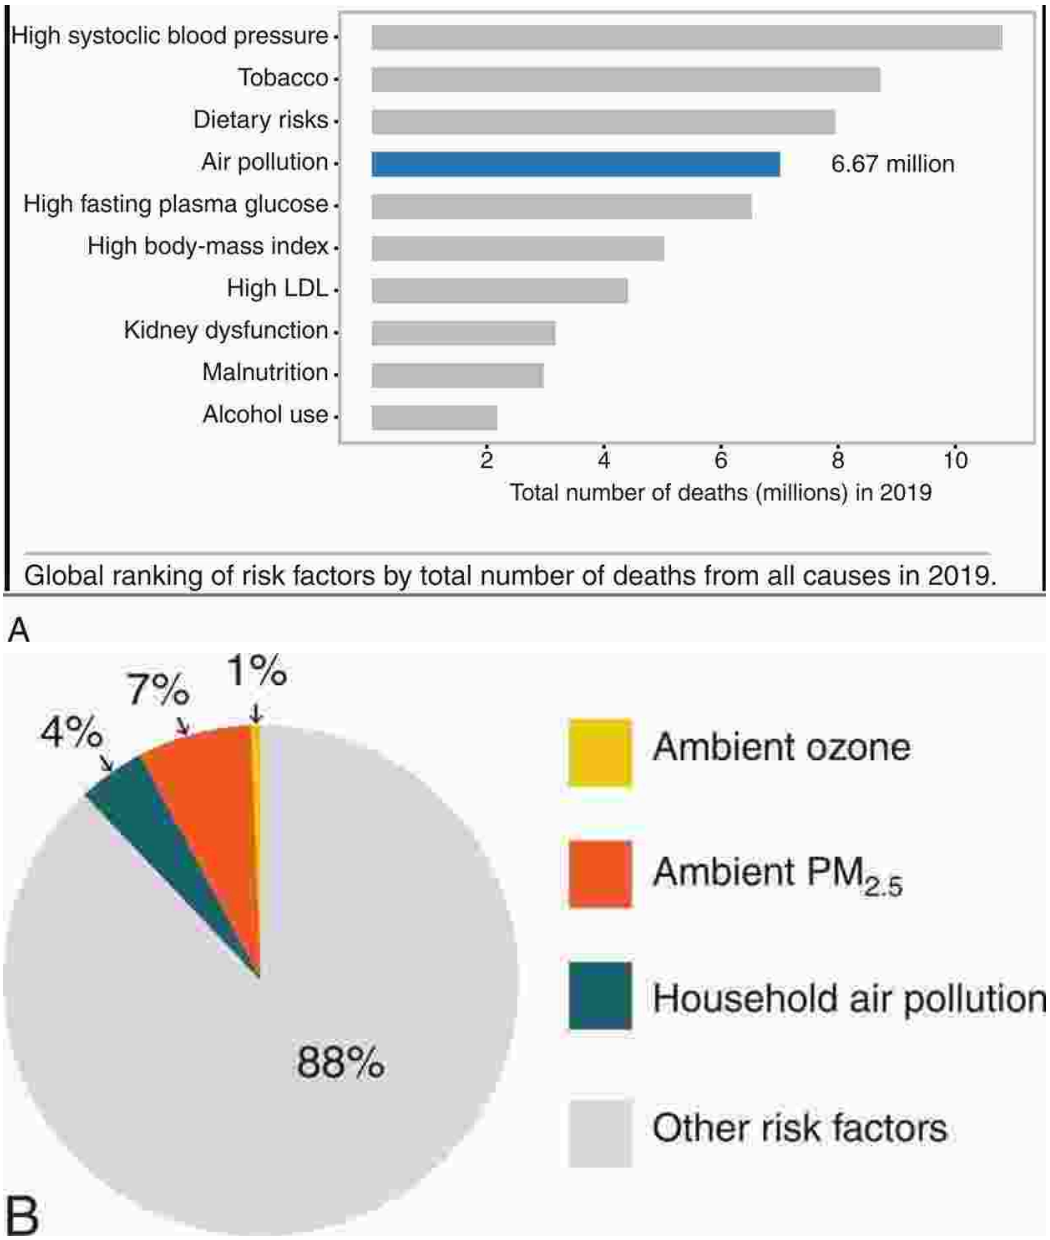

FIG. 2.17 Global Ranking of Risk Factors and Deaths from Air Pollution.

(A) Bar graph showing rankings by total numbers of deaths in 2019. **(B)** Percentage of global deaths from individual pollutants. (Data from Health Effects Institute. State of Global Air 2020 Report. Data source: Global Burden of Disease Study. IHME; 2020. https://www.stateofglobalair.org/resources.)

Part A is a horizontal bar graph ranking total number deaths in 2019, by cause. Approximate data from the graph are as follows. Dietary risks, 7.5 million. Air pollution, 6.67 million. High fasting plasma glucose, 6.3 million. High body-mass index, 5 million. High L D L, 4.5 million. Kidney dysfunction, 3.2 million. Malnutrition, 3 million. Alcohol use, 2.1 million. Part B is a pie chart showing the distribution of global deaths from individual pollutants. The data from the graph are as follows. Ambient P M sub 2.5, 7 percent; household air pollution, 4 percent; Ambient ozone, 1 percent; Other risk factors, 88 percent.

The EPA has identified the following six pollutants as "criteria" air pollutants: carbon monoxide, lead, nitrogen oxides, photochemical oxidants, ground-level ozone particle pollution known as particulate matter, and sulfur oxides (Figs. 2.18 through 2.20).[18]Table 2.6 defines each of the criteria pollutants with sources and known human health impacts.

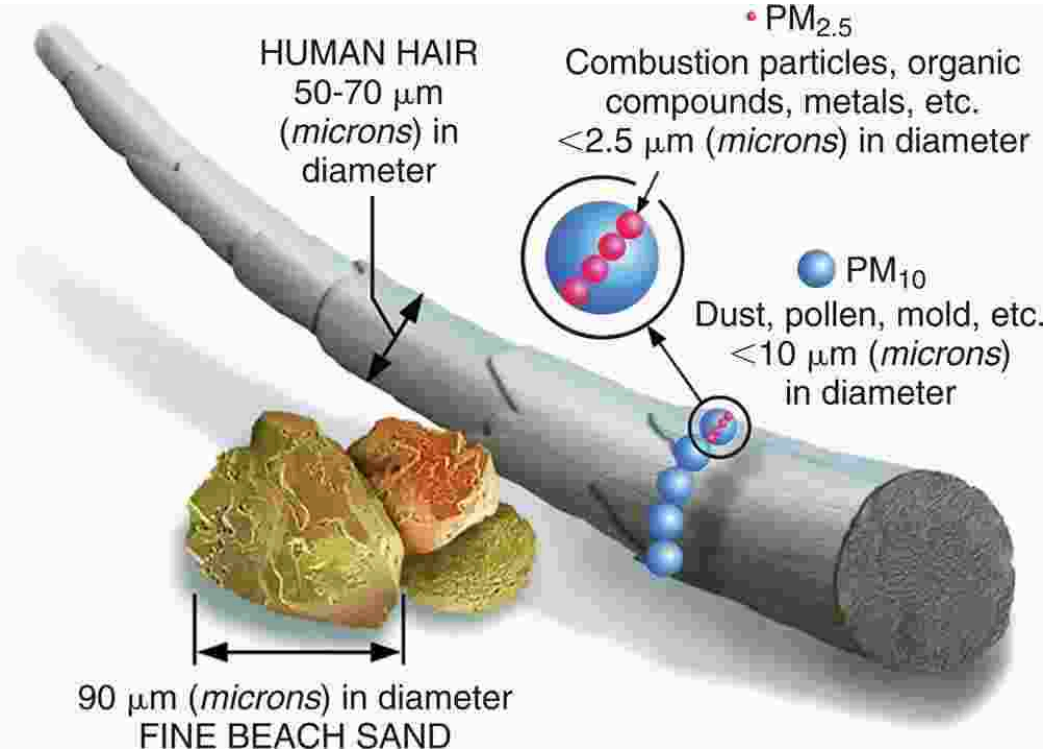

FIG. 2.18 **Particle Sizes and Pollution.** (From Environmental Protection Agency. Particulate matter updated March 18, 2013. Washington, DC; 2013.)

An illustration compares the sizes of fine beach sand and human hair. Human hair is 50 to 70 micrometers or microns in diameter. Fine beach sand is 90 micrometers or microns in diameter. P M 10 substances on a hair stand include dust, pollen, and mold that are less than 10 micrometers or microns in diameter. P M 2.5 substances, on P M 10 substances, include combustion particles, organic compounds, and metals that are less than 2.5 micrometers or microns in diameter.

FIG. 2.19 Air Pollution Globally. (A) Global map of population-weighted annual average $PM_{2.5}$ concentrations in 2019.
(B) Countries included in the seven Global Burden of Disease (GBD) Super Regions. That is, countries grouped by similar cause-of-death patterns. (C) Trends in population-weighted annual average PM 2.5 concentrations globally and in the GBD Super Regions, 2010–2019. (Data from Health Effects Institute. *State of Global Air 2020 Report*. Data source: Global Burden of Disease Study. IHME; 2020. https://www.stateofglobalair.org/resources, to explore data for a certain country or region.)

Two maps and a graph show data for global air pollution. Map A shows the prevalence of P M 2.5 substances in picograms per cubic meter. The approximate data from the graph are as follows. Less than 15 picograms per cubic meter: North America, Greenland, South America, Europe, Asia, and Australia. 15 picograms per cubic meter to 30 picograms per cubic meter: Latin America, Caribbean, South Africa, Middle East, East Asia. 30 picograms per cubic meter to 45 picograms per cubic meter: parts of South Africa, Middle East, and Central Asia. 45 picograms per cubic meter to 75 picograms per cubic meter: parts of North Africa, Middle East, and Southeast Asia. 75 picograms per cubic meter to 85 picograms per cubic meter: South Asia and parts of Western Africa. Map B is a color-

coded world map grouping countries by similar cause-of-death patterns or global burden of diseases, G B D. In increasing order of patterns, the regions color-coded are as follows: South Asia; North Africa and Middle East; Sub-Saharan Africa; Latin America and Caribbean; Central, Europe, Eastern Europe, and Central Asia; Southeast Asia, East Asia, and Oceania; and High-Income. Line Graph C show annual population-weighted P M sub 2.5 substances in micrograms per cubic meter. The vertical axis ranges from 0 to 80 units, in increments of 20. The horizontal axis ranges from 20 10 to 20 19, in increments of 1 year. The data from the map and graph are as follows. 75 micrograms per cubic meter to 85 micrograms per cubic meter: South Asia. 40 micrograms per cubic meter to 50 micrograms per cubic meter: Sub-Saharan Africa, North Africa, Middle East, Southeast Asia, East Asia, and Oceania. 20 micrograms per cubic meter: Central Europe, Eastern Europe, Central Asia, Latin America, and Caribbean. The W H O Guideline is at about 13 micrograms per cubic meter and includes high-income countries: North America, South America, Greenland, Western Europe, Japan, Australia, and New Zealand.

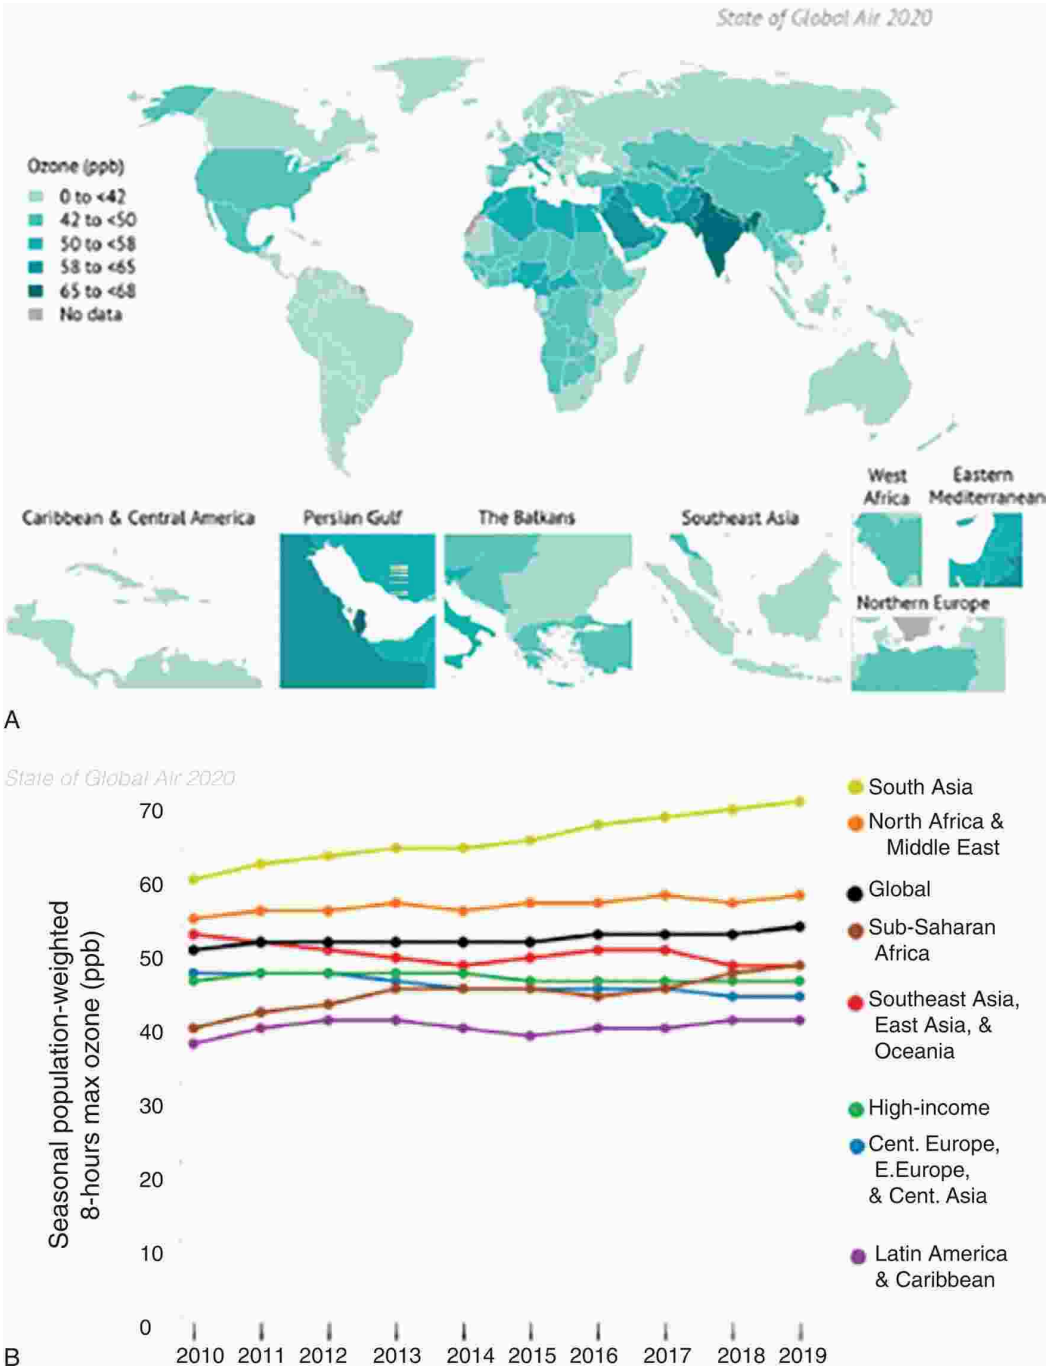

FIG. 2.20 Ozone Globally.
(A) Global map of population-weighted average seasonal 8-hour maximum ozone concentrations in 2019. **(B)** Trends in population-weighted average seasonal 8-hour maximum ozone concentration globally and in the Global Burden of Disease (GBD) Super Regions, 2010–2019.

(Data from Health Effects Institute. *State of Global Air 2020 Report*. Data source: Global Burden of Disease Study. IHME; 2020. https://www.stateofglobalair.org/resources.)

Map A shows data for global zone levels in parts per billion. Less than 42 parts per billion: Canada, Greenland, South America, Eastern Europe, Central Europe, Central Asia, parts of South Africa, Oceania, Australia, and New Zealand. 42 parts per billion to 40 parts per billion: United States, Western Europe, parts of Africa, Middle East, and Eastern Asia. 50 parts per billion to 58 parts per billion: Northern Africa and Middle East. 58 parts per billion to 65 parts per billion: Eastern Mediterranean. 65 parts per billion to 68 parts per billion: South Asia. Graph B shows seasonal populated-weighted 8-hour max ozone levels in parts per billion over the years for the period between 20 10 and 20 19. The vertical axis ranges from 0 to 70 units, in increments of 10. The horizontal axis ranges from 20 10 to 20 19, in increments of 1. The approximate data from the graph are as follows. South Asia: 57 parts per billion in 20 10 to 68 parts per billion in 20 19. North Africa and Middle East: 50 parts per billion from 20 10 to 20 19. Global: 48 parts per billion from 20 10 to 49 parts per billion 20 19. Sub-Saharan Africa: 38 parts per billion in 20 10 to 42 parts per billion in 20 19. Southeast Asia, East Asia, and Oceania: 50 parts per

billion in 20 10 to 42 parts per billion in 20 19. High-Income Countries: 42 parts per billion from 20 10 to 20 19. Central Europe, Eastern Europe, and Central Asia: 44 parts per billion in 20 10 to 40 parts per billion in 20 19. Latin America and Caribbean: 35 parts per billion in 20 10 to 38 parts per billion in 20 19.

Table 2.6

Environmental Protection Agency Criteria of Ambient Air Pollutants

Air Pollutant	Criteria and Sources	Human Health Impacts
Carbon Monoxide (CO)	• Colorless, odorless gas • Sources: emitted during combustion processes, defective furnaces, occupation exposure (coal mining, firefighting, welding, engine repair), or exposure to tobacco smoke (first or secondhand)	• Unborn babies, infants, people with chronic heart disease or lung disease, and anemia are at the highest risk of CO poisoning • Causes reduction of oxygen delivery to organs, such as the heart and brain, by binding to hemoglobin (**carboxyhemoglobin**) reducing the blood's oxygen-carrying capacity • Disruption of cellular oxidative processes • Binding to myoglobin and hepatic cytochromes • Lipid peroxidation of brain lipids

Air Pollutant	Criteria and Sources	Human Health Impacts
		• At very high levels can cause death
Nitrogen Oxides (NO_X)	• Emitted from cars, trucks, buses, power plants, and off-road equipment • Industrial sources include power plants, industrial boilers, cement kilns, and turbines • Natural sources include biological decay processes and lightning strikes	• People with asthma, children, and the elderly are generally at greater risk for the health effects of NO_2 • Exposures over short periods can aggravate respiratory diseases, particularly asthma, leading to respiratory symptoms (such as coughing, wheezing or difficulty breathing) • Longer exposures to elevated concentrations of NO_2 may contribute to the development of asthma and potentially increase susceptibility to respiratory infections

Air Pollutant	Criteria and Sources	Human Health Impacts
Ground-level/Tropospheric Ozone (O_3)	• Ground-level ozone is created by chemical reactions between oxides of nitrogen (NOX) and volatile organic compounds (VOCs) in the presence of sunlight. • The main sources of NOX and VOCs are emissions from industrial facilities and electrical utilities, motor vehicle exhaust, gasoline vapors, and	• People with asthma, children, older adults, and people active outdoors are highest health risk from inhalation of ozone • Can cause coughing and sore or scratchy throat • Inflame and damage the airways making it difficult to breathe deeply • Aggravate existing lung diseases • Increases frequency of asthma attacks

Air Pollutant	Criteria and Sources	Human Health Impacts
	chemical solvents.	
Particulate Matter (PM); PM_{10} and $PM_{2.5}$	• PM is a complex mixture of extremely small particles and liquid droplets that get into the air. • $PM_{2.5}$ poses the greatest risk to health and are the main cause of haze or reduced visibility. • Most particles form in the atmosphere as a result of combustion reactions from power plants, industries,	• Irritation of eyes, nose, and throat • Respiratory effects (asthma, bronchitis) • Cardiac arrhythmias and heart attacks • Can get deep into the lungs and even get into the bloodstream

Air Pollutant	Criteria and Sources	Human Health Impacts
	and automobiles. • Over 90% of the world's population live in areas where ambient particulate matter ($PM_{2.5}$) levels are above the WHO guideline for healthy air	
Sulfur Dioxide (SO_2)	• Largest source of SO_2 in the atmosphere is the burning of fossil fuels by power plants and other industrial facilities	• Children, the elderly, and those who have asthma are most sensitive to SO_2 health impacts • Short-term exposure can cause respiratory dysfunction and difficulty breathing • SO_2 can react with other compounds in the atmosphere to

Air Pollutant	Criteria and Sources	Human Health Impacts
	• Smaller sources of SO_2 emissions include industrial processes such as extracting metal from ore • A natural source of SO_2 is from volcanic eruptions	form fine particles that may get deep into the lungs causing additional health concerns
Lead	See text under Lead	See text under Lead

Household air pollution

From the most recent report, 3.8 billion people cook using solid fuels (e.g., coal, charcoal, wood, dung, kerosene, agricultural residue) (Fig. 2.21). Nearly 50% of the world's population is exposed to household air pollution from the burning of solid fuels, which contributes to 3.8 million premature deaths per year (2018) from illnesses caused by these practices.[19] These inefficient practices produce high levels of household air pollution with a range of health-damaging pollutants, including carbon monoxide and small soot particles that penetrate deep into the lungs. Indoor smoke can be 100 times higher than acceptable levels for fine particles.[17] These exposures are particularly high for women and young children. Most individuals exposed to

indoor pollutants live in developing countries. Individuals exposed to indoor pollution along with outdoor pollution face a double health burden.[20] Household air pollution is a significant contributor to ambient $PM_{2.5}$.[21]

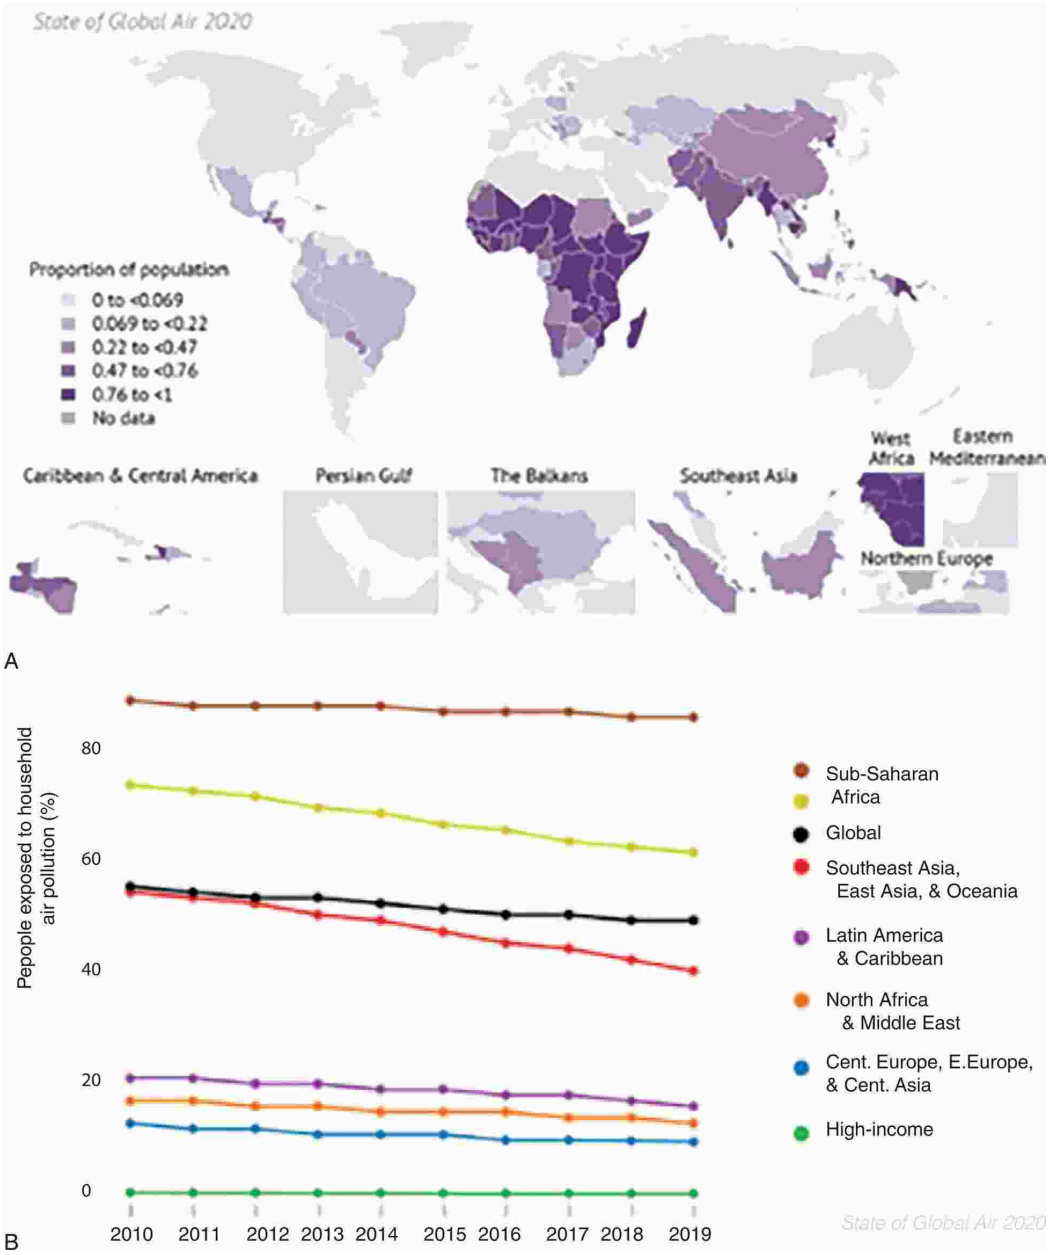

FIG. 2.21 Household Air Pollution. (A) Global map of the proportion of each country's population cooking with solid fuels in 2019. (B) Trends in the proportion of population cooking with solid fuels globally and in the GBD Super Regions, 2010–2019. (Data from Health Effects Institute. *State of Global Air 2020 Report*. Data source: Global Burden of Disease Study. IHME; 2020. https://www.stateofglobalair.org/resources.)

Part A: A map and line graph show data for percentage of people exposed o household air pollution over the years, for the period from 20 10 to 20 19. The approximate data from the map are as follows. 0 to 0.69: High-Income Countries. 0.069 to 0.22: Latin America, Caribbean, and Eastern Europe. 0.22 to 0.47: Parts of Southern Africa and Southeast Asia. 0.47 to 0.76: South Asia. 0.76 to 1: Parts of Africa and Southeast Asia. Part B: The vertical axis ranges from 0 to 80 units in increments of 20. The horizontal axis ranges from 20 10 to 20 19, in increments of 1. The approximate data from the graph are as follows. Sub-Saharan Africa: 85 percent from 20 10 to 20 19. South Africa: 75 percent in 20 10 to 62 percent in 20 19. Global: 57 percent in 20 10 to 56 percent in 20 19. Southeast Asia, East Asia, and Oceania: 57 percent in 20 10 to 40 percent in 20 19. Latin America and Caribbean: 21 percent in 20 10 to 20 percent in 20 19. North Africa and Middle East: 19 percent from 20 10 to 20 19. Central Europe, Eastern Europe, and Central Asia: 18 percent in 20 10 to 17 percent in 20 19. High-Income Countries: 0 percent from 20 10 to 20 19.

Reducing outdoor emissions from household coal and biomass energy systems, agricultural waste incineration, forest fires, and certain agroforestry activities (e.g., charcoal production) would reduce key rural and peri-urban air pollution sources in developing regions.[17] Reducing outdoor air pollution decreases emissions of

CO_2 and short-lived climate pollutants; for example, black carbon particles and methane. These actions would contribute to mitigating climate change. Since 2010, the use of solid fuels has fallen slowly and steadily in most regions, especially in South Asia, Southeast Asia, East Asia, and Oceania Super Regions (see Fig. 2.21B).

COVID-19 infection has raised awareness to an invisible threat to our respiratory and cardiovascular health and has brought renewed attention to air pollution. Although COVID-19's effects may appear in a few weeks, the health consequences of air pollution may take years to manifest in the form of chronic diseases (see Emerging Science Box: Long-Term Exposure to Air Pollution and Increased Risk of Severe COVID-19 Outcomes). Respiratory and cardiovascular health have made individuals more vulnerable to the effects of COVID-19.[21]

Heavy Metals as Environmental Pollutants

The most common heavy metals associated with harmful effects in humans include lead, mercury, arsenic, and cadmium. Damage from metals includes involvement of DNA repair mechanisms, tumor suppressor functions, and interference with signal transduction pathways.

Lead

Lead (Pb) is a heavy toxic metal present in paint of older homes (built before 1978), the environment, and the workplace. Lead may be found in hazardous concentrations in food, water, and air, and it is one of the most common overexposures found in industry.[22] Despite efforts to reduce exposure through government regulation, lead exposure persists in homes, the environment, and the workplace for many people, and lead toxicity is still a primary hazard to children. Older buildings, where lead-based paint is peeling from the walls, are a particular hazard to children (see Emerging Science Box: Lead Poisoning). Lead-based paint has a sweet taste, and toddlers are apt to find paint chips on the floor and put them into their mouths. Although Pb was removed from paint in

the United States in 1978, many homes in the United States still contain leaded paint, and chipped and peeling leaded paint constitutes a significant source of current childhood exposure.[23,24]

The chipped paint can disintegrate at friction surfaces to form lead dust. Another source of contamination is lead dust dispersed along roadways from previous leaded gasoline emissions. When lead was removed from gasoline, blood lead levels (BLLs) dropped significantly.[25]

Previous emissions of leaded fuel created large dispersions of lead dust in the environment. Particulate lead (2 to 10 μm) does not degrade and persists in the environment, making it a notable source of human exposure.[26] Other airborne sources include smelters and piston-engine airplanes.[27] Drinking water exposed to lead occurs from outdated fixtures, plumbing without corrosion control, and solders. Because well water is not subject to EPA regulation, it may not be tested for lead. Although the average blood levels of lead in children in the United States have dropped since the 1970s, there are at-risk populations with higher-than-average BLLs. Children living at or below the poverty line who live in older housing are at greatest risk. Importantly, the CDC reports "no safe blood lead level in children has been identified."[28] Millions of children are being exposed to lead in their homes, increasing their risks for damage to the brain and nervous system, slowed growth and development, learning and behavior problems (e.g., reduced IQ, attention-deficit/hyperactivity disorder [ADHD], juvenile delinquency, and criminal behavior), and hearing and speech problems.

The neurologic effect of lead in exposed children is the driving force for reducing lead levels in the environment. Children are more susceptible than adults to the effects of lead for several reasons:

1. Children have increased hand-to-mouth behavior and thus are prone to putting objects found in their environment into their mouths.
2. The blood–brain barrier in children is immature during fetal development, contributing to greater accumulation in the developing brain.
3. Infant absorption of lead is greater than that in adults. In adults, the body burden of lead is found in bone. In children, growth results in a rapid turnover in skeletal bone, causing a continuous leaching of lead into blood.[29,30]
4. In cases of compromised nutrition, where dietary intake of iron and calcium is insufficient, children are more likely to have elevated BLLs.[29]

Elevated BLLs in children are linked to cognitive deficits and behavioral changes, including antisocial behavior, acting out in school, and attention deficits.[29] These deficits can persist even after the individuals are no longer exposed to lead within their environment. Lead interferes with the normal remodeling of cartilage and bone in children (remodeling increases lead reintroduction). Radiologic studies often reveal *lead lines* in children. Lead accumulates in gums, causing hyperpigmentation. Particularly worrisome is lead exposure during pregnancy because the developing fetal nervous system is especially vulnerable to lead toxicity. Lead can cross the placental barrier, exposing the fetus *in utero*, which may result in significant cognitive impairment and subsequent learning disabilities.

From the most recent National Health and Nutrition Examination Survey (NHANES) data set, approximately 535,000 children between 1 and 5 years of age have an elevated blood lead concentration.[24,31] Blood levels of lead were defined by the Advisory Committee on Childhood Lead Poisoning Prevention of the CDC as greater than or equal to 5 mcg/dL based on the 97.5 percentile of blood lead concentrations.[32] The rates in adults of elevated BLLs in 2013 was 20.4 per 100,000 employed adults (16 years and older). These levels showed a blood lead concentration over 10 mcg/dL.[33] Higher risk occupations include metal welding, battery manufacturing and recycling, shipbuilding and

shipbreaking, firing range instruction and bullet salvaging, lead smelting and refining, painting and construction work, pipefitting, and plumbing.[24,34] Less common exposures occur from contaminated pewter and ceramic dining ware, imported spices and cosmetics, folk remedies, ingestion of lead foreign bodies, and retained leaded bullets.[24,35] As demonstrated by the Flint, Michigan water crisis, soluble lead concentrations in drinking water can be at critical levels. Lead poisoning from degrading lead pipes is a pervasive problem that needs immediate scientifically based, data-driven risk assessments that inform decisions involving drinking water systems.[36]

Pathophysiology

The pathogenic effects of lead are multifactorial and complex. Lead is an easily absorbed metal that binds to sulfhydryl groups in proteins and interferes with calcium (Ca^{++}) metabolism. A key event underlying the effects of lead exposure in humans is the alteration of cellular ion status (disruption of divalent cations, altered ion transport mechanisms, and disruption of protein function from displacement of metal enzyme cofactors). Because calcium (Ca++) is a crucial cell signal carrier and regulates critical cellular functions, its interference leads to hematologic, skeletal, neurologic, GI, and renal toxicities.[37] The change in intracellular Ca^{++} concentrations is most likely due to alterations in ion transport mechanisms and, importantly, the inhibition of transport proteins such as Na^{+}, K^{+} - ATPase, and Ca^{++} channels. Specifically, Pb interferes with these proteins by displacing or competing with normal metal cofactors (e.g., lead binds to calcium-activated proteins with higher affinity than Ca^{++}) or through proteins important in Ca^{++}-dependent cell signaling (protein kinase C or calmodulin).[37] Lead disrupts other divalent metals, including zinc and magnesium, leading to alterations in neurotransmitter function, inhibiting heme synthesis, and, from impaired mitochondrial function, decreasing cellular energy. Lead is toxic to multiple enzyme systems. Lead causes abnormal conformational changes in the protein structure, resulting in altered protein functions.

Antagonism of normal metal ion functions by lead leads to oxidative stress.[37,38] Lead-induced oxidative stress is possibly the result of a multi-pathway process and results from binding to and subsequent inhibition of the function of *delta aminolevulinic acid dehydratase (ALAD)* because of

competition of lead ions with normal zinc ions leading to the accumulation of *delta-aminolevulinic acid* (*δ-ALA*) in blood and urine. With accumulation of δ-ALA, it undergoes conformational protein change and autooxidation resulting in the generation of ROS.[38] Other sources of lead-induced oxidative stress are membrane lipid oxidation, NADPH oxidation, and antioxidant depletion.[37]

ROS causes the following changes:

- DNA damage, impaired DNA repair, cell apoptosis, or carcinogenesis
- Peroxidation of cell membrane lipids and cell damage
- Inactivation of enzyme proteins
- Prevention of protein folding
- Protein aggregation
- Conformational changes affecting cell structure and function and cause cell damage[38]

These *key* events from lead exposure affect the nervous, immune, endocrine, cardiovascular, musculoskeletal, renal, and reproductive systems and have negative developmental effects, such as delayed puberty onset, as well as cancer. A causal relationship is determined for lead and cardiovascular effects.[37]

Clinical Manifestations

Lead affects the nervous, cardiovascular, reproductive, endocrine, musculoskeletal (including teeth), renal, and immune systems. The clinical manifestations vary depending on the dose and chronicity of exposure. Most children are asymptomatic; however, the primary concern, even at low BLLs, is the intelligence quotient (IQ) scores and markers of academic achievement.[32,39,40]

Evaluation, Prevention, and Treatment

Diagnosis involves the medical history, clinical signs, and determination of routes of exposure. The main method of evaluation is laboratory analysis of the BLL. According to the CDC, experts now use a reference level of 5 mcg/dL to identify children with BLLs that are much higher than normal.[28]

The most important strategy for lowering exposures to lead is prevention. Prevention methods include individual and family prevention, preventive medicine, and public health. There is an urgent need to focus on preventive strategies, especially for fetal development and the developing child. The key for adults is prevention of exposures at the workplace and home. The main methods of treatment are removal of the source of exposure and, for those with high blood levels, chelation therapy. Additionally, treatment may include correcting deficiencies of iron, calcium, and zinc; irrigating the bowel; removing strategic bullets or shrapnel; and administering medications for control of seizures.

Cadmium and arsenic

See Table 2.7 for a summary of the toxic effects of cadmium and arsenic.

Table 2.7

Summary of Toxic Effects of Cadmium and Arsenic

Metals	Key Concepts
Arsenic	Arsenic salts were the poison of choice during the Renaissance in Italy. Deliberate poisoning by arsenic is rare today; however, its exposure is an important health concern in many areas worldwide. Arsenic is found naturally in soils and water and used in products (wood preservers, herbicides, agricultural products). It can be released from mines and smelting industries and may be present in some Chinese and Indian herbal medicines. Inorganic arsenic may be present in ground water with large concentrations found in Bangladesh, Chile, and China. Most toxic forms are the trivalent compounds arsenic trioxide, sodium arsenate, and arsenic trichloride. Arsenic trioxide is used as a therapy for acute promyelocytic leukemia; ingestion of large quantities of arsenic causes acute gastrointestinal, cardiovascular, and CNS toxicities that often are fatal. These effects are partially attributed to replacement of phosphates in ATP and interference of mitochondrial oxidative phosphorylation and the function of some proteins.

Metals	Key Concepts
	Chronic exposure causes skin lesions (hyperpigmentation, hyperkeratosis) and the development of cancers (lung, bladder, skin). The mechanism for arsenic carcinogenesis has not been fully defined. Arsenic present in drinking water has been correlated with nonmalignant respiratory disease.
Cadmium	Compared with the other metals discussed, cadmium poisoning is a more modern problem. Pollution in the environment and occupationally is from mining, electroplating, and production of nickel-cadmium batteries, which are often disposed of in household waste. Food is an important source of cadmium because cadmium can contaminate soil and plants directly or from fertilizers and irrigation water. The most probable mechanism of toxicity is the generation of ROS. The main toxic effects of excess cadmium are obstructive lung disease and renal tubular damage. It also can cause skeletal abnormalities associated with calcium loss. In Japan, cadmium-containing water used to irrigate rice fields caused a disease in postmenopausal women known as “Itai-Itai” (ouch-ouch), a combination of osteoporosis and osteomalacia associated with renal disease.

Metals	Key Concepts
	Cadmium is associated with higher risk of lung cancer in populations living near zinc smelters.

ATP, adenosine triphosphate; *CNS*, central nervous system; *ROS*, reactive oxygen species.

Data from Kumar V, Abbas A, Aster J, eds. *Robbins & Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.

Mercury

Mercury (quicksilver) is a neurotoxic elemental metal liquid at room temperature and is widely present in the environment. Mercury is a global threat to human and environmental health. It can be released into the air, water, and soil through industrial processes, including mining, metal and cement production, fuel extraction, and combustions of fossil fuels (especially coal). Sources of exposure include natural geologic sources, vehicle emissions, consumer products, industrial waste, and landfills and disposal sites. Climate change and thawing of enormous areas of frozen lands may release long-stored mercury into lakes, rivers, and oceans.

Mercury also is found in dental amalgam; some vaccine preservatives; food products (e.g., rice); and terrestrial and marine animals, some of which are consumed by humans. The previously common practice of allowing school children to handle mercury in chemistry classes is no longer permitted. Similarly, the once ubiquitous mercury-filled household thermometer is being phased out of production. There are safe and cost-effective replacements for mercury for many healthcare applications and for pharmaceuticals; goals have been set to phase out some mercury-containing devices altogether. Since 2001, thimerosal (a preservative in multidose vials of vaccines containing ethyl mercury) was removed from childhood vaccines in the United States.[41]

There are three forms of mercury: metallic mercury (elemental mercury), inorganic mercury compounds (mostly mercuric chloride), and organic mercury. A prominent source of mercury is contaminated fish (mostly methylmercury, [MeHg]). Inorganic mercury is converted to organic mercury, such as methylmercury, by bacteria. Methylmercury enters the food chain and, in carnivorous fish (especially swordfish and

shark), it may be concentrated to high levels greater than the surrounding water.[1]

Acute exposures from release of methylmercury from industrial sources caused the disaster at Minamata Bay and the Agano River in Japan and led to widespread mortality and morbidity. Known as *Minamata disease*, the disorders included deafness, blindness, intellectual disability, cerebral palsy, and central nervous system (CNS) defects in children exposed in utero. The developing brain is extremely sensitive to methylmercury.[1] Mercury is found in many species of fish, including grouper, tuna, seabass, marlin, halibut, tilefish, swordfish, shark, and king mackerel.[42] The FDA has recommended that women planning to become pregnant, pregnant women, nursing mothers, and young children avoid eating fish with a high mercury content (>1 part per million [ppm]), such as shark, swordfish, tile fish, and king mackerel. Fish that are lower in methylmercury include shrimp, canned light tuna, salmon, pollock, and catfish.[43] Like Pb, mercury binds with high affinity to sulfhydryl groups in some proteins, leading to tissue damage in the CNS and kidney.[1]

Lipid solubility of methylmercury and metallic mercury increases their accumulation in the brain, altering neuromotor, cognitive, and behavioral functions. An antioxidant, intracellular glutathione acting as a sulfhydryl donor, is the main protective mechanism from mercury-induced CNS and kidney damage.

Ethanol

Alcohol (ethanol) is the primary choice of mood-altering drugs available in the United States. According to the 2019 National Survey on Drug Use and Health (NSDUH), 85.6% of people aged 18 or older reported that they drank alcohol at some point in their lifetime; 69.5% reported that they drank in the past year; and 54.9% reported that they drank in the past month.[44] An estimated 95,000 people (approximately 68,000 men and 27,000 women) die from alcohol-related causes annually, making alcohol the third leading preventable cause of death in the United States. The first is tobacco, and the second is poor diet and physical inactivity.[45] A blood alcohol concentration of 80 mg/dL is the legal definition for driving while intoxicated in the United States. The amount of alcohol intake required to achieve this blood level will vary, depending on age, sex, percent body fat,

metabolic rate, and genetically controlled factors influencing alcohol metabolism.[46]

Nutritional deficiencies remain one of the most frequent complications of alcohol-related disease. Although inadequate dietary intake is a significant cause of the vitamin deficiency, other possible mechanisms may also be involved. Alcohol is absorbed by diffusion in the stomach, duodenum, and jejunum. Chronic alcohol consumption breaks down the gut barrier function (causing leaky gut), which leads to impaired gut motility, delaying gastric emptying time; induces chemical gastritis; and increases the orocaecal transit time leading to impaired absorption of nutrients (e.g., folic acid, thiamine, vitamin B_6, magnesium, and phosphorus).[47,48] Folic acid deficiency, in particular, is problematic in persons consuming large quantities of alcohol. Ethanol alters folic acid (folate) homeostasis by decreasing intestinal absorption of folate, increasing liver retention of folate, and increasing the loss of folate through urinary and fecal excretion. Folic acid deficiency becomes especially serious when alcohol is consumed during pregnancy and may contribute to *fetal alcohol syndrome*.[49] Thiamine (vitamin B1) deficiencies result in significant neurologic sequela, common in persons with alcohol abuse. Wernicke encephalopathy is an acute neurological crisis that results from depleted thiamine stores and is characterized by the clinical triad of encephalopathy, oculomotor dysfunction, and gait ataxia.[47] Magnesium is the second most abundant micronutrient in the human body, and deficiency is almost universal in individuals with high levels of alcohol consumption and/or liver disease. Urinary excretion of magnesium is increased secondary to alcohol consumption, and total body stores of magnesium become depleted. Most of the alcohol ingested is metabolized to *acetaldehyde* in the liver. Acetaldehyde is a highly toxic substance and known carcinogen, with particular implications for head and neck cancer. It is responsible for both the acute effects of alcohol ingestion and for numerous disease processes associated with chronic alcohol consumption. The major pathway involves alcohol dehydrogenase (ADH), an enzyme located in the cytosol of hepatocytes. The microsomal ethanol-oxidizing system (MEOS) depends on cytochrome P-450 (CYP2E1), an enzyme needed for cellular oxidation. Activation of CYP2E1 requires a high ethanol concentration and thus is thought to be important in the accelerated ethanol metabolism (i.e., tolerance) noted in persons with chronic alcoholism (Fig. 2.22).

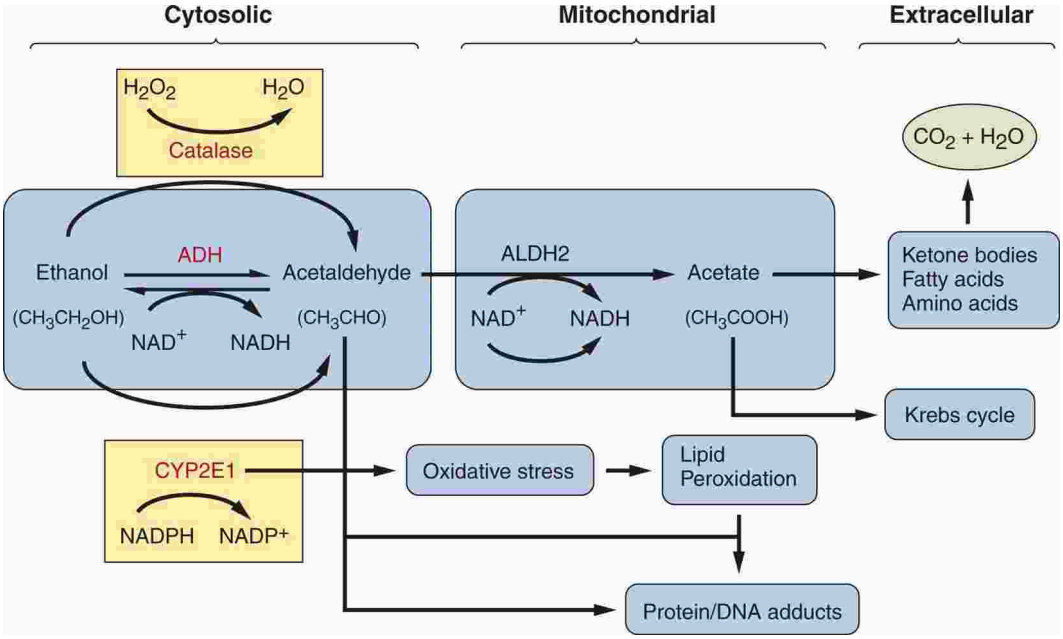

FIG. 2.22 Ethanol Metabolism Pathway.
Ethanol is metabolized into acetaldehyde through the cytosolic enzyme alcohol dehydrogenase *(ADH)*, the microsomal enzyme cytochrome P-450 2E1 (CYP2E1), and the peroxisomal enzyme catalase. The ADH enzyme reaction is the main ethanol metabolic pathway involving an intermediate carrier of electrons, namely, nicotinamide adenine dinucleotide (NAD +), which is reduced by two electrons to form NADH. Acetaldehyde is metabolized mainly by aldehyde dehydrogenase 2 (ALDH2) in the mitochondria to acetate and NADH before being cleared into the systemic circulation. (Adapted from Zhang Y, Ren J. ALDH2 in alcoholic heart diseases: Molecular mechanism and clinical implications. *Pharmacology and Therapeutics*, 2011;132[1]:86–92.)

A multi-part flow-diagram shows ethanol metabolism pathway is cytosolic, mitochondrial, and extracellular regions. Cytosolic region. H 2 O 2 converts to H 2 O in the presence of catalase. A reversible reaction between Ethanol, C H 3 C H 2 O H), and Acetaldehyde (C H 3 C H

O) in the presence of A D H, releasing N A D ions and N A D H. C Y P 2 E 1 results in N A D P H to N A D P ions. Mitochondrial region. Acetaldehyde, in the presence of A L D H 2 to Acetate (C H 3 C O O H), while utilizing positively charged N A D and releasing N A D H. C Y P 2 E 1 results in Oxidative Stress, leading to Lipid Peroxidation. Extracellular region. Acetate results in Ketone Bodies, Fatty Acids, Amino Acids, and Krebs Cycle, releasing C O 2 and H 2 O.

The major effects of acute alcoholism involve the CNS. The result of ethanol breakdown is thought to be the result of hepatic aldehyde dehydrogenase 2 (ALDH2) and contributes to alcohol's behavioral effects and alcoholism.[50] ALDH2 mediates low-dose ethanol induced increases in GABA levels, affecting tonic inhibition and alteration of balance and coordination skills.

After alcohol is ingested, it is absorbed, unaltered, from the stomach and small intestine. Fatty foods and milk slow absorption. After absorption, alcohol is distributed to all body tissues and fluids in direct proportion to blood concentration levels. Individuals differ widely in their capability to metabolize alcohol. Genetic differences in the hepatic metabolism of alcohol are related to levels of hepatic aldehyde dehydrogenases. There is considerable variability in alcohol tolerance among different ethnic groups. Persons with chronic alcoholism tend to develop an increased tolerance because of the enhanced production of metabolic enzymes.

Alcohol may exert both positive and negative effects on cardiovascular system. While numerous studies have validated the so-called *J-curve* or *U-shaped* inverse association between alcohol and overall or cardiovascular mortality, there are several factors that may modulate this effect. Among light to moderate drinkers, in the absence of binge drinking, mortality rates tend to be lower than in nondrinkers; mortality rates are higher among heavy drinkers. These findings, however, may be confounded by medical care and social relationships. The proposed mechanisms for observed cardiovascular benefit includes one or more of the following

effects: increased levels of high-density lipoprotein–cholesterol (HDL-C), decrease in levels of low-density lipoprotein (LDL), prevention of clot formation, reduction in platelet aggregation, decrease in blood pressure, increase in coronary vessel vasodilation, increase in coronary blood flow, decrease in coronary inflammation, decrease in atherosclerosis, limited ischemia–reperfusion injury, and decreased diabetic vessel pathology. According to the Dietary Guidelines for Americans, recent evidence reveals that even drinking within the recommended limits may increase risks, including cancer, cardiovascular disease, and death.[51] The current recommendation is no more than two drinks per day for men and no more than one drink per day for women. One drink is defined as 12 oz 5% ABV beer, 5 oz 12% ABV wine, 1.5 oz of 40% ABV (80-proof) spirits, or 8 oz 7% ABV malt liquor.[52] Consuming alcohol in greater than recommended amounts is associated with numerous health hazards, including increased risk for alcoholism, high blood pressure, obesity, stroke, breast cancer, suicide, and accidents.

Acute alcohol intoxication (drunkenness) primarily affects the CNS, causing dose-related CNS depression. Alcohol consumption induces varying levels of sedation, drowsiness, loss of motor coordination, delirium, altered behavior, and loss of consciousness. Alcohol blood levels of approximately 200 g/dL causes drowsiness, and toxic blood levels (300 to 400 mg/dL) result in a lethal coma or respiratory arrest caused by medullary center depression. Additionally, acute alcoholism may induce reversible hepatic and gastric changes.[1]

Binge drinking, defined as four standard alcoholic drinks on one occasion for women and five drinks for men, has significant health hazards. Chronic drinking and binge drinking cause alcoholic liver disease (ALD) with the spectrum ranging from *hepatic steatosis* (fatty change) and *steatohepatitis* (fatty and inflammatory changes) to cirrhosis of the liver. These alterations can lead to hepatocellular carcinoma. Alcohol can induce damage to mitochondrial DNA, lipid accumulation, and oxidative stress. Additionally, there is evidence that alcohol drinking in adolescents, especially binge drinking, can result in neurocognitive changes affecting both gray and white brain matter and may result in risk-taking behaviors.

Chronic alcoholism causes structural alterations in practically all organs and tissues in the body because most tissues contain enzymes capable of ethanol oxidation or nonoxidative metabolism. The most significant

changes, however, occur in the liver. Excessive consumption of alcohol is the leading cause of alcohol-related liver disease, morbidity, and mortality.[53] Hepatic changes, initiated by acetaldehyde, are far reaching and include inflammation, fat deposition, and liver enlargement. On the cellular level, changes include protein transport malfunctions, increased intracellular water, decreased mitochondrial fatty acid oxidation, excessive membrane rigidity, and liver cell necrosis. Chronic, excessive alcohol consumption typically results in cirrhosis of the liver and the associated portal hypertension. Other disorders associated with chronic alcoholism include alcoholic cardiomyopathy; increased risk of hypertension, gastritis, and pancreatitis; regressive changes in skeletal muscle; and an increased risk for oral, esophagus, pharynx, larynx, liver, and breast cancer (Fig. 2.23).[54] The risk is even greater with concurrent smoking or use of smokeless tobacco. Chronic alcoholism can lead to massive bleeding from gastritis, gastric ulcer, and esophageal varices (associated with cirrhosis).

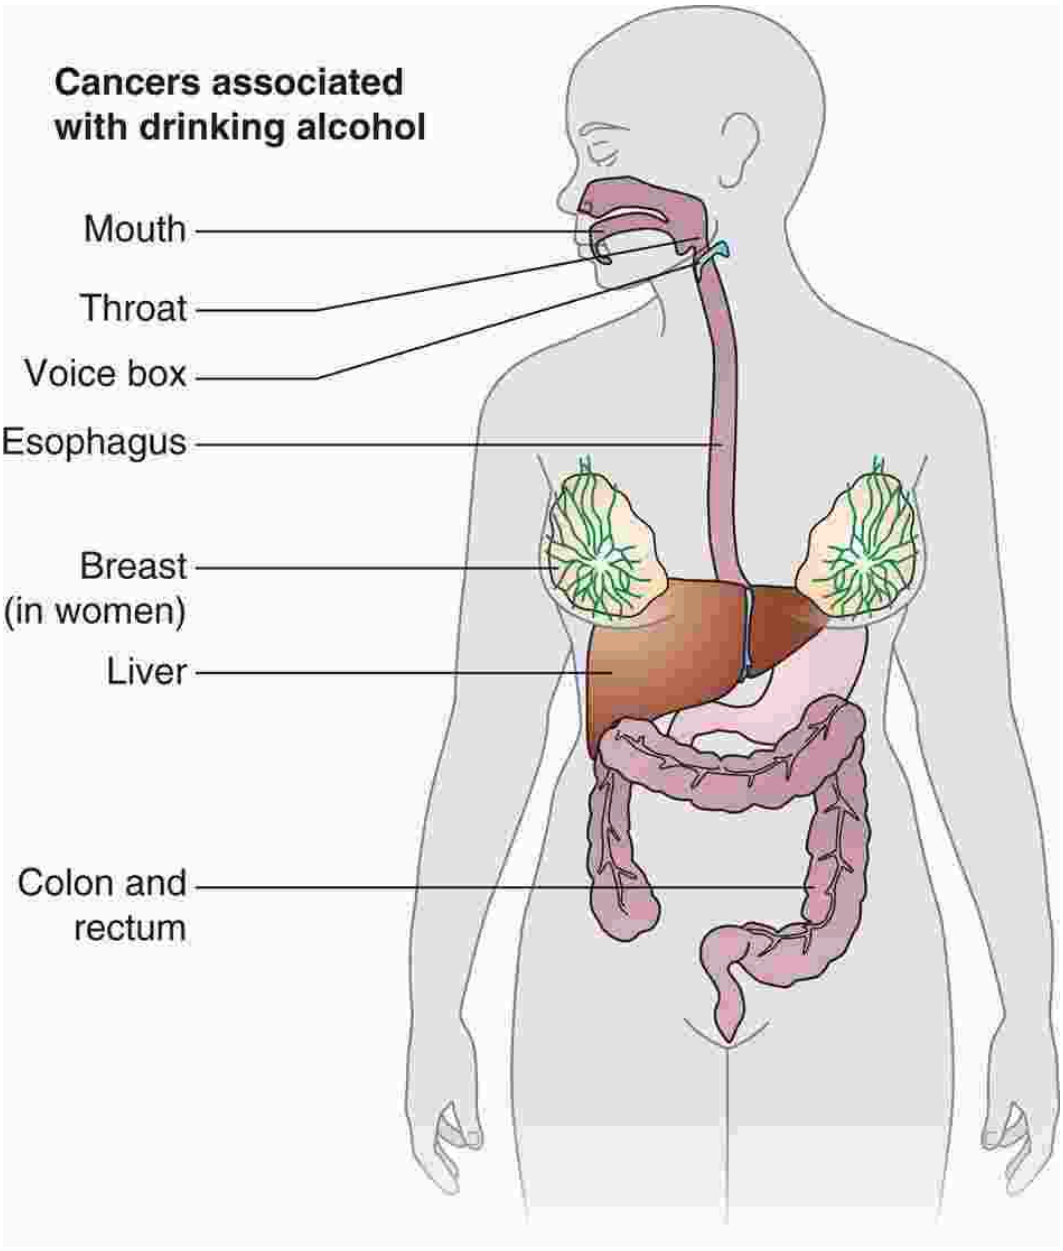

FIG. 2.23 Cancers Associated with Drinking Alcohol. (Data from National Cancer Institute Alcohol and Cancer Risk National Cancer Institute, National Institutes of Health. U.S. Department of Health and Human Services; 2018. https://www.cancer.gov/about-cancer/causes-prevention/risk/alcohol/alcohol-fact-sheet. Accessed October 1, 2021.)

An illustration of the digestive tract in the human body identifies parts affected by cancers associated with drinking alcohol: mouth, throat, voice box, esophagus, breast (in women), liver, and colon and reticulum.

Over long periods, excessive alcohol intake weakens the immune system, putting persons at increased risk of a variety of immune defects, including cytokine production, inflammation, increased susceptibility to infection, increased incidence and severity of pneumonia, and enhanced progression of human immunodeficiency disease.[55–57] The immune system is weakened because chronic ethanol abuse causes a decrease in the number of circulating T cells (responsible for cell mediated immunity) and B cells (responsible for antibody-mediated immunity). Despite reduced B-cell numbers, serum concentrations of immunoglobulins (IgA, IgG, and IgE) are increased. In particular, the levels of antibodies against liver-specific autoantigens are increased in individuals with ALD, which may promote alcohol-related liver damage. Alcohol exposure in utero has been shown to interfere significantly with the development of T cells and B cells, which ultimately may increase risk for infections during adulthood.[55]

Alcohol ingestion during pregnancy is associated with *cognitive deficiencies* and *neurobehavioral disorders*, including fetal alcohol syndrome (FAS). Fetal alcohol spectrum disorders (FASDs) are a range of physical effects, behavioral disorders, or cognitive deficits caused by prenatal alcohol exposure. These conditions can range from mild to severe with FAS at the more severe end of the spectrum. Conservative estimates indicate that up to 1 in 20 U.S. schoolchildren may be affected by FASDs, making these disorders more common than autism spectrum disorder, currently estimated to affect 1 in 54 children.[58,59]

FAS syndrome is characterized by growth retardation, facial anomalies, cognitive impairment, and ocular malformations. A diagnosis of FAS is made based on identifying one or more structural, neurologic, or functional CNS abnormalities (e.g., small head size, problems with attention and hyperactivity, poor coordination); prenatal or postnatal growth deficit in height, weight, or both; and abnormal facial features (e.g., smooth philtrum (ridge between nose and upper lip, thin vermillion

border, and small palpebral fissures) (Fig. 2.24) with confirmed prenatal alcohol exposure; although confirmation is not required to make a diagnosis.[60] Alcohol readily crosses the placenta, reaching the fetus in 1 to 2 hours, and produces fetal blood levels that are equivalent to maternal alcohol levels. Amniotic fluid acts as a reservoir for alcohol, prolonging fetal exposure.[61] Overall, maternal ingestion of alcohol can be catastrophic for the developing fetus. Autopsies of children with FAS have revealed widespread, severe damage, including failure of certain brain regions to develop, malformations of brain tissue, and failure of certain cells to migrate to their necessary location during development.[62] Imaging studies reveal that in addition to an overall reduction in brain size, the corpus callosum is reduced in size or missing, the cerebellum is significantly reduced in size, and the basal ganglia and caudate nucleus are significantly reduced.

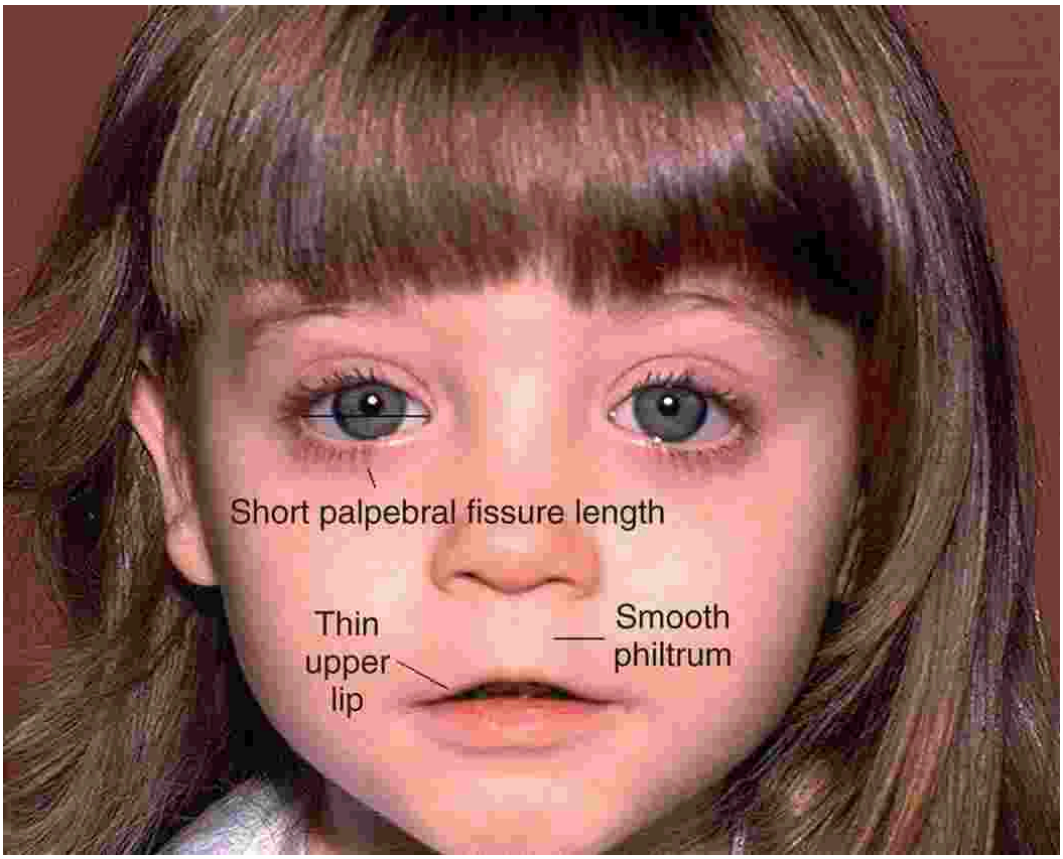

FIG. 2.24 Diagnostic Facial Features of Fetal Alcohol Syndrome.
Three diagnostic facial features of fetal alcohol syndrome: (1) short palpebral fissure lengths, (2) smooth philtrum, and (3) thin upper lip. (© 2022 Susan (Astley) Hemingway PhD, University of Washington.)

A close-up shows the face of a young girl, under 5 years of age, identifying facial features that are diagnostic of fetal alcohol syndrome: short palpebral fissure length, smooth philtrum, and thin upper lip.

Social or Street Drugs

The social or recreational use of psychoactive and narcotic drugs is a major problem in many parts of the world. Popular drugs are methamphetamine ("meth"), marijuana, cocaine, heroin, and,

increasingly, fentanyl. Many of these drugs have a high risk for addiction and dependence, and some can cause respiratory distress and death. The 10 drugs most frequently involved in overdose deaths include heroin, oxycodone, methadone, morphine, hydrocodone, and fentanyl; the benzodiazepines alprazolam and diazepam; and the stimulants cocaine and methamphetamine.[63] Although opiates, both prescription and illicit, are causes of drug overdose deaths, recent increases in drug overdose deaths are driven by continuing increases in synthetic opioids other than methadone, such as illicitly manufactured fentanyl (IMF) (Fig. 2.25).[64] Overall, drug overdose deaths rose from 2018 to 2019, with 70,630 deaths reported in 2019.

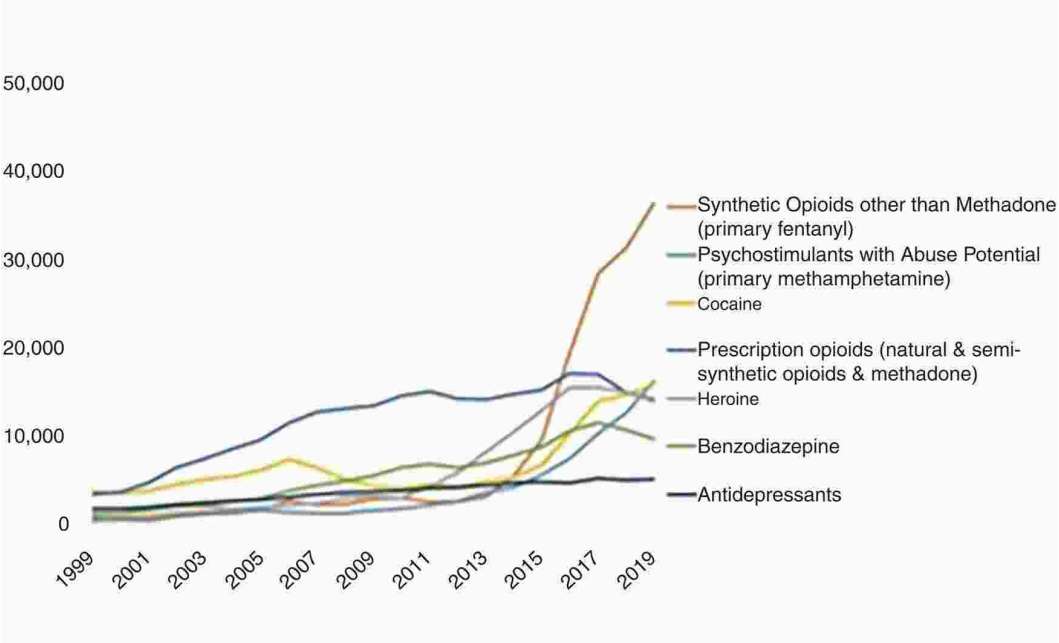

FIG. 2.25 Drug-Involved Overdose Deaths by Specific Category All Ages, 1999–2019. (From Centers for Disease Control and Prevention, National Center for Health Statistics. Multiple Cause of Death 1999–2019 on CDC WONDER Online Database, released December 2020. https://wonder.cdc.gov/controller/datarequest/D77.)

A line graph plots number of deaths by specific case of drug-involved overdose. The vertical axis ranges from 0 to 50,000 units, in increments of 10,000. The horizontal axis ranges from 19 99 to 20 19, in increments of 2 years. The approximate data from the graph are as follows. Synthetic opioids other than methadone (primarily fentanyl): from negligible in 19 99 to over 35,000 in 20 19. Psychostimulants with abuse potential (primarily methamphetamine): from negligible in 19 99 to about 15,000 in 20 19. Cocaine: from about 400 in 19 99 to about 15,000 in 20 19. Prescription opioids (natural and semi-synthetic opioids and methadone): from about 400 in 19 99 to over 15,000 in 20 19. Heroin: from negligible in 19 99

to about 15,000 in 20 19. Benzodiazepines: from negligible in 19 99 to about 10,000 in 20 19. Antidepressants: from negligible in 19 99 to about 4,000 in 20 19.

Opioid-involved overdose deaths rose from 21,088 in 2010 to 47,600 in 2017 and remained steady in 2018 with 46,802 deaths. A significant increase occurred in 2019 to 49,860 overdose deaths.[65]

Although this increase affected all ethnic groups, non-Hispanic whites experienced the most devastating increase, with adults ages 45 to 54 suffering the highest rates of mortality, according to the National Center for Health Services.[63] Increases in drug overdose deaths are seen more in males, with female rates remaining steady. Drug overdoses from heroin and natural and semisynthetic opioids (e.g., oxycodone and hydrocodone) have started to decline over the last several years.[66]

Unintentional and Intentional Injuries

Unintentional and intentional injuries are an important health problem in the United States. In 2019, there were 220,551 deaths from injury. This breaks down to 173,040 deaths from unintentional injury (3rd leading cause of death in the United States) and another 47,511 deaths from intentional injury (10th leading cause of death in the United States).[67] In 2019. the number of deaths because of unintentional poisoning was 65,773, at a rate of 20.0 deaths per 100,000. Motor vehicle accident-related deaths accounted for 37,595, with a rate of 11.5 deaths per 100,000. Fatalities caused by firearms in 2018 were 39,740, with many more individuals reporting nonfatal firearm-related injuries.[67] The rate of deaths attributable to drug overdose in 2019 was reported to be 70,630, with a rate of 21.6 per 100,000.[66]

Death rates because of unintentional falls were reported, in 2019, to be 39,433, or a rate of 12.0 per 100,000, which has continued to increase over the last 5 years. Fall death rates increased 30% from 2007 to 2016 for older adults. Each year 7 million individuals are treated in emergency departments for fall injuries, with 3.1 million being greater than age 65.[68] More than 95% of hip fractures are caused by falls, and falls are the leading cause of traumatic brain injuries (TBI).

Sexual violence affects millions of people each year in the United States. Specifically, more than 1 in 3 women and nearly 1 in 4 men have experienced sexual violence involving physical contact. Furthermore, 1 out of every 5 women and 1 in 38 men have experienced an attempted or completed rape.[69] In 2019, rape or sexual assault victimizations declined to 1.7 per 1000 from 2.7 per 1000 persons aged 12 or older in 2018.[70] Child sexual abuse is when a child younger than 18 years of age experiences sexual violence without consent. Sexual violence includes sex trafficking, which is the use of force, fraud, or coercion to make an individual engage in commercial sex.[69] Sports- and recreation-related injuries accounted for 2.7 million visits to the emergency department between 2010 and 2016 for individuals 5 to 24 years of age. The top five most frequent activities that caused ED visits for sports injuries were football (14.1%), basketball (12.5%), pedal cycling (9.9%), soccer (7.1%), and ice or roller skating or skateboarding (6.9%).[71]

The 10 leading causes of death (heart disease, cancer, unintentional injuries, chronic lower respiratory diseases, stroke, Alzheimer disease, diabetes, influenza and pneumonia, kidney disease, and suicide) have remained constant over the last few years. These 10 leading causes accounted for 73.8% of all deaths in the United States in 2018.[72]

In 2020, COVID-19 was the third leading cause of death, following heart disease and cancer, respectively. The COVID-19 pandemic caused approximately 375,000 deaths in the United States during 2020. The overall age-adjusted death rate in 2020 increased by 15.9%. Overall death rates were highest among non-Hispanic Black persons and non-Hispanic American Indian or Alaska Native persons.[73]

Unintentional injury is the fourth leading cause of death and highest among those between ages 1 and 34 years; intentional injury (suicide, homicide) ranks between the second and fourth leading causes of death in these age groups. Unintentional hospital-acquired conditions do occur and can have severe consequences, including death and long-term injury, as well as contribute to adverse mental and emotional effects on the individual and the healthcare providers.[74] Examples of hospital-acquired conditions include adverse drug events, catheter-associated urinary tract infections, central-line-associated bloodstream infections, pressure injuries, and surgical site infections, among others. The magnitude of healthcare-associated morbidity and mortality can be linked to healthcare-

associated infections (HAI). While progress has been made to decrease HAI, every year, 1 in 25 hospitalized persons will acquire at least one infection related to hospital care; additional infections occur in other healthcare settings.[75] Many HAIs are caused by antibiotic-resistant microbials, which lead to complications such as sepsis and eventually death.

The Agency for Health Care Research and Quality (AHRQ) report found that overall hospital-acquired infections and adverse drug events dropped from 99 per 1000 acute care discharges to 86 per 1000 discharges between 2014 and 2017, representing a decrease in 910,000 healthcare-associated conditions. Opportunities to improve patient safety by reducing infections, pressure injuries, and other healthcare-related conditions exist.[76]

Medical errors are a serious public health problem and a leading cause of death in the United States.[77] It is challenging to know a consistent cause of errors and minimize the effects on patient safety. According to the WHO, globally, as many as 4 in 10 persons are harmed in primary and outpatient health care.[78] In high-income countries, it is estimated that 1 in 10 persons is harmed while receiving hospital care,[79] and nearly 50% of harms are preventable.[80] The most detrimental errors are related to diagnosis, prescription, and the use of medicines.[79] Recognizing, improving, and ensuring patient safety is a growing challenge to health service delivery. The 72nd World Health Assembly in 2019 adapted resolution WHA72.6 on global action on patient safety, the Global Patient Safety Action Plan 2021 to 2030. It has urged member states, and where applicable, regional economic integration organizations to recognize patient safety as a health priority.[81] Maintaining a culture that works toward recognizing safety challenges and implementing solutions, rather than harboring a culture of blame, shame, and punishment, is important. Healthcare organizations and hospitals need a culture that focuses on patient safety and system improvement by viewing medical errors as challenges that must be overcome.[77]

The more common terms used to describe and classify unintentional and intentional injuries, and brief descriptions of important features of these injuries are presented in Table 2.8.

Table 2.8

Unintentional and Intentional Injuries

Type of Injury	Description
 A Blunt-Force Injuries	Mechanical injury to body resulting in tearing, shearing, or crushing; most common type of injury seen in healthcare settings; caused by blows or impacts; motor vehicle accidents and falls most common cause (see Photo A)
	Contusion (bruise): Bleeding into skin or underlying tissues; initial color will be red-purple, then blue-black, then yellow-brown or green; duration of bruise depends on extent, location, and degree of vascularization; bruising of soft tissue may be confined to deeper structures; *hematoma* is collection of blood in soft tissue; *subdural hematoma* is blood between inner surface of dura mater and surface of brain; can result from blows, falls, or sudden acceleration/deceleration of head as occurs in *shaken baby syndrome; epidural hematoma* is collection of blood between inner surface of skull and dura; is most often associated with a skull fracture *Laceration:* Tear or rip resulting when tensile strength of skin or tissue is exceeded; is ragged and irregular with abraded edges; an extreme example is *avulsion*, where a wide

Type of Injury	Description
	area of tissue is pulled away; lacerations of internal organs are common in blunt-force injuries; lacerations of liver, spleen, kidneys, and bowel occur from blows to abdomen; thoracic aorta may be lacerated in sudden deceleration accidents; severe blows or impacts to chest may rupture heart with lacerations of atria or ventricles *Fracture:* Blunt-force blows or impacts can cause bone to break or shatter (see Chapter 44)
 Sharp-Force Injuries	Cutting and piercing injuries accounted for 2734 deaths in 2007; men have a higher rate (1.37/100,000) compared with women (0.44/100,000); differences by race are as follows: whites 0.71/100,000; blacks 2.12/100,000; and other groups 0.80/100,000
	Incised wound: A wound that is *longer* than it is *deep;* wound can be straight or jagged with sharp, distinct edges without abrasion; usually produces significant external bleeding with little internal hemorrhage; these wounds are noted in sharp-force injury suicides; in addition to a deep, lethal cut, there will be superficial

Type of Injury	Description
	incisions in same area called *hesitation marks* (see Photo B) *Stab wound:* A penetrating sharp-force injury that is *deeper* than it is *long;* if a sharp instrument is used, depths of wound are clean and distinct but can be abraded if object is inserted deeply and wider portion (e.g., hilt of a knife) impacts skin; depending on size and location of wound, external bleeding may be surprisingly small; after an initial spurt of blood, even if a major vessel or heart is struck, wound may be almost completely closed by tissue pressure, thus allowing only a trickle of visible blood despite copious internal bleeding *Puncture wound:* Instruments or objects with sharp points but without sharp edges produce puncture wounds; classic example is wound of foot after stepping on a nail; wounds are prone to infection, have abrasion of edges, and can be very deep *Chopping wound:* Heavy, edged instruments (axes, hatchets, propeller blades) produce wounds with a combination of sharp- and blunt-force characteristics

Type of Injury	Description
 Gunshot Wounds	Accounted for >33,636 deaths in the United States in 2015; men more likely to die compared with women (18.16 vs. 2.73/100,000); black men ages 15–24 years have greatest death rate (86.95/100,000); gunshot wounds are either penetrating (bullet remains in body) or perforating (bullet exits body); bullet also can fragment; most important factors or appearances are whether it is an entrance or exit wound and range of fire
	Entrance wound: All wounds share some common features; overall appearance is most affected by range of fire
	Contact range entrance wound: Distinctive type of wound when gun is held so muzzle rests on or presses into skin surface; there is searing of edges of wound from flame and soot or smoke on edges of wound in addition to hole; hard contact wounds of head cause severe tearing and disruption of tissue (because of thin layer of skin and muscle overlying bone); wound is gaping and jagged, known as *blow back;* can produce a patterned abrasion that mirrors weapon used (see Photo C)
	Intermediate (distance) range entrance wound: Surrounded by gunpowder tattooing or stippling; *tattooing* results from fragments of burning or unburned pieces of gunpowder

Type of Injury	Description
	exiting barrel and forcefully striking skin; *stippling* results when gunpowder abrades but does not penetrate skin (see Photo D) *Indeterminate range entrance wound:* Occurs when flame, soot, or gunpowder does not reach skin surface, but bullet does; *indeterminate* is used rather than *distant* because appearance may be same regardless of distance; for example, if an individual is shot at close range through multiple layers of clothing, the wound may look the same as if the shooting occurred at a distance *Exit wound:* Has the same appearance regardless of range of fire; most important factors are speed of projectile and degree of deformation; size cannot be used to determine whether hole is an exit or entrance wound; usually has clean edges that can often be reapproximated to cover defect; skin is one of toughest structures for a bullet to penetrate; thus it is not uncommon for a bullet to pass entirely through body but stopp just beneath skin on "exit" side
	Wounding potential of bullets: Most damage done by a bullet is a result of amount of energy transferred to tissue impacted; speed of bullet has much greater effect than increased size; some bullets are designed to expand or fragment when striking an

Type of Injury	Description
	object, for example, *hollow-point* ammunition; lethality of a wound depends on what structures are damaged; wounds of brain may not be lethal; however, they are usually immediately incapacitating and lead to significant long-term disability; a person with a "lethal" injury (wound of heart or aorta) also may not be immediately incapacitated

Asphyxiation

Asphyxial injuries are caused by the failure of cells to receive or use oxygen. Deprivation of oxygen may be partial *(hypoxia)* or total *(anoxia)*. Asphyxiation can be grouped into four general categories: *suffocation, strangulation, chemical asphyxiants*, and *drowning*.

Suffocation

Suffocation, or the process of dying as a result of lack of oxygen, can result from either a *lack of oxygen in the environment* or from a *blockage of the respiratory airways* (see Choking Asphyxiation section below). Persons can become entrapped in an enclosed space that is lacking in adequate oxygen. This scenario will occur if a child becomes trapped in an abandoned refrigerator or if a toddler's head becomes entangled in a plastic bag. Both scenarios have been linked to fatalities. Unintentional suffocation is the leading cause of injury death among infants <1 year old in the United States, and about 82% are attributable to accidental suffocation and strangulation in bed. Investigators analyzed data from 2011 to 2014 and found cases were most frequently attributed to soft bedding (69%), followed by overlay (19%) and wedging. Soft bedding deaths occurred most often in an adult bed (49%), in a prone position (82%), with a blanket/s obstructing the airway (34%). Overlay deaths occurred most often in an adult bed (71%), overlaid by the mother (47%). Wedging deaths occurred most often when the infant became entrapped between the mattress and a wall (48%).[82] Suffocation also can occur when another gas displaces oxygen in the environment. Methane, the largest

component of sewer gas, has caused fatal asphyxiation when it has displaced atmospheric oxygen. Children have died from methane asphyxiation shortly after falling into a pit containing sewage; rescue workers have a very narrow time frame in which to save the child. Volcanos have been known to belch carbon dioxide (CO_2) gas in amounts sufficient to displace the normal oxygen level in the atmosphere for several miles, resulting in widespread death of humans and animals within the area. Normal ambient oxygen level in the atmosphere is 21%. A reduction to a level of 16% poses immediate danger. If the level drops below 5%, death can ensue within minutes. History and forensic examination are important in diagnosing suspected asphyxiation because even autopsy may not demonstrate specific physical findings in such cases.

Choking asphyxiation occurs when there is an obstruction of the pulmonary airways. An object may become lodged in a large airway, directly obstructing breathing. Injury or disease also may result from soft tissue swelling surrounding the airway, leading to a partial or complete obstruction and subsequent asphyxiation. Treatment requires locating and removing the obstructing object immediately or, in the case of airway swelling, reversing the swelling before asphyxiation occurs. *Compressional asphyxiation* occurs when mechanical compression of the chest or abdomen prevents normal respiratory movements. Usual signs and symptoms include florid facial congestion and *petechiae* (pinpoint skin hemorrhages) of the eyes and face. An individual entrapped beneath a heavy object, which impairs chest expansion, may become asphyxiated.

Strangulation

Strangulation is caused by compression of the blood vessels and air passages resulting from external pressure on the neck. The compression causes hypoxia from impaired blood flow to the brain. The amount of force needed to compress the jugular veins (2 kg) or carotid arteries (5 kg) is significantly less than the force required to crush the trachea (15 kg). Injury or death, which occurs secondary to strangulation, results from the impaired cerebral blood flow, not from lack of airflow. With a complete blockage of the carotid arteries, unconsciousness will typically occur within 10 to 15 seconds.

Hanging strangulation occurs when a noose or similar object is placed around the neck, after which the support under the victim's feet is

suddenly removed so that the body falls freely. Death or severe injury results as the noose tightens, cutting off airflow through the trachea. Hanging strangulation is usually an intentional event, such as suicide, homicide, or a judicial hanging. However, it can also be accidental. This form of strangulation typically produces severe soft tissue injury and cervical spinal trauma. The body does not need to be completely suspended for death to occur. Hanging may cause petechiae in the eyes or face; however, this finding is uncommon. More typically, an inverted V–shaped ligature mark about the neck is seen at autopsy.

Ligature strangulation does not require suspension. Instead, some form of cord encircles and tightens about the neck. This event may be intentional, as in the case of homicide with use of a garrote from behind the victim. It also may be accidental, as when a child becomes accidentally entangled in cords of window blinds. Autopsy will reveal a horizontal mark about the neck, without an inverted V pattern. Petechiae are more common in this scenario because intermittent opening and closure of the blood vessels may occur as a result of the victim's struggle. Internal injuries of the neck are rare.

Manual strangulation occurs when an assailant's hands compress the neck of the victim to the point where death by asphyxiation occurs. There is evidence of variable amounts of external trauma to the neck. Contusions and abrasions are either caused directly by the assailant or by the victim clawing at their own neck in an attempt to remove the assailant's hands. Internal damage can be quite severe; bruising of deep structures, including fractures of the hyoid bone, the tracheal cartilage, and the cricoid cartilages occur. Petechiae are common. Non-fatal strangulation (NFS) can be a cause of serious injury.[83]

Chemical asphyxiants

A number of substances can act as chemical asphyxiants. They either prevent the delivery of oxygen to the tissues or block oxygen utilization. Carbon monoxide is the most common chemical asphyxiant. Carbon monoxide (CO) is an odorless, colorless, nonirritating, and undetectable gas; it is often mixed with a visible or odorous compound. CO is produced by incomplete combustion of fuels, such as gasoline. CO produces hypoxic injury, specifically, oxygen deprivation. As a systemic asphyxiant, CO causes death by inducing CNS depression. Normally, oxygen molecules are carried to tissues bound to the hemoglobin in RBCs.

Because the affinity of CO for hemoglobin is 300 times greater than that of oxygen, CO quickly binds with hemoglobin, preventing oxygen molecules from binding to hemoglobin, and they are thus transported to tissues. Minute amounts of CO can produce a significant percentage of *carboxyhemoglobin* (carbon monoxide bound with hemoglobin). With increasing levels of carboxyhemoglobin, hypoxia occurs insidiously, evoking widespread ischemic changes in the CNS. Individuals are often unaware of exposure. Death may occur in an individual who believes they are simply feeling sleepy; thus no evasive action is taken. The use of CO monitors in homes is therefore strongly recommended. Diagnosis can be made from the measurement of carboxyhemoglobin levels in blood. Victims of CO poisoning may have a cherry red coloration to the skin and mucous membranes.

Symptoms related to CO poisoning include headache, giddiness, tinnitus (ringing in the ears), chest pain, confusion, nausea, weakness, and vomiting. CO is an environmental air pollutant found in combustion fumes produced by cars and trucks, small gasoline engines, stoves, gas ranges, gas refrigerators, heating systems, lanterns, burning charcoal or wood, and cigarette smoke. Chronic exposure can occur in people working in confined spaces, such as underground garages and tunnels. Fumes can accumulate in enclosed or semi-enclosed spaces. Individuals most susceptible to CO poisoning are fetuses, infants, and people with chronic heart disease, respiratory problems, and anemia.

Cyanide is an extremely toxic salt. Cyanide acts as an asphyxiant by combining with the ferric (iron) ion in hemoglobin, facilitating its transport to tissues. When present in tissues, cyanide inhibits the formation of cytochrome oxidase by interrupting the electron transport chain within the mitochondria. As a result, the mitochondria can no longer aerobically generate ATP, and oxygen can no longer bind to the final molecule in the electron transport chain. The host dies from oxygen deprivation, even though abundant oxygen may be present. As with CO poisoning, victims of cyanide poisoning may have a cherry red coloration to the skin and mucus membranes. With the presence of cyanide, an odor of bitter almonds may be detected; however, the ability to smell cyanide is a genetic trait that is present in only 20% to 40% of the general population.

Hydrogen sulfide, one of several sewer gases, is a chemical asphyxiant and neurotoxin; it interferes with the body's ability to carry oxygen. It has a characteristic “rotten egg” odor that is detectable even at very low levels.

Victims of hydrogen sulfide poisoning may have brown-tinged blood in addition to the nonspecific signs of asphyxiation. Methane, another sewer gas, is nontoxic but readily causes asphyxiation by displacing oxygen. Because of the presence of asphyxiant gases, caution is indicated when working in areas containing septic tanks, cesspools, and manure pits. Numerous fatalities have occurred in persons working in these environments.

Drowning

Drowning is death from inhalation of and suffocation by a liquid, usually water. Drowning ranks fifth among the unintentional injury death in the United States[84] and is the third leading cause of unintentional injury death worldwide, accounting for 7% of all injury-related deaths.[85,86] An estimated 236,000 annual drowning deaths occur worldwide. In the United States, drowning is the second leading cause of unintentional injury death in children aged 1 to 14 years. Males have the highest risk of drowning, with twice the mortality rate of females.[85] The major mechanism of injury is hypoxemia (low blood oxygen levels). Contrary to previous prevailing views, there is no evidence that drowning deaths result from fluid and electrolyte disturbances or from blood hemolysis. In freshwater drownings, large amounts of water can pass through the alveolar–capillary interface. Even in this setting, there is no evidence that an increase in blood volume results in either hemolysis or electrolyte derangements. With drowning, airway obstruction is the more important consideration because, in as many as 15% of drownings, little or no water enters the lungs. Vagal-mediated laryngospasms may close off the airway producing a phenomenon known as dry-lung drowning.

Regardless of the mechanism, cerebral hypoxia leads to unconsciousness in a matter of minutes. Whether this status progresses to death depends on several factors, including the age and the health of the individual. One of the most important determinants is water temperature. Irreversible injury develops much more rapidly in warm water than in cold water. Survival after up to 1 hour has been reported in children who were submerged in very cold water. Complete submersion is not enough to cause drowning. An incapacitated or helpless individual (e.g., persons with epilepsy or alcoholism, infants) may drown in water only a few inches deep.

No specific or diagnostic findings *prove* that a person recovered from the water is actually a drowning victim. In cases where water has entered the lung, there may be large amounts of foam exiting the nose and mouth. This same phenomenon, however, could occur with other causes of death, including drug overdoses. A body recovered from water could have been that of a victim of some other type of fatal injury. Drowning may represent an effort to obscure the actual cause of death. When treating a living victim recovered from water, it is essential to keep an index of suspicion for any underlying condition that may have predisposed the person to become incapacitated, causing him or her to fall into the water.

Infectious Injury

The pathogenicity (virulence) of microorganisms lies in their ability to survive and proliferate within the host. The disease-producing potential of a microorganism is a function of its ability to (1) invade and destroy cells, (2) produce toxins, and (3) produce damaging hypersensitivity reactions (see Chapter 9).

Immunologic and Inflammatory Injury

Cellular membranes are injured as a result of direct contact with immune or inflammatory-mediated responses, such as phagocytes (lymphocytes and monocytes) and biochemical substances generated during an inflammatory response. Potentially injurious biochemical agents include histamine, antibodies, lymphokines, complement system products, and proteases (see Chapter 7). A variety of mechanisms for potential cellular injury exist. The complement system is responsible for several membrane alterations associated with immunologic injury. Membrane alterations can facilitate a rapid leakage of potassium out of the cell, along with an influx of water. Antibodies can bind and occupy receptor molecules located on the plasma membrane, interfering with its function. Antibodies also can block or destroy cellular junctions, obstructing intercellular communication. Other mechanisms include genetic and epigenetic factors, nutritional imbalances, and physical agents, which are summarized inTable 2.9.

Table 2.9

Examples of Mechanisms of Cellular Injury

Mechanism	Characteristics	Examples
Genetic factors	Alter cell's nucleus and plasma membrane's structure, shape, receptors, or transport mechanisms	Sickle cell anemia, Huntington disease, muscular dystrophy, abetalipoproteinemia, familial hypercholesterolemia See Chapters 4 and 5
Epigenetic factors	Induction of mitotically heritable alterations in gene expression without changing DNA	Gene silencing in cancer See Chapter 6
Nutritional imbalances	Pathophysiologic cellular effects develop when nutrients are not consumed in diet and transported to body's cells *or* when excessive amounts of nutrients are consumed and transported	Protein deficiency, protein-calorie malnutrition, glucose deficiency, lipid deficiency (hypolipidemia), hyperlipidemia (increased lipoproteins in blood causing deposits of fat in heart, liver, and muscle), vitamin deficiencies
Physical Agents		
Temperature extremes	*Hypothermic injury* results from chilling or freezing of cells, creating high	Frostbite (see Chapter 46)

Mechanism	Characteristics	Examples
	intracellular sodium concentrations; abrupt drops in temperature lead to vasoconstriction and increased viscosity of blood, causing ischemic injury, infarction, and necrosis; reactive oxygen species (ROS) are important in this process	
	Hyperthermic injury is caused by excessive heat and varies in severity according to nature, intensity, and extent of heat	Burns, burn blisters, heat cramps usually from vigorous exercise with water and salt loss; heat exhaustion with salt and water loss causes heme contraction; heat stroke is life-threatening with a clinical rectal temperature of 106°F
	Tissue injury caused by compressive waves of air or fluid impinging on body, followed by sudden wave of decreased pressure; changes may collapse thorax, rupture internal solid organs, and cause widespread hemorrhage: carbon dioxide and nitrogen	*Blast injury* (air or immersion), decompression sickness (caisson disease or "the bends"); recently reported in a few individuals with subdural hematomas after riding high-speed roller coasters

Mechanism	Characteristics	Examples
	that are normally dissolved in blood precipitate from solution and form small bubbles (gas emboli), causing hypoxic injury and pain	
Illumination	Fluorescent lighting and halogen lamps create harmful oxidative stresses; ultraviolet light has been linked to skin cancer. Blue light induces ROS and S-opsin (light sensitive protein) aggregation.	Eyestrain, obscured vision, cataracts, headaches, melanoma
Mechanical stresses	Injury is caused by physical impact or irritation; they may be overt or cumulative. *Compression* is a perpendicular force, *tension* is a stretching force, *torsion* is a twisting force. Fluid *shear forces* or layers rubbing against each other.	Faulty occupational biomechanics, leading to overexertion disorders A pile of material squished or compressed together Pulling on a rope is a tension force Torsion when wringing something dry like a wet towel Shear forces in the vascular channels from endothelial cells

Mechanism	Characteristics	Examples
Noise	Can be caused by acute loud noise or cumulative effects of various intensities, frequencies, and duration of noise; considered a public health threat	Hearing impairment or loss; tinnitus, temporary threshold shift (TTS), or loss can occur as a complication of critical illness, from mechanical trauma, ototoxic medications, infections, vascular disorders, and noise

Impacts of Climate Change on Human Health

Climate conditions are changing globally due to increasing levels of greenhouse gases (carbon dioxide, methane, nitrous oxide, and fluorinated gases) in the atmosphere, trapping more and more heat. Anthropogenic activities producing these greenhouse gases have increased (e.g., combustion of fossil fuels, raising of livestock, especially cattle, agricultural practices), and studies indicate a strong correlation between increasing greenhouse gas concentrations in the atmosphere (especially carbon dioxide) and increasing global temperatures. Climate change affects social and environmental determinants of human health, including clean air, safe drinking water, sufficient food, and secure shelter. Climate change will have both direct and indirect effects on human health, and a summary of the main expected health impacts from climate change and climate variability is outlined in the table below (Table 2. 10).

Table 2.10

Summary of Expected Health Impacts of Climate Variability and Climate Change

	Climate Change Effects	Health Risks	Health Impacts
Direct Effects	Increased number of warm days and nights; increased frequency and intensity of heat waves; increased fire risk in low rainfall conditions	Excess heat-related mortality; increased incidence of heat exhaustion and heat stroke; exacerbated circulatory, cardiovascular, respiratory, and kidney diseases; increased premature mortality related to ozone and air pollution produced by fires, particular during heat waves	Increased risk of injury, disease, and death due to more intense heat waves and fires
	Decreased number of cold days and nights	Lower cold-related mortality and reduced cardiovascular and respiratory diseases particularly for the elderly in	Modest improvements in cold-related mortality and morbidity

	Climate Change Effects	Health Risks	Health Impacts
		cold and temperate climates	
Effects mediated through natural systems	Higher temperatures and humidity; changing and increasingly variable precipitation; higher sea surface and freshwater temperatures	Accelerated microbial growth, survival, persistence, transmission, virulence of pathogens; shifting of geographic and seasonal distributions of diseases (e.g., cholera, schistosomiasis) and ecological changes (e.g., harmful algal blooms); lack of water leading to poor hygiene; flood damage to water and sanitation infrastructures contamination of water sources through overflow	Increased risks of food- and water-borne diseases

	Climate Change Effects	Health Risks	Health Impacts
	Higher temperatures and humidity; changing and increasingly variable precipitation	Accelerated parasite replication and increased biting risks; prolonged transmission seasons; re-emergence of formerly prevalent diseases; changing distribution and abundance of disease vectors; reduced effectiveness of vector control interventions	Increases risks of vector-borne diseases
Effects heavily mediated by human systems	Higher temperatures and changes in precipitation	Lower food production in the tropics; lower access to food due to reduced supply and higher prices; combined effects of undernutrition and infectious diseases; chronic effects	Increased risk of undernutrition resulting from diminished food production in poor regions

	Climate Change Effects	Health Risks	Health Impacts
		of stunting and wasting in children	
	Higher temperatures and humidity	Outdoor and unprotected workers obliged to work either in physiologically unsafe conditions or to lose income and livelihood opportunities	Consequences on workers' health include lost work capacity and reduced labor productivity in vulnerable populations

Note. Table adapted from World Health Organization. 2.1 Public health rational. *Operational framework for building climate resilient health systems*; 2015. https://www.who.int/publications-detail-redirect/operational-framework-for-building-climate-resilient-health-systems. Accessed October 1, 2021.

Wildfires are becoming more common and are projected to worsen with climate change. Wildfire smoke can increase ambient air pollution (see section on air pollution). Fires will increase excess mortality and morbidity from burns, smoke, and mental health effects[88–90]; however, data are needed on long-term health effects of wildfire smoke on individuals, including vulnerable populations.[87,91]

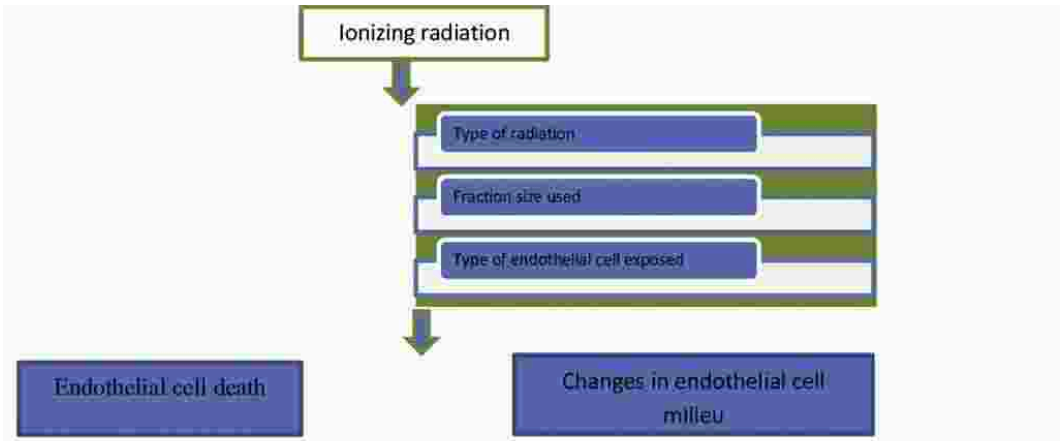
Ionizing Radiation

Ionizing radiation (IR) is any form of radiation capable of removing orbital electrons from atoms, resulting in the production of negatively charged free electrons and positively charged ionized atoms. Ionizing radiation is emitted by x-rays, γ-rays, and alpha and beta particles (which are emitted from atomic nuclei in the process of radioactive decay). Ionizing radiation of three types (x-radiation, gamma radiation, and neutrons) was classified as a carcinogen in 2004.

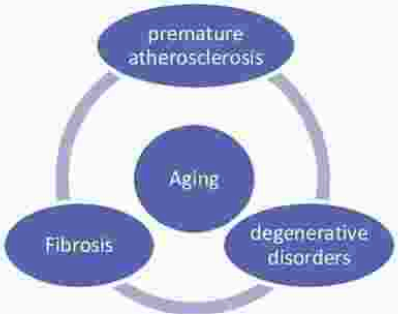
The environment is a source of exposure to IR through emissions from radioactive material, primarily uranium, thorium, and potassium. Other sources of IR are from medical procedures (e.g., x-rays, computed tomography [CT] scans) used to aid in the diagnosis and treatment of disease. Medical radiation now comprises about 48% to 50% of the per capita radiation doses compared with 15% in the 1980s; since 1980, medical radiation exposure has increased 600% in the U.S. population.[92]

The main determinants of the biologic effects of ionizing radiation depend on several factors and include the following:

1. *Rate of delivery*. Because the effect of radiant energy is cumulative, divided doses may allow cells to repair between exposures, called *fractionated doses*. *Field size*. Doses of radiation delivered to shielded smaller fields are safer than smaller doses delivered to larger fields, which may be lethal.1
2. *Cell proliferation*. Rapidly dividing cells are more vulnerable to injury because ionizing radiation damages DNA. Vulnerable tissues have a high rate of cell division and include *gonads, bone marrow, lymphoid tissue*, and the *mucosa of the gastrointestinal tract*. Injury is manifested early after exposure.
3. *Oxygen effects and hypoxia*. A main mechanism of damage to DNA by ionizing radiation is from generation of ROS from reactions with free radicals by radiolysis of water. Tissue with low oxygenation (hypoxia) is less sensitive to radiation, for example, the center of rapidly growing tumors.
4. *Vascular damage*. Endothelial cell damage is an important effect of radiotherapy and can result in narrowing or occlusion of blood vessels, leading to impaired healing, fibrosis, and chronic ischemic atrophy. These changes can appear months or years after exposure. Radiation both initiates and accelerates atherosclerosis, leading to stroke, coronary artery disease, and peripheral artery disease (Fig. 2.26).[93–95]



1. Apoptosis (acute) - bone marrow, CNS injury, radiation enteropathy ▪ p53-mediated ▪ Sphingomyelin ceramide pathway 2. Endothelial cell senescence (chronic) - CAD, PAD, CVA, aging ▪ PI3K/Akt/mTOR ▪ Insulin-like growth factor ▪ IGFBP-5 ▪ CD44 ▪ PLAT ▪ JAGGED-1 ▪ SPRY-4 ▪ NEMO ▪ XIAP	1. Cell adhesion molecules ▪ ↑ selectin, integrin, immunoglobulin family 2. Coagulation status ▪ ↓ thrombomodulin, ↑thrombin and platelet activation ▪ ↑ circulating vWF 3. Reactive oxygen species ▪ ↑ superoxide, peroxynitrite 4. Cytokines ▪ ↑ IL-1,IL-6,IL-8,TNFα-reactive protein 5. Angiogenic pathways ▪ ↑ type III collagen, PAI-1, SMA 6. Metabolic pathways ▪ ↑ glycolysis, altered mitochondrial oxidation and lipid pathways 7. Immunologic alterations ▪ ↑ TLR, ↑CXCL6 overt immune activation



A

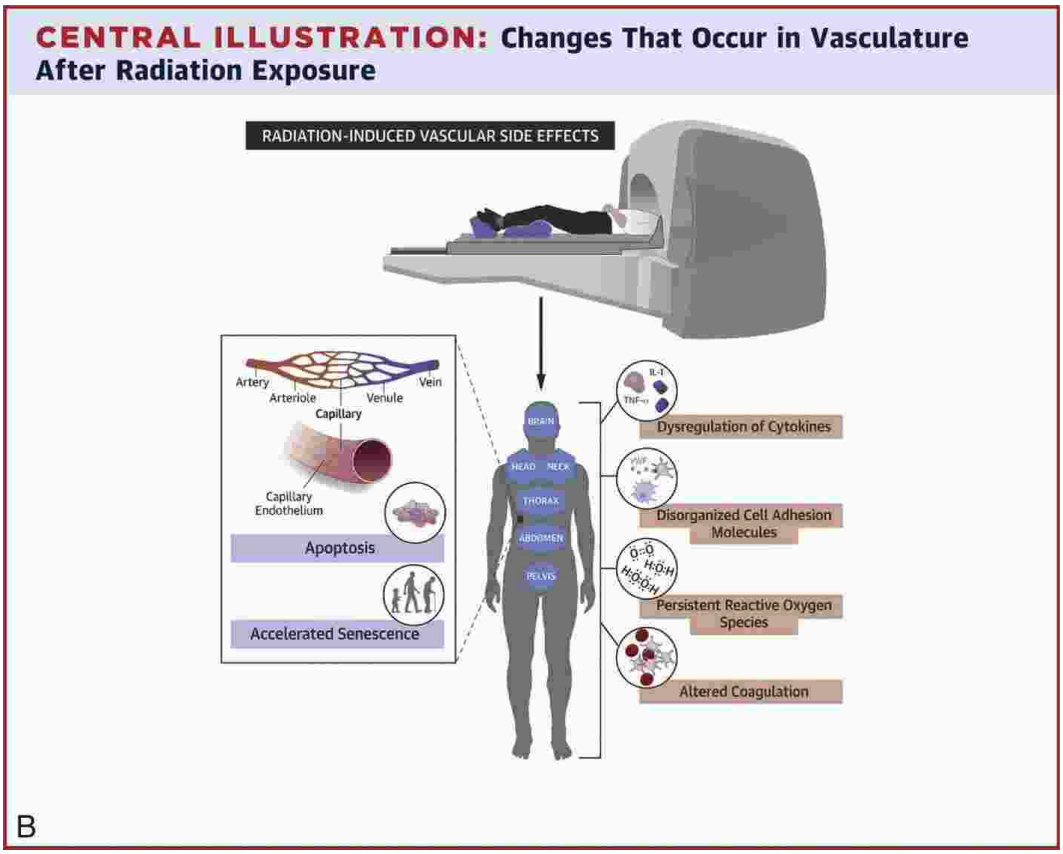


FIG. 2.26 Radiation and Vascular Damage: A Working Model.
(A) Proposed Changes in Endothelial Cells. **(B)** Changes that occur in vasculature after radiation. *IGFBP5*, Insulin-like growth factor binding protein 5; *PLAT*, tissue plasminogen activator; *JAGGED-1*, a cell surface protein; *SPRY4*, gene; *NEMO*, NF-kappa-B essential modulator; *XIAP*, X-linked inhibitor of apoptosis; *vWF*, Von Willebrand factor; *IL*, interleukin; *TNFα*, tumor necrosis factor alpha; *TLR*, toll-like receptors. (B, From Venkatesulu BP, Mahadevan LS, Aliru ML, et al. Radiation-induced endothelial vascular injury. *JACC: Basic to Translational Science*, 2018;3[4]:563–572.)

Illustration A represents proposed changes in endothelial cells. Ionizing radiation leads to endothelial cell death or changes in endothelial cell milieu, depending on the type of radiation, fraction size used, and the type of endothelial cell exposed. The following two changes are

identified in endothelial cell death. 1. Apoptosis (acute): bone marrow, C N S injury, radiation enteropathy: p 53 mediated or sphingomyelin ceramide pathway. 2. Endothelial cell senescence, chronic, C A D, P A D, C V A, and aging: P I 3 K per A k t per m T O R, Insulin-like growth factor, I G F B P-5, C D 44, P L A T, J A G G E D-1, S P R Y-4, N E M O, and X I A P. The following seven changes are identified under changes in endothelial cell milieu. 1. Cell adhesion molecules: increased selectin, integrin, immunoglobulin family. 2. Coagulation status: decreased thrombomodulin, increased thrombin and platelet activation, decreased circulating v W F. 3. Reactive oxygen species: increased superoxide, peroxynitrite. 4. Cytokines: increased I L-1, I L-6, I L-8, T N F alpha-reactive protein. 5. Angiogenic pathways: increased glycolysis, altered mitochondrial oxidation and lipid pathways. 7. Immunologic alterations: increased T L R, increased C X C L 6 overt immune activation. Death or changes in endothelial cells result in aging: premature atherosclerosis, degenerative disorders, and fibrosis. Illustration B is titled, Central Illustration: Changes That Occur in Vasculature After Radiation Exposure. A diagram illustrates a person undergoing a C T scan. An accompanying diagram of a human body shows and identifies the following parts as being affected: brain, head, neck, thorax, abdomen, and pelvis. Effects include dysregulation of cytokines, disorganized cell adhesion molecules, persistent reactive oxygen species, and altered coagulation. A closeup of a capillary endothelium shows and labels the following parts: artery, arteriole, capillary,

venule, and vein. It also illustrates apoptosis and accelerated senescence.

Late effects in tissues with a low rate of cell proliferation (brain, kidney, liver, muscle, subcutaneous tissue) may include cell death, atrophy, and fibrosis. These effects are associated with vascular damage from the release of proinflammatory mediators in irradiated tissue.[1]

Cellular damage from IR in the absence of effective repair involves two types of damage: (1) early or late tissue reactions (previously called *deterministic*) and (2) stochastic (those that occur by chance) or random effects. High doses of radiation cause substantial cell death and result in detectable tissue reactions within days (early) or sometimes months to years (late) after exposure (Fig. 2.27).

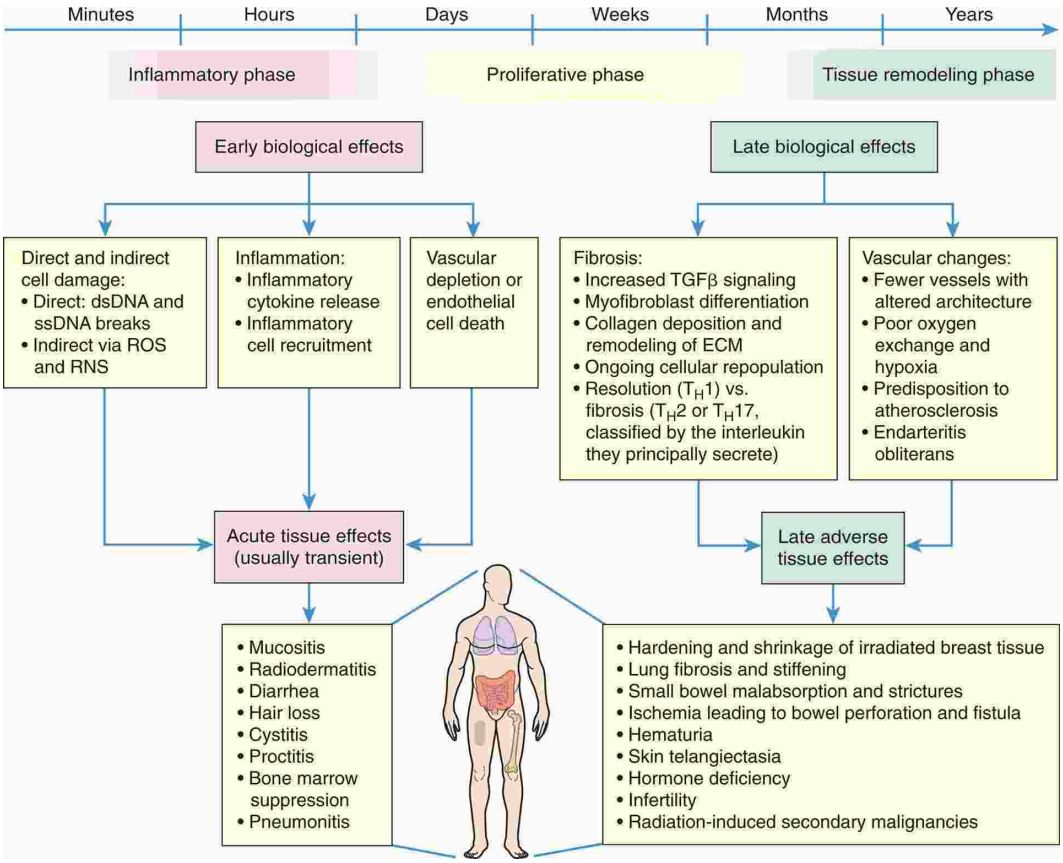

FIG. 2.27 Early and Late Tissue Effects of Radiation. Early biologic events cause acute effects that are normally transient and resolve within 3 months of completing therapy. These events can lead to biologic effects over time, for example, fibrosis, vascular changes, and secondary malignancies. Severity is increased for these biologic effects with higher radiation dose per fraction. *dsDNA*, Double-stranded DNA; *ECM*, extracellular matrix; *ROS*, reactive oxygen species; *RNS*, reactive nitrogen species; *ssDNA*, single-stranded DNA; *TGFβ*, transforming growth factor-beta; *TH*, T helper cell. (From International Commission on Radiological Protection. Ann ICRP. 2012;41[1/2]).

A timeline and two flow diagrams represent early and late tissue effects of radiation. The timeline shows minutes, hours, days, weeks, months, and years.

Inflammatory phase occurs between minutes and hours. Proliferative phase occurs between days and weeks. Tissue remodeling phase occurs between months and years. The first flow diagram represents early biological effects. There are three effects. 1. Direct and indirect cell damage. Direct: d s D N A and s s D N A breaks. Indirect via R O S and R N S. 2. Inflammation including inflammatory cytokine release and inflammatory cell recruitment. 3. Vascular depletion or endothelial cell death. All three effects result in acute tissue effects, usually transient, and can lead to the following: mucositis, radiodermatitis, diarrhea, hair loss, cystitis, proctitis, bone marrow suppression, and pneumonitis. The second flow diagram represents late biological effects. There are two effects. 1. Fibrosis: increased T G F beta signaling, myofibroblast differentiation, collagen deposition and remodeling of E C M, ongoing cellular repopulation, and resolution T H 1 bs fibrosis T H 2 or T H 17, classified by the interleukin they principally secrete. 2. Vascular changes: fewer vessels with altered architecture, poor oxygen exchange and hypoxia, predisposition to atherosclerosis, and endarteritis obliterans. Both effects lead to late adverse tissue effects and can result in the following: hardening and shrinkage of irradiated breast tissue, lung fibrosis and stiffening, small bowel malabsorption and strictures, ischemia leading to bowel perforation and fistula, hematuria, skin telangiectasia, hormone deficiency, infertility, and radiation-induced secondary malignancies.

IR can cause a large spectrum of genetic changes because all phases of the cell cycle can be affected. Irradiation during mitosis induces chromosomal aberrations. DNA may be damaged *directly* or *indirectly* by interaction with reactive products (e.g., free electrons, hydroxyl radicals, hydrogen free radicals) (Fig. 2.28).

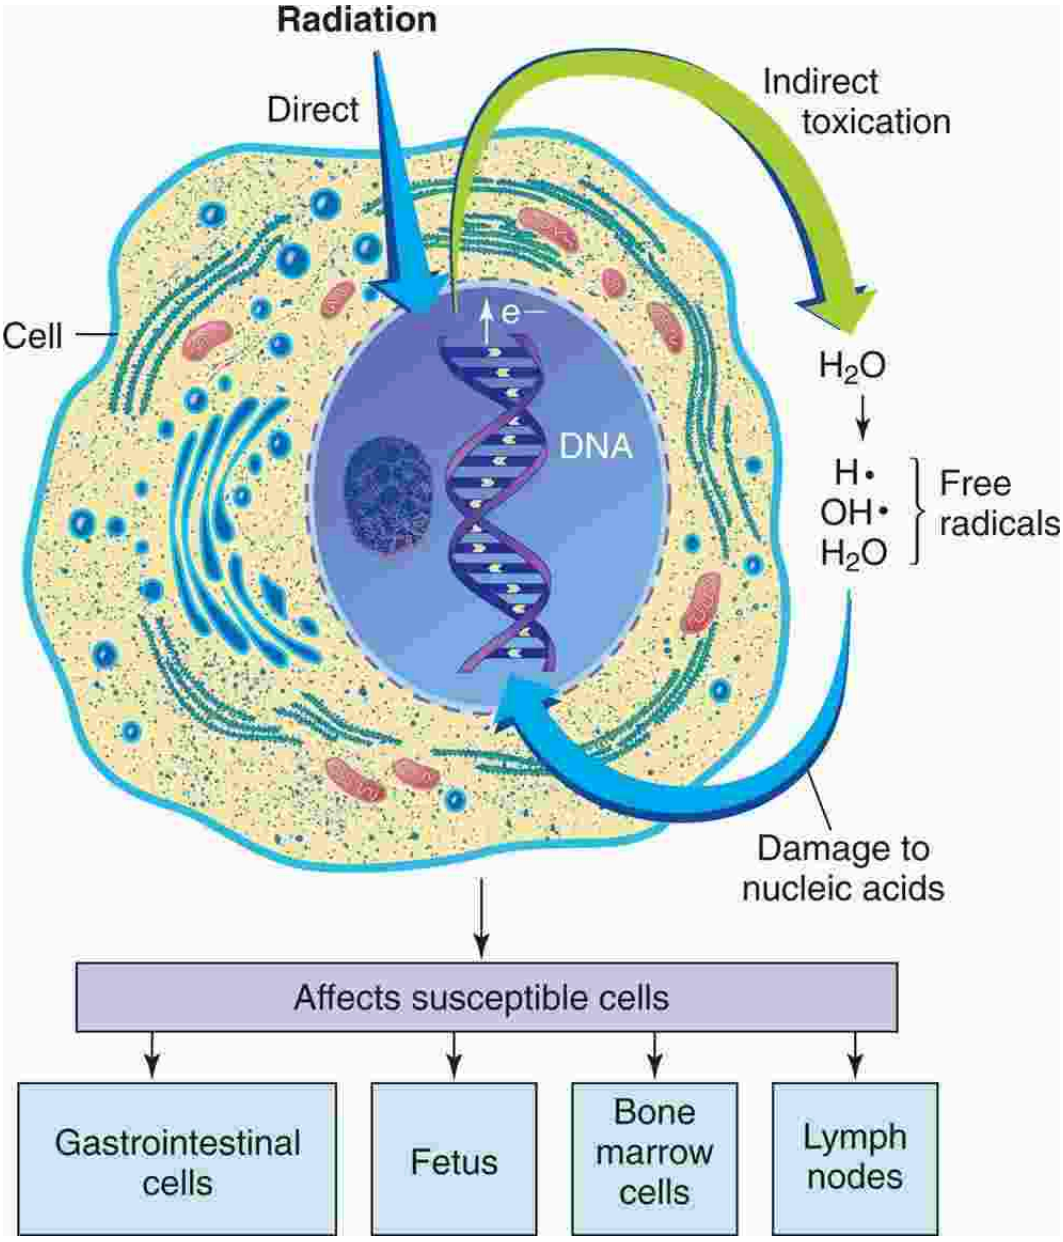

FIG. 2.28 Cellular Damage Caused by Ionizing Radiation.

Radiation can damage macromolecules in two ways: (1) directly, in which the micromolecules are ionized and (2) indirectly, in which water is ionized and produces free radicals that in turn damage macromolecules. Cells that are particularly susceptible to damage are those of the gastrointestinal tract, bone marrow, lymph nodes, fetus, and ovarian follicles.

A diagram of a cell shows radiation directly affecting the D N A. Water produces free radicals in indirect toxication: H, O H, and H 2 O. This in turn results in damage to nucleic acids, forming a cycle. Radiation affects susceptible cells, resulting in gastrointestinal cells, fetus, bone marrow cells, and lymph nodes.

Stochastic effects are produced at random, without a threshold level of dose, and the main effects include carcinogenesis and genetic mutation. The severity of the outcome is *not* related to dose but rather to the entire tissue and stress response.[96,97] More simply, IR causes damage that initiates DNA repair mechanisms, alterations in gene expression, and various stress responses.

The nontargeted effects of IR include bystander effects and genomic instability. Bystander effects, or effects on cells not directly in the radiated field, are affected by the radiation and show high levels of mutations, chromosomal aberrations, and membrane signaling changes leading to what some call "horizontal transmission." Stress response signals can generate between cells damaged by targeted effects of IR.[98] Current study includes the bystander effects and the role of exosomes mediating microRNA transfer and communication between the directly irradiated cells and the nonirradiated cells (also see Chapters 12 and 13).[99]

Radiation-induced genomic instability (RIGI) is where generations of cells derived from an irradiated progenitor cell appear normal, but time-lethal (i.e., irreversible) and nonlethal mutations appear in distant offspring, sometimes called "vertical transmission."[100,101] Genomic instability is associated with a diverse set of biological endpoints (see Chapter 4) and is present in the majority of cancers, which drive tumor development and evolution.[101] Importantly, a new paradigm shift of the effects of IR or radiobiology is occurring (also see Chapter 13). These effects represent a tissue response or cell stress response from IR. Not all cells and tissues have the same sensitivity to radiation, although all cells can be affected. Radiosensitivity depends partly on the rate of mitosis and cellular maturity. Because fetal cells are both immature and undergoing rapid cycling, the fetus is at great risk for injury caused by IR. Particularly

vulnerable are embryonic germ cells, which are precursors of ova and sperm. Throughout life, cells of the bone marrow, intestinal mucosa, testicular seminiferous epithelium, and ovarian follicles are susceptible to injury because they are always undergoing mitosis, which ensures the presence of vulnerable, immature daughter cells. In utero radiation exposure in the Japanese A-bomb survivors was associated with an increased adult-onset risk of solid tumors.[102] The studies of diagnostic x-rays in utero revealed a risk of pediatric leukemia and other cancers.[97]

Therefore, other imaging modalities, including magnetic resonance imaging (MRI), plain radiograph, ultrasound, and nuclear medicine studies, should be considered first before performing CT.[103] For example, presentations such as appendicitis first require evaluation with MRI instead of CT.[104] For evaluating intra-abdominal trauma, it is crucial to optimize CT setting to minimize the dose. CT protocols should be optimized to minimize unnecessary radiation exposure, and unnecessary multiphasic protocols should get simplified into a single-phase protocol. Plain films are obtained more frequently than CTs, but multiple plain films can easily accumulate. Technologists should optimally position individuals to avoid repeat examinations. Radiographs are only obtained when it is critical for clinical management.[103]

The International Commission on Radiological Protection (ICRP) emphasizes that protection should be optimized for whole-body exposures and for specific tissues, particularly the lens of the eye, the heart, and the cerebrovascular system.[105]

Radiation-induced cancers are also found in the "cancer-prone" ages (usually 50 to 80 years of age), independent of age at exposure; therefore, the latency period between radiation exposure and the potential appearance of a cancer decreases significantly with increasing age at exposure.[106]

Changes in Atmospheric Pressure

Sudden increases or decreases in atmospheric pressure cause blast injury, which can be transmitted by either air (air blast) or water (immersion blast). With sudden increases in pressure, tissue injury is caused by compressive waves of air impinging on the body, followed by a sudden wave of decreased pressure. The pressure changes may collapse the thorax, rupture internal solid organs, and cause widespread hemorrhage.

In increased pressure caused by immersion blast, water pressure is applied suddenly to all sides of the body, forcing the body up out of the water. The positive pressure compresses the abdomen and ruptures hollow internal organs, such as the spleen, kidneys, and liver.

Decompression Sickness

Decompression sickness (DCS) (diver disease, the bends, or caisson disease) is a condition arising with sudden decreases in pressure; carbon dioxide and nitrogen that are normally dissolved in the blood come out of solution and form tiny bubbles called *gas emboli*. Deep-sea divers, scuba divers, and underwater construction workers who return to the surface too quickly develop DCS. The incidence of DCS is rare with a greater (2.5 times) risk for males than females.[107] Individuals presenting with clinical manifestations involving only the skin, musculoskeletal system, or lymphatic systems are considered to have Type I DCS; individuals with type II DCS have symptoms associated with the CNS (headache and visual disturbances).[107] Oxygen is quickly redissolved, but nitrogen bubbles may persist and obstruct blood vessels. Ischemia resulting from gas emboli causes cellular hypoxia, particularly in the muscles, joints, and tendons. Emboli and interstitial gas accumulate around the joints and skeletal muscles, causing the individual to bend in pain. Tissues of the heart and brain also may be affected by emboli, causing necrosis. Dehydration increases the risk of decompression sickness because immersion of the body in water increases venous return to the heart. As a counter-regulatory measure, the cardiac atria secrete atrial natriuretic peptide (ANP), causing diuresis (the Gauer-Henry reflex). At the same time, with a decreased secretion of ADH from the hypothalamus, the kidneys excrete water. The result is a reduction of blood volume. During ascent, fluid is lost in expired air. The total volume deficiency changes the rheological (flow of matter) dynamics in blood and promotes the onset of decompression sickness.[108,109] The gases can be promptly redissolved in blood by raising the atmospheric pressure, which is accomplished by placing the individual in a decompression chamber and increasing the pressure until it approximates pressure at the depth to which the diver had descended. This redissolves the gas bubbles in the blood. Pressure is then decreased gradually until it equals the pressure at the surface of the water. This slows the release of gas bubbles out of solution.

Nitrogen concentrations can have a crippling anesthetic effect on the brain. This narcosis has been referred to as "rapture of the deep," where both physical and cognitive abilities may be seriously impaired.[110] Thus, when a person dives to great depths, both the volume of nitrogen and the volume of oxygen must be decreased. This is accomplished by the addition of an "inert" gas (one that has no metabolic activity within the body). It has been suggested that problems associated with deep, long-duration dives could be avoided by replacing the nitrogen in a diver's gas supply with helium, an inert gas and nature's second lightest gas.[111] Helium has not been shown to have an anesthetic or narcotic effect on divers at depth breathing compressed gases, but it does inflict a greater decompression burden upon divers as compared to nitrogen.[112] Decompression sickness also can happen with very rapid ascent to high altitude in an aircraft that is not properly pressurized.[113] Although decompression sickness is not a concern when people ascend slowly (e.g., on foot) to a low atmospheric pressure environment, such as altitudes higher than 10,000 feet, there is a significant decrease in available oxygen because of decreased partial pressure of the inspired gases. The hypoxemia that occurs may result in pathologic conditions unique to the hypoxic environment at high altitude.

High-Altitude Illness: HAPE, HACE, AMS

High-altitude illness, in the form of high-altitude pulmonary edema (HAPE) or high-altitude cerebral edema (HACE), is potentially fatal.[114] A less serious and more common form of HAI is acute mountain sickness (AMS). HAI is due to hypobaric (having a specific gravity lower than that of cerebrospinal fluid) hypoxia, is not associated with age or physical conditioning, and is easily treated when mild.[115] Several factors are proposed to influence AMS, including rate of ascent to altitude, final altitude reached, altitude at which a person sleeps, and individual physiologic differences.[116] Other risk factors that magnify the effects of hypoxia include certain preexisting cardiopulmonary conditions, residence at low altitude, prior history of high-altitude illness, and level of exertion at altitude.[114,117]

AMS is defined as the presence of a combination of nonspecific symptoms that appear within a few hours after ascent to altitude and may include headache, loss of appetite, nausea, vomiting, weakness, lassitude,

dizziness, and difficulty sleeping.[117,118]Fig. 2.29 summarizes current hypotheses of the pathophysiology of AMS and HACE. Symptoms are usually most noticeable during the first few days at altitude and may reappear on further ascent to a higher altitude. AMS is usually a relatively benign, self-limited condition and does not include abnormal neurologic symptoms or signs. An increase in severity of symptoms or signs of neurologic dysfunction, such as ataxia or altered consciousness, indicates transition to HACE.[119]

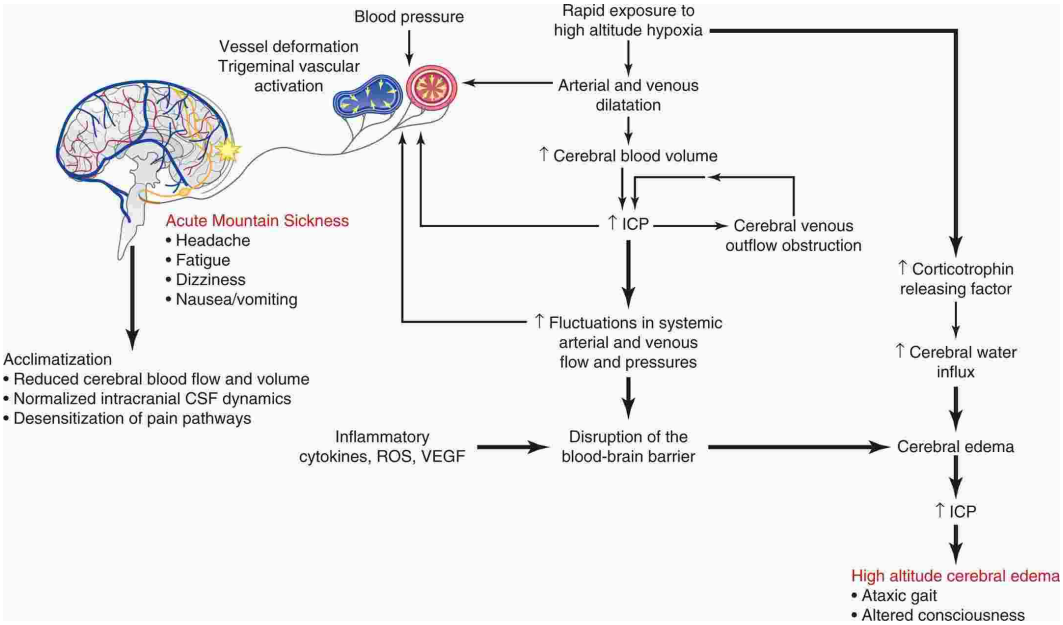

FIG. 2.29 Working Model of Pathophysiology of Acute mountain Sickness and High-Altitude Cerebral Edema.
Rapid exposure to high-altitude hypoxia results in changes in cerebral blood flow and volume that can cause acute mountain sickness. With acclimatization, most individuals will recover. Some individuals progress to sustained increases in ICP with decreased cerebral venous outflow, alterations in vascular pressures and flow, inflammation, loss of the integrity of the blood brain barrier, and changes in hypothalamic hormone release. The result is high-altitude cerebral edema, which can be fatal. *ICP*, Intracranial pressure; *ROS*, reactive oxygen species; *VEGF*, vascular endothelial growth factor. (Modified from Davis, C, Hackett, P. Advances in the prevention and treatment of high-altitude illness. *Emergency Medicine Clinics of North America*, 2017;35[2]:241–260.)

An illustrated flow diagram represents the working model of pathophysiology of acute mountain sickness and high-altitude cerebral edema. Rapid exposure to high altitude hypoxia results in arterial and venous

dilatation and increased corticotrophin releasing factor. Increased corticotrophin releasing factor leads to increased cerebral water influx, resulting in cerebral edema. Cerebral edema results in increased I C P. Arterial and venous dilatation results in a three-stage cycle: increased cerebral blood volume, I C P, and cerebral venous outflow obstruction. This further leads to increased fluctuations in systemic arterial and venous flow and pressures, resulting in disruption of the blood-brain barrier. Inflammatory cytokines, R O S, and V E G F also lead to disruption of the blood-brain barrier, and thus, cerebral edema. The three-stage cycle and fluctuations in systemic arterial and venous flow and pressures also lead to blood pressure and vessel deformation and trigeminal vascular activation. This leads to acute mountain sickness or acclimatization. Acute mountain sickness includes headache, fatigue, dizziness, and nausea or vomiting. Acclimatization includes reduced cerebral blood flow and volume, normalized intracranial C S F dynamics, and desensitization of pain pathways.

HACE is a clinical diagnosis defined as the onset of ataxia, altered consciousness (including confusion, impaired mentation, stupor, and coma), and severe lassitude. Frequently present are severe headache, nausea, and vomiting. In both AMS and HACE, headache is most likely initially produced by hypoxemia-induced cerebral vasodilation and a significant increase in blood flow. In addition, recent MRI studies suggest that in persons ascending to high altitudes and suffering moderate to severe AMS, some degree of cerebral edema occurs. However, in milder forms of AMS (a subjective distinction), brain edema is present in some

MRI studies, but not in all.[117] The cerebral edema may be either cytotoxic or vasogenic in nature (see Chapter 17).

As potentially lethal as HACE can be, HAPE is thought to account for most deaths from high-altitude illness.[118] HAPE is a noncardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure. The proposed mechanism for HAPE is uneven hypoxia-induced vasoconstriction, which increases capillary bed pressures and promotes a shift in fluid and vascular leakage (Fig. 2.30).[120] The disruption to the endothelial barrier causes an influx of fluid, proteins, and hemorrhage into alveolar spaces.[121] At a molecular level, the proposed mechanisms for the development of pulmonary edema at altitude include the nitric oxide pathway, the renin-angiotensin system, heat shock protein, pulmonary surfactant proteins, and hypoxia inducible factor.[115] The incidence of HAPE also is related to the rate of ascent, the ultimate altitude reached, and the individual's susceptibility to HAPE (e.g., congenital or acquired pulmonary circulation abnormalities increases susceptibility).

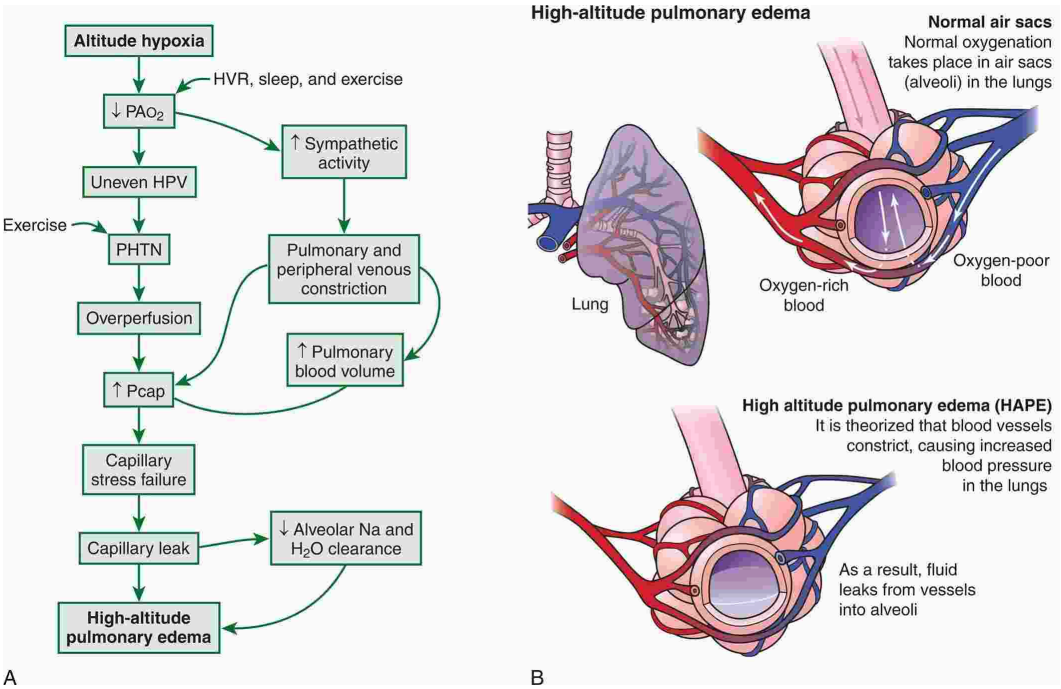

FIG. 2.30 High-Altitude Pulmonary Edema.
(A) In high-altitude pulmonary edema (HAPE), the proposed mechanism is uneven pulmonary vasoconstriction, such that high microvascular pressure occurs in the pulmonary capillary beds that are not protected by arteriolar vasoconstriction. Capillary hypertension results in fluid shifts via Starling principles and stretching or disruption of cellular junctions and pores. Other factors involved include inadequate ventilatory response, increased sympathetic nervous system tone, inadequate production of endothelial nitric oxide and impaired or delayed clearance of alveolar fluid. (B) Schematic of high-altitude pulmonary edema. *HPV*, Hypoxic pulmonary vasoconstriction; *HVR*, hypoxic ventilatory response; *PHTN*, pulmonary hypertension. (A, From Davis, C, Hackett, P. Advances in the prevention and treatment of high-altitude illness. *Emergency Medicine Clinics of North America*, 2017;35[2]:241–260.)

A flow diagram illustrates how altitude hypoxia leads to high-altitude pulmonary edema. There are nine major

stages in the mechanism, amplified by four additional factors. Stage 1. Altitude hypoxia. Stage 2. P A O sub 2, amplified by H V R, sleep, and exercise. Stage 3. Uneven H P V. Stage 4. P H T N, amplified by exercise. Stage 5. Overperfusion. Stage 6. P cap. Stage 7. Capillary stress failure. Stage 8. Capillary leak. Stage 9. High-altitude pulmonary edema. Stage 2 also leads to sympathetic activity, which results in pulmonary and peripheral venous constriction and subsequently to pulmonary blood volume, both of which amplify Stage 6. Stage 8 leads to Alveolar N a and H 2 O clearance, which leads to Stage 9. Illustration B. The illustration at the top left shows the structures in the left lung. The illustration at the top right shows a closeup of a normal air sac. Normal oxygenation takes place in air sacs, or alveoli, in the lungs. The flow of oxygen-rich blood and oxygen-poor blood are traced. The illustration at the bottom shows a closeup of a high-altitude pulmonary edema, H A P E. It is theorized that blood vessels constrict, causing increased blood pressure in the lungs. As a result, fluid leaks from vessels into alveoli.

Manifestations of Cellular Injury

Cellular Manifestations: Accumulations

Metabolic disturbances can result from cell injury, particularly where there is excessive intracellular accumulation of biochemical substances. Cellular accumulations, also known as infiltrations, can occur with both sustained cell injury and with normal but inefficient cell function. Two categories of substances can produce infiltrations:

1. *Normal cellular substances*—excess water, proteins, lipids, and carbohydrates
2. A*bnormal substances*—including *endogenous* substances (products of abnormal metabolism and synthesis) and *exogenous* substances (infectious agents or minerals)

Products can accumulate transiently or permanently and can be toxic or harmless. Infiltrations may occur in the cytoplasm, typically within the lysosomes, or in the nucleus. Most accumulations result from four main types of mechanisms, all of which lead to abnormal intracellular accumulations (Fig. 2.31). The four mechanisms are

1. Insufficient removal of the normal substance because of altered configuration or transport. Example: steatosis, fatty changes in the liver.
2. Accumulation of abnormal substance because of defects in protein folding, packaging, transport, secretion, or abnormal degradation. Such occurrences are usually secondary to gene mutation. Example: α_1*- antitrypsin*.
3. Inadequate degradation of metabolites because of a lack of enzymes, usually a lysosomal enzyme. Example: *storage diseases*.
4. Accumulation of harmful exogenous materials. Example: heavy metals and mineral dust inhalation and ingestion or the presence of pathogenic microorganisms.

Accumulation of exogenous materials

FIG. 2.31 Mechanisms of Intracellular Accumulations. (From Kumar V, Abbas AK, Aster JC. Robbins & *Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020.)

Four illustrative pairs of diagrams show the mechanisms of intracellular accumulations. 1. Abnormal metabolism: Normal cell converts to fatty liver cell with accumulation of fat molecules. 2. Defect in protein folding, transport: Protein mutation in normal cell results in accumulation of abnormal proteins within the cell. 3. Lack of enzymes. Enzymes in the normal cell are balanced with complex substrate proportional to soluble products. In the absence of soluble products, endogenous materials accumulate, leading to lysosomal storage disease. 4. Ingestion of indigestible materials. A normal cell is surrounded by indigestible materials. On ingestion, exogenous materials accumulate within the cell.

In all storage diseases, the cells attempt to digest, or catabolize, the "stored" substances resulting in excessive amounts of metabolites accumulating within the cells. These metabolites are expelled into the ECM, where they are attacked by phagocytic cells, usually macrophages (see Chapter 7). Some of these scavenger cells circulate throughout the body; others remain fixed in tissues, particularly in liver or spleen tissue. As more and more macrophages and other phagocytes migrate to tissues that are producing excessive metabolites, the affected tissues begin to swell. The engorgement results in organ enlargement. This mechanism causes hepatomegaly (enlarged liver) or splenomegaly (enlarged spleen). Enlargement of one or both organs is a clinical manifestation of many storage diseases.

Water

Cellular swelling is the most common degenerative change; it results from a shift of extracellular water into the cells. In hypoxic injury, the movement of fluid and ions into the cell is associated with acute metabolic failure and the loss of ATP production. The energy-dependent sodium pump, which transports sodium ions out of the cell, requires ATP. Adenosine triphosphatase (ATPase) is the active transport enzyme; it is reduced with hypoxia. Inadequate levels of ATP and ATPase permit sodium to accumulate within the cell while potassium diffuses outward. Increased intracellular sodium concentration raises osmotic pressure, drawing more water into the cell. The cisternae of the ER become distended and are predisposed to rupture. Once ruptured, the cisternae reunite, forming large vacuoles that isolate water, a process called *vacuolation*. Progressive vacuolation results in cytoplasmic swelling, termed oncosis *(hydropic degeneration)* or vacuolar degeneration (Fig. 2.32). If cellular swelling affects the majority of cells within an organ, the organ increases in weight, becomes distended, and takes on a pale appearance.

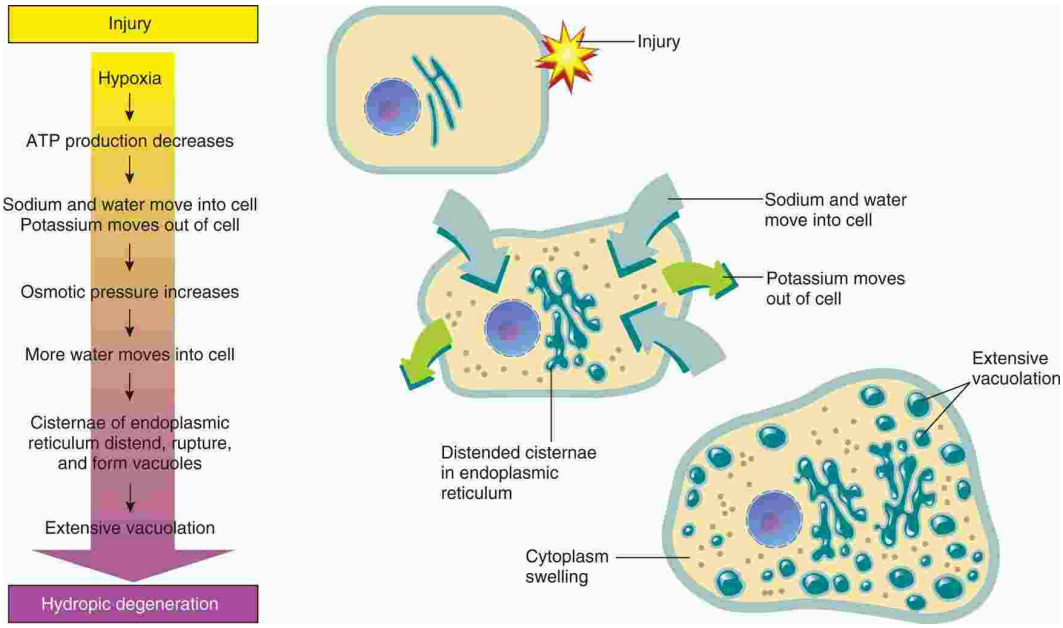

FIG. 2.32 The Process of Oncosis or Vacuolar Degeneration.
ATP, Adenosine triphosphate.

An illustrated flow diagram represents oncosis or vacuolar degeneration. Left panel. The flow diagram begins with injury and undergoes the following seven stages to result in hydropic degeneration. Stage 1. Hypoxia. Stage 2. A T P production decreases. Stage 3. Sodium and water move into cell. Potassium moves out of cell. Stage 3. Osmotic pressure increases. Stage 4. More water moves into cell. Stage 5. Cisternae of endoplasmic reticulum distend, rupture, and form vacuoles. Stage 7. Extensive vacuolation. Right panel. An illustration shows cell experience an injury. Sodium and water move into cell. Potassium moves out of cell. This results in distended cisternae in endoplasmic reticulum, leading to extensive vacuolation and cytoplasm swelling.

Cellular swelling is reversible or sublethal. It is an early manifestation of almost all types of cellular injury, including injuries that are severe or lethal. Cellular swelling is associated with high fever, hypokalemia (decreased blood potassium), and certain infections.

Lipids and Carbohydrates

Certain metabolic disorders result in an abnormal intracellular accumulation of carbohydrates and lipids. These substances may accumulate throughout the body, but they are found primarily in the spleen, liver, and CNS. Accumulations within CNS cells are associated with neurologic deficits and severe intellectual impairment. Lipids accumulate in Tay-Sachs disease, Niemann-Pick disease, and Gaucher disease. When carbohydrates accumulate, mucopolysaccharide diseases (mucopolysaccharidoses) result. Mucopolysaccharidoses are progressive disorders, typically affecting multiple organs and, particularly, the liver, spleen, heart, and blood vessels. Mucopolysaccharides accumulate at various sites throughout the body: reticuloendothelial cells, endothelial cells, intimal smooth muscle cells, and fibroblasts. Carbohydrate accumulations are associated with cataracts (corneal clouding), joint stiffness, intellectual deficits, and the characteristic eye changes seen in Graves' disease (hyperthyroidism).

Although lipids sometimes accumulate in heart, muscle, and kidney cells, the most common site of intracellular lipid accumulation, or fatty change (steatosis), is liver cells because the liver is the main organ involved in fat metabolism (Fig. 2.33). Hepatic metabolism and secretion of lipids are crucial to proper body function; therefore, any imbalances or deficiencies in these processes lead to major pathologic changes. As lipids accumulate in the cells, increased vacuolation pushes the nucleus and other organelles aside. The outward appearance of the liver becomes yellow and greasy. In developed countries, the most common causes of fatty changes to the liver are alcohol abuse and nonalcoholic fatty liver disease, often associated with obesity and diabetes (see Chapters 22, 23, and 41). Other causes include protein malnutrition, toxins, and anoxia. Mechanisms for lipid accumulation in the liver include the following:

1. Increased movement of free fatty acids into the liver (for example, starvation increases triglyceride metabolism in adipose tissue, and fatty acids are released and enter liver cells)

FIG. 2.33 Fatty Liver.
The liver appears yellow. (From Damjanov I, Linder J. *Pathology: A color atlas*. St. Louis: Mosby; 2000.)

Many pathologic states show accumulation of cholesterol and cholesterol esters. Atherosclerosis is characterized by plaques containing lipids, cholesterol, calcium, macrophages, and other substances. The coronary and carotid arteries are particularly prone to plaques. Their presence in these vessels can result in myocardial infarction and stroke. Cholesterol-rich deposits in the gallbladder commonly lead to obstruction from cholelithiasis (gall stones). Niemann-Pick disease is characterized by lipid accumulation in the spleen, liver, lungs, bone marrow, and brain, secondary to a genetic lack of sphingomyelinase, an enzyme that affects cholesterol transport.

Glycogen

Glycogen is the storage form of glucose, with 90% found in the liver. Glycogen serves as a readily available source of energy needed for normal cell function. Intracellular accumulations of glycogen are

seen in a large group of genetic disorders called *glycogen storage diseases*. Accumulations also are noted disorders affecting glucose and glycogen metabolism. Glycogen storage diseases have profound detrimental effects on growth and development and negatively impact various organ and body system functions. As with water and lipid accumulation, glycogen accumulation results in excessive vacuolation in the cytoplasm. Excess glycogen accumulation is evident in 80% of persons with diabetes. The high levels of blood glucose and excess glycogen cause a multiplicity of problems in the individual with diabetes (see Chapter 22).

Proteins

Proteins provide cellular structure and account for most of the cell's dry weight. Proteins are synthesized on ribosomes from the essential amino acids. Intracellular accumulation of excess protein damages cells in two ways. First, protein metabolism results in the release of lysosomal enzymes, which can damage cellular organelles. Second, excessive amounts of protein in the cytoplasm crowd cell organelles, disrupting their function and intracellular communication.

Protein excess accumulates primarily in two locations: in the epithelial cells of the renal convoluted tubules and in the antibody-forming plasma cells (B lymphocytes) of the immune system. A variety of renal disorders result in excessive excretion of protein molecules into urine (proteinuria) (see Chapter 38). Normally, protein is conserved with little or no protein escaping into urine. Proteinuria suggests cellular injury or altered cellular function, or both. Excess protein aggregates can accumulate in and distend the ER, producing *Russell bodies*, large homogenous eosinophilic inclusions. Russell bodies have been identified in multiple myeloma, which is a cancer of the plasma cells.

A number of disease states result from mutations, which impair protein folding. Partially folded intermediates accumulate within the cell. Emphysema without a history of smoking can result from α_1-antitrypsin deficiency, a genetic mutation that impairs protein folding. Cell injury is associated with the accumulation of

cytoskeleton proteins. The *neurofibrillary tangle* found in the brain in Alzheimer disease contains these types of proteins.

Pigments

Pigment accumulations may be normal or abnormal, endogenous (produced within the body), or exogenous (produced outside the body). Endogenous pigments, derived from amino acids (tyrosine, tryptophan), include melanin and blood proteins (porphyrins, hemoglobin, and hemosiderin). Lipofuscin, a lipid-rich pigment known as the "aging pigment," imparts a yellow-brown color to cells, which are undergoing slow, regressive, or atrophic changes. The most common exogenous pigment is carbon black (coal dust), a pervasive air pollutant in urban areas. Inhaled carbon black interacts with lung macrophages. Lymphatics transport it to regional pulmonary lymph nodes where it accumulates. This accumulation blackens lung tissues and pulmonary nodes, causing a variety of respiratory disorders. Other exogenous pigments include mineral dusts: silica, iron particles, lead, silver salts, and dyes used for tattoos.

Melanin

Melanin is a brown-black pigment derived from the amino acid *tyrosine*. Melanin is synthesized by epidermal cells called *melanocytes* and is stored in membrane-bound cytoplasmic vesicles called *melanosomes*. It accumulates in epithelial cells (keratinocytes) of the skin and retina where it serves to protect the tissue from the harmful effects of prolonged exposure to sunlight. Melanin is essential in the prevention of skin cancer. Persons with absent or low levels of melanin (lighter-skinned persons) are more susceptible to skin cancer (see Chapters 13 and 46). Particularly hazardous are episodes of sunburn during the early years of life because these events increase the life-long risk for developing skin cancer. Ultraviolet radiation from nonnatural sources (tanning salon lamps) also is associated with an increased risk for skin cancer. Individuals who

have more darkly pigmented skin because of the presence of higher levels of melanin are proportionately less susceptible to skin cancers.

Ultraviolet light from sunlight and other sources stimulates the synthesis of melanin. Melanin absorbs ultraviolet rays during subsequent exposures. Melanin also may serve to trap harmful free radicals derived by the action of ultraviolet light on skin. Melanin accounts for the brown to black coloration seen in *pigmented nevi*, benign skin moles. Melanin also is found in cancerous skin lesions, particularly *malignant melanoma*, a highly aggressive and lethal form of skin cancer. It is characterized by irregular black skin lesions, which rapidly metastasize to other organs.

Albinism is a congenital inherited disorder characterized by the complete or partial absence of melanin. Individuals with albinism are extremely predisposed to developing skin cancer because they experience sunburn upon even minimal exposure to sunlight. In humans, the disorder is inherited as either an autosomal recessive or a sex-linked recessive genetic disorder, depending on the type of albinism involved. The mechanism for albinism is a defect in tyrosinase, a copper-containing enzyme, which catalyzes the production of melanin from the amino acid tyrosine.

Hemoproteins

Hemoproteins are essential endogenous pigments. They include hemoglobin and oxidative enzymes, the cytochromes. Numerous disorders result from abnormalities involving these pigments, particularly iron uptake, metabolism, excretion, and storage (see Chapter 28). Excessive intracellular iron storage results from accumulations of hemoprotein, originating when this substance is transferred from the bloodstream into cells. Iron enters blood from three primary sources: (1) tissue stores, (2) the intestinal mucosa, and (3) macrophages. Macrophages remove and destroy dead or defective RBCs. The amount of iron in blood plasma also depends on the metabolism of the major iron-transport protein, *transferrin*.

Iron is stored in tissue cells in two forms: ferritin, the major vehicle for iron storage, and with greater levels of iron present, as

hemosiderin, an intracellular, yellow-brown pigment. Excess accumulation of hemosiderin usually occurs in the mononuclear phagocyte systems (MPSs) and, to a lesser extent, in the liver, kidneys, lungs, spleen, lymph nodes, and bone marrow. Iron overload, also known as hemochromatosis, refers to an accumulation of iron within the body and results from a variety of mechanisms (see Chapter 29).

In contrast to hemochromatosis, a chronic and systemic disorder, hemosiderosis is a transient, localized deposition of iron. It usually does not result in tissue damage. Transient hemosiderin accumulation within tissues can be seen in bruising where ruptured blood vessels result in RBCs exiting the circulatory system. The RBCs diffuse into tissues surrounding the site of injury. A local hemorrhage (bruise) forms after a contusion. The skin surrounding the site of impact injury first appears red or dark blue, or both, or, in lay terminology, "black and blue" as blood accumulates under the skin. Depending on the nature of the trauma, the color change can be quite profound (deep, blackish blue) and extend over a large area (Fig. 2.34). Over the course of a few days to several weeks, the blue coloration is gradually replaced by characteristic color changes—green, yellow, and brown-pigmentation to the skin. The colors reflect the sequential degradation of hemoglobin (red–blue) to biliverdin (green) to bilirubin (yellow) and, finally, to hemosiderin (golden brown). Eventually, the abnormal pigmentation resolves, and the normal skin color returns.

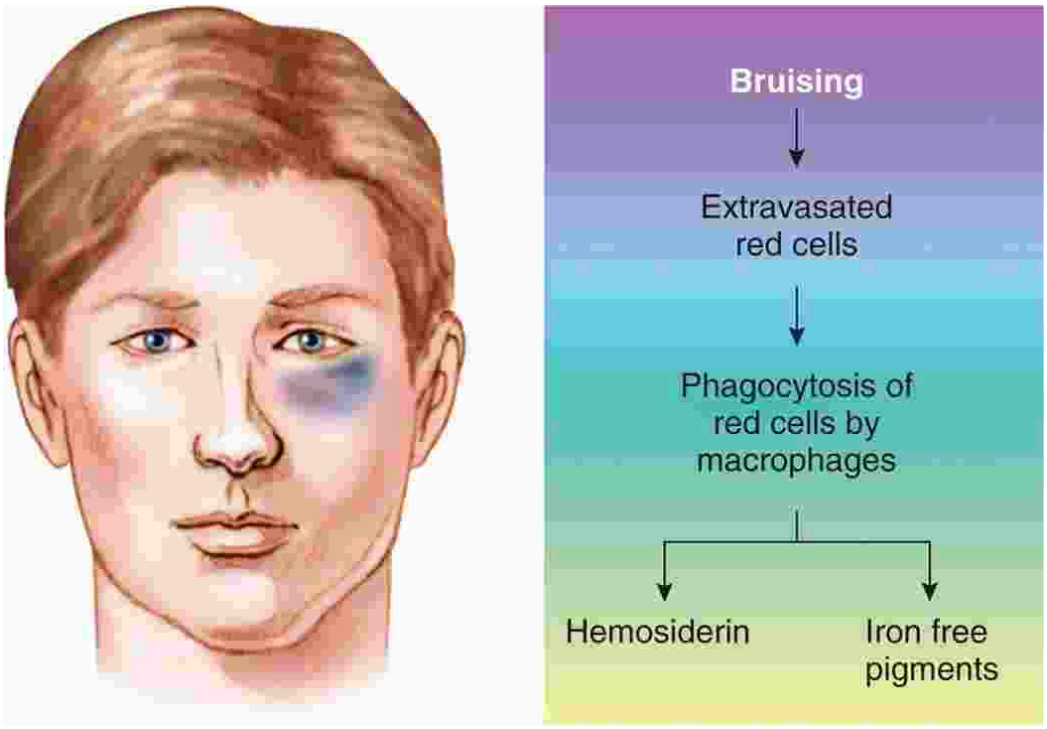

FIG. 2.34 Hemosiderin Accumulation as Noted as the Color Changes in a "Black Eye."

Two illustrations represent hemosiderin accumulation. Left panel. An illustration shows a face with a blackish-purple bruise under the left eye. Right panel. A four-level flow chart. Level 1. Bruising. Level 2. Extravasated red cells. Level 3. Phagocytosis of red cells by macrophages. Level 4. Hemosiderin and iron-free pigments.

Bilirubin is a normal, yellow-to-green pigment of bile derived from the porphyrin structure of hemoglobin. Excess bilirubin within cells and tissues causes jaundice (icterus), a yellowing of the skin, and sclera of the eye. Jaundice occurs when the bilirubin level exceeds 2 mg/dL of plasma, compared with the normal values of 0.4 to 1 mg/dL. Hyperbilirubinemia develops because of one of several

mechanisms: (1) destruction of erythrocytes (RBCs) causing *hemolytic jaundice;* (2) diseases affecting the metabolism and excretion of bilirubin in the liver (e.g., cirrhosis); and (3) diseases causing obstruction of the common bile duct (e.g., gallstones or pancreatic tumors). Various drugs can cause the obstruction of normal bile flow through the liver, increasing blood levels of bilirubin.

Calcium

Calcium salts accumulate in both injured and dead tissues (Fig. 2.35), a process that results in *cellular calcification*. An important mechanism for cellular calcification is the influx of extracellular calcium in injured mitochondria. Another mechanism that causes calcium accumulation in alveoli, gastric epithelium, and renal tubules is the excretion of acid at these sites, leading to the local production of hydroxyl ions. Hydroxyl ions result in precipitation of calcium hydroxide ($Ca[OH]_2$) and hydroxyapatite ($Ca_5[PO_4]_3[OH]$), a mixed salt. Damage occurs when calcium salts clump and harden, interfering with normal cellular structure and function. Pathologic calcification can be dystrophic or metastatic. Dystrophic calcification refers to calcification occurring in dying or necrotic tissues. It is present in chronic tuberculosis of the lungs, lymph nodes, arteries with advanced atherosclerosis (narrowing as a result of plaque accumulation), and in injured heart valves (Fig. 2.36). Calcification impedes the smooth opening or closing of heart valves and presents clinically as a heart murmur (see Chapter 32). Calcification of the coronary arteries predisposes them to severe narrowing and thrombosis, which can lead to myocardial infarction. Dystrophic calcification is frequently found in the center of tumors. Over time, necrosis and subsequent calcification occur in the inner regions of growing tumors as they are progressively deprived of oxygen. Calcium salts appear as gritty, clumped granules that can become stone-like. Psammoma bodies (named for the Greek word denoting "sand") are laminated, calcified structures, which resemble grains of sand. They are concentric and commonly found within tumors;

however, the exact mechanism responsible for their formation remains unclear.

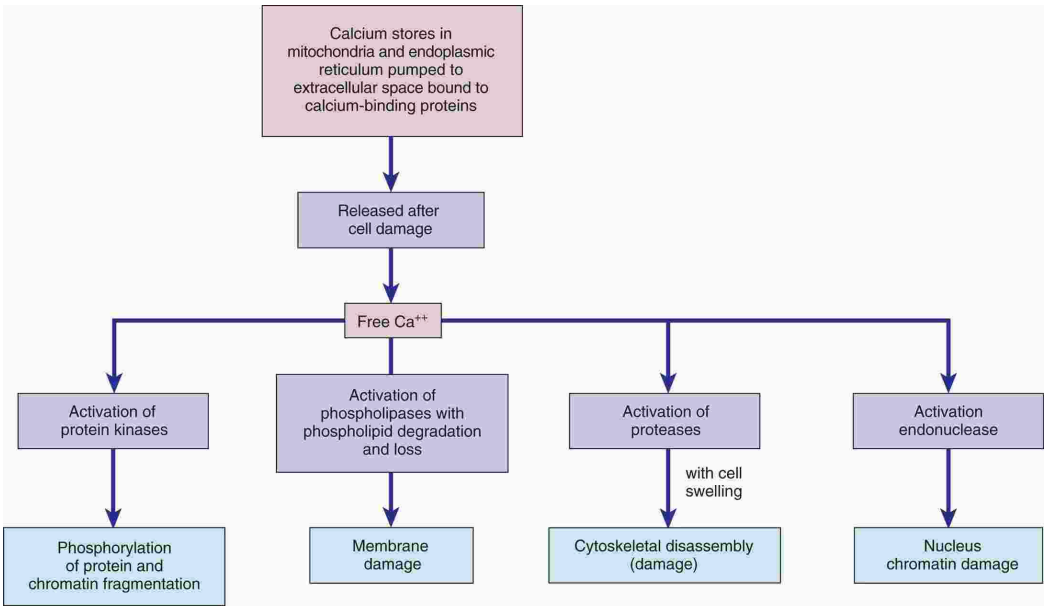

FIG. 2.35 Free Cytosolic Calcium: A Destructive Agent.
Normally, calcium is removed from the cytosol by adenosine triphosphate (ATP)–dependent calcium pumps. In normal cells, calcium is bound to buffering proteins, such as calbindin or parvalbumin and is contained in the endoplasmic reticulum and the mitochondria. If there is abnormal permeability of calcium ion channels, direct damage to membranes, or depletion of ATP (i.e., hypoxic injury), calcium increases in the cytosol. If the free calcium cannot be buffered or pumped out of cells, uncontrolled enzyme activation takes place, causing further damage. Uncontrolled entry of calcium into the cytosol is an important final common pathway in many causes of cell death.

A hierarchy diagram represents free cytosolic calcium. Level 1 in the hierarchy. Calcium stores in mitochondria and endoplasmic reticulum pumped to

extracellular space bound to calcium-binding proteins. Level 2 in the hierarchy. Released after cell damage. Level 3. Free calcium ions. Free calcium ions lead to the following four process. 1. Activation in protein kinases. This leads to phosphorylation of protein and chromatic fragmentation. 2. Activation of phospholipases with phospholipid degradation and loss. This leads to membrane damage. 3. Activation of proteases. This leads to cytoskeletal disassembly or damage. 4. Activation of endonuclease. This leads to nucleus chromatin damage.

FIG. 2.36 Aortic Valve Calcification.
(A) Calcified aortic valve is an example of dystrophic calcification. **(B)** Algorithm showing the dystrophic mechanism of calcification. (A, From Damjanov I. *Pathology for the health professions*, 4th edition. St Louis: Saunders; 2012.)

Close-up A is a macroscopic image of a calcified aortic valve. Flow diagram B represents the algorithm for dystrophic mechanism of calcification. There are four stages in the algorithm. Stage 1. Necrosis or degeneration of tissue. Stage 2. Release of enzymes. Stage 3. Breakdown of organic phosphates and alteration of p H. Stage 4. Increased deposition of calcium.

Metastatic calcification consists of mineral deposits that occur in undamaged, normal tissues secondary to hypercalcemia (excess calcium in the blood). Frequent causes of hypercalcemia include hyperparathyroidism, toxic levels of vitamin D, hyperthyroidism, Addison disease (adrenocortical insufficiency), and excess calcium supplementation. Hypercalcemia can develop secondary to the increased bone demineralization, resulting from bone tumors, leukemia, and disseminated cancers. It also may occur in advanced renal failure with phosphate retention. As phosphate levels increase, the activity of the parathyroid gland increases resulting in higher levels of circulating calcium.

Urate

In humans, uric acid (urate) is the major end product of purine catabolism. Humans lack the enzyme urate oxidase present in most other mammals. This enzyme is needed to convert uric acid to

allantoin. Because urate crystals are not degraded by lysosomal enzymes, they persist in dead cells. Normally, serum urate concentration is stable, measuring approximately 5 mg/dL in postpubertal males and 4.1 mg/dL in postpubertal females. With elevated serum urate levels, sodium urate crystals accumulate in tissues, leading to a group of painful disorders collectively called gout. These disorders include acute arthritis, chronic gouty arthritis, tophi (firm, nodular, subcutaneous deposits of urate crystals surrounded by fibrosis), and nephritis (inflammation of the nephron). In all these disorders, cell injury and inflammation are characteristic findings (see Chapters 38 and 44).

Systemic Manifestations of Cellular Injury

Dead and injured cells initiate local inflammation and, with more severe injury, cause systemic inflammation. Inflammation promotes systemic manifestations of cellular injury, including fatigue, malaise, altered appetite, and fever. Fever may occur because of endogenous pyrogens (fever-inducing substances) released during the inflammatory response. Table 2.11 summarizes the most significant systemic manifestations of cellular injury.

Table 2.11

Systemic Manifestations of Cellular Injury

Manifestation	Cause
Fever	Release of endogenous pyrogens (interleukin-1, tumor necrosis factor-α, prostaglandins) from bacteria or macrophages; acute inflammatory response
Increased heart rate	Increase in oxidative metabolic processes resulting from fever
Increase in leukocytes (leukocytosis)	Increase in total number of white blood cells because of infection; normal is 5000–9000/mm^3 (increase is directly related to severity of infection)
Pain	Various mechanisms, such as release of bradykinins, obstruction, pressure
Presence of cellular enzymes	Release of enzymes from cells of tissue[a] in extracellular fluid
Lactate dehydrogenase (LDH) (LDH isoenzymes)	Release from red blood cells, liver, kidney, skeletal muscle
Creatine kinase (CK) (CK isoenzymes)	Release from skeletal muscle, brain, heart
Aspartate aminotransferase (AST/serum glutamic-oxaloacetic transaminase [SGOT])	Release from heart, liver, skeletal muscle, kidney, pancreas

Manifestation	Cause
Alanine aminotransferase (ALT/serum glutamic pyruvic transaminase [SGPT])	Release from liver, kidney, heart
Alkaline phosphatase (ALP)	Release from liver, bone
Amylase	Release from pancreas
Aldolase	Release from skeletal muscle, heart

[a]The rapidity of enzyme transfer is a function of the weight of the enzyme and the concentration gradient across the cellular membrane. The specific metabolic and excretory rates of the enzymes determine how long levels of enzymes remain elevated.

Cellular Death

With sufficient structural or physiologic damage, cell injury becomes irreversible, and cells die. Cells die from accidental cell death (ACD) or regulated cell death (RCD).[122] There are two main types of cell death, necrosis or apoptosis (Fig. 2.37 and Table 2.12). Historically, necrosis has been referred to as "accidental" cell death, whereas apoptosis is known as "regulated" cell death. Although necrosis was considered passive or accidental, occurring after severe and sudden injury, some forms of necrosis are genetically controlled through a defined molecular pathway called necroptosis. Also, the distinction between apoptosis and necrosis may not always be clear; cells may progress from one to the other. Usually, however, they are considered non-overlapping pathways of cell death because their morphological features and functional consequences are mostly different.[1] An increased understanding of RCD is emerging with associative distinct morphological changes and immunologic consequences.[122]

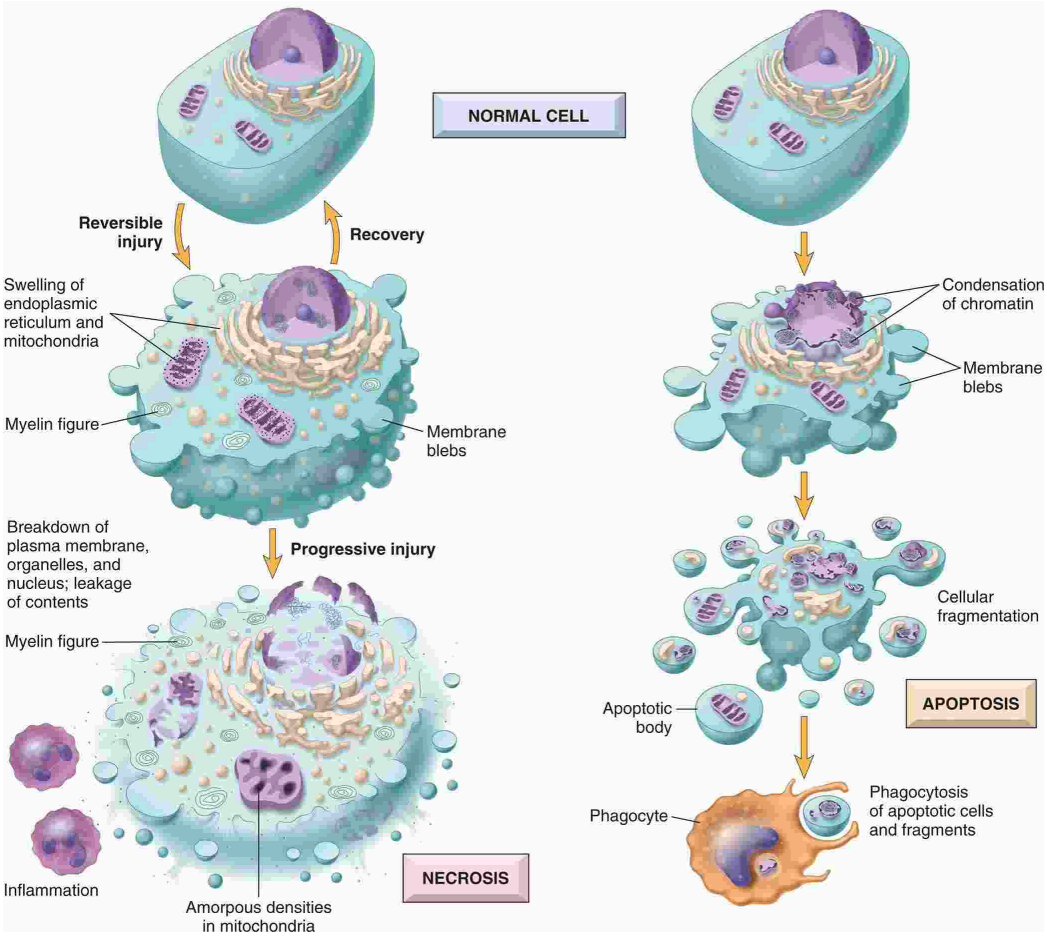

FIG. 2.37 Schematic Illustration of the Morphologic Changes in Cell Injury Culminating in Necrosis or Apoptosis. Myelin figures come from degenerating cellular membranes and are noted within the cytoplasm or extracellularly. (From Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020:38.)

Two iterative sets of illustrations represent the effect of necrosis and apoptosis on a normal cell. Necrosis. A reversible injury on a normal cell results in its recovery. Injury could be one or more of the following conditions: swelling of endoplasmic

reticulum and mitochondria, myelin figure, and membrane blebs. Progressive injury includes breakdown of plasma membrane, organelles, and nucleus, or leakage of contents. The diagram highlights myelin figure, inflammation, and amorphous densities in mitochondria. Apoptosis includes the following steps: 1. A normal cell. 2. A cell affected by condensation of chromatin and membrane blebs. 3. A cellular fragmentation and apoptotic bodies. 4. Phagocytosis of apoptotic cells and fragments and a closeup of a phagocyte.

Table 2.12

Features of Necrosis and Apoptosis

Feature	Necrosis	Apoptosis
Cell size	Enlarged (swelling)	Reduced (shrinkage)
Nucleus	Pyknosis, karyorrhexis, karyolysis	Fragmentation into nucleosome-size fragments
Plasma membrane	Disrupted	Intact; altered structure, especially orientation of lipids
Cellular contents	Enzymatic digestion; may leak out of cell	Intact; may be released in apoptotic bodies
Adjacent inflammation	Frequent	No
Physiologic or pathologic role	Usually pathologic (culmination of irreversible cell injury)	Often physiologic, means of eliminating unwanted cells; may be pathologic after some forms of cell injury, especially deoxyribonucleic acid (DNA) damage

From Kumar V, et al. Cellular responses to stress and toxic insults: Adaptation, injury, and death. In: Kumar V, Abbas AK, Aster JC, eds. *Robbins & Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020.

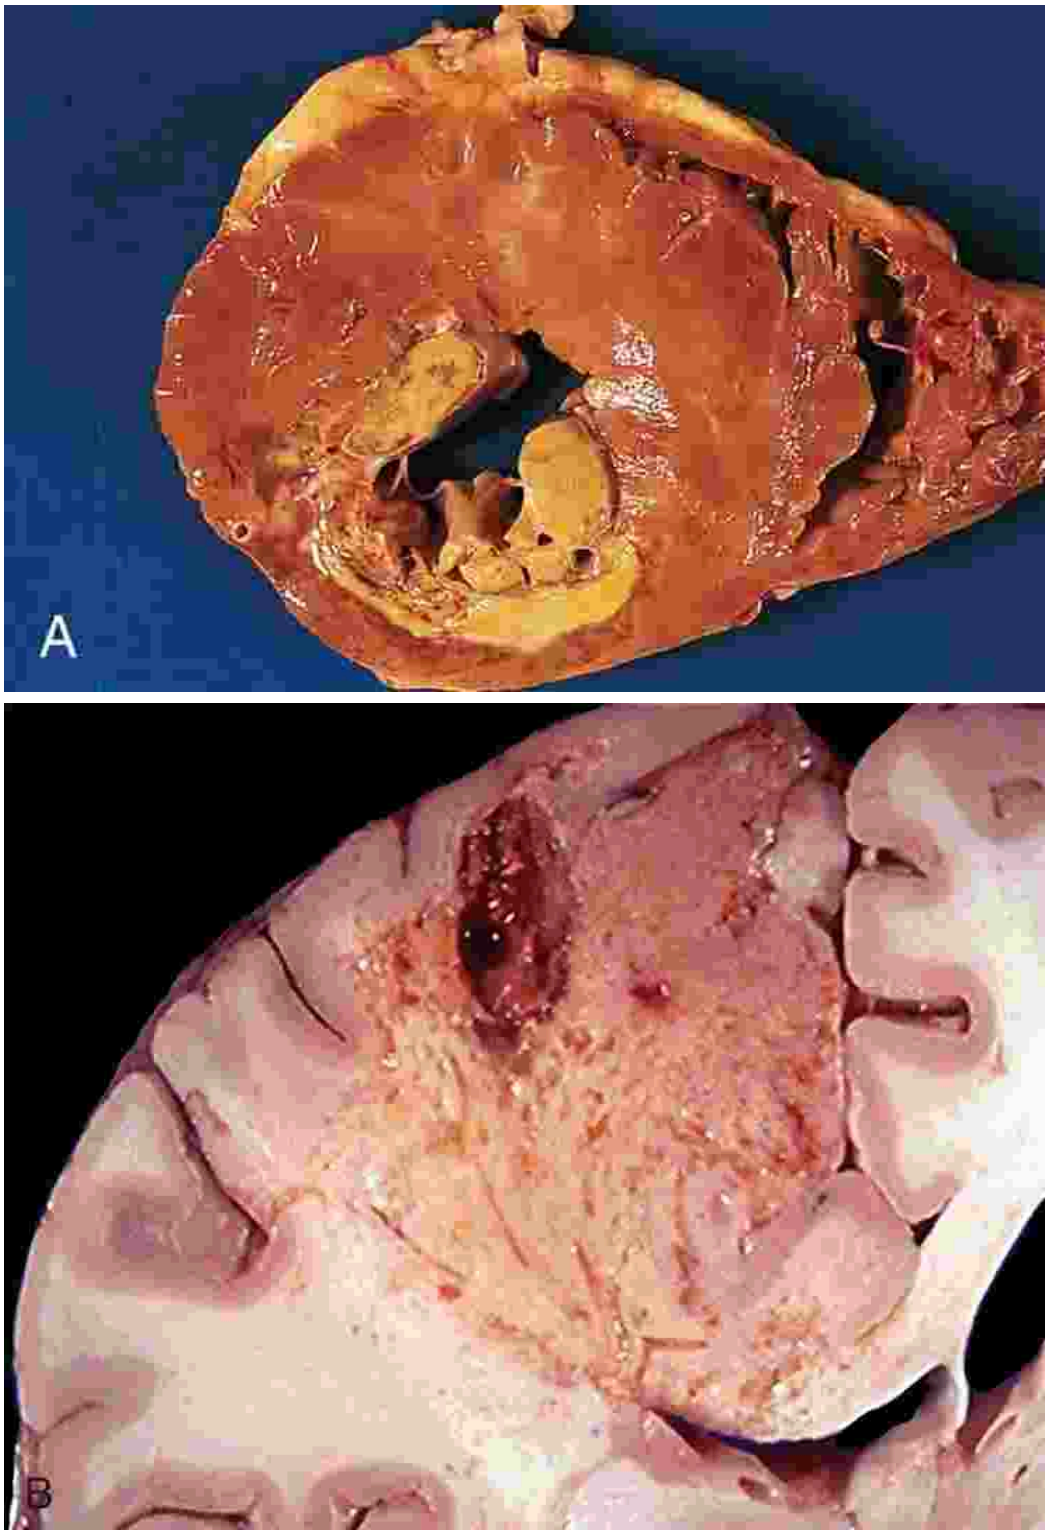
Necrosis

Necrosis is the cellular consequence of severe injury. Causes of necrosis include ischemia, exposure to microbial toxins, chemical and physical agents (e.g., burns), and rare occurrences such as when active proteases leak out from cells and damage the surrounding tissues (for example, pancreatitis).[1] Necrosis is a form of cell destruction characterized by ruptured plasma and lysosomal membrane structures, denaturation of cellular proteins, leakage of cellular contents, rapid loss of ATP, swelling of organelles, severe mitochondrial damage, and local inflammation. Certain substances released from injured cells are called damage-associated molecular patterns (DAMPs) (see Chapter 7). DAMPs include ATP released from damaged mitochondria, uric acid from the breakdown of DNA, and many other molecules usually shielded within healthy cells that, when released, become an indicator of severe cell injury.[1] DAMPs are recognized by macrophage receptors and other cells and trigger phagocytosis of the debris and production of cytokines that prompt inflammation (see Chapter 7). The processes of inflammatory cells and release of proteolytic enzymes, phagocytosis, and enzymatic digestion lead to clearance of the necrotic tissue.[1]

Necrosis is the sum of cellular changes occurring after local cell injury (see Fig. 2.37). In the later stages of necrosis, when most organelles are disrupted, karyolysis (enzymatic hydrolysis of nuclear chromatin) is well underway. In some cells, pyknosis, a process where the nucleus shrinks into a small, dense mass of genetic material, occurs. Eventually, lysosomal enzymes break up the pyknotic nucleus. Karyorrhexis is fragmentation of the nucleus into small particles or "nuclear dust."

Different patterns of necrosis tend to occur in different organs or tissues, sometimes indicating the mechanism or cause of cellular injury. The main forms of necrosis are *coagulative*, *liquefactive*, *caseous*, *fat*, and *fibrinoid* (Fig. 2.38A–E). These forms of necrosis occur mostly in the kidneys, heart, and adrenal glands. Another form, gangrenous

necrosis, is not a distinctive type of cell death but, instead, refers to large areas of tissue death.



A
B

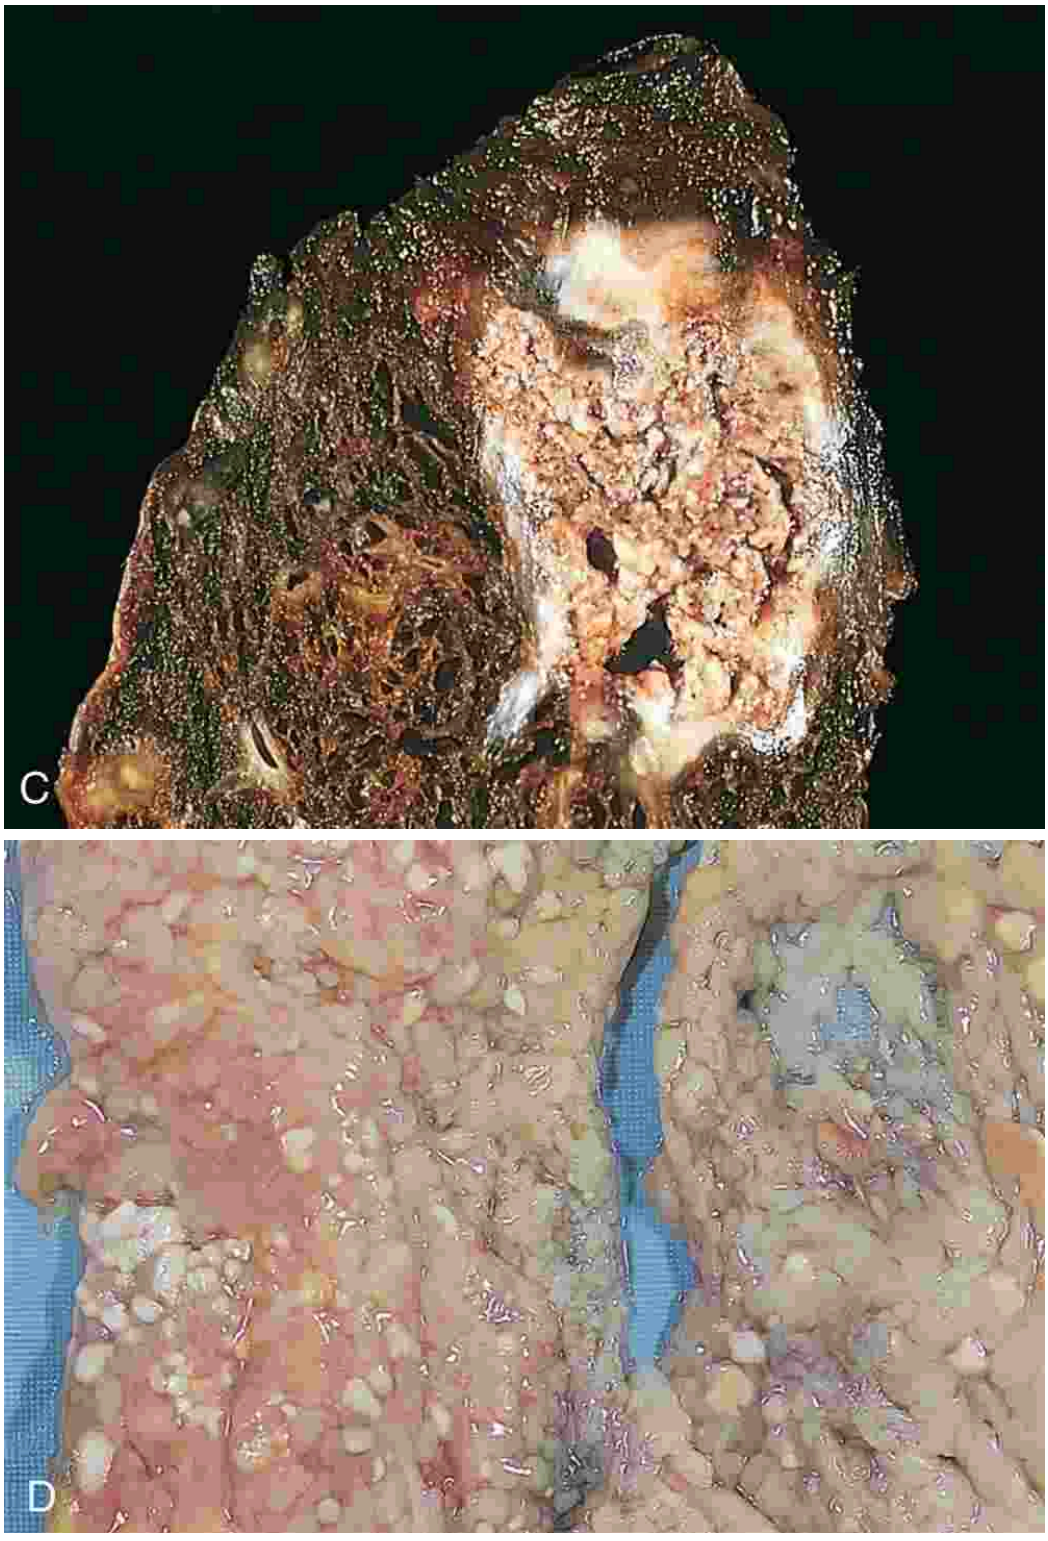


FIG. 2.38 Types of Necrosis.
(A) Coagulative necrosis of myocardium of posterior wall of left ventricle of heart. A large

anemic *(white)* infarct is readily apparent; note also the necrosis of papillary muscle. (From **(B)** Liquefactive necrosis of the brain. The area of infarction is softened as a result of dissolution of tissue. (From **(C)** Caseous necrosis. Tuberculosis of the lung, with a large area of caseous necrosis containing yellow-white and cheesy debris (From **(D)** Fat necrosis. Areas of white chalky deposits represent foci or fat necrosis with calcium soap formation (saponification) at sites of lipid breakdown in the mesentery. (From **(E)** Fibrinoid Necrosis in an Artery. Wall of the artery shows a circumferential bright pink area of necrosis with inflammation (neutrophils with dark nuclei). It occurs when complexes of antigens and antibodies are deposited in the walls of arteries. The type of injury is often called immunologically mediated vasculitis syndromes. (From (A, From Damjanov I, Linder J, eds. Anderson's pathology, 10th edition. St Louis: Mosby; 1996; B to E from Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020:41.)

Closeup A is a cross-section of the left ventricle of a human heart, with coagulative necrosis of myocardium of the posterior wall. Closeup B is a cross-section of a human brain, with liquefactive necrosis. Closeup C is a cross-section of a human lung, with caseous necrosis. Closeup D is a section of a mesentery, affected by fat necrosis. Part E is a

macroscopic image of an artery, affected by fibroid necrosis.

Coagulative necrosis occurs as a result of protein denaturation, where albumin is transformed from a gelatinous, transparent state into a firm, opaque substance (see Fig. 2.38A). The localized area of coagulative necrosis is called an infarct.

Liquefactive necrosis is characterized by digestion of the dead cells transforming tissue into a viscous liquid. It commonly results from hypoxic injury within the CNS (see Fig. 2.38B). It is also seen in focal bacterial and sometimes in fungal infections because microbes stimulate the accumulation of leukocytes and their release of enzymes. The necrotic material is called pus, which is creamy and yellow.

Caseous necrosis commonly results from pulmonary tuberculosis or infection caused by *Mycobacterium tuberculosis* (see Fig. 2.38C). Caseous, Latin for cheese, refers to the curdled or cheese-like gross appearance. It combines elements of both coagulative and liquefactive necrosis. Dead cells disintegrate, but the debris is not completely hydrolyzed. Instead, a granulomatous inflammatory response ensues. Soft and granular tissues form the end-product, resembling clumped cheese. An inflammatory wall encloses the areas of caseous necrosis, forming the characteristic granulomas of pulmonary tuberculosis (see Chapter 35).

Fatty necrosis is cellular dissolution caused by lipases, potent enzymes found in the breast and abdominal structures, especially within the pancreas (see Fig. 2.38D). Lipases break down triglycerides, releasing free fatty acids. The fatty acids combine with calcium, magnesium, and sodium ions, creating soaps, a process known as *saponification*. The necrotic tissue formed appears opaque and chalky white.

Fibrinoid necrosis is a unique form of vascular damage typically seen in immune reactions involving blood vessels (see Fig. 2.38E). It occurs from injury, and complexes of antigens and antibodies are

deposited in the walls of arteries. The type of injury is often called immunologically-mediated vasculitis syndromes.

Gangrenous necrosis refers to tissue death but does not denote a specific pattern of cell death. It results from severe hypoxic injury, commonly secondary to the blockage of major arterial vessels supplying a region of the body. Gangrenous necrosis is particularly common with severely compromised circulation of the lower leg, either from acute or chronic disorders. With hypoxia, bacterial invasion, which enters a wound, can readily result in gangrenous necrosis. *Dry gangrene* typically results from coagulative necrosis. The skin becomes very dry and shriveled, and skin coloration in such cases is brown or black. *Wet gangrene*, the more lethal form, develops secondary to necrotizing bacterial infections, particularly infection with gram-positive cocci, gram-negative rods, or anaerobic microorganisms, especially *Clostridium* spp. These microorganisms invade the site, causing a liquefactive necrosis. Wet gangrene causes the affected tissues to become cold, swollen, and black, and a foul odor is present. Wet gangrene also can affect internal organs, usually secondary to hypoxia. The presentation is similar regardless of the site involved. Wet gangrene is an aggressive disorder, which spreads rapidly to surrounding tissue. Left untreated, it can rapidly progress to death.

Gas gangrene refers to a type of wet gangrene caused by tissue infection with *Clostridium* spp., most commonly *Clostridium perfringens*. These microorganisms are widely present in soil and proliferate under conditions of low oxygen tension. Deep puncture wounds from soil-contaminated objects are common sources of infection. Once established at the site of infection, the microorganisms produce hydrolytic enzymes and toxins, which destroy tissue and cause bubbles of gas to form in the affected region. The infection progresses rapidly, spreading to adjacent tissue. Untreated, death typically occurs within 12 hours secondary to overwhelming sepsis, shock, and renal shutdown

Apoptosis

Apoptosis is a distinct type of cell death that differs from necrosis in several ways (see Fig. 2.37 and Table 2.12). Apoptosis is an active process of cellular self-destruction, resulting in *programmed cell death*. It occurs in both physiologic and pathologic tissue changes. In the average adult, 10 billion new cells are created every day, and the same number of cells are destroyed daily. If cells did not undergo apoptosis, endless cell proliferation would result. Normal physiologic death by apoptosis occurs during embryogenesis; involution of hormone-dependent tissue after hormone withdrawal, such as involution of the lactating breast after weaning; cell loss in proliferating cell populations, such as immature lymphocytes in the bone marrow or thymus that do not express appropriate receptors; and elimination of possibly harmful lymphocytes that may be self-reactive and cause the death of cells after they perform useful functions (e.g., neutrophils after an acute inflammatory reaction).[1] Death by apoptosis causes loss of cells in many pathologic states, including the following:

- *Severe cell injury:* When cell injury exceeds the capacity for repair mechanisms, cell signaling triggers apoptosis.
- *Accumulation of misfolded proteins:* This condition results from either genetic mutations or free radicals. Excessive accumulation of misfolded proteins in the ER leads to a condition known as endoplasmic reticulum stress (ER stress) (see Chapter 1). ER stress culminates in cell death secondary to apoptosis. It has been linked to several degenerative diseases of the CNS and other organs (Fig. 2.39).
- *Infections (particularly viral):* Apoptosis may be the result of the host's immune response to the presence of a virus infecting the cell. Cytotoxic T lymphocytes respond to viral infections by inducing apoptosis, thus eliminating infectious cells. This process, however, can result in tissue damage. The same mechanism can result in cell death in tumor-related disease and organ transplant rejection.

- *Obstruction in tissue ducts:* Obstruction of blood flow to an organ results in pathologic atrophy, a process commonly noted in the pancreas, kidney, or parotid gland.

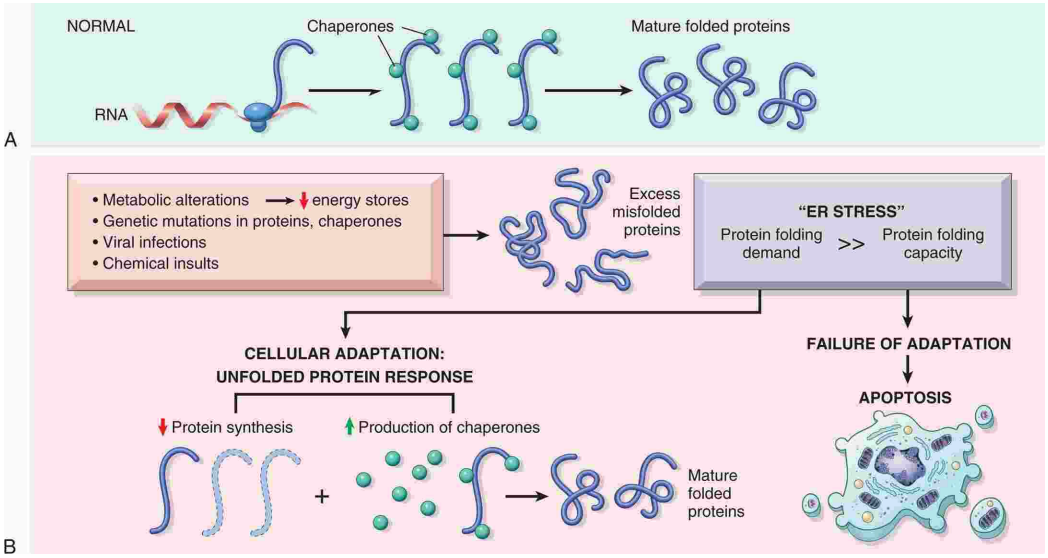

FIG. 2.39 The Unfolded Protein Response, Endoplasmic Stress, and Apoptosis.
(A) In normal or healthy cells, the newly made proteins are folded with help from chaperones and then incorporated into the cell or secreted. **(B)** Various stressors can cause endoplasmic reticulum (ER) stress, whereby the cell is challenged to cope with the increased load of misfolded proteins. The accumulation of the protein load initiates the *unfolded protein response* in the ER; if restoration of the protein fails, the cell dies by apoptosis. An example of a disease caused by misfolding of proteins is Alzheimer disease. (From Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020:55.)

Illustration A shows the stages in the incorporation of proteins in a normal cell: R N A, chaperones, and mature folded proteins. Illustration B shows the process diagram for endoplasmic reticulum stress. Stage 1. Metabolic alterations resulting in decreased

energy stores, genetic mutations in proteins, chaperones, viral infections, and chemical insults. Stage 2. Excess misfolded proteins, resulting in E R Stress, where protein folding demand is much greater than the protein folding capacity. Failure of adaptation at Stage 2 results in Apoptosis. Cellular adaptation at Stage 2 results in an unfolded protein response, where decreased protein synthesis and increased production of chaperones leads to mature folded proteins.

Excessive or insufficient apoptosis is known as *dysregulated apoptosis*. A low rate of apoptosis can encourage survival of abnormal cells, particularly mutated cells, which predispose the individual to develop cancer. Similarly, defective apoptosis may fail to eliminate lymphocytes implicated in attacking host tissue (self-antigens), thus leading to autoimmune disorders. Excessive apoptosis occurs in several neurodegenerative diseases and with ischemic injury, such as with myocardial infarction and stroke, and in the context of virus-infected cells.

Initiation of apoptosis requires tightly regulated cell signaling. Key components involve proteases, enzymes that divide other proteins. Caspases are a family of aspartic acid-specific enzymes that trigger proteolytic activity in response to signals, which induce apoptosis. Specifically, activated caspases cleave other proteins within the system, initiating a series of sequential reactions known as the "suicide" cascade. The cascade results in a rapid and contained cell death. Caspase activation triggers two different but convergent pathways: the *mitochondrial (intrinsic) pathway* and the *death receptor (extrinsic) pathway* (Fig. 2.40). Cells undergoing apoptosis release chemical factors, which recruit phagocytes. The phagocytes quickly engulf cellular remnants, reducing their

potential to induce damaging inflammation. Cell death secondary to necrosis is less contained because injured cells swell and burst, spilling their contents into the extracellular spaces, triggering an inflammatory response.

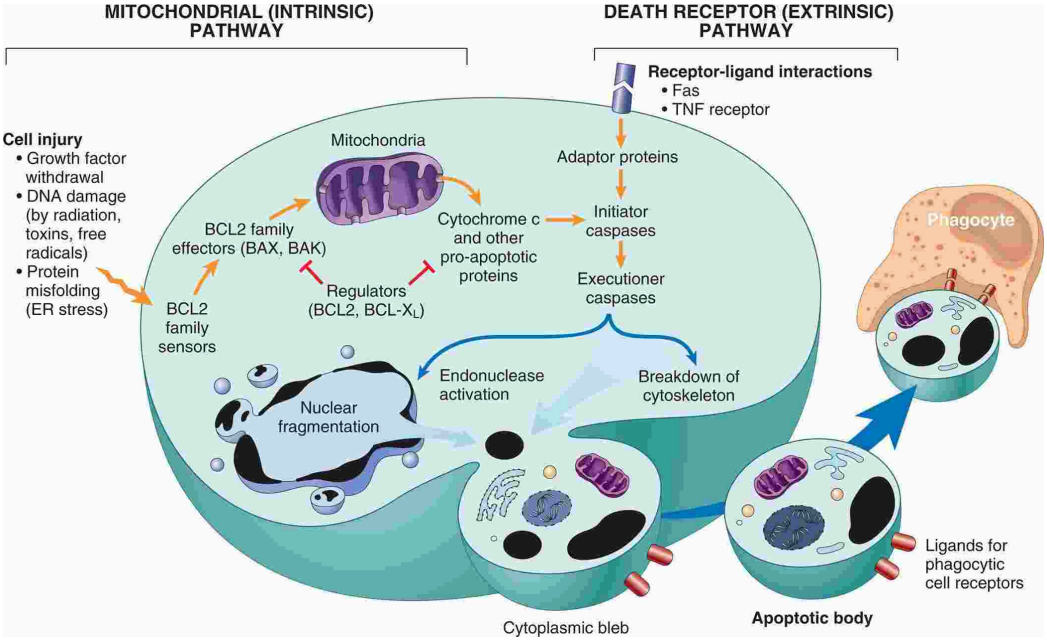

FIG. 2.40 Mechanisms of Apoptosis.
Two pathways of apoptosis differ in their induction and regulation, and both culminate in the activation of "executioner" caspases. The induction of apoptosis by the mitochondrial pathway involves BCL2 family, which causes leakage of mitochondrial proteins. The regulation of the death receptor pathway involves the proteases, called caspases. *ER*, Endoplasmic reticulum. (From Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathophysiologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2020.)

An illustrated process diagrams shows the mechanisms of apoptosis. The illustration shows a cross-section of a cell structure. There are two sections in the mechanism of apoptosis. Section 1. Mitochondrial, intrinsic, pathway. Cell injury: growth factor withdrawal, D N A damage, by radiation, toxins, and free radicals, and protein

misfolding, E R stress. B C L 2 family sensors. B C L 2 family effectors, B A X, B A K. Amplifying regulators: B C L 2, B C L-X L. Cytochrome c and other pro-apoptotic proteins. Nuclear fragmentation. Section 2. Death receptor, extrinsic, pathway. Receptor-ligand interactions: Fas and T N F receptor. Adaptor proteins. Initiator caspases, amplified by cytochrome c and other pro-apoptotic proteins. Executioner caspases. Breakdown of cytoskeleton. Cytoplasmic bleb from the cell results in an apoptotic body with ligands for phagocytic cell receptors that bind to phagocytes.

Autophagy

The Greek term autophagy means "eating of self." Autophagy is a "recycling factory" as well as a survival mechanism. It is a self-destructive process that delivers cytoplasmic contents to the lysosome for degradation. Box 2.4 includes terminology used to describe autophagy.

Box 2.4

The Major Forms of Autophagy

Macroautophagy, the most common term to refer to autophagy, involves the sequestration and transportation of parts (cargo) of the cytosol in an autophagic vacuole (autophagosome).

Microautophagy is the inward invagination of the lysosomal membrane for cargo delivery.
Chaperone-mediated autophagy is the chaperone-dependent proteins that direct cargo across the lysosomal membrane.

When cells are starved or nutrient deprived, autophagy initiates a "cannibalization response" that digests the cell and recycles the contents. Autophagy can maintain cellular metabolism under conditions of starvation. Under conditions of stress, autophagy removes damaged organelles, thus enhancing the likelihood of survival. Autophagy also has been implicated in physiologic states (e.g., aging), and pathologic processes (e.g., cancer, heart disease, neurodegeneration diseases, inflammation, and infection). The process begins with a cup-shaped, curved membrane known as a *phagophore* (Fig. 2.41). This membrane expands and engulfs intracellular contents—organelles, ribosomes, and proteins—forming a double membrane *autophagosome*. The autophagosome fuses with the lysosome, forming an *autophagolysosome*. Lysosomal acid proteases then degrade the autophagosome into amino acids and other elemental substances. These end-products are transported out of the cytoplasm, where they are subsequently utilized for the synthesis of macromolecules or for fueling metabolism.

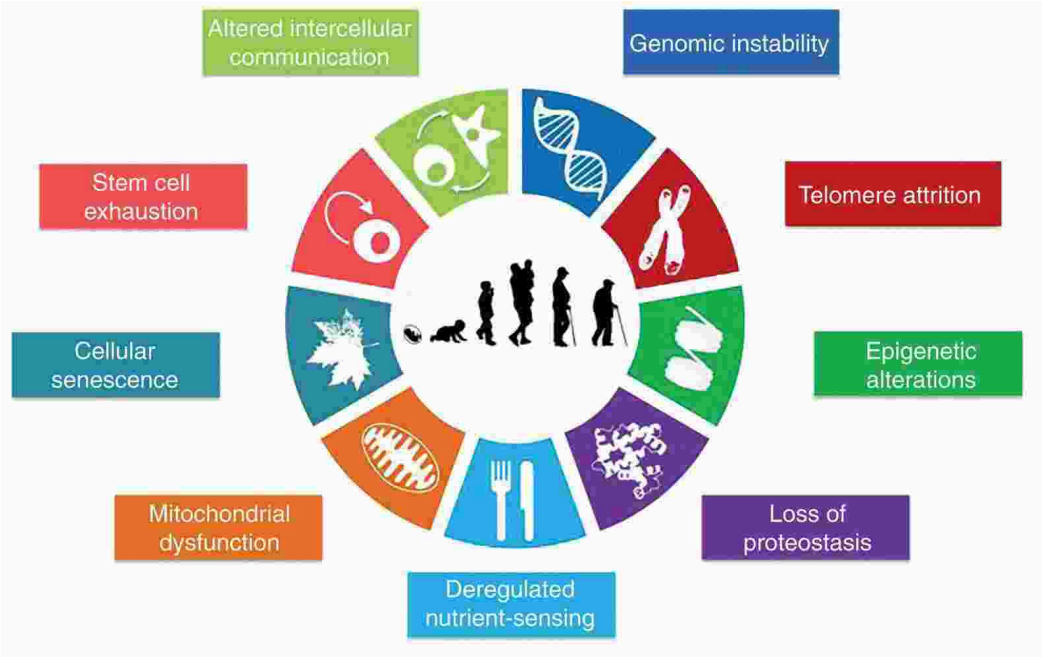

FIG. 2.41 Hallmarks of Aging.
Emerging are the hallmarks of aging: genomic instability, telomere attrition, epigenetic alterations, loss of proteostasis, deregulated nutrient-sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication. (From López-Otin C, Blasco MA, Partridge L, et al. The hallmarks of aging. *Cell*, 2013;153(6):1194–1217.)

An illustration lists the hallmarks of aging: genomic instability, telomere attrition, epigenetic alterations, loss of proteostasis, deregulated nutrient-sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication.

The "garbage collecting" and recycling functions characterizing autophagy become less efficient and less discriminating in aging

individuals. Consequently, harmful agents accumulate and cause increasing cell damage as people age. Failure to clear protein products in neurons of the CNS has been linked with dementia. Similarly, failure to clear mitochondria, which generates ROS, can lead to nuclear DNA mutations and cancer. These processes may even partially define normal aging. Enhancing autophagy may serve to decrease the incidence of cancer and prevent the development of certain degenerative diseases.

Aging and Altered Cellular and Tissue Biology

Aging is defined as a time-dependent functional decline which is universal and, so far, inevitable. Life span is the period from birth to death, and its study offers insight into the aging process. Aging is associated with a gradual loss of homeostatic mechanisms. It is a complex process involving a multiplicity of factors; however, the underlying causes of aging are conceptualized as the "Hallmarks of Aging." Investigators have focused on genomic instability, telomere attrition, epigenetic alterations, loss of proteostasis or maintenance of protein homeostasis, deregulated nutrient-sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication (Table 2.13). These hallmarks are identifying the differences between the young cell and the old cell (Fig. 2.42). Active investigation includes the study of genetic signatures in humans with exceptional longevity. One area of current research is epigenetic mechanisms that modulate gene expression and the role of intrauterine environment. Lifelong patterns of health, the effects of personality, behavioral patterns, and social support also are thought to be highly relevant.

Table 2.13

Hallmarks of Aging

Hallmarks	Characteristics
Genomic Instability	Aging is the accumulation of genetic damage throughout life. Integrity and stability of DNA is constantly challenged by exogenous factors (physical, chemical, biological) and endogenous factors (DNA replication errors reactive oxygen species [ROS], spontaneous hydrolytic factors).
Telomere Attrition	Chromosomal regions, such as telomeres, are susceptible to age-related deterioration. Telomeres are short, repeated sequences of DNA at the ends of linear chromosomes; they enable the complete replication of chromosome ends. Animal models have established links between telomere loss, cellular senescence, and aging.
Epigenetic Alterations	Epigenetic alterations affect all cells and tissues throughout life (see Chapter 6). Epigenetic changes involve DNA methylation patterns, histone changes, and chromatin remodeling. Chromatin modifying proteins (such as SIRT1) are involved in DNA repair, proteostasis, mitochondrial function, nutrient-sensing pathways, and inflammation. Collectively, the epigenome holds promise of improving age-related pathologies and extending healthy lifespan. Resveratrol upregulates SIRT1

Hallmarks	Characteristics
	activity and has been studied in relation to aging.
Loss of Proteostasis	Impaired protein homeostasis or proteostasis is linked to aging. Proteostasis involves mechanisms of corrected folded proteins (see Chapter 1), heat-shock family of proteins (protect cells under stress, such as different temperatures), and mechanisms for degradation of proteins. Chronic expression of unfolded, misfolded or aggregated proteins contributes to some age-related pathologies (Alzheimer disease, Parkinson disease), cataracts.
Deregulated Nutrient-sensing	Genetic mutations can reduce the function of growth hormone (GH), insulin-like growth factor (IGF-1) receptor, insulin receptor and intracellular effectors such as, Ak strain transforming enzyme (AKT), mammalian target of rapamycin (mTOR), and Forkhead box O proteins (FOXO), all have been linked to longevity. In investigated species, dietary restriction (DR) increases lifespan or health span. Anabolic signaling accelerates aging and decreased nutrient signaling extends longevity.
Mitochondrial Dysfunction	As cells and organisms age, the efficiency of the respiratory chain diminishes, increasing electron leakage and reducing adenosine triphosphate (ATP). Multiple sources of data support increased ROS increases aging, mitochondrial

Hallmarks	Characteristics
	dysfunction, and global cellular damage. Multiple mechanisms causing defective mitochondria include mutations, deletions in mitochondrial DNA (mtDNA), oxidation of mitochondrial proteins, destabilization of the respiratory chain, changes in lipid composition of mitochondrial membranes, fission and fusion events, and defective autophagy. Endurance training and alternate-day-fasting may improve health span.
Cellular Senescence	Cellular senescence is defined as stable arrest of the cell cycle linked to phenotypic changes. Cellular senescence is not a generalized property of all tissues in aged organisms. The accumulation of senescent cells with aging reflects either an increase in the rate of senescent cells and/or a decrease in their clearance because of a decreased immune response. The primary purpose, however, of senescence is to prevent the propagation of damaged cells and to trigger their demise by the immune system. It is possible, therefore, that it plays a protective stress response, for example, as a potent anticancer mechanism. However, the accumulation of senescent cells drives aging and age-related diseases. Senescent cells produce and secrete a complex of factors, collectively known as the **senescent-associated secretory-phenotype (SASP)**.

Hallmarks	Characteristics
Stem Cell Exhaustion	The decline in the regenerative potential of tissues is often called stem cell exhaustion. For example, hemopoiesis declines with age resulting in a decrease of adaptive immune cells (immunosenescence), an increased incidence of anemia, and myeloid malignancies. Telomere shortening is also a cause of stem cell decline. From animal studies, a functional attrition of other stem cells has been found in the forebrain, the bone, muscle fibers, and others. An excessive increase in stem cells is also deleterious because it can exhaust stem cell niches. Transplantation of muscle-derived stem cells from young mice to old mice extends lifespan and improves degenerative changes in these mice. Experiments call *parabiosis* ("living beside," a technique that combines two living organisms, such as one young and one old) have demonstrated that the decline in neural and muscle stem cell function in old mice can be reversed by systemic factors from young mice. Stem cell exhaustion is thought to be one of the "key" culprits of aging.
Altered Intracellular Communication	Aging involves changes at the level of intercellular communication, including endocrine, neuroendocrine, or neuronal.
Inflammation	An aging-associated alteration in intercellular communication is "inflammaging," a smoldering pro-

Hallmarks	Characteristics
	inflammatory phenotype that accompanies aging in mammals. Inflammaging results from multiple causes, such as the accumulation of pro-inflammatory tissue damage, a dysfunctional immune system to clear pathogens, dysfunctional host cells, propensity to secrete pro-inflammatory cytokines, enhanced activation of the NF-κB transcription factor, or a defective autophagy response. Importantly, evidence indicates that aging-related changes in one tissue can lead to aging-specific deterioration of other tissues, emphasizing the inter-organ concept, or "contagious aging" of the aging phenotype. The microenvironment is involved, as well as the microbiome.

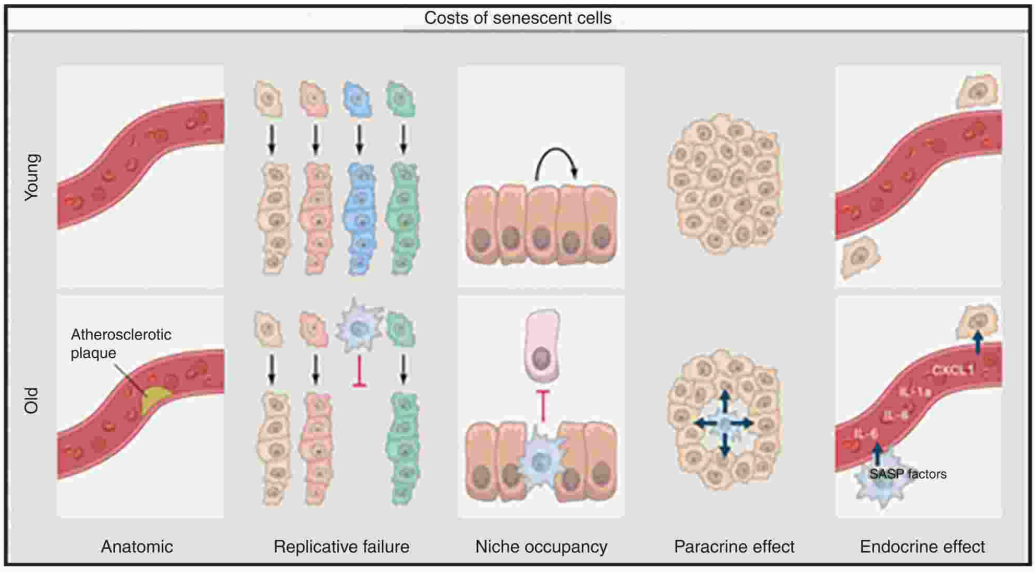
A



B

FIG. 2.42 Benefits and Costs of Senescence. **(A)** Senescence allows tumor suppression by boosting local anti-tumor immunity. The activation of the *CDKN2A* locus appears to limit the size of atherosclerotic plaques, thus reducing blood vessel obstruction. Senescence resulting from $p21^{CIP}$ expression during embryogenesis might

be required for properties of fetal development. Senescence contributes to wound healing and overall host immunity. **(B)** Accumulation of senescent cells can lead to anatomic lesions such as in atherosclerotic plaque. Loss of replicative capacity of some senescent cells, such as T cells or pancreatic β cells, may result in defects in tissue regeneration. Occupancy of prized "niches" by senescent cells may impair tissue homeostasis. Paracrine and endocrine amplification of pro-inflammatory hormones and enzymes promotes tissue dysfunction locally and at the organismal level (From He S, Sharpless NE. Senescence in health and disease. *Cell*, 2017;169(6);1000–1011.)

Two illustrations depict the benefits of roles of cellular senescence and the detrimental effects of senescent cells.Top panel, the benefit of senescence affords tumor suppression in a cell-intrinsic manner and contributes to wound healing and host immunity. Bottom panel, accumulation of senescent cell leading to anatomic lesion, replicative failure, niche occupancy, paracrine effect, and endocrine effect.

Pathways that regulate the aging process and associated disease risks include senescence, proteostasis, and changes in metabolism. Senescence is a process leading to permanent proliferative arrest or nondividing state of cells *(replicative senescence)* in response to various stressors. Mechanisms of replicative senescence include progressive telomere shortening or repeated sequences of DNA

present at the ends of linear chromosomes that regulate replication of chromosome ends and protect them against fusion and deterioration.[123] The two best-studied mechanisms of senescence are (1) impeding the replicative potential of tissue stem cells (another hallmark of aging, stem cell exhaustion), immune cells (immunosenescence), and stromal cells; and (2) disrupting organ function from release of pro-inflammatory factors (e.g., interleukin 6 [IL-6]and tumornecrosis factor alpha [TNF-α]) by senescent cells.[94,123]

Senescent cells accumulate with time and contribute to tissue dysfunction. The biologic understanding of senescence in humans is limited, but it seems significant because of two factors: (1) senescence causes a loss of tissue-repair capacity because of cell cycle arrest in progenitor cells, and (2) it produces proinflammatory and matrix-degrading molecules in what is known as the *senescence-associated secretory phenotype (SASP)*. Fig. 2.43 shows the benefits and costs of senescence.

Diet is believed to play a significant role in both the development and the prevention of age-related diseases. A major research challenge has been to separate the causes of cell and tissue aging from the changes that characterize it. Understanding the physiology of aging supports public health efforts to promote healthy aging and delay the progression to vulnerability and frailty.

Traditionally, aging has not been considered a disease; rather it has been regarded as a normal process. Disease has been defined as deviation from the normal state secondary to injury or abnormal function. Conceptually this distinction has been clear; however, issues involving cellular injury or damage challenge traditional views. Life span can be altered in animals. But extending life span is not equivalent to delaying aging. For example, death can be prevented through treatment of an acute infection, but the *rate* of aging continues. What is critical is extending a person's *health span*, which results in an increase in life span and a decrease in time spent in a frail state. The passage of time cannot be stopped *(chronologic aging)*, but it may be possible to delay the decline in health, or

biologic aging. Table 2.14 presents examples of degenerative changes and tissue and systemic aging.

Table 2.14

Aging: Examples of Degenerative Extracellular Changes and Tissue and Systemic Aging

Degenerative extracellular changes	Binding of collagen; increase in free radicals; alterations of tendons, ligaments, bones, and joints; development of peripheral vascular disease, particularly, arteriosclerosis Extracellular matrix with increased cross-linking, decreased synthesis, and increased degradation of collagen Oxidative stress damages cellular function Development of cardiovascular diseases with endothelial cell shifts to proinflammatory, proliferative, and procoagulative state
Tissue and systemic aging	Progressive stiffness or rigidity affects many systems (arterial, pulmonary, musculoskeletal) Peripheral resistance to blood flow Thymus atrophy occurs at puberty, causing a decreased response to T-dependent antigens (foreign proteins), increased formation of autoantibodies and immune complexes, decreasing effectiveness of immune function later in life

	Reproductive system loss of ova and spermatogenesis decreased in men Responsiveness to hormones decreases in the breast and endometrium Stomach decreases in the rate of emptying and secretion of hormones and hydrochloric acid Muscular atrophy decreases motor tone and contractility Sarcopenia or loss of muscle mass and strength Decrease in height Reduction in circumference of the neck, thighs, and arms; widening of the pelvis; lengthening of the nose and ears Increase in body weight in middle age followed by a decrease in stature, weight, fat-free mass, and body mass As the amount of fat increases, the percentage of total body water decreases. Increased body fat distribution (abdominal) is associated with non-insulin-dependent diabetes and heart disease. Total body potassium concentration decreases

Normal Life Span and Life Expectancy

The maximal life span of humans is 80 to 100 years, and it does not vary significantly among populations. In primitive societies, few individuals reach the maximal life span. However, in societies with improved sanitation, housing, nutrition, and health care, many individuals attain the maximal life span. Life expectancy is the *average* number of years of life remaining at a given age (Box 2.5). Life expectancy in the United States has declined since 2014.[124] Life expectancy in the United States in 1980 was 73.6 years, in 2014 was 78.9 years, and in 2018 was 78.7 years. These trends have been driven by increasing mortality among working-age adults, particularly those of lower socioeconomic status.[125] Although working-age adults with a 4-year college degree have experienced gains in life expectancy, those with a high school diploma have experienced a decline. Differences in longevity are not the same across racial and ethnic groups, with elevated rates of mortality among Black and American Indian adults.[126]

Box 2.5

Life Expectancy Differences Across the United States

- Improved public health strategies and health advances in the United States between the years 1900 and 2000 added about 30 years to life expectancy.
- The increase in life expectancy, however, does not apply to all Americans.
- Women outnumber men in each successive age group from 65 years and older.
- The historic advances in life expectancy resulted in a larger older adult population and, for some, problems of disability, disease, and socioeconomic hardship.

- Although U.S. spending on health care far exceeds that of other countries, rates of life expectancy and key measures of health lag behind those of other high-income countries.
- The National Center for Health Statistics has reported that Americans, on average, have a life expectancy of 78.8 years, a decline from 78.9 in 2014.
- The decline in life expectancy is attributed to rising fatalities from heart disease and stroke; diabetes; drug overdoses; accidents, including unintentional injuries; and other conditions.
- Chronic health problems associated with modifiable risk factors, such as smoking, poor nutrition, overweight, and lack of physical activity, represent 6 of the 10 costliest in terms of health care burden.
- The preventable conditions lead to injuries and diseases and cause soaring medical and labor costs that burden U.S. employers and bankrupt families.
- All these conditions are highly amenable to population-based preventive strategies.
- The current generation of children and young adults in the United States could become the first generation to have shorter life spans, multiple medical conditions, and fewer years of healthy life.

Frailty

Frailty, a common clinical syndrome in older adults, is characterized by overall weakness, decreased stamina, and functional decline. The individual is susceptible to functional and cognitive decline, falls, chronic illnesses, hospitalization, and mortality.[127] This presentation is often described as frailty syndrome. Criteria indicating compromised functioning include low grip strength, slowed walking speed, low physical activity, and unintentional weight loss.[128] The pathophysiology of frailty includes several interrelated physiologic

systems (Fig. 2.43). It is complex, with multiple aging mechanisms influenced by genetic factors, epigenetic factors, or both, as well as environmental factors. Frailty also can involve such alterations as osteopenia, cognitive impairment, and anemia. Differences between men and women in presentation include the following: (1) Higher baseline levels of muscle mass in men may be protective against frailty; (2) testosterone and growth hormone can provide advantages to men in muscle mass maintenance; however, high testosterone in men may weaken immune response; (3) cortisol is more dysregulated, especially in older women; (4) alterations in immune function and immune responsiveness to sex steroids make men more susceptible to sepsis and infection, and make women more susceptible to chronic inflammatory conditions and loss of muscle mass; (5) chronic inflammation plays a more critical role in the pathophysiology of frailty in females; and (6) lower levels of activity and caloric intake may increase the risk of frailty in women.[129] Sarcopenia and cachexia are common sequelae of aging and also occur secondary to many chronic illnesses.

FIG. 2.43 Frailty.
Frailty is a disorder of multiple interrelated physiologic systems. A gradual decline progresses with aging, but in frailty this decline becomes accelerated. Homeostatic mechanisms begin to fail, and vulnerability becomes disproportionate to changes in health status after a relatively minor stressor event. (Reprinted with permission from Elsevier. From Clegg A, et al. Frailty in elderly people, *Lancet* 2013;381(9868):752–762.)

A process diagram represents the sequence of stages leading to frailty. Epigenetic mechanisms affect genetic factors and environmental factors leading to cumulative molecular and cellular damage. This leads to reduced physiological reserve: brain, endocrine, immune, skeletal muscle, cardiovascular, respiratory, and renal. Amplified by physical activity and nutritional factors, this leads to frailty. Amplified by stress, frailty leads to falls, delirium, and fluctuating disability, which leads to back to frailty. Falls, delirium, and fluctuating disability also lead to reduced physiological reserve, increased care needs, admission to hospital, and admission to long-term care.

Somatic Death

Somatic death is systemic death of the entire body. Unlike the changes that follow cellular death, postmortem change is diffuse and

does not involve an inflammatory response. In some instances, postmortem evaluation by autopsy is the only opportunity to macroscopically observe organs and take optimal samples for histological and molecular analyses (see Emerging Science Box: COVID-19 and Postmortem Changes).[130] Within minutes after death, postmortem changes appear, and it becomes readily evident that death has occurred. Upon somatic death, there is complete cessation of respiration and circulation, followed rapidly by a host of other changes. The surface of the skin becomes pale and yellowish, marking the first stage after death known as pallor mortis. In instances of death secondary to carbon monoxide poisoning, drowning, or chloroform poisoning, this phenomenon may not be apparent; instead, a lifelike coloration of the cheeks and lips may persist even after death has occurred.[131] Postmortem reduction of body temperature is algor mortis. Immediately after death, body temperature gradually falls and then decreases more rapidly (approximately 1.0°F to 1.5°F/hr.) until body temperature equals environmental temperature.

In cases of death caused by certain infective diseases, body temperature may transiently rise for a short time.

Blood pressure within the retinal vessels decreases, causing muscle tension to decrease and the pupils to become dilated. The face, nose, and chin begin to look "sharp" or "peaked" as blood and fluids drain from these areas. Gravity causes blood to settle in the most dependent, or lowest, tissues, causing a purple discoloration called livor mortis, which appears within half-an-hour to 1 hour of death and becomes fixed within 6 to 8 hours after death. Similarly, muscle stiffening or rigidity begins within a few hours of death, leading to the development of full body rigor mortis.[132] The smaller muscles are usually affected first, particularly the muscles of the jaws. Rigor mortis is caused by acidic compounds accumulating within the muscles due to the breakdown of carbohydrate and the depletion of ATP. This interferes with ATP-dependent detachment of myosin from actin (contractile proteins).[133] The development of rigor mortis is a process of change in the intensity of muscular rigidity

over time. Initially, the muscular intensity is weak and affects involuntary muscles first and then voluntary muscles; subsequently, the intensity increases and reaches the maximum; finally, intensity decreases and practically disappears.[132] Rigor mortis develops sequentially, maintaining a steady state for approximately 12 hours, and becomes fully developed, affecting the entire body. Then, it gradually diminishes, and the body becomes flaccid in the following 12 to 14 hours. The disappearance of rigor mortis is the same as its order of appearance. The disappearance of rigor mortis denoted by flaccidity of muscles is caused by the action of alkaline liquids produced by putrefaction.[132,134] Putrefaction is the decomposition of the body carried out by microbes. Natural gut bacteria migrate into the blood vessels and spread all over the body while other external micro-organisms enter the body through the alimentary canal, respiratory tract, and open wounds. Without the body's natural defense and immune mechanisms, the bacteria continue to replicate, feeding on the proteins and carbohydrates of the blood and body parts. The principal bacterial agent causing putrefaction is the gram-positive, anaerobic, and rod-shaped *Clostridium welchi*.[135] Signs of putrefaction—state of decay with foul-smelling odor—are generally obvious about 24 to 48 hours after death. Putrefaction changes vary depending on the temperature of the environment. The most visible is greenish discoloration of the skin, particularly on the abdomen. The discoloration is from bacteria generating hydrogen sulfide and then reacting with the hemoglobin forming sulfahemoglobin, which stains the surrounding area green. The greenish-blue discoloration seen in superficial blood vessels, which is often visible through the skin, is from putrefaction of erythrocytes, and is known as "marbling" of the skin.[136] Slippage or loosening of the skin from underlying tissues occurs at the same time. After this, swelling or bloating of the body and liquefactive changes occur, sometimes causing opening of the body cavities. At a microscopic level, putrefactive changes are associated with the release of enzymes and lytic dissolution called postmortem autolysis.

Decomposition occurs when the organic matter of the body is broken down into elemental matter and recycled into the earth's biosphere. The body's own enzymes and chemicals drive this process. Putrification may be ongoing simultaneously. Skeletonization, the final stage after death, occurs when the various tissues of the body have degraded and decayed to the point of exposing the skeleton. When all the organic matter of the body is gone, the process is complete, and only disarticulated bones will remain. Depending on the environment surrounding the skeleton, bones can persist for periods lasting from several years to relatively indefinitely. Under rare circumstances, fossilization may occur. At this stage, the bones are infiltrated and replaced with inorganic mineral deposits. If this process transpires, the fossilized bones will have the permanence of rocks, thus accounting for many museum specimens. Fossilization is uncommon and only occurs under select and relatively unusual environmental conditions.

Summary Review

Cellular Adaptation

1. Injury to cells and their surrounding environment, called the *extracellular matrix*, leads to tissue and organ injury. Cellular adaptation is an alteration that enables the cell to maintain a steady state despite adverse conditions.
2. The most significant *adaptive* changes include atrophy, hypertrophy, hyperplasia, and metaplasia. Dysplasia is not a true cellular adaptation but rather atypical hyperplasia.
3. Atrophy is a decrease in cellular size, can affect any organ, and is most common in skeletal muscle, the heart, secondary sex organs, and the brain. Pathologic atrophy occurs as a result of disuse, insufficient blood supply, insufficient hormonal or neural stimulation, and decreased amino acid uptake.
4. Physiologic atrophy occurs with early development; for example, the thymus gland involutes and atrophies.

5. Aging causes brain cells and endocrine-dependent organs, such as the gonads, to become atrophic.
6. Hypertrophy is an increase in the size of cells caused by increased work demands or hormonal stimulation. Hypertrophy can be physiologic or pathologic. Amounts of protein in the plasma membrane, endoplasmic reticulum, microfilaments, and mitochondria are increased.
7. Hyperplasia is an increase in the number of cells caused by an increased rate of cellular division. Compensatory hyperplasia enables certain organs to regenerate. The main mechanism for hyperplasia is the production of hormones or growth factors. Hormonal hyperplasia occurs chiefly in estrogen-dependent organs to replace lost tissue or support new growth, such as during pregnancy.
8. Pathologic hyperplasia is the abnormal proliferation of normal cells in response to excessive hormonal stimulation or the effects of growth factors on target cells.
9. Dysplasia, or atypical hyperplasia, is an abnormal change in the size, shape, and organization of mature tissue cells. Importantly, the term dysplasia is not cancer and may not progress to cancer. Dysplastic tissues that do not involve the entire thickness of the epithelium may be completely reversible.
10. Metaplasia is the reversible replacement of one mature cell type by another, sometimes less differentiated, cell type. It is found in association with tissue damage, repair, and regeneration. Metaplasia develops from reprogramming of local tissue stem cells or colonization by differentiated cell populations from adjacent sites.

Cellular Injury

1. Injury to cells and to the extracellular matrix (ECM) leads to injury of tissues and organs, ultimately determining the

structural patterns of disease. Injured cells may recover (reversible injury) or die (irreversible injury).

2. Cellular injury is caused by a lack of oxygen (hypoxia), free radicals, caustic or toxic chemicals, infectious agents, unintentional and intentional injury, inflammatory and immune responses, genetic factors, insufficient nutrients, or physical trauma from many causes. Injurious stimuli cause cell stress.
3. Cell injury can be acute or chronic, and it can be reversible or irreversible. It can involve necrosis, apoptosis, autophagy, accumulation, or pathologic calcification.
4. Four biochemical themes are important to cell injury: (a) depletion of ATP, (b) decreased levels of oxygen and increased levels of oxygen-derived free radicals, (c) increased concentration of intracellular calcium and loss of calcium steady state, and (d) defects in membrane permeability.
5. The sequence of events leading to cell death is commonly decreased ATP production, failure of active transport mechanisms (the Na^+-K^+ pump), cellular swelling, detachment of ribosomes from the endoplasmic reticulum, cessation of protein synthesis, mitochondrial swelling as a result of calcium accumulation, vacuolation, leakage of digestive enzymes from lysosomes, autodigestion of intracellular structures, lysis of the plasma membrane, and death.
6. Injury to cell components includes membrane damage, protein folding defects, mitochondrial compromise, and DNA damage.
7. The initial insult in hypoxic injury is usually ischemia—the cessation of blood flow into vessels that supply the cell with oxygen and nutrients. Hypoxia can induce inflammation, and inflamed lesions can become hypoxic. Hypoxia is a prominent feature encountered in bacterial infections, wounds, cardiovascular defects, and cancer.

8. Restoration of oxygen after ischemic injury can result in reperfusion (reoxygenation) injury. Reperfusion injury results from the generation of highly reactive oxygen intermediates or radicals and promotes proinflammatory neutrophil adhesion to the endothelium.
9. Inherent reactive oxygen species (ROS) from aerobic metabolism play a crucial biologic role, not just in various diseases but also in cellular communication and cell function. ROS reversibly modulates many intracellular signaling pathways. ROS can affect protein functions through several mechanisms, including regulation of protein expression, posttranslational modifications, and alteration of protein stability.
10. Reduction-oxidation- (redox) dependent regulation and the roles of ROS include both normal physiologic and pathologic roles. These expanding roles include proliferation and differentiation, immune function, stem cell self-renewal, tumor progression, autoimmunity, stem cell exhaustion, senescence, and longevity.
11. Cell injury produced by free radicals, particularly ROS, is an important mechanism of cell damage in many conditions, including chemical and radiation injury, ischemia-reperfusion injury, microbial killing by phagocytes, and cellular aging.
12. A significant mechanism of membrane damage is injury caused by free radicals, including oxidative stress. Oxidative stress can activate several intracellular signaling pathways because ROS can modulate enzymes and transcription factors. Free radicals are difficult to control and initiate chain reactions.
13. Sources of oxidants are numerous and include cellular organelles, particularly mitochondria, endoplasmic reticulum, and peroxisomes, NADPH oxidases, and other enzymes.
14. Free radicals can cause (a) lipid peroxidation or the destruction of unsaturated fatty acids, (b) alterations of

proteins, protein loss, and protein misfolding, and (c) mutations in DNA.

15. Mitochondria contain their own DNA, called *mitochondrial DNA* (mtDNA), and can encode proteins involved in energy production. mtDNA encodes enzymes involved in oxidative phosphorylation, and mutations affecting these genes exert their damaging effects on organs most dependent on oxidative phosphorylation, such as the CNS, skeletal muscle, cardiac muscle, liver, and kidneys. Emerging is the role mitochondria have in mediating environmental changes and genomic responses.
16. Humans are exposed to thousands of chemicals that have inadequate toxicologic data. Toxicity pathways or cellular response pathways result in adverse health effects when disturbed. Components of these pathways include oxidative stress, heat shock response, DNA damage response, hypoxia, ER stress, mental stress, inflammation, and osmotic stress.
17. The initial insult in chemical and toxic injury is damage or destruction of the plasma membrane. Two general mechanisms include direct toxicity and conversion to toxic intermediates or metabolites. Examples of chemical agents that cause cellular injury include air pollutants, insecticides, herbicides, alcohol, lead, carbon monoxide, ethanol, mercury, opioids (heroin, morphine, prescription drugs for pain), and social or street drugs.
18. Drug overdoses dramatically increased with the COVID-19 pandemic as a contributing factor. The leading cause of poisoning in children is cosmetics and personal care products, cleaning substances, and analgesics. The use of e-cigarettes, or vaping, by adolescents, children, and young adults has become a leading cause of lung injury.
19. Under investigation are the beneficial effects of chemical compounds called *phytochemicals*. Examples of these products include certain fruits and plants, chamomile, silymarin, carrot, ginger root, milk thistle seed, rosemary leaf, turmeric, and others.

20. Globally, snakebite envenoming or poisoning by venom can have significant morbidity and mortality. Global data show 4.5 to 5.4 million people per year get bitten by snakes. Most snakebites in the United States are from pit vipers, with the majority from rattlesnakes. In the United States, about 9000 people per year suffer a snake bite, and 5 deaths occur. Worldwide, 1.8 to 2.7 million develop clinical illness and 81,000 to 138,000 deaths from complications.
21. High-risk groups for snakebite include rural agricultural workers, herders, fishermen, hunters, working children, living in poorly constructed homes, and those with limited education and medical resources. Risks also occur for professional snake handlers, and hiking or walking and stepping on snakes or moving close to them while they are hiding.
22. Snakes have hollow fangs in their anterior mouth and inject venom into subcutaneous tissue. Venom has both fibrinolytic and protein C activation, which can cause coagulopathy. Certain species can cause neurotoxic effects, including cranial nerve dysfunction, weakness, and paralysis. In total, snakebites can cause various local, hematologic, neurologic, and systemic effects.
23. The world's largest single environmental health risk is air pollution. Air pollution was the fourth leading risk factor for premature death globally, with nearly 12% of all deaths and more than 6.67 million in 2019 alone. Three types of air pollution that impact human health are ambient (outdoor) fine particle pollution, ambient tropospheric ozone, and household air pollution. Air pollution is contamination of the environment by any chemical, physical, or biologic agent that modifies natural characteristics of the atmosphere.
24. Six pollutants as criteria air pollutants: carbon monoxide, lead, nitrogen oxides, photochemical oxidants, ground-level ozone particle pollution or particulate matter, and sulfur

oxides. Fine particles or particulate matter $PM_{2.5,}$ pose the greatest risk to health.

25. By reducing air pollution levels, countries can lower the burden of diseases from stroke, heart disease, lung cancer, and chronic and acute respiratory diseases, including asthma. Prompt and sustained health benefits can come from improved air quality.
26. Ground level, or tropospheric, ozone is a highly reactive pollutant that causes adverse effects on human health, food crops, and other vegetation.
27. Indoor air pollution from the use of solid fuels was estimated to cause 2.31 to close to 4 million premature deaths globally.
28. Heavy metals commonly associated with harmful effects in humans include lead, mercury, arsenic, and cadmium. Studies of the involvement of metals in pathophysiology include DNA repair mechanisms, tumor suppressor functions, and interference with signal transduction pathways.
29. Unintentional and intentional injuries are an important health problem in the United States. Injuries include motor vehicle crashes, opioid overdoses, poisonings, sports and recreation-related injuries, firearms, falls, blunt force (tearing, shearing, crushing of tissues), asphyxia (suffocation, strangulation, chemical asphyxiants, drowning), and others, including injury from medical care itself.
30. Injury from microorganisms lies in their ability to survive and proliferate in the human body. Injury depends on the microorganisms' ability to invade and destroy cells, produce toxins, and produce damaging hypersensitivity reactions. In 2020, COVID-19 was the third leading cause of death, following heart disease and cancer.
31. Activation of inflammation and immunity, which occurs after cellular injury or infection, involves powerful biochemicals and proteins capable of damaging normal (uninjured and uninfected) cells.

32. Globally, the direct and indirect impacts of climate change on human health continue to be observed. The direct effects on health include increasing temperatures, which include heat-related mortality and morbidity, increased occurrence and intensity of storms, which increase injury, death, and psychological stressors. Indirect climate change affects health because of altered environmental conditions, such as water quality and quantity, foodborne disease from changing ecosystems intensify food and nutritional security.
33. Climate is changing beyond the range of the recent geological era because levels of carbon dioxide, methane, nitrous oxide, and fluorinated gases called greenhouse gases trap heat in the atmosphere. Wildfires are becoming more common and are projected to worsen with climate change.
34. Genetic disorders injure cells by altering the nucleus and the plasma membrane's structure, shape, receptors, or transport mechanisms.
35. Deprivation of essential nutrients (proteins, carbohydrates, lipids, vitamins) can cause cellular injury by altering cellular structure and function, particularly of transport mechanisms, chromosomes, the nucleus, and DNA. Excessive amounts of other nutrients, for example, carbohydrates, can lead to obesity, changes in insulin utilization, and diabetes.
36. Injurious physical agents include temperature extremes and climate change, changes in atmospheric pressure, ionizing radiation, illumination, mechanical stresses (e.g., repetitive body movements), and noise.

Manifestations of Cellular Injury

1. Manifestations of cellular injury include accumulations of water, lipids, carbohydrates, glycogen, proteins, pigments, hemosiderin, bilirubin, calcium, and urate.
2. Accumulations harm cells by “crowding” the organelles and by causing excessive (and sometimes harmful) metabolites to

be produced during their catabolism. The metabolites are released into the cytoplasm or expelled into the extracellular matrix.

3. Cellular swelling, the accumulation of excessive water in the cell, is caused by the failure of transport mechanisms and is a sign of many types of cellular injury.
4. Accumulations of organic substances—lipids, carbohydrates, glycogen, proteins, and pigments—are caused by disorders in which (a) cellular uptake of the substance exceeds the cell's capacity to catabolize (digest) or use it or (b) cellular anabolism (synthesis) of the substance exceeds the cell's capacity to use or secrete it.
5. Calcium salts accumulate in both injured and dead tissues resulting in cellular calcification. Mechanisms include the influx of extracellular calcium in injured mitochondria, and calcium can accumulate in alveoli, gastric epithelium, and renal tubules because of the excretion of acid at these sites, leading to the local production of hydroxyl ions. Damage occurs when calcium salts clump and harden, interfering with normal cellular structure and function.
6. Dystrophic calcification (accumulation of calcium salts) is always a sign of pathologic change because it occurs only in injured or dead cells. Free calcium in the cytosol can cause activation of protein kinases, activation of phospholipases and membrane damage, and damage or disassembly of the cytoskeleton. Metastatic calcification, however, can occur in uninjured cells in individuals with hypercalcemia.
7. Disturbances in urate metabolism can result in hyperuricemia and deposition of sodium urate crystals in tissue, leading to a painful disorder called *gout*.
8. Systemic manifestations of cellular injury include fever, leukocytosis, increased heart rate, pain, and serum elevations of enzymes in the plasma.

Cellular Death

1. Cells die from accidental cell death (ACD) or regulated cell death (RCD). Cell death has historically been classified as necrosis and apoptosis. Necrosis is characterized by rapid loss of the plasma membrane structure, organelle swelling, mitochondrial dysfunction, and the lack of typical features of apoptosis. Apoptosis is known as regulated or programmed cell process by the "dropping off" of cellular fragments called *apoptotic bodies*. Oxidative stress can lead to various types of RCD as well as the antioxidant defenses. Other forms of cell loss include autophagy.
2. The five major types of necrosis are coagulative, liquefactive, caseous, fat, and fibrinoid. Different types of necrosis occur in different tissues.
3. Gangrenous necrosis, or gangrene, is tissue necrosis caused by hypoxia and subsequent bacterial invasion.
4. Autophagy is a recycling factory, a self-destructive process, and a survival mechanism. It degrades cytoplasmic components and organelles in lysosomes and salvages key metabolites to promote metabolic and nutrient homeostasis. Autophagy has a central role in cell homeostasis. It is important in diverse processes and conditions such as development, cell proliferation, remodeling, aging, cancer, heart disease, neurodegenerative diseases, inflammation, infection, metabolic diseases, and cell death.

Aging

1. Aging is a time-dependent functional decline. It is difficult to determine the physiologic (normal) from the pathologic changes of aging. The hallmarks of aging include genomic instability, telomere attrition, epigenetic alterations, loss of proteostasis or maintenance of protein homeostasis, deregulated nutrient-sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication.

2. Senescence is a process of permanent proliferative arrest or nondividing state called replicative senescence. Senescence is important because it causes a loss of tissue-repair capacity, and it produces proinflammatory and matrix-degrading molecules known as the senescence-associated secretory phenotype (SASP).
3. Aging is associated with increased levels of circulating cytokines and proinflammatory markers. There are changes in the immune system with aging known as *inflammaging*. The microbiota plays a fundamental role in the induction and function of the immune system. Diet is believed to have a major influence on both the development and the prevention of age-related diseases.
4. Humans have an inherent maximal life span (80 to 100 years) that is dictated by currently unknown intrinsic mechanisms.
5. Although the maximal life span has not changed significantly over time, the average life span, or life expectancy, has declined since 2014.
6. Frailty is a common clinical syndrome in older adults, leaving a person vulnerable to falls, functional decline, disability, disease, and death. The syndrome is complex, involving oxidative stress, dysregulation of inflammatory cytokines and hormones, malnutrition, physical inactivity, and muscle changes. Women have a higher risk of frailty than men.

Somatic Death

1. Somatic death is death of the entire organism. Postmortem change is diffuse and does not involve the inflammatory response.
2. Manifestations of somatic death are progressive, occurring in a sequenced manner. Death typically begins with the cessation of respiration and circulation and characteristic dilation of the pupils and culminates with the skeletonization of the body. The stages of death are (1) pallor mortis, (2) algor

mortis, (3) rigor mortis, (4) livor mortis, (5) putrefaction, (6) decomposition, and (7) skeletonization.

3. Depending on the environment surrounding the bones, a rare eighth stage, fossilization, may occur.

Emerging Science Box Long-Term Exposure to Air Pollution and Increased Risk of Severe COVID-19 Outcomes

Past findings have indicated that long-term air pollution exposure (especially fine particulate matter, $PM_{2.5}$) increases the risk of severe outcomes during outbreaks of infectious diseases, such as with the 2003 outbreak of severe acute respiratory syndrome (SARS) caused by a type of coronavirus called SARS-CoV. Locations in China with "moderate or high long-term air pollution index (API) had SARS case fatality rates 126% and 71% higher, respectively than locations with low AP" (Cui et al., 2003). Late December 2019, an outbreak of a novel coronavirus, COVID-19 (close relative to SARS-CoV), originated in Wuhan, China, and then rapidly spread to many other countries. By late 2020, 215 countries and territories reported having cases of COVID-19. This disease mainly affects the respiratory system and lung function (same as SARS-CoV), but many cases have shown this virus to attack other parts of the body, such as the brain causing anosmia (loss of smell and taste); has formed blood clots causing stroke and heart attacks; and even damaged kidneys requiring persons to be on dialysis. A study *(pre-print)* conducted by researchers from the Harvard T.H. Chan School of Public Health (2020) has findings consistent with the study conducted in China by Cui et al. (2003). They found statistically significant evidence that an increase of 1 $\mu g/m^3$ in long-term $PM_{2.5}$ exposure was associated with an 8% increase in the COVID-19 mortality rate. Long-term exposure to $PM_{2.5}$ is associated with cardiovascular and respiratory comorbidities that have been found to dramatically increase the risk of death in COVID-19 affected individuals. All of these results

highlight the importance of continuing to enforce existing air pollution regulations and to work on improving air quality in areas with the highest rates of air pollution-related deaths, such as in China or India.

Data from Cui Y, et al. Air pollution and case fatality of SARS in the People's Republic of China: An ecologic study. *Environmental Health*, 2003;2(1):15. doi:10.1186/1476-069X-2-15; Wu X, et al. Exposure to air pollution and COVID-19 mortality in the United States: A nationwide cross-sectional study. Preprint. *medRxiv*, 2020;2020.04.05.20054502. doi:10.1101/2020.04.05.20054502.

Emerging Science BoxLead Poisoning

In 2012, the Centers for Disease Control and Prevention (CDC) updated recommendations on children's blood lead levels. The shift is to focus on primary prevention of lead exposure to reduce or eliminate dangerous and toxic sources in children's environments. At least 4 million households have children living in houses where they are being exposed to high levels of lead. Experts now use a reference level of 5 micrograms per deciliter (mcg/dL) to identify children with blood lead levels that are much higher than most children's levels. (This new level is based on the US population of children ages 1–5 years who are in the highest percentile [2.5% of children] when tested for lead.) The CDC will update the reference value every 4 years using the most recent National Health and Nutrition Examination Survey (NHANES) based on the 97.5th percentile of blood lead distribution in children.

The recommendation for when medical treatment is advised for children with high blood lead levels has not changed. Chelation therapy is recommended in a child with blood lead test result showing ≥45 mcg/dL.

Emerging Science BoxCOVID-19 and Postmortem Changes

Since the novel Coronavirus disease 2019 (COVID-19) became pandemic, there has been an abundance of information gained from post-mortem evaluation by autopsy. Approximately 15% of those affected undergo a severe disease and 5%–6% are critical (respiratory failure, and/or multiple organ dysfunction/failure); however, COVID-19 pathogenesis is still not sufficiently understood. Thus, systematic examination is mandatory to comprehend the extent and mechanisms of this novel disease. Autopsy is the only opportunity to macroscopically observe organs and take optimal samples for histological and molecular analyses. Thereby, autopsy is very likely superior to postmortem core needle biopsies. Consequently, several reports have recently demonstrated that autopsy-based examinations generate important insights into the disease manifestations, the mechanisms of organ failure, and the association with viral distribution. Disseminated diffuse alveolar damage at different stages (the histopathological correlate of acute respiratory distress syndrome) was the major histologic finding. Diffuse alveolar damage was detectable in all lobes but appeared unevenly distributed with pronounced manifestation in middle and lower lung fields. Minor neutrophil infiltration was indicative of secondary infection and/or aspiration. Mild lymphocytic myocarditis and signs of epicarditis were detectable. Liver histology showed minimal periportal lymphoplasmacellular infiltration and signs of fibrosis. There was no morphologically detectable pathology in other organs. Specifically, no signs of encephalitis or central nervous system vasculitis were found. At the time of autopsy, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was still detectable in the respiratory tracts of all affected persons. Polymerase chain reaction testing

was positive in pleural effusion but negative in all cerebrospinal fluid (CSF) samples.

SARS-CoV-2 preferentially infects cells in the respiratory tract, but its direct affinity for organs other than the lungs remains poorly defined. The highest levels of SARS-CoV-2 copies per cell were detected in the respiratory tract, and lower levels were detected in the kidneys, liver, heart, brain, and blood. These findings indicate a broad organotropism of SARS-CoV-2.

Data from Puelles VG, et al. Multiorgan and renal tropism of SARS-CoV-2. *New England Journal of Medicine*, 2020. doi:10.1056/NEJMc2011400; Schaller T, et al. Postmortem examination of patients with COVID-19. *Journal of the American Medical Association*, 2020. doi: 10.1001/jama.2020.8907.

- Magnesium , 126

Acid-Base Balance , 127
- Hydrogen Ion and pH , 127
- Buffer Systems , 127
- Acid-Base Imbalances , 129

The cells of the body live in a fluid environment that requires electrolyte and acid-base concentrations to be maintained within a very narrow range. A balance is maintained by an integration of renal, hormonal, neural, and respiratory functions. Changes in electrolyte concentration affect the electrical activity of nerve and muscle cells and cause shifts of fluid from one compartment to another. Fluid fluctuations also affect blood volume and therefore blood pressure. Alterations in acid-base balance disrupt the cellular function of enzyme systems and can cause cell injury. Disturbances in fluid and electrolyte or acid-base balance are common and can be life-threatening. Understanding how

alterations occur and the body's ability to compensate or correct the disturbance is important for comprehending many pathophysiologic conditions.

Distribution of Body Fluids

Body fluids are distributed among functional compartments, or spaces, and provide a transport medium for cellular and tissue function. **Intracellular fluid (ICF)** is all the fluid within cells and comprises approximately two-thirds of total body water (TBW). **Extracellular fluid (ECF)** is all the fluid outside the cells and comprises approximately one-third of TBW. ECF includes the interstitial fluid, the intravascular fluid, and the various transcellular fluids. The **interstitial fluid** is the fluid surrounding the cells and found in the spaces between cells but not within the blood vessels. The **intravascular fluid** is the fluid found within blood vessels; it is more commonly known as the blood plasma. The **transcellular fluids**, the smallest component of ECFs, are the fluids contained within epithelial-lined cavities of the body. The major transcellular fluids are summarized in Table 3.1. Other transcellular fluids include pleural, synovial, peritoneal, pericardial, and intraocular fluids.

Table 3.1

Approximate Concentrations of Electrolytes in Transcellular Fluids

Fluid	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	HCO_3^- HCO^-_3 (mEq/L)
Saliva	33	20	34	40
Gastric juice[a]	60	9	84	0
Bile	149	5	101	45
Pancreatic juice	141	5	77	92
Ileal fluid	129	11	116	29
Cecal fluid	80	21	48	22
Cerebrospinal fluid	141	3	127	23
Sweat	45	5	58	0

Fluid	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	HCO_3^- HCO^-_3 (mEq/L)
Saliva	33	20	34	40
Gastric juice[a]	60	9	84	0
Bile	149	5	101	45
Pancreatic juice	141	5	77	92
Ileal fluid	129	11	116	29
Cecal fluid	80	21	48	22
Cerebrospinal fluid	141	3	127	23
Sweat	45	5	58	0

[a]The Cl^- concentration exceeds the Na^+, K^+ concentration by 15 mEq/L in gastric juice. This largely represents the secretions of hydrochloric acid by parietal cells.

The sum of fluids within all compartments constitutes the **total body water (TBW)** (Table 3.2). The volume of TBW is usually expressed as a percentage of body weight in kilograms. Average TBW volumes are summarized in Table 3.3.

Table 3.2

Distribution of Body Water

Fluid Compartment	% of Body Weight	Volume (L) in Medium Weight Young or Middle-aged Adult Male	VOLUME (L) in Medium Weight Young or Middle-aged Adult Female
Intracellular fluid (ICF) of body water	40	28	24
Extracellular fluid (ECF) of body water	20	14	11
Interstitial of ECF	(15)	(11)	(9)
Intravascular of ECF	(5)	(3)	(2)
Total body water (TBW)	Adult male 58 ± 8% Adult female 48 ± 6%	42	35

Fluid Compartment	% of Body Weight	Volume (L) in Medium Weight Young or Middle-aged Adult Male	VOLUME (L) in Medium Weight Young or Middle-aged Adult Female
Intracellular fluid (ICF) of body water	40	28	24
Extracellular fluid (ECF) of body water	20	14	11
Interstitial of ECF	(15)	(11)	(9)
Intravascular of ECF	(5)	(3)	(2)
Total body water (TBW)	Adult male 58 ± 8% Adult female 48 ± 6%	42	35

The values listed are based on the average total water in the body.

Table 3.3

Total Body Water (%) in Relation to Body Weight

Body Build	Newborn (up to 1 month)	Infant (1 month to 1 year)	Child (1–10 years)	Young or Middle-aged Adult Male	Young or Middle-aged Adult Female	Older Adult Male	Older Adult Female
Medium weight	74	60	60	48–50	34	46–48	32–33

Body Build	Newborn (up to 1 month)	Infant (1 month to 1 year)	Child (1–10 years)	Young or Middle-aged Adult Male	Young or Middle-aged Adult Female	Older Adult Male	Older Adult Female
Medium weight	74	60	60	48–50	34	46–48	32–33

NOTE: The values listed are based on the average total water in the body as a percentage of body weight. Note: Formulas for calculating estimates of total body water considering sex, age, height, and weight are available at: MD App, Total Body Water (TBW) Calculator; https://www.mdapp.co/total-body-water-tbw-calculator-448/. Data from Buchkremer F, Segerer S. Body surface area, creatinine excretion rate, and total body water: Reference data for adults in the United States. *Kidney Medicine*. 2021;3(2):312–313; Watson PE, Watson ID, Batt RD. Relationship between total body water and surface area in normal and obese subjects. *Journal of Clinical Pathology*. 1971;24:234–238; Mendley SR, Majkowski NL, Schoeller DA. Validation of estimates of total body water in pediatric dialysis patients by deuterium dilution. *Kidney International*. 2005;67(5):2056-2062.

Although daily fluid intake may fluctuate widely, the body regulates water volume within a relatively narrow range. The primary sources of body water are drinking of fluids, ingestion of water in food, and derivation of water from oxidative metabolism. Most water is lost through renal excretion. Lesser amounts are eliminated through the stool and through vaporization from the skin and lungs. Skin losses of water include visible sweat and insensible (invisible) water loss (Table 3.4). Fluid loss from the body must be replaced daily to maintain normal fluid balance.

Table 3.4

Normal Water Gains and Losses (70-kg Man)

	Daily Intake (mL)		Daily Output (mL)
Drinking ≈60%	1400–1800	Urine ≈60%	1400–1800
Water in food ≈30%	700–1000	Stool ≈2%	100
Water of oxidation ≈10%	300–400	Skin ≈10%	300–500
		Lungs ≈28%	600–800
Total	2400–3200	**Total**	2400–3200

	Daily Intake (mL)		Daily Output (mL)
Drinking ≈60%	1400–1800	Urine ≈60%	1400–1800
Water in food ≈30%	700–1000	Stool ≈2%	100
Water of oxidation ≈10%	300–400	Skin ≈10%	300–500
		Lungs ≈28%	600–800
Total	2400–3200	**Total**	2400–3200

The amount of fluid within the various compartments is relatively constant with solutes (e.g., salts) and water being exchanged between compartments to maintain their unique compositions. The percentage of TBW varies with the amount of body fat and age. Fat is hydrophobic (water repelling), and very little water is contained in adipose (fat) cells. Individuals with more body fat have proportionately less TBW and tend to be more susceptible to dehydration.

Aging and Distribution of Body Fluids

The distribution and amount of TBW change with age (see Table 3.3). In newborn infants, TBW is approximately 70% to 80% of body weight because infants store less fat. In the immediate postnatal period, a physiologic loss of body water occurs, equivalent to approximately 5% of body weight as the infant adjusts to a new environment. Infants are particularly susceptible to significant changes in TBW because of their high metabolic rate and potential for evaporative fluid loss attributable to their greater body surface area in proportion to total body size. Loss of fluids from diarrhea can represent a significant proportion of body weight in infants. Renal mechanisms that regulate fluid and electrolyte conservation may not be mature enough to counter the losses, so dehydration can develop rapidly.

During childhood, TBW slowly decreases to 60% to 65% of body weight. At adolescence the percentage of TBW approaches adult proportions, and sex differences begin to appear. Males eventually have a greater percentage of body

water as a function of increasing muscle mass. Females have more body fat and less muscle as a function of estrogens and therefore have less body water.

With increasing age, the percentage of TBW declines further still. The decrease is caused in part by an increased amount of fat and a decreased amount of muscle and by a reduced ability to regulate sodium and water balance. With older age, the kidneys become less efficient at conserving sodium and therefore have difficulty concentrating the urine. Insensible water loss through the skin may increase and thirst perception may be impaired. The normal reduction of TBW in older adults becomes clinically important when the body is under physiologic stress, such as development of fever or dehydration; loss of body fluids at such times can be severe and life-threatening.

Water Movement Between ICF and ECF

Water moves between ICF and ECF compartments primarily as a function of osmotic forces. (See Chapter 1.) Water moves freely by diffusion through the lipid bilayer cell membrane and through **aquaporins**, a family of water channel proteins that provide permeability to water.[1] Sodium is responsible for the osmotic balance of the ECF space and potassium helps maintain the ICF osmotic balance. The osmotic force of ICF proteins and other nondiffusible substances is balanced by the active transport of ions out of the cell. Water crosses cell membranes freely; thus the osmolality of TBW normally is at equilibrium. Under normal conditions, the ICF is not subject to rapid changes in osmolality; however, when the ECF osmolality changes, water moves from one compartment to another until osmotic equilibrium is reestablished.

Water Movement Between Plasma and Interstitial Fluid

The distribution of water and the movement of nutrients and waste products between the plasma in the tissue capillaries and interstitial spaces occurs as a result of changes in hydrostatic pressure and osmotic/oncotic pressure at the arterial and venous ends of the capillary (see Fig. 1.25). Hydrostatic pressure pushes water out of the capillaries; osmotic/oncotic pressure pulls water into the capillaries. Water, sodium, and glucose readily move across the capillary membrane. Under normal conditions, plasma proteins (particularly albumin) do not cross the capillary membrane. They maintain physiologic osmolality by generating oncotic pressure within the plasma.

Filtration refers to fluid movement out of the capillary and into the interstitial space. *Reabsorption* refers to fluid movement into the capillary from the interstitial space. As plasma flows from the arterial to the venous end of the capillary, four forces, sometimes called Starling forces, determine whether the net effect is filtration or reabsorption.

1. **Capillary hydrostatic pressure (blood pressure)** facilitates the outward movement of water from the capillary to the interstitial space.
2. **Capillary (plasma) oncotic pressure** osmotically attracts water from the interstitial space back into the capillary.
3. **Interstitial hydrostatic pressure** facilitates the inward movement of water from the interstitial space into the capillary.
4. **Interstitial oncotic pressure** osmotically attracts water from the capillary into the interstitial space.

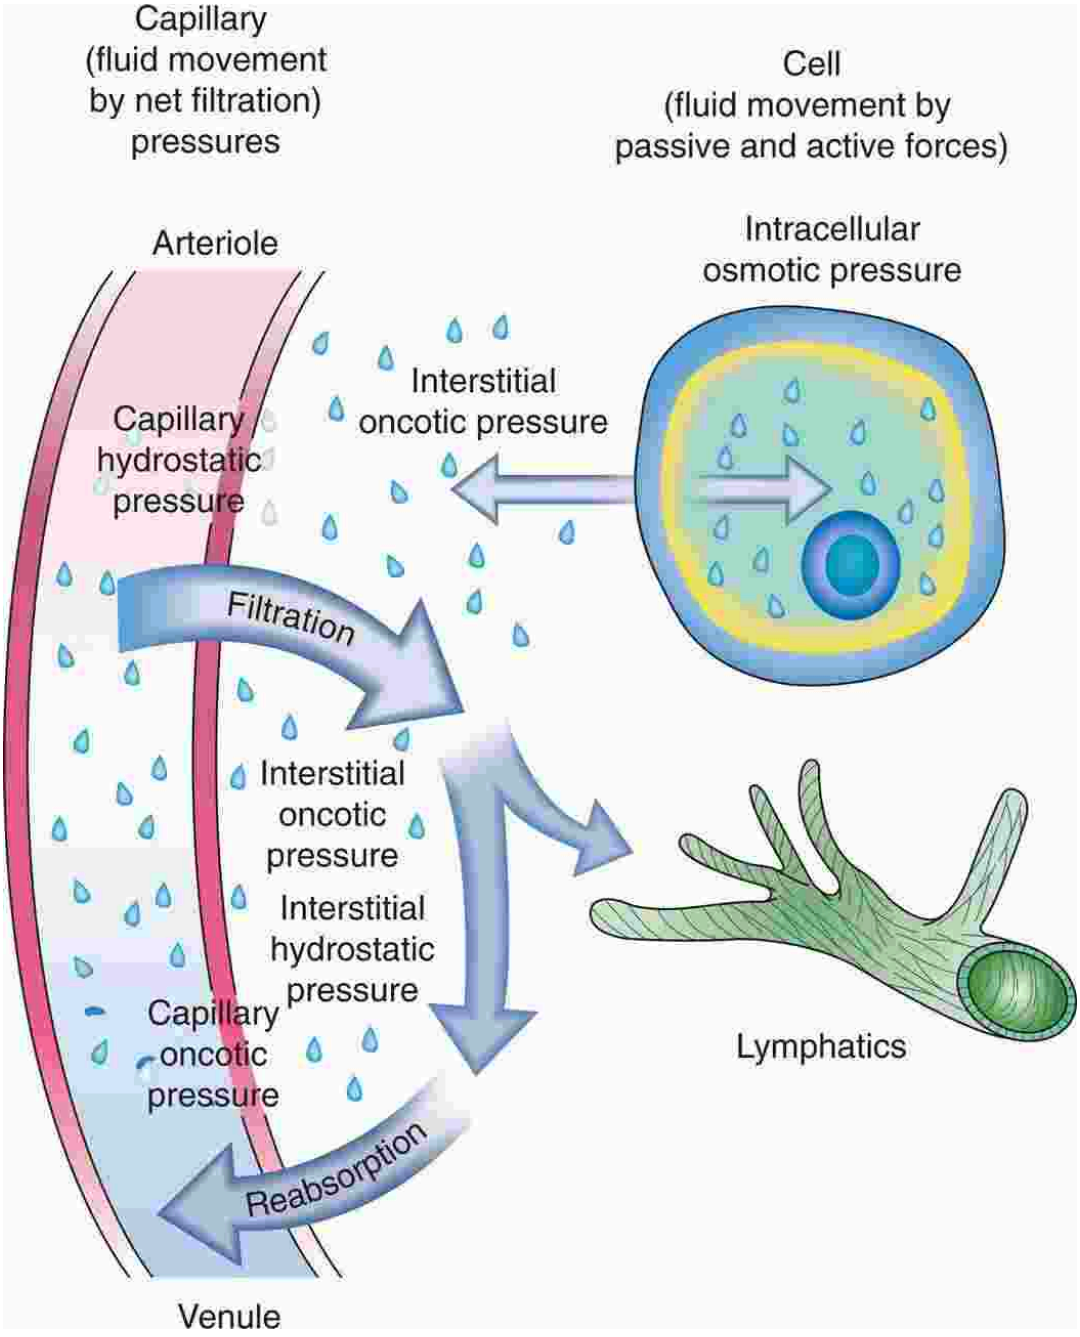
The forces controlling the net movement of fluid across the capillary wall are summarized by these equations:

$$\textit{Net filtration} = (\text{Forces favoring filtration}) - (\text{Forces opposing filtration})$$

$$\textit{Forces favoring filtration} = \text{Capillary hydrostatic pressure and interstitial oncotic pressure}$$

$$\textit{Forces opposing filtration} = \text{Capillary oncotic pressure and interstitial hydrostatic pressure}$$

At the arterial end of the capillary, hydrostatic pressure exceeds capillary oncotic pressure and water moves into the interstitial space (filtration). At the *venous end* of the capillary, oncotic pressure within the capillary exceeds capillary hydrostatic pressure; thus fluids move into the capillary to enter into the circulation (reabsorption). Interstitial hydrostatic pressure promotes the movement of approximately 10% of the interstitial fluid, along with small amounts of protein, into the lymphatic vessels, which is then returned to the systemic circulation. These two systems, the lymphatic and circulatory systems, connect at a location near the left internal jugular vein where the lymphatic thoracic duct joins the left subclavian vein. Because significant amounts of albumin do not normally cross the capillary membrane, interstitial oncotic pressure normally is minimal. Fig. 3.1 illustrates **net filtration**.



Arterial Capillary Pressures		Venous Capillary Pressures	
Capillary hydrostatic pressure	35 mm Hg	Capillary hydrostatic pressure	18 mm Hg
Interstitial fluid hydrostatic pressure	2 mm Hg	Interstitial fluid hydrostatic pressure	1 mm Hg
Net hydrostatic pressure	**33 mm Hg**	**Net hydrostatic pressure**	**17 mm Hg**
Capillary oncotic pressure	24 mm Hg	Capillary oncotic pressure	25 mm Hg
Interstitial fluid oncotic pressure	0 mm Hg	Interstitial fluid oncotic pressure	0 mm Hg
Net oncotic pressure	**24 mm Hg**	**Net oncotic pressure**	**25 mm Hg**
Net filtration pressure	**+9 mm Hg**	**Net filtration pressure**	**–8 mm Hg**

FIG. 3.1 Capillary Filtration Forces.
Water, electrolytes, and small molecules exchange freely between the vascular compartment and the interstitial space at the site of capillaries and small venules. The rate and amount of exchange are driven by the physical forces of hydrostatic and oncotic pressures and the permeability and surface area of the capillary membranes. The two opposing hydrostatic pressures are capillary hydrostatic pressure and interstitial hydrostatic pressure. The two opposing oncotic pressures are capillary oncotic pressure and interstitial oncotic pressure. The *forces that favor filtration* from the capillary are capillary hydrostatic pressure and interstitial oncotic pressure, and the *forces that oppose filtration* are capillary oncotic pressure and interstitial hydrostatic pressure. The sum of these forces is known as *net filtration pressure*. In the example of normal exchange illustrated here, a small amount of fluid moves to the lymph vessels, which accounts for the net filtration difference between the arterial and venous ends of the capillary.

A three-part illustration and a two-part table demonstrate capillary filtration process. The first part of the illustration shows capillary fluid movement by net filtration pressures. The arteriole is identified at the top and the venule is identified at the bottom. Capillary hydrostatic pressure at the arteriole undergoes filtration, interstitial oncotic pressure, interstitial hydrostatic pressure, and capillary oncotic pressure, before reabsorption at the venule. The second part of the illustration shows a call with fluid movement by passive and active forces: intracellular osmotic pressure and interstitial oncotic pressure. The third part of the illustration shows lymphatics. The first part of the table shows arterial capillary pressures, and the second part of the table shows venous capillary pressures. The data from the table are as follows. Capillary hydrostatic pressure: 35 millimeters of mercury in arteriole and 18 millimeters of mercury in venule. Interstitial fluid hydrostatic pressure: 2 millimeters of mercury in arteriole and 1

millimeters of mercury in venule. Net hydrostatic pressure: 22 millimeters of mercury in arteriole and 17 millimeters of mercury in venule. Capillary oncotic pressure: 24 millimeters of mercury in arteriole and 25 millimeters of mercury in venule. Interstitial fluid oncotic pressure: 0 millimeters of mercury in arteriole and 0 millimeters of mercury in venule. Net oncotic pressure: 24 millimeters of mercury in arteriole and 25 millimeters of mercury in venule. Net filtration pressure: positive 9 millimeter of mercury in arteriole and negative 8 millimeters of mercury in venule.

An important factor in capillary filtration of fluid is the integrity of the capillary membrane. Increases in membrane permeability may permit the escape of plasma proteins into the interstitial space. The normal net filtration is altered, with the osmotic movement of water into the interstitial space causing tissue edema.

Alterations in Water Movement

Edema

Edema is the excessive accumulation of fluid within the interstitial spaces. It results from a shift of fluid from the capillaries (intravascular fluid) or lymphatic vessels into the tissues (Fig. 3.2). The four most common mechanisms are:

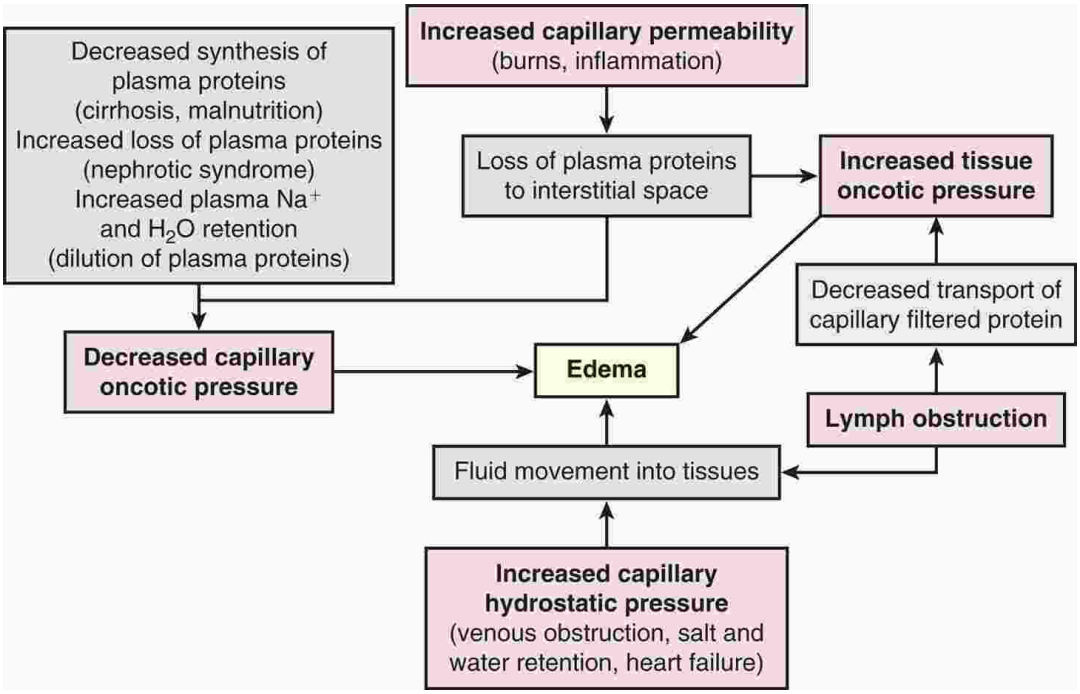


FIG. 3.2 Mechanisms of Edema Formation.

A process diagram illustrates the mechanisms of edema formation. 1. Increased capillary permeability, including burns and inflammation. 1 leads to 2. 2. Loss of plasma proteins to interstitial space. 2 leads to 3 and 5. 3. Increased tissue oncotic pressure. 4. Decreased synthesis of plasma proteins, including cirrhosis, malnutrition. Increased loss of plasma proteins, including nephrotic syndrome. Increased plasma sodium ions and water retention, including dilution of plasma proteins. 4 also leads to 5. 5. Decreased capillary oncotic pressure. 6. Increased capillary hydrostatic pressure, including venous obstruction, salt and water retention, and heart failure. 6 leads to 8. 7. Lymph obstruction. 7 leads to 8 and 9. 8. Fluid movement into tissues. 3, 5, and 8 lead to 10. 9. Decreased transport of capillary filtered protein. 10. Edema.

1.Increased capillary hydrostatic pressure
2.Decreased capillary oncotic pressure
3.Increased capillary membrane permeability

4.Lymph channel obstruction

Pathophysiology

Increased capillary hydrostatic pressure results from either venous obstruction or sodium and water retention. Venous obstruction results in an increased hydrostatic pressure behind the obstruction, pushing fluid from the capillaries into the interstitial spaces. Common causes of venous obstruction include thrombophlebitis, blood clots, hepatic venous outflow obstruction, right heart failure, tight clothing around the extremities, and prolonged standing. Excessive sodium and water retention result in edema secondary to plasma volume overload. The overload produces an increased capillary hydrostatic pressure. Common predisposing causes include heart failure, oliguric kidney disease, and cirrhosis of the liver. In these circumstances, the volume of interstitial fluid exceeds the capacity of the lymphatics to return fluid to the vascular system.

Decreased capillary oncotic pressure occurs when plasma proteins, especially albumin, are lost or production is diminished. Decreased synthesis of plasma proteins occurs with severe liver disease or protein malnutrition. Losses of plasma proteins occur with glomerular diseases of the kidney (nephrotic syndrome), hemorrhage, serous drainage from open wounds or burns, and occasionally from protein-losing enteropathies.[2] Decreased oncotic attraction of fluid within the capillary causes more fluid to filter into the interstitial space than is reabsorbed into the systemic circulation through the capillaries. As fluid accumulates within the tissues, edema worsens.

Increased capillary membrane permeability resulting in edema occurs with *inflammation and immune responses*. (Immunity is discussed in Chapters 7, 8, and 9; inflammation is discussed in Chapters 7 and 9.) The increased vessel permeability permits significant amounts of proteins to escape from within blood vessels (the vascular space) into the interstitial space, producing edema. This edema results primarily from interstitial fluid protein accumulation, which increases the oncotic pressure in the interstitial space; localized decreased capillary oncotic pressure may also contribute. These responses are often the result of trauma such as burns or crushing injuries, neoplastic disease, allergic reactions, and infection.

Lymphatic channel obstruction causing edema occurs when the *lymphatic channels are blocked*. The lymphatic system normally absorbs interstitial fluid, along with small amounts of protein. These substances travel through a *one-way system* of progressively larger lymphatic vessels until they are returned to the systemic circulation. When lymphatic channels are blocked or surgically removed, proteins and fluids are not reabsorbed and accumulate in the interstitial space, causing **lymphedema**. Lymphedema of the arm or leg can occur after surgical removal of axillary or femoral lymph nodes, associated with the surgical treatment of cancer.[3]

Clinical Manifestations

Edema may be localized or generalized. *Localized edema* is usually limited to the site of tissue injury, as in a sprained joint. Local edema can also occur within particular organs, causing for example, vasogenic cerebral edema in the brain, pulmonary edema in the lungs, or laryngeal edema. Edema of specific organs, such as the brain, lung, or larynx, can be life-threatening. *Generalized edema* is manifested by a more uniform distribution of fluid in interstitial spaces throughout the body. *Anasarca* refers to a severe generalized edema. *Dependent edema*, in which fluid accumulates in gravity-dependent areas of the body, might appear in the feet and legs when standing and in the sacral area and buttocks when supine. Dependent edema can be identified by using the fingers to press into edematous fluid in tissues overlying bony prominences. A pit will be left in the skin, hence the term *pitting edema* (Fig. 3.3).

FIG. 3.3 Pitting Edema. (From Bloom A, Ireland J. *Color atlas of diabetes*, 2nd edition. St. Louis: Mosby; 1992.)

Edema is associated with sudden weight gain, swelling and puffiness, tight-fitting clothes and shoes, and limited movement of affected joints. It usually presents along with symptoms associated with the underlying pathologic condition. Fluid accumulation increases the distance required for nutrients, oxygen, and wastes to move between capillaries and cells in the tissues. Increased tissue pressure also may diminish capillary blood flow, leading to ischemia. Therefore wounds heal more slowly and risk of infection or pressure injury increases.

Fluid accumulation within a body cavity or space is referred to as an *effusion*. Examples include a *pleural effusion* (fluid accumulation in the pleural space) and a *pericardial effusion* (fluid accumulation within the membrane surrounding the heart). Fluid accumulation in the peritoneal cavity is called *ascites*. The region where edema fluid or an effusion accumulates sometimes is referred to as a *third space;* the term *third spacing* is used to refer to the process of this fluid accumulation. Fluid trapped in such spaces is unavailable for metabolic processes

or perfusion. Common third spacing situations include ascites, large local interstitial edema, pleural effusion, pericardial effusion, and rapid movement of fluid into the intestinal lumen with an acute intestinal obstruction. Although a person with generalized edema appears swollen because of excess fluid, hypovolemia (decreased intravascular volume) can develop as a result of the fluid sequestering. With severe burns, large amounts of vascular fluid are lost into the interstitial spaces and shock often occurs secondary to the resulting reduced blood volume (see Chapter 48).

Clinically, lymphedema presents differently from edema secondary to fluid accumulation from the capillaries. With edema from capillary sources, the edematous tissue is easily compressed (i.e., pitting edema). By contrast, lymphedema is firm and noncompressible. In severe cases, lymphedema can be profound and causes gross enlargement and distortion of the body parts affected.

Evaluation and Treatment

Medical treatment for edema varies, depending on the underlying conditions that cause fluid retention. Generalized edema often is treated symptomatically, commonly with diuretics. Diuretics may be used until the underlying disorder has been corrected or continued chronically if the underlying disorder persists. In addition to diuretics, symptomatic treatment includes elevating edematous limbs, applying compression stockings, avoiding prolonged standing, and restricting salt intake.

Sodium, Chloride, and Water Balance

The combined influences of the kidneys and hormones have a central role in maintaining sodium and water balance. Because water follows the osmotic gradients established by changes in salt concentration, sodium concentration and water balance are integrally related. The amount of sodium in the ECF is regulated by the renal effects of aldosterone from the adrenal cortex and natriuretic peptides from the heart. Water balance is primarily regulated by the renal response to **antidiuretic hormone (ADH**; also known as *arginine-vasopressin*) from the posterior pituitary and is discussed in the Water Balance section.

Sodium accounts for 90% of the ECF cations (positively charged ions) (Table 3.5). The *amount* of sodium in the ECF is regulated by renal tubular reabsorption of sodium and water within the kidney in response to neural and hormonal influences. That process is a major regulator of ECF volume. The *concentration* of sodium in the ECF reflects water balance, which is regulated by ADH and is discussed later. Sodium in concert with chloride and bicarbonate, the two major anions (negatively charged ions), influences water distribution by contributing to extracellular osmotic forces. Sodium has an important role in other physiologic

functions, including nerve impulse conduction, regulation of acid-base balance, cellular chemical reactions, and transport of substances across the cellular membrane (see Chapter 1).

In general, sodium intake matches sodium excretion. The average dietary intake of sodium ranges from 5 to 6 g/day; the minimal daily requirement of sodium is 500 mg. Sweating depletes sodium and water volume and increases the body's sodium requirement.

Hormonal regulation of sodium (and potassium) balance is mediated by **aldosterone**, a mineralocorticoid (steroid) synthesized and secreted from the adrenal cortex. Aldosterone is a component of the renin-angiotensin-aldosterone system (Fig. 3.4). Aldosterone secretion is influenced by a number of factors, including circulating blood volume, blood pressure, and plasma concentrations of sodium and potassium. When the circulating blood volume or blood pressure is reduced, increased amounts of **renin**, an enzyme secreted by the juxtaglomerular cells of the kidney, are released. More renin also is released when sodium levels in the renal tubules are depressed or there is increased firing of the renal sympathetic nerves. Once released, renin stimulates the formation of **angiotensin I**, an inactive polypeptide from *angiotensinogen*, a substance secreted by the liver. Angiotensin-converting enzyme (ACE), found primarily in pulmonary vessels and to a lesser extent in endothelial and renal epithelial cells, converts angiotensin I to **angiotensin II**, a potent vasoconstrictor. Vasoconstriction elevates blood pressure and restores renal perfusion. Restoring renal perfusion inhibits further release of renin. Angiotensin II also stimulates both the secretion of aldosterone from the adrenal cortex and ADH from the posterior pituitary. Aldosterone promotes sodium and water reabsorption, in addition to the excretion of potassium within the renal tubules. The net effect is to increase blood volume and blood pressure (see Fig. 3.4).

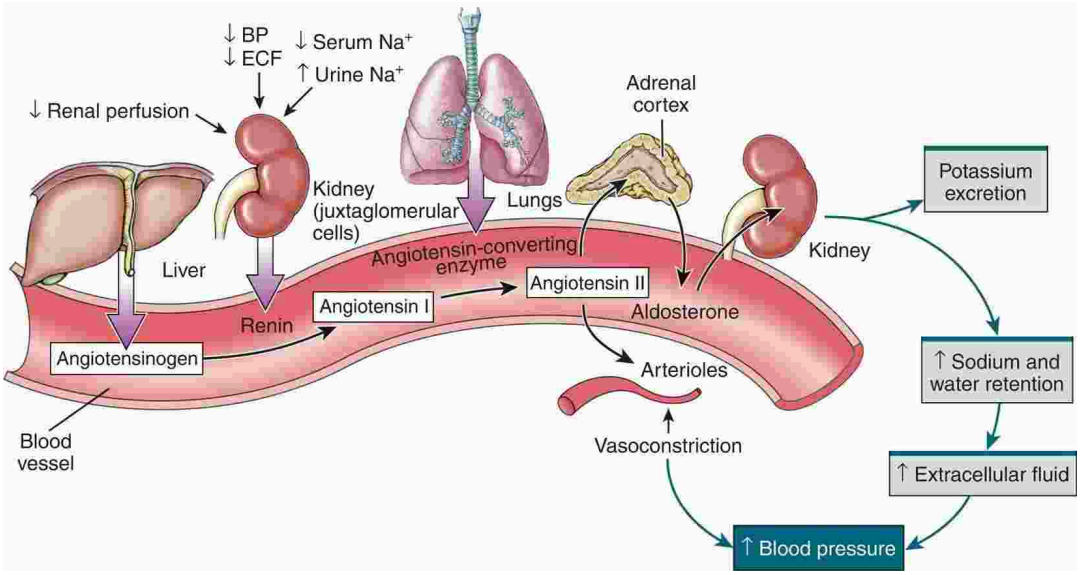

FIG. 3.4 The Renin-Angiotensin-Aldosterone System.
BP, Blood pressure; *ECF*, extracellular fluid; *Na*$^{+}$, sodium ion. (Modified from Herlihy B, Maebius N. *The human body in health and disease*, 4th edition. Philadelphia: Saunders; 2011. Borrowed from Lewis, et al. *Medical-surgical nursing: Assessment and management of clinical problems*, 9th edition. St. Louis: Mosby; 2014.)

An illustrated flow diagram represents the renin-angiotensin-aldosterone system. The illustration shows a blood vessel. Liver secretes angiotensinogen in the blood vessel. Decreased renal perfusion, decreased blood pressure, decreased extracellular fluid, decreased serum sodium ions, and increased urine sodium ions in the juxtaglomerular cells of the kidney secretes renin in the blood vessel, converts angiotensinogen to angiotensin 1. Angiotensin-converting enzyme from the lung contribute to angiotensin 2. Angiotensin 2 affects adrenal cortex and arterioles. Adrenal cortex secretes to aldosterone, which affects the kidney. Kidney excretes potassium and leads to increased sodium and water retention, which results in increased extracellular fluid, contributing to increased blood pressure. Angiotensin 2 acts on arterioles,

causing vasoconstriction, and results in increased blood pressure.

Drugs used for the treatment of hypertension include ACE inhibitors and angiotensin receptor blockers (ARBs). Both of these classes of drugs inhibit the renin-angiotensin-aldosterone system (RAAS) and lower blood pressure.

Natriuretic peptides are hormones primarily produced by the myocardium. Atrial natriuretic peptide (ANP) is produced by the atria. B-type natriuretic peptide (BNP) is produced by the ventricles. Urodilatin (an ANP analogue) is synthesized within the kidney. Natriuretic peptides are released from the heart when the transmural atrial pressure increases (increased volume) or the tension in the left ventricular wall increases, which commonly occurs with heart failure, or when the mean arterial pressure increases (Fig. 3.5). Measurement of BNP is used as a means to assist with the initial diagnosis and management of people with heart failure. Urodilatin is released from distal tubular kidney cells when there is increased arterial pressure and increased renal blood flow. These hormones are natural antagonists to the RAAS; although they are less powerful than aldosterone, they can moderate its physiologic effect on extracellular volume. Natriuretic peptides cause vasodilation and increase renal sodium and water excretion, decreasing blood pressure. Natriuretic peptides sometimes are called a "third factor" in sodium regulation. An increased glomerular filtration rate is considered to be the first factor, and aldosterone is considered to be the second factor.

FIG. 3.5 The Natriuretic Peptide System.
ANP, Atrial natriuretic peptide; *BNP*, brain natriuretic peptide; *GFR*, glomerular filtration rate.

A flowchart represents the natriuretic peptide system as: â€¢ Increase total body sodium ions. â€¢ Increased drinking and osmotic shift of water out of cells. These give out 3 results (leading to each other) as: â€¢ Increased plasma volume. â€¢ Increased atrial stretching detected by atrial endocrine cells. â€¢ Atrial natriuretic peptide, brain natriuretic peptide release. This leads to: â€¢ Action on glomerulus to increase G F R; inhibition of renin-angiotensin-aldosterone system; inhibition of proximal tubule sodium ions reabsorption. These give out 2 results (leading to each other) as: â€¢ Increased sodium and water excretion. â€¢ Decreased blood volume and decreased blood pressure.

Chloride (Cl^-) is the major anion in the ECF and provides electroneutrality, particularly in relation to sodium. Chloride transport is generally passive, except in the renal tubules, and follows the active transport of sodium so that increases or decreases in chloride concentration are proportional to changes in sodium concentration. Chloride concentration tends to vary inversely with changes in the concentration of bicarbonate (HCO_3^-), the other major ECF anion.

Water balance is regulated by the secretion of ADH, also known as arginine-vasopressin. ADH is synthesized by neurons with cell bodies in the hypothalamus that release ADH from their axon terminals in the posterior pituitary. It is secreted in larger amounts when plasma osmolality increases (the major stimulus) or if circulating blood volume decreases enough to cause a drop in blood pressure (Fig. 3.6). Increased plasma osmolality occurs when there is a decrease in water or an excess amount of sodium in relation to TBW. The increased osmolality stimulates hypothalamic osmoreceptors, which cause increased release of ADH. This hormone increases water reabsorption from the renal distal tubules and collecting ducts into the plasma (see Chapter 37). Stimulation of the hypothalamic osmoreceptors also causes thirst, which stimulates the individual to consume liquids. The net effect of both increased water intake and increased renal reabsorption of water is to decrease plasma osmolality, returning it to a normal status. ADH increases urine concentration

and decreases urine volume as less water is excreted into the urine. The restoration of plasma osmolality, blood volume, and blood pressure then reduces ADH secretion back to its baseline level.

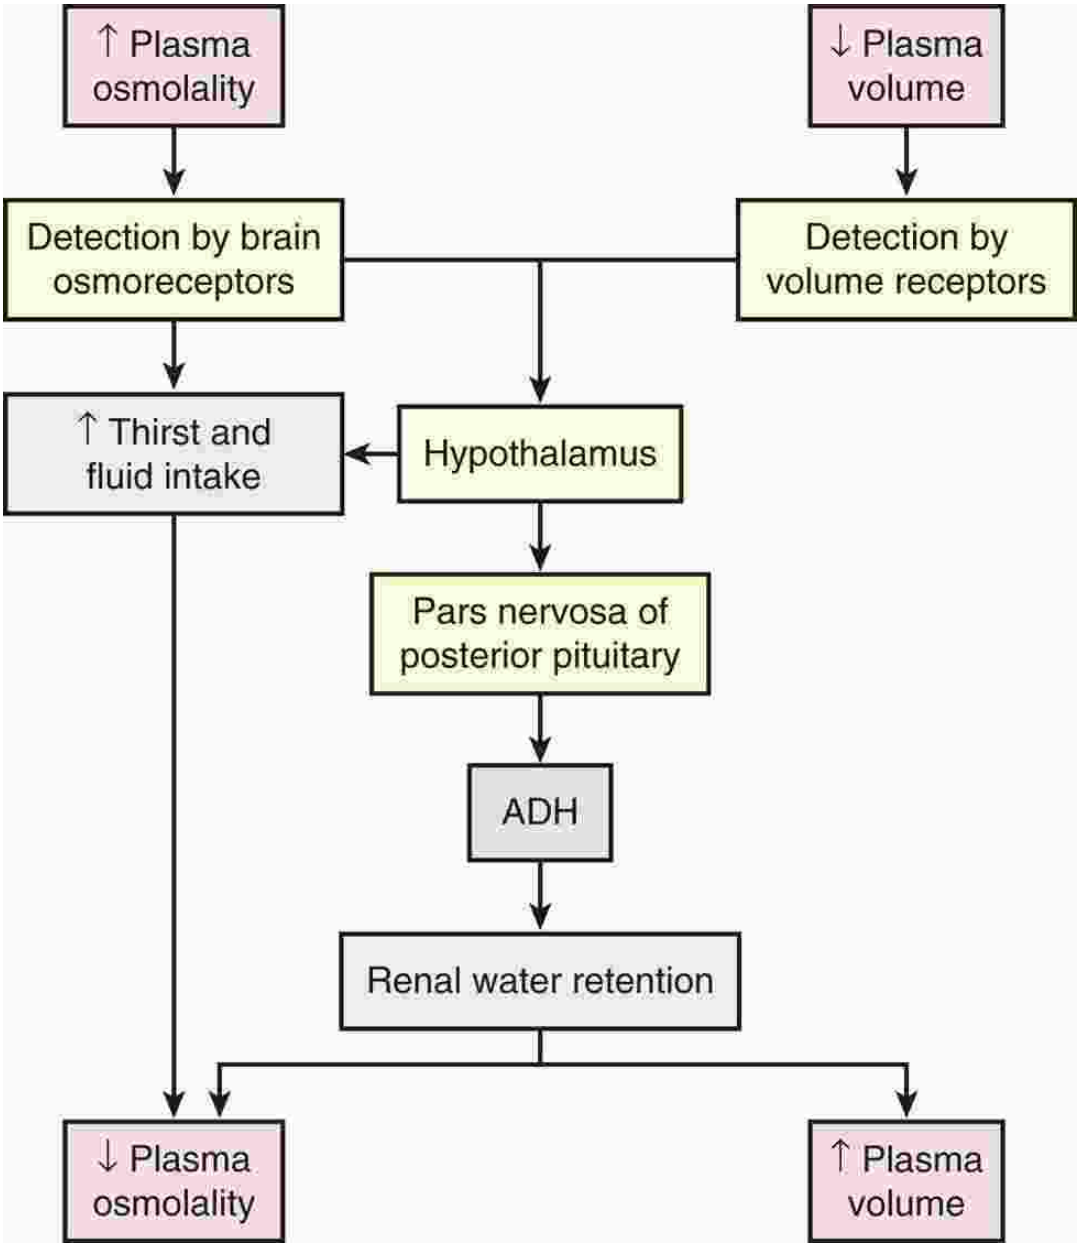

FIG. 3.6 The Antidiuretic Hormone *(ADH)* System.

A flowchart represents the sequence of processes within the antidiuretic hormone or A D H system. The data from the flowchart are summarizes as follows. Increased plasma osmolality is detected by brain osmoreceptors, which spikes thirst and fluid intake, leading to decreased plasma osmolality. Increased plasma osmolality, detected by brain osmoreceptors, and decreased plasma volume, detected by volume receptors,

affects the hypothalamus either by spiking thirst and fluid intake or by causing pars nervosa of posterior pituitary. Increased thirst and fluid intake reduces plasma osmolality. Pars nervosa of posterior pituitary causes A D H to retain renal water. Renal water retention leads to decreased plasma osmolality or increased plasma volume.

With fluid loss secondary to vomiting, diarrhea, or excessive sweating, a decrease in systemic blood volume and blood pressure often follows. Volume-sensitive receptors and baroreceptors, both of which are nerve endings sensitive to changes in blood volume and pressure, also stimulate thirst and the release of ADH, which prompts fluid consumption. The volume receptors are located in the right and left atria and in the thoracic vessels; baroreceptors are found in the aorta, pulmonary arteries, and carotid sinus. When arterial and atrial pressure drops, baroreceptors signal the hypothalamus to release ADH. The reabsorption of water mediated by the renal response to ADH promotes the restoration of plasma volume and blood pressure (see Fig. 3.6). Higher concentrations of ADH stimulate peripheral arterial vasoconstriction, thus increasing arterial blood pressure.

Alterations in Sodium, Water, and Chloride Balance

Alterations in sodium and water balance are closely related. Serum sodium imbalances occur with gains or losses of body water. Extracellular volume imbalances develop with gains or losses of salt. These alterations can be classified as changes in *tonicity* (i.e., the change in the concentration of solutes in relation to the amount of water present).[4] Normal plasma osmolality is 275 to 295 milliosmoles (mOsm)/kg. Solutions are classified as isotonic, hypertonic, or hypotonic as a function of the solute concentration compared with that of normal body cells (Table 3.6 and Fig. 3.7). *Isotonic solutions* have solute concentrations that are equal to that of normal cells; *hypertonic* or *hypotonic* solutions have higher or lower solute concentration, respectively. Changes in tonicity (solute concentration of solutes that cannot cross semipermeable membranes) affect the volume of water within the extracellular compartment, resulting in *isovolemia*, *hypervolemia*, or *hypovolemia* (i.e., normal volume, excess volume, or less than normal volume in the blood, respectively).

Table 3.6

Water and Solute Imbalances

Tonicity	Mechanism
Isotonic (isoosmolar) imbalance	Gain or loss of extracellular fluid (ECF) resulting in a concentration equivalent to a 0.9% sodium chloride (salt) solution (normal saline); no shrinking or swelling of cells
Hypertonic (hyperosmolar) imbalance	Imbalance that results in an ECF concentration >0.9% salt solution; that is, water loss or solute gain; cells shrink in a hypertonic fluid
Hypotonic (hypo-osmolar) imbalance	Imbalance that results in an ECF <0.9% salt solution; that is, water gain or solute loss; cells swell in a hypotonic fluid
Formula for calculating Serum osmolarity	(2 × [Na] + [Glu]/18+ BUN/2.8

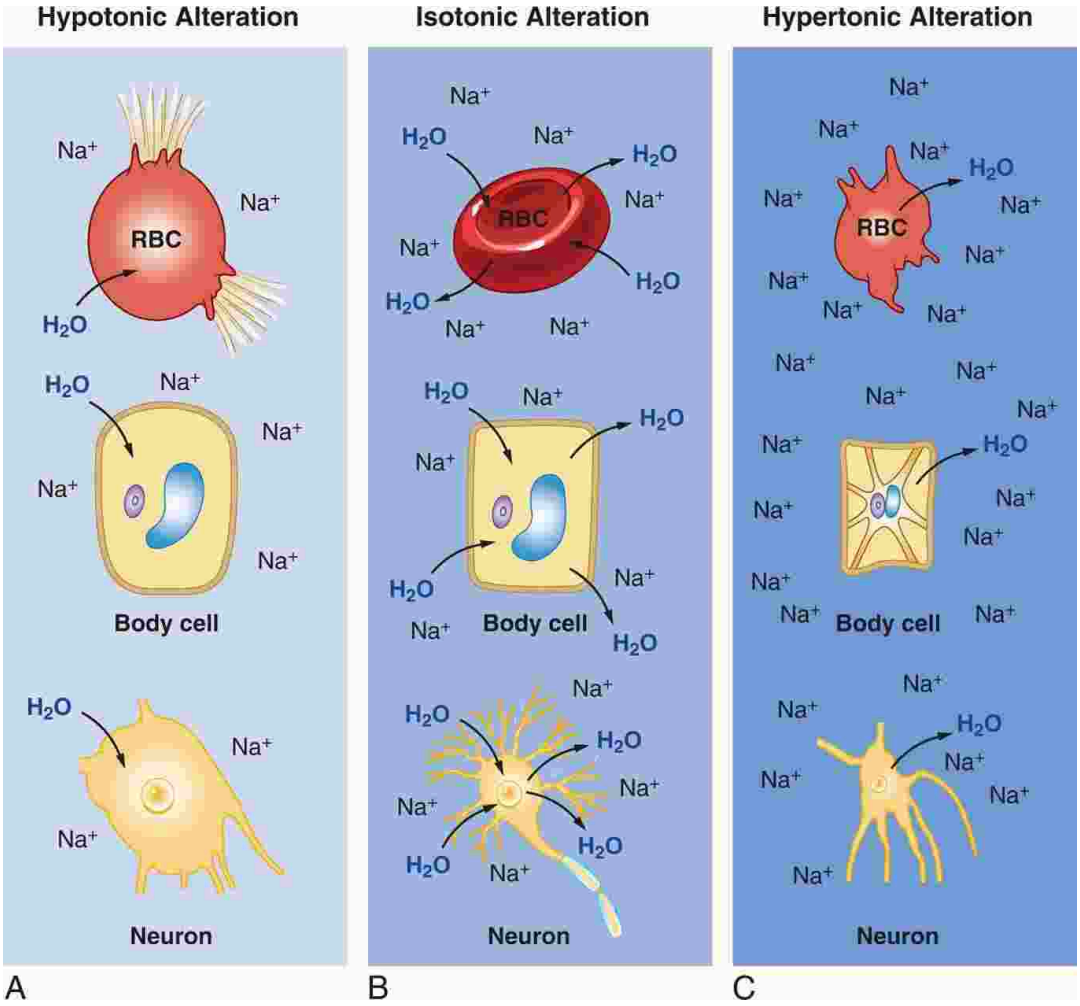

FIG. 3.7 Effects of Alterations in Extracellular Sodium Concentration in RBCs, Body Cells, and Neurons.
(A)*Hypotonic Alteration:* Decrease in ECF sodium ion *(Na^+)* concentration (hyponatremia) results in ICF osmotic attraction of water with swelling and potential busting of cells.
(B)*Isotonic Alteration:* Normal concentration of sodium in the ECF and no change in shifts of fluid in or out of cells.
(C)*Hypertonic Alteration:* An increase in ECF sodium concentration (hypernatremia) results in osmotic attraction of water out of cells with cell shrinkage. *ECF*, Extracellular fluid; *ICF*, intracellular fluid; *RBC*, red blood cell.

Three illustrations, A, B, and C, demonstrate the effects of hypotonic, isotonic, and hypertonic alterations, respectively, in R B C, body cell, and neuron. Illustration A, hypotonic alteration. When the concentration of sodium ions is less, the R

B C, the body cell, and the neuron attract water, leading to swelling and or busting of the cells. Illustration B, isotonic alteration. When the concentration of sodium ions is normal, the osmolality of water in R B C, body cell, and neuron, is even. Illustration C, hypertonic alteration. When the concentration of sodium ions is high, the R B C, the body cell, and the neuron expel water, leading to shrinking of the cells.

Isotonic Alterations

Isotonic alterations are the most common and occur when changes in TBW are accompanied by proportional changes in the concentration of electrolytes. *Isotonic fluid loss* causes hypovolemia. For example, if an individual loses pure plasma or ECF, fluid volume is depleted, but the number and type of electrolytes (e.g., sodium) and the osmolality remain within a normal range (275 to 295 mOsm/kg). Causes include hemorrhage, severe wound drainage, and excessive diaphoresis (sweating). There is loss of extracellular volume with weight loss, dryness of skin and mucous membranes, decreased urine output, increased hematocrit value, and symptoms of hypovolemia. Indicators of hypovolemia include a rapid heart rate and flattened neck veins and can present with a normal or decreased blood pressure. In severe states, hypovolemic shock (severe hypotension) can occur. Isotonic fluids containing electrolytes and glucose are given orally, intravenously (IV) (i.e., 0.9% saline solution or Ringer's lactate [RL] solution), and in some cases, subcutaneously (hypodermoclysis). A variety of isotonic oral fluid replacement solutions are available as beverages and pediatric oral replacement solutions without a prescription.

Isotonic fluid excesses cause hypervolemia. Causes include excessive administration of sodium-containing IV fluids, hypersecretion of aldosterone, the effects of drugs such as prednisone and other corticosteroids (cause renal reabsorption of sodium and water), or oliguric kidney disease. Increased dietary sodium intake causes mild hypervolemia in many individuals , until the resulting decreased aldosterone secretion allows renal excretion of the excess sodium and water. As plasma volume expands, hypervolemia with sudden weight gain develops, because a liter of fluid weighs 1 kg. The diluting effect of excess plasma volume leads to a decreased hematocrit and decreased plasma protein concentration. The neck veins may distend, and the blood pressure increases. Increased capillary hydrostatic pressure leads to edema formation. If the plasma volume is great enough, pulmonary edema and heart failure develop. These presentations may be acute or chronic, depending on the underlying

pathophysiology causing the fluid overload. Diuretics are commonly used for treatment.

Hypertonic Alterations

Hypertonic fluid alterations develop when the osmolality of the ECF is elevated above normal (greater than 295 mOsm/kg). The most common causes are hypernatremia (increased concentration of ECF sodium), a deficit of ECF water, or both. In either case the ECF hypertonicity attracts water from the intracellular space, causing ICF dehydration. A primary increase in the amount of ECF sodium causes an osmotic attraction of water and symptoms of *hypervolemia*. In contrast, a hypertonic state caused primarily by loss of electrolyte-free water leads to *hypovolemia* (Table 3.7).

Table 3.7

Causes and Consequences of Hypertonic Imbalances

Causative Factor	Mechanism	ECF Effects	ICF Effects
Increased sodium (hypernatremia)	Excessive hypertonic salt solutions Intravenous hypertonic sodium Saline-induced abortions Select infant formulas Hyperaldosteronism Cushing syndrome	Hypervolemia Weight gain Bounding pulse Increased blood pressure Edema Venous distention Neuromuscular symptoms Muscle weakness	Intracellular dehydration Thirst Fever Decreased urine output Shrinkage of brain cells Confusion Coma Seizures Cerebral hemorrhage

ECF, Extracellular fluid; *ICF*, intracellular fluid.

Hypernatremia

Pathophysiology

Hypernatremia occurs when serum sodium levels exceed 145 mEq/L. Increased levels of serum sodium cause hypertonicity. Hypernatremia can be hypovolemic, euvolemic, or hypervolemic, depending on the accompanying ECF water volume. Risk factors include advanced age, impaired mental state, fever, diarrhea, and vomiting.

Hypovolemic hypernatremia occurs when a loss of sodium is accompanied by a relatively greater loss of body water. Causes include use of loop diuretics (diuretics that inhibit sodium and chloride reabsorption in the kidney loop of Henle) or diuretic stages of renal disease in which the kidneys fail to concentrate urine and excrete a large volume of urine, and osmotic diuresis from diabetes mellitus induced hyperglycemia or use of mannitol (an osmotic diuretic).

Isovolemic hypernatremia is the most common and occurs when there is a *loss of electrolyte-free water* with a near normal body sodium concentration. Causes include inadequate water intake; excessive sweating (sweat is hypotonic); fever with hyperventilation and increased water loss from lungs; burns; vomiting; diarrhea; and central or nephrogenic diabetes insipidus (lack of ADH or inadequate renal response to ADH). Infants with severe diarrhea are vulnerable and at increased risk because they cannot communicate thirst. Insufficient water intake occurs particularly in individuals who are comatose, confused, immobilized, or receiving gastric feedings. The term **dehydration** can refer to water deficit but also is commonly used to indicate both sodium and water loss (isotonic or isoosmolar dehydration) or even hypovolemic hypernatremia.

Hypervolemic hypernatremia is rare. It occurs when there is an increase in TBW accompanied by a greater increase in total body sodium, resulting in hypervolemia with elevated serum sodium concentration. One cause is infusion of hypertonic saline solutions in an effort to replace sodium in cases of salt depletion that can occur with renal impairment or heart failure. Other causes include oversecretion of adrenocorticotropic hormone (ACTH) or aldosterone as can occur with Cushing syndrome or adrenal hyperplasia and deliberate ingestion of large amounts of soy sauce or concentrated salt water. High amounts of dietary sodium rarely cause hypervolemic hypernatremia in a healthy individual because the aldosterone and ADH responses allow the kidneys to correct the osmolality. Symptoms of hypervolemic hypernatremia include weight gain, bounding pulse, increased blood pressure, and may include lethargy and other cerebral manifestations of hypernatremia.

Because chloride follows sodium, **hyperchloremia** (elevation of serum chloride concentration greater than 105 mEq/L) often accompanies hypernatremia. Plasma bicarbonate deficits, as occur in hyperchloremic metabolic acidosis, are discussed later in the chapter. There are no specific symptoms for chloride excess, and treatment is related to management of the underlying disorder.

Clinical Manifestations

Central nervous system signs are the most serious signs of hypernatremia and are related to shrinking of brain cells, brain dehydration, and alterations in membrane potentials. Signs include weakness, lethargy, muscle twitching, and hyperreflexia (hyperactive reflexes). Confusion, coma, and seizures can occur. Hypernatremia with marked water deficit is manifested by signs and symptoms of both intracellular and extracellular dehydration with volume depletion (Box 3.1).

Box 3.1

Signs and Symptoms of Dehydration

Increased serum sodium concentration
Thirst
Headache
Sudden weight loss
Oliguria and concentrated urine
Hard stools
Decreased skin turgor
Dry mucous membranes
Decreased sweating and tears
Elevated body temperature
Soft eyeballs
Sunken fontanels in infants
Prolonged capillary refill time
Tachycardia
Weak pulses
Postural hypotension
Low blood pressure
Hypovolemic shock
Lethargy
Weakness
Confusion
Coma

Evaluation and Treatment

Serum sodium levels are greater than 145 mEq/L and urine specific gravity is greater than 1.030, unless the cause is diabetes insipidus. Hematocrit and plasma protein levels will be elevated if there is an accompanying water loss. The history, physical examination, and laboratory values provide information about underlying disorders and events. The treatment for isovolemic and hypovolemic hypernatremia is to give oral water or an isotonic salt-free fluid (5% dextrose in water) until the serum sodium concentration returns to normal. Fluid replacement must be given slowly to prevent cerebral edema. Treatment for hypervolemic hypernatremia is to administer loop diuretics. Serum sodium levels need to be closely monitored and the underlying clinical condition managed.

Hypotonic Alterations

Hypotonic fluid imbalances occur when the osmolality of the ECF is less than 275 mOsm/kg. The most common causes are decreased sodium concentration (hyponatremia) or excess of electrolyte-free water (water intoxication). Either problem leads to an intracellular overhydration (cell swelling). When there is a decreased sodium concentration, the osmotic pressure of the ECF decreases; water moves into the cell, where the higher osmotic pressure pulls it in (see Fig. 3.7A). As water leaves the ECF, plasma volume decreases, resulting in symptoms of hypovolemia. When there is electrolyte-free water excess (water intoxication), the ECF volume is elevated, causing symptoms of hypervolemia (Table 3.8). Cerebral and pulmonary edema occurs in conjunction with extreme water intoxication.

Table 3.8

Causes and Consequences of Hypotonic Imbalances

Causative Factor	Mechanism	ECF Effects	ICF Effects
Decreased sodium (hyponatremia)	Inadequate intake Hypoaldosteronism Excessive diuretic therapy Loop diuretics Thiazides	Extracellular volume contraction and hypovolemia (but may not if there is water excess)	Increased intracellular water; edema Brain cell swelling, irritability, depression, confusion Systemic cellular edema, including weakness, anorexia, nausea, and diarrhea
Water excess	Excessive pure water intake Excessive administration of hypotonic intravenous solutions Drinking water to replace isotonic fluid losses Tap water enemas	Extracellular volume expands with hypervolemia (but may not if fluid is trapped in intracellular space)	Edema (see above)

Causative Factor	Mechanism	ECF Effects	ICF Effects
	Psychogenic polydipsia Renal water retention Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)		
Other factors	Isotonic dehydration treated with intravenous D_5W; glucose in D_5W solution is metabolized to water, contributing to hyponatremia Nephrotic syndrome Cirrhosis Cardiac failure	Hypervolemia or hypovolemia	Edema (see above)

D_5W, Dextrose 5% in water; *ECF*, extracellular fluid; *ICF*, intracellular fluid.

Hyponatremia

Pathophysiology

Hyponatremia develops when the serum sodium concentration decreases to less than 135 mEq/L. Hyponatremia results from a loss of sodium, inadequate intake of sodium, or dilution of sodium by water excess. Sodium depletion usually causes hypoosmolality with an associated movement of water into cells (see Fig. 3.7A). Cell dysfunction or even membrane rupture may then occur.

Hypovolemic hyponatremia occurs with a loss of total body fluid that involves a greater loss of body sodium *(hypotonic hyponatremia)* than body water. The extracellular volume is decreased. Causes include prolonged vomiting, severe diarrhea, inadequate secretion of aldosterone (e.g., adrenal insufficiency), and renal losses from diuretics. ADH will be released to facilitate repletion of blood volume.

Isovolemic hyponatremia occurs when there is loss of sodium without a significant loss of water (**pure sodium deficit**). Causes can include water retention secondary to syndrome of inappropriate antidiuretic hormone (SIADH; see Chapter 22, which enhances water retention), hypothyroidism, pneumonia,

and glucocorticoid deficiency. **Inadequate intake of dietary sodium** is rare but possible in individuals consuming low-sodium diets, particularly when diuretics are also being used.

Dilutional hypotonic hyponatremia (water intoxication) occurs when there is intake of large amounts of electrolyte-free water or replacement of fluid loss with IV 5% dextrose in water, which dilutes sodium. The glucose is metabolized to carbon dioxide and water, leaving a hypotonic solution with a diluting effect. Excessive sweating stimulates thirst and intake of large amounts of electrolyte-free water, as can occur in endurance athletes. Some individuals with psychogenic disorders develop water intoxication from compulsive water drinking. Other causes can include tap water enemas, aspiration of fresh water from nonfatal drowning, use of selective-serotonin reuptake inhibitors (SSRIs), and SIADH. When the body is functioning normally, it is quite difficult to produce an excess of TBW by water intoxication because water balance is regulated by ADH action on the kidneys.

Hypervolemic hyponatremia occurs when the total body sodium amount is increased and there is excess water. The increased sodium leads to an increase in ECF volume, and the serum sodium concentration is decreased. Causes include heart failure, cirrhosis of the liver, and nephrotic syndrome. Edema typically is present in these cases.

Hypertonic hyponatremia develops with the shift of water from the ICF to the ECF, as occurs with hyperglycemia, hyperlipidemia, and hyperproteinemia. The osmotic fluid shift to the ECF in turn dilutes the concentration of sodium (pseudohyponatremia) and other electrolytes.

Clinical Manifestations

Serum sodium concentration is less than 135 mEq/L, and with severe sodium deficits, the concentration is less than 120 mEq/L. The high concentration of intracellular solutes, compared with the low concentration of extracellular solutes (hyponatremia), causes an osmotic shift of water into the cells, and cell swelling occurs. The decrease in the ECF sodium concentration changes the cell's ability to depolarize and repolarize normally, altering the action potential in neurons and muscle (see Chapter 1). Clinical manifestations are related to impaired nerve conduction and neurologic changes (see Table 3.8). Hyponatremia is a major cause of morbidity and mortality among individuals hospitalized in intensive care units and in older adults.

Nausea and vomiting are more common with less severe hyponatremia (i.e., decreases between 125 and 130 mEq/L). Neurologic symptoms occur with severe hyponatremia (i.e., decreases less than 125 mEq/L or less severe very rapid decreases) and include lethargy, headache, confusion, apprehension, seizures, and coma.[5] Hypovolemic hyponatremia with pure sodium loss is accompanied by loss of ECF with symptoms of hypotension, tachycardia, and decreased urine

output. Hypervolemic hyponatremia is accompanied by weight gain, edema, ascites, and jugular vein distention. Cerebral edema can be a life-threatening complication of hyponatremia caused by increased shifts of fluid to the intracellular space and increased intracranial pressure.

Evaluation and Treatment

Evaluation of hyponatremia includes the history, physical examination, and laboratory tests for serum and urine sodium. In hyponatremic states, serum sodium concentration decreases to less than 135 mEq/L. With pure sodium deficits, the hematocrit and plasma protein levels may be elevated. Urine specific gravity is less than 1.010 when renal function is normal because sodium is maximally conserved. Evaluation of urine sodium concentration and urine osmolality assists with differential diagnosis. High urine sodium level (normal is 40 to 220 mEq/L in 24 hours) and high urine osmolality are associated with cerebral salt wasting syndrome and adrenal insufficiency. Low urine sodium level (30 mEq/L in 24 hours) and high urine osmolality are associated with extrarenal losses, such as vomiting and diarrhea or severe burns, heart failure, or cirrhosis. Serum osmolality is usually decreased, but secondary conditions of hyperlipidemia, hyperglycemia, or hyperproteinemia can increase serum osmolality.

Treatment of hyponatremia depends on the contributing disorder and severity and acuity of sodium loss. Losses of sodium and water volume are calculated from the clinical evaluation, and appropriate solutions then are selected for replacement. Restriction of water intake is required in most cases of dilutional hyponatremia because body sodium levels may be normal or increased even though serum concentrations are low. Hypertonic saline solutions are used cautiously with severe hyponatremia or the presence of symptoms such as seizures. Rapid correction of chronic hyponatremia can lead to osmotic demyelination syndrome with axonal damage in the brain resulting in neurologic disability or death.[6] Arginine-vasopressin (ADH) receptor antagonists (vaptans) are a class of drugs used for the treatment of hypervolemic and isovolemic hyponatremia, particularly with SIADH.[7] Serum sodium concentration must be monitored to prevent overcorrection.

Hypochloremia

Hypochloremia, a low level of serum chloride (less than 97 mEq/L), is rare and usually occurs with hyponatremia or an elevated bicarbonate concentration, as in metabolic alkalosis. Sodium deficit associated with restricted intake, use of diuretics, and vomiting is accompanied by chloride deficiency. Cystic fibrosis is a genetic disease characterized by hypochloremia (see Chapters 36 and 42). In all cases, treatment of the underlying cause is required.

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

Potassium

Potassium (K^+) is the major intracellular electrolyte and is found in most body fluids (see Table 3.5). Total body potassium content is approximately 4000 mEq, with most of it located in the cells. The ICF concentration of K^+ is approximately 150 to 160 mEq/L; the ECF concentration is approximately 3.5 to 5.0 mEq/L. This concentration gradient is maintained by an *active transport system*, the sodium-potassium adenosine triphosphatase pump (Na^+-K^+ ATPase pump) (see Chapter 1). The ratio of ICF K^+ concentration to ECF K^+ concentration is the major determinant of the resting potential of cells, which makes K^+ balance crucial for the transmission and conduction of nerve impulses, maintenance of normal cardiac rhythms, and contraction of skeletal and smooth muscles (Figs. 3.8A and 1.27). Daily dietary intake of potassium is 40 to 150 mEq/day, with an average of 1.5 mEq/kg body weight. Approximately 90% of dietary potassium is absorbed in the gastrointestinal tract and is transported rapidly into the cells after ingestion. The distribution of potassium between the intracellular and ECFs is influenced by several factors. Insulin, epinephrine, and alkalosis all facilitate the shift of potassium into cells. Insulin deficiency, aldosterone deficiency, some types of acidosis, cell lysis, and strenuous exercise promote a shift of potassium out of cells. Glucagon blocks entry of potassium into cells; glucocorticoids promote potassium excretion. Aldosterone promotes renal excretion of K^+ by the distal tubules, accounting for 90% to 95% of K^+ excretion.[8]

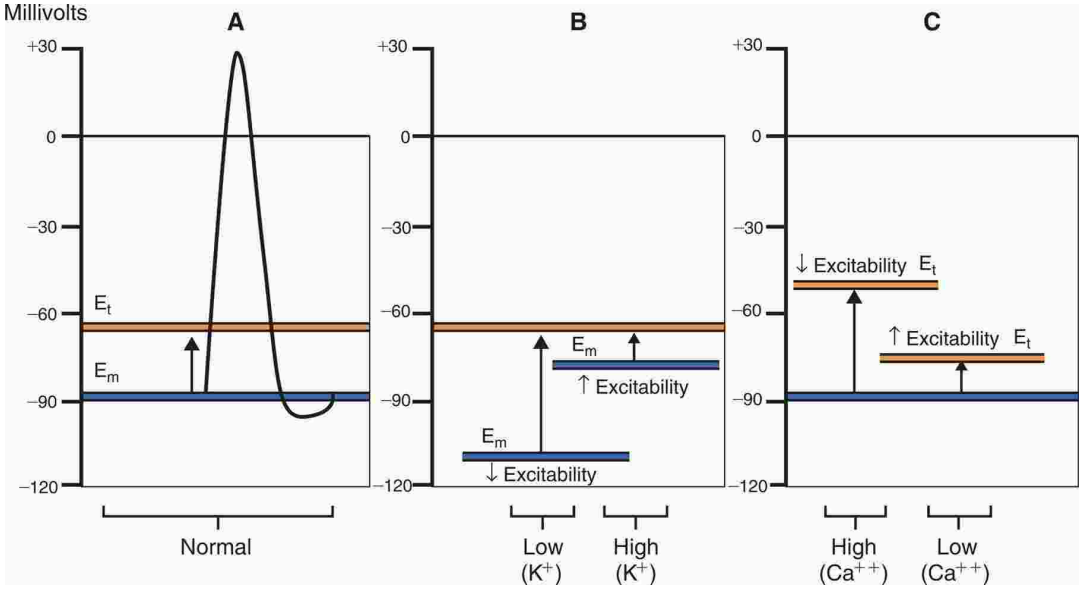

FIG. 3.8 Effects of Potassium (K^+) and Calcium (Ca^{++}) Ions on Membrane Excitability.
(A) Normal membrane excitability: Potassium affects the resting membrane potential *(E_m)*, and calcium affects the threshold potential *(E_t)*. **(B)** Effects of potassium ion (K^+) changes on membrane potential. **(C)** Effect of calcium ion (Ca^{++}) on threshold potential. NOTE: *Hyperpolarization* can be caused by either hypokalemia (E_m more negative) or hypercalcemia (E_t less negative)—the distance between E_m and E_t is increased (decreased excitability); and *hypopolarization* can be caused by either mild hyperkalemia (E_m less negative) or hypocalcemia (E_t more negative)—the distance between E_m and E_t is decreased (increased excitability).

Three graphs, A, B, and C, plot the effects of potassium and calcium ions on membrane excitability. The vertical axes represent millivolts and range from negative 120 to positive 30, in increments of 30. The horizontal axes represent membrane excitability. Graph A. The horizontal axis represents normal membrane excitability. The resting membrane potential, E sub m, is a solid horizontal line at about negative 90 millivolts. The threshold potential, E sub t, is a solid horizontal line at about

negative 55 millivolts. An upward arrow from E sub m reaches E sub t. A narrow, sharp peak shoots from E sub m to positive 30 millivolts at the center of the graph. It then falls sharply to a little below E sub m before returning to E sub m. Graph B. The horizontal axis represents the concentrations of the potassium ions. E sub t is a solid horizontal line at about negative 55 millivolts. At low concentrations, E sub m is a solid horizontal line at about negative 110 millivolts, with decreased excitability. An upward arrow from the line reaches E sub m. At high concentrations, E sub m is a solid horizontal line at about negative 75 millivolts, with increased excitability. An upward arrow from the line reaches E sub t. Graph C. The horizontal axis represents the concentrations of the calcium ions. E sub m is a solid horizontal line at about negative 90 millivolts. At high concentrations, E sub t is a solid horizontal line at about negative 40 millivolts, with decreased excitability. An upward arrow from E sub m reaches E sub t. At low concentrations, E sub t is a solid horizontal line at about negative 75 millivolts, with increased excitability. An upward arrow from E sub m reaches E sub t.

As the predominant ICF ion, potassium exerts a major influence on the regulation of ICF osmolality and fluid balance as well as on intracellular electrical neutrality in relation to hydrogen (H^+) and Na^+ levels. Potassium can move out of cells, along with water, with an increased ECF osmolarity.

Insulin contributes to the regulation of plasma potassium levels by stimulating the Na^+-K^+ ATPase pump, thereby promoting the movement of K^+ into liver and muscle cells. Clinically, insulin (usually with dextrose to prevent hypoglycemia) is used to treat severe hyperkalemia. In cases of hyperglycemia, dangerously low levels of plasma potassium can result when insulin is administered to treat elevated glucose levels. Particularly in emergency settings, it is crucial to check potassium levels before administering insulin for hyperglycemia. Monitoring potassium status is a key factor in any diabetes treatment regimen involving the administration of insulin.

In addition to conserving sodium, *aldosterone* regulates the potassium concentration. Aldosterone is secreted from the adrenal cortex in response to increases in plasma potassium concentration or stimulation by angiotensin II, part of the RAAS; it stimulates the secretion of potassium into the urine by the distal renal tubules. Aldosterone also increases the secretion of potassium from the colon and sweat glands.

Although potassium is found in most body fluids, the kidney is the most significant regulator of potassium balance. Potassium is freely filtered by the renal glomerulus; 90% is reabsorbed by the proximal tubule and loop of Henle. In the distal tubules, *principal cells* secrete potassium under the influence of aldosterone, and *intercalated cells* reabsorb potassium. The net effect of secretion and reabsorption determines the amount of potassium excreted from the body. Evidence suggests that the gut also may sense the amount of K^+ ingested and stimulate renal K^+ excretion, independent of aldosterone.[9]

The potassium concentration in the distal tubular cells is determined primarily by the plasma concentration of potassium in the *peritubular capillaries*. When plasma potassium concentration increases, potassium is secreted into the urine by the distal tubules, which is facilitated by the action of aldosterone. Decreased levels of plasma potassium result in decreased distal tubular secretion, although approximately 5 to 15 mEq/day will continue to be lost. Changes in the rate of filtrate (urine) flow through the distal tubule also influence the concentration gradient for potassium secretion. When the urine flow rate is high (e.g., with diuretic use), the potassium concentration in the distal tubular urine is lower; more potassium subsequently is secreted into the urine.[10]

Changes in **pH** (hydrogen ion concentration) also affect the potassium balance. During acute acidosis, hydrogen ions accumulate in the ICF. Unless the anion portion of the acid (e.g., acetoacetate or lactate) has entered the ICF, the accumulated H^+ would create a charge imbalance. To maintain ionic balance, potassium shifts out of the cell and into the ECF. This shift occurs, in part, because of a decrease in the Na^+-K^+ ATPase pump activity and can contribute to hyperkalemia. Decreased ICF potassium also results in decreased potassium secretion by the distal tubular cells, increasing the potential for hyperkalemia. In acute alkalosis, hydrogen ions within the ICF move to the ECF, resulting in a shift of potassium into the cell to maintain ionic balance. This contributes to development of hypokalemia; in addition, potassium secretion increases within the distal tubular cells, which increases the potential for hypokalemia. The management of alterations associated with acid-base imbalances requires concurrent treatment of changes in K^+ concentration.

In summary, renal regulation of potassium includes:

1. The action of aldosterone

2. The concentration gradient for K^+ at the distal tubule and collecting duct
3. The distal tubule flow rate and distal tubule sodium delivery
4. Changes in pH (causing acidosis or alkalosis)

Potassium loss occurs through normal body functions, but without causing hypokalemia, unless the individual has very low dietary potassium intake. Average daily losses of K^+ are as follows:

Location	Daily Loss (mEq/L)
Stool	5–10
Sweat	0–20
Urine	40–120

Potassium adaptation is the ability of the body to adapt to increased levels of K^+ intake over time. A sudden increase in K^+ level may be fatal. If the intake is slow, the kidney can increase the urinary excretion of K^+ and maintain K^+ balance.

Hypokalemia

Pathophysiology

Potassium deficiency, or **hypokalemia**, develops when the serum K^+ concentration decreases to less than 3.5 mEq/L. Because intracellular and total body stores of K^+ are difficult to measure, changes in K^+ balance are reflected by the plasma concentration, although not always accurately. In general, lowered serum K^+ level indicates a loss of total body K^+. When K^+ is lost from the ECF, the change in the concentration gradient favors the movement of K^+ from the cell into the ECF. The ICF/ECF concentration ratio is maintained, but the amount of total body K^+ is depleted.

Factors contributing to the development of hypokalemia include a reduced intake of potassium, an increased entry of K^+ into cells, and increased losses of K^+. A dietary deficiency of K^+ may occur in people who have inadequate intake of potassium-rich fruits and vegetables (influenced by fad diets, food insecurity, or lack of transportation to purchase fresh produce), and in individuals with alcoholism or eating disorders. A reduced K^+ intake generally becomes a problem when combined with other causes of K^+ depletion.

ECF hypokalemia can develop without losses of total body K^+. As discussed previously, with some types of acidosis, potassium shifts from the ECF to the ICF in exchange for hydrogen ions to maintain the plasma acid-base balance. In

alkalosis, ECF hydrogen moves out of the cell to correct the alkalosis, and K^+ moves into the cell to maintain an ionic balance. Insulin promotes cellular uptake of K^+, and insulin administration can cause an ECF potassium deficit, particularly with the intake of high carbohydrate loads. For this reason, it is crucial to evaluate potassium status in emergency settings when treating a person with diabetes who presents with severe hyperglycemia and/or diabetic ketoacidosis (DKA). Failure to do so before administering IV insulin can result in life-threatening hypokalemia. Treating DKA typically requires administration of supplemental potassium simultaneously with IV insulin and rehydration therapy. With DKA, the overall insulin deficit results in potassium shifts from the ICF to the ECF, due to lack of insulin action on the Na^+-K^+ ATPase pump. A normal serum potassium level usually is maintained; however, potassium excretion through the kidney continues, resulting in a deficit of total body potassium. The deficit becomes clinically evident when insulin treatment and rehydration therapy are initiated. Accordingly, in the treatment of hyperglycemia with or without DKA, the standard of care is potassium supplementation with close monitoring.

Treatment of pernicious anemia with vitamin B_{12} or folate also may precipitate hypokalemia if the formation of new red blood cells causes enough K^+ uptake to effect an extracellular decrease in K^+ concentration. **Familial hypokalemic periodic paralysis** is a rare genetically transmitted disease that causes K^+ to shift into the intracellular space with episodes of extreme muscle weakness.

Losses of K^+ from body stores are most commonly caused by gastrointestinal and renal disorders. Diarrhea, intestinal drainage tubes, fistulae, excessive ingestion of black licorice, and laxative overuse can all result in hypokalemia. Normally, only 5 to 10 mEq of potassium and approximately 100 mL of water are excreted in the stool each day. With diarrhea, fluid and electrolyte losses can be voluminous, with several liters of fluid and 100 to 200 mEq of K^+ lost per day. Vomiting or continuous nasogastric suction frequently is associated with K^+ depletion. The loss occurs in part because of the K^+ lost from the gastric fluid. However, the loss principally is caused by renal compensation for volume depletion and metabolic alkalosis, which occurs secondary to losses of sodium, chloride, and hydrogen ion. The loss of fluid and sodium stimulates the secretion of aldosterone, which in turn results in renal loss of K^+.

Renal losses of K^+ are related to increased secretion of K^+ by the distal tubule. Predisposing factors include the use of diuretics, excessive aldosterone secretion, an increased distal tubular flow rate, and a low plasma magnesium concentration. Many diuretics inhibit the reabsorption of sodium chloride, resulting in increased urine production. With enhanced fluid excretion, the increased flow through the distal tubule also promotes potassium excretion. If

sodium loss is severe, the compensating aldosterone secretion (which causes secondary hyperaldosteronism) may further deplete K^+ stores. Primary hyperaldosteronism with excessive secretion of aldosterone from an adrenal adenoma also causes K^+ wasting. Many kidney diseases impair the kidney's ability to conserve sodium. The decreased sodium reabsorption produces a diuretic effect. As a result, the increased flow through the distal tubule promotes the secretion of K^+. Magnesium deficiency increases loop of Henle and distal potassium secretion, causing secondary hypokalemia.[11] Several medications, including amphotericin B, gentamicin, and nafcillin, cause hypokalemia by increasing the rate of potassium excretion. Rare hereditary defects in renal potassium transport (Bartter and Gitelman syndromes) also can result in hypokalemia (Table 3.9).

Table 3.9

Causes of Potassium Alterations

Hypokalemia <3.5 mEq/L	**Causes**
Decreased intake: starvation or eating disorders, inadequate replacement	Intake
Increased renal loss: renal concentrating defect, K^+-losing diuretics, hyperaldosteronism, vomiting, diarrhea, use of specific medications	Loss
Shift from ECF to ICF: metabolic alkalosis, insulin administration, gene mutations in K^+ transport	Cellular shifts
Hyperkalemia >5.0 mEq/L	Causes
Excess dietary or intravenous intake	Intake
Decreased renal loss: oliguric renal disease, K^+-sparing diuretics, hypoaldosteronism	Loss
Shift from ICF to ECF: some types of metabolic acidosis, massive cell injury or death	Cellular shifts

ECF, Extracellular fluid; *ICF*, intracellular fluid; *K^+*, potassium.

Clinical Manifestations

Mild losses of K^+ are usually asymptomatic. With severe hypokalemia (<2.5 mEq/L), neuromuscular excitability decreases, causing skeletal muscle weakness,

smooth muscle atony, cardiac dysrhythmias, glucose intolerance, and impaired urinary concentrating ability.

Symptoms occur in proportion to the rate of potassium depletion. The body can accommodate slow losses of potassium. Decreases in the ECF potassium concentration may facilitate a shift in potassium away from the intracellular space and into the ICF. This dynamic promotes the return of the potassium concentration gradient toward a more normal status, reducing neuromuscular symptoms. With acute and severe potassium loss, the changes in neuromuscular excitability are more profound. Skeletal muscle weakness initially occurs in the larger muscles of the legs and arms and ultimately affects the diaphragm, compromising ventilation. With severe losses, paralysis and respiratory arrest may occur. Loss of smooth muscle tone may result in a variety of gastrointestinal manifestations, such as constipation, intestinal distention, anorexia, nausea, vomiting, and paralytic ileus (paralysis of the intestinal muscles). Table 3.10 contains a summary of K^+ alterations.

Table 3.10

Organ System Manifestations of Potassium Alterations

Organ System	Hypokalemia <3.5 mEq/L	Hyperkalemia >5.0 mEq/L
Cardiovascular	Postural hypotension Dysrhythmias ECG changes (flattened T waves, U waves, ST depression, peaked P wave, prolonged QT interval) Weak, irregular pulse rate Ventricular fibrillation	Dysrhythmias ECG changes (peaked T waves, prolonged PR interval, absent P wave with widened QRS complex) Bradycardia Heart block Cardiac arrest
Nervous	Lethargy Fatigue Confusion Paresthesias Decreased tendon reflexes	Anxiety Tingling Numbness
Gastrointestinal	Nausea and vomiting Decreased motility Distention Decreased bowel sounds Ileus	Nausea and vomiting Early: Diarrhea Early: Colicky pain

Organ System	**Hypokalemia <3.5 mEq/L**	**Hyperkalemia >5.0 mEq/L**
Kidney	Inability to concentrate urine Water loss Thirst Kidney damage	Oliguria Kidney damage
Skeletal and smooth muscle	Weakness Flaccid paralysis Respiratory arrest Constipation Bladder dysfunction	Early: hyperactive muscles and reflexes SLate: weakness and flaccid paralysis

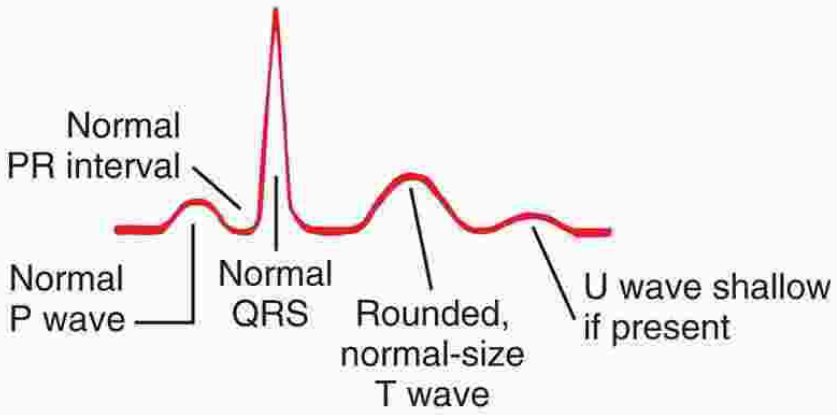
Organ System	Hypokalemia <3.5 mEq/L	Hyperkalemia >5.0 mEq/L
Cardiovascular	Postural hypotension Dysrhythmias ECG changes (flattened T waves, U waves, ST depression, peaked P wave, prolonged QT interval) Weak, irregular pulse rate Ventricular fibrillation	Dysrhythmias ECG changes (peaked T waves, prolonged PR interval, absent P wave with widened QRS complex) Bradycardia Heart block Cardiac arrest
Nervous	Lethargy Fatigue Confusion Paresthesias Decreased tendon reflexes	Anxiety Tingling Numbness
Gastrointestinal	Nausea and vomiting Decreased motility Distention Decreased bowel sounds Ileus	Nausea and vomiting Early: Diarrhea Early: Colicky pain
Kidney	Inability to concentrate urine Water loss Thirst Kidney damage	Oliguria Kidney damage
Skeletal and smooth muscle	Weakness Flaccid paralysis Respiratory arrest Constipation Bladder dysfunction	Early: hyperactive muscles and reflexes SLate: weakness and flaccid paralysis

ECG, Electrocardiogram.

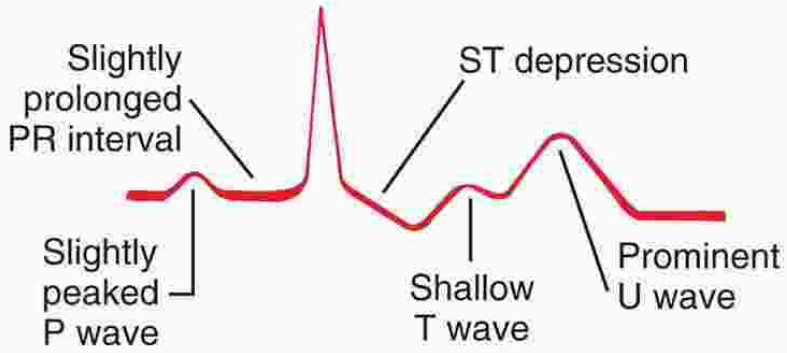
The cardiac effects of hypokalemia are related to changes in membrane excitability. As the ECF potassium concentration decreases, the resting membrane potential becomes more negative (i.e., *hyperpolarized;* e.g., from −90 to −100 millivolts). A hyperpolarized membrane requires a greater stimulus to trigger an action potential (Fig. 3.8B). Potassium also contributes to the repolarization phase of the action potential; hypokalemia delays ventricular repolarization. Consequently, hypokalemia may result in various dysrhythmias, including sinus bradycardia, atrioventricular block, and paroxysmal atrial tachycardia. The characteristic changes in the electrocardiogram (ECG) reflect *delayed ventricular repolarization* with slowed conduction and pacemaker activity. The amplitude of the T wave decreases, the amplitude of the U wave increases, and the ST segment is depressed (Fig. 3.9). In severe states of hypokalemia, P waves peak, the QT interval is prolonged, and T-wave inversions may be seen. Hypokalemia enhances the therapeutic effect of digitalis by slowing the Na^+-K^+

pump and excessively increasing intracellular calcium and sodium concentrations. The risk of digitalis toxicity is increased.

Normokalemia



Hypokalemia



Hyperkalemia

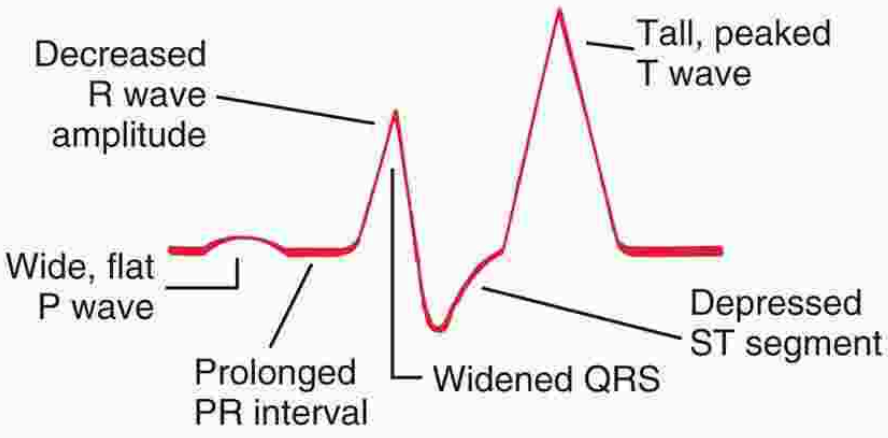


FIG. 3.9 Electrocardiogram Changes With Potassium Imbalance.

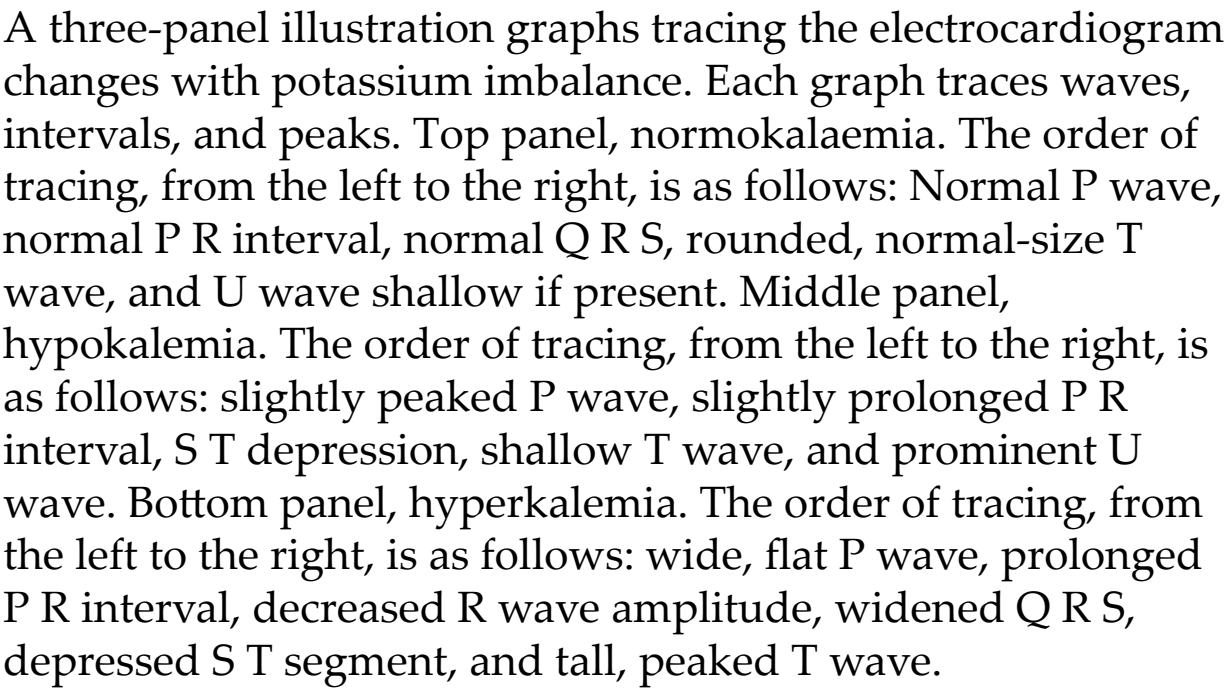

Concurrent alterations in *plasma calcium concentration* also contribute to changes in neuromuscular excitability associated with hypokalemia. Increases in ECF calcium concentration tend to make the threshold potential (E_t) less negative. The result is decreased membrane excitability and potentiation of hyperpolarization, amplifying the neuromuscular effects of hypokalemia (see Fig. 3.8C).

A wide range of metabolic dysfunctions may result from potassium deficiency. Carbohydrate metabolism is affected. Hypokalemia depresses insulin secretion and alters hepatic and skeletal muscle glycogen synthesis. Renal function is impaired by a decreased responsiveness to ADH, resulting in a decreased ability to concentrate urine, causing polyuria (increased urine). Polydipsia (increased thirst) may occur. Chronic potassium deficits lasting more than 1 month may damage renal tissue, with resulting interstitial fibrosis and tubular atrophy.

Evaluation and Treatment

The diagnosis of hypokalemia is based on serum K^+ levels. Hypokalemia can result from disorders associated with potassium loss or from shifts of extracellular potassium into the intracellular space. Treatment involves replacing lost potassium to restore normal levels and correcting the associated fluid and acid-base imbalances. Once these have been corrected, further potassium loss

should be prevented by correcting the underlying mechanism. In particular, individuals should be encouraged to eat potassium-rich foods. With normal renal function, the maximal rate of oral replacement is 40 to 80 mEq/day. A maximal safe rate of IV replacement is 20 mEq/h. Potassium is irritating to blood vessels and can result in considerable pain for the individual. Accordingly, IV infusions containing potassium should not exceed 40 mEq/L. Replacement therapy requires close monitoring of the plasma potassium concentration. Hypokalemia concurrent with hypomagnesemia is refractory to treatment until magnesium levels are corrected.

Hyperkalemia

Pathophysiology

Hyperkalemia is defined as an ECF potassium concentration greater than 5.5 mEq/L.[11a] Increases in the total body potassium level are relatively rare, largely because of efficient renal excretion. Acute increases in the serum potassium level are handled quickly through increased renal excretion of potassium, with some uptake also into cells.

Hyperkalemia may be caused by *excessive intake*, a *shift of potassium from the ICF to the ECF*, or *decreased renal excretion*.[12] If renal function is normal, slow and long-term increases in K^+ intake are usually well tolerated through K^+ adaptation. Dietary excesses of potassium are uncommon, but accidental ingestion of potassium salt substitutes can cause toxicity. Acute K^+ loading can exceed renal excretion rates. Use of stored whole blood, administration of IV boluses of penicillin G, or excessive replacement of K^+ can precipitate hyperkalemia, particularly if renal function is impaired. Drugs that decrease renal potassium excretion (e.g., ACE inhibitors, ARBs, potassium-sparing diuretics, and aldosterone antagonists) also may contribute to hyperkalemia.

Potassium shifts from the ICF to the ECF occur when there is a *change in cell membrane permeability* caused by cell hypoxia, some types of acidosis, or insulin deficiency. Hypoxia can lead to hyperkalemia by diminishing the efficiency of cell membrane active transport, resulting in the escape of K^+ to the ECF. Burns, massive crush injuries, and extensive surgeries can cause cell trauma and release of ICF potassium to the ECF. If renal function is sustained, K^+ will be excreted. As cell repair begins, hypokalemia may develop if the excreted K^+ is not replaced.

In states of *acidosis*, hydrogen ions shift into the cells in exchange for ICF potassium, unless the anion portion of the acid also enters cells; therefore hyperkalemia and acidosis often occur together. Insulin promotes cellular entry of K^+; consequently, *insulin deficits*, which occur with conditions such as DKA, are often accompanied by hyperkalemia. Hyperkalemia may result secondary to

digitalis toxicity. High levels of digitalis inhibit the Na^+-K^+ ATPase transport pump, allowing potassium to remain outside the cell.

Decreased renal function is commonly associated with hyperkalemia. Oliguria (urine output <30 mL/h) secondary to acute kidney injury or end-stage renal disease typically presents with elevations of serum K^+ concentration. The severity of hyperkalemia is a function of the amount of K^+ intake, the degree of acidosis, and the rate of renal cell damage. *Hypoaldosteronism* can cause decreases in the urinary excretion of K^+. For example, Addison disease, characterized by adrenal cortical insufficiency, often presents with hyperkalemia secondary to decreased aldosterone secretion.

Clinical Manifestations

Symptoms vary with the severity of hyperkalemia. With a mild presentation, increased neuromuscular irritability may manifest as restlessness, intestinal cramping, and diarrhea. Severe hyperkalemia decreases the resting membrane potential from −90 to −70 millivolts, resulting in muscle weakness, loss of muscle tone, and paralysis. In mild states of hyperkalemia, myocardial cell repolarization is more rapid and reflected in the ECG as narrow and taller T waves with a shortened QT interval. Severe hyperkalemia (serum levels ≥6 mEq/L) causes delayed cardiac conduction, preventing repolarization of heart muscle. There is a decrease in conduction velocity, depressed ST segment, prolonged PR interval, and widening of the QRS complex (loss of atrial activity) (see Fig. 3.9). Brady dysrhythmias and delayed conduction are common in hyperkalemia; severe hyperkalemia can cause ventricular fibrillation or cardiac arrest.

Changes in the ratio of intracellular to extracellular K^+ concentration contribute to the clinical presentation of hyperkalemia (see Table 3.9). If extracellular K^+ concentration increases without a significant change in intracellular K^+ concentration, the resting membrane potential becomes more positive (e.g., changes from −90 to −80 millivolts) and the cell membrane is **hypopolarized** (the inside of the cell becomes less negative or partially depolarized [increased excitability]) (see Fig. 3.8B). With mild elevations in extracellular K^+ concentration, the cell more rapidly repolarizes and becomes more irritable (peaked T waves). An action potential then is initiated more rapidly because the distance between the resting membrane potential and the threshold potential has been decreased. With more severe hyperkalemia, the resting membrane potential approaches or exceeds the threshold potential (wide QRS merging with T wave). In this case the cell is not able to repolarize and therefore does not respond to excitation stimuli. The most serious consequence is cardiac arrest.

Like the effects of hypokalemia, the neuromuscular effects of hyperkalemia are related to the rate of increase in the ECF potassium concentration and the presence of other contributing factors, such as acidosis and calcium balance.

Long-term increases in ECF potassium concentration result in shifts of K^+ into the cell because the tendency is to maintain a normal ratio of intracellular/extracellular potassium concentrations. Acute elevations of extracellular K^+ concentration affect neuromuscular irritability because this ratio is disrupted.

Because calcium influences the threshold potential, changes in ECF calcium concentration can augment or override the effects of hyperkalemia. With hypocalcemia the threshold potential becomes more negative, enhancing the neuromuscular effects of hyperkalemia. Hypercalcemia causes the threshold potential to become less negative, counteracting the effects of hyperkalemia on resting membrane potential (see Fig. 3.8C).

Evaluation and Treatment

Hyperkalemia is a common finding in many clinical settings (e.g., renal disease, massive trauma, insulin deficiency, Addison disease, use of potassium salt substitutes, or some types of metabolic acidosis). How rapidly symptoms evolve often is a function of the underlying cause. An ECG will identify conduction abnormalities or dysrhythmias.

Management of hyperkalemia includes both treating the contributing causes and correcting excessive potassium concentration. Normalizing the extracellular potassium concentration can be achieved with a variety of methods; the treatment chosen is related to the cause and severity of the problem. Calcium gluconate can be administered to restore membrane excitability when serum potassium levels are dangerously high. Administration of glucose, which readily stimulates insulin secretion, or administration of glucose and insulin for those with diabetes, facilitates cellular entry of potassium. Renin-angiotensin-aldosterone system inhibitor therapy and use of the newer oral potassium binders optimize therapy. Buffered solutions correct metabolic acidosis and lower serum potassium level. Dialysis effectively removes potassium in cases of renal dysfunction.[13]

Calcium and Phosphate

The total body content of calcium is approximately 1200 g. Most calcium (99%) is located in bone as hydroxyapatite (an inorganic compound that contributes to bone rigidity), and the remainder is in the plasma and body cells. The total fraction of calcium circulating in the blood is small (9.0 to 10.5 mg/dL), and approximately 50% is bound to plasma proteins, primarily albumin. Approximately 40% is in the free or ionized form (5.5 to 5.6 mg/dL). Ionized calcium has the most important physiologic functions. Approximately 20% of ingested calcium is absorbed in the small intestine, primarily in the duodenum.

Calcium (Ca2+) is a necessary ion for many fundamental metabolic and cellular processes. In bound form, it is the major cation associated with the structure of bones and teeth. The ionized form serves as an enzymatic cofactor for blood clotting and is required for hormone secretion and the function of cell receptors. Plasma membrane stability, permeability, and repair are directly related to calcium ions, as is the transmission of nerve impulses and the contraction of muscles. Calcium metabolism is linked to phosphate and magnesium metabolism.

Phosphate (HPO_4^-) is found primarily in bone (85%), with smaller amounts found within the intracellular and extracellular spaces. In the plasma, phosphate exists in phospholipids and phosphate esters and as inorganic phosphate, which is the ionized form. The normal serum levels of inorganic phosphate range from 2.5 to 4.5 mg/dL and may be as high as 6.0 to 7.0 mg/dL in infants and young children. Intracellular phosphate has many metabolic forms, including the high-energy structures creatine phosphate and adenosine triphosphate (ATP). Phosphate acts as an intracellular and extracellular anion buffer in the regulation of acid-base balance; in the form of ATP, it provides energy for muscle contraction.

Calcium and phosphate concentrations are rigidly controlled. They are related by the product of calcium and phosphate (HPO_4^-) concentrations, which is a constant (K) [**Ca2+)** × HPO_4^- = K]. Thus, if the concentration of one ion increases or decreases, that of the other normally increases or decreases.

Calcium and phosphate balance is regulated by three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin. Acting together, these substances determine the amount of dietary calcium and phosphate absorbed from the intestine, the deposition and absorption of calcium and phosphate from bone, and the renal reabsorption and excretion of calcium and phosphate by the kidney.

The parathyroid glands secrete PTH in response to low levels of serum calcium. (The specific actions of PTH in relation to calcium and phosphate are described in Chapter 21.) **Parathyroid hormone (PTH)** controls levels of ionized calcium and phosphate in the blood and other ECFs. Renal regulation of calcium and phosphate balance requires PTH. PTH stimulates reabsorption of calcium along the distal tubule of the nephron and inhibits phosphate reabsorption by the proximal tubule of the nephron. The net result is an increase in serum calcium concentration and increased urinary excretion of phosphate. Fig. 3.10 summarizes hormonal regulation of calcium.

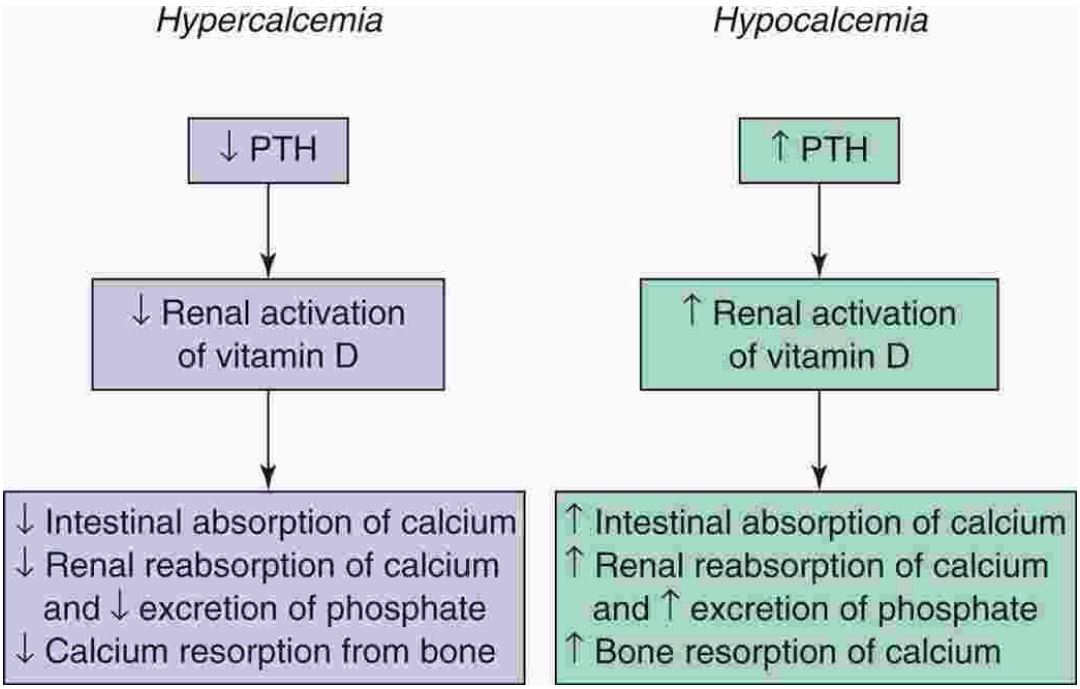

FIG. 3.10 Hormonal Regulation of Calcium Balance.
PTH, Parathyroid hormone.

Two flowcharts represent hormonal regulation of calcium balance. Flowchart on the left, hypercalcemia. â€¢ Decreased P T H. â€¢ Decreased renal activation of vitamin D. â€¢ Decreased intestinal absorption of calcium. Decreased reabsorption of calcium and decreased excretion of phosphate. Decreased calcium resorption from bone. Flowchart on the right, hypocalcemia. â€¢ Increased P T H. â€¢ Increased renal activation of vitamin D. â€¢ Increased intestinal absorption of calcium. Increased renal reabsorption of calcium and increased excretion of phosphate. Increased bone resorption of calcium.

Another compound important to calcium and phosphate regulation is vitamin D. **Vitamin D** (cholecalciferol) is a fat-soluble steroid ingested in food or synthesized in the skin in the presence of ultraviolet light. Several steps of activation are required before vitamin D can act on target tissues. The first step occurs in the liver; final activation is in the kidney. The renal activation of vitamin D begins when the serum calcium level decreases and stimulates secretion of PTH. PTH then acts to increase calcium reabsorption and enhance renal excretion

of phosphate, producing decreased phosphate levels. The combination of low calcium level and increased PTH secretion causes the renal activation of vitamin D. The activated vitamin D (vitamin D_3—calcitriol) then circulates as a hormone in the plasma and acts to increase absorption of calcium and phosphate in the small intestine, enhance bone calcification, increase renal tubular reabsorption of calcium, and increase excretion of phosphate. When end-stage renal disease occurs, vitamin D is not activated; serum calcium levels decrease; and phosphate levels increase.

As calcium levels increase, an opposite adaptation occurs, leading to suppression of PTH secretion, decreased renal vitamin D activation, decreased intestinal calcium absorption, and increased renal phosphate reabsorption. **Calcitonin** (produced by C cells of the thyroid gland) decreases calcium levels by inhibiting osteoclastic activity in bone and increasing renal calcium and phosphate excretion.

The fractions of serum calcium that are freely ionized or bound to plasma proteins are influenced by pH. In states of acidosis, levels of ionized calcium increase. When alkalosis develops, with an increase in pH, the amount of protein-bound calcium increases and the physiologically active, ionized calcium level decreases. The decreased concentration of ionized calcium may be great enough to cause symptoms of hypocalcemia, such as tetany.

Hypocalcemia

Pathophysiology

Hypocalcemia occurs when serum total calcium concentrations are less than 9.0 mg/dL and ionized levels are less than 5.5 mg/dL. In general, deficits in calcium are related to inadequate intestinal absorption, decreases in levels of PTH and vitamin D, or deposition of ionized calcium into bone or soft tissue.[14]

Nutritional deficiencies of calcium can occur in the instance of inadequate sources of dairy products or green, leafy vegetables, eating disorders, and malabsorption syndromes (celiac disease or short bowel syndrome). Excessive amounts of dietary phosphorus also bind with calcium in the gastrointestinal tract, so neither mineral is absorbed when such an excess occurs. Removal of the parathyroid glands (e.g., during total thyroidectomy) with the resulting loss of PTH also causes hypocalcemia. Severe hypomagnesemia suppresses PTH secretion, also causing hypocalcemia. Vitamin D deficiency, which can result from inadequate intake or lack of exposure to sunlight, causes decreased intestinal absorption of calcium. Malabsorption of fat, including fat-soluble vitamin D, also may contribute to calcium deficiency. Neoplastic bone metastases may inhibit bone resorption and increase calcium deposition into bone, thereby decreasing serum calcium levels.

Blood transfusions are also a common cause of hypocalcemia because the citrate solution used in storing whole blood binds with calcium and makes it unavailable to the tissues. Pancreatitis causes release of lipases into soft tissue spaces, so the free fatty acids that are formed bind calcium, causing a decrease in the concentration of ionized calcium. Metabolic or respiratory alkalosis causes symptoms of hypocalcemia because the change in pH enhances protein binding of ionized calcium. Hypoalbuminemia lowers total serum calcium levels by decreasing the amount of bound calcium in the plasma.

Clinical Manifestations

Many individuals with chronic hypocalcemia are asymptomatic. The clinical manifestations are a function of severity and rapidity of onset. Severe manifestations are caused by an increase in neuromuscular excitability with partial depolarization of nerves and muscles. As the threshold potential becomes more negative and approaches the resting membrane potential (hypopolarization) (see Fig. 3.8C), a smaller stimulus is required for initiating an action potential. The symptoms include paresthesias around the mouth and in the digits, carpopedal spasm (muscle spasms in the hands and feet), hyperreflexia, seizures, laryngospasm, and anxiety.

Two clinical signs of increased neuromuscular excitability are Chvostek sign and Trousseau sign. *Chvostek sign* is elicited by tapping on the facial nerve over the zygomatic arch. A positive sign is a strong twitch of the nose or lip. *Trousseau sign* is contraction of the hand and fingers when the arterial blood flow in the arm is occluded for 3 to 5 minutes with the use of a blood pressure cuff.

The characteristic ECG change is a prolonged QT interval, indicating prolonged ventricular depolarization and decreased cardiac contractility. Intestinal cramping and hyperactive bowel sounds also may be present because hypocalcemia affects the smooth muscles of the gastrointestinal tract. Table 3.11 contains a summary of the manifestations of calcium level alterations.

Table 3.11

Alterations in Calcium, Phosphate, and Magnesium Levels

Causes	Manifestations
Hypocalcemia (<8.5 mg/dL)	
Inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreases in PTH and vitamin D levels; nutritional deficiencies occur with inadequate sources of dairy products or green, leafy vegetables; alkalosis, elevated calcitonin level	Increased neuromuscular excitability; tingling, muscle spasms (particularly in hands, feet, and facial muscles), intestinal cramping, hyperactive bowel sounds; osteoporosis and fractures; severe cases show seizures and tetany; prolonged QT interval, cardiac arrest
Hypercalcemia (>10.5 mg/dL)	
Hyperparathyroidism; secretion of PTH and PTH-related protein from cancer cells; sarcoidosis; excess vitamin D; overuse of calcium-containing antacids	Many nonspecific; fatigue, weakness, lethargy, anorexia, nausea, constipation; impaired renal function, kidney stones; dysrhythmias, bradycardia, cardiac arrest; bone pain, osteoporosis, fractures
Hypophosphatemia (<2.0 mg/dL)	
Intestinal malabsorption related to vitamin D deficiency, overuse of magnesium- and aluminum-containing antacids, long-term alcohol abuse, and malabsorption syndromes; respiratory alkalosis; increased renal excretion of phosphate associated with hyperparathyroidism	Conditions related to reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism; leukocyte and platelet dysfunction; deranged nerve and muscle function; in severe cases, irritability, confusion, numbness, coma, seizures; possibly respiratory failure (because of muscle weakness), cardiomyopathies, bone resorption (leading to rickets or osteomalacia)
Hyperphosphatemia (>4.7 mg/dL)	

Causes	Manifestations
Acute or chronic oliguric renal disease with significant loss of glomerular filtration; treatment of metastatic tumors with chemotherapy that releases large amounts of phosphate into serum; long-term use of laxatives or enemas containing phosphates; hypoparathyroidism	Symptoms primarily related to low serum calcium levels (caused by high phosphate levels) similar to symptoms of hypocalcemia; when prolonged, calcification of soft tissues in lungs, kidneys, joints
Hypomagnesemia (<1.5 mEq/L)	
Malnutrition, malabsorption syndromes, alcoholism, urinary losses (renal tubular dysfunction, loop diuretics)	Behavioral changes, irritability, increased reflexes, muscle cramps, ataxia, nystagmus, tetany, seizures, tachycardia, hypotension
Hypermagnesemia (>3.0 mEq/L)	
Usually oliguric renal disease; also excessive intake of magnesium-containing antacids, adrenal insufficiency	Lethargy, drowsiness; loss of deep tendon reflexes; nausea and vomiting; muscle weakness; hypotension; bradycardia; respiratory depression or arrest; heart block, cardiac arrest

Causes	Manifestations
Hypocalcemia (<8.5 mg/dL)	
Inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreases in PTH and vitamin D levels; nutritional deficiencies occur with inadequate sources of dairy products or green, leafy vegetables; alkalosis, elevated calcitonin level	Increased neuromuscular excitability; tingling, muscle spasms (particularly in hands, feet, and facial muscles), intestinal cramping, hyperactive bowel sounds; osteoporosis and fractures; severe cases show seizures and tetany; prolonged QT interval, cardiac arrest
Hypercalcemia (>10.5 mg/dL)	
Hyperparathyroidism; secretion of PTH and PTH-related protein from cancer cells; sarcoidosis; excess vitamin D; overuse of calcium-containing antacids	Many nonspecific; fatigue, weakness, lethargy, anorexia, nausea, constipation; impaired renal function, kidney stones; dysrhythmias, bradycardia, cardiac arrest; bone pain, osteoporosis, fractures
Hypophosphatemia (<2.0 mg/dL)	
Intestinal malabsorption related to vitamin D deficiency, overuse of magnesium- and aluminum-containing antacids, long-term alcohol abuse, and malabsorption syndromes; respiratory alkalosis; increased renal excretion of phosphate associated with hyperparathyroidism	Conditions related to reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism; leukocyte and platelet dysfunction; deranged nerve and muscle function; in severe cases, irritability, confusion, numbness, coma, seizures; possibly respiratory failure (because of muscle weakness), cardiomyopathies, bone resorption (leading to rickets or osteomalacia)
Hyperphosphatemia (>4.7 mg/dL)	
Acute or chronic oliguric renal disease with significant loss of glomerular filtration; treatment of metastatic tumors with chemotherapy that releases large amounts of phosphate into serum; long-term use of laxatives or enemas containing phosphates; hypoparathyroidism	Symptoms primarily related to low serum calcium levels (caused by high phosphate levels) similar to symptoms of hypocalcemia; when prolonged, calcification of soft tissues in lungs, kidneys, joints
Hypomagnesemia (<1.5 mEq/L)	
Malnutrition, malabsorption syndromes, alcoholism, urinary losses (renal tubular dysfunction, loop diuretics)	Behavioral changes, irritability, increased reflexes, muscle cramps, ataxia, nystagmus, tetany, seizures, tachycardia, hypotension
Hypermagnesemia (>3.0 mEq/L)	
Usually oliguric renal disease; also excessive intake of magnesium-containing antacids, adrenal insufficiency	Lethargy, drowsiness; loss of deep tendon reflexes; nausea and vomiting; muscle weakness; hypotension; bradycardia; respiratory depression or arrest; heart block, cardiac arrest

PTH, Parathyroid hormone.

Evaluation and Treatment

Serum and ionized calcium, albumin, phosphate, and magnesium levels are evaluated. Further evaluation includes renal function and measurement of PTH and vitamin D. Severe symptoms of hypocalcemia require emergency treatment with IV 10% calcium gluconate, volume repletion, and ECG monitoring. The underlying cause must be identified. Oral calcium replacement should be initiated, and serum calcium levels should be monitored. Decreasing phosphate intake facilitates long-term management of hypocalcemia.

Hypercalcemia

Pathophysiology

Hypercalcemia with total serum calcium concentrations exceeding 10.5 mg/dL (5.2 mEq/L) can be caused by a number of diseases. The most common among these are hyperparathyroidism (which can be associated with thyrotoxicosis); many different types of cancer; sarcoidosis; and vitamin D toxicity. Many

malignant tumors produce PTH or PTH-related protein, which causes bone resorption, thus elevating the serum calcium levels. Mild hypomagnesemia also stimulates PTH secretion and increases serum calcium. Sarcoidosis appears to increase vitamin D levels. Prolonged immobilization can also lead to hypercalcemia from enhanced bone resorption and decreased calcium deposition into bone. Acidosis decreases serum binding of calcium to albumin, increasing ionized calcium levels.

Clinical Manifestations

Many symptoms of hypercalcemia are nonspecific and related to severity and rapidity of onset. Because serum calcium levels are increased, a greater amount of calcium is also contained inside the cells. The threshold potential becomes more positive (hyperpolarized) (e.g., moves from −60 to −50 millivolts) and the cell membrane becomes refractory to depolarization (decreased excitability) and results in a greater difference between threshold potential and resting membrane potential (see Fig. 3.8C). Thus, many of the symptoms are related to loss of cell membrane excitability. Fatigue, weakness, lethargy, anorexia, nausea, and constipation are common.

Mental status changes and confusion may occur. Impaired renal function frequently develops with polyuria or formation of kidney stones from precipitates of calcium salts. A shortened QT segment and depressed widened T waves also may be observed on the ECG, with bradycardia and varying degrees of heart block. Table 3.11 contains a summary of the manifestations of alterations in calcium levels.

Evaluation and Treatment

With elevated serum calcium levels, often a reciprocal decrease in serum phosphate values occurs. Specific diagnostic procedures to identify the contributing pathologic condition are required.

Treatment is related to the severity of symptoms and the underlying disease. When renal function is normal, oral phosphate administration is effective. When acute illness and high calcium levels are present, treatment options include IV administration of large amounts of normal saline to enhance renal excretion of calcium, administration of bisphosphonates in the absence of renal dysfunction, and administration of calcitonin. Bisphosphonates and denosumab are used for malignancy-associated hypercalcemia, and cinacalcet is approved for the reduction of **hypercalcemia** associated with parathyroid carcinoma.[15] Ultimately, the underlying pathologic condition must be treated.

Hypophosphatemia

Pathophysiology

Hypophosphatemia is a serum phosphate level less than 2.0 mg/dL and is usually an indication of phosphate deficiency. In some conditions, total body phosphate concentration is normal, but serum concentrations are low. The most common causes are intestinal malabsorption and increased renal excretion of phosphate. Inadequate absorption is associated with vitamin D deficiency, use of magnesium- and aluminum-containing antacids (which bind with phosphorus), long-term alcohol abuse, malabsorption syndromes, and refeeding syndromes after starvation. Respiratory alkalosis can cause severe hypophosphatemia because of cellular use of phosphorus for accelerated glycolysis (ATP) formation. Increased renal excretion of phosphorus is associated with hyperparathyroidism. Risk of hypophosphatemia has also been associated with IV iron therapy for treatment of pernicious anemia.[16] Genetic mutations in fibroblast growth factor 23 (FGF23) are associated with decreased renal reabsorption of phosphorus.

Clinical Manifestations

The consequences of phosphate deficiency are not clinically evident until hypophosphatemia is severe, and multiple organ systems can be affected. There is reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism. When phosphate is depleted, erythrocyte 2,3-DPG (diphosphoglycerate) and ATP levels become low and diminish the release of oxygen to the tissues, leading to hypoxia with bradycardia and varying degrees of heart block.

Leukocyte and platelet dysfunctions also are associated with hypophosphatemia. There is a greater risk of infection and blood-clotting impairment, with potential for hemorrhage. Nerve and muscle function can be affected because of derangement in energy metabolism. Muscle weakness may become serious enough to cause respiratory failure, and cardiomyopathies also can develop. Irritability, confusion, numbness, coma, and seizures develop with severe phosphate losses. In response to low phosphate levels, bone resorption occurs and may lead to rickets or osteomalacia. (Table 3.11 contains a summary of the manifestations of phosphate level alterations).

Evaluation and Treatment

To correct the condition, the underlying cause must be identified and treated. The rate and amount of replacement are determined by the cause and presenting symptoms.[17]

Hyperphosphatemia

Pathophysiology

Hyperphosphatemia, or an elevated serum phosphate level of more than 4.7 mg/dL, develops with exogenous or endogenous addition of phosphorus to

the ECF or with significant loss of glomerular filtration and chronic kidney disease. Because most phosphate is located in cells, rapid cell destruction associated with treatment of metastatic tumors with chemotherapy can release large amounts of phosphate into the ECF. Long-term use of phosphate-containing enemas or laxatives also may lead to hyperphosphatemia. Hypoparathyroidism can cause elevated phosphate levels by increasing renal tubular reabsorption of phosphate.

High levels of serum phosphate also lower serum calcium levels, and increased amounts of phosphate and calcium are deposited in bone and soft tissues. Serum calcium levels may become low enough to cause symptoms of hypocalcemia, including tetany.

Clinical Manifestations

Symptoms of hyperphosphatemia are related primarily to low serum calcium levels and thus are comparable with symptoms of hypocalcemia. With prolonged hyperphosphatemia, calcification of soft tissues occurs in the lungs, kidneys, and joints. (See Table 3.11 contains a summary of the manifestations of alterations in phosphate concentration.)

Evaluation and Treatment

To correct hyperphosphatemia, the underlying pathologic condition must be identified and treated. Aluminum hydroxide may be administered because it binds phosphate in the gastrointestinal tract and is then eliminated; however, aluminum can be toxic, causing encephalopathy and osteomalacia. Nonaluminum, non–calcium phosphate binders (e.g., lanthanum carbonate or sevelamer) are used but can have serious side effects and are costly.[18] Newer iron-based binders are being evaluated.[19] Dialysis is required for management of end-stage chronic kidney disease.

Magnesium

Magnesium (Mg^{++}) is a major intracellular cation, second to potassium. Approximately 40% to 60% is stored in muscle and bone, with 30% in the cells. A small amount (1%) is in the plasma. Plasma concentration is 1.5 to 3.0 mg/dL with approximately one-third bound to plasma proteins and the rest in ionized form. Regulation of magnesium metabolism is balanced by dietary intake, small intestinal absorption, and renal reabsorption and excretion. Low serum levels cause renal conservation of magnesium. Magnesium is a cofactor in intracellular enzymatic reactions, protein synthesis, and nucleic acid stability. Extracellular magnesium is necessary for normal neuromuscular excitability and nerve conduction. Magnesium improves myocardial metabolism and cell function; influences vascular smooth muscle tone (reduces peripheral vascular resistance

and afterload); reduces cardiac dysrhythmias; and improves lipid and glucose metabolism. Magnesium also reduces vulnerability to oxygen-derived free radicals and systemic inflammation, improves human endothelial function, and inhibits platelet function, including platelet aggregation and adhesion.

Magnesium has been shown to counteract vascular calcification by inhibiting hyperphosphatemic-induced crystalline calciprotein particle formation in vascular smooth muscle.[20] Calcium and magnesium often interact in reactions at the intracellular level, with magnesium being an antagonist of calcium. Mg^{++} reduces PTH secretion mainly when a moderate-low calcium concentration is present.

Hypomagnesemia occurs when serum magnesium concentration is less than 1.5 mEq/L and clinical symptoms are present.[11] Malnutrition, malabsorption syndromes, alcoholism, renal tubular dysfunction, metabolic acidosis, use of loop and thiazide diuretics, and prolonged use of proton pump inhibitors can cause magnesium losses. Hypomagnesemia is associated with insulin resistance, diabetes mellitus, left ventricular hypertrophy, systemic inflammation, hypoalbuminemia, and osteoporosis. Because extracellular magnesium inhibits potassium channels, loss of magnesium results in movement of potassium out of the cell, with renal excretion resulting in hypokalemia. Signs and symptoms of hypomagnesemia are often absent and develop with severe losses. Clinical manifestations are similar to those of hypocalcemia. Neuromuscular irritability, positive Chvostek and Trousseau signs, increased reflexes, muscle weakness, ataxia, nystagmus, tetany, seizures, and tachydysrhythmias may be observed. Treatment is intramuscular or IV administration of magnesium sulfate. Magnesium supplementation may be beneficial in the treatment of preeclampsia, migraine, depression, cardiovascular disease, metabolic syndrome, and asthma.[21–23]

Hypermagnesemia, in which magnesium concentration is greater than 3.0 mEq/L, is rare and usually is caused by oliguric renal disease. Magnesium-containing antacids or cathartics can potentiate excess magnesium levels. Excess magnesium concentration inhibits calcium-mediated nerve conduction and depresses skeletal muscle contraction and nerve function. Signs and symptoms include nausea and vomiting, decreased deep tendon reflexes, muscle weakness, hypotension, bradycardia, and respiratory depression. Treatment is avoidance of magnesium-containing substances and removal of magnesium by dialysis.[24] (See Table 3.11 contains a summary of the manifestations of magnesium level alterations.)

ACID-Base Balance

Acid-base balance and hydrogen ion concentration must be regulated within a narrow range for normal body function. Slight changes in amounts of hydrogen ion and pH changes can significantly alter biologic processes in cells and tissues. Hydrogen ions are required to maintain membrane integrity and the speed of enzymatic reactions.[25] Many pathologic conditions disturb acid-base balance, and the degree of severity may be more harmful than the disease process itself.

Hydrogen Ion and pH

The concentration of hydrogen ions in body fluids is very small—approximately 0.0000001 mg/L. This number is expressed as the negative logarithm 10^{-7} mg/L and is indicated on the pH scale as pH 7.0, a neutral status. Values less than 7.0 are more acid. Values more than 7.0 are more alkaline. Accordingly, the pH number indicates the acidity or alkalinity of a solution. The pH scale is logarithmic, not linear, meaning the difference between numbers on the scale is not constant. Each number on the scale is 10 times more acid or more alkaline than the preceding number. Accordingly, a pH of 5 is 10 times more acid than a pH of 6; a pH of 4 is 10 times more acid than a pH of 5 and 100 times more acid than a pH of 6. As the pH changes by one unit from a pH 7 to a pH 6, the H^+ increases 10-fold, making the solution much more acid than a neutral solution with a pH of 7.0. Solutions with an excess of hydrogen ions are acidic in nature; solutions with an excess of hydroxide ions (OH^-) are basic, or alkaline, in nature. In arterial blood, the normal pH range is 7.35 to 7.45, with 7.4 being the midpoint of that normal range. Accordingly, a blood pH less than 7.35 is defined as acidic, and a pH greater than 7.45 is defined as alkaline, or basic (Table 3.12).

Table 3.12

pH of Body Fluids

Body Fluid	pH	Factors Affecting pH
Gastric juices	1.0–3.0	Hydrochloric acid production
Urine	5.0–6.0	H^+ ion excretion from waste products
Arterial blood	7.35–7.45	pH is slightly higher because there is less carbonic acid (H_2CO_3)
Venous blood	7.37	pH is slightly lower because there is more carbonic acid
Cerebrospinal fluid	7.32	Decreased bicarbonate and higher carbon dioxide content decrease pH
Pancreatic fluid	7.8–8.0	Contains bicarbonate produced by exocrine cells
Bile	7.0–8.0	Contains bicarbonate
Small intestine fluid	6.5–7.5	Contains alkaline fluid from pancreas, liver, and gallbladder

The average person generates 50 to 100 mEq/day of acid from the metabolism of proteins, carbohydrates, and fats, as well as from loss of alkaline fluids in the stool. To maintain a normal pH, acids must be balanced by base substances within the body. A base is a substance that accepts hydrogen ions; an acid is a substance that donates hydrogen ions. Body acids exist in two forms: **volatile** acids (substances that can be eliminated as carbon dioxide [CO_2] gas) and **nonvolatile** acids (substances that can be eliminated only by the kidney). The sole volatile acid formed in the body is carbonic acid (H_2CO_3), a *weak acid*, which means that in body fluids, some of the carbonic acid molecules release their hydrogen ions, but other carbonic molecules do not. In the presence of the enzyme carbonic anhydrase, it readily dissociates into CO_2 and water (H_2O). The CO_2 is eliminated through pulmonary ventilation. The rest of the body acids are nonvolatile acids, such as lactic acid, phosphoric acid, sulfuric acid, acetoacetic acid, and beta-hydroxybutyric acid. A few nonvolatile acids are *strong acids*, meaning they readily release their hydrogen ions; however, most of the nonvolatile acids are weak acids. Nonvolatile acids are secreted into the urine by the renal tubules in amounts of approximately 50 to 100 mEq of hydrogen per day, or approximately 1 mEq/kg of body weight.

Mechanisms to Maintain Normal pH

The body has three mechanisms, or lines of defense, to maintain the acid-base balance: (1) physiologic (chemical) buffer systems (plasma bicarbonate, phosphate, hemoglobin [Hb], and protein), the first line of defense; (2) respiratory acid-base control, the second line of defense; and (3) renal acid-base control, the third line of defense. The physiologic buffers function instantaneously to correct alterations in the acid-base balance. The lungs and the kidneys work in concert to maintain a normal pH. The lungs respond relatively quickly (within seconds to minutes), but the kidneys require more time (hours to days) to bring the system into balance. Although the lungs respond more quickly, mechanisms involving the kidney produce more long-term acid-base balance.

Buffer Systems

Buffer systems resist changes in pH and maintain pH within the normal range. Metabolic processes primarily generate H^+ (acid) ions. Unchecked, these ions would alter the pH of the body. **Buffers** can absorb excessive H^+ ions (acid) or hydroxide ions (OH^-) (base) to minimize fluctuations in pH. The buffer systems are located in both the ICF and the ECF compartments, and function at different rates (Table 3.13). The most important are the plasma buffer systems, which have two components: carbonic acid–bicarbonate and the protein Hb. The important intracellular buffers are phosphate and protein. Ammonia and phosphate can attach hydrogen ions and are important renal buffers.

Table 3.13

Buffer Systems

Buffer Pairs	Buffer System	pK Values	Reaction	Rate
HCO_3^- / H_2CO_3	Bicarbonate	6.1	$H^+ + HCO_3^- \rightleftarrows H_2O + CO_2$	Instantaneous
Hb^-/HHb	Hemoglobin	7.3	$HHb \rightleftarrows H^+ + Hb^-$	Instantaneous
$HPO_4^- / H_2PO_3^-$	Phosphate	6.8	$HPO_4^- + H^+ \rightleftarrows H_2PO_4^-$	Instantaneous
Pr^-/HPr	Plasma proteins	6.7	$HPr \rightleftarrows H^+ + Pr^-$	Instantaneous
Organs	Mechanism			Rate
Lungs	Regulates retention or elimination of CO_2 and therefore H_2CO_3 concentration			Minutes to hours
Ionic shifts	Exchange of intracellular potassium and sodium for hydrogen			2–4 hours
Kidneys	Bicarbonate reabsorption and regeneration, ammonia formation, phosphate buffering			Hours to days
Bone	Exchanges of calcium and phosphate, release of carbonate			Hours to days

Buffer Pairs	Buffer System	pK Values	Reaction	Rate
HCO_3^- / H_2CO_3	Bicarbonate	6.1	$H^+ + HCO_3^- \rightleftarrows H_2O + CO_2$	Instantaneous
Hb^-/HHb	Hemoglobin	7.3	$HHb \rightleftarrows H^+ + Hb^-$	Instantaneous
$HPO_4^- / H_2PO_3^-$	Phosphate	6.8	$HPO_4^- + H^+ \rightleftarrows H_2PO_4^-$	Instantaneous
Pr^-/HPr	Plasma proteins	6.7	$HPr \rightleftarrows H_+ + Pr_-$	Instantaneous
Organs	Mechanism			Rate
Lungs	Regulates retention or elimination of CO_2 and therefore H_2CO_3 concentration			Minutes to hours
Ionic shifts	Exchange of intracellular potassium and sodium for hydrogen			2–4 hours
Kidneys	Bicarbonate reabsorption and regeneration, ammonia formation, phosphate buffering			Hours to days
Bone	Exchanges of calcium and phosphate, release of carbonate			Hours to days

H^+, Hydrogen ion; HCO_3^-, bicarbonate; H_2CO_3, carbonic acid; Hb^-, hemoglobin; *HHb*, hydrogenated hemoglobin; $H_2PO_4^-$, monobasic phosphate; HPO_4^-, dibasic phosphate; *HPr*, hydrogenated protein; Pr^-, protein.

Carbonic Acid–Bicarbonate Buffering

Cellular respiration results in the production of CO_2, which combines with water to form carbonic acid (H_2CO_3). H_2CO_3 dissociates, forming one hydrogen (H^+) ion and one bicarbonate ion (HCO_3^-) in the blood. The bicarbonate ion is a base component of the **buffer system**, and the hydrogen ion is the acid component. These reactions are readily reversible, depending on whether an acid or a base environment exists. The reactions can move in one or the other direction to maintain a neutral pH. Accordingly, these reactions can correct for imbalances in pH by releasing hydrogen ions or absorbing hydrogen ions as the need arises. If excess H^+ ions are present, the buffer absorbs these ions. If excess bicarbonate ions are present, the buffer releases H^+ ions. The relationship between bicarbonate (HCO_3^-) and carbonic acid (H_2CO_3) usually is expressed as a ratio. Under normal conditions, the bicarbonate level is approximately 24 mEq/L and the carbonic acid level is approximately 1.2 mEq/L when the arterial CO_2 ($PaCO_2$) is 40 mm Hg. Therefore the ratio of bicarbonate to carbonic acid is 20:1 (24/1.2). This ratio maintains a normal pH of 7.40 (Fig. 3.11).

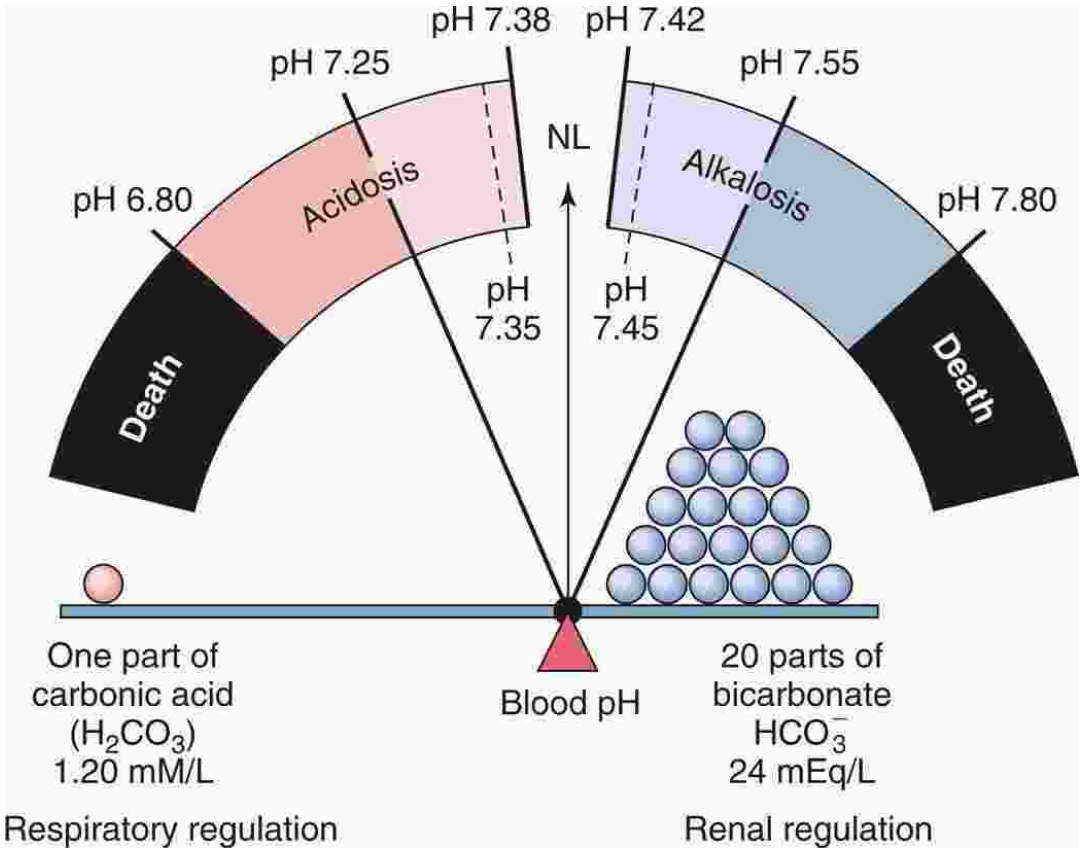

FIG. 3.11 Ratio of Carbonic Acid and Bicarbonate Concentration in Maintaining pH Within Normal Limits. An increase in H_2CO_3 or decrease in HCO_3^- concentration causes acidosis. A decrease in H_2CO_3 or increase in HCO_3^- concentration causes alkalosis. *NL*, Normal. (From Monahan, FD, et al. *Medical-surgical nursing: Health and illness perspectives*, 8th edition. St. Louis: Mosby; 2007.)

A fulcrum balance shows one part of carbonic acid, H 2 C O 3, on the left pan, and 20 parts of bicarbonate, H C O 3 ion, on the right pan. The fulcrum, blood p H, is closer to the right pan. The left pan represents respiratory regulation and measures 1.20 millimoles per liter. The right pan represents renal regulation and measures 24 milliequivalents per liter. A gauge traced from the fulcrum represents the p H limits. From the left to the right, the gauge shows the following segments: â€¢ Up to p H 6.80: death. â€¢ p H 6.80 to p H 7.25: high acidosis.

â€¢ p H 7.25 to p H 7.38: low acidosis. â€¢ p H 7.35 to p H 7.45: N L, normal. â€¢ p H 7.42 to p H 7.55 low alkalosis. â€¢ p H 7.55 to p H 7.80: high alkalosis. â€¢ beyond p H 7.80: death.

Both the lungs and the kidneys augment the action of the bicarbonate–carbonic acid buffer system. The lungs eliminate CO_2 and water and can increase the amount of CO_2 eliminated by increasing the rate and depth of ventilation. Although the lungs do not respond as rapidly as the physiologic buffering system, they have twice the ability to correct for pH imbalances compared with all the chemical buffering systems combined. Similarly, the kidneys augment the **carbonic acid–bicarbonate buffer** system by reabsorbing or regenerating bicarbonate from CO_2 and water in the renal tubules or excreting hydrogen ions into the urine. The renal response takes considerably longer than does the respiratory response. However, the kidneys' ability to regulate and maintain a normal pH is necessary because the kidneys are the only organs that can excrete nonvolatile acids.

The pH ratio equation of 20/1 can be symbolically expressed as follows:

$$\text{pH} = 20/1 = \frac{\text{Base}}{\text{Acid}} \quad \text{or} \quad \text{pH} = \frac{\text{Renal regulation (slow)}}{\text{Pulmonary regulation (fast)}}$$

Changes in either the numerator or the denominator will change the pH. For example, if the amount of bicarbonate is decreased, the pH also decreases, causing a state of acidosis (Fig. 3.12). The pH can be returned to a normal range if the value of the denominator or the amount of carbonic acid also decreases. When a disease process causes an alteration in the bicarbonate/carbonic acid ratio, the kidneys or lungs (i.e., the organ not responsible for causing the alteration) respond to restore the ratio and maintain a normal pH.

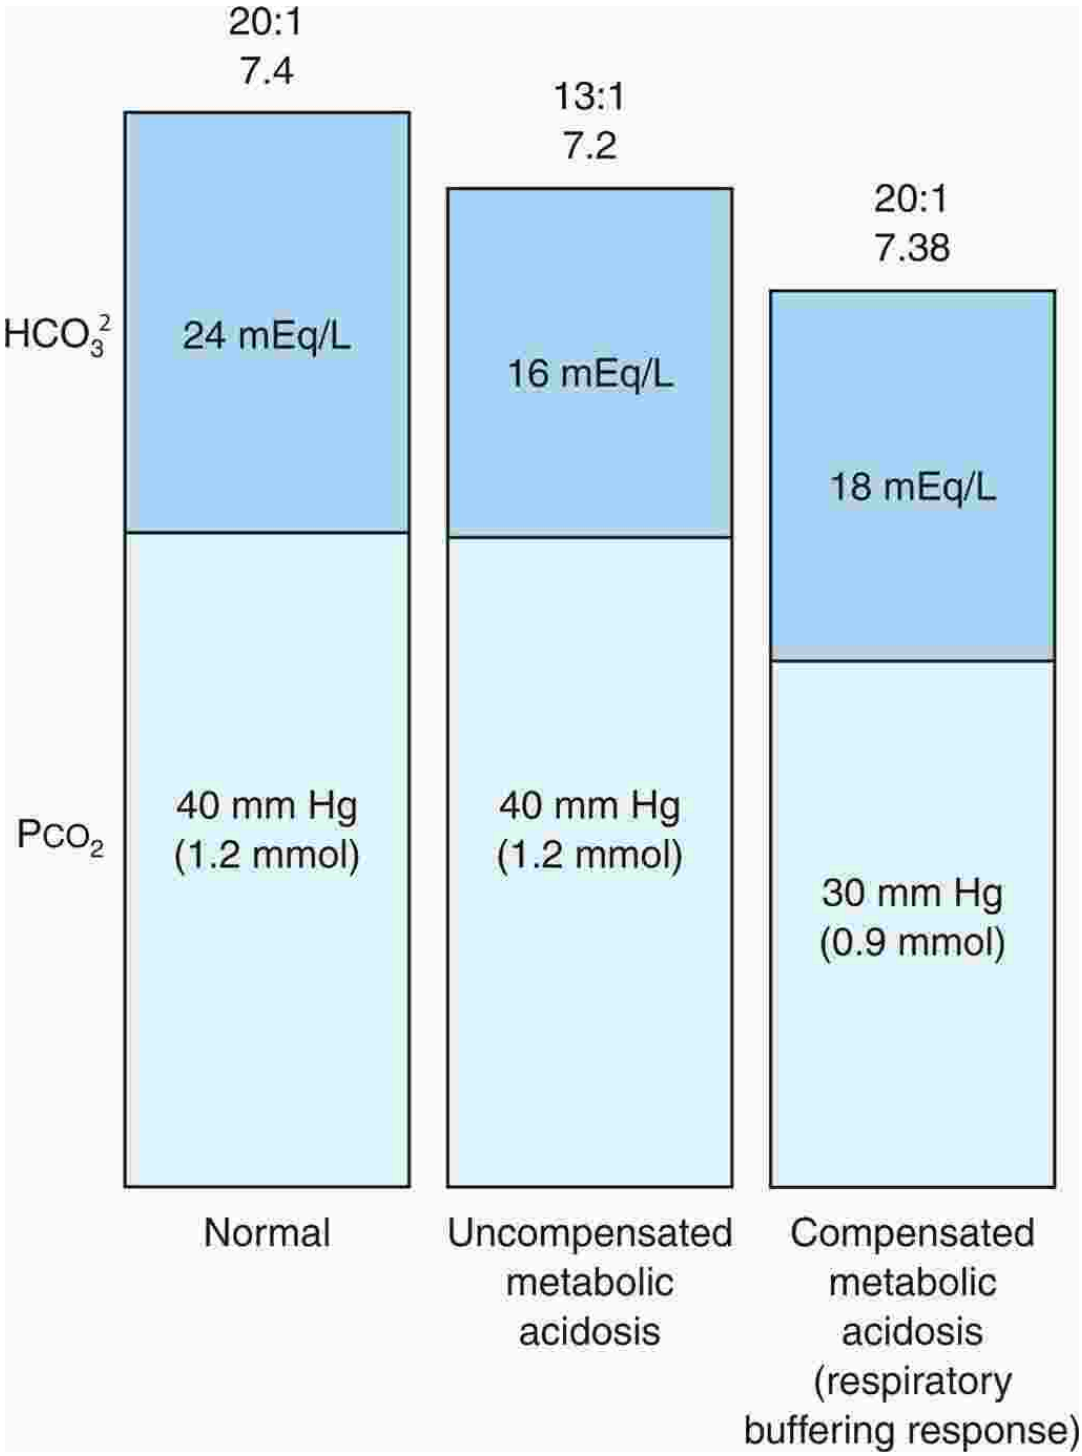

FIG. 3.12 Compensated Maintenance of $[^{HCO_3^-}]/PCO_2$ (H_2CO_3) Ratio in Metabolic Acidosis.

Three stacked bars represent ratios of partial pressure of carbon dioxide and bicarbonate in metabolic acidosis. Left bar,

normal in the ratio 20 to 1 of 7.4. P C O sub 2, 40 millimeters of mercury or 1.2 millimoles. H C O sub 3 sup 2, 24 milliequivalents per liter. Middle bar, uncompensated metabolic acidosis in the ratio 13 to 1 of 7.2. P C O sub 2, 40 millimeters of mercury of 1.2 millimoles. H C O sub 3 sup 2, 16 milliequivalents per liter. Right bar, compensated metabolic acidosis or respiratory buffering response in the ration 20 to 1 of 7.38. P C O sub 2, 30 millimeters of mercury or 0.9 millimoles. H C O sub 3 sup 2, 18 milliequivalents per liter.

Protein Buffering

All proteins can attach or release a hydrogen ion. Most proteins are inside cells; hence protein-based buffering is primarily an intracellular buffer system. Hb in erythrocytes is an excellent blood protein buffer. As the pH increases, Hb loses hydrogen ions, and the reverse happens when the pH decreases. Hb also affects the pH through a different mechanism when it binds CO_2 to form carbaminohemoglobin ($HHbCO_2$). The bound CO_2 is transported to the lungs, where it is released from the body through ventilation. This dynamic is important because CO_2 is a *potential acid*. Unbound CO_2 can react in water to form H_2CO_3, a weak acid. Carbonic acid releases hydrogen ion, lowering the pH. By binding CO_2, the Hb is preventing CO_2 from becoming carbonic acid; it thereby prevents the release of excess H^+ ions into the environment. The pH control system is illustrated in Fig. 3.13.

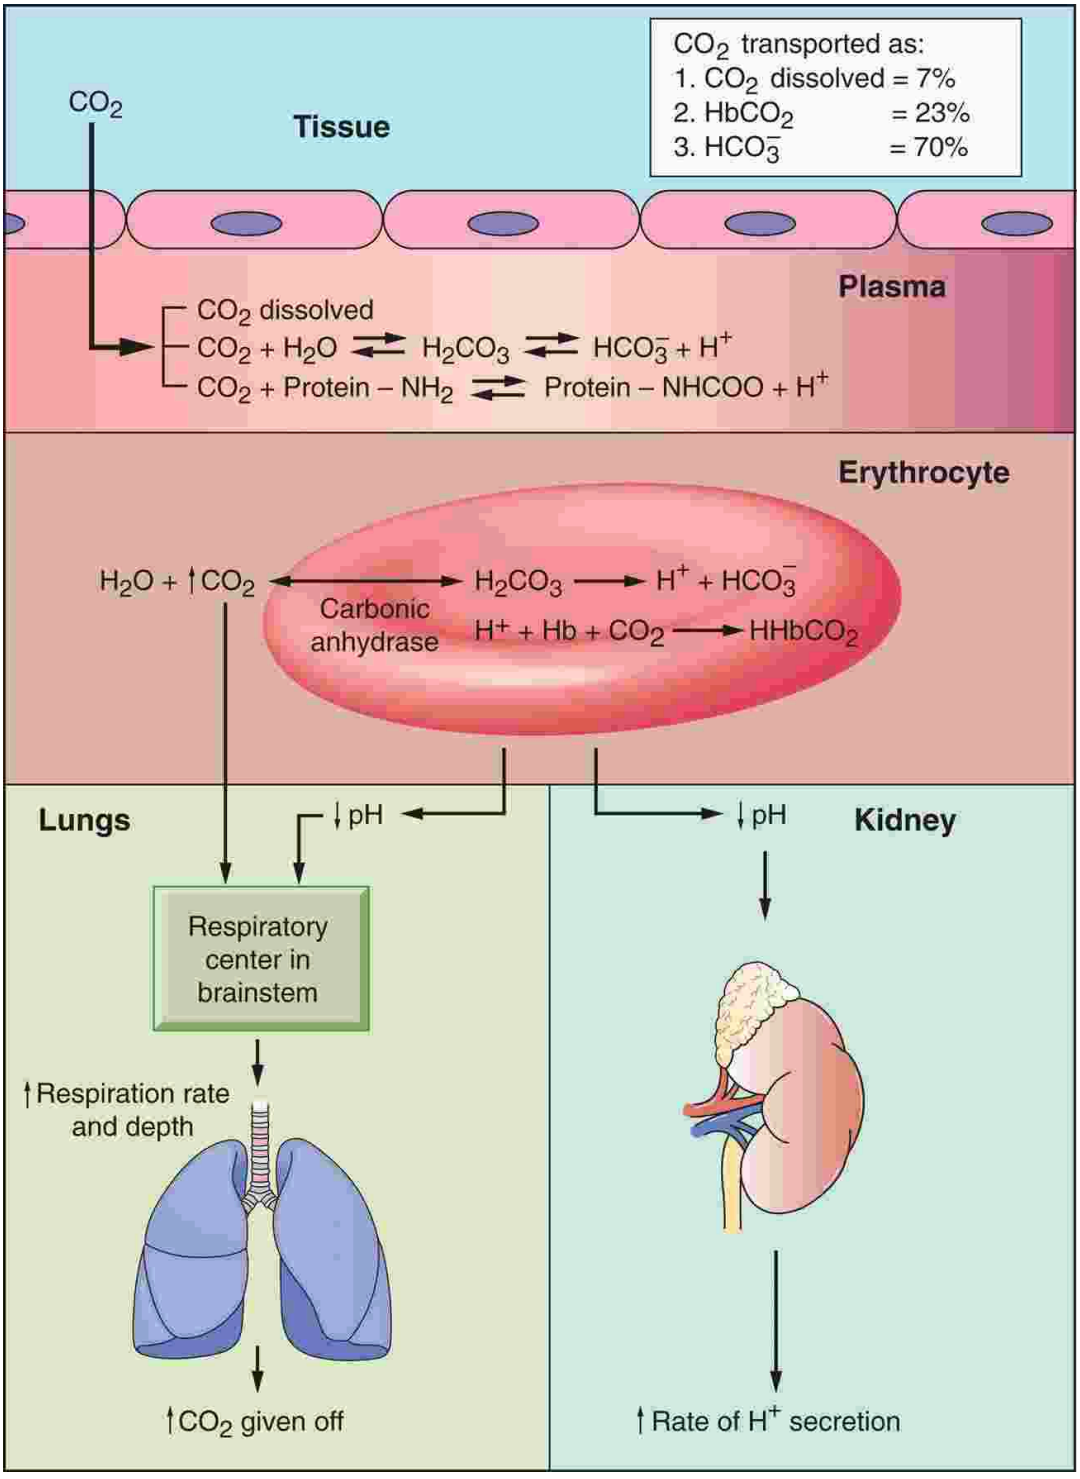

FIG. 3.13 Integration of pH Control Mechanisms.
CO_2 is produced in tissue cells and diffuses to plasma, where it is transported as dissolved CO_2, or it combines with water to form carbonic acid (H_2CO_3), or it combines with protein from which hydrogen has been released. Most of the CO_2 diffuses

into the red blood cells and combines with water to form H_2CO_3. The H_2CO_3 dissociates to form hydrogen ion (H^+) and bicarbonate (HCO_3^-). Hydrogen ion combines with hemoglobin that has released its oxygen to form hydrogenated hemoglobin (HHb), which buffers the hydrogen ion and makes venous blood slightly more acidic than arterial blood. The increase in H^+ concentration coupled with elevated CO_2 levels results in $HHbCO_2$ and an increase in the respiratory rate (eliminates CO_2) and secretion of H^+ by the kidneys.

An illustration demonstrates the integration of p H control mechanisms in tissue, plasma, erythrocyte, lungs, and kidney. Tissue. C O 2 is transported as: 1. C O 2 dissolved equals 7 percent. 2. H b C O 2 equals 23 percent. 3. H C O 3 ion equals 70 percent. Plasma. C O 2 from tissue. â€¢ C O 2 dissolved. â€¢ C O 2 plus H 2 O reversible with H 2 C O 3 reversible with H C O 3 ion and H ion. â€¢ C O 2 plus protein minus N H 2 reversible with protein minus N H C O O and H ion. Erythrocyte. â€¢ H 2 O and expelled C O 2 reversible under carbonic anhydrase with H 2 C O 3, which produces H ion and H C O 3 ion. â€¢ H ion with H b and C O 2 produces H H b C O 2. Lungs. Expelled C O 2 and decreased p H from erythrocyte reach the respiratory center in brainstem. This increases respiration rate and depth, giving off C O 2. Kidney. Decreased p H from erythrocyte reaches kidney, increasing rate of H ion secretion.

Respiratory and Renal Buffering

The respiratory system regulates acid-base balance by controlling the rate of ventilation when there is metabolic acidosis or alkalosis. Central chemoreceptors sense increases or decreases in pH and $PaCO_2$ When acidemia exists, the respiratory rate increases (eliminating CO_2 and thus reducing carbonic acid concentration) (see Fig. 3.13). When alkalemia occurs, the respiratory rate decreases (retaining CO_2 and increasing carbonic acid concentration).

The renal buffering of H^+ ions requires the use of carbonic anhydrase in renal tubular cells to combine CO_2 and H_2O to form H_2CO_3. The H^+ ion is secreted from the tubular cell and buffered in the lumen by phosphate and ammonia. The bicarbonate is reabsorbed. The end effect is the addition of new bicarbonate to the blood, which contributes to the alkalinity of the plasma, because the hydrogen ion is excreted from the body (Fig. 3.14-1).

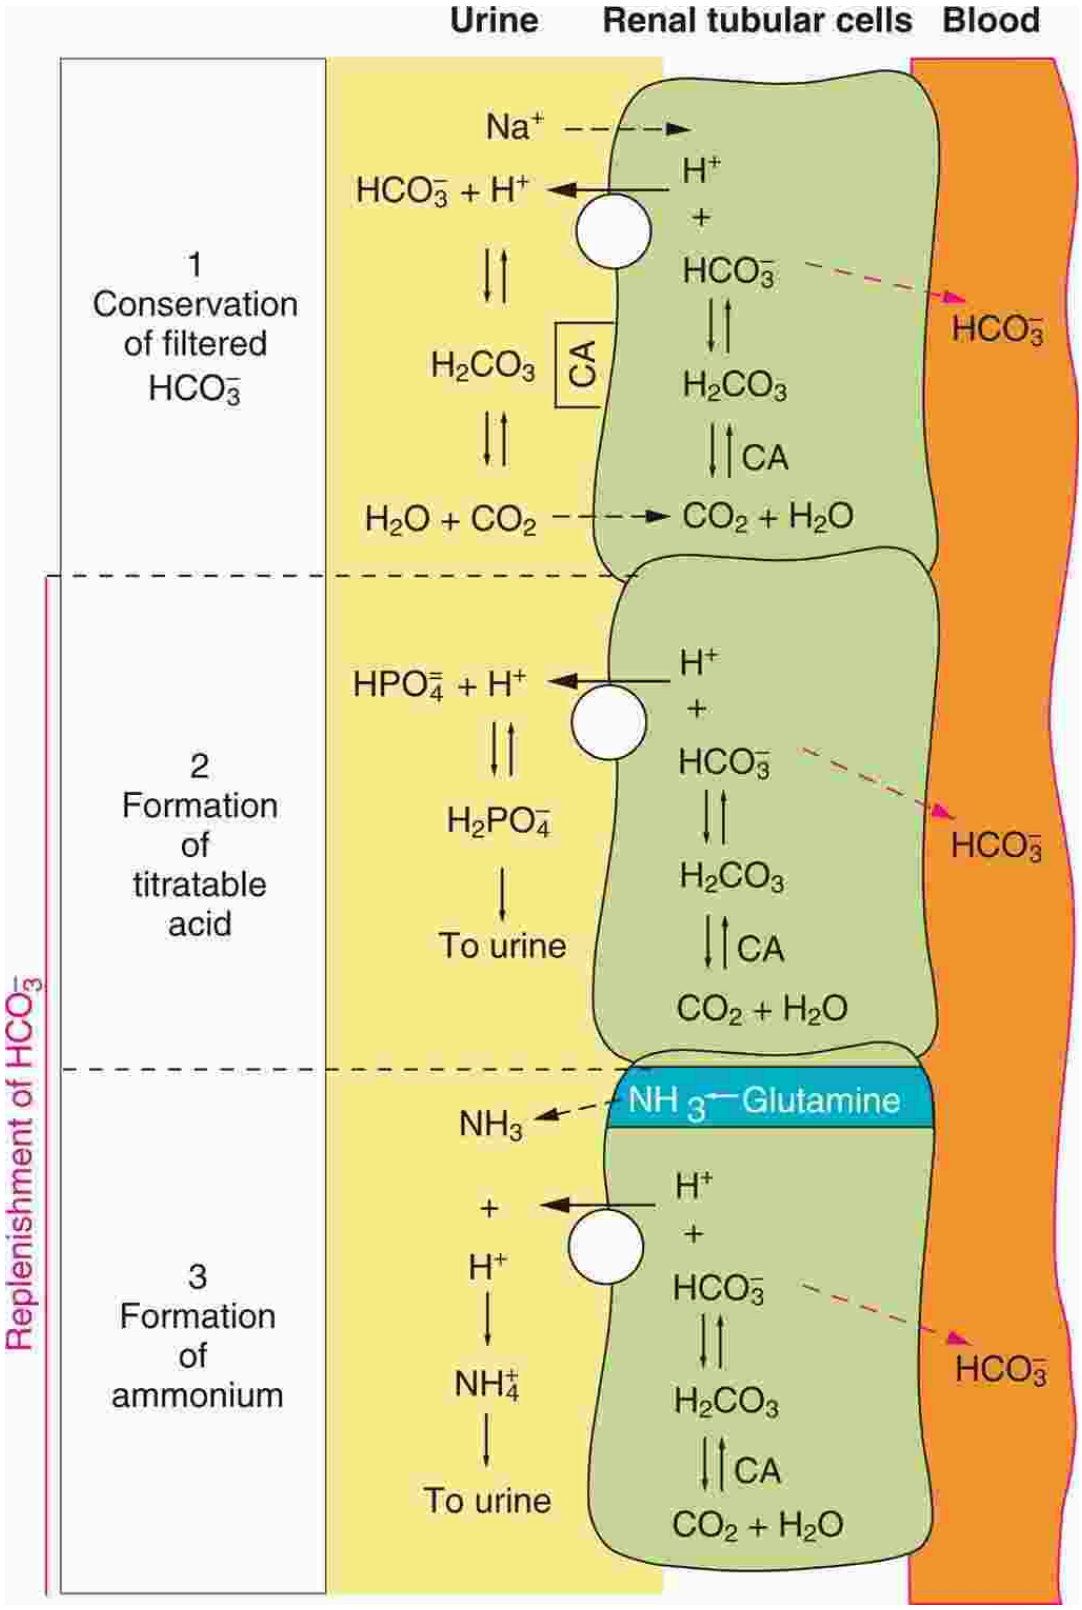

FIG. 3.14 **Renal Excretion of Acid.**

1, *Conservation of Filtered Bicarbonate*. Filtered bicarbonate (

HCO_3^-) combines with secreted hydrogen ion (H^+) to form carbonic acid (H_2CO_3), which then is converted to water (H_2O) and carbon dioxide (CO_2) by carbonic anhydrase (CA); both diffuse into the renal tubular cell. The CO_2 and H_2O combine to form H_2CO_3 in the presence of CA, and the resulting bicarbonate ion (HCO_3^-) is reabsorbed into the blood. **2**, *Formation of Titratable Acid*. Hydrogen ion (H^+) is secreted and combines with dibasic phosphate (HPO_4^-) to form monobasic phosphate ($H_2PO_4^-$). The secreted hydrogen ion (H^+) is formed from the dissociation of H_2CO_3, and the remaining HCO_3^- is reabsorbed into the blood. **3**, *Formation of Ammonium Ions*. Ammonia (NH_3) is produced from glutamine in the renal tubular cell and diffuses to the urine where it combines with H^+ to form ammonium ion (NH_4^+). Once NH_4^+ has been formed it cannot return to the renal tubular cell (diffusional trapping) and the bicarbonate remaining in the renal tubular cell is reabsorbed into the blood. NOTE: The white circles with the arrows on top represent a renal tubular cell active transport pump.

An illustration of renal tubular cells between urine and blood demonstrates the renal excretion of acid in three stages.1. Conservation of filtered H C O 3 ion. â€¢ Urine. urine. â€¢ Renal tubular cell. Glutamine to N H 3. H ion and H C O 3 ion reversible with H 2 C O 3 reversible under C A with C O 2 and H 2 O. â€¢ Blood. H C O 3 ion from renal tubular cell to blood.

Two additional buffer systems are active in the renal tubules, the *phosphate buffer* and the *ammonia buffer*. Once H^+ has reacted with all available, any additional H^+ ions react with either the phosphate or the ammonia buffer systems. The *phosphate buffer* functions both in the renal tubules and in the ICF. The two components of this system, monobasic phosphate (HPO_4^-) and dibasic phosphate ($H_2PO_4^-$), usually function in association with sodium to form a sodium salt. As with any buffer, these components bind or release H^+ to maintain physiologic neutrality (pH 7.40) (Fig. 3.14-2). The *ammonia buffer* functions within the renal tubules. The components for this system are ammonia (NH_3) and ammonium ion (NH_4^+) (Fig. 3.14-3). Both monobasic phosphate and ammonium ion (NH_4^+) are lipid insoluble, preventing them from diffusing back across the tubular cells and into the blood; thus, they are excreted in the urine.

Other Buffers

A cellular ion exchange mechanism is also an important buffering system. The best example is the shift of potassium in exchange for hydrogen during states of acidosis or alkalosis. During acidosis, potassium tends to leave the intracellular space in exchange for hydrogen. The reverse occurs during alkalosis. Although the ionic shifts facilitate buffering, the changes in intracellular or extracellular potassium concentrations may have serious consequences (e.g., hyperkalemia or hypokalemia).

Acid-Base Imbalances

Pathophysiologic changes in the concentration of H^+ ion or base in the blood lead to acid-base imbalances. **Acidemia** is a state in which the pH of arterial blood is less than 7.35. A systemic increase in hydrogen ion concentration or a loss of base is termed **acidosis**. **Alkalemia** is a state in which the pH of arterial blood is greater than 7.45. A systemic decrease in hydrogen ion concentration or an excess of base is termed **alkalosis**. These changes may be caused by either *respiratory* or *metabolic* processes, or both. If the altered pH occurs secondary to biochemical processes within the body or to renal dysfunction, it is *metabolic*. If the alteration in pH is secondary to an alteration with ventilation, it is *respiratory*. Accordingly,

four clinical alterations in the acid-base status can develop: *respiratory acidosis, metabolic acidosis, respiratory alkalosis*, and *metabolic alkalosis*.[25]

Arterial blood gases are measured to determine which of the four alterations is present. This measurement typically includes four parameters: the blood pH, PaO_2 (oxygen), $PaCO_2$ (carbon dioxide), and (bicarbonate).[26] The PaO_2 provides information about the person's oxygenation status, but it does not directly provide information about the acid-base status. The blood pH, $PaCO_2$, and bicarbonate level, when evaluated together, provide information about whether an individual is experiencing acidosis or alkalosis, and whether the cause is respiratory or metabolic. Fig. 3.15 summarizes the relationships among pH, $PaCO_2$, and bicarbonate during different acid-base alterations. Fig. 3.11 summarizes the relationship among pH, the partial pressure of carbon dioxide (respiratory regulation), and the concentration of bicarbonate (renal regulation) during alkalosis and acidosis. An individual can experience both metabolic and respiratory disorders at the same time. In such cases, the person may have a mixed acid-base alteration.

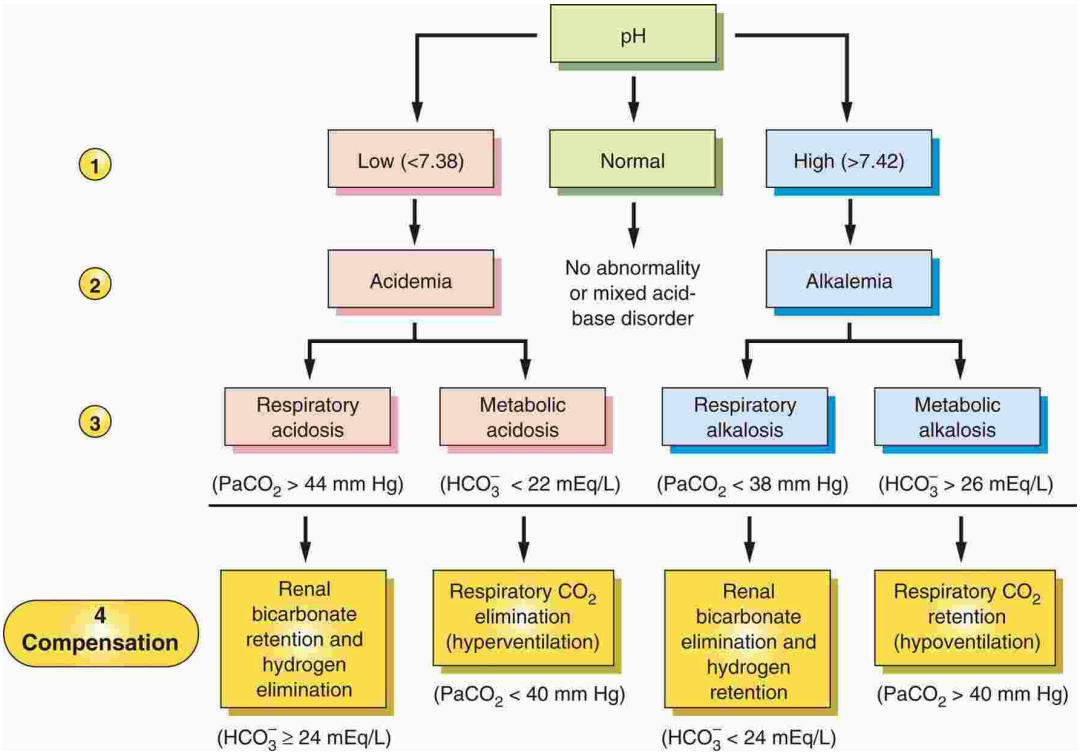

FIG. 3.15 Primary and Compensatory Acid-Base Changes. A systematic approach can be used to interpret the cause of an acid-base imbalance. **1**, Is the pH low or high? **2**, If the pH is low, there is acidemia; if the pH is high, there is alkalemia. **3**, If the pH is low (acidemia), is the cause respiratory (high $Paco_2$) or metabolic (low HCO_3^-)? If the pH is high (alkalemia), is the cause respiratory (low $Paco_2$) or metabolic (high HCO_3^-)? **4**, Is there compensation for the primary acid-base disorder? *(a)* HCO_3^- will be ≥24 mEq/L if there is renal compensation for a primary respiratory acidosis; *(b)* $Paco_2$ will be <40 mm Hg if there is respiratory compensation of a primary metabolic acidosis; *(c)* HCO_3^- will ≤24 mEq/L if there is renal compensation for primary respiratory alkalosis; *(d)* $Paco_2$ will be >40 mm Hg if there is respiratory compensation for primary metabolic alkalosis. NOTE: Examine the pH first. Then examine the changes in HCO_3^- and $Paco_2$. HCO_3^- concentration will be elevated when there is primary metabolic alkalosis or renal compensation for primary respiratory acidosis. HCO_3^- concentration will be decreased when there is primary metabolic acidosis or renal compensation for primary

respiratory alkalosis. $Paco_2$ will be elevated when there is primary respiratory acidosis or respiratory compensation for primary metabolic alkalosis. $Paco_2$ will be decreased when there is primary respiratory alkalosis or respiratory compensation for metabolic acidosis.

A hierarchy diagram, comprising four levels, represents the primary and compensatory acid-base changes of p H. Level 1. p H can be low (below 7.38), normal, or high (above 7.42). Level 2. Low p H causes acidemia. Normal p H does not cause any abnormality of mixed acid-base disorder. High p H causes alkalemia. Level 3. Acidemia leads to respiratory acidosis or metabolic acidosis. Alkalemia leads to respiratory alkalosis or metabolic alkalosis. Level 4. â€¢ Under respiratory acidosis, when P a C O 2 greater than 44 millimeters of mercury, renal bicarbonate retention and hydrogen elimination, where H C O 3 ion is greater than or equal to 23 milliequivalents per liter. â€¢ Under metabolic acidosis, when H C O 3 ion less than 22 milliequivalents per liter, respiratory C O 2 elimination or hyperventilation, where P a C O 2 less than 40 millimeters of mercury. â€¢ Under respiratory alkalosis, when P a C O 2 less than 38 millimeters of mercury, renal bicarbonate elimination and hydrogen retention, where H C O 3 ion less than 24 milliequivalents per liter. â€¢ Under metabolic alkalosis, when H C O 3 ion greater than 26 milliequivalents per liter, respiratory C O 2 retention or hypoventilation, where P a C O 2 is greater than 40 millimeters of mercury.

Renal and respiratory adjustments to *primary* changes in pH are known as **compensation**. With compensation, a 20:1 ratio may be achieved, but the actual values for HCO_3^- and H_2CO_3 concentrations are not normal (see Fig. 3.12). The respiratory system compensates for changes in pH by increasing or decreasing ventilation, a rapid response occurring within minutes to hours. The renal system compensates by producing more acidic or more alkaline urine, which may take

hours to days. **Correction** occurs when the values for both components of the buffer pair ratio (bicarbonate and carbonic acid) return to normal.

Carbon dioxide is referred to as a *potential acid* because it is readily converted to carbonic acid. Breathing more shallowly and slowly (hypoventilation) causes a retention of CO_2 (hypercapnia), whereas breathing more rapidly and deeply (hyperventilation) blows off CO_2 (hypocapnia). In this manner, the lungs compensate for excess acidity or alkalinity of the blood. The $PaCO_2$ and bicarbonate levels provide information on the source of the altered pH and also indicate whether any compensation is ongoing. A low blood pH signals acidosis. If the $PaCO_2$ is high, the source of the problem is respiratory (e.g., retained CO_2). Such a scenario might occur with an opioid overdose, in which respirations are depressed and CO_2 is retained. This individual is described as having a primary *respiratory acidosis*. If the pH is low and the $PaCO_2$ is normal or low, the acidosis is not caused by respiratory factors. Instead, it is caused by metabolic processes within the body. In this case, the individual is described as having a primary *metabolic acidosis*. An example of a primary metabolic acidosis is an individual experiencing DKA from a lack of insulin secretion or administration. The diabetic individual, lacking insulin, cannot metabolize glucose. The body metabolizes fat stores, and as a result, acid by-products are released into the blood, causing *metabolic acidosis*.

Metabolic Acidosis

Pathophysiology

In **metabolic acidosis**, the concentration of nonvolatile (non–carbonic) acids increase. Less commonly this condition can result if bicarbonate (base) is lost from the ECF or cannot be regenerated by the kidney (Table 3.14). Metabolic acidosis can occur quickly, as in lactic acidosis secondary to poor perfusion or hypoxemia. It can also occur more slowly, as in oliguric renal disease (failure to excrete acid), ingestion of acid precursors that are metabolized to acids, starvation states (excess production of ketoacids from excess metabolism of fats and proteins), or DKA (excess production of ketoacids from lack of insulin) (see Chapter 22).

Table 3.14

Causes of Metabolic Acidosis

Increased Non–Carbonic Acids (Elevated Anion Gap)	Bicarbonate Loss (Normal Anion Gap)
Increased H^+ load—overproduction of acid	Diarrhea
Ketoacidosis (e.g., diabetes mellitus, alcoholic ketoacidosis, starvation)	Ureterosigmoidoscopy Early chronic kidney disease
Lactic acidosis (e.g., shock)	Proximal renal tubule acidosis
Ingestions (e.g., ammonium chloride, ethylene glycol, methanol, salicylates, paraldehyde)	
Decreased H^+ excretion	
Acute or chronic oliguric renal disease	
Distal renal tubule acidosis	

Increased Non–Carbonic Acids (Elevated Anion Gap)	Bicarbonate Loss (Normal Anion Gap)
Increased H^+ load—overproduction of acid	Diarrhea
Ketoacidosis (e.g., diabetes mellitus, alcoholic ketoacidosis, starvation)	Ureterosigmoidoscopy Early chronic kidney disease
Lactic acidosis (e.g., shock)	Proximal renal tubule acidosis
Ingestions (e.g., ammonium chloride, ethylene glycol, methanol, salicylates, paraldehyde)	
Decreased H^+ excretion	
Acute or chronic oliguric renal disease	
Distal renal tubule acidosis	

The buffer systems manage the excess acid and attempt to maintain the arterial pH within a normal range. Hydrogen ions will move to the intracellular space, and potassium will move to the extracellular space to maintain an ionic balance. Buffering by bicarbonate lowers the serum value of hydrogen ions and increases the previously decreased pH. The respiratory system compensates for a metabolic acidosis as the reduced pH stimulates hyperventilation, lowering the $PaCO_2$ and the amount of H_2CO_3 circulating in the blood. The kidneys excrete the excess acid as NH_4^+ and titratable acid ($H_2PO_4^-$). When acidosis is severe, buffers become depleted and cannot compensate for the increasing H^+ load and the pH

continues to decrease. The ratio of bicarbonate to carbonic acid decreases to less than 20:1 (Fig. 3.16). In states of metabolic acidosis, potassium may be redistributed from the intracellular to the extracellular space and is reabsorbed at the apical membrane of the renal collecting tubule. There is also an increase in the levels of ionized calcium because acidosis decreases the amount of calcium bound to albumin.

The evaluation of the **anion gap** can be helpful when used cautiously to distinguish different factors contributing to metabolic acidosis.[27] Normally, the concentrations of cations and anions in the plasma are equivalent. However, some anions, such as protein, sulfates, phosphates, and organic acids, are not measured in the common laboratory evaluations of the blood. Therefore the normal anion gap represents these unmeasured negative ions (sulfate, phosphate, lactate, ketoacids, albumin). A convenient measure of the anion gap is the difference between the sum of Na^+ and K^+ concentrations and the sum of HCO_3^- and Cl^- concentrations, or approximately 10 to 12 mEq/L:

$$\text{Anion gap} = \left[Na^+ (140) + K^+ (4.0) \right] - [HCO_3^- (24) + Cl^- (110)] = 10 - 12 \text{ mEq/L}$$

In metabolic acidosis a **normal anion gap** is characteristic of conditions related to bicarbonate loss with retention of chloride to maintain an ionic balance. This is

called **hyperchloremic metabolic acidosis**, and it occurs with chronic kidney disease or prolonged diarrhea with bicarbonate loss. An elevated anion gap is characteristic of acidosis associated with accumulation of anions other than chloride (see Table 3.14). With severe pH disturbances, changes in the concentration of serum albumin, which behaves as an anion, can have a significant impact on the anion gap and a correction for this measure can be used in these cases.[28]

Clinical Manifestations

Metabolic acidosis is manifested by changes in the neurologic, respiratory, gastrointestinal, and cardiovascular systems. Early symptoms include headache and lethargy, which progress to confusion and coma in severe acidosis. The respiratory system's efforts to compensate for the increase in metabolic acids result in what are termed *Kussmaul respirations*, a form of hyperventilation in which ventilations are deep and rapid. This represents the body's attempt to increase the pH by expelling carbon dioxide (respiratory compensation), which in turn decreases the carbonic acid concentration. Other symptoms include anorexia, nausea, vomiting, diarrhea, and abdominal discomfort. Death can result in the most severe and prolonged cases, preceded by dysrhythmias and hypotension.

Evaluation and Treatment

The diagnosis of metabolic acidosis is established from the health history, clinical symptoms, and laboratory findings. Arterial blood pH is less than 7.35, and bicarbonate concentration is less than 22 mEq/L. The anion gap can facilitate identifying the specific cause. The oxyhemoglobin curve is shifted to the right (see Fig. 34.16), reducing Hb affinity for oxygen and impairing tissue oxygenation.

The underlying condition must be determined to establish effective treatment with a buffering solution. During severe acidosis (pH ≤ 7.1), base administration is required to elevate the pH to a safe level, particularly if there is oliguric renal disease. Accompanying sodium and water deficits must also be corrected.[28] Use of bicarbonate for alkali therapy for treatment of chronic metabolic acidosis can be controversial, and a new drug is currently under investigation as an alternative treatment option (Emerging Science Box: Veverimer for Treatment of Chronic Metabolic Acidosis).

Emerging Science BoxVeverimer for Treatment of Chronic Metabolic Acidosis

Metabolic acidosis is a common and difficult problem to manage among individuals with chronic kidney disease (CKD). As CKD progresses, there is

saturation of the body's buffering capacity and net acid excretion decreases to less than net endogenous acid production, resulting in chronic metabolic acidosis. Chronic acidosis causes increased protein catabolism and muscle wasting; loss of bone mineral density and impaired growth in children with increased risk of renal osteodystrophy in adults; and stimulation of inflammation with progression of kidney injury and increased mortality. Daily administration of oral alkali products, such as sodium bicarbonate and sodium citrate, neutralizes endogenously produced and retained acids associated with CKD and maintains serum sodium bicarbonate levels within a normal range. A low-protein, fruit- and vegetable-enriched diet and supplementation with water-soluble vitamins has a similar effect. Both approaches can prevent or decrease the severity of metabolic acidosis in CKD. However, low-protein diets may lead to muscle wasting, and sodium bicarbonate supplements can increase total body carbon dioxide and sodium load with potential for an increased risk for edema, hypertension, and heart failure.

Veverimer is an investigational oral drug with a different approach to treating the chronic metabolic acidosis of CKD. Veverimer is nonabsorbed polymer that selectively binds hydrogen ions and chloride ions in the gastrointestinal tract and removes them in feces. Serum bicarbonate concentration increases and total body acid decreases without administering sodium. There is a presumed equivalent loss of endogenous chloride and therefore no fluid, sodium, or potassium losses with a decrease in serum anion gap. It is proposed that, in individuals with CKD and comorbidities such as peripheral edema, hypertension, cardiovascular disease, or heart failure, treatment with veverimer would be an effective alternative to sodium-based alkali therapies. Additional clinical trials are in progress to evaluate mechanism of action, safety profiles, interaction with colonic bacteria, and its use in other forms of chronic acidosis such as diabetic ketoacidosis. Application for approval by the US Food and Drug Administration is in progress.

Metabolic Alkalosis

Pathophysiology

Metabolic alkalosis occurs when bicarbonate concentration is increased, usually caused by excessive loss of metabolic acids or, less commonly, by large intake of bicarbonate or substances that are metabolized to bicarbonate. With alkalemia, hydrogen ions are redistributed from the intracellular to the extracellular space and potassium moves to the intracellular space to preserve electroneutrality.[29] When acid loss is caused by vomiting or gastric suctioning, renal compensation is not very effective because loss of chloride (an anion) in hydrochloric acid (HCl) stimulates renal retention of bicarbonate (an anion). The result is known as **hypochloremic metabolic alkalosis** (Fig. 3.17). Renal compensation is not very effective because the volume depletion and loss of electrolytes stimulate a paradoxical response by the kidneys. The kidneys increase bicarbonate reabsorption to maintain an anionic balance because the ECF chloride concentration is decreased. The resulting excretion of H^+ and reabsorption of bicarbonate prevent correction of the alkalosis.

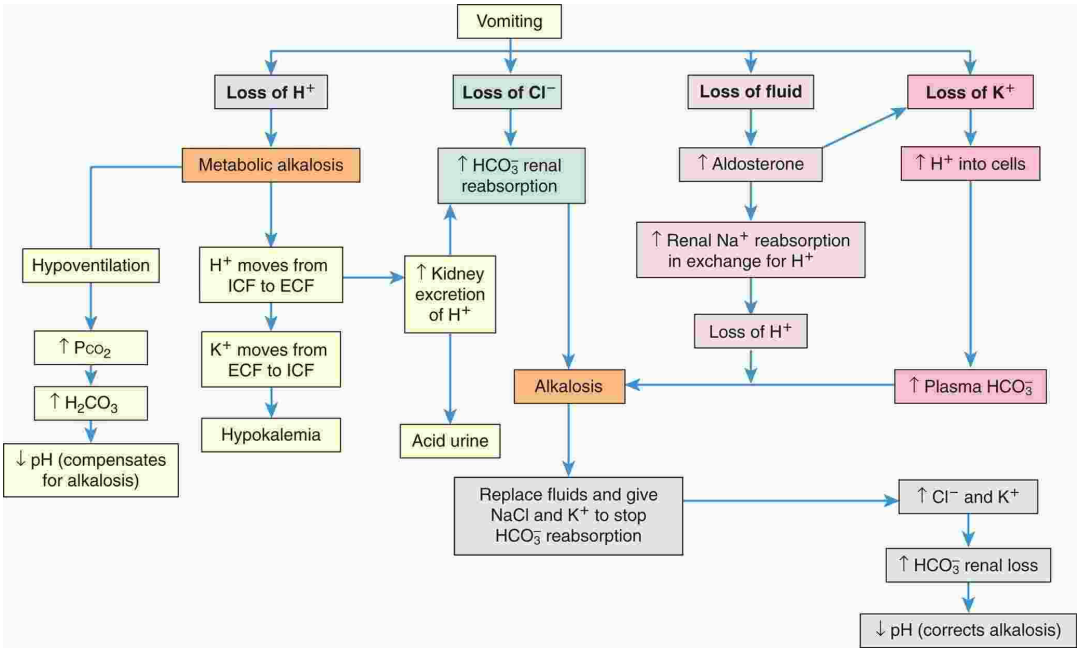

FIG. 3.17 Metabolic Alkalosis With Compensation and Correction.
See text for abbreviations. (From Patton KT, Thibodeau, GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

A flowchart shows the metabolic alkalosis with compensation and correction. Vomiting can cause loss of H ions, chlorine ions, fluid, or potassium ion. Loss of H ions lead to metabolic alkalosis, which can cause: â€¢ Hypoventilation. Increased P C O 2. Increased H 2 C O 3. Decreased p H (compensates for alkalosis). â€¢ H ion moves from I C F to E C F. K ions moves from E C F to I CF. Hypokalemia. â€¢ H ion moves from I C F to E C F. Increased kidney excretion of H ion. Acidic urine or increased H C O 3 ion renal reabsorption. Loss of C l ions leads to increased H C O 3 ion renal reabsorption, which can cause alkalosis and the following changes: â€¢ Replace fluids and give N a C l and K ion to stop H C O 3 ion reabsorption. â€¢ Increased C l and K ions. â€¢ Increased H C O 3 ion renal loss. â€¢ Decreased p H (corrects alkalosis). Loss of fluid leads to: â€¢ Increased aldosterone (can also lead to loss of potassium ions). â€¢ Increased renal N a ion reabsorption in exchange for

H ion. â€¢ Loss of H ions. â€¢ Alkalosis and subsequent changes. Loss of potassium ions leads to: â€¢ Increased H ions into cells. â€¢ Increased plasma H C O 3 ions. â€¢ Alkalosis and subsequent changes.

Hyperaldosteronism also can lead to alkalosis as a result of sodium bicarbonate retention and loss of hydrogen and potassium. Diuretics may produce a mild alkalosis because they promote greater excretion of sodium, potassium, and chloride than of bicarbonate. Overuse of baking soda (sodium bicarbonate) as an antacid also can cause metabolic alkalosis, as can massive blood transfusions, which contain citrate that the liver metabolizes to bicarbonate.

Respiratory compensation for metabolic alkalosis occurs when the elevated pH inhibits the respiratory center. The rate and depth of ventilation are decreased, causing retention of carbon dioxide. The ratio of HCO_3^- concentration to H_2CO_3 concentration is reduced toward normal. Respiratory compensation is not very efficient because the need for oxygen limits this compensation. Chronic or severe metabolic alkalosis requires therapeutic intervention (Fig. 3.18).

Clinical Manifestations

Because of the many causes of metabolic alkalosis, the symptoms vary. Some common symptoms, such as weakness, muscle cramps, and hyperactive reflexes, are related to volume depletion and electrolyte losses. Because alkalosis increases binding of Ca^{++} to plasma proteins (albumin), ionized calcium concentration decreases, causing excitable cells to become hypopolarized, which initiates an action potential more easily. Paresthesia (especially numbness/tingling of the fingertips and perioral area), tetany, and seizures may develop (see section on Hypocalcemia).

Respirations are slow and shallow to increase carbon dioxide retention. The oxyhemoglobin curve is shifted to the left, decreasing the dissociation of oxyhemoglobin, promoting hypoxemia, and increasing the risk of dysrhythmias (see Fig. 34.16). Atrial tachycardia is a potential problem.

Evaluation and Treatment

The health history provides significant clues to the diagnosis of metabolic alkalosis. The arterial pH is greater than 7.45, and bicarbonate levels exceed 26 mEq/L. With respiratory compensation, the $PaCO_2$ increases to greater than

40 mm Hg. With hypochloremic metabolic alkalosis, serum chloride values are less than normal. Serum potassium levels are usually depleted because H^+ is released from the cells in exchange for potassium to help regulate the pH level. The potassium is then secreted from renal distal tubule cells into the urine.

With hypochloremic alkalosis or contraction alkalosis with volume depletion, a sodium chloride solution is required for *correction*. The renal stimulus to increase ECF volume by retaining Na^+ is diminished, and HCO_3^- can be excreted as $NaHCO_3$ in the urine. The administration of potassium corrects alkalosis caused by hyperaldosteronism or hypokalemia. The potassium causes H^+ to move back into the ECF and decreases loss of H^+ from the distal tubule.

Respiratory Acidosis

Pathophysiology

Respiratory acidosis occurs when there is alveolar hypoventilation resulting in **hypercapnia** (an excess of carbon dioxide in the blood). The arterial carbon dioxide pressure ($PaCO_2$) is greater than 45 mm Hg and the pH is less than 7.35 (Fig. 3.19). Decreased alveolar ventilation, in relation to the metabolic production of carbon dioxide, produces an increased concentration of carbonic acid, which results in respiratory acidosis. The common causes include depression of the respiratory center (brainstem trauma, oversedation), paralysis of the respiratory muscles, disorders of the chest wall (kyphoscoliosis, obesity hypoventilation syndrome, flail chest), and disorders of the lung parenchyma (e.g., pneumonitis, pulmonary edema, and chronic obstructive lung disease).

FIG. 3.19 Respiratory Acidosis With Compensation and Correction.
See text for abbreviations. (From Patton KT, Thibodeau, GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

Respiratory acidosis may be acute or chronic. Airway obstruction is the most common cause of acute respiratory acidosis (e.g., acute airway edema and bronchoconstriction from an acute asthma episode, or upper airway angioedema). Acute compensation for respiratory acidosis is not effective because the renal buffer mechanism takes time to function. Furthermore, the protein buffers provide marginal assistance, and HCO_3^- is not a good buffer for its conjugate acid (carbonic acid). Acute uncompensated respiratory acidosis is characterized by decreased arterial pH, elevated $PaCO_2$, and normal or slightly increased bicarbonate concentration.

Chronic respiratory acidosis is commonly associated with chronic obstructive pulmonary disease and deformities of the chest wall or neuromuscular disorders. Renal compensation is effective and is established over several days. The acidosis produced from CO_2 retention stimulates the kidney to secrete H^+ ions and regenerate bicarbonate. Serum bicarbonate and $PaCO_2$levels are both elevated, and pH is restored toward normal (see Fig. 3.19).

Clinical Manifestations

The symptoms of respiratory acidosis are related to acuity of onset and severity of $PaCO_2$ retention. Initial symptoms include headache, restlessness, blurred

vision, and apprehension. Lethargy, muscle twitching, tremors, seizures, and coma may follow. Chronic acidosis causes myocardial depression, dysrhythmias, and hypotension. Neurologic symptoms are caused by a decrease in the pH of cerebrospinal fluid and cerebral vasodilation. CO_2 readily moves into vascular smooth muscle, causing both cerebral and peripheral vasodilation. The respiratory rate may be rapid at first and gradually becomes depressed, because over time, the respiratory center adapts to increasing levels of CO_2. Cyanosis does not occur unless there is an accompanying hypoxemia, and the skin may instead be pink from vasodilation caused by the elevated CO_2 level.

Evaluation and Treatment

The primary diagnostic indicators are an arterial pH less than 7.35 and hypercapnia. Acute respiratory acidosis must be distinguished from chronic respiratory acidosis and any accompanying metabolic acidosis. The health history and clinical laboratory data are helpful in making a determination whether the respiratory acidosis is acute, chronic, or acute on chronic.

In many cases, restoration of adequate alveolar ventilation removes excess CO_2. If alveolar ventilation cannot be maintained spontaneously because of drug overdose or neuromuscular disorders, mechanical ventilation is required. When the hypercapnia is caused by alterations in gas diffusion at the alveolar-capillary membrane, ventilation may not be effective. The values of arterial pH, PCO_2, PO_2, and HCO_3^- must be carefully monitored. The reduction of $PaCO_2$ must not be done too rapidly because of the associated risks, including respiratory alkalosis with seizures and death.[30]

The underlying diseases are treated to achieve maximal ventilation. In the presence of hypoxemia and hypercapnia, oxygen can function as a respiratory depressant when the respiratory center is no longer stimulated by the lower pH and elevated $PaCO_2$ value. Therefore, when oxygen is administered in this situation, the individual should be monitored for respiratory depression.

Respiratory Alkalosis

Pathophysiology

Respiratory alkalosis occurs when there is alveolar hyperventilation and decreased concentration of plasma carbon dioxide (termed **hypocapnia**), thus increasing the ratio of HCO_3^- to PCO_2 (H_2CO_3). Hyperventilation can result from a variety of causes, including hypoxemia (e.g., high altitudes); hypermetabolic states such as fever, severe anemia, and thyrotoxicosis; early salicylate intoxication; and anxiety or panic disorder. Improper settings on mechanical ventilators can cause iatrogenic respiratory alkalosis. Secondary respiratory

alkalosis may develop from hyperventilation stimulated by metabolic acidosis, causing a mixed acid-base disorder.

The onset of acute respiratory alkalosis occurs within minutes of hyperventilation. Cellular buffers provide immediate response (i.e., protein and shifts of H^+ from ICF to ECF). The H^+ shifts are not very effective if the $PaCO_2$ level is significantly decreased. Renal compensation occurs with chronic respiratory alkalosis and is characterized by decreased hydrogen excretion and decreased bicarbonate reabsorption (Fig. 3.20).

FIG. 3.20 Respiratory Alkalosis With Compensation and Correction.
See text for abbreviations. (From Patton KT, Thibodeau, GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

Clinical Manifestations

Respiratory alkalosis, like metabolic alkalosis, is irritating to the central and peripheral nervous systems. Symptoms include dizziness, confusion, tingling of extremities (paresthesias), seizures, and coma. Cerebral vasoconstriction reduces the cerebral blood flow. Carpopedal spasm and other symptoms of hypocalcemia are similar to those of metabolic alkalosis. Deep and rapid respirations (tachypnea) are primary symptoms of the disorders that cause respiratory alkalosis.

Evaluation and Treatment

The underlying disturbance must be identified. The arterial pH is greater than 7.45, and the $PaCO_2$ is less than 38 mm Hg. In acute states, bicarbonate levels are normal. With chronic respiratory alkalosis, a compensatory decrease in the bicarbonate level occurs and the pH is closer to normal.

Treating the underlying disturbance is the most effective treatment. Hypoxemia must be corrected and hypermetabolic states reversed. Symptoms from hyperventilation caused by anxiety or acute pain can be corrected by

managing the acute pain, anxiety-reducing conversation, assisting the individual to breathe more slowly while counting, or occasionally by rebreathing from a paper bag, which increases the concentration of inspired CO_2 and reverses the respiratory alkalosis. However, the use of paper bag rebreathing is associated with hypoxemia and can harm individuals with underlying cardiac and respiratory disorders. It may even worsen the situation if the hyperventilation is a compensatory response to a metabolic acidosis.

Mixed Acid-Base Disorders

Mixed acid-base disorders are two or more primary acid-base disorders occurring at the same time. They are more common in hospitalized individuals, often those in critical care with comorbid conditions (i.e., combined metabolic and respiratory disorders or combinations of acute and chronic disorders). For these individuals, the clinical history and analysis of electrolytes, medications, the anion gap, and the osmolality of plasma and urine are informative. The primary disorder is assessed, and then the degree of compensation is evaluated to determine if it is adequate, greater, or lesser than expected. Renal and respiratory compensation rarely returns the pH to normal. Therefore mixed acid-base disorders can have alterations in $PaCO_2$ and/or bicarbonate and a normal pH. Examples of conditions with mixed acid-base disorders include individuals with chronic obstructive pulmonary disease who develop heart failure and are treated with high doses of diuretics, or individuals who have acute kidney injury and vomiting or severe hypoxia with extracellular volume depletion.[31,32]

Summary Review

Distribution of Body Fluids

1. Body fluids are distributed among functional compartments and are classified as ICF or ECF.
2. The sum of all fluids is the TBW, which varies with age and amount of body fat and is higher in infants because they have less body fat. With older age, the percent of TBW decreases as there is loss of muscle and an increase in body fat.
3. Water moves between the ICF and ECF compartments principally by osmosis.
4. Water moves between the plasma and interstitial fluid by osmosis and hydrostatic pressure, which occur across the capillary membrane.
5. Movement across the capillary wall is called *net filtration* and is described according to Starling forces (forces favoring filtration minus forces opposing filtration).

Alterations in Water Movement

1. Edema is the excessive accumulation of fluid within the interstitial spaces.
2. Edema is caused by venous or lymphatic obstruction or increased vascular volume (increases hydrostatic pressure), plasma protein losses, or increased capillary membrane permeability (decreases plasma oncotic pressure).
3. The pathophysiologic process that leads to edema is related to an increase in forces favoring fluid filtration from the capillaries into the tissues.
4. Edema may be localized or generalized and usually is associated with swelling and puffiness, tighter-fitting clothes and shoes, limited movement of the affected area, and, in severe cases, weight gain.
5. An effusion is fluid accumulation within a body cavity or space sometimes called a third space.

Sodium, Chloride, and Water Balance

1. Sodium accounts for 90% of the ECF cations.
2. Sodium balance and water balance are intimately related; chloride levels are generally proportional to changes in sodium levels.
3. Sodium balance is regulated by aldosterone, which increases reabsorption of sodium by the distal tubule of the kidney.
4. Renin and angiotensin are enzymes that promote or inhibit secretion of aldosterone and thus regulate sodium and water balance.
5. ANH is also involved in decreasing renal tubular resorption and promoting urinary excretion of sodium.
6. Water balance is regulated by the sensation of thirst and by the level of ADH, which is initiated by an increase in plasma osmolality or a decrease in circulating blood volume.

Alterations in Sodium, Water, and Chloride Balance

1. Alterations in water balance may be classified as isotonic, hypertonic, or hypotonic.
2. Isotonic alterations occur when changes in TBW are accompanied by proportional changes in concentrations of electrolytes.
3. Hypertonic alterations develop when the osmolality of the ECF is increased to greater than normal, usually because of an increased concentration of ECF sodium or a deficit of ECF water.
4. Hypernatremia occurs when ECF sodium levels exceed 145 mEq/L.

5. Hypernatremia can be hypovolemic, euvolemic, or hypervolemic, depending on the accompanying ECF water volume.
6. Hyperchloremia occurs when ECF chloride exceeds 105 mEq/L and often accompanies hypernatremia.
7. Hypotonic alterations occur when the osmolality of the ECF is less than normal.
8. Hyponatremia occurs when the serum sodium concentration decreases to less than 135 mEq/L and may be caused by inadequate intake of sodium or dilution of the body's sodium level.
9. Water excess is rare but can be caused by compulsive water drinking, decreased urine formation, or the syndrome of inappropriate secretion of ADH.
10. Hyponatremia usually causes movement of water into cells.
11. Hypochloremia is usually the result of hyponatremia or elevated bicarbonate concentrations.

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

1. Potassium is the predominant ICF ion; it functions to regulate ICF osmolality, maintain the resting membrane potential, and deposit glycogen in liver and skeletal muscle cells.
2. Potassium balance is regulated by the kidney, by aldosterone and insulin secretion, and by changes in pH.
3. A mechanism known as *potassium adaptation* allows the body to accommodate slowly to increased levels of potassium intake.
4. Hypokalemia (serum potassium concentration <3.5 mEq/L) indicates loss of total body potassium, although ECF hypokalemia can develop without losses of total body potassium, and plasma K^+ levels may be normal or elevated when the amount of total body potassium is depleted.
5. Hypokalemia may be caused by reduced potassium intake, increased ICF to ECF potassium concentration, loss of potassium from body stores, increased aldosterone secretion (e.g., caused by hypernatremia), and increased renal excretion.
6. Hyperkalemia (potassium levels >5.0 mEq/L) may be caused by increased potassium intake, a shift from ICF to ECF potassium, or decreased renal excretion.
7. Calcium is a necessary ion in the structure of bones and teeth, in blood clotting, in hormone secretion and the function of cell receptors, and in membrane stability.

8. Phosphate acts as a buffer in acid-base regulation and provides energy for muscle contraction.
9. Calcium and phosphate concentrations are rigidly controlled by PTH, vitamin D, and calcitonin.
10. Hypocalcemia (total serum calcium concentration <9.0 mg/dL) is related to inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreased PTH and vitamin D levels.
11. Hypercalcemia (serum calcium concentration >10.5 mg/dL) can be caused by a number of diseases, including hyperparathyroidism, bone metastases, sarcoidosis, and excess vitamin D.
12. Hypophosphatemia is a serum phosphate level less than 2.0 mg/dL and is usually caused by intestinal malabsorption and increased renal excretion of phosphate.
13. Hyperphosphatemia is a serum phosphate level more than 4.7 mg/dL and develops with acute or chronic renal failure with significant loss of glomerular filtration.
14. Magnesium is a major intracellular cation.
15. Magnesium functions in enzymatic reactions and often interacts with calcium at the cellular level.
16. Hypomagnesemia (serum magnesium concentrations <1.5 mEq/L) may be caused by malabsorption syndromes.
17. Hypermagnesemia (serum magnesium concentrations >3.0 mEq/L) is rare and is usually caused by renal failure.

Acid-Base Balance

1. Hydrogen ions, which maintain membrane integrity and the speed of enzymatic reactions, must be concentrated within a narrow range if the body is to function normally.
2. Hydrogen ion concentration is expressed as pH, which represents the negative logarithm of hydrogen ions in solution (e.g., a negative logarithm 10^{-7} mg/L is indicated on the pH scale as pH 7.0, a neutral status). In arterial blood, the normal pH range is 7.35 to 7.45
3. Different body fluids have different pH values.
4. The renal and respiratory systems, together with the body's buffer systems, are the principal regulators of acid-base balance.
5. Buffers are substances that can absorb excessive acid or base to minimize fluctuations in pH.
6. The principal plasma buffers are bicarbonate, protein (Hb), and phosphate.

7. The lungs and kidneys act to compensate for changes in pH by increasing or decreasing ventilation (increasing or decreasing carbon dioxide in the form of carbonic acid) and by producing more acidic or more alkaline urine.
8. Correction is a process different from compensation; correction occurs when the values for both components of the buffer pair are returned to normal.
9. Acid-base imbalances are caused by changes in the concentration of H^+ in the blood; an increase causes acidosis, and a decrease causes alkalosis.
10. An abnormal increase or decrease in bicarbonate concentration causes metabolic acidosis or metabolic alkalosis; changes in the rate of alveolar ventilation produce respiratory acidosis or respiratory alkalosis.
11. Metabolic acidosis is caused by an increase in the concentrations of non–carbonic acids or by loss of bicarbonate from the ECF.
12. Metabolic alkalosis occurs with an increase in bicarbonate concentration usually caused by loss of metabolic acids from conditions such as vomiting, gastrointestinal suctioning, excessive bicarbonate intake, hyperaldosteronism, and diuretic therapy.
13. Respiratory acidosis occurs with a decrease of alveolar ventilation and an increase in levels of carbon dioxide, or hypercapnia.
14. Respiratory alkalosis occurs with alveolar hyperventilation and excessive reduction of carbon dioxide concentration, or hypocapnia.

Genetics is the study of biologic inheritance. An understanding of genetics is essential to study human, animal, plant, or microbial life. In the 19th century, microscopic studies of cells led scientists to suspect the nucleus of the cell contained the important mechanisms of inheritance. Scientists found chromatin, the substance giving the nucleus a granular appearance, which is observable in nondividing

cells. Just before the cell divides, the chromatin condenses to form discrete, dark-staining organelles, which are called chromosomes. (Cell division is discussed in Chapter 1.) With the rediscovery of Mendel's important breeding experiments at the turn of the 20th century, it soon became apparent the chromosomes contained genes, the basic units of inheritance (Fig. 4.1).

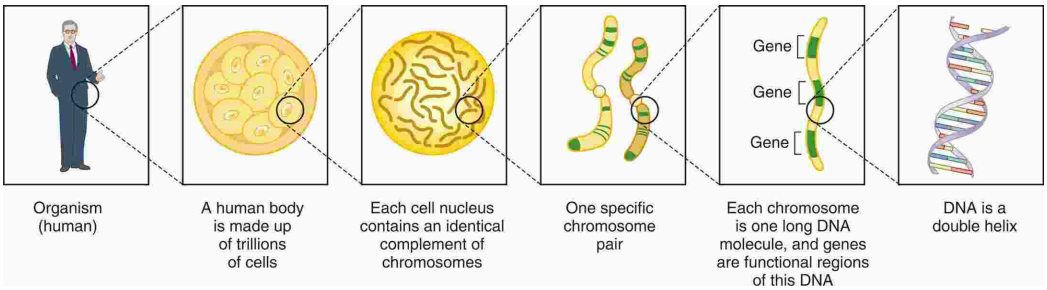

FIG. 4.1 Successive Enlargements from a Human to the Genetic Material.

A series of illustrations shows the successive enlargements from a human to the genetic material. From the left to the right, the enlargement are as follows. • The illustration shows a person standing. Text reads, organism (human). • The illustration shows a cluster of cells. Text reads, a human body is made up of trillions of cells. • The illustration shows a cell with chromosome-filled nucleus. Text reads, each cell nucleus contains an identical complement of chromosomes. • The illustration shows a pair of chromosomes. Text reads, one specific chromosome pair. • The illustration shows a chromosome with alternating gene and functional sequences. Text reads, each chromosome is one long D N A molecule, and genes are functional regions of this D N A. • The illustration shows a D N A helical structure. Text reads, D N A is a double helix.

The primary constituent of chromatin is deoxyribonucleic acid (DNA). Genes are composed of sequences of DNA. By serving as the blueprints of proteins in the body, genes ultimately influence all

aspects of body structure and function. Humans have approximately 20,000 protein-coding genes and at least an additional 9000 to 10,000 genes that encode various types of ribonucleic acid (RNA; see below) that are not translated into proteins. An error in one of these genes often leads to a recognizable genetic disease.

To date, more than 20,000 genetic traits and diseases have been identified and cataloged. As infectious diseases continue to be more effectively controlled, the proportion of beds in pediatric hospitals occupied by children with genetic diseases has risen. In addition to genetic diseases in children, there are many common diseases that primarily affect adults and are now known to have important genetic components, such as hypertension, coronary heart disease, diabetes, and cancer.

Great progress continues to be made in the diagnosis of genetic diseases and in the understanding of genetic mechanisms underlying them. With the huge strides being made in molecular genetics, "gene therapy"—the utilization of normal genes to correct genetic disease—has begun (Fig. 4.2).[1,2]

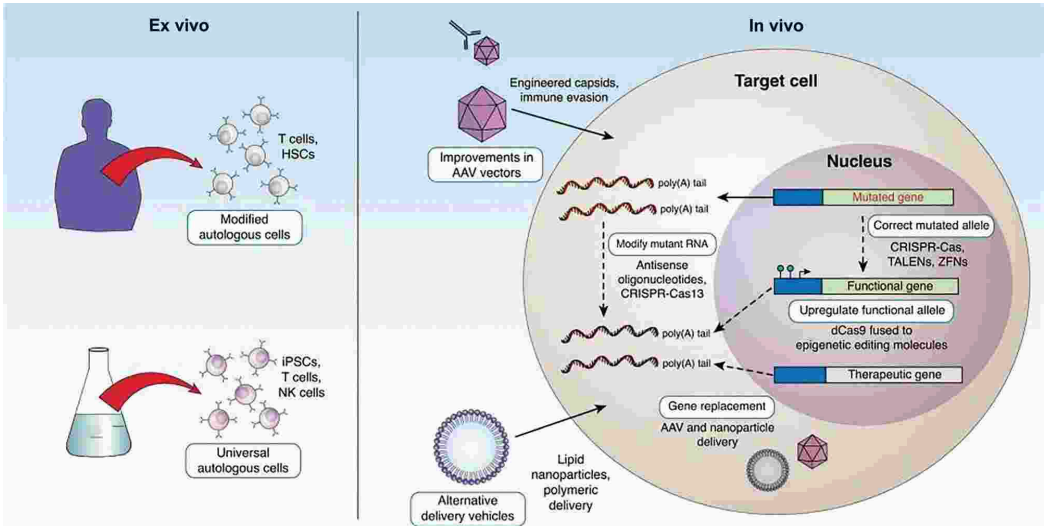

FIG. 4.2 Gene Therapy.
Schematic of ex vivo and in vivo gene therapy strategies *(colored blue)* for treating genetic diseases. Ex vivo methods *(left panel)*, autologous cells can be isolated from the person directly and genetically modified to cause a therapeutic effect, Allogenic cells can be produced and readily available “off the shelf”. In vivo strategies require targeting of specific cells to achieve a therapeutic gene or correct pathological mechanisms to enable functional gene expression *(dashed arrows)*. From Bulaklak K, Gersbach CA. The once and future gene therapy. *Nature Communications*, 2020;11(1). doi:10.1038/s41467-020-19505-2.

An illustration shows two strategies of gene therapy: ex vivo and in vivo. Left panel, ex vivo. The illustration at the top shows modified autologous cells comprising T cells and H S Cs, from a human body. The illustration at the bottom shows universal autologous cells comprising i P S Cs, T cells, and N K

cells, from a solution in a beaker. Right panel, in vivo. The illustration shows a target cell, engineered capsids, and alternative delivery vehicles. Alternative delivery vehicles deliver lipid nanoparticles and polymerics. Engineered capsids and immune evasion occur as a result of improvements in A A V vectors. The target cell comprises a nucleus. The nucleus comprises mutated gene, functional gene, and therapeutic gene. The mutated gene is made of poly (A) tails. Correct mutated allele (CRISP R-Cas, TALENs, and Z F N) of the mutated gene produces the functional gene. Mutant R N A (antisense, oligonucleotides, and CRISP R-Cas 13) can modify the poly (A) tail. Upregulation of function allele occurs when d Cas 9 is fused to epigenetic editing molecules. Gene replacement (A A V and nanoparticle delivery) produces a therapeutic gene with poly (A) tail.

DNA, RNA, and Proteins: Heredity at the Molecular Level

Definitions

Composition and Structure of DNA

Genes are composed of DNA, which has three basic components: the five-carbon monosaccharide deoxyribose; a phosphate molecule; and four types of nitrogenous bases. Two of the bases, cytosine and thymine, are single carbon-nitrogen rings called pyrimidines. The

other two bases, adenine and guanine, are double carbon-nitrogen rings called purines. The four bases are commonly represented by their first letters: A (adenine), C (cytosine), T (thymine), and G (guanine).

Watson and Crick demonstrated how these molecules are physically assembled as DNA, proposing the double-helix model in which DNA appears like a twisted ladder with chemical bonds as its rungs (Fig. 4.3). The two sides of the ladder consist of deoxyribose and phosphate molecules, united by strong phosphodiester bonds. Projecting from each side of the ladder, at regular intervals, are the nitrogenous bases. The base projecting from one side is bound to the base projecting from the other by a weak hydrogen bond. Therefore, the nitrogenous bases form the rungs of the ladder; adenine pairs with thymine, and guanine pairs with cytosine. Each DNA subunit —consisting of one deoxyribose molecule, one phosphate group, and one base—is called a nucleotide.

FIG. 4.3 Watson-Crick Model of the DNA Molecule.
The DNA structure illustrated here is based on that published by James Watson *(photograph, left)* and Francis Crick *(photograph, right)* in 1953. Note that each side of the DNA molecule consists of alternating sugar and phosphate groups. Each sugar group is bonded to the opposing sugar group by a pair of nitrogenous bases (adenine–thymine or cytosine–guanine). The sequence of these pairs constitutes a genetic code that determines the structure and function of a cell. (Illustration from Herlihy B. *The human body in health and illness*, 5th edition. St. Louis: Saunders; 2015.)

An illustration accompanying a photo of James Watson and Francis Crick depicts the D N A structure demonstrated by Watson and Crick. The illustration depicts a double-helix D N A that appears like a twisted ladder with chemical bonds as its rungs. The two sides of the ladder consist of alternating glucose and phosphate group bonded by phosphodiester bonds. The nitrogen bases thymine, guanine, adenine, and cytosine are united by hydrogen bonds.

DNA as the Genetic Code

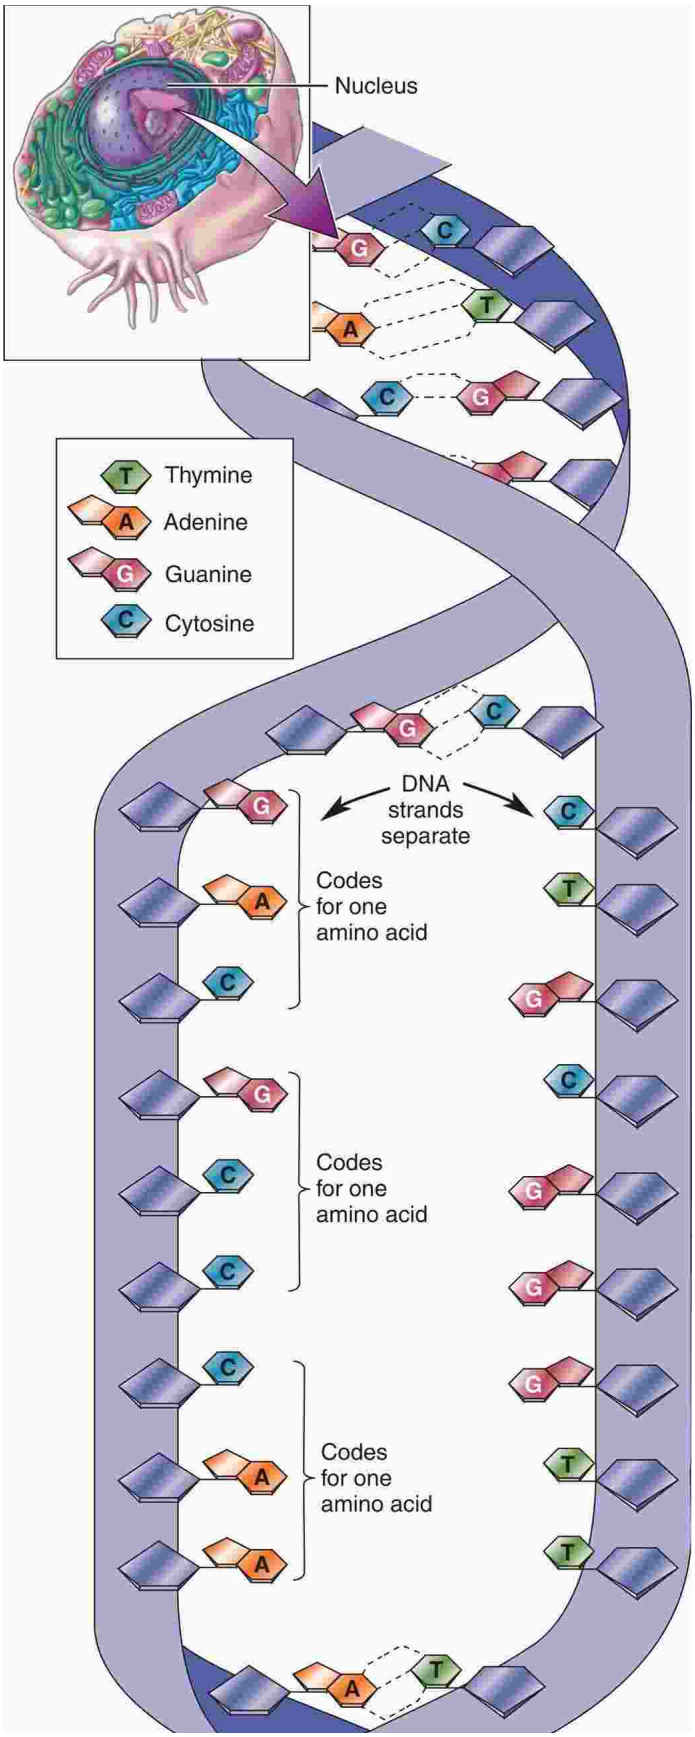
DNA directs the synthesis of all the body's proteins. Proteins are composed of one or more polypeptides (intermediate protein compounds), which in turn consist of sequences of amino acids. The body contains 20 different types of amino acids; they are specified by

the 4 nitrogenous bases. To specify (code for) 20 different amino acids with only 4 bases, different combinations of bases, occurring in groups of 3 (triplets), are used. These triplets of bases are known as codons. Each codon specifies a single amino acid in a corresponding protein. Because there are 64 (4 times 4 times 4) possible codons but only 20 amino acids, there are many cases in which several codons correspond to the same amino acid.

The genetic code is universal: with a few rare exceptions, all living organisms use precisely the same DNA codes to specify proteins. A notable exception is mitochondria, the cytoplasmic organelles in which cellular respiration takes place (see Chapter 1)—they have their own extranuclear DNA. Several codons of DNA encode different amino acids, compared with the same nuclear DNA codons.

Replication of DNA

DNA replication consists of breaking the weak hydrogen bonds between the bases, leaving a single strand with each base unpaired (Fig. 4.4). The consistent pairing of adenine with thymine and of guanine with cytosine, known as complementary base pairing, is the key to accurate replication. The unpaired base attracts a free nucleotide only if the nucleotide has the proper complementary base. When replication is complete, a new double-stranded molecule identical to the original is formed. The single strand is said to be a template, or molecule on which a complementary molecule is built, and is the basis for synthesizing the new double strand.



Nucleus

A Adenine
G Guanine
C Cytosine
DNA strands separate
Codes for one amino acid
Codes for one amino acid
Codes for one amino acid

FIG. 4.4 Replication of DNA.
The two chains of the double helix separate and each chain serves as the template for a new complementary chain. (From Herlihy B. *The human body in health and illness*, 5th edition. St. Louis: Saunders; 2015.)

Several different proteins are involved in DNA replication. The most important of these proteins is an enzyme known as DNA polymerase. This enzyme travels along the single DNA strand, adding the correct nucleotides to the free end of the new strand and checking to ensure that its base is complementary to the template base. This mechanism of DNA proofreading substantially enhances the accuracy of DNA replication (Fig. 4.5).

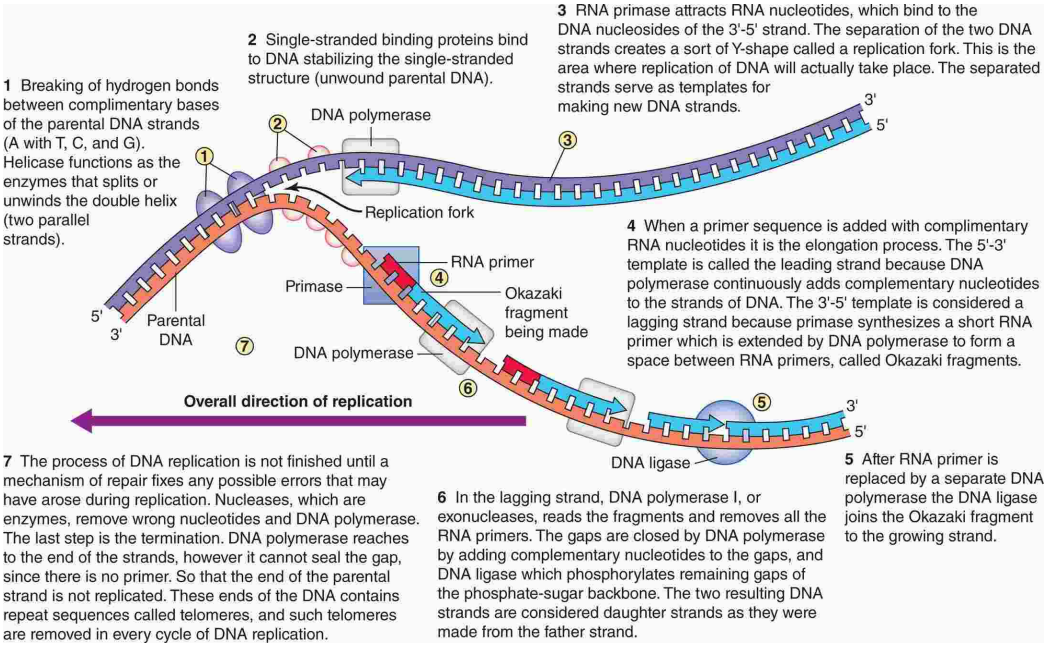

FIG. 4.5 Process of DNA Replication.
The hydrogen bonds between the two original strands are broken, allowing the bases in each strand to undergo complementary base pairing with free bases. The process proceeds in the 5′ to 3′ direction on each strand forming two new double strands of DNA.

An illustration shows a broken D N A double strand to demonstrate the process of D N A replication. The following structures on the illustration are labeled, from the left to the right: parental D N A, D N A polymerase, replication fork, primase, R N A primer, Okazaki fragment being made, D N A polymerase, and D N A ligase. Overall direction of replication occurs from the right to the left. 1. Breaking of hydrogen bonds between complimentary bases of the parental D N A strands (A with T, C, and G).

Helicase functions as the enzymes that splits or unwinds the double helix (two parallel strands). 2. Single-stranded binding proteins bind to D N A stabilizing the single-stranded structure (unwound parental D N A). 3. R N A primase attracts R N A nucleotides, which bind to the D N A nucleosides of the 3 prime to 5 prime strand. The separation of the two D N A strands creates a sort of Y-shape called a replication fork. This is the area where replication of D N A will actually take place. The separated strands serve as templates for making new D N A strands. 4. When a primer sequence is added with complimentary R N A nucleotides it is the elongation process. The 5 prime-3 prime template is called the leading strand because D N A polymerase continuously adds complementary nucleotides to the strands of D N A. The 3 prime to 5 prime template is considered a lagging strand because primase synthesizes a short R N A primer which is extended by D N A polymerase to form a space between R N A primers, called Okazaki fragments. 5. After R N A primer is replaced by a separate D N A polymerase the D N A ligase joins the Okazaki fragment to the growing strand. 6. In the lagging strand, D N A polymerase I, or exonucleases, reads the fragments and removes all the R N A primers. The gaps are closed by D N A polymerase by adding

complementary nucleotides to the gaps, and D N A ligase which phosphorylates remaining gaps of the phosphate-sugar backbone. The two resulting D N A strands are considered daughter strands as they were made from the father strand. 7. The process of D N A replication is not finished until a mechanism of repair fixes any possible errors that may have arose during replication. Nucleases, which are enzymes, remove wrong nucleotides and D N A polymerase. The last step is the termination. D N A polymerase reaches to the end of the strands, however it cannot seal the gap, since there is no primer. So that the end of the parental strand is not replicated. These ends of the D N A contains repeat sequences called telomeres, and such telomeres are removed in every cycle of D N A replication.

Mutation

A mutation is any alteration of genetic material. One type of mutation is the base pair substitution, in which one base pair replaces another. This replacement *can* result in a change in the amino acid sequence. However, because of the redundancy of the genetic code, many of these mutations do not change the amino acid sequence and, thus, have no consequence. Such mutations are called silent mutations. Base pair substitutions altering amino acids consist of two basic types: missense mutations, which produce a change (i.e., the “sense”) in a single amino acid; and nonsense mutations, which produce one of the three stop codons (UAA, UAG, or UGA; where U is uracil; A is adenine; and G is guanine) in the messenger

RNA (mRNA) (Fig. 4.6). Missense mutations (see Fig. 4.6A) produce a single amino acid change, whereas nonsense mutations (see Fig. 4.6B) produce a premature stop codon in the mRNA. Stop codons terminate translation of the polypeptide.

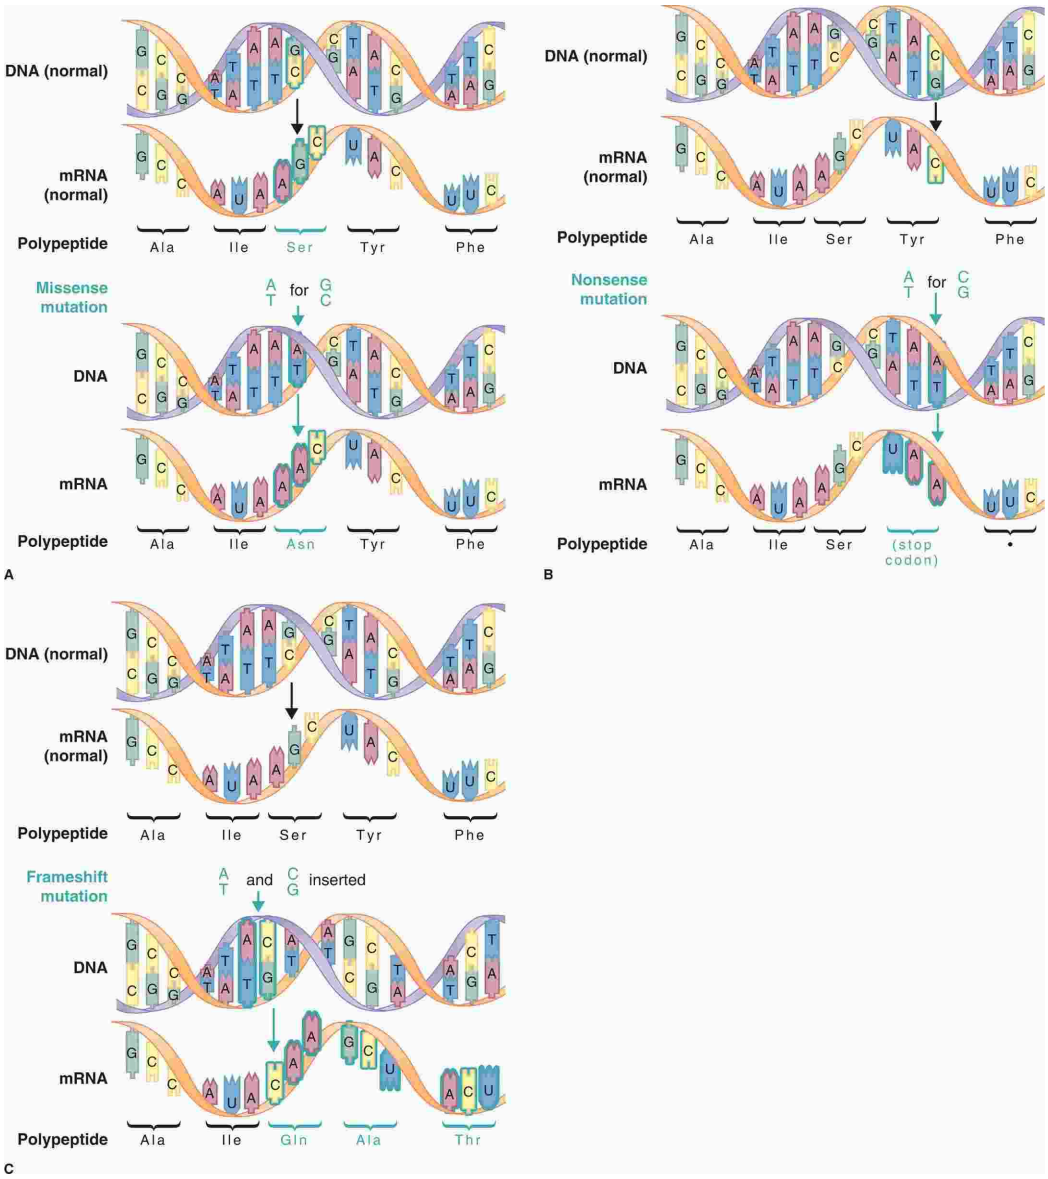

FIG. 4.6 Base Pair Substitution.
Missense mutations **(A)** produce a single amino acid change, whereas nonsense mutations **(B)** produce a stop codon in the messenger ribonucleic acid *(mRNA)*. Stop codons terminate translation of the polypeptide. **(C)** Frameshift Mutations. Frameshift mutations result from the addition or deletion of a number of bases that is not a multiple of 3. This mutation alters all of the codons downstream from the site of insertion or

deletion. (B and C, From Jorde LB, Carey JC. *Medical genetics*, 4th edition. St. Louis: Mosby; 2010.)

Three illustrations A through C depict the substitution of nitrogen base in the polypeptide chain formed by normal m R N A and polypeptide chain formed by m R N A after mutation. The nitrogen base in the polypeptide chain formed by normal m R N A is Alanine, Isoleucine, Serine, Tyrosine, Phenylalanine. Illustration A depicts the substitution of nitrogen base in the polypeptide chain formed by m R N A after missense mutation and substitution is given as follows: Alanine, Isoleucine, Asparagine, Tyrosine, Phenylalanine. Illustration B depicts the substitution of nitrogen base in the polypeptide chain formed by m R N A after nonsense mutation and substitution is given as follows: Alanine, Isoleucine, Serine, stop codon. Illustration C depicts the substitution of nitrogen base in the polypeptide chain formed by m R N A after frameshift mutation and substitution is given as follows: Alanine, Glutamine, Alanine, Threonine.

The frameshift mutation involves the insertion or deletion of one or more base pairs of the DNA molecule. As Fig. 4.6C shows, these mutations change the entire "reading frame" of the DNA sequence because the deletion or insertion is not a multiple of three base pairs (the number of base pairs in a codon). Frameshift mutations can thus greatly alter the amino acid sequence and typically cause a

premature stop codon. (*In-frame* insertions or deletions, in which a multiple of three bases is inserted or lost, tend to have less severe disease consequences than do frameshift mutations.) Individuals that have non-sense, frame-shift mutations, missense mutations, or gene duplications may have the complete inability or have an increased ability to metabolize certain drugs (Emerging Science Box: Predictions of Individual Response to Pharmacotherapies Based on Genotype-Phenotype Correlations).

Emerging Science Box

Predictions of Individual Response to Pharmacotherapies Based on Genotype-Phenotype Correlations

Providing individualized pharmacological treatment for disease has been a long-time goal in healthcare, however, this becomes challenging due to the complexity and multivariate genetic components involved. Cytochrome P450 CYP2D6 is the most widely studied polymorphic drug-metabolizing enzyme. The gene encoding the CYP2D6 enzyme is located on chromosome 22. This gene displays a large genetic diversity among human population, including non-sense, frame-shift, and missense mutations and gene duplications. CYP2D6 genetic variation influences the metabolism of numerous drugs, and this marked inter-individual variation in activity can have significant clinical consequences affecting drug efficacy and safety. Individuals with a deficiency of the CYP2D6 enzyme, usually inherited as an autosomal recessive trait, have a decreased ability to metabolize certain drugs (e.g., antidepressants, neuroleptics, some antiarrhythmics, lipophilic β-adrenoceptor blockers, and opioids). However, CYP2D6 activity can range from complete absence to increased activity. The clinical importance of the polymorphism depends on whether the parent compound, metabolite(s), or both are metabolized or formed by CYP2D6, whether one or both are active, and if so, the potency of

the active species, as well as the overall contribution of the CYP2D6-dependent pathway to the clearance of the drug. Increased understanding of the mechanisms underlying genotype–phenotype correlations associated with the genetic variability of the CYP2D6 will improve knowledge acquisition on the metabolizing function of CYP2D6. The research conducted on CYP2D6 could provide accurate predictions and implications for individual responses to pharmacological treatments.

Data from Pey AL. Towards accurate genotype-phenotype correlations in the CYP2D6 gene. *Journal of Personalized Medicine*, 2020;10(4):158. doi:10.3390/jpm10040158. PMID: 33049937. PMCID: PMC7711719; Nofziger C, Turner AJ, Sangkuhl K, et al. PharmVar GeneFocus: CYP2D6. *Clinical Pharmacology and Therapeutics*, 2020;107(1):154–170. doi:10.1002/cpt.1643.

Agents known as mutagens increase the frequency of mutations. Examples include radiation and chemicals, such as nitrogen mustard, vinyl chloride, alkylating agents, formaldehyde, and sodium nitrite. Mutations are rare events. The rate of spontaneous mutations (those occurring in the absence of exposure to known mutagens) in humans is about 10−4 to 10−7 per gene per generation. This rate varies from one gene to another. Some DNA sequences have particularly high mutation rates and are known as mutational hot spots.

From Genes to Proteins

DNA is formed and replicated in the cell nucleus, but protein synthesis takes place in the cytoplasm. The DNA code is transported from nucleus to cytoplasm, and subsequent protein is formed through two basic processes: transcription and translation. These processes are mediated by RNA, which is chemically similar to DNA except the sugar molecule is ribose rather than deoxyribose, and uracil rather than thymine is one of the four bases. The other bases of RNA, as in DNA, are adenine, cytosine, and guanine. Uracil is structurally similar to thymine, so it also can pair with adenine.

DNA usually occurs as a double strand, whereas RNA usually occurs as a single strand.

Transcription

Transcription is the process by which RNA is synthesized from a DNA template. Key steps of gene transcription are shown in Fig. 4.7.[3] The result is the formation of mRNA from the base sequence specified by the DNA molecule. Transcription of a gene begins when an enzyme called RNA polymerase binds to a promoter site on the DNA. A promoter site is a sequence of DNA that specifies the beginning of a gene. In addition to RNA polymerase, proteins called transcription factors are involved in the process of converting, or transcribing, DNA into RNA (Fig. 4.8). Transcription factors initiate and regulate the transcription of genes; they are the master regulators of gene expression.[4] The action of transcription factors enables unique expression of each gene in different cell types and during development. Transcription factors bind to DNA sequences called transcription factor binding sites near genes to regulate gene expression via transcription. Transcription factors have DNA-binding domains that give them the ability to bind to specific sequences of DNA called *enhancer* or *promote*r sequences. Certain transcription factors bind to a DNA promoter sequence near the transcription start site and help form the *transcription initiation complex*. Other transcription factors bind to regulatory sequences, such as enhancer sequences, and can either stimulate or repress transcription of the related gene. Regulation of transcription is the most common form of gene control.

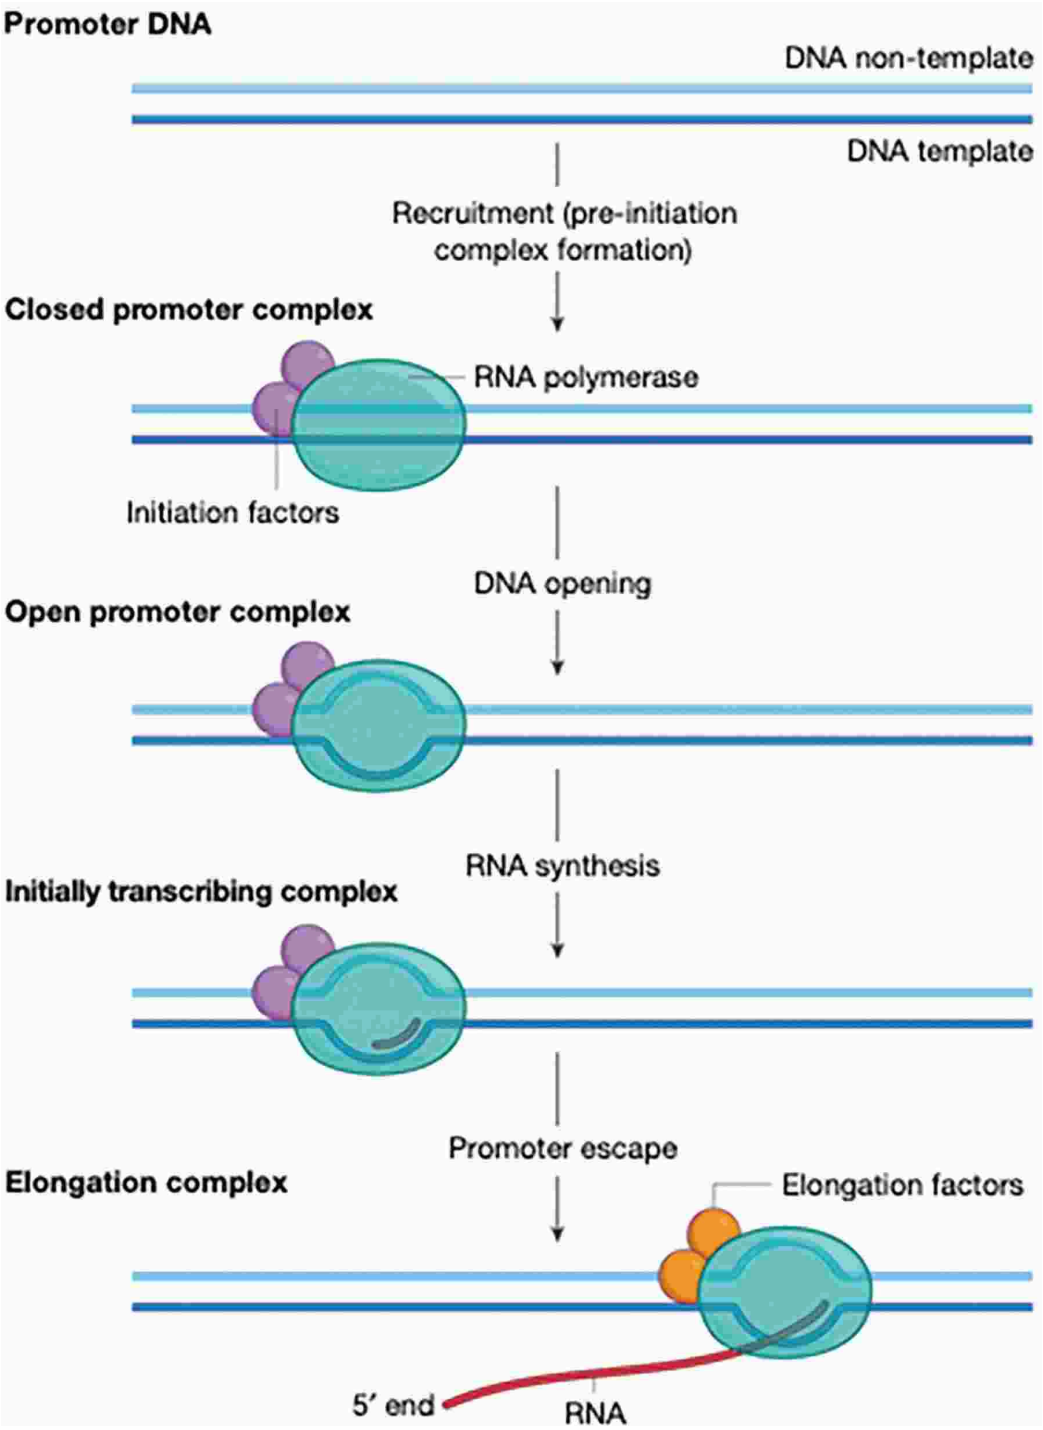

FIG. 4.7 Key Steps of Gene Transcription.
The RNA polymerase enzyme associates with transcription initiation factors to recognize promoter DNA and form a pre-initiation complex (PIC). Later DNA opening converts the closed

promoter complex to the open promoter complex, which contains the DNA template strand in the polymerase active site. DNA-dependent RNA synthesis subsequently generates an initially transcribing complex. When RNA grows to a certain critical length, the polymerase escapes from the promoter and forms an elongation complex that can bind elongation factors. Eventually, polymerase dissociation from DNA and RNA terminates the transcription cycle (not shown). (From Cramer P. Organization and regulation of gene transcription. *Nature*, 2019;573(7772):45–54. doi:10.1038/s41586-019-1517-4.)

An illustrated flowchart shows the key steps of gene transcription, from the top to the bottom. • Promoter D N A. There is a D N A non-template at the top and a D N A template at the bottom. Promoter D N A triggers recruitment (pre-initiation complex formation). • Closed promoted complex. An R N A polymerase with initiation factors is attached to the templates, opening the D N A. • Open promoter complex triggers R N A synthesis. • Initially transcribing complex triggers promoter escape. • Elongation factors on the polymerase extends the 5 prime end of the R N A.

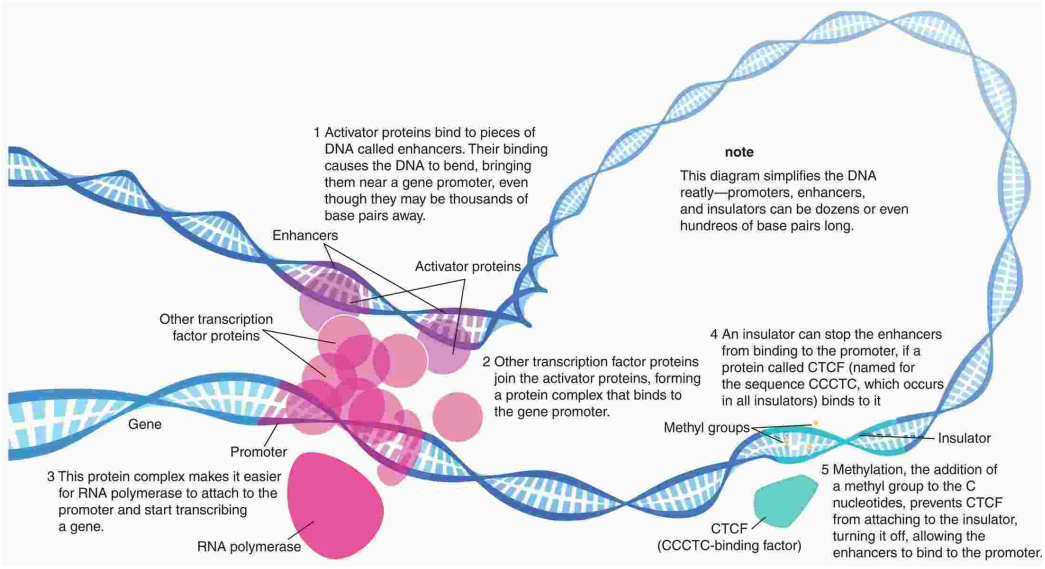

FIG. 4.8 Transcription Factors and Simplified Schematic of Gene Expression.
Transcription factors are proteins and bind to specific sites on DNA. They read and interpret the genetic blueprint of the DNA, thereby controlling transcription or the flow of genetic information from DNA to mRNA. Transcription factors are essential for gene expression (e.g., proteins that function as receptors, enzymes, or biomarkers). Not only do transcription factors act downstream from biological stimuli but they can be downstream of signaling cascades promoted by various environmental stimuli (hormones, temperature). Transcription factors can alter gene expression to promote pathophysiology. (From Song K. *Transcription Factors*. Wikimedia Commons; 2012. https://commons.wikimedia.org/wiki/File:Transcription_Factors.png.)

An illustration shows the transcription factors and simplified schematic of gene expression. The illustration shows a gene sequence with D N A

helical structure. Other structures on and around the D N A include R N A polymerase, enhancers, activator proteins, promoter, other transcription factor proteins, methyl groups, insulator, and C T C F (C C C T C-binding factor). The sequence of gene expression is as follows. 1. Activator proteins bind to pieces of D N A called enhancers. Their binding causes the D N A to bend, bringing them near a gene promoter, even though they may be thousands of base pairs away. 2. Other transcription factor proteins join the activators proteins, forming a protein complex that binds to the gene promoter. 3. This protein complex makes it easier for R N A polymerase to attach to the promoter and start transcribing a gene. 4. An insulator can stop the enhancers from binding to the promoter, if a protein called C T C F (named for the sequence C C C T C, which occurs in all insulators) binds to it. 5. Methylation, the addition of a methyl group to the C nucleotides, prevents C T C F from attaching to the insulator, turning it off, allowing the enhancers to bind to the promoter.

Predictive models for 94 human transcription factors demonstrate their utility in genome-wide association studies.[5] Advances in fluorescence microscopy have made it possible to visualize real-time transcription factor dynamics.[6]

The sequence of bases in the mRNA is thus complementary to the template strand, and except for the presence of uracil instead of thymine, the mRNA sequence is identical to that of the other DNA strand. Transcription continues until a termination sequence—codons that act as signals for the termination of protein synthesis—is reached. Then the RNA polymerase detaches from the DNA, and the transcribed mRNA is freed to move out of the nucleus and into the cytoplasm (see Figs. 4.7 and 4.8).

Gene Splicing

When the mRNA is first transcribed from the DNA template, it reflects exactly the base sequence of the DNA. In eukaryotes, many RNA sequences are removed by nuclear enzymes, and the remaining sequences are spliced together to form the functional mRNA that migrates to the cytoplasm. The excised sequences are called introns (intervening sequences), and the sequences that are left to code for proteins are called exons.

Translation

In translation, RNA directs the synthesis of a polypeptide (Fig. 4.9), interacting with transfer RNA (tRNA), a cloverleaf-shaped strand of about 80 nucleotides. The tRNA molecule has a site where an amino acid attaches. The three-nucleotide sequence at the opposite side of the cloverleaf is called the anticodon. It undergoes complementary base pairing with an appropriate codon in the mRNA, which specifies the sequence of amino acids through tRNA.

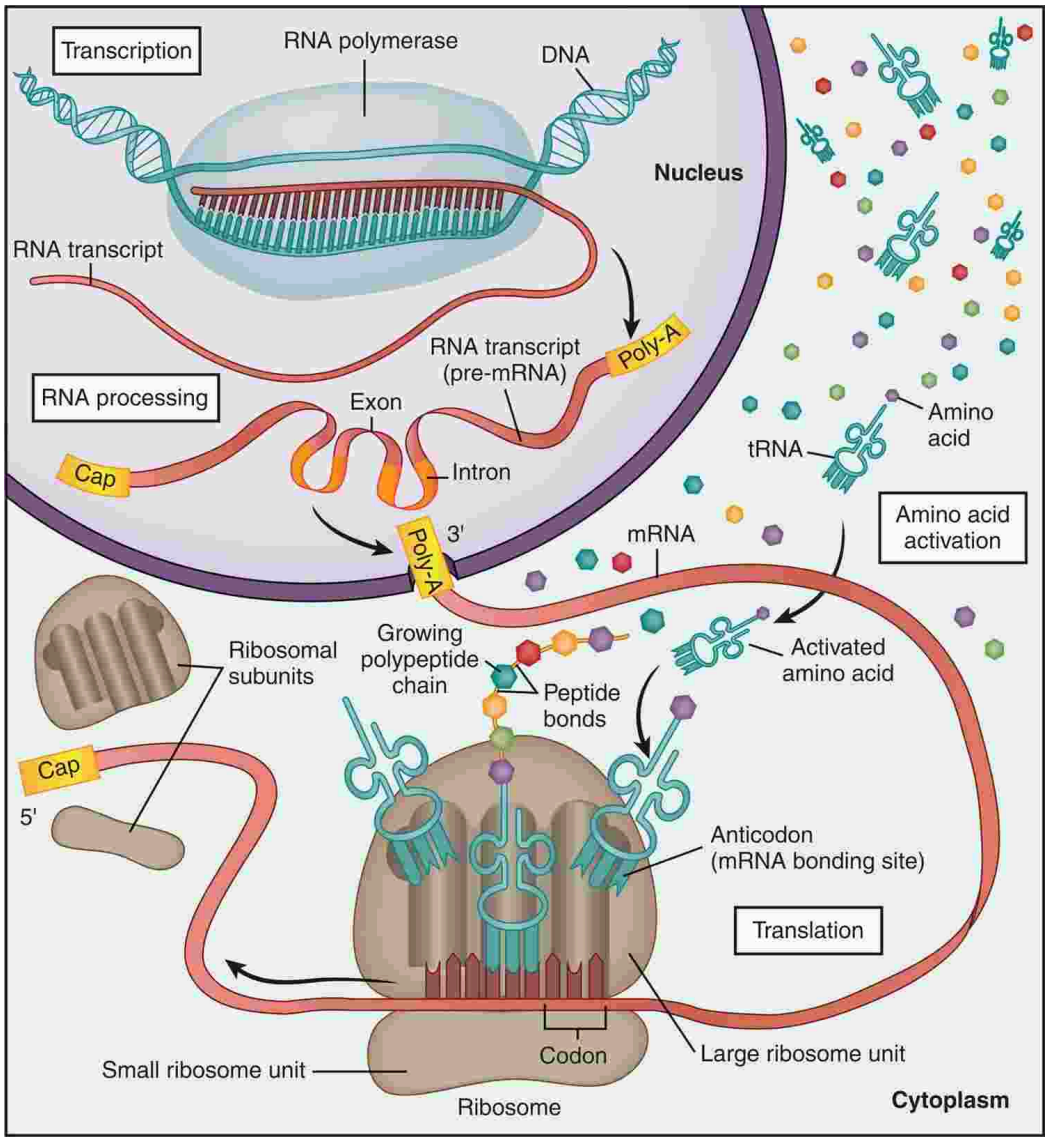

FIG. 4.9 Protein Synthesis.
The site of transcription is the nucleus and the site of translation is the cytoplasm. See the text for details.

An illustration shows cytoplasm around a nucleus, labeling the different structures that contribute to protein synthesis. The synthesis occurs over the following stages. • Transcription (in the nucleus). The nucleus comprises an R N A polymerase. • R N

A processing. The R N A transcript (pre-m R N A) comprises exon and intron between cap and poly-A. • Amino acid activation. The m R N A, with a poly-A (3 prime) end and a cap (5 prime) end, is released into the cytoplasm. The cytoplasm comprises amino acid units, t R N A, ribosome, and ribosomal units. An activated amino acid is a t R N A bound to an amino acid unit. Multiple amino acid units form a growing polypeptide chain, connected by peptide bonds. • Translation. The activated amino acid bonds with the anticodon (m R N A binding site) of the large ribosome unit against the codon on the small ribosome unit.

The site of actual protein synthesis is in the ribosome, which consists of approximately equal parts of protein and ribosomal RNA (rRNA). During translation, the ribosome first binds to an initiation site on the mRNA sequence and then binds to its surface so that base pairing can occur between tRNA and mRNA. The ribosome then moves along the mRNA sequence, processing each codon and translating an amino acid by way of the interaction of mRNA and tRNA.

The ribosome provides an enzyme that catalyzes the formation of covalent peptide bonds between the adjacent amino acids, resulting in a growing polypeptide. When the ribosome arrives at a termination signal on the mRNA sequence, translation and polypeptide formation cease; the mRNA, ribosome, and polypeptide separate from one another; and the polypeptide is released into the cytoplasm to perform its required function.

Chromosomes

Human cells can be categorized into gametes (sperm and egg cells) and somatic cells, which include all cells other than gametes. Each somatic cell nucleus has 46 chromosomes in 23 pairs (Fig. 4.10). These are diploid cells, and the individual's father and mother each donate one chromosome per pair. New somatic cells are formed through mitosis and cytokinesis. Gametes are haploid cells: They have only 1 member of each chromosome pair, for a total of 23 chromosomes. Haploid cells are formed from diploid cells by meiosis (Fig. 4.11).

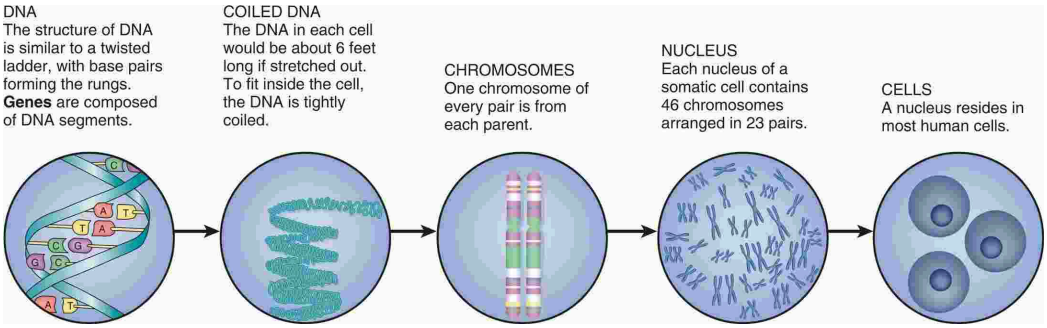

FIG. 4.10 From Molecular Parts to the Whole Somatic Cell.

An iterative illustration shows how molecular parts form the whole somatic cell. From the left to the right, the sequence is as follows. • D N A. The structure of D N A is similar to a twisted ladder, with base pairs forming the rungs. Genes are composed of D N A segments. • Coiled D N A. The D N A in each cell would be about 6 feet long if stretched out. To fit inside the cell, the DNA is tightly coiled. • Chromosomes. One chromosome of every pair is from each parent. • Nucleus. Each nucleus of a somatic cell contains 46 chromosomes arranged in 23 pairs. • Cells. A nucleus resides in most human cells.

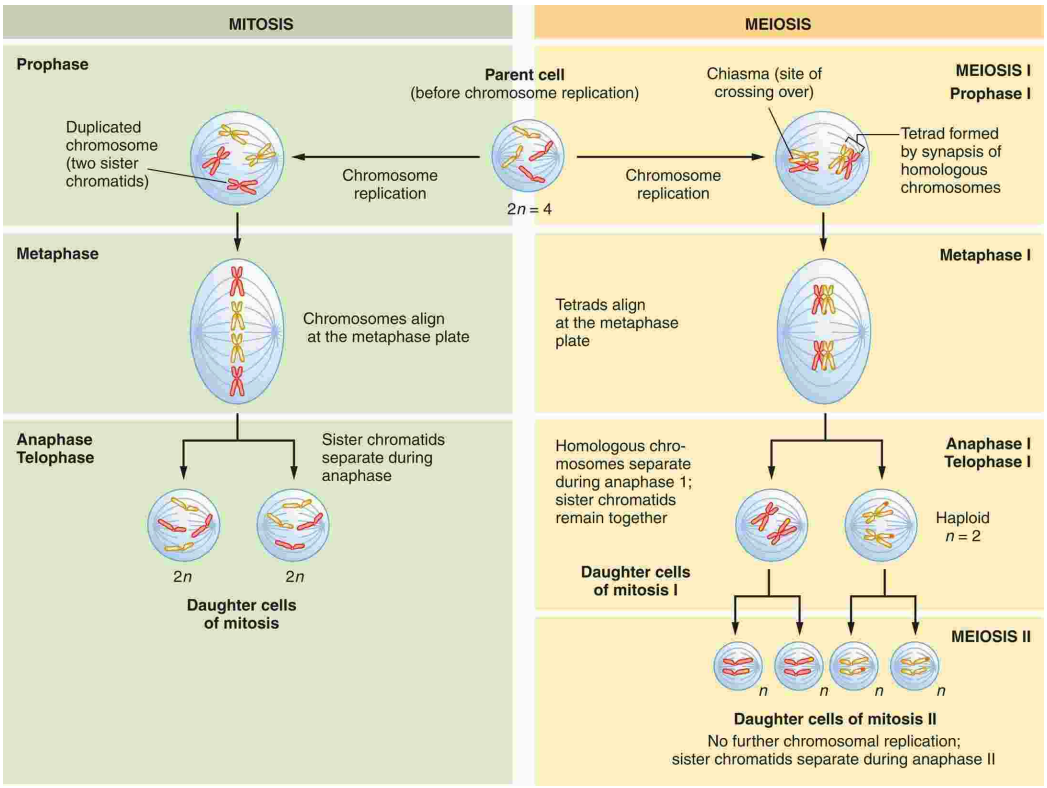

FIG. 4.11 Phases of Meiosis and Comparison to Mitosis. (From Jorde LB, Carey JC. *Medical genetics*, 5th edition. St. Louis: Elsevier; 2016.)

Two illustrated flowcharts show the phases of meiosis and comparison to mitosis. The parent cell, before chromosome replication comprises 2 n (equals 4). Left panel, mitosis. There are three stages. • Prophase. Chromosomes are duplicated, that is, two sister chromatids are produced. • Metaphase. Chromosomes align at the metaphase plate. • Anaphase and Telophase. Sister chromatids separate during anaphase, producing daughter cells of mitosis, 2 n each. Right panel, meiosis. There are three stages. • Prophase 1. Chromosome replication.

The chiasma (site of crossing over) and the tetrad formed by synapsis of homologous chromosomes are labeled in the illustration. • Metaphase 1. Tetrads align at the metaphase plate. • Anaphase 1 and Telophase 1. Homologous chromosomes separate during anaphase 1; sister chromatids remain together. Daughter cells of mitosis 1 are diploid with n equals 2. • Meiosis 2. Daughter cells of mitosis 2 are generated. No further chromosomal replication; sister chromatids separate during anaphase 2. Daughter cells of mitosis 2 are haploid with n equals 1.

In 22 of the 23 chromosome pairs, the two members of each pair are virtually identical in microscopic appearance: thus, they are homologous (Fig. 4.12B). These 22 chromosome pairs are homologous in both males and females and are termed autosomes. The remaining pair of chromosomes, the sex chromosomes, consists of two homologous X chromosomes in females and a nonhomologous pair, X and Y, in males.

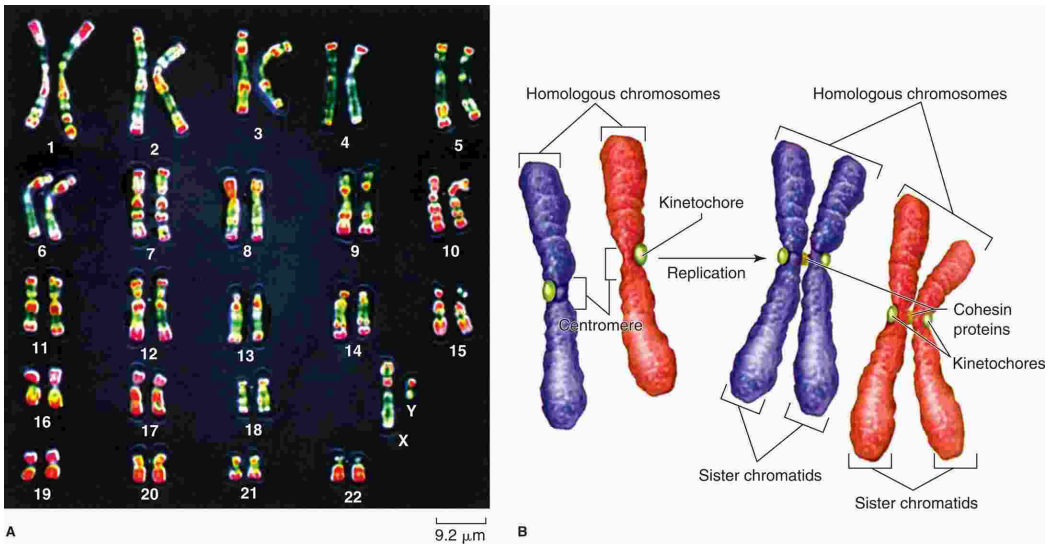

FIG. 4.12 Karyogram of Chromosomes. **(A)** Human karyogram. **(B)** Homologous chromosomes and sister chromatids. (From Raven PH, et al. *Biology*, 8th edition. New York: McGraw-Hill, 2008.)

Left panel, A. A human karyogram of 22 pairs with X Y pair. Right panel, B. An illustration shows the structures of homologous chromosomes and sister chromatids. Homologous chromosomes comprise a centromere and kinetochore. The replication of homologous chromosomes create sister chromatids.

Fig. 4.12A, illustrates a metaphase spread, which is a photograph of the chromosomes as they appear in the nucleus of a somatic cell during metaphase. (Chromosomes are easiest to visualize during this stage of mitosis.) In Fig. 4.12A, the chromosomes are arranged according to size, with the homologous chromosomes paired. The 22 autosomes are numbered according to length, with chromosome 1 being the longest and chromosome 22 the shortest. A karyotype, or karyogram, is an ordered display of chromosomes. Some natural variation in relative chromosome length can be expected from

person to person, so it is not always possible to distinguish each chromosome by its length. Therefore, the position of the centromere (region of DNA responsible for movement of the replicated chromosomes into the two daughter cells during mitosis and meiosis) also is used to classify chromosomes (see Figs. 4.12B and 4.13).

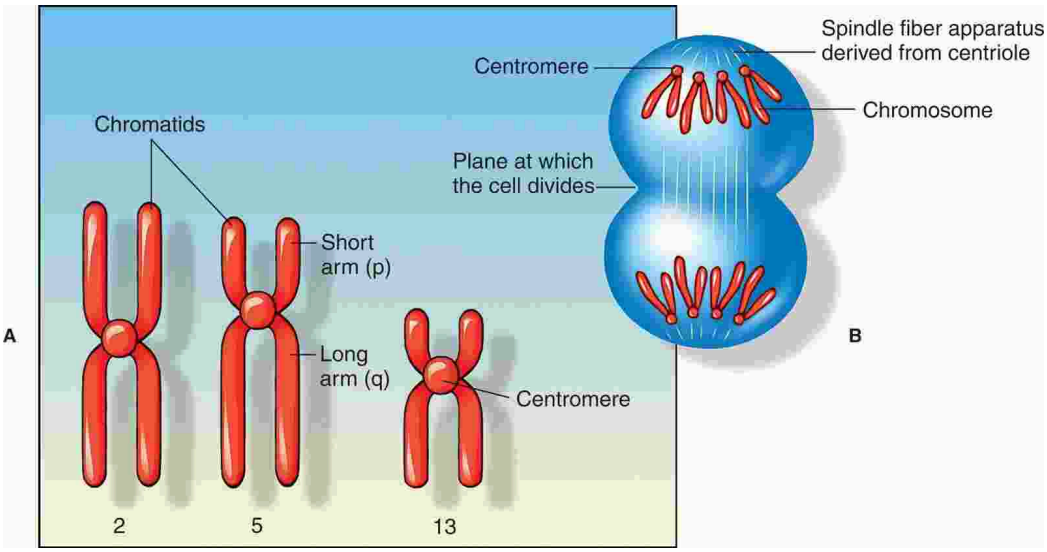

FIG. 4.13 Structure of Chromosomes.
(A) Human chromosomes 2, 5, and 13. Each is replicated and consists of two chromatids. Chromosome 2 is a metacentric chromosome because the centromere is close to the middle; chromosome 5 is submetacentric because the centromere is set off from the middle; chromosome 13 is acrocentric because the centromere is at or very near the end. **(B)** During mitosis, the centromere divides and the chromosomes move to opposite poles of the cell. At the time of centromere division, the chromatids are designated as chromosomes.

Left panel, A. An illustration shows the structure of human chromosomes 2, 5, and 13. The structure comprises a centromere with short arms (p) at the top and long arms (q) at the bottom. Right panel, B. An illustration shows the division of chromosomes. The following structures are identified: spindle fiber

apparatus derived from centriole, centromere, chromosome, and plane at which the cell divides.

The chromosomes in Fig. 4.12 were stained with Giemsa stain, resulting in distinctive chromosome bands. These form various patterns in the different chromosomes so that each chromosome can be distinguished easily. Using banding techniques, researchers can number chromosomes and study individual variations. Missing or duplicated portions of chromosomes, which often result in serious diseases, also are readily identified. More recently, techniques have been devised permitting each chromosome to be visualized with a different color.

Chromosome Aberrations and Associated Diseases

Chromosome abnormalities are the leading known cause of intellectual disability and miscarriage. Estimates indicate that a major chromosome aberration occurs in at least 1 in 12 conceptions. Most of these fetuses do not survive to term; about 50% of all recovered first-trimester spontaneous abortuses have major chromosome aberrations.[7]

The number of live births affected by these abnormalities is significant; approximately 1 in 150 has a major diagnosable chromosome abnormality.[7]

Polyploidy

Cells with a multiple of the normal number of chromosomes are euploid cells (Greek *eu* = good or true). Because normal gametes are haploid and most normal somatic cells are diploid, they are both euploid forms. When a euploid cell has more than the diploid number of chromosomes, it is said to be a polyploid cell. Several types of body tissues, including some liver, bronchial, and epithelial tissues, are normally polyploid. A zygote that has three copies of

each chromosome, rather than the usual two, has a form of polyploidy called triploidy. Nearly all triploid fetuses are spontaneously aborted or stillborn. The prevalence of triploidy among live births is approximately 1 in 10,000. Tetraploidy, a condition in which euploid cells have 92 chromosomes, has been found primarily in early abortuses, although occasionally affected infants have been born alive. Like triploid infants, however, they do not survive. Triploidy and tetraploidy are relatively common conditions, accounting for approximately 10% of all known miscarriages.[8]

Aneuploidy

A cell that does not contain a multiple of 23 chromosomes is an aneuploid cell. A cell containing three copies of one chromosome is said to be trisomic (a condition termed trisomy) and is aneuploid. Monosomy, the presence of only one copy of a given chromosome in a diploid cell, is the other common form of aneuploidy. Among the autosomes, monosomy of any chromosome is lethal, but newborns with trisomy of chromosomes 13, 18, 21, or X can survive. This difference illustrates an important principle: *In general, loss of chromosome material has more serious consequences than duplication of chromosome material*.

Aneuploidy of the sex chromosomes is less serious than that of the autosomes. Very little genetic material—only about 50 genes—is located on the Y chromosome. For the X chromosome, inactivation of extra chromosomes (see the X-linked Inheritance section) largely diminishes their effect. A zygote bearing *no* X chromosome, however, will not survive.

Aneuploidy is usually the result of nondisjunction, an error in which homologous chromosomes or sister chromatids fail to separate normally during meiosis or mitosis (Fig. 4.14). Nondisjunction produces some gametes that have two copies of a given chromosome and others that have no copies of the chromosome. When such gametes unite with normal haploid gametes, the resulting zygote is monosomic or trisomic for that

chromosome. Occasionally, a cell can be monosomic or trisomic for more than one chromosome.

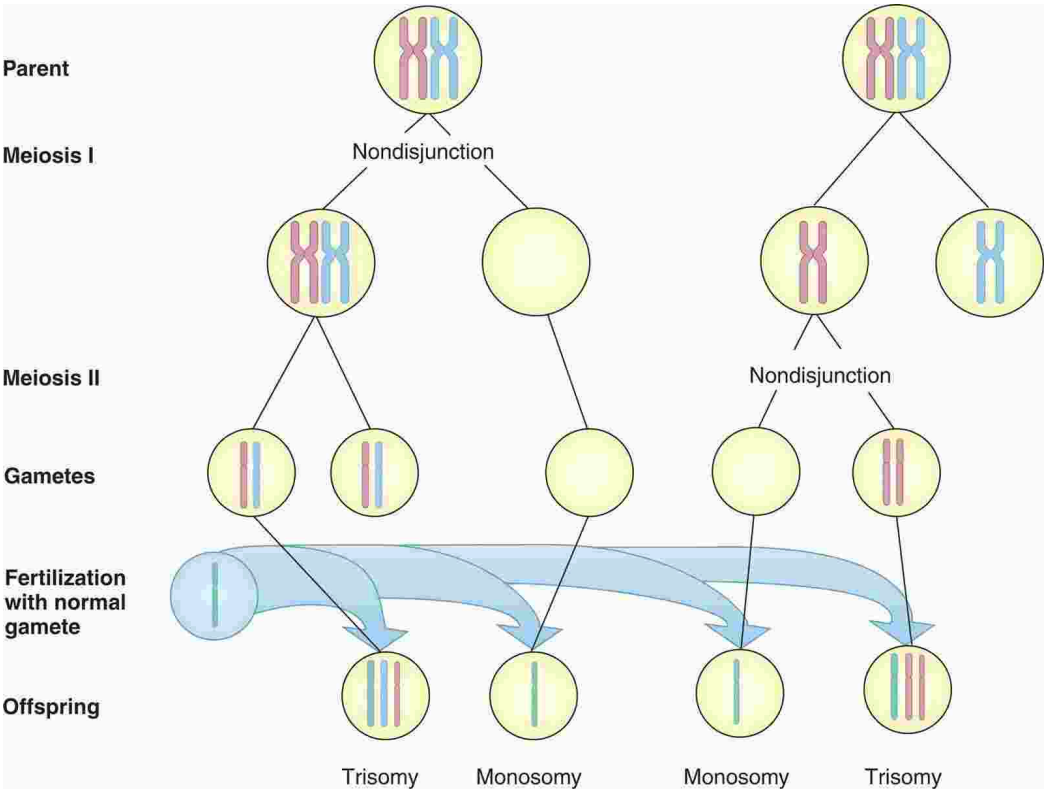

FIG. 4.14 Nondisjunction.
Nondisjunction causes aneuploidy when chromosomes or sister chromatids fail to divide properly. (From Jorde LB, Carey JC. *Medical genetics*, 5th edition. St. Louis: Elsevier; 2016.

An illustration shows the process of nondisjunction. Nondisjunction at parent stage. • Meiosis 1. Both parents' chromosomes pass to the same daughter cell. • Meiosis 2. The gametes from the daughter cell pass on to two daughter cells. • Offspring. Fertilization with normal gamete results in trisomy or monosomy. Nondisjunction at meiosis 1 stage. • Meiosis 1. Parent chromosomes pass to one daughter cell each. • Meiosis 2. The gametes from the daughter cell pass on to one daughter cell. •

Offspring. Fertilization with normal gamete results in monosomy or trisomy.

Autosomal aneuploidy

Trisomy can occur for any chromosome, but fetuses with other trisomies of chromosomes (other than 13, 18, 21, or X) do not survive to term. Trisomy 16, for example, is the most common trisomy among abortuses, but it is not seen in live births.

Partial trisomy, in which only an extra portion of a chromosome is present in each cell, can occur also. The consequences of partial trisomies are not as severe as those of complete trisomies. Trisomies may occur in only some cells of the body. Individuals affected are said to be chromosomal mosaics, meaning that the body has two or more different cell lines, each of which has a different karyotype. Mosaics are often formed by early mitotic nondisjunction occurring in one embryonic cell but not in others.

The best-known example of aneuploidy in an autosome is trisomy of chromosome 21, which causes Down syndrome (named after J. Langdon Down, who first described the syndrome in 1866). Down syndrome is seen in approximately 1 in 800 to 1 in 1000 live births; its principal features are shown and outlined in Fig. 4.15 and Table 4.1.

FIG. 4.15 Child with Down Syndrome. (Courtesy Drs. A. Olney and M. MacDonald, University of Nebraska Medical Center, Omaha, Nebraska.)

Table 4.1

Characteristics of Various Chromosome Disorders

Disease/Disorder	Features
Down Syndrome	
Trisomy of Chromosome 21	
Intelligence quotient (IQ)	Usually ranges from 20 to 70 (intellectual disability)
Male/female findings	Virtually all males are sterile; some females can reproduce
Face	Distinctive: low nasal bridge, epicanthal folds, protruding tongue, low-set ears
Musculoskeletal system	Poor muscle tone (hypotonia), short stature
Systemic disorders	Congenital heart disease (one-third to half of cases), reduced ability to fight respiratory tract infections, increased susceptibility to leukemia—overall reduced survival rate; by age 40 years, usually develop symptoms similar to those of Alzheimer disease
Mortality	About 75% of fetuses with Down syndrome abort spontaneously or are stillborn; 20% of infants die before age 10 years; those who live beyond 10 years have life expectancy of about 60 years
Causative factors	97% caused by nondisjunction during formation of one of parent's gametes or during early embryonic development; 3% result from translocations; in 95% of cases, nondisjunction occurs when mother's egg

Disease/Disorder	Features
	cell is formed; remainder involve paternal nondisjunction; 1% are mosaics—these have a large number of normal cells, and effects of trisomic cells are attenuated and symptoms are generally less severe
Turner Syndrome	
(45,X) Monosomy of X Chromosome	
IQ	Not considered to be intellectually disabled, although some impairment of spatial and mathematical reasoning ability is found
Male/female findings	Found only in females
Musculoskeletal system	Short stature common, characteristic webbing of neck, widely spaced nipples, reduced carrying angle at elbow
Systemic disorders	Coarctation (narrowing) of aorta, edema of feet in newborns, usually sterile and have gonadal streaks rather than ovaries; streaks are sometimes susceptible to cancer
Mortality	About 15%–20% of spontaneous abortions with chromosome abnormalities have this karyotype, most common single-chromosome aberration; highly lethal during gestation, only about 0.5% of these conceptions survive to term
Causative factors	75% inherit X chromosome from mother, thus caused by meiotic error in father; frequency low compared with other sex chromosome aneuploidies (1:5000 newborn females); 50% have simple monosomy of X

Disease/Disorder	Features
	chromosome; remainder have more complex abnormalities; combinations of 45, X cells with XX or XY cells common
Klinefelter Syndrome	
(47,XXY) XXY Condition	
IQ	Moderate degree of mental impairment may be present
Male/female findings	Have a male appearance but usually sterile; 50% develop female-like breasts (gynecomastia); occurs in 1:1000 male births
Face	Voice somewhat high pitched
Systemic disorders	Sparse body hair, sterile, small testicles
Causative factors	50% of cases the result of nondisjunction of X chromosomes in mother, frequency rises with increasing maternal age; also involves XXY and XXXY karyotypes with degree of physical and mental impairment increasing with each added X chromosome; mosaicism fairly common with most prevalent combination of XXY and XY cells

Disease/Disorder	Features
Down Syndrome	
Trisomy of Chromosome 21

Klinefelter Syndrome	
(47,XXY) XXY Condition	
IQ	Moderate degree of mental impairment may be present
Male/female findings	Have a male appearance but usually sterile; 50% develop female-like breasts (gynecomastia); occurs in 1:1000 male births
Face	Voice somewhat high pitched
Systemic disorders	Sparse body hair, sterile, small testicles
Causative factors	50% of cases the result of nondisjunction of X chromosomes in mother, frequency rises with increasing maternal age; also involves XXY and XXXY karyotypes with degree of physical and mental impairment increasing with each added X chromosome; mosaicism fairly common with most prevalent combination of XXY and XY cells

The risk of having a child with Down syndrome increases greatly with maternal age. As Fig. 4.16 demonstrates, women younger than 30 years of age have a risk ranging from about 1 in 1000 births to 1 in 2000 births. The risk begins to rise substantially after age 35 years and reaches 3% to 5% for women older than 45 years of age. This dramatic increase in risk is caused by the age of maternal egg cells,

which are held in an arrested state of prophase I from the time they are formed in the female embryo until they are shed in ovulation. Thus, an egg cell formed by a 45-year-old woman is itself 45 years old. This long-suspended state causes defects to accumulate in the cellular proteins responsible for meiosis, leading to nondisjunction. The risk of Down syndrome, as well as other trisomies, does not increase with paternal age.

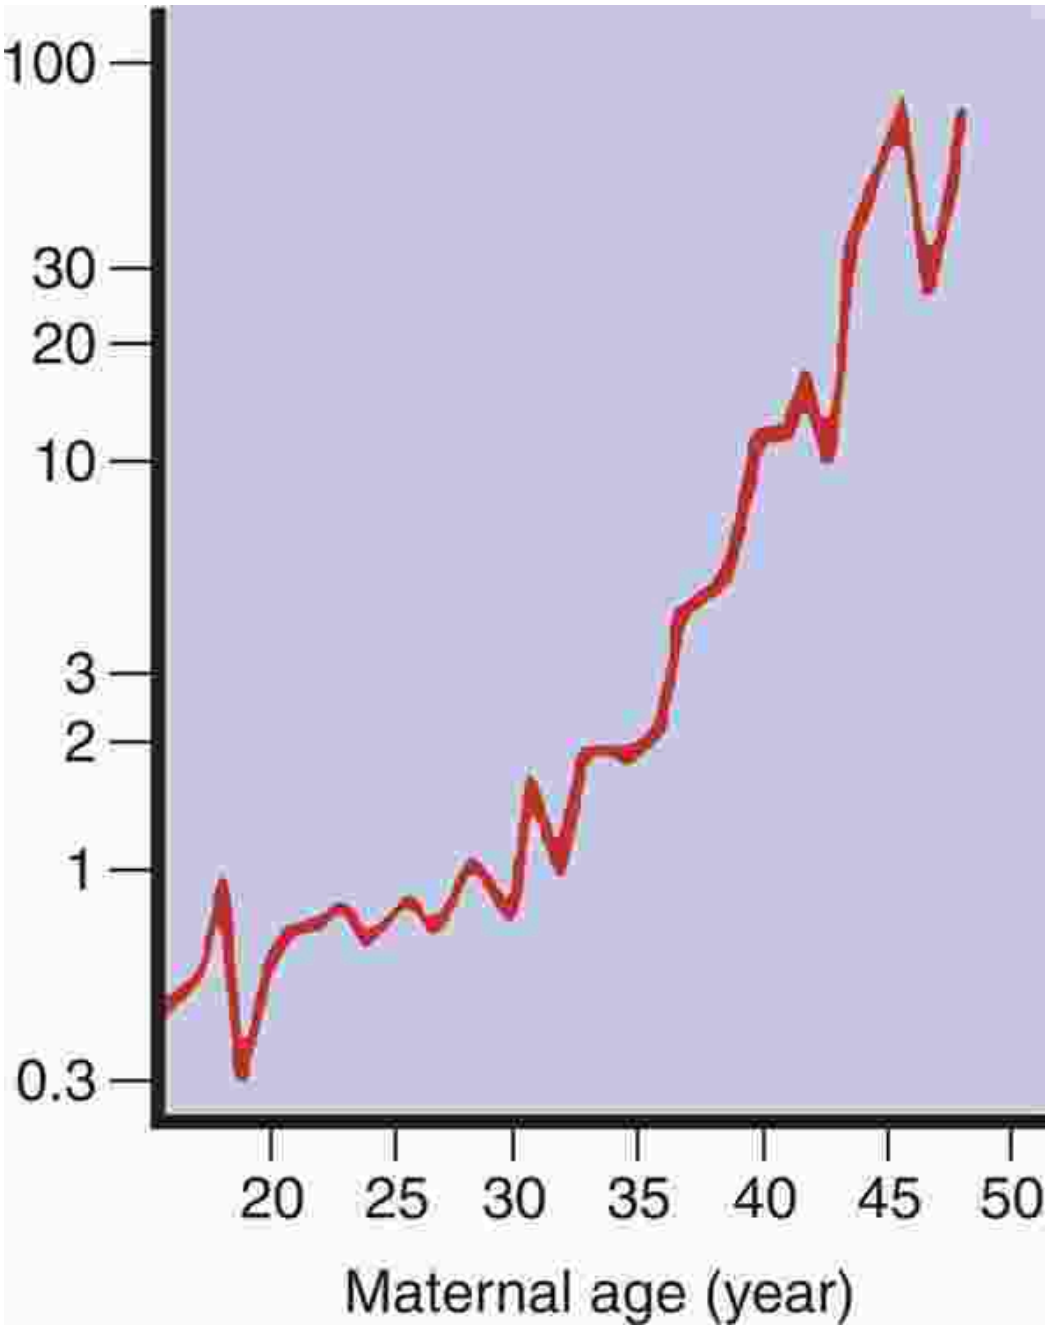

FIG. 4.16 Down Syndrome Increases With Maternal Age.
Rate is per 1000 live births related to maternal age.

A graph plots rate of down syndrome births per 1000 live births by maternal age. The truncated horizontal

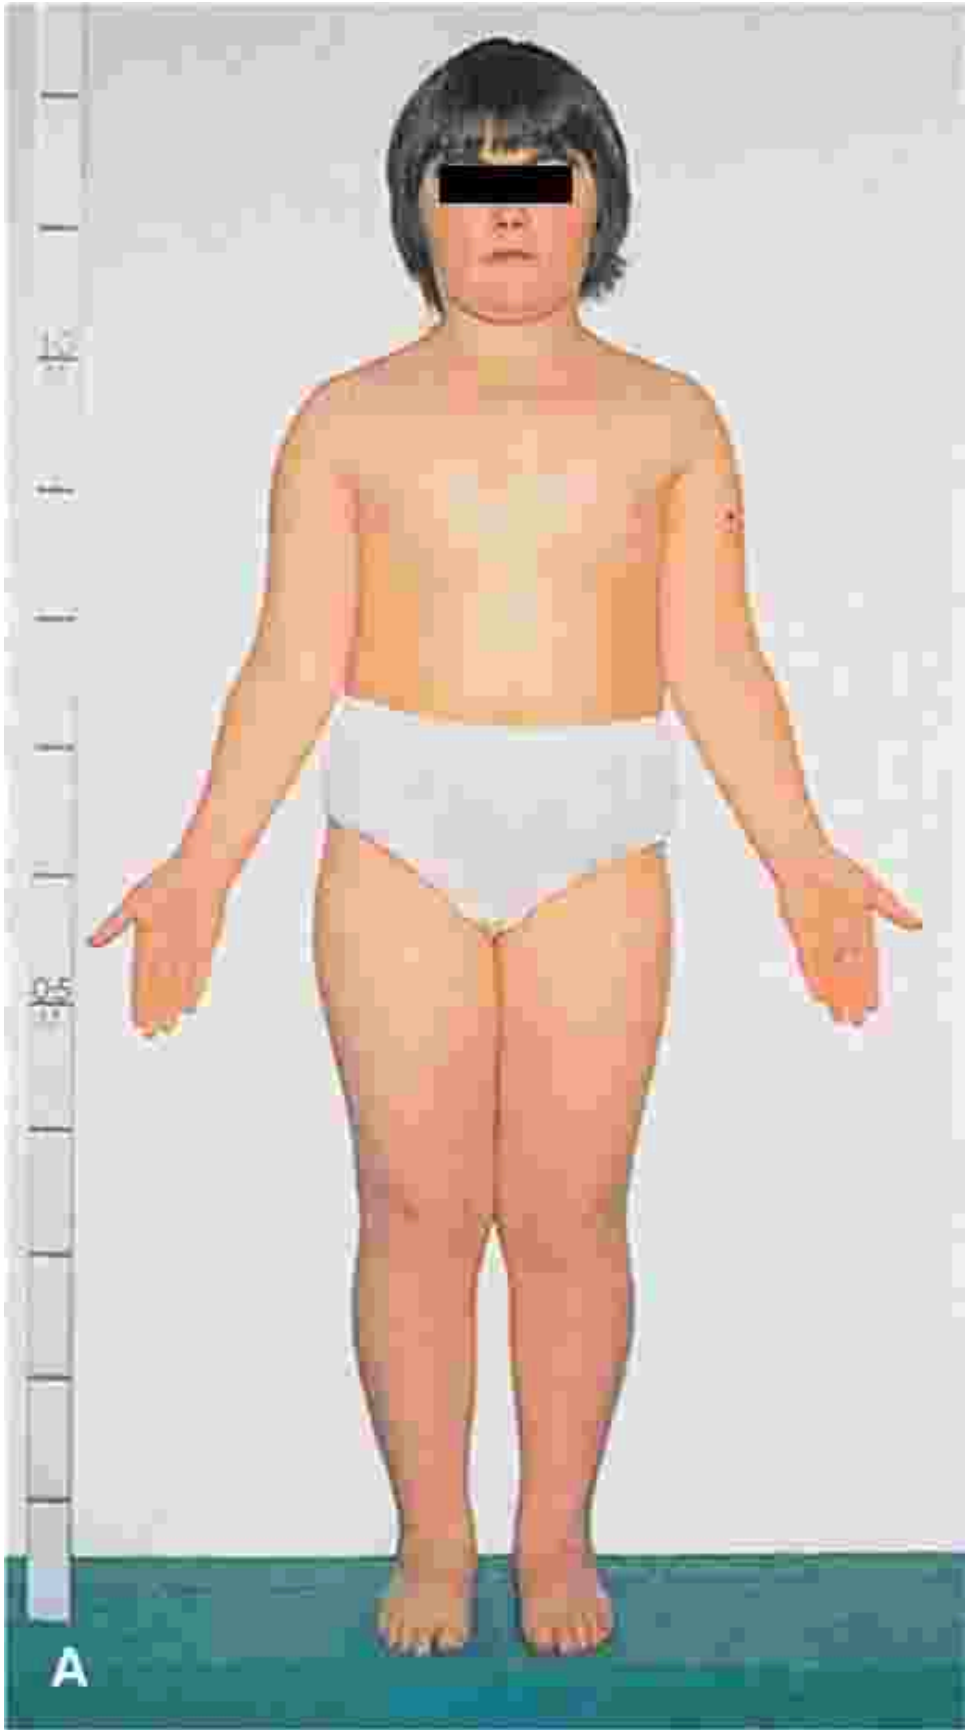
axis ranges from 20 to 50, in increments of 5 years. The vertical axis shows rates from 0.3 to 100, with inconsistent ticks. The graph shows a staggered curve rising from about (0, 0.5) to (50, 95). Other approximate points that the curve passes through include (20, 0.3), (25, 0.9), (30, 0.9), (35, 2), (40, 8), and (45, 30).

Sex chromosome aneuploidy

The incidence of sex chromosome aneuploidies is fairly high. Among live births, about 1 in 500 males and 1 in 900 females have a form of sex chromosome aneuploidy. Because these conditions are generally less severe than autosomal aneuploidies, all forms except complete absence of any X chromosome material allow at least some individuals to survive.

One of the most common sex chromosome aneuploidies, affecting about 1 in 1000 newborn females, is trisomy X. Instead of two X chromosomes, these females have three X chromosomes in each cell. Most of these females have no overt physical abnormalities, although sterility, menstrual irregularity, or intellectual disability is sometimes seen. Some females have four X chromosomes, and they are more often intellectually disabled. Those with five or more X chromosomes generally have more severe intellectual disability and various physical defects.

A condition that leads to more serious problems is the presence of a single X chromosome and no homologous X or Y chromosome, so that the individual has a total of 45 chromosomes. The karyotype is usually designated 45,X, and it causes a set of symptoms known as Turner syndrome (Fig. 4.17; see Table 4.1). Individuals with at least two X chromosomes and one Y chromosome in each cell (47,XXY karyotype) have a disorder known as Klinefelter syndrome (Fig. 4.18; see Table 4.1).



A

FIG. 4.17 Turner Syndrome.
(A) A sex chromosome is missing, and the person's chromosomes are 45,X. Characteristic signs are short stature, female genitalia, webbed neck, shield-like chest with underdeveloped breasts and widely spaced nipples, and imperfectly developed ovaries. (From Patton KT, Thibodeau GA. *Anatomy & physiology*, 8th edition. St. Louis: Mosby; 2013. Courtesy Nancy S. Wexler, PhD, Columbia University.)

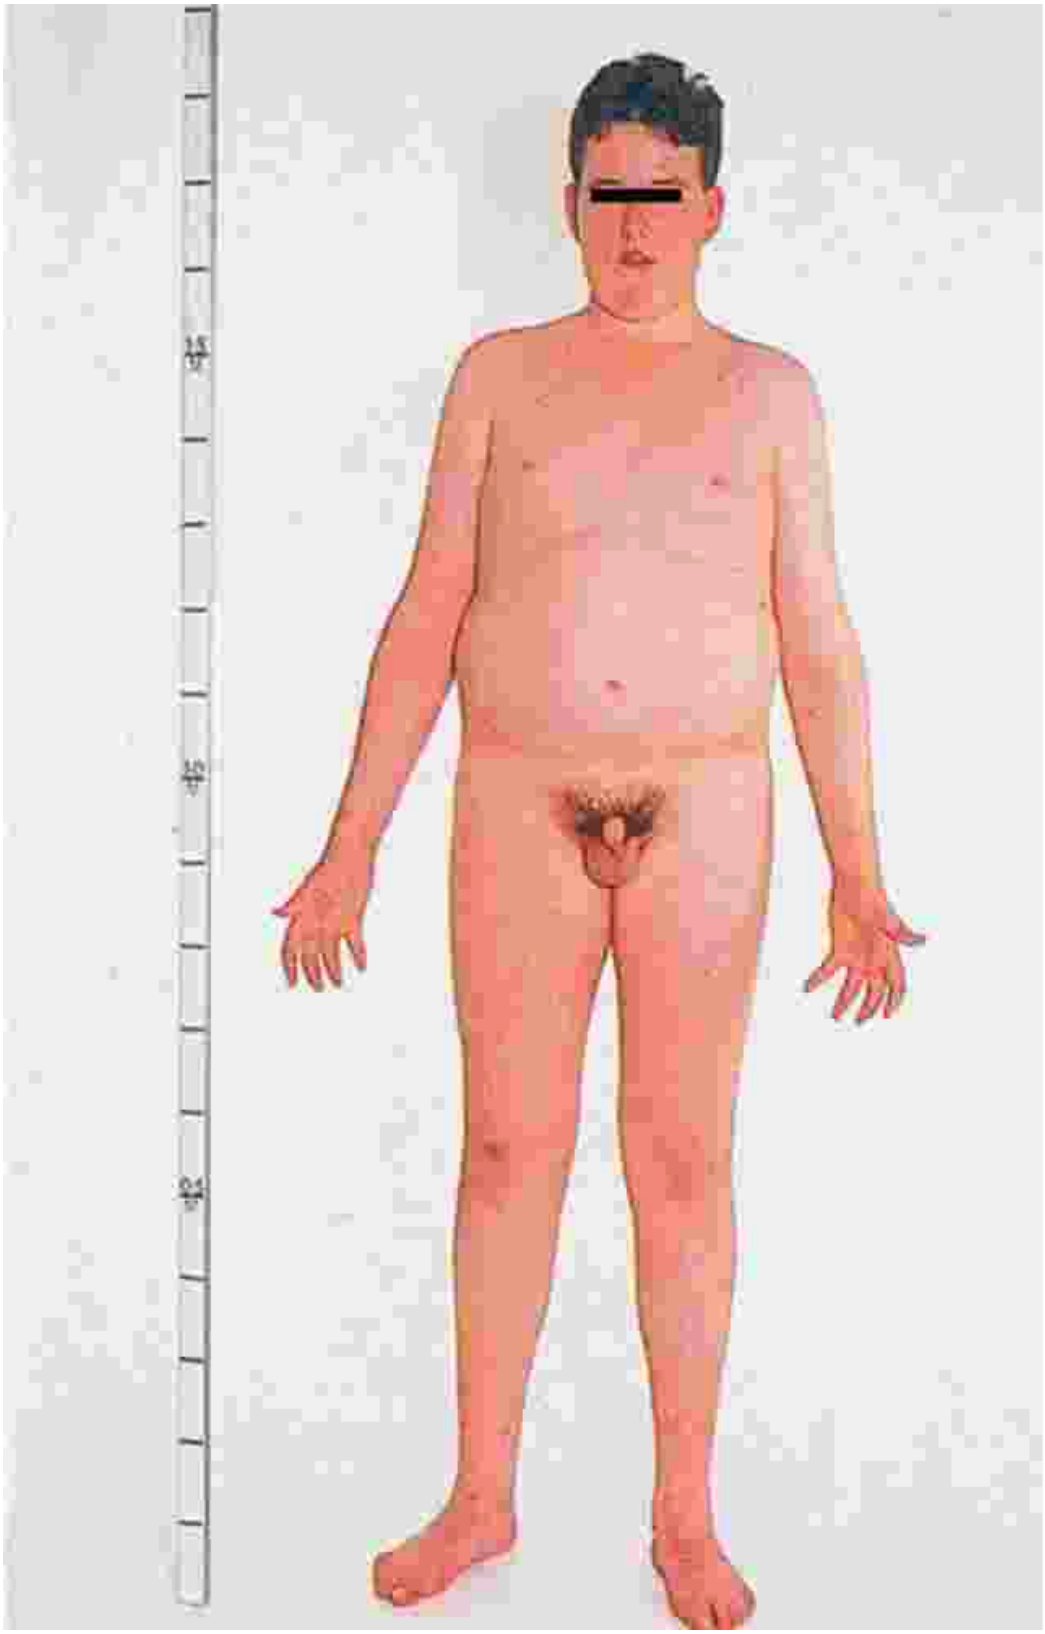


FIG. 4.18 Klinefelter Syndrome.
This young man exhibits many characteristics of Klinefelter syndrome: small testes, some development of the breasts, sparse body hair, and long limbs. This syndrome results from the presence of two or more X chromosomes with one Y chromosome (genotypes XXY or XXXY, for example). (From Patton KT, Thibodeau GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016. Courtesy Nancy S. Wexler, PhD, Columbia University.)

Abnormalities of Chromosome Structure

In addition to the loss or gain of whole chromosomes, parts of chromosomes can be lost or duplicated as gametes are formed, and the arrangement of genes on chromosomes can be altered. Unlike aneuploidy and polyploidy, these changes sometimes have no serious consequences for an individual's health. Some of them can even remain entirely unnoticed, especially when very small pieces of chromosomes are involved. Nevertheless, abnormalities of chromosome structure can also produce serious disease in individuals or their offspring.

During meiosis and mitosis, chromosomes usually maintain their structural integrity, but chromosome breakage occasionally occurs. Mechanisms exist to "heal" these breaks and usually repair them perfectly with no damage to the daughter cell. However, some breaks remain or heal in a way that alters the chromosome's structure. The risk of chromosome breakage increases with exposure to harmful agents called clastogens (e.g., ionizing radiation, viral infections, or some types of chemicals).

Deletions

Broken chromosomes and lost DNA cause deletions (Fig. 4.19). Usually, a gamete with a deletion unites with a normal gamete to form a zygote. The zygote thus has one chromosome with the

normal complement of genes and one with some missing genes. Because many genes can be lost in a deletion, serious consequences result, even though one normal chromosome is present. The most often cited example of a disease caused by a chromosomal deletion is the cri du chat syndrome. The term literally means “cry of the cat” and describes the characteristic cry of the affected child. Other symptoms include low birth weight, severe intellectual disability, microcephaly (smaller than normal head size), and heart defects. The disease is caused by a deletion of part of the short arm of chromosome 5.

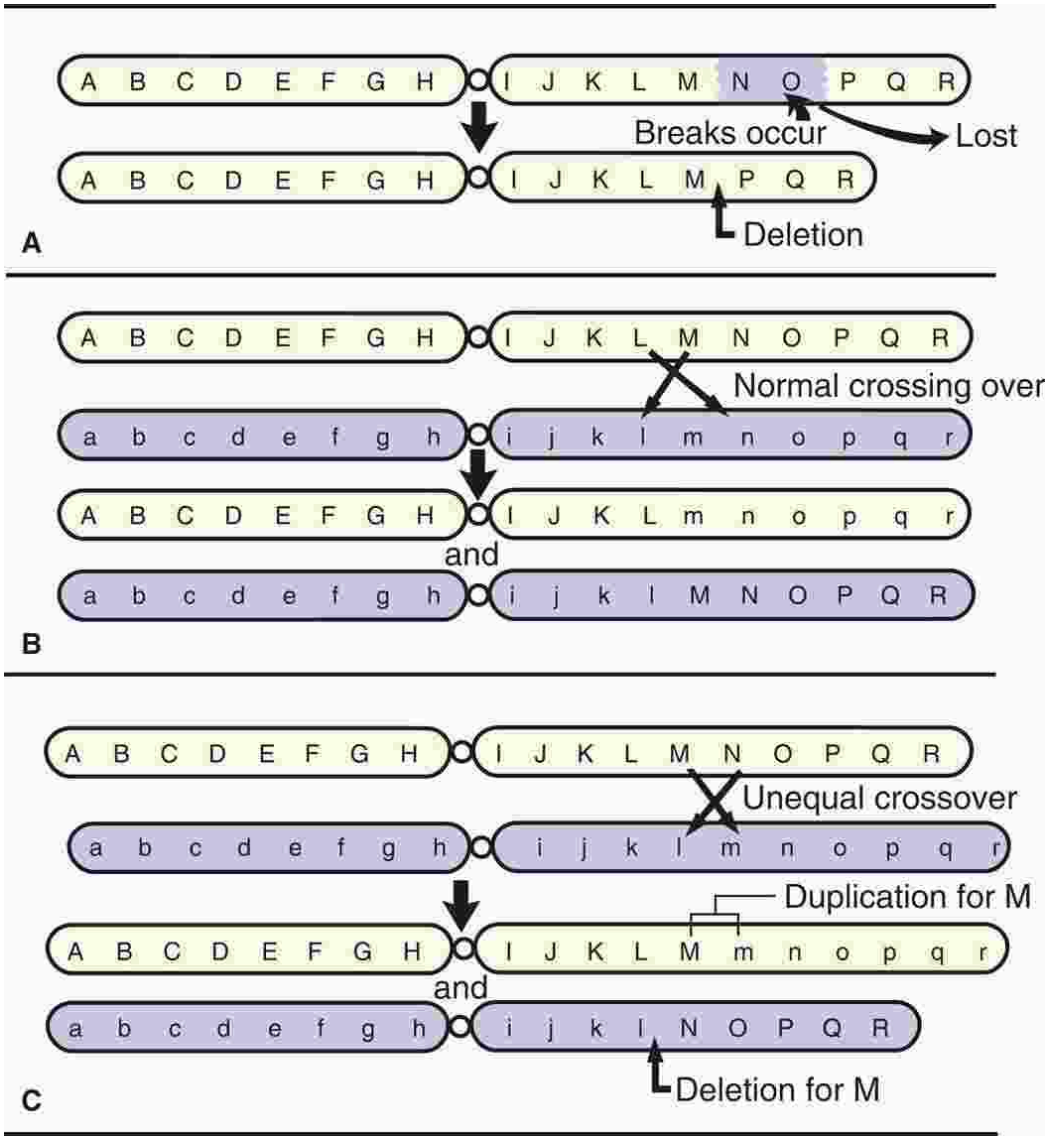

FIG. 4.19 Abnormalities of Chromosome Structure.
(A) Deletion occurs when a chromosome segment is lost. (B) Normal crossing over. (C) The generation of duplication and deletion through unequal crossover.

Three illustrations A through C depict the structural chromosomal abnormalities. Illustration A depicts the broken chromosomes and lost D N A causing

deletion. Illustration B depicts the normal crossing over between two genes. Illustration C depicts the unequal crossover generating duplication and deletion.

Duplications

A deficiency of genetic material is more harmful than an excess, so duplications usually have less serious consequences than deletions. For example, a deletion of a region of chromosome 5 causes cri du chat syndrome, but a duplication of the same region causes intellectual disability, but less serious physical defects.

Inversions

An inversion occurs when two breaks take place on a chromosome, followed by the reinsertion of the missing fragment at its original site but in inverted order. Therefore, a chromosome symbolized as ABCDEFG might become ABEDCFG after an inversion.

Unlike deletions and duplications, no loss or gain of genetic material occurs, so inversions are "balanced" alterations of chromosome structure, and they often have no apparent physical effect. Some genes are influenced by neighboring genes, however, and this position effect, a change in a gene's expression caused by its position, sometimes results in physical defects in these persons. Inversions can cause serious problems in the offspring of individuals carrying the inversion because the inversion can lead to duplications and deletions in the chromosomes transmitted to the offspring.

Translocations

The interchange of genetic material between nonhomologous chromosomes is called translocation. A reciprocal translocation occurs when breaks take place in two different chromosomes and the material is exchanged (Fig. 4.20A). As with inversions, the carrier of

a reciprocal translocation is usually normal, but his or her offspring can have duplications and deletions.

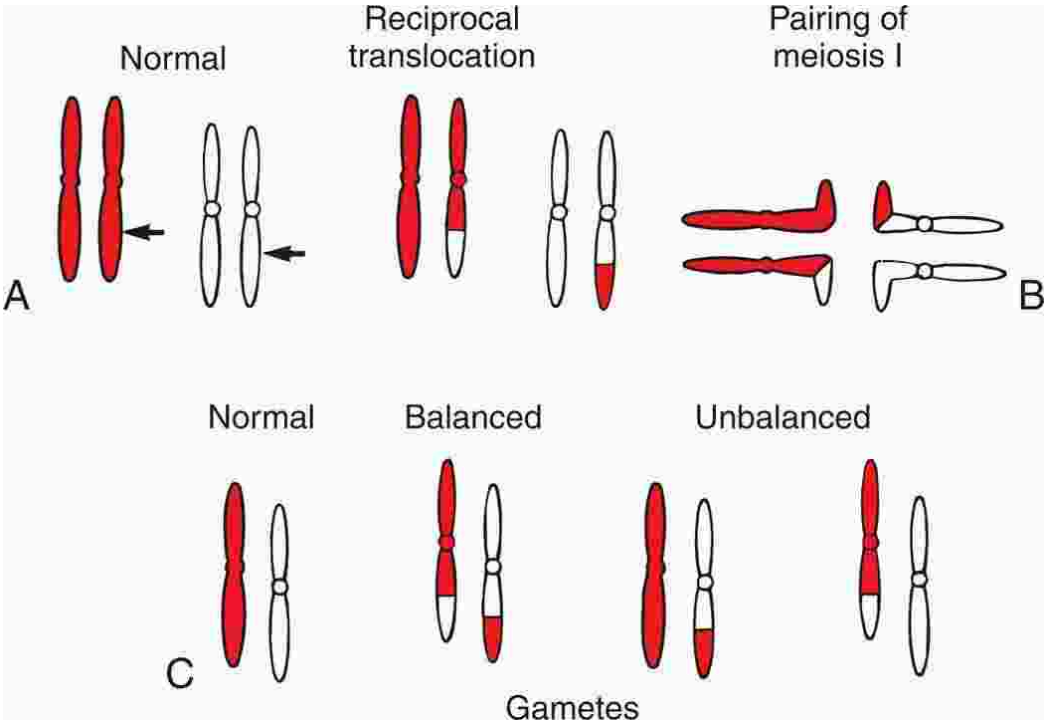

FIG. 4.20 Normal and Abnormal Chromosome Translocation.
(A) Normal chromosomes and reciprocal translocation. **(B)** Pairing at meiosis. **(C)** Consequences of translocation in gametes; unbalanced gametes result in zygotes that are partially trisomic and partially monosomic and, consequently, develop abnormally.

Three illustrations A through C depict the translocation of the normal and abnormal chromosomes. Illustration A depicts normal chromosomes undergo reciprocal translocation. Illustration B depicts the pairing between 4 chromosomes with 2 normal chromosomes and 2 translocated chromosomes. Illustration C depicts the

normal, balanced, and unbalanced gametes that are developing abnormally.

A second and clinically more important type of translocation is Robertsonian translocation. In this disorder, the long arms of two nonhomologous chromosomes fuse at the centromere, forming a single chromosome. Robertsonian translocations are confined to chromosomes 13, 14, 15, 21, and 22 because the short arms of these chromosomes are very small and contain no essential genetic material. The short arms are usually lost during subsequent cell divisions. Because the carriers of Robertsonian translocations lose no important genetic material, they are unaffected, although they have only 45 chromosomes in each cell. Their offspring, however, may have serious monosomies or trisomies. For example, a common Robertsonian translocation involves the fusion of the long arms of chromosomes 21 and 14. An offspring who inherits a gamete carrying the fused chromosome can receive an extra copy of the long arm of chromosome 21 and develop Down syndrome. Robertsonian translocations are responsible for approximately 3% to 5% of Down syndrome cases. Parents who carry a Robertsonian translocation involving chromosome 21 have an increased risk for producing multiple offspring with Down syndrome.

Fragile sites

Several areas on chromosomes develop distinctive breaks and gaps (observable microscopically) when the cells are cultured. Most of these fragile sites do not appear to be related to disease. However, one fragile site, located on the long arm of the X chromosome, is associated with *fragile X syndrome*. The most important feature of this syndrome is intellectual disability. With a relatively high population prevalence (affecting approximately 1 in 4000 males and 1 in 8000 females), fragile X syndrome is the second most common genetic cause of intellectual disability (after Down syndrome).

In fragile X syndrome, females who inherit the mutation do not necessarily express the disease condition, but they can pass it on to descendants who do express it. Ordinarily, a male who inherits a disease gene on the X chromosome expresses the condition because he has only one X chromosome. An uncommon feature of this disease is that about one-third of carrier females are affected, although less severely than males. Unaffected transmitting males have been shown to have more than about 50 repeated DNA sequences near the beginning of the fragile X gene. These trinucleotide sequences, which consist of CGG sequences duplicated many times, cause fragile X syndrome when the number of copies exceeds 200.[9] The number of these repeats can increase from generation to generation. More than 20 other genetic diseases, including Huntington disease and myotonic dystrophy, also are caused by this mechanism.[10]

Elements of Formal Genetics

The mechanisms by which an individual's set of paired chromosomes produces traits are the principles of genetic inheritance. Mendel's work with garden peas first defined these principles. Later geneticists have refined Mendel's work to explain patterns of inheritance for traits and diseases that appear in families.

Analysis of traits that occur with defined, predictable patterns has helped geneticists assemble the pieces of the human gene map. Current research focuses on determining the RNA or protein products of each gene and understanding the way they contribute to disease. Eventually, diseases and defects caused by single genes can be traced and therapies to prevent and treat such diseases can be developed.

Traits caused by single genes are called mendelian traits (after Gregor Mendel). Each gene occupies a position along a chromosome, known as a locus. The genes at a particular locus can have different forms (i.e., they can be composed of different nucleotide sequences) called alleles. A locus that has two or more alleles that each occur

with an appreciable frequency in a population is said to be polymorphic (or to have a polymorphism).

Because humans are diploid organisms, each chromosome is represented twice, with one member of the chromosome pair contributed by the father and one by the mother. At a given locus, an individual has one allele whose origin is paternal and one whose origin is maternal. When the two alleles are identical, the individual is homozygous at that locus. When the alleles are not identical, the individual is heterozygous at that locus.

Phenotype and Genotype

The composition of genes at a given locus is known as the genotype. The outward appearance of an individual, which is the result of both genotype and environment, is the phenotype. For example, an infant who is born with an inability to metabolize the amino acid phenylalanine has the single-gene disorder known as phenylketonuria (PKU) and thus has the PKU genotype. If the condition is left untreated, abnormal metabolites of phenylalanine will begin to accumulate in the infant's brain and irreversible intellectual disability will occur. Intellectual disability is thus one aspect of the PKU phenotype. By imposing dietary restrictions to exclude food that contains phenylalanine, however, intellectual disability can be prevented. Foods high in phenylalanine include proteins found in milk, dairy products, meat, fish, chicken, eggs, beans, and nuts. Although the child still has the PKU genotype, a modification of the environment (in this case, the child's diet) produces an outwardly normal phenotype.

Dominance and Recessiveness

In many loci, the effects of one allele mask those of another when the two are found together in a heterozygote. The allele whose effects are observable is said to be dominant. The allele whose effects are hidden is said to be recessive (from the Latin root for “hiding”). Traditionally, for loci having two alleles, the dominant allele is

denoted by an uppercase letter and the recessive allele is denoted by a lowercase letter. When one allele is dominant over another, the heterozygote genotype *Aa* has the same phenotype as the dominant homozygote *AA*. For the recessive allele to be expressed, it must exist in the homozygote form, *aa*.

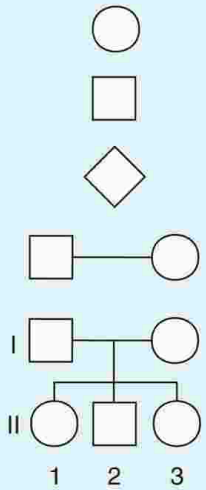
A carrier is an individual who has a disease gene but is phenotypically normal. Many genes for a recessive disease occur in heterozygotes, who carry one copy of the gene but do not express the disease. When recessive genes are lethal in the homozygous state, they are eliminated from the population when they occur in homozygotes. By "hiding" in carriers, however, recessive genes for diseases are passed on to the next generation.

Transmission of Genetic Diseases

The pattern in which a genetic disease is inherited through generations is termed the mode of inheritance. Knowing the mode of inheritance can reveal much about the disease-causing gene itself, and members of families with the disease can be given reliable genetic counseling.

The known single-gene diseases can be classified into four major modes of inheritance: autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive. The first two types involve genes known to occur on the 22 pairs of autosomes. The last two types occur on the X chromosome; very few disease-causing genes occur on the Y chromosome.

The pedigree chart summarizes family relationships and shows which members of a family are affected by a genetic disease (Fig. 4.21). Generally, the pedigree begins with one individual in the family, the proband. This individual is usually the first person in the family diagnosed or seen in a clinic.



Normal female

Normal male

Sex not specified

Single bar indicates mating

Normal parents and normal offspring, two girls and a boy, in birth order indicated by the numbers; I and II indicate generations

Single parent as presented means partner is normal or of no significance to the analysis

Double bar indicates a consanguineous mating (mating between close relatives)

Fraternal twins (not identical)

Identical twins

2 and 6

Multiple individuals of each sex

and

Darkened square or circle means affected individual; arrow (when present) indicates the affected individual is the propositus (proband)

Autosomal heterozygous recessive

Carrier—not likely to manifest disease

FIG. 4.21 Symbols Commonly Used in Pedigrees.
(From Jorde LB, Carey JC. *Medical genetics*, 5th edition. St. Louis: Elsevier; 2016.)

An illustrated chart shows pedigree symbols and their definitions. • Circle: Normal female. • Square: Normal male. • Diamond: Sex not specified. • Square on the left connected to a circle on the right with a single bar: Single bar indicates mating. • Two-level pedigree chart. Generation 1. Square on the left connected to a circle on the right with a single bar. Generation 2. Circle (1), square (2), and circle (1), each connected to the single bar at level 1. Normal parents and normal offspring, two girls and a boy, in birth order indicated by the numbers. • Square in generation 1 connected to two circles in generation 2. Single parent as presented means partner is normal or of no significance to the analysis. • Circle on the left connected to square on the right connected by two bars. Double bar indicates a consanguineous mating (mating between close relatives). • Single bar in generation 1 connected to circle on the left and square on the right in generation 2. Fraternal twins (not identical). • Single bar in generation 1 connected to two circles in generation 2 via a triangle bridge. Identical twins. • Circle with number 2 and square with number 6. Multiple individuals of each sex. • Solid colored circle and solid colored square.

Darkened square or circle means affected individual; arrow (when present) indicates the affected individual is the propositus (proband). • Half colored circle and half colored square. Autosomal heterozygous recessive. • Circle with dot at the center. Carrier-not likely to manifest disease. • Struck circle and struck square. Dead. • Struck circle with text, S B 29 w k. Stillbirth at 29 weeks gestation.

Autosomal Dominant Inheritance

Characteristics of Pedigrees

Diseases caused by autosomal dominant genes are rare, with the most common occurring in fewer than 1 in 500 individuals. Therefore, it is uncommon for two individuals who are both affected by the same autosomal dominant disease to produce offspring together. Fig. 4.22A illustrates this unusual pattern. Affected offspring are usually produced by the union of a normal parent with an affected heterozygous parent. The Punnett square in Fig. 4.22B illustrates this mating. The affected parent can pass either a disease-causing allele or a normal allele to the next generation. On average, half the children will be heterozygous and will express the disease, and half will be normal.

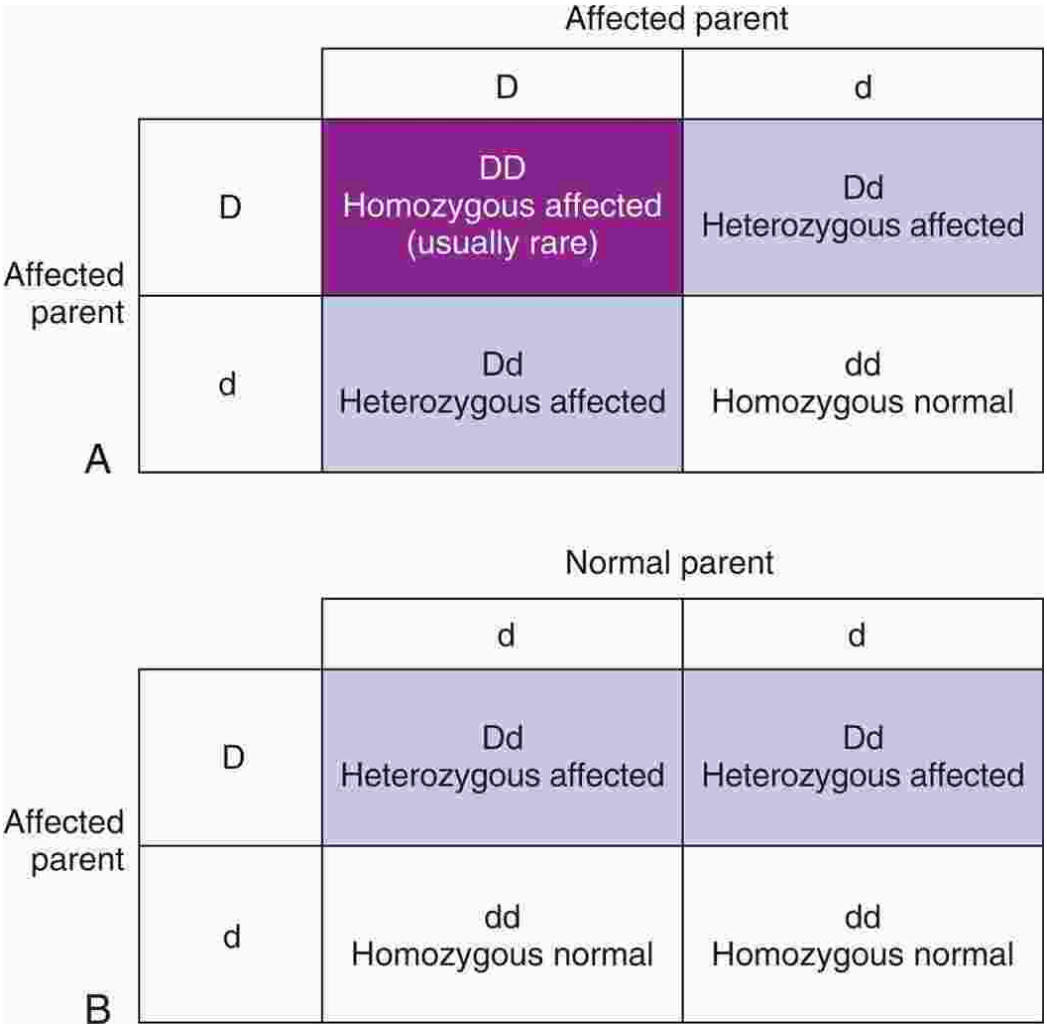

FIG. 4.22 Punnett Square and Autosomal Dominant Traits.
(A) Punnett square for the mating of two individuals with an autosomal dominant gene. Here both parents are affected by the trait. **(B)** Punnett square for the mating of a normal individual with a carrier for an autosomal dominant gene.

Two two-by-two matrices represent the Punnett Square and autosomal dominant traits. Top panel, A, affected parent and affected parent. The combination of traits, clockwise from the bottom-left, are as

follows. • Affected parent with cap D, affected parent with small d: heterozygous affected. • Affected parent with cap D, affected parent with cap D: homozygous affected (usually rare). • Affected parent small d, affected parent with cap D: heterozygous affected. • Affected parent small d, affected parent with small d: Homozygous normal. Top panel, B, normal parent and affected parent. The combination of traits, clockwise from the bottom-left, are as follows. • Affected parent with small d, normal parent with small d: homozygous normal. • Affected parent with cap D, normal parent with small d: heterozygous affected. • Affected parent with cap D, normal parent with small d: heterozygous affected. • Affected parent with small d, normal parent with small d: homozygous normal.

The pedigree in Fig. 4.23 shows the transmission of an autosomal dominant allele. Several important characteristics of this pedigree support the conclusion that the trait is caused by an autosomal dominant gene:

1. The two sexes exhibit the trait in approximately equal proportions; males and females are equally likely to transmit the trait to their offspring.
2. No generations are skipped. If an individual has the trait, one parent must also have it. If neither parent has the trait, none of the children will have it (apart from new mutations, as discussed later).

3. Affected heterozygous individuals transmit the trait to approximately half their children, and because gamete transmission is subject to chance fluctuations, all or none of the children of an affected parent may have the trait. When large numbers of matings of this type are studied, however, the proportion of affected children closely approaches one-half.

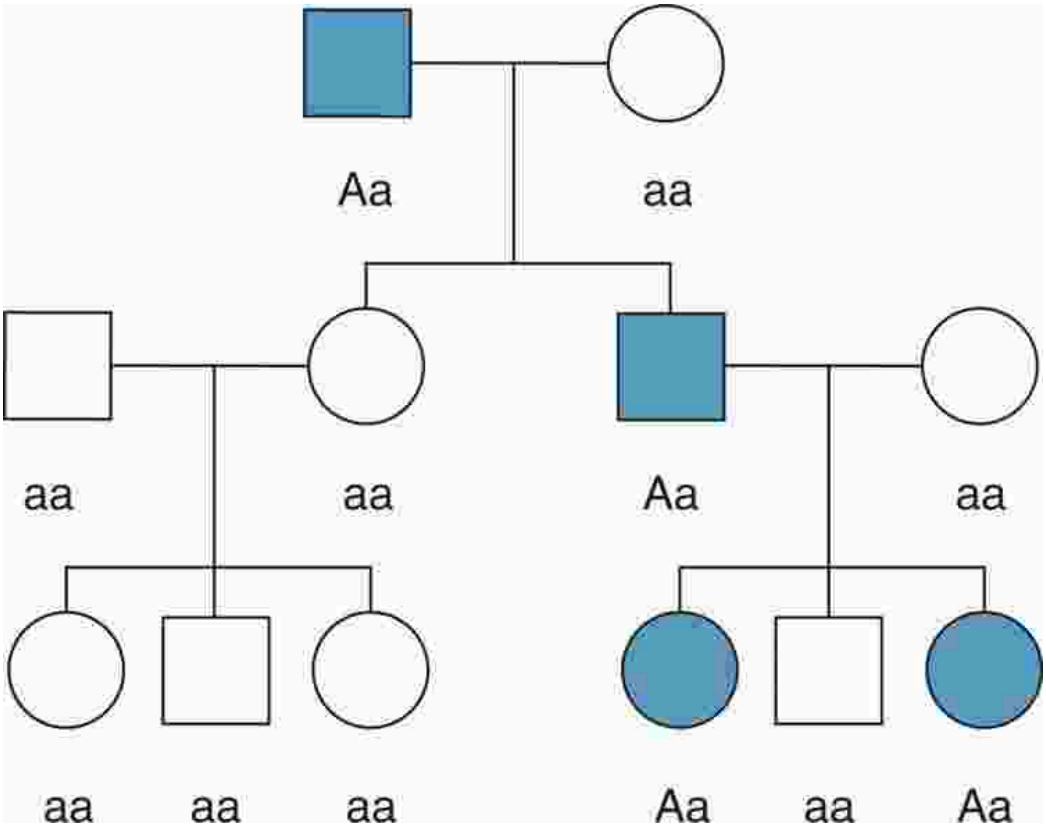

FIG. 4.23 Pedigree Illustrating the Inheritance Pattern of Postaxial Polydactyly, an Autosomal Dominant Disorder.
Affected individuals are represented by shading.
(From Jorde LB, Carey JC. *Medical genetics*, 5th edition. St. Louis: Elsevier; 2016.)

A pedigree chart illustrates the inheritance pattern of postaxial polydactyly. • Generation 1. Solid square, cap A small a, mates with circle, small a small a. • Generation 2. Two offspring of generation 1: circle, small a small a (mates with square, small a small a), and solid square, cap A small a (mates with circle, small a small a). • Generation 3. Three offspring of square (small a small a) and circle (small a small a):

circle (small a small a), square (small a small a), and circle (small a small a). Three offspring of solid square (cap A small a) and circle (small a small a): solid circle (cap A small a), square (small a small a), and solid circle (cap A small a).

Recurrence Risks

Parents at risk for producing children with a genetic disease nearly always ask the question, "What is the *chance* that our child will have this disease?" The probability that an individual will develop a genetic disease is termed the recurrence risk. When one parent is affected by an autosomal dominant disease (and is a heterozygote) and the other is unaffected, the recurrence risk for each child is one-half.

An important principle is that each birth is an independent event, much like a coin toss. Thus, even though parents may have already had a child with the disease, their recurrence risk remains one-half. Even if they have produced several children, all affected (or all unaffected) by the disease, the law of independence dictates that the probability their next child will have the disease is still one-half. Parents' misunderstanding of this principle is a common problem encountered in genetic counseling.

If a child is born with an autosomal dominant disease and there is no history of the disease in the family, the child is probably the product of a new mutation. The gene transmitted by one of the parents has thus undergone a mutation from a normal allele to a disease-causing allele. The alleles at this locus in most of the parent's other germ cells are still normal. In this situation, the recurrence risk for the parent's subsequent offspring is not greater than that of the general population. The offspring of the affected child, however, will have a recurrence risk of one-half (probability of 0.5). Because these diseases often reduce the potential for reproduction, many autosomal dominant diseases result from new mutations.

Delayed Age of Onset

One of the best-known autosomal dominant diseases is Huntington disease, a neurologic disorder whose main features are progressive dementia and increasingly uncontrollable limb movements (chorea; discussed further in Chapter 17). A key feature of this disease is its delayed age of onset: Symptoms usually are not seen until 40 years of age or later. Thus, those who develop the disease often have borne children before they become aware that they have the disease-causing mutation. If the disease was present at birth, nearly all affected persons would die before reaching the reproductive age, and the occurrence of the disease-causing allele in the population would be much lower. An individual whose parent has the disease has a 50% chance of developing it during middle age. He or she is thus confronted with a torturous question: Should I have children, knowing that there is a 50:50 chance that I may have this disease-causing gene and will pass it to half my children? A DNA test can now be used to determine whether an individual has inherited the trinucleotide repeat mutation that causes Huntington disease.

Penetrance and Expressivity

The penetrance of a trait is the percentage of individuals with a specific genotype who also exhibit the expected phenotype. Incomplete penetrance means individuals who have the disease-causing genotype may not exhibit the disease phenotype at all, even though the genotype and the associated disease may be transmitted to the next generation. A pedigree illustrating the transmission of an autosomal dominant mutation with incomplete penetrance is provided in Fig. 4.24. Retinoblastoma, the most common malignant eye tumor affecting children, typically exhibits incomplete penetrance. About 10% of the individuals who are obligate carriers of the disease-causing mutation (i.e., those who have an affected parent and affected children and therefore must themselves carry the mutation) do not have the disease. The penetrance of the disease-causing genotype is then said to be 90%.

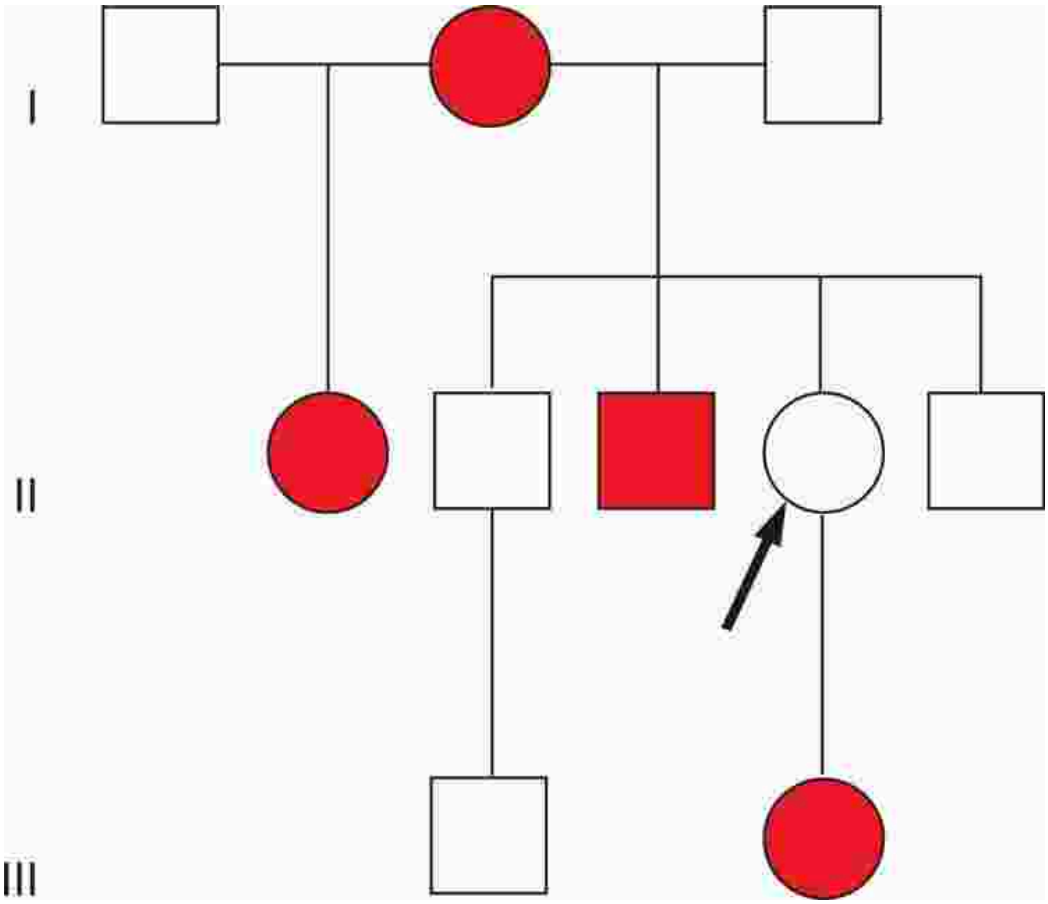

FIG. 4.24 Pedigree for Retinoblastoma Showing Incomplete Penetrance.
Female with marked arrow in line II must be heterozygous, but she does not express the trait.

A pedigree chart illustrates retinoblastoma showing incomplete penetrance. • Generation 1. Square bar solid circle bar square. • Generation 2. One offspring of first square and circle: solid circle. Four offspring of solid circle and second square: square, solid square, circle, and square. • Generation 3. One offspring of first square: square. One offspring of circle (highlighted with an arrow): solid circle.

The gene responsible for retinoblastoma is a tumor-suppressor gene. The normal function of its protein product is to regulate the cell cycle, so cells do not divide uncontrollably. When the protein is altered because of a genetic mutation, its tumor-suppressing capacity is lost and a tumor can form (see Chapters 12 and 20).[11]

Expressivity is the extent of variation in phenotype associated with a particular genotype. If the expressivity of a disease is variable, penetrance may be complete, but the severity of the disease can vary greatly. A good example of variable expressivity in an autosomal dominant disease is neurofibromatosis type 1, or von Recklinghausen disease. As in retinoblastoma, the mutations that cause neurofibromatosis type 1 occur in a tumor-suppressor gene.[12] The expression of this disease varies from a few harmless café-au-lait (light brown) spots on the skin to numerous neurofibromas, scoliosis, seizures, gliomas, neuromas, malignant peripheral nerve sheath tumors, hypertension, and learning disorders (Fig. 4.25).

FIG. 4.25 Neurofibromatosis: Tumors.
The most common is sessile or pedunculated.

Early tumors are soft, dome-shaped papules or nodules that have a distinctive violaceous hue. Most are benign. (From Habif et al. Skin disease: Diagnosis and treatment, 2nd edition. St. Louis: Mosby; 2005.)

Several factors cause variable expressivity. Genes at other loci sometimes modify the expression of a disease-causing gene. Environmental (i.e., nongenetic) factors also can influence expression of a disease-causing gene. Finally, different mutations at a locus can cause variation in severity. For example, a mutation that alters only one amino acid of the factor VIII gene usually produces a mild form of hemophilia A, whereas a "stop" codon (premature termination of translation) usually produces a more severe form of this blood coagulation disorder.

Epigenetics and Genomic Imprinting

Although this chapter focuses on DNA sequence variation and its consequence for disease, there is increasing evidence that the same DNA sequence can produce dramatically different phenotypes because of chemical modifications altering the expression of genes (these modifications are collectively termed epigenetic; see Chapter 6). An important example of such a modification is DNA methylation, the attachment of a methyl group to a cytosine base followed by a guanine base in the DNA sequence (Fig. 4.26). These sequences, which are common near many genes, are termed CpG islands. When the CpG islands located near a gene become heavily methylated, the gene is less likely to be transcribed into mRNA. In other words, the gene becomes transcriptionally inactive. One study showed that identical (monozygotic) twins accumulate different methylation patterns in the DNA sequences of their somatic cells as they age, causing increasing numbers of phenotypic differences. Intriguingly twins with more differences in their lifestyles (e.g., smoking versus nonsmoking) accumulated larger numbers of differences in their methylation patterns. The twins, despite having identical DNA sequences, become more and more different as a

result of epigenetic changes, which, in turn, affect the expression of genes (see Fig. 6.8).

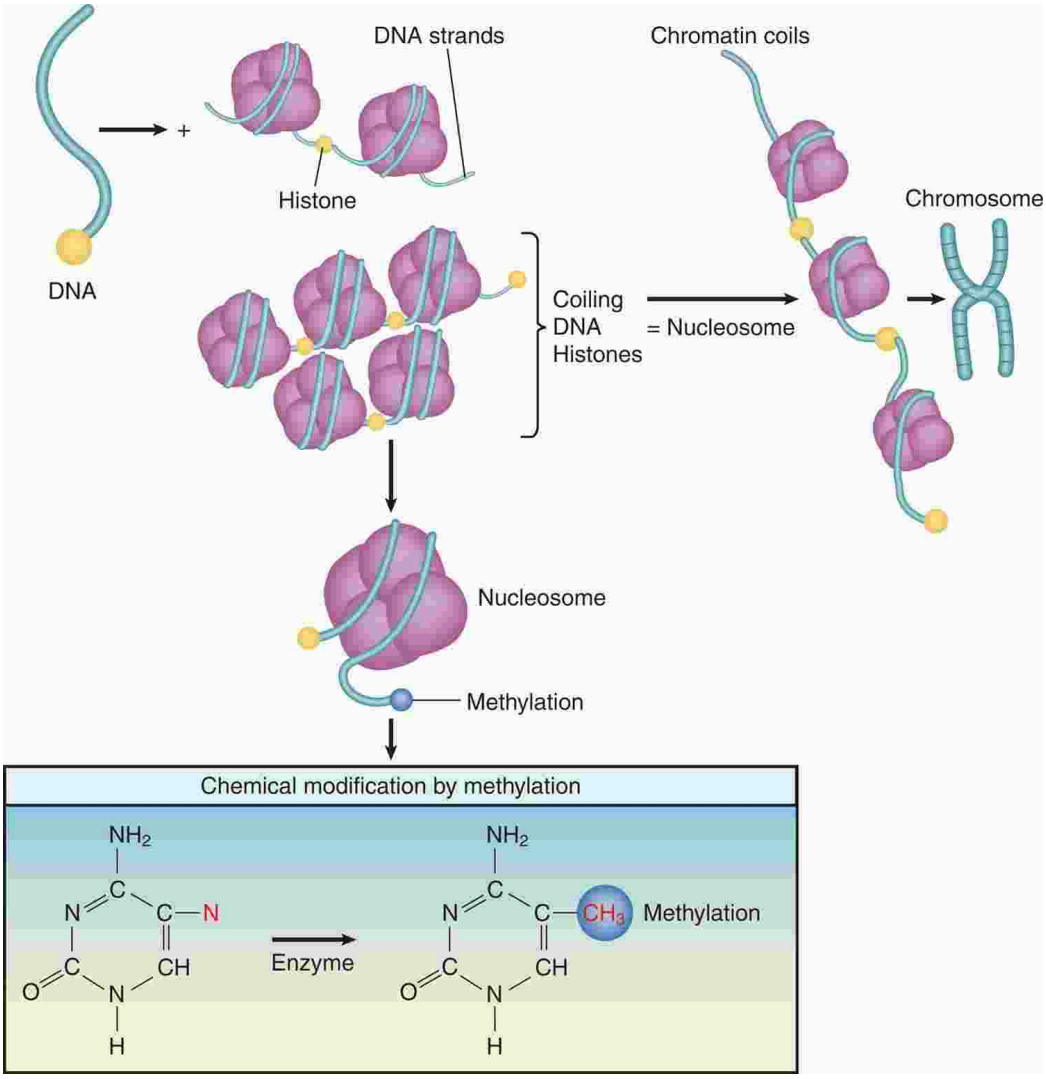

FIG. 4.26 Epigenetic Modifications.
Because deoxyribonucleic acid (DNA) is a long molecule, it needs packaging to fit in the tiny nucleus. Packaging involves *coiling* of the DNA in a "left-handed" spiral around spools, made of four pairs of proteins individually known as *histones* and collectively termed the *histone octamer*. The entire spool is called a nucleosome (also see Fig. 1.2). Nucleosomes are organized into chromatin, the repeating building blocks of a chromosome. Histone modifications are correlated with methylation, are reversible, and occur at multiple sites. Methylation occurs at the 5 position of

cytosine and provides a “footprint” or signature as a unique epigenetic alteration *(red)*. When genes are expressed, chromatin is open or active; however, when chromatin is condensed because of methylation and histone modification, genes are inactivated.

An illustration depicts the schematic representation of epigenetic modifications that regulate chromatin organization and gene expression which shows D N A is packed around histone proteins to form nucleosomes.

Epigenetic alteration of gene activity can have important disease consequences. For example, a major cause of one form of inherited colon cancer (termed *hereditary nonpolyposis colorectal cancer [HNPCC]*) is the methylation of a gene whose protein product repairs damaged DNA. When this gene becomes inactive, damaged DNA accumulates, eventually resulting in colon tumors. Epigenetic changes are also discussed in Chapters 6, 12, and 13.

Approximately 100 human genes are thought to be methylated differently, depending on which parent transmits the gene. This epigenetic modification, characterized by methylation and other changes, is termed genomic imprinting. For each of these genes, one of the parents *imprints* the gene (inactivates it) when it is transmitted to the offspring. An example is the insulin-like growth factor 2 gene *(IGF2)* on chromosome 11, which is transmitted by both parents, but the copy inherited from the mother is normally methylated and inactivated (imprinted). Thus, only one copy of *IGF2* is active in normal individuals. However, the maternal imprint is occasionally lost, resulting in two active copies of *IGF2*. This causes excess fetal growth and contributes to a condition known as *Beckwith-Wiedemann syndrome* (see Chapter 6).

A second example of genomic imprinting is a deletion of part of the long arm of chromosome 15 (15q11–q13), which, when inherited from the father, causes the offspring to manifest a disease known as *Prader-Willi syndrome* (short stature, obesity, hypogonadism). When the same deletion is inherited from the mother, the offspring develop *Angelman syndrome* (intellectual disability, seizures, ataxic gait). The two different phenotypes reflect the fact that different genes are normally active in the maternally and paternally transmitted copies of this region of chromosome 15.

Autosomal Recessive Inheritance

Characteristics of Pedigrees

Like autosomal dominant diseases, diseases caused by autosomal recessive genes are rare in populations, although there can be numerous carriers. Cystic fibrosis, the most common lethal recessive disease in white children, occurs in about 1 in 2500 births. Approximately 1 in 25 whites carries a copy of a mutation that causes cystic fibrosis (see Chapter 36). Carriers are phenotypically unaffected. Some autosomal recessive diseases are characterized by delayed age of onset, incomplete penetrance, and variable expressivity.

Fig. 4.27 shows a pedigree for cystic fibrosis. The gene responsible for cystic fibrosis encodes a chloride ion channel in some epithelial cells. Defective transport of chloride ions leads to a salt imbalance, which results in secretions of abnormally thick, dehydrated mucus. Some digestive organs, particularly the pancreas, become obstructed, causing malnutrition, and the lungs become clogged with mucus, making them highly susceptible to bacterial infections. Death from lung disease or heart failure occurs by age 40 years in about half the individuals with cystic fibrosis.

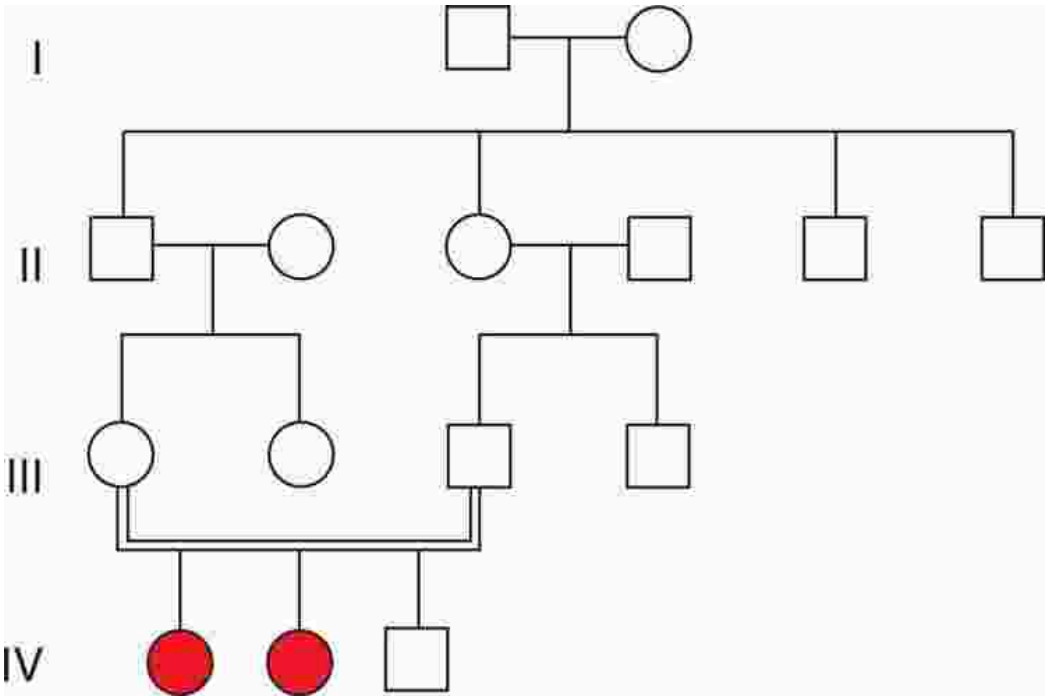

FIG. 4.27 Pedigree for Cystic Fibrosis. Cystic fibrosis is an autosomal recessive disorder. The double bar denotes a consanguineous mating. Because cystic fibrosis is relatively common in European populations, most cases do not involve consanguinity.

A pedigree chart shows the descent of cystic fibrosis to the fourth generation. • Generation 1. Square bar circle. • Generation 2. Four offspring of generation 1: square (mates with circle), circle (mates with square), square, and square. • Generation 3. Two offspring of first square of generation 1: circle and circle. Two offspring of circle of generation 1: square and square. • First circle of generation 3 double bar first square

of generation 3. • Generation 4: Solid circle, solid circle, and square.

The important criteria for discerning autosomal recessive inheritance include the following:

1. Males and females are affected in equal proportions.
2. Consanguinity (marriage between related individuals) is sometimes present, especially in cases of rare recessive diseases.
3. The disease may be seen in siblings of affected individuals but usually not in their parents.
4. On average, one-fourth of the offspring of carrier parents will be affected.

Recurrence Risks

In most cases of recessive disease, both parents of affected individuals are heterozygous carriers. On average, one-fourth of their offspring will be normal homozygotes, half will be phenotypically normal carrier heterozygotes, and one-fourth will be homozygotes with the disease (Fig. 4.28). Thus, the recurrence risk for the offspring of carrier parents is 25%. However, in any given family, there are chance fluctuations.

	D	d
D	DD Homozygous normal	Dd Heterozygous carrier
d	Dd Heterozygous carrier	dd Homozygous affected

FIG. 4.28 Punnett Square for the Mating of Heterozygous Carriers Typical of Most Cases of Recessive Disease.

A two-by-two matrices represents the Punnett Square and autosomal dominant traits. The combination of traits, clockwise from the bottom-left, are as follows. • Cap D, small d: heterozygous carrier. • Cap D, cap D: homozygous normal. • Cap D, small d: Heterozygous carrier. • Small d, small d: Homozygous affected.

If two parents have a recessive disease, they each must be homozygous for the disease. Therefore, all their children also must be affected. This distinguishes recessive from dominant inheritance because two parents both affected by a dominant gene are nearly always both heterozygotes, and thus one-fourth of their children will be unaffected.

Because carrier parents usually are unaware that they both carry the same recessive allele, they often produce an affected child before becoming aware of their condition. Carrier detection tests can identify heterozygotes by analyzing the DNA sequence to reveal a

mutation. Some recessive diseases for which carrier detection tests are routinely used include PKU, sickle cell disease, cystic fibrosis, Tay-Sachs disease, hemochromatosis, and galactosemia.

Consanguinity

Consanguinity and inbreeding are related concepts. Consanguinity refers to the mating of two related individuals, and the offspring of such mating are said to be *inbred*. Consanguinity is sometimes an important characteristic of pedigrees for recessive diseases because relatives share a certain proportion of genes received from a common ancestor. The proportion of shared genes depends on the closeness of their biologic relationship. Consanguineous mating produces a significant increase in recessive disorders and are seen most often in pedigrees for rare recessive disorders.

X-Linked Inheritance

Some genetic conditions are caused by mutations in genes located on the sex chromosomes, and this mode of inheritance is termed sex linked. Only a few diseases are known to be inherited as X-linked dominant or Y chromosome traits, so only the more common X-linked recessive diseases are discussed here.

Because females receive two X chromosomes, one from the father and one from the mother, they can be homozygous for a disease allele at a given locus, homozygous for the normal allele at the locus, or heterozygous. Males, having only one X chromosome, are hemizygous for genes on this chromosome. If a male inherits a recessive disease gene on the X chromosome, he will be affected by the disease because the Y chromosome does not carry a normal allele to counteract the effects of the disease gene. Because a single copy of an X-linked recessive gene will cause disease in a male, whereas two copies are required for disease expression in females, more males are affected by X-linked recessive diseases than are females.

X Inactivation

In the late 1950s, Mary Lyon proposed that one X chromosome in the somatic cells of females is permanently inactivated, a process termed X inactivation.[13] This proposal, the Lyon hypothesis, explains why most gene products coded by the X chromosome are present in equal amounts in males and females, even though males have only one X chromosome and females have two X chromosomes. This phenomenon is called dosage compensation. The inactivated X chromosomes are observable in many interphase cells as highly condensed intranuclear chromatin bodies, termed Barr bodies (after Barr and Bertram, who discovered them in the late 1940s). Normal females have one Barr body in each somatic cell, whereas normal males have no Barr bodies.

X inactivation occurs very early in embryonic development—approximately 7 to 14 days after fertilization. In each somatic cell, one of the two X chromosomes is inactivated. In some cells, the inactivated X chromosome is the one contributed by the father; in other cells, it is the one contributed by the mother. Once the X chromosome has been inactivated in a cell, all the descendants of that cell have the same chromosome inactivated (Fig. 4.29). Thus, inactivation is said to be random but *fixed*.

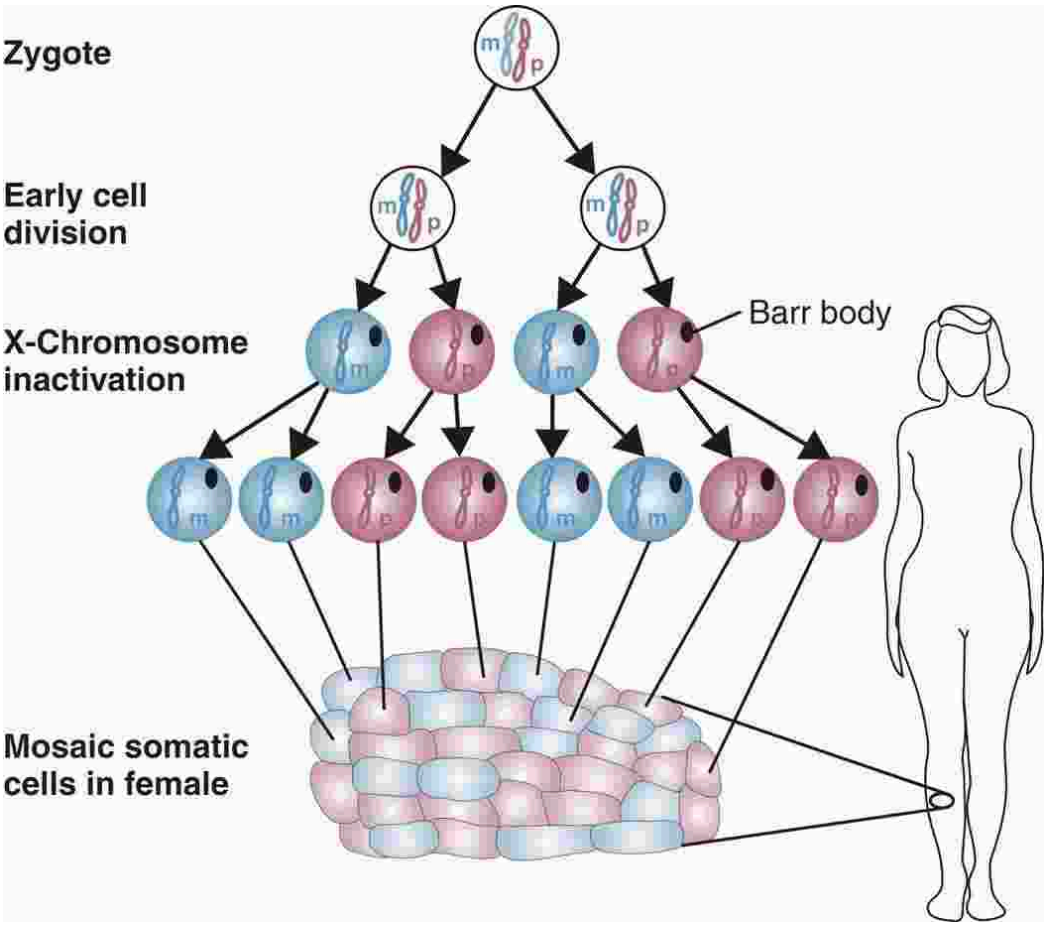

FIG. 4.29 The X Inactivation Process.
The maternal *(m)* and paternal *(p)* X chromosomes are both active in the zygote and in early embryonic cells. X inactivation then takes place, resulting in cells having either an active paternal X or an active maternal X. Females are thus X chromosome mosaics, as shown in the tissue sample at the bottom of the page. (From Jorde LB, Carey JC. *Medical genetics*, 5th edition. St. Louis: Elsevier; 2016.)

An illustration represents the X inactivation process. • Zygote. The illustration shows a maternal chromosome and a paternal chromosome. • Early cell division. The illustration shows two daughter

cells. • X-chromosome inactivation. The daughter cells divide to sister chromatids with a Barr body each. • Mosaic somatic cells in female.

Some individuals do not have the normal number of X chromosomes in their somatic cells. For example, males with Klinefelter syndrome typically have two X chromosomes and one Y chromosome. These males do have one Barr body in each cell. Females whose cell nuclei have three X chromosomes have two Barr bodies in each cell, and females whose cell nuclei have four X chromosomes have three Barr bodies in each cell. Females with Turner syndrome have only one X chromosome and no Barr bodies. Thus, the number of Barr bodies is always one less than the number of X chromosomes in the cell. All but one X chromosome are always inactivated.

Persons with abnormal numbers of X chromosomes, such as those with Turner syndrome or Klinefelter syndrome, are not physically normal. This situation presents a puzzle because they presumably have only one active X chromosome, the same as individuals with normal numbers of chromosomes. This is probably because the distal tips of the short and long arms of the X chromosome, as well as several other regions on the chromosome arm, are not inactivated. Thus, X inactivation is also known to be *incomplete*. The inactivated X chromosome DNA is heavily methylated. Inactive X chromosomes can be at least partially reactivated in vitro by administering 5-azacytidine, a demethylating agent.

Sex Determination

The process of sexual differentiation, in which the embryonic gonads become either testes or ovaries, begins during the sixth week of gestation. A key principle of mammalian sex determination is that one copy of the Y chromosome is sufficient to initiate the process of gonadal differentiation that produces a male fetus. The number of X chromosomes does not alter this process. For example, an individual

with two X chromosomes and one Y chromosome in each cell is still phenotypically a male. Thus, the Y chromosome contains a gene that begins the process of male gonadal development.

This gene, termed *SRY* (for "sex-determining region on the Y"), has been located on the short arm of the Y chromosome.[14] The *SRY* gene lies just outside the pseudoautosomal region (Fig. 4.30A and B), which pairs with the distal tip of the short arm of the X chromosome during meiosis and exchanges genetic material with it (crossover), just as autosomes do. The DNA sequences of these regions on the X and Y chromosomes are highly similar. The rest of the X and Y chromosomes, however, do not exchange material and are not similar in DNA sequence.

FIG. 4.30 Distal Short Arms of the X and Y Chromosomes Exchange Material During Meiosis in the Male.
The region of the Y chromosome in which this crossover occurs is called the *pseudoautosomal region*. The *SRY* gene, which triggers the process leading to male gonadal differentiation, is located just outside the pseudoautosomal region. Occasionally, the crossover occurs on the centromeric side of the *SRY* gene, causing it to lie on an X chromosome instead of a Y chromosome. An offspring receiving this X chromosome will be an XX male, and an offspring receiving the Y chromosome will be an XY female. (A, from Raven PH, et al. *Biology*, 8th edition. New York: McGraw-Hill; 2008. B, From Jorde LB, Carey JC. *Medical genetics*, 5th edition. Philadelphia: Elsevier; 2016.)

Top panel, A. A photomicrograph shows a Y chromosome and an X chromosome. Bottom panel, B. An illustration shows the exchange of material during meiosis in the male. The illustration identifies the pseudo-autosomal region: X p and Y p (with S R Y). • Normal crossover. Normal female (X p) and normal male (Y p with S R Y). • Crossover occurs below S R Y. X X male (X p with S R Y) and X Y female (Y p).

Other genes that contribute to male differentiation are located on other chromosomes. Thus, *SRY* triggers the action of genes on other chromosomes. This concept is supported by the fact that the *SRY*

protein product is similar to other proteins known to regulate gene expression.

Occasionally, the crossover between X and Y occurs closer to the centromere than it should, placing the *SRY* gene on the X chromosome after crossover. This variation can result in offspring with an apparently normal XX karyotype but a male phenotype. Such XX males are seen in about 1 in 20,000 live births and resemble males with Klinefelter syndrome. Conversely, it is possible to inherit a Y chromosome that has lost the *SRY* gene (the result of either a crossover error or a deletion of the gene). This situation produces an XY female. Such females have gonadal streaks rather than ovaries and have poorly developed secondary sex characteristics.

Characteristics of Pedigrees

X-linked pedigrees show distinctive modes of inheritance. The most striking characteristic is that females seldom are affected. To express an X-linked recessive trait fully, a female must be homozygous: either both her parents are affected, or her father is affected, and her mother is a carrier. Such matings are rare.

The following are important principles of X-linked recessive inheritance:

1. The trait is seen much more often in males than in females.
2. Because a father can give a son only a Y chromosome, the trait is never transmitted from father to son.
3. The gene can be transmitted through a series of carrier females, causing the appearance of one or more "skipped generations."
4. The gene is passed from an affected father to all his daughters, who, as phenotypically normal carriers, transmit it to approximately half their sons, who are affected.

A relatively common X-linked recessive disorder is Duchenne muscular dystrophy (DMD), which affects approximately 1 in 3500 males. As its name suggests, this disorder is characterized by

progressive muscle degeneration. Affected individuals usually are unable to walk by age 10 or 12 years. The disease affects the heart and respiratory muscles, and death caused by respiratory or cardiac failure usually occurs before age 20 years. Identification of the disease-causing gene (on the short arm of the X chromosome) has greatly increased our understanding of the disorder.[15]

The *DMD* gene is the largest gene ever found in humans, spanning more than 2 million DNA bases. It encodes a previously undiscovered muscle protein, termed dystrophin. Extensive study of dystrophin indicates that it plays an essential role in maintaining the structural integrity of muscle cells: it may also help regulate the activity of membrane proteins. When dystrophin is absent, as in DMD, the cell cannot survive, and muscle deterioration ensues. Most cases of DMD are caused by frameshift deletions of portions of the *DMD* gene and thus involve alterations of the amino acids encoded by the DNA following the deletion.

Recurrence Risks

The most common mating type involving X-linked recessive genes is the combination of a carrier female and a normal male (Fig. 4.31A). On average, the carrier mother will transmit the disease-causing allele to half her sons (who are affected) and half her daughters (who are carriers).

FIG. 4.31 Punnett Square and X-Linked Recessive Traits.
(A) Punnett square for the mating of a normal male (X_HY) and a female carrier of an X-linked recessive gene (X_HX_h). **(B)** Punnett square for the mating of a normal female (X_HX_H) with a male affected by an X-linked recessive disease (X_hY). **(C)** Punnett square for the mating of a female who carries an X-linked recessive gene (X_HX_h) with a male who is affected with the disease caused by the gene (X_hY).

Three Punnett Squares and their X-linked recessive traits. Top panel, clockwise from the bottom-left. • Father (cap Y) and mother (cap X sub cap H), normal: Cap X sub cap H cap Y. • Father (cap X sub cap H) and mother (cap X sub cap H), normal: Cap X sub cap H cap X sub cap H. • Father (cap X sub cap H) and mother (cap X sub small h), carrier: Cap X sub small h cap X sub cap H. • Father (cap Y) and mother (cap X sub small h), affected: Cap X sub small h cap Y. Middle panel, clockwise from the bottom-left. • Father (cap Y) and mother (cap X sub cap H), normal: Cap X sub cap H cap Y. • Father (cap X sub small h) and mother (cap X sub cap H), carrier: Cap X sub cap H cap X sub small h. • Father (cap X sub small h) and mother (cap X sub cap H), carrier: Cap X sub cap H cap X sub small h. • Father (cap Y) and mother (cap X sub cap H), normal: Cap X sub cap H

cap Y. Bottom panel, clockwise from the bottom-left. • Father (cap Y) and mother (cap X sub cap H), normal: Cap X sub cap H cap Y. • Father (cap X sub small h) and mother (cap X sub cap H), carrier: Cap X sub cap H cap X sub small h. • Father (cap X sub small h) and mother (cap X sub small h), affected: Cap X sub small h cap X sub small h. • Father (cap Y) and mother (cap X sub small h), affected: Cap X sub small h cap Y.

The other common mating type is an affected father and a normal mother (see Fig. 4.31B). In this situation, all the sons will be normal because the father can transmit only his Y chromosome to them. Because all the daughters must receive the father's X chromosome, they will all be heterozygous carriers. Because the sons *must* receive the Y chromosome and the daughters *must* receive the X chromosome with the disease gene, these are precise outcomes and not probabilities. None of the children will be affected.

The final mating pattern, less common than the other two, involves an affected father and a carrier mother (see Fig. 4.31C). With this pattern, on average, half the daughters will be heterozygous carriers, and half will be homozygous for the disease allele and thus affected. Half the sons will be normal, and half will be affected. Some X-linked recessive diseases, such as DMD, are fatal or incapacitating before the affected individual reaches reproductive age, and therefore, affected fathers are rare.

Sex-Limited and Sex-Influenced Traits

A sex-limited trait can occur in only one sex, often because of anatomic differences. Inherited uterine and testicular defects are two obvious examples. A sex-influenced trait occurs much more often in one sex than in the other. For example, male-pattern baldness occurs

in both males and females but is much more common in males. Autosomal dominant breast cancer, which is much more commonly expressed in females than in males, is another example of a sex-influenced trait.

Linkage Analysis and Gene Mapping

Locating genes on specific regions of chromosomes has been one of the most important goals of human genetics. The location and identification of a gene can tell much about the function of the gene, the interaction of the gene with other genes, and the likelihood that certain individuals will develop a genetic disease.

Classic Pedigree Analysis

During the first meiotic stage, the arms of homologous chromosome pairs intertwine and sometimes exchange portions of their DNA (Fig. 4.32) in a process known as crossover. During crossover, new combinations of alleles can be formed. For example, two loci on a chromosome have alleles *A* and *a* and alleles *B* and *b*. Alleles *A* and *B* are located together on one member of a chromosome pair, and alleles *a* and *b* are located on the other member. The genotype of this individual is denoted as *AB*/*a0b*.

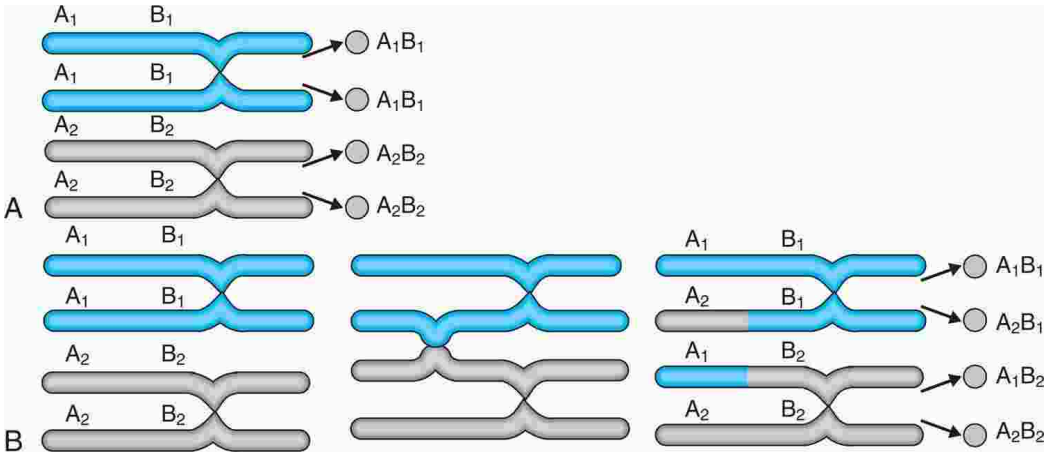

FIG. 4.32 **Genetic Results of Crossover.**
(A) No crossing over. **(B)** Crossing over with recombination.

Two illustrations A and B depict crossing over between two genes. Illustration A depicts no crossing-over between two genes, the results of the combination of two alleles are given as follows A 1 B 1, A 2 B 2. Illustration B depicts the crossing-over with recombination between two genes, the result of the crossover recombination is given as follows A 1 B 1, A 2 B 1, A 1 B 2, A 2 B 2.

As Fig. 4.32A shows, the allele pairs would be transmitted together when no crossover occurs. However, when crossover occurs (Fig. 4.32B), all four possible pairs of alleles can be transmitted to the offspring. The process of forming such new arrangements of alleles is called recombination. Loci that are located very close to one another are unlikely to experience recombination and are said to demonstrate linkage. The frequency of recombination can be assessed in families and is used to determine the relative positions of loci on chromosomes (the gene map, discussed below).

Complete Human Gene Map: Prospects and Benefits

The major goals of the Human Genome Project were to find the locations of all human genes (the "gene map") and to determine the entire human DNA sequence. These goals have now been accomplished, and the genes responsible for approximately 5000 mendelian conditions have been identified (Fig. 4.33).[7,16]This has greatly increased our understanding of the mechanisms that underlie many diseases, such as retinoblastoma, cystic fibrosis, neurofibromatosis, and Huntington disease. The project also has led to more accurate diagnosis of these conditions and, in some cases, more effective treatment.[17] DNA sequencing has become much less expensive and more efficient in recent years. Consequently, hundreds of thousands of individuals have now been sequenced, leading, in many cases, to the identification of disease-causing genes.[16]

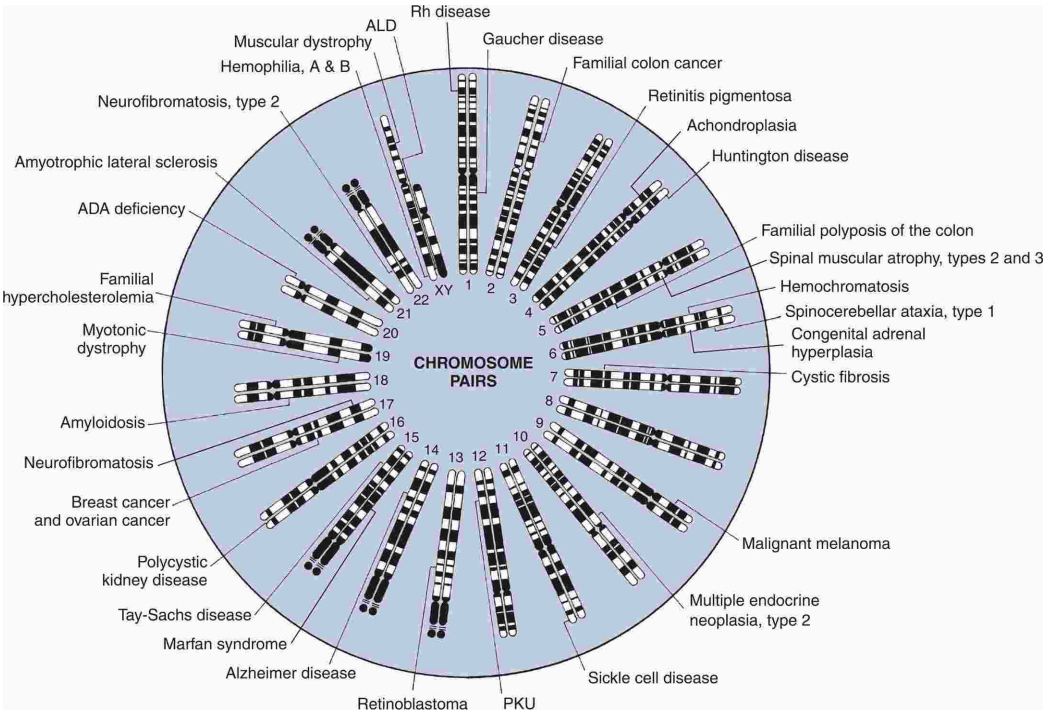

FIG. 4.33 Example of Diseases: A Gene Map.
ADA, Adenosine deaminase; *ALD*, adrenoleukodystrophy; *PKU*, phenylketonuria.

An illustration depicts the gene map representing the 23 chromosome pairs in the inner circle and corresponding diseases in the outer circle. The pairs of chromosomes and the examples of disease's clockwise direction are as follows. 1. R h disease and Gaucher disease. 2. Familial colon cancer. 3. Retinitis pigmentosa. 4. Achondroplasia and Huntington disease. 5. Familial polyposis of the colon and spinal muscular atrophy types 2 and 3. 6. Hemochromatosis and Spinocerebellar ataxia type 1 and Congenital adrenal hyperplasia. 7. Cystic fibrosis. 8. Nil. 9. Malignant melanoma. 10. Multiple endocrine neoplasia, type 2. 11. Sickle cell disease. 12.

phenylketonuria. 13. Retinoblastoma. 14. Alzheimer disease. 15. Marfan syndrome and Tay-Sachs disease. 16. Polycystic kidney disease. 17. Breast cancer and ovarian cancer and Neurofibromatosis. 18. Amyloidosis. 19. Myotonic dystrophy and familial hypercholesterolemia. 20. Adenosine deaminase deficiency. 21. Amyotrophic lateral sclerosis. 22. Neurofibromatosis, type 2. X Y. Hemophilia, A and B and muscular dystrophy and adrenoleukodystrophy.

Summary Review

DNA, RNA, and Proteins: Heredity at the Molecular Level

1. Genes, the basic units of inheritance, are composed of sequences of deoxyribonucleic acid (DNA) and are located on chromosomes.
2. Each subunit of DNA, called a nucleotide, is composed of one deoxyribose, a phosphate molecule, and one of four types of nitrogenous bases. The physical structure of DNA is a double helix. The two strands connect by the nitrogenous bases, with thymine bonding to adenine, and guanine bonding to cytosine.
3. The four DNA bases code for amino acids, which in turn make up proteins. The amino acids are specified by triplet sets of nitrogenous bases in specific orders, called codons. Several codons correspond to the same amino acid in many cases.
4. DNA replication is based on complementary base pairing, in which a single strand of DNA serves as the template for

attracting complementary bases that form a new strand of DNA.

5. DNA polymerase is the primary enzyme involved in replication. It adds bases to the new DNA strand and performs "proofreading" functions.
6. A mutation is an alteration of genetic material (e.g., base pair substitution, frameshift mutation). Substances that cause mutations are called mutagens.
7. Mutations are rare events, and the rate of mutations varies from gene to gene. Mutational hot spots are DNA sequences with particularly high mutation rates.
8. Transcription and translation, the two basic processes in which proteins are specified by DNA, both involve ribonucleic acid (RNA). RNA is chemically similar to DNA, but it is single stranded, has a ribose sugar molecule, and has uracil rather than thymine as one of its four nitrogenous bases (uracil pairs with the base adenine).
9. Transcription is the process by which a DNA template synthesizes a RNA, thus forming messenger RNA (mRNA). Proteins called transcription factors are involved in the process of converting—or transcribing—DNA into RNA.
10. Much of the RNA sequence is spliced from the mRNA before the mRNA leaves the nucleus. The excised sequences are called introns, and those that remain to code for proteins are called exons.
11. Translation is the process by which RNA directs the synthesis of polypeptides. This process takes place in the ribosomes, which consist of proteins and ribosomal RNA (rRNA).
12. During translation, mRNA interacts with transfer RNA (tRNA), a molecule that has an attachment site for a specific amino acid and an anticodon, a region that matches up with a three-base codon on the mRNA. The ribosome moves along the mRNA, matching different tRNAs to codons on the mRNA, and forming a growing chain of amino acids called a polypeptide.

Chromosomes

1. Human cells consist of diploid somatic cells (body cells with 23 pairs of chromosomes, 46 total) and haploid gametes (sperm and egg cells with 23 total chromosomes).
2. Humans have 23 pairs of chromosomes. Twenty-two of these pairs are autosomes, ones that appear virtually identical (homologous) between males and females). The remaining pair consists of the sex chromosomes. Females have two homologous X chromosomes as their sex chromosomes; males have an X and a Y chromosome.
3. A karyogram is an ordered display of chromosomes arranged according to length and the location of the centromere. The karyogram is the visual representation of the individual's chromosome karyotype.
4. Various types of stains can be used to make chromosome bands more visible. Chromosome bands can be used to identify chromosomes and identify variations.
5. About 1 in 150 live births has a major diagnosable chromosome abnormality. Chromosome abnormalities are the leading known cause of intellectual disability and miscarriage.
6. Euploid cells are ones with the normal number of chromosomes. Polyploidy is a condition in which a cell has some multiple of the normal number of chromosomes. Humans have been observed to have triploidy (three copies of each chromosome) and tetraploidy (four copies of each chromosome); both conditions are lethal.
7. Aneuploidy is when a cell does not have a multiple of 23 chromosomes; there is an extra or missing single chromosome. Trisomy is a type of aneuploidy in which one chromosome is present in three copies. A partial trisomy is one in which only part of a chromosome is present in three copies. Monosomy is a type of aneuploidy in which one chromosome is present in only one copy.

8. In general, monosomies cause more severe physical defects than do trisomies, illustrating the principle that the loss of chromosome material has more severe consequences than the duplication of chromosome material.
9. Down syndrome, a trisomy of chromosome 21, is the best-known disease caused by a chromosome aberration. It affects 1 in 800 to 1 in 1000 live births.
10. Most aneuploidies of the sex chromosomes have less severe consequences than those of the other chromosomes.
11. The most observed sex chromosome aneuploidies are the 47,XXX karyotype, 45,X karyotype (Turner syndrome), 47,XXY karyotype (Klinefelter syndrome), and 47,XYY karyotype.
12. Abnormalities of chromosome structure include deletions, duplications, inversions, and translocations.

Elements of Formal Genetics

1. Mendelian traits are caused by single genes, each of which occupies a position, or locus, on a chromosome.
2. Alleles are different forms of genes located at the same locus on a chromosome.
3. At any given locus in a somatic cell, an individual has two genes, one from each parent. An individual may be homozygous (alleles are identical) or heterozygous (alleles are different) for a locus.
4. An individual's genotype is his or her genetic makeup, and the phenotype reflects the interaction of genotype and environment.
5. In a heterozygote, a dominant gene's effects mask those of a recessive gene. The recessive gene is expressed only when it is present in two copies.

Transmission of Genetic Diseases

1. Genetic diseases caused by single genes usually follow autosomal dominant, autosomal recessive, X-linked dominant, or X-linked recessive modes of inheritance. Pedigree charts are important tools in the analysis of modes of inheritance.
2. Autosomal dominant inheritance affects males and females equally and the two sexes are equally likely to transmit to their offspring. Skipped generations are not seen in classic autosomal dominant pedigrees. Affected heterozygous individuals transmit the trait to approximately half their children.
3. Recurrence risks specify the probability that future offspring will inherit a genetic disease. For single-gene diseases, recurrence risks remain the same for each offspring, regardless of the number of affected or unaffected offspring.
4. Many genetic diseases have a delayed age of onset: symptoms are not seen until sometime after birth.
5. The penetrance of a trait is the percentage of individuals with a specific genotype who also exhibit the expected phenotype. A gene that is not always expressed phenotypically is said to have incomplete penetrance.
6. Expressivity is the extent of variation in phenotype associated with a particular genotype. If the expressivity of a disease is variable, penetrance may be complete, but the severity of the disease can vary greatly.
7. Epigenetics involves changes, such as the methylation of DNA bases, that do not alter the DNA sequence but can alter the expression of genes.
8. Genomic imprinting, which is associated with methylation, results in differing expression of a disease gene, depending on which parent transmitted the gene.
9. Autosomal recessive inheritance affect males are females in equal proportions. Consanguinity (mating of related individuals) is sometimes present in families with autosomal recessive diseases, and it becomes more prevalent with rarer recessive diseases. The disease may be seen in siblings but

not their parents. The recurrence risk for autosomal recessive diseases is 25%.

10. Most commonly, biologic parents of children with autosomal recessive diseases are both heterozygous carriers of the disease gene.
11. Carrier detection tests for autosomal recessive diseases are routinely available.
12. In each normal female somatic cell, one of the two X chromosomes is inactivated early in embryonic development. X inactivation is random, fixed, and incomplete (i.e., only part of the chromosome is inactivated) and involves methylation.
13. Gender is determined embryonically by the presence of the *SRY* gene on the Y chromosome. Embryos that have a Y chromosome (and thus the *SRY* gene) become males, whereas those lacking the Y chromosome become females. When the Y chromosome lacks the *SRY* gene, an XY female can be produced. Similarly, an X chromosome that contains the *SRY* gene can produce an XX male.
14. Sex linked inheritance is caused by mutations in genes on sex chromosomes. X-linked genes are those that are located on the X chromosome. Nearly all known X-linked diseases are caused by X-linked recessive genes.
15. Males are hemizygous for genes on the X chromosome. If a male inherits a recessive disease gene on the X chromosome, he will be affected by the disease because the Y chromosome does not carry a normal allele to counteract the effects.
16. X-linked recessive inheritance produces traits more often in males than in females because males need only one copy of the gene to express the disease. Because a father can give a son only a Y chromosome, biologic fathers cannot pass X-linked genes to their sons. Skipped generations often are seen in X-linked recessive disease pedigrees because the gene can be transmitted through carrier females. The gene is passed from an affected father to his daughters, who transmit to approximately half of their sons.

17. Recurrence risks for X-linked recessive diseases depend on the carrier and affected status of the mother and father.
18. A sex-limited trait is one that occurs only in one sex (gender). A sex-influenced trait is one that occurs more often in one sex than in the other.

Linkage Analysis and Gene Mapping

1. During meiosis I, crossover occurs and can cause recombination of alleles located on the same chromosome. Loci that are located very close to one another are unlikely to experience recombination and are said to demonstrate linkage.
2. The major goals of the Human Genome Project were to find the locations of all human genes (the "gene map") and to determine the entire human DNA sequence. These goals have now been accomplished and the genes responsible for approximately 5000 mendelian conditions have been identified.

- Multifactorial Disorders in the Adult Population 174

Chapter 4 focuses on diseases that are caused by single genes or by abnormalities of single chromosomes. Much progress has been made in identifying specific mutations that cause these diseases, leading to better risk estimates and, in some cases, more effective treatment of the disease. However, these conditions form only a portion of the total burden of human genetic disease. Most congenital malformations are not caused by single genes or chromosome defects. Many common adult diseases, such as cancer, heart disease,

and diabetes, have genetic components, but again they are usually not caused by single genes or by chromosomal abnormalities. These diseases, whose treatment collectively occupies the attention of most healthcare practitioners, are the result of a complex interplay of multiple genetic and environmental factors.

Factors Influencing Incidence of Disease in Populations

Concepts of Incidence and Prevalence

How common is a given disease, such as diabetes, in a population? Well-established measures are used to answer this question.

The **incidence rate** is the number of new cases of a disease reported during a specific period (typically 1 year) divided by the number of individuals in the population. The denominator is often expressed as *person-years*. The incidence rate can be contrasted with the **prevalence rate**, which is the proportion of the population affected by a disease at a specific point in time. Prevalence is thus determined by both the incidence rate and the length of the survival period in affected individuals. For example, the prevalence rate of acquired immunodeficiency syndrome (AIDS) is larger than the yearly incidence rate because most people with AIDS survive for at least several years after diagnosis.

Many diseases vary in prevalence from one population to another. Cystic fibrosis is relatively common among Europeans, occurring approximately once in every 2500 births. In contrast, it is quite rare in Asians, occurring only once in every 90,000 births. Similarly, sickle cell disease affects approximately 1 in 600 American Blacks, but it is seen much less frequently in Whites. Both diseases are single-gene disorders, and they vary among populations because disease-causing mutations are common in different populations. (This is in turn the result of differences in the evolutionary history of these populations.) Nongenetic (environmental) factors have little influence on the current prevalence of these diseases.

The picture often becomes more complex with the common diseases of adulthood. For example, colon cancer was until recently relatively rare in Japan, but it is the second most common cancer in the United States. In contrast, stomach cancer is common in Japan but relatively rare in the United States. These statistics, in themselves, cannot distinguish environmental from genetic influences in the two populations. However, because large numbers of Japanese emigrated first to Hawaii and then to the US mainland, we can observe what happens to the rates of stomach and colon cancer among the migrants. It is important that the Japanese émigrés maintained a genetic identity, marrying largely among themselves. Among first-generation Japanese in Hawaii, the frequency of colon cancer rose several-fold—not yet as high as in the US mainland but higher than that in Japan. Among second-generation Japanese on the US mainland, colon cancer rates rose to 5%, equal to the US average. At the same time, stomach cancer has become relatively rare among Japanese Americans.

These observations strongly indicate an important role for environmental factors in the etiology of cancers of the colon and stomach. In each case, diet is a likely culprit—a high-fat, low-fiber diet in the United States is thought to increase the risk of colon cancer, whereas techniques used to preserve and season the fish commonly eaten in Japan are thought to increase the risk of stomach cancer. It is interesting that the incidence of colon cancer in Japan has increased dramatically during the past several decades as the Japanese population has adopted a more "Western" diet. However, these results do not rule out the potential contribution of genetic factors in common cancers. Genes also play a role in the etiology of colon and other cancers.

Analysis of Risk Factors

The comparison just discussed is one example of the analysis of risk factors (in this case, diet) and their influence on the prevalence of disease in populations. A common measure of the effect of a specific risk factor is the **relative risk**. This quantity is expressed as a ratio:

Increased rate of the disease among individuals exposed to a risk factorIncidence rate of the disease among individuals not exposed to a risk factor

A classic example of a relative risk analysis was carried out in a sample of more than 40,000 British physicians to determine the relationship between cigarette smoking and lung cancer. This study compared the incidence of death from lung cancer in physicians who smoked with those who did not. The incidence of death from lung cancer was 1.66 (per 1000 person-years) in heavy smokers (more than 25 cigarettes daily), but it was only 0.07 in the nonsmokers. The ratio of these two incidence rates is 1.66/0.07, which yields a relative risk of 23.7. Thus it is concluded that the risk of dying from lung cancer increased by approximately 24-fold in heavy smokers compared with nonsmokers. Many other studies have obtained similar risk figures.

Although cigarette smoking clearly increases one's risk of developing lung cancer (as well as heart disease, as will be seen later), it is equally clear that *most* smokers do not develop lung cancer. Other lifestyle factors are likely to contribute to one's risk of developing this disease (e.g., exposure to cancer-causing substances in the air, such as asbestos fibers). In addition, differences in genetic background may be involved. Smokers who have variants in genes that are involved in the metabolism of components of tobacco smoke (e.g., *CYP1A1* and *GSTM1*) are at significantly increased risk of developing lung cancer.

Many factors can influence the risk of acquiring a common disease such as cancer, diabetes, or high blood pressure. These include age, gender, diet, amount of exercise, and family history of the disease. Usually, complex interactions occur among these genetic and nongenetic factors. The effects of each factor can be quantified in terms of relative risks. The following discussion demonstrates how genetic and environmental factors contribute to the risk of developing common diseases.

Principles of Multifactorial Inheritance

Basic Model

Traits in which variation is thought to be caused by the combined effects of multiple genes are **polygenic** ("many genes"). When environmental factors are also believed to cause variation in the trait, which is usually the case, the term **multifactorial trait** is used.[1]

Many **quantitative traits** (those, such as blood pressure, that are measured on a continuous numeric scale) are multifactorial. Because they are caused by the additive effects of many genetic and environmental factors, these traits tend to follow a normal, or bell-shaped, distribution in populations.

An example illustrates this concept. To begin with the simplest case, suppose (unrealistically) that height is determined by a single gene with two alleles, *A* and *a*. Allele *A* tends to make people tall, whereas allele *a* tends to make them short. If there is no dominance at this locus, then the three possible genotypes *(AA, Aa, aa)* will produce three phenotypes: tall, intermediate, and short, respectively. Assume that the gene frequencies of *A* and *a* are each 0.50. When looking at a population of individuals, the height distribution depicted in Fig. 5.1A, will be observed.

FIG. 5.1 Distribution of Height. **(A)** Distribution of height in a population, assuming that height is controlled by a single locus with genotypes *AA, Aa*, and *aa*. **(B)** Distribution of height, assuming that height is controlled by two loci. Five distinct genotypes are shown instead of three, and the distribution begins to look more like the normal distribution. **(C)** Height is portrayed, realistically, as a trait with a continuous statistical distribution. Because many genes contribute to height and tend to segregate independently of one another, the cumulative contribution of different combinations of alleles to height forms a continuous distribution of possible heights, in which the extremes are much rarer than the intermediate values. Variation also can be caused by environmental factors such as nutrition. (**A** and **B**, Adapted from Jorde LB, Carey JC, Bamshad MJ. *Medical genetics*, 6th edition. Philadelphia: Elsevier; 2020; C, From Raven PH, et al. *Biology*, 8th edition. New York: McGraw-Hill; 2008.

A. A bar chart represents the distribution of population frequency in single genotypes. The horizontal axis represents the genotypes a a, A a, and A A. Data from the diagram are as follows. A a: less frequency; A a: High frequency; A A: Less frequency. B. A bar chart represents the distribution of population frequency in double genotypes. The horizontal axis represents the genotypes a a b b, A a B b, a a B B, A a B B, A A B B, A a b b, A a B b, A A B b, and A A B B. Data from the diagram are as

follows. A a b b: Less frequency; a a B b, A a b b: Medium frequency; a a B B; A a B b, A A b b: High frequency; A a B B, A A B b: Medium frequency; A A B B: Less frequency. All data are approximate. C. A histogram represents the relation between height and the number of individuals. The horizontal axis represents the height, and the vertical axis represents the number of individuals. The bar shows the statistical distribution from 5 feet 0 inches, 5 feet 6 inches, and 20. 0 through 6 feet 0 inches, 0. A curve is plotted from (0, 0) through (5 feet 5 inches, 25), (6 feet 0 inches, 5). All data are approximate.

Now suppose, a bit more realistically, that height is determined by two loci instead of one. The second locus also has two alleles, *B* (tall) and *b* (short), and they affect height in exactly the same way as alleles *A* and *a*. There are now nine possible genotypes in our population: *aabb*, *aaBb*, *aaBB*, *Aabb*, *AaBb*, *AaBB*, *AAbb*, *AABb*, and *AABB*. An individual may have zero, one, two, three, or four "tall" alleles, so now five distinct phenotypes are possible (see Fig. 5.1B). Although the height distribution in this fictional population is still not normal compared with an actual population, it approaches a normal distribution more closely than in the single-gene case just described.

From extension of this example, *many* genes and environmental factors influence height, each having a small effect. Then many phenotypes are possible, each differing slightly from the others, and the height distribution of the population approaches the bell-shaped curve shown in Fig. 5.1C.

It should be emphasized that the individual genes underlying a multifactorial trait such as height follow the mendelian principles of segregation and independent assortment, just like any other gene.

The only difference is that many of them *act together* to influence the trait. More than 400 genes have now been shown to be associated with variation in human height.

Blood pressure is another example of a multifactorial trait. A correlation exists between parents' blood pressures (systolic and diastolic) and those of their children. The evidence is good that this correlation is partially caused by genes, but blood pressure is also influenced by environmental factors, such as diet, exercise, and stress. Two goals of genetic research are the identification and measurement of the relative roles of genes and environment in the causation of multifactorial diseases.

Threshold Model

Several diseases do not follow the bell-shaped distribution. Instead, they appear to be either present or absent in individuals, yet they do not follow the inheritance patterns expected of single-gene diseases. A commonly used explanation for such diseases is that there is an underlying **liability distribution** for the disease in a population (Fig. 5.2).

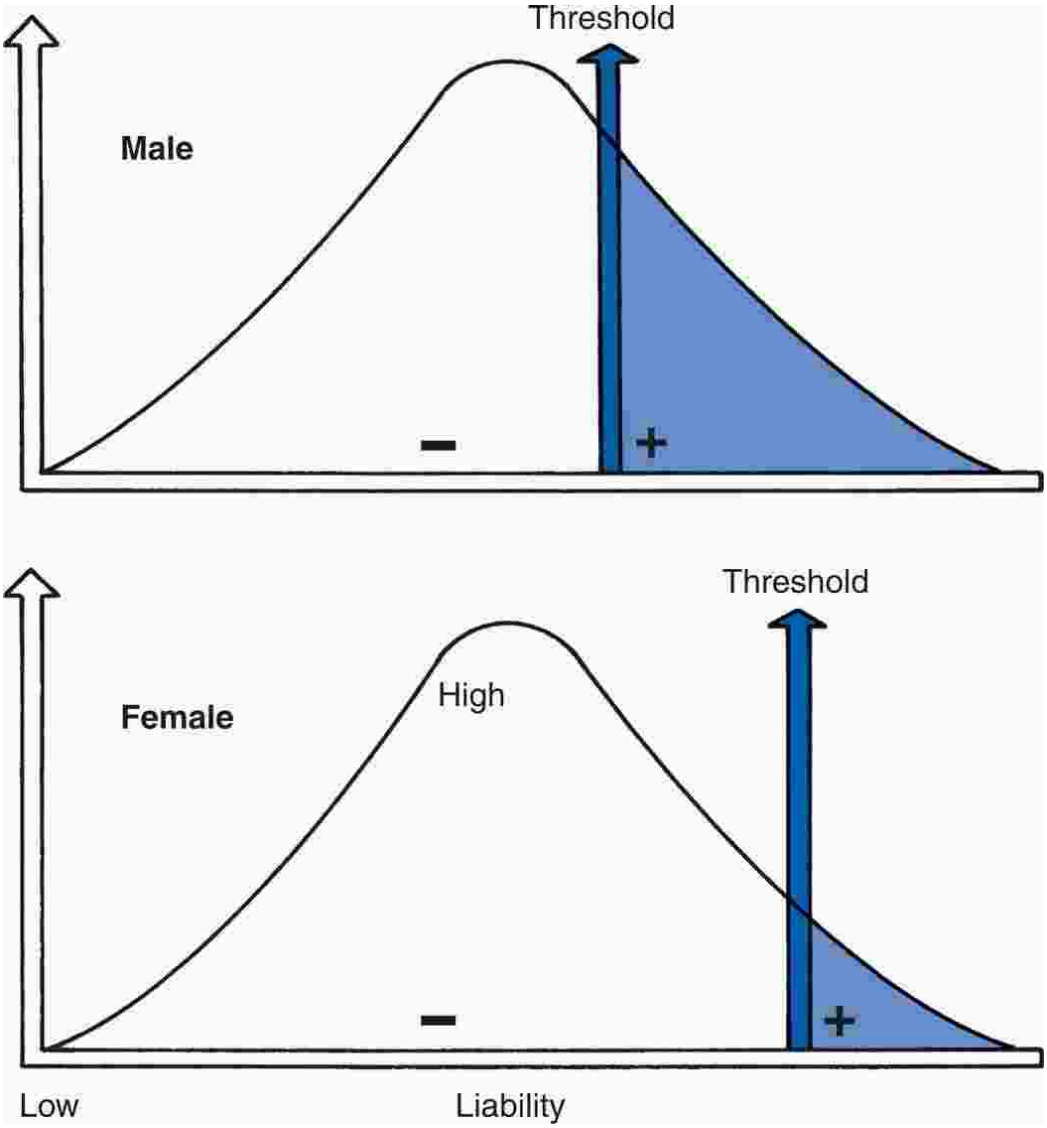

FIG. 5.2 Threshold of Liability for Pyloric Stenosis in Males and Females. To be affected with the disease, an individual must exceed the threshold on the liability distribution. This figure shows two thresholds, a lower one for males and a higher one for females (as in pyloric stenosis; see text). (From Jorde LB, Carey JC, Bamshad MJ. *Medical genetics*, 6th edition. Philadelphia: Elsevier; 2020)

Two graphs represent the liability threshold for pyloric stenosis in males and females. The graph on

the top depicts the threshold of liability for pyloric stenosis in males, which shows a bell-shaped curve with an upward arrow indicating a lower threshold. The graph on the bottom depicts the threshold of liability for pyloric stenosis in the female, which shows a bell-shaped curve with an upward arrow indicating a higher threshold.

Those individuals who are on the "low" end of the distribution have little chance of developing the disease in question (i.e., they have few of the alleles or environmental factors that would cause the disease). Individuals who are closer to the "high" end of the distribution have more of the disease-causing genes and environmental factors and are more likely to develop the disease. For diseases that are either present or absent, it is thought that a **threshold of liability** must be crossed before the disease is expressed. Below the threshold, an individual appears normal; above it, he or she is affected by the disease.

A disease that is thought to correspond to this threshold model is *pyloric stenosis*, a disorder that presents shortly after birth and is caused by a narrowing or obstruction of the pylorus, the area between the stomach and intestine. Chronic vomiting, constipation, weight loss, and imbalance of electrolyte levels result from the condition, but it sometimes resolves spontaneously or can be corrected by surgery. The prevalence of pyloric stenosis is approximately 3 per 1000 live births in Whites. It is much more common in males than females, affecting 1 of 200 males and 1 of 1000 females. It is thought that this difference in prevalence reflects two thresholds in the liability distribution—a lower one in males and a higher one in females (see Fig. 5.2). A lower male threshold implies that fewer disease-causing factors are required to generate the disorder in males.

The liability threshold concept may explain the pattern of recurrence risks for pyloric stenosis seen in Table 5.1. Note that males, having a lower threshold, always have a higher risk than females. However, the sibling recurrence risk also depends on the sex of the proband (i.e., the first affected individual diagnosed in a family). It is higher when the proband is female than when the proband is male. This reflects the concept that females, having a higher liability threshold, must be exposed to more disease-causing factors than males to develop the disease. Thus a family with an affected female must have more genetic and environmental risk factors, producing a higher recurrence risk for pyloric stenosis in future offspring. It would be expected that the highest risk category would be *male* relatives of *female* probands; Table 5.1 shows that this is the case.

Table 5.1

Recurrence Risks (%) for Pyloric Stenosis, Subdivided by Genders of Affected Probands and Relatives

Relatives	MALE PROBANDS		FEMALE PROBANDS	
	London	Belfast	London	Belfast
Brothers	3.8	9.6	9.2	12.5
Sisters	2.7	3.0	3.8	3.8

Relatives	MALE PROBANDS		FEMALE PROBANDS	
	London	Belfast	London	Belfast
Brothers	3.8	9.6	9.2	12.5
Sisters	2.7	3.0	3.8	3.8

NOTE: The risks differ somewhat between the two populations.

Data from Carter CO. Genetics of common single malformations. *British Medical Bulletin*, 1976;32(1):21–26.

A similar pattern has been observed in studies of *autism spectrum disorder*, a behavioral disorder in which the male to female ratio is close to 3:1.[2] As expected for a multifactorial disorder, the recurrence risk for siblings of male probands (6.6) is lower than that of siblings of female probands (10.2).[3] When the sex ratio for a disease is reversed (i.e., more affected females than males), one would expect a higher recurrence risk when the proband is male.

Several other congenital malformations are thought to correspond to this model. They include isolated *cleft lip and/or cleft palate (CL/P), neural tube defects (anencephaly, spina bifida), clubfoot (talipes)*, and some forms of congenital heart disease. In this context, "isolated" means that this is the only observed disease feature (i.e., the feature is not part of a larger constellation of findings, as in CL/P secondary to trisomy 13). In addition, many common adult diseases, such as *hypertension, coronary heart disease* (CHD), *stroke, diabetes mellitus* (types 1 and 2), and *some cancers*, are caused by complex genetic and environmental factors and can thus be considered multifactorial diseases.

Recurrence Risks and Transmission Patterns

Although sibling recurrence risks can be given with confidence for single-gene diseases (e.g., 50% for typical autosomal dominant diseases, 25% for autosomal recessive diseases), the situation is more complicated for multifactorial diseases. This is because the number of genes contributing to the disease is usually not known, the precise allelic constitution of the parents is not known, and the extent of environmental effects can vary substantially. For most multifactorial diseases, **empirical risks** (i.e., risks based on direct observation of data) have been derived. To estimate empirical risks, a large series of families is examined in which one child has developed the disease (the proband). Then the siblings of each proband are surveyed to calculate the percentage of siblings who also have developed the disease. For example, in the United States approximately 3% of siblings of individuals with neural tube defects also have neural tube defects (Box 5.1). Thus the recurrence risk for parents who have had

one child with a neural tube defect is 3% in the United States. For conditions such as CL/P that are not lethal or severely debilitating, recurrence risks also can be estimated for the offspring of affected parents. Because each multifactorial disease has different numbers and types of risk factors, empirical recurrence risks vary for each disease.

Box 5.1

Neural Tube Defects

Neural tube defects (NTDs), which include *anencephaly*, *spina bifida*, and *encephalocele* (as well as several other less common forms), are one of the most important classes of birth defects, and they are seen in 0.5–2 of 1000 pregnancies. The prevalence of NTDs among different populations varies considerably, with an especially high rate among some northern Chinese populations (as high as 6 or more per 1000 births). The prevalence of NTDs has been decreasing in many parts of the United States and Europe during the past three decades, partly because of dietary changes.

Normally the neural tube closes at approximately the fourth week of gestation. A defect in closure, or a subsequent reopening of the neural tube, results in a neural tube defect. Spina bifida (see Fig. 5.4A) is the most observed NTD and consists of a protrusion of spinal tissue through the vertebral column (the tissue usually includes meninges, spinal cord, and nerve roots). Approximately 75% of individuals with spina bifida have secondary hydrocephalus, which sometimes in turn produces intellectual disability. Paralysis or muscle weakness, lack of sphincter control, and clubfeet are often observed. A study conducted in British Columbia showed that survival rates for people with spina bifida have improved dramatically over the past several decades. Less than 30% of people born between 1952 and 1969 survived to 10 years of age, whereas 65% of those born between 1970 and 1986 survived to this age. Anencephaly (see Fig. 5.4B) is characterized by partial or complete absence of the cranial vault and calvarium

and partial or complete absence of the cerebral hemispheres. At least two-thirds of newborns with anencephaly are stillborn; term deliveries do not survive more than a few hours or days.

NTDs are thought to arise from a combination of genetic and environmental factors. In most populations surveyed thus far, empirical recurrence risks for siblings of affected people range from 2% to 5%. Consistent with a multifactorial model, the recurrence risk increases with additional affected siblings. Studies conducted in Great Britain showed that the sibling recurrence risk was approximately 5% when one sibling was affected and 10% when two were affected. A Hungarian study showed that the overall prevalence of NTDs was 1 in 300 births and that the sibling recurrence risks were 3%, 12%, and 25% after one, two, and three affected offspring, respectively. Recurrence risks tend to be slightly lower in populations with lower NTD prevalence rates, as predicted by the multifactorial model. Recurrence risk data support the idea that the major forms of NTDs are caused by similar factors. An anencephalic conception increases the recurrence risk for subsequent spina bifida conceptions, and vice versa.

NTDs can usually be diagnosed prenatally, sometimes by ultrasound and usually by an elevation in α-fetoprotein (AFP) level in the maternal serum or amniotic fluid (see Chapter 20). A spina bifida lesion can be either open or closed (i.e., covered with a layer of skin). Fetuses with open spina bifida are more likely to be detected by AFP assays.

A major epidemiologic finding is that mothers who supplement their diet with folic acid at the time of conception are less likely to produce children with NTDs. This result has been replicated in several different populations and thus appears to be well confirmed. It has been estimated that as many as 50% to 70% of NTDs can be avoided simply by dietary folic acid supplementation. (Traditional prenatal vitamin supplements have little effect because administration does not usually begin until well after the time that the neural tube closes.) It is now recommended that all women of reproductive age supplement

their diet with 0.4 mg of folic acid each day; many foods in the United States are supplemented with folic acid. Consequently, average folate levels in US females have doubled, and the incidence of neural tube defects has declined by 30% to 50% in the past decade.

Because mothers would be likely to ingest similar amounts of folic acid from one pregnancy to the next, folic acid deficiency could well account for at least part of the elevated sibling recurrence risk for NTDs. This is an important example of a *nongenetic* factor that contributes to familial clustering of a disease. It is likely that there is genetic variation in response to folic acid, which helps to explain why most mothers with folic acid deficiency do not bear children with NTDs and why some who ingest adequate amounts of folic acid nonetheless bear children with NTDs. To address this issue, researchers are testing for associations between NTDs and variants in several genes whose products (e.g., methylene tetrahydrofolate reductase) are involved in folic acid metabolism.

Data from Copp AJ, Stanier P, Greene ND. Neural tube defects: Recent advances, unsolved questions, and controversies. *Lancet Neurology*, 2013;12(8):799– 810; Daly LE, Kirke PN, Molloy A, et al. Folate levels and neural tube defects: implications for prevention. *JAMA*, 1995;274(21):1698–1702.

In contrast to most single-gene diseases, recurrence risks for multifactorial diseases can change substantially from one population to another because gene frequencies as well as environmental factors can differ among populations (note the differences between the London and Belfast populations in Table 5.1).

It is sometimes difficult to distinguish polygenic or multifactorial diseases from single-gene diseases that have reduced penetrance or variable expression. Large data sets and good epidemiologic data are necessary to make the distinction. Several criteria are commonly used to define multifactorial inheritance.

First, *the recurrence risk becomes higher if more than one family member is affected*. For example, the sibling recurrence risk for a *ventricular*

septal defect (VSD, a type of congenital heart defect) is 3% if one sibling has been affected by a VSD but increases to approximately 10% if two siblings have been diagnosed with VSDs.[4] The same trend is seen for other multifactorial diseases such as neural tube defects and autism. In contrast, the recurrence risk for single-gene diseases remains the same regardless of the number of affected siblings. It should be emphasized that this increase does not mean that the family's risk has changed. Rather, it means that there is more information about the family's true risk; because they have had two affected children, they are probably located higher on the liability distribution than a family with only one affected child. In other words, they have more risk factors (genetic or environmental) and are more likely to produce an affected child.

Second, *if the expression of the disease in the proband is more severe, the recurrence risk is higher*. This is again consistent with the liability model because a more severe expression indicates that the affected individual is at the extreme tail end of the liability distribution (see Fig. 5.2). His or her relatives are thus at a higher risk for inheriting disease genes. For example, the occurrence of a bilateral (both sides) CL/P confers a higher recurrence risk on family members than does the occurrence of a unilateral (one side) cleft.

Third, *the recurrence risk is higher if the proband is of the less commonly affected sex* (see the preceding discussion of pyloric stenosis). This is because an affected individual of the less susceptible sex is usually at a more extreme position on the liability distribution.

Fourth, *the recurrence risk for the disease usually decreases rapidly in more remotely related relatives* (Table 5.2). Although the recurrence risk for single-gene diseases decreases by 50% with each degree of relationship (e.g., an autosomal dominant disease has a 50% recurrence risk for siblings, 25% for uncle-nephew relationships, 12.5% for first cousins), it decreases much more quickly for multifactorial diseases. This reflects the fact that many genes and environmental factors must combine to produce a trait. All the necessary risk factors are unlikely to be present in less closely related family members.

Table 5.2

Recurrence Risks (%) for First-, Second-, and Third-Degree Relatives

Degree	RISK			
	First Degree	Second Degree	Third Degree	General Population
Cleft lip/palate	4	0.7	0.3	0.1
Clubfoot	2.5	0.5	0.2	0.1
Congenital hip dislocation	5	0.6	0.4	0.2

Degree	RISK			
	First Degree	Second Degree	Third Degree	General Population
Cleft lip/palate	4	0.7	0.3	0.1
Clubfoot	2.5	0.5	0.2	0.1
Congenital hip dislocation	5	0.6	0.4	0.2

Finally, *if the prevalence of the disease in a population is f, the risk for offspring and siblings of probands is approximately* $\sqrt{f}$. This does not hold true for single-gene traits because their recurrence risks are largely independent of population prevalence. It is not an absolute rule for multifactorial traits either, but many such diseases tend to conform to this prediction. Examination of the risks given in Table 5.2 shows that the first three diseases follow the prediction well. However, the observed sibling risk for the fourth disease, infantile autism, is substantially higher than that predicted by $\sqrt{f}$.

Nature and Nurture: Disentangling the Effects of Genes and Environment

Family members share genes and a common environment. Family resemblance in traits such as blood pressure reflects both genes (nature) and environment (nurture). For centuries people have debated the relative importance of these two types of factors. It is a

mistake, of course, to view them as mutually exclusive. Few traits are influenced only by genes or only by environmental factors. Most are influenced by both. It is useful to try to determine the *relative* influence of genetic and environmental factors (Fig. 5.3). See Emerging Science Box: Polygenic Risk Scores and Disease Prediction for more information on polygenic risk scores and disease prediction. This can lead to a better understanding of disease etiology. It can also help in planning public health strategies. A disease in which the genetic influence is relatively small, such as lung cancer, may be prevented most effectively through emphasis on lifestyle changes (avoidance of tobacco). When a disease has a relatively larger genetic component, as in breast cancer, examination of family history should be emphasized in addition to lifestyle modification. Here, two research strategies are reviewed that often are used to estimate the relative influence of genes and environment: twin studies and adoption studies.

FIG. 5.3 Continuum of Genetic Diseases. Some diseases (e.g., cystic fibrosis) are strongly determined by genes, whereas others (e.g., infectious diseases) are strongly determined by environmental factors. (From Jorde LB, Carey JC, Bamshad MJ. *Medical genetics*, 6th edition. Philadelphia: Elsevier; 2020.)

An illustration of the continuum depicts the relative influence of genetic factors and environmental and lifestyle factors. The environmental, lifestyle and genetic factor determines influenza, measles, diabetes, and heart disease. Genetic factor determines cystic fibrosis and hemophilia A.

Twin Studies

Twins occur with a frequency of approximately 1 in 100 births in White populations. They are a bit more common in Blacks and a bit less common among Asians. **Monozygotic (MZ, identical) twins** originate when the developing embryo divides to form two separate but identical embryos. Because they are genetically identical, MZ twins are an example of natural clones. **Dizygotic (DZ, fraternal) twins** are the result of a double ovulation followed by the fertilization of each egg by a different sperm. Thus DZ twins are genetically no more similar than siblings. Because two different

sperm cells are required to fertilize the two eggs, it is possible for each DZ twin to have a different father. MZ twinning rates are constant across populations, whereas DZ twinning rates vary somewhat. DZ twinning increases with maternal age until approximately 40 years, after which it declines.

Because MZ twins are genetically identical, any differences between them should be caused only by environmental effects.[5] MZ twins should thus resemble one another very closely for traits that are strongly influenced by genes. DZ twins provide a convenient comparison because their environmental differences should be like those of MZ twins but their genetic differences are as great as those between siblings. Twin studies thus usually consist of comparisons between MZ and DZ twins.[6]

If both members of a twin pair share a trait (e.g., a CL), they are said to be **concordant**. If they do not share the trait, they are **discordant**. For a trait determined totally by genes, MZ twins should always be concordant, whereas DZ twins should be concordant less often, because they, like full siblings, share only 50% of their DNA. Concordance rates may differ between opposite-sex DZ twin pairs and same-sex DZ pairs for some traits, such as those that have different frequencies in males and females. For such traits, only same-sex DZ twin pairs should be used when comparing MZ and DZ concordance rates, because MZ twins are necessarily of the same sex.

Emerging Science Box Polygenic Risk Scores and Disease Prediction

The great majority of DNA variants associated with common diseases have only a small effect on disease risk. Individually, they have little value in predicting disease risk. However, by amalgamating the predicted effects of these variants, it is possible to identify a portion of the population that has a significantly elevated risk of disease. The **polygenic risk score** (also sometimes termed genetic risk score) adds the effects of many disease-

associated variants together. For everyone, the number of copies of a disease-associated variant (either 0, 1, or 2) is weighted (multiplied) by the increase in risk associated with the variant (e.g., a variant that increases risk by 5% could have a weight of 0.05, while a variant that increases risk by 10% would have a weight of 0.10). The weighted effects of all disease-associated variants are then added together to yield the risk score for an individual.

As discussed in the text, genetic studies have revealed hundreds of DNA variants associated with nearly every common disease (e.g., heart disease, common cancers, diabetes, psychiatric diseases). Polygenic risk scores have now been estimated for these diseases. Persons with high scores (e.g., top 1%, or top 5%, representing the right tail of the distribution shown in Fig. 5.7) have substantial elevations in disease risk. The increase in risk, which is typically on the order of threefold to fivefold, is like the elevation in risk associated with some single-gene disorders, such as autosomal dominant familial hypercholesterolemia.

Polygenic risk score estimation can be sensitive to the same factors that influence disease identification studies, such as differences in genetic ancestry. Thus a score estimated for one population group (e.g., East Asians) is unlikely to be accurate for another. Before polygenic risk scores are used widely in the clinical setting, it will be important to validate them with extensive follow-up studies. With appropriate evaluation and validation, polygenic risk scores have the potential to identify members of the population who may need earlier or more aggressive screening or intervention. Their use could become an important component of precision medicine.

Data from Khera AV, et al. Genome-wide polygenic scores for common diseases identify individuals with risk equivalent to monogenic mutations. *Nature Genetics*, 2018;50(9):1219–1224. https://doi.org/10.1038/s41588-018-0183-z

Table 5.3 gives concordance rates for several traits. Note that the concordance rates for contagious diseases such as measles are quite similar in MZ and DZ twins. This is expected because a contagious

disease is unlikely to be influenced markedly by genes. In contrast, the concordance rates are quite dissimilar for *schizophrenia* and *bipolar affective disorder*, suggesting a sizable genetic component for these diseases. The MZ correlations for dermatoglyphics (fingerprints), which are determined almost entirely by genes, are close to 1.0.

Table 5.3

Concordance Rates in Monozygotic and Dizygotic Twins for Selected Traits and Diseases

Trait or Disease	CONCORDANCE RATE		
	MZ Twins	DZ Twins	Heritability

DZ, Dizygotic; *MZ*, monozygotic.

[a]Several heritability estimates exceed 1. Because it is impossible for greater than 100% of the variance of a trait to be genetically determined, these values indicate that other factors, such as shared environmental factors, must be operating.

[b]Because these are quantitative traits, correlation coefficients are given rather than concordance rates.

NOTE: Heritability, which is defined as the proportion of the variation in a trait that is due to genetic factors, can be measured as $2(C_{MZ} - C_{DZ})$, where C_{MZ} and C_{DZ} are the concordance rates for MZ twins and DZ twins, respectively. These figures were compiled from a large variety of sources and represent primarily European and US populations.

At one time, twins were thought to provide a perfect "natural laboratory" in which to determine the relative influences of genetics and environment, but several difficulties arose. One of the most important is the assumption that the environments of MZ and DZ twins are equally similar. As one would expect, MZ twins are often treated more similarly than DZ twins. A greater similarity in environment can make MZ twins more concordant for a trait, inflating the apparent influence of genes. In addition, MZ twins may be more likely to seek the same type of environment, further reinforcing environmental similarity. On the other hand, it has been suggested that MZ twins tend to develop personality differences to assert their individuality.

Adoption Studies

Studies of adopted children also are used to estimate the genetic contribution to a multifactorial trait. Children born to parents who have a disease but are then subsequently adopted by parents lacking the disease can be studied to find out whether these children develop the disease. In some cases, such children develop the disease more often than a comparative control population (i.e., adopted children who were born to parents who do *not* have the disease). This provides some evidence that genes may be involved in the

causation of the disease, because the adopted children do not share an environment with their affected natural parents. For example, approximately 8% to 10% of adopted children of a schizophrenic parent develop *schizophrenia*, whereas only 1% of adopted children of unaffected parents develop schizophrenia.

As with twin studies, several precautions must be exercised in interpreting the results of adoption studies. First, prenatal environmental influences could have long-lasting effects on an adopted child. Second, children are sometimes adopted after they are several years old, ensuring that some environmental influence would have been imparted by the natural parents. Finally, adoption agencies sometimes try to match the adoptive parents with the natural parents in terms of background, socioeconomic status, and other factors. All these factors could exaggerate the apparent influence of biologic inheritance.[7]

These reservations, as well as those summarized for twin studies, underscore the need for caution in basing conclusions on twin and adoption studies. These approaches do not provide definitive measures of the role of genes in multifactorial disease, nor can they identify specific genes responsible for disease. Instead, they serve a useful purpose in providing a preliminary indication of the extent to which a multifactorial disease may be caused by genetic factors. Sophisticated molecular techniques are being used to identify the specific genes that underlie predisposition to multifactorial diseases.

This discussion should make clear that most common diseases are not the result of either genetics *or* environment. Instead, genetic and nongenetic factors usually interact to influence one's likelihood of developing a common disease. In some cases, a genetic predisposition may interact with an environmental factor to increase the risk of disease acquisition to a much higher level than would either factor acting alone. A good example of a **gene-environment interaction** is given by α_1-antitrypsin deficiency, a genetic condition that causes pulmonary emphysema and is greatly exacerbated by cigarette smoking (Box 5.2).

Box 5.2

α1-Antitrypsin Deficiency: Interaction of Genes and Environment-Lifestyle

α_1-Antitrypsin (AAT) deficiency is one of the most common autosomal recessive disorders among Whites, affecting approximately 1 in 2500 members of this ethnic group. AAT, synthesized primarily in the liver, is a serine protease inhibitor. It does bind trypsin, as its name suggests. However, AAT binds much more strongly to neutrophil elastase, a protease that is produced by neutrophils (a type of leukocyte) in response to infections and irritants. It carries out its binding and inhibitory role primarily in the lower respiratory tract, where it prevents elastase from digesting the alveolar septi of the lung.

Individuals with less than 10%–15% of the normal level of AAT activity will experience significant lung damage and typically develop emphysema during their 30 s, 40 s, or 50 s. In addition, at least 10% develop liver cirrhosis because of the accumulation of variant AAT molecules in the liver; AAT deficiency accounts for nearly 20% of all nonalcoholic liver cirrhosis cases in the United States. An important feature of this disease is that cigarette smokers with AAT deficiency develop emphysema much earlier than do nonsmokers. This is because cigarette smoke irritates lung tissue, increasing secretion of neutrophil elastase. At the same time, it inactivates AAT, so there is also less inhibition of elastase. One study showed that the median age of survival of nonsmokers with AAT deficiency was 62 years, whereas it was only 40 years for smokers with this disease. Because the combination of cigarette smoking (an environmental factor) and the AAT mutation (a genetic factor) produces more severe disease than either factor alone, it is an example of a gene-environment interaction.

Typically, AAT deficiency is tested first by a straightforward assay for reduced serum AAT concentration. Because a variety of conditions can reduce serum AAT level, additional testing,

through a type of protein electrophoresis or DNA testing, is carried out to confirm a diagnosis of AAT deficiency. Direct DNA testing became feasible with the identification of *SERPINA1*, the gene that encodes AAT. More than 100 *SERPINA1* mutations have been identified, but only 2 missense variants, labeled the *S* and *Z* alleles, are common and clinically significant. Approximately 95% of cases of AAT deficiency are either *ZZ* homozygotes or *SZ* compound heterozygotes. The latter genotype generally produces less severe disease symptoms. Two large studies have indicated that the risk of developing emphysema among *ZZ* homozygotes is 70% for nonsmokers and 90% for smokers.

Genetics of Common Diseases

Some common multifactorial disorders, the congenital malformations, are present at birth. Others, including heart disease, cancer, diabetes, and most psychiatric disorders, are seen primarily in adolescents and adults. Because these disorders are complex, unraveling their genetics is a daunting task. Nonetheless, significant progress is being made.

Congenital Malformations

Congenital diseases are present at birth. Approximately 2% of newborns present with a congenital malformation; most of these are multifactorial in etiology. Table 5.4 lists some more common congenital malformations. Sibling recurrence risks for most of these disorders range from 1% to 5%.

Table 5.4

Prevalence Rates of Common Congenital Malformations in Whites

Disorder	Prevalence Per 1000 Births (Approximate)
Cleft lip/palate	1
Clubfoot	1
Congenital heart defects	4–8
Hydrocephaly	0.5–2.5
Isolated cleft palate	0.4
Neural tube defects	1–3
Pyloric stenosis	3

Some congenital malformations, such as CL/P and pyloric stenosis, are relatively easy to repair and thus are not considered to be serious problems. Others, such as neural tube defects, usually have more severe consequences. Although some cases of congenital malformations occur in the absence of any other problems, it is quite common for them to be associated with other disorders. For example, hydrocephaly and clubfoot are often seen secondary to spina bifida, CL/P is often seen in babies with trisomy 13, and congenital heart defects are seen in children with many other disorders, including Down syndrome (Fig. 5.4).

FIG. 5.4 Spina Bifida and Anencephaly. **(A)** Spina bifida in a newborn. **(B)** Anencephaly, showing the absence of the cranial vault. (From Jones KL, *Smith DM. Smith's recognizable patterns of human malformation*, 6th edition. Philadelphia: Saunders; 2006:705.)

Environmental factors also cause some congenital malformations. An example is thalidomide, a sedative used during pregnancy in the early 1960s. When ingested during early pregnancy, this drug often caused **phocomelia** (severely shortened limbs) in babies. Maternal exposure to retinoic acid, which is used to treat acne, can cause congenital defects of the heart, ear, and central nervous system. Maternal rubella infection can cause congenital heart defects.

Multifactorial Disorders in the Adult Population

Until quite recently, very little was known about specific genes responsible for common adult diseases. With the more powerful laboratory and analytic techniques now available, this situation is changing. This section reviews recent progress in understanding the genetics of the major common adult diseases.

Coronary Heart Disease

It is well known that CHD is the leading killer of Americans, accounting for approximately 25% of all deaths in the United States. It is caused by *atherosclerosis* (narrowing because of the formation of lipid-laden lesions) of the coronary arteries. This narrowing impedes blood flow to the heart and can eventually result in a *myocardial infarction* (destruction of heart tissue caused by an inadequate supply of oxygen). When atherosclerosis occurs in arteries supplying blood to the brain, a *stroke* can result. Many risk factors for heart disease have been identified, including obesity, cigarette smoking, hypertension, elevated cholesterol level, and positive family history (usually defined as having one or more affected first-degree relatives). Many studies have examined the role of family history in

CHD, and they show that an individual with a positive family history is two to seven times more likely to have heart disease than is an individual with no family history (this would be the relative risk of heart disease because of a positive family history). In general, these studies also show that the risk increases if (1) there are more affected relatives; (2) the affected relative or relatives are female (the less commonly affected sex) rather than male; and (3) the age of onset in the affected relative is early (before 55 years). For example, one study showed that men between the ages of 20 and 39 years had a relative risk of 3 for CHD if they had one affected first-degree relative. The relative risk increased to 13 if two first-degree relatives were affected with CHD before 55 years of age.[8]

What part do genes play in the familial clustering of heart disease? Because of the key role of lipids in atherosclerosis, many studies are focusing on the genetic determination of various lipoproteins.[9]

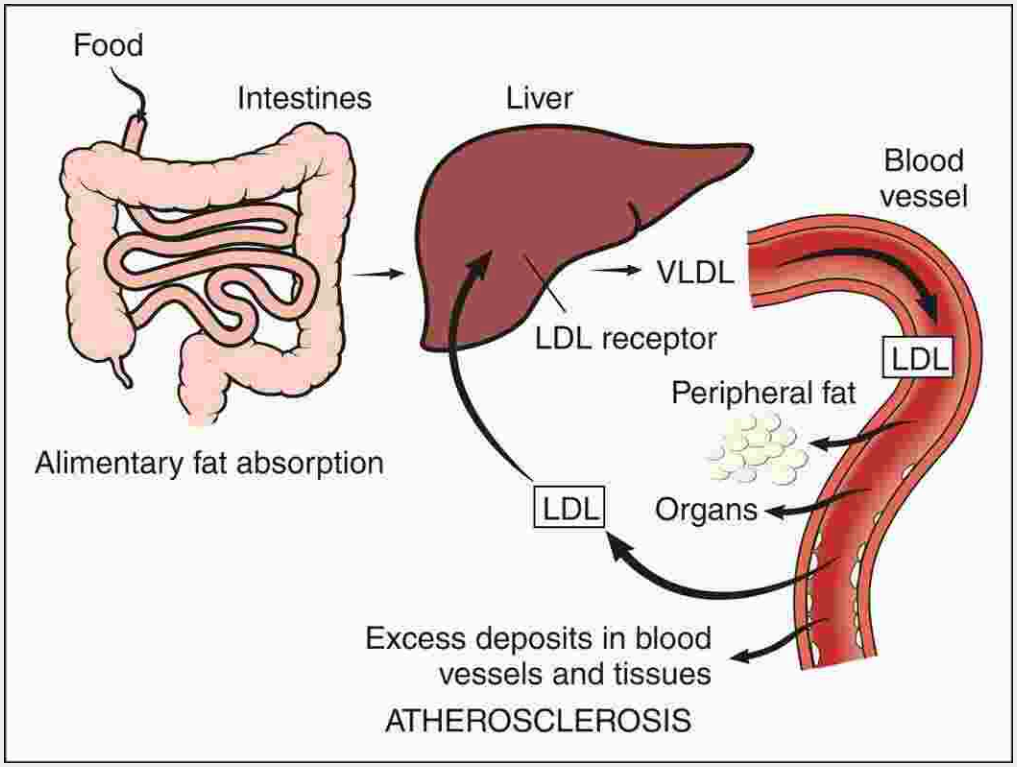
An important advance in this area has been the identification of several genes that encode the processing of low-density lipoproteins and that, when mutated, can cause *familial hypercholesterolemia* (Box 5.3). Many other genes involved in lipid variation, coagulation, and hypertension have been identified, including several genes encoding apolipoproteins (the protein components of lipoproteins) (Fig. 5.5). Functional analysis of these genes is leading to an increased understanding and eventually more effective treatment of CHD. Xanthomas, which are fatty deposits, are often noted in individuals with familial hypercholesterolemia (Fig. 5.6).[10]

Box 5.3

Familial Hypercholesterolemia

Autosomal dominant familial hypercholesterolemia (FH) is an important cause of heart disease, accounting for approximately 5% of myocardial infarctions in individuals younger than 60 years of age. FH is one of the most common autosomal dominant disorders: in most populations surveyed to date, approximately 1

in 500 people is a heterozygote. Plasma cholesterol levels are approximately twice as high as normal (i.e., approximately 300–400 mg/dL), resulting in substantially accelerated atherosclerosis and distinctive cholesterol deposits in skin and tendons (*xanthomas* [see Fig. 5.6]). Data compiled from five studies showed that approximately 75% of men with FH developed coronary disease, and 50% had a fatal myocardial infarction by 60 years. The corresponding percentages for women were lower (45% and 15%) because women generally develop heart disease at a later age than men.



Consistent with Hardy-Weinberg predictions, approximately 1 in 1 million births is homozygous for the FH gene. Homozygotes are much more severely affected, with cholesterol levels ranging from 600 to 1200 mg/dL. Most experience myocardial infarctions before 20 years of age, and a myocardial infarction at 18 months of

age has been reported. If untreated, most FH homozygotes die before 30 years of age.

All cells require cholesterol as a component of their plasma membrane. They can either synthesize their own cholesterol or, preferably, obtain it from the extracellular environment, where it is carried primarily by low-density lipoprotein (LDL). In a process known as *endocytosis*, LDL-bound cholesterol is taken into the cell via LDL receptors on the cell's surface (see Fig. 5.5). FH is most caused by a reduction in the number of functional LDL receptors on cell surfaces. Lacking the normal number of LDL receptors, cellular cholesterol uptake is reduced and circulating cholesterol levels increase.

Much of what we know about endocytosis has been learned through the study of LDL receptors. The process of endocytosis and the processing of LDL in the cell are described in detail in Fig. 5.5 (endocytosis is discussed in Chapter 1). These processes result in a fine-tuned regulation of cholesterol levels within cells, and they influence the level of circulating cholesterol as well.

The identification of the LDL receptor gene in 1984 was critical in understanding exactly how LDL receptor defects cause FH. More than 1000 different mutations, including missense and nonsense substitutions as well as insertions and deletions, have been identified in the LDL receptor gene. These can be grouped into five broad classes according to their effects on the activity of the receptor. Class 1 mutations result in no detectable protein product. Thus heterozygotes would produce only half the normal number of LDL receptors. Class 2 mutations in the LDL receptor gene result in production of the LDL receptor, but it is altered such that it cannot leave the endoplasmic reticulum. It is eventually degraded. Class 3 mutations produce an LDL receptor that can migrate to the cell surface but incapable of normal binding to LDL. Class 4 mutations, which are comparatively rare, produce receptors that are normal except that they do not migrate specifically to coated pits and thus cannot carry LDL into the cell. The final group of mutations, class 5, produces an LDL receptor that cannot dissociate from the LDL particle after entry into the

cell. The receptor cannot return to the cell surface and is degraded. Each class of mutations reduces the number of effective LDL receptors, resulting in decreased LDL uptake and hence elevated levels of circulating cholesterol. The number of effective receptors is reduced by approximately half in FH heterozygotes, and homozygotes have virtually no functional LDL receptors.

Understanding the defects that lead to FH has helped to develop effective therapies for the disorder. Dietary reduction of cholesterol (primarily through the reduced intake of saturated fats) has only modest effects on cholesterol levels in FH heterozygotes. Because cholesterol is reabsorbed into the gut and then recycled through the liver (where most cholesterol synthesis takes place), serum cholesterol levels can be reduced by the administration of bile acid–absorbing resins, such as cholestyramine. The absorbed cholesterol is then excreted. It is interesting that reduced recirculation from the gut causes the liver cells to form additional LDL receptors, lowering circulating cholesterol levels. However, the decrease in the concentration of intracellular cholesterol also stimulates cholesterol synthesis by liver cells, so the overall reduction in plasma LDL level is only approximately 15% to 20%. This treatment is much more effective when combined with agents that reduce cholesterol synthesis by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase (the "statin" class of drugs). Decreased synthesis leads to further production of LDL receptors. When these therapies are used in combination, serum cholesterol levels in FH heterozygotes can be reduced to approximately normal levels.

The picture is less encouraging for FH homozygotes. The therapies just discussed can enhance cholesterol elimination and reduce its synthesis, but they are largely ineffective because homozygotes have few or no LDL receptors. Liver transplants, which provide hepatocytes that have normal LDL receptors, have been successful in some cases, but this option is often limited by a lack of donors. Plasma exchange carried out every 1–2 weeks, in combination with drug therapy, can reduce cholesterol levels by approximately 50%. However, this therapy is difficult to continue

for long periods. Somatic cell gene therapy, in which hepatocytes carrying normal LDL receptor genes are introduced into the portal circulation, is now being tested. It may eventually prove to be an effective treatment for FH homozygotes.

FH also can be caused by inherited mutations in the gene that encodes apolipoprotein B. In addition, a small number of FH cases are caused by mutations in the gene that encodes PCSK9 (proprotein convertase subtilisin/kexin type 9), an enzyme that plays a key role in degrading LDL receptors. Gain-of-function mutations in the *PCSK9* gene reduce the number of LDL receptors, causing FH. Loss-of-function mutations in this gene can increase the number of LDL receptors, resulting in exceptionally low circulating LDL levels. These findings have led to the development of drugs that inhibit PCSK9 activity, thus lowering LDL cholesterol levels. These drugs, which have been approved for clinical use, can reduce LDL cholesterol levels by approximately 50% in the general population of persons with hypercholesterolemia and produce significant effects even in those who are using statin drugs.

The FH story illustrates how medical research has made important contributions both to our understanding of basic cell biology and to our advances in clinical therapy. The process of receptor-mediated endocytosis, elucidated largely by research on the LDL receptor defects, is of fundamental significance for cellular processes throughout the body. Equally important is that this research, by clarifying how cholesterol synthesis and uptake can be modified, has led to significant improvements in therapy for this important cause of heart disease. The discovery of rare mutations in PCSK9 has led to PCSK9 inhibitor drugs that may benefit millions of persons with high cholesterol levels.

M, Rabès JP, et al. Genetic heterogeneity of autosomal dominant hypercholesterolemia. *Clinical Genetics*, 2008;73(1):1–13.

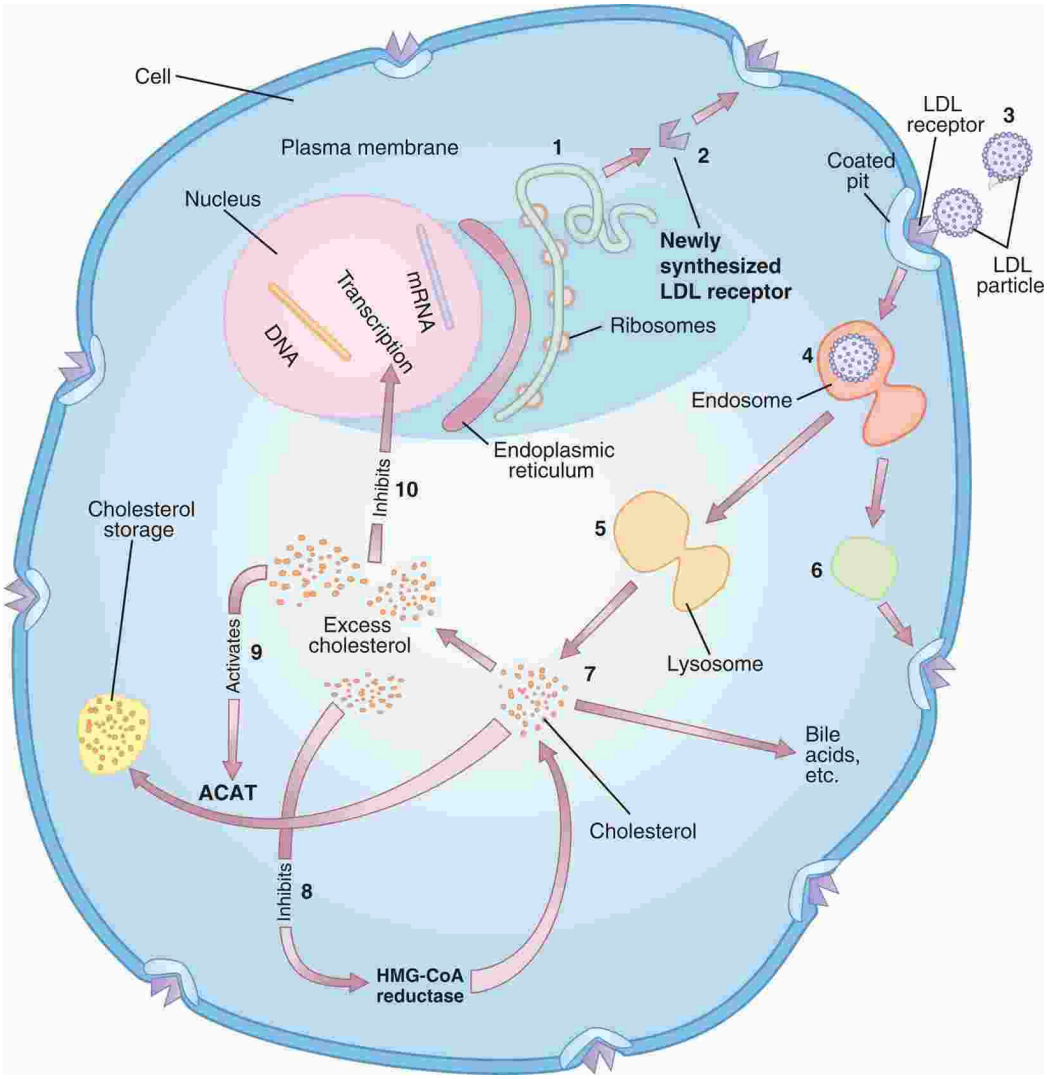

FIG. 5.5 Process of Receptor-Mediated Endocytosis. 1, The low-density lipoprotein *(LDL)* receptors, which are glycoproteins, are synthesized in the endoplasmic reticulum of the cell. *2*, From here, they pass through the Golgi apparatus to the cell surface, where part of the receptor protrudes outside the cell. *3*, The circulating LDL particle is bound by the LDL receptor and localized in cell surface depressions called *coated pits* (so named because they are coated with a protein called *clathrin*). *4*, The coated pit invaginates, bringing the LDL particle inside the cell. *5*, Once inside the cell, the LDL

particle is separated from the receptor, taken into a lysosome, and broken down into its constituents by lysosomal enzymes. *6*, The LDL receptor is recirculated to the cell surface to bind another LDL particle (each LDL receptor goes through this cycle approximately once every 10 minutes even if it is not occupied by an LDL particle). *7*, Free cholesterol is released from the lysosome for incorporation into cell membranes or metabolism into bile acids or steroids. Excess cholesterol can be stored in the cell as a cholesterol ester or removed from the cell by associating with high-density lipoprotein *(HDL). 8*, As cholesterol levels in the cell rise, cellular cholesterol synthesis is reduced by inhibition of the rate-limiting enzyme 3-hydroxy-3-methylglutaryl coenzyme A *(HMG-CoA)* reductase. *9*, Rising cholesterol levels also increase the activity of acyl coenzyme A (acyl CoA):cholesterol acyltransferase *(ACAT)*, an enzyme that modifies cholesterol for storage as cholesterol esters. *10*, In addition, the number of LDL receptors is decreased by lowering the transcription rate of the LDL receptor gene itself. This decreases cholesterol uptake. (From Jorde LB, Carey JC, Bamshad MJ. *Medical genetics*, 6th edition. Philadelphia: Elsevier; 2020.)

An illustration depicts the process of receptors involved in the mediated endocytosis, which shows the cell membrane with numbers indicating 1. Ribosome; 2. Newly synthesized L D L receptor; 3. L D L particles; 4. Endosome; 5. Lysosome; 6. Synthesized lysosome; 7. Cholesterol; 8. Excess

cholesterol inhibits H M G-C o A reductase; 9. Activates A C A T; 10. Inhibits transcription of m R N A.

FIG. 5.6 Xanthoma. Fatty deposits, referred to as xanthomas as seen here on the knuckles, are often noted in individuals with familial hypercholesterolemia. (From Jorde LB, Carey JC, Bamshad MJ. *Medical genetics*, 6th edition. Philadelphia: Elsevier; 2020.)

Environmental factors, many of which are easily modified, are also important causes of CHD. Abundant epidemiologic evidence

shows that cigarette smoking and obesity increase the risk of CHD, whereas exercise and a diet low in saturated fats decrease the risk. Indeed, the approximate 50% decline in CHD prevalence in the United States during the past 40 years is usually attributed to a decrease in the proportion of adults who smoke cigarettes, a decreased consumption of saturated fats, and an increased emphasis on exercise and a generally healthier lifestyle.

Hypertension

Systemic hypertension, which has a worldwide prevalence of approximately 25% to 30%, is a key risk factor for heart disease, stroke, and kidney disease. Studies of blood pressure correlations within families indicate that approximately 20% to 40% of the variation in both systolic and diastolic blood pressure is caused by genetic factors. The fact that this figure is substantially less than 100% indicates that environmental factors also must be important causes of blood pressure variation. The most important environmental risk factors for hypertension are increased sodium intake, decreased physical activity, psychosocial stress, and obesity (but, as discussed later, the latter factor is itself influenced by both genes and environment).

Blood pressure regulation is a highly complex process that is influenced by many physiologic systems, including various aspects of kidney function (see Chapter 37), cellular ion transport, and heart function (refer to Chapter 31).[11]

Because of this complexity, much research is now focused on specific components that may influence blood pressure variation, such as the renin-angiotensin system (involved in sodium reabsorption and vasoconstriction), vasodilators such as nitric oxide and the kallikrein-kinin system, and ion-transport systems such as adducin and sodium-lithium counter-transport (Fig. 5.7). These individual factors are more likely to be under the control of smaller numbers of genes than is blood pressure itself, simplifying the task of identifying these genes and their role in blood pressure regulation. For example, linkage and association studies have

implicated several genes involved in the renin-angiotensin system (e.g., the genes that encode angiotensinogen, angiotensin-converting enzyme, angiotensin receptors) in the causation of hypertension.

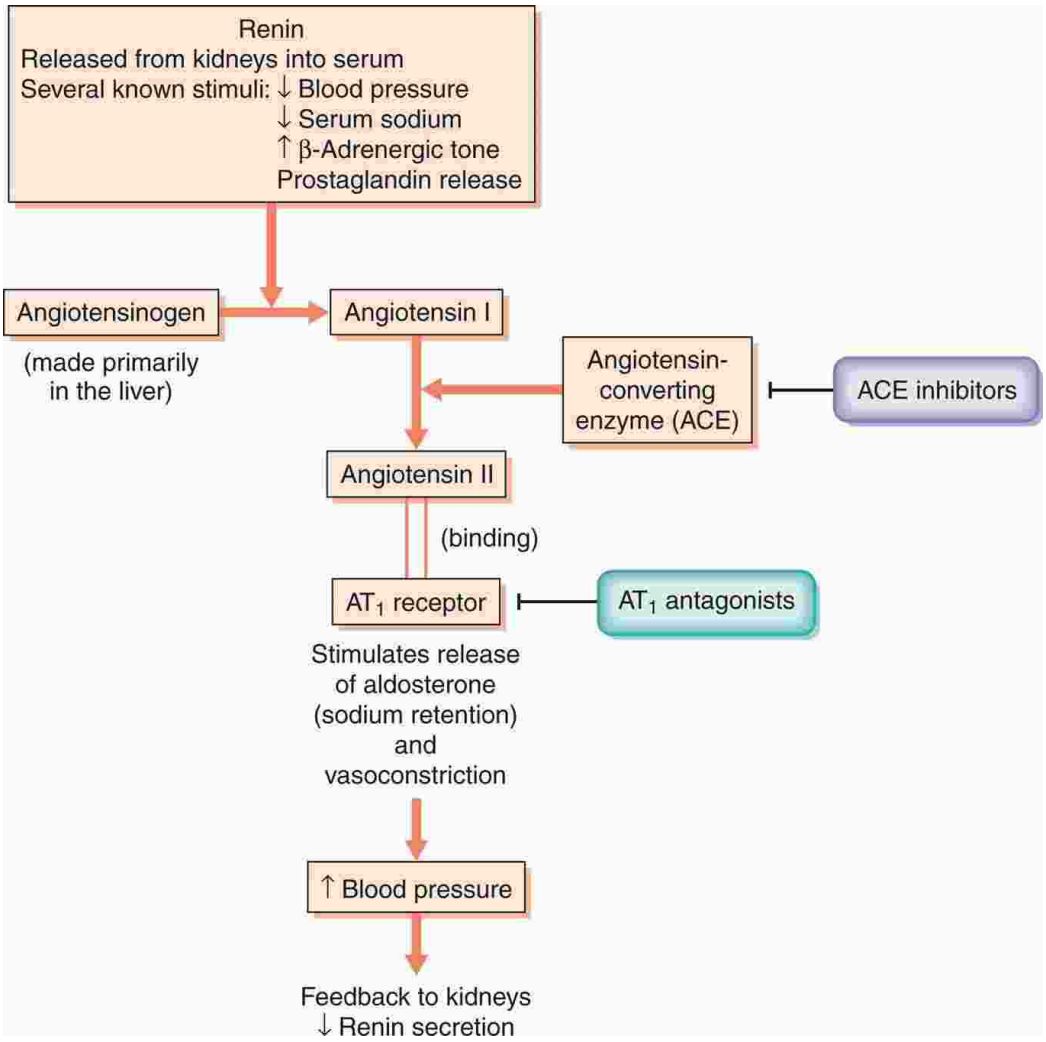

FIG. 5.7 Renin-Angiotensin-Aldosterone System. (Adapted from Khera AV, Chaffin M, Aragam KG, et al., 2018. Nature genetics in Jorde LB, Carey JC, Bamshad MJ. *Medical genetics*, 6th edition. Philadelphia: Elsevier; 2020.)

The flow chart summarizes the renin-angiotensin-aldosterone system. The chart begins as follows. • Renin released from kidneys into serum responses to several know stimuli: Decreased blood pressure, decreased serum sodium, increased beta-adrenergic tone, and prostaglandin release which leads to

angiotensinogen (made primarily in liver). • Angiotensinogen made primarily in the liver leads to angiotensin 1. • Angiotensin 1 leads to angiotensin 2 by angiotensin-converting enzyme (A C E). • Angiotensin 2 on bindings A T 1 receptor stimulates the release of aldosterone (sodium retention and vasoconstriction) by A T 1 antagonist which inhibits the A T 1 receptor. • A T 1 receptor stimulates the release of aldosterone sodium retention and vasoconstriction, leading to increased blood pressure. • Increased blood pressure leads to feedback to the kidneys, which decreases renin secretion.

Cancer

Cancer is the second leading cause of death in the United States. It is well established that many major types of cancer (e.g., breast, colon, prostate, ovarian) cluster strongly in families. Clustering is caused by both inherited genes and shared environmental factors. Although numerous cancer-causing genes are being isolated,[12] environmental and lifestyle factors play an important role in causing cancer (see Chapter 13). In particular, tobacco use is estimated to account for one-third of all cancer cases in the United States, making it the most important known cause of cancer.[13]

Typically, environmental factors cause cancer by creating somatic mutations (see Chapter 4) in specific cell types. Thus cancer can be caused both by inherited genetic variants and by noninherited somatic mutations acquired during an individual's lifetime. See Emerging Science Box: Polygenic Risk Scores and Disease Prediction.

Breast cancer

Breast cancer is the most common cancer among women, with 82% of breast cancers diagnosed among women aged 50 years and older.[14]

Approximately 13% of women (1 in 8) will be diagnosed with invasive breast cancer in their lifetime.[14] Formerly the leading cause of cancer death among women, it has been surpassed by lung cancer. Breast cancer aggregates strongly in families; for example, if a woman has one affected first-degree relative, her risk of developing breast cancer doubles. This risk increases further if the age of onset in the affected relative is early and if the cancer is bilateral (tumors in both breasts).

An autosomal dominant form of breast cancer accounts for approximately 5% to 10% of breast cancer cases in the United States.[15]

Genes responsible for this form of breast cancer have been identified on chromosomes 17 *(BRCA1)* and 13 *(BRCA2)*, and these genes can be tested for inherited cancer-causing mutations.[16,17]

It is reported that women who inherit a mutation in *BRCA1* or *BRCA2* experience a 50% to 80% lifetime risk of developing breast cancer.[15] However, in a seminal paper of more than 8000 unselected cases of breast or ovarian cancer, the average cumulative risk of developing breast cancer with a *BRCA1* mutation was 65%.[18]*BRCA1* mutations also increase the risk of ovarian cancer among women (39%), and they confer a modestly increased risk of prostate and colon cancers.[15]*BRCA2* mutations also confer an increased risk of ovarian cancer (11%).[15] Approximately 5% to 8% of males who inherit a *BRCA2* mutation will develop breast cancer, representing a 100-fold increase over the risk in the general male population.[19] Evaluation of the *BRCA1* and *BRCA2* gene products, which are both involved in deoxyribonucleic acid (DNA) repair, is yielding valuable evidence on the etiology of breast cancer in general.

Although *BRCA1* and *BRCA2* mutations are the most commonly known causes of inherited breast cancer, this disease also can be

caused by inherited mutations in several other genes (e.g., *ATM, CDH1, CHEK2, NBN, NF1, PALB2, PTEN, STK11,* and *TP53*).[16] Germline mutations in a tumor-suppressor gene called *PTEN* are responsible for Cowden disease, which is characterized by multiple benign tumors and an increased susceptibility to breast cancer. Despite the significance of these genes, it should be emphasized that more than 90% of breast cancer cases are not inherited as mendelian diseases (also see Chapter 6).

Colorectal cancer

Colorectal cancer is second only to lung cancer in the number of cancer deaths occurring annually in the United States, with approximately 148,000 new cases and 53,000 deaths annually.[20] Approximately 1 in 21 Americans will develop colorectal cancer. Like breast cancer, it clusters in families (in fact, familial clustering of this form of cancer was reported in the medical literature as early as 1881). The risk of colorectal cancer in people with one affected first-degree relative is two to three times higher than that in the general population.

This familial aggregation is caused in part by subsets of colorectal cancer cases that are inherited as single-gene traits. For example, *familial adenomatous polyposis* occurs in approximately 1 in 8000 Whites. The gene responsible for this disorder, *APC*, encodes a tumor suppressor.[21] Importantly, somatic mutations of *APC* are found in at least 85% of all colon tumors. Thus, although inherited *APC* mutations cause rare familial adenomatous polyposis, somatic mutations are involved in the great majority of all common colorectal cancers.

Among hereditary forms of colorectal cancer, the most frequent is *hereditary nonpolyposis colorectal cancer*, which accounts for 3% to 4% of colorectal cancer cases and is caused by mutations in any of six genes.[22,23] Research has shown that all of these genes are involved in the vital process of DNA repair. When this function is compromised, cancer-causing mutations can persist in cells, leading eventually to growth of a tumor.

Other colorectal cancer cases are likely to be caused by a complex interaction of multiple genes. In addition, environmental factors, such as a high-fat, low-fiber diet, are thought to increase the risk of colorectal cancer.

Prostate cancer

Prostate cancer is the second most diagnosed cancer in men (after skin cancer), with approximately 165,000 new cases annually in the United States and a lifetime risk of 11%.[24,25]

Prostate cancer is second only to lung cancer as a cause of cancer death in men, causing more than 30,000 deaths each year. Having an affected first-degree relative increases the risk of developing prostate cancer by a factor of 2 to 3, and the heritability of prostate cancer is estimated to be approximately 40%.

The relatively late age of onset of most prostate cancer cases (median age 72 years) makes genetic analysis especially difficult. However, loss of heterozygosity (see Chapter 12) has been observed in several genomic regions in prostate tumor cells, possibly indicating the presence of genetic alterations in these regions. In addition, genome-wide association studies have identified several dozen polymorphisms associated with prostate cancer risk. Several of these are in chromosome 8q24, which contains polymorphisms associated with several other cancers as well (colon, pancreas, and esophagus). Although the 8q24 region contains no protein-coding genes, it contains enhancer elements that affect expression of the *MYC* oncogene, located approximately 250 kilobytes (kb) from 8q24.[26]

Nongenetic factors for prostate cancer may include a high-fat diet. Because prostate cancer usually progresses slowly and because it can be detected by digital examination and by the prostate-specific antigen (PSA) test, fatal metastasis can usually be prevented.

Cancer gene identification

Recently developed techniques, including large-scale DNA sequencing, have identified hundreds of genes that are mutated in

various cancers. Some of these genes contribute directly to a growth advantage in tumors and are considered primary causes of cancer. Approximately 150 such **driver genes** have been described.[12,27] A much larger number of genes undergo somatic mutations during tumorigenesis, but these genes do not directly confer a growth advantage to cells; these are termed **passenger genes**.[27] The gene responsible for retinoblastoma (see Chapter 20), which normally acts as a "brake" on cell division, is an example of a well-known driver gene. The *APC* gene, discussed previously, is another example.

Although many types of cancer, such as retinoblastoma or familial adenomatous polyposis, are relatively rare, study of the causative genes has provided many important insights into the nature of carcinogenesis in general. This can lead to more effective treatment and prevention of all cancers.

Diabetes mellitus

Like the other disorders discussed in this chapter, the etiology of diabetes mellitus is complex and not fully understood (see Chapter 22). Nevertheless, progress is being made in understanding the genetic basis of this disorder, which is a leading cause of blindness, heart disease, and kidney failure.[28,29]

An important advance has been the recognition that diabetes is a heterogeneous group of disorders, all characterized by elevated blood glucose level. The focus here is on the two major types of diabetes: type 1 (insulin-dependent diabetes mellitus [IDDM]) and type 2 (non–insulin-dependent diabetes mellitus [NIDDM]).

Type 1 diabetes

Type 1 diabetes, which is characterized by T-cell infiltration of the pancreas and destruction of the insulin-producing beta cells, usually (although not always) presents before age 40. Individuals with type 1 diabetes must receive exogenous insulin to survive. In addition to T-cell infiltration of the pancreas, autoantibodies are formed against pancreatic cells; the latter can be observed long before clinical symptoms occur. These findings, along with a strong association

between type 1 diabetes and the presence of several major histocompatibility complex (MHC) class II alleles, indicate that this is an autoimmune disease. Over the past few decades, the incidence of type 1 diabetes has increased substantially.

Siblings of individuals with type 1 diabetes face a substantial elevation in risk: approximately 6%, as opposed to a risk of approximately 0.3% to 0.5% in the general population. The recurrence risk is also elevated when there is a diabetic parent, although this risk varies with the sex of the affected parent. The risk for offspring of diabetic mothers is only 1% to 3%, whereas it is 4% to 6% for the offspring of diabetic fathers (because type 1 diabetes affects males and females in approximately equal proportions in the general population, this risk difference is inconsistent with the sex-specific threshold model for multifactorial traits). Twin studies show that the empirical risks for identical twins of people with type 1 diabetes range from 30% to 70%. In contrast, the concordance rates for DZ twins are 5% to 10%. The fact that type 1 diabetes is not 100% concordant among identical twins indicates that genetic factors are not solely responsible for the disorder. There is good evidence that specific viral infections contribute to the causation of type 1 diabetes in at least some individuals, possibly by activating an autoimmune response.

The association of specific MHC class II alleles (see Chapter 22) and type 1 diabetes has been studied extensively, and it is estimated that these alleles account for approximately 40% of the familial clustering of type 1 diabetes. Approximately 95% of Whites with type 1 diabetes have the human leukocyte antigen (HLA) (part of the MHC), DR3, and/or DR4 alleles, whereas only approximately 50% of the general White population has either of these alleles. If an affected proband and a sibling are heterozygous for the DR3 and DR4 alleles, the sibling's risk of developing type 1 diabetes is nearly 20% (i.e., approximately 40 times higher than the risk in the general population). In addition, the presence of aspartic acid at position 57 of the HLA DQ chain is strongly associated with resistance to type 1 diabetes. In fact, those who do not have this amino acid at position 57 (and instead are homozygous for a different amino acid) are 100

times more likely to develop type 1 diabetes. The aspartic acid substitution alters the shape of the HLA class II molecule and thus its ability to bind and present peptides to T cells. Altered T-cell recognition may help protect individuals with the aspartic acid substitution from an autoimmune episode.

The insulin gene, which is located on the short arm of chromosome 11, is another logical candidate for type 1 diabetes susceptibility. Polymorphisms within and near this gene have been tested for association with type 1 diabetes. It is estimated that inherited genetic variation in the insulin region accounts for approximately 10% of the familial clustering of type 1 diabetes.

More than 50 additional genes have been shown to be associated with susceptibility to type 1 diabetes. The most significant of these are cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), which encodes a protein involved in the regulation of T-cell proliferation, and *PTPN22*, which encodes a lymphoid-specific tyrosine phosphatase that negatively regulates T-cell activation. It is interesting that variation in the latter gene has been associated with several other autoimmune diseases, including systemic lupus erythematosus (SLE), rheumatoid arthritis, and autoimmune thyroid disease.

Type 2 diabetes

Type 2 diabetes accounts for more than 90% of all diabetes cases and affects 10% to 20% of the adult populations of many high-income countries. Several features distinguish it from type 1 diabetes. There is nearly always some endogenous insulin production in people with type 2 diabetes, and the disease can often be treated successfully with dietary modification and/or oral drugs. People with type 2 diabetes suffer from insulin resistance (i.e., their cells have difficulty in using insulin). This disease typically occurs among people older than age 40 and, in contrast to type 1 diabetes, is seen more commonly among the obese. However, the incidence of type 2 diabetes is rising dramatically among adolescents and young adults in developed countries and is strongly correlated with an increased

incidence of obesity. Neither MHC associations nor autoantibodies are commonly seen in this form of diabetes. MZ twin concordance rates are substantially higher than those seen in type 1 diabetes, ranging from 70% to 90% (because of age dependence, the concordance rate increases if older subjects are studied). The empirical recurrence risks for first-degree relatives of type 2 diabetes cases are higher than those for type 1, generally ranging from 15% to 40%. The differences between type 1 and type 2 diabetes are summarized in Table 5.5.

Table 5.5

Comparison of Major Features of Types 1 and 2 Diabetes

Feature	Type 1 Diabetes	Type 2 Diabetes
Age of onset	Usually <40 years	Usually >40 years (except maturity-onset diabetes of the young [MODY])
Insulin production	None	Partial
Insulin resistance	No	Yes
Autoimmunity	Yes	No
Obesity	Not common	Common
Monozygotic (MZ) twin concordance	0.30–0.70	0.35–0.60
Sibling recurrence risk	1%–6%	10%–40%

Hundreds of studies have been undertaken to identify genes that may contribute to type 2 diabetes susceptibility, and more than 250

genes and more than 400 genomic variants are now known to be associated with risk of this disease.[30] An important risk factor is *TCF7L2*, which encodes a transcription factor involved in the secretion of insulin. A variant of *TCF7L2* is associated with a 50% increased risk of developing type 2 diabetes.[31] A significant association has also been observed between type 2 diabetes and a common allele of the gene that encodes peroxisome proliferator–activated receptor-gamma (PPAR-γ), a nuclear receptor that is involved in adipocyte differentiation and glucose metabolism.[32] This receptor is the target of thiazolidinediones (TZDs), a class of drugs commonly used to increase insulin sensitivity in those with type 2 diabetes. Although the disease-associated allele confers only a 25% increase in the risk of developing type 2 diabetes, it is found in more than 75% of individuals of European descent and thus helps to account for a significant proportion of type 2 diabetes cases. Variation in *KCNJ11*, which encodes a potassium channel necessary for glucose-stimulated insulin secretion, confers an additional 20% increase in type 2 diabetes susceptibility. The associations between diabetes susceptibility and each of these genes have been widely replicated in multiple populations.

The two most important risk factors for type 2 diabetes are positive family history and obesity; the latter increases insulin resistance. The disease tends to rise in prevalence when populations adopt a diet and exercise pattern typical of US and European populations. Increases have been seen, for example, among Japanese immigrants to the United States and among some native populations of the South Pacific, Australia, and the Americas. Several studies, conducted on male and female subjects, have shown that regular exercise can substantially lower one's risk of developing type 2 diabetes, even among individuals with a family history of the disease. This is partly because exercise reduces obesity. However, even in the absence of weight loss, exercise increases insulin sensitivity and improves glucose tolerance.

Because of the dramatic increase in obesity in the United States and other developed countries, the prevalence of type 2 diabetes is

also rising rapidly, and the average age of onset is decreasing (one study estimates that up to one-third of Americans born in the year 2000 will develop type 2 diabetes).[33] A small proportion of type 2 diabetes cases occurs early in life, often before 25 years of age, and typically exhibits autosomal dominant inheritance (unlike most type 2 diabetes cases). This subset is termed *maturity-onset diabetes of the young* (MODY). Studies of MODY pedigrees have shown that approximately half of cases of the disease are caused by mutations in the glucokinase gene. Glucokinase converts glucose to glucose-6-phosphate in the pancreas. In addition to the glucokinase gene, five other genes, all of which are involved in pancreatic development or regulation of insulin levels, have now been shown to be causes of MODY. Currently, 13 MODY genes are known.[34]

Obesity

Obesity is most defined as a body mass index (BMI) greater than 30. (BMI is defined as W/H^2, in which W is weight in kilograms and H is height in meters.) Using this criterion, more than one-third of American adults are obese, and an additional one-third are overweight (BMI greater than 25 but less than 30). The proportion of obese adults and children continues to increase rapidly. Although obesity itself is not a "disease," it is an important risk factor for several common diseases, including heart disease, stroke, type 2 diabetes, and cancers of the prostate, breast, and colon.

As one might expect, there is a strong correlation between obesity in parents and their children. This could easily be ascribed to common environmental effects: parents and children usually share similar dietary and exercise habits. However, there is good evidence for genetic components as well. Four adoption studies each showed that the body weights of adopted individuals correlated significantly with their natural parents' body weights but not with those of their adoptive parents. Twin studies also provide evidence for a genetic effect on body weight, with most studies yielding heritability estimates between 0.60 and 0.80.

Research, aided substantially by mouse models, has shown that many genes each play a role in human obesity. Important among these are the genes that encode leptin (Greek, “thin”) and its receptor. The leptin hormone is secreted by adipocytes (fat storage cells) and binds to receptors in the hypothalamus, the site of the body's appetite control center. Cloning of the human leptin gene and its receptor led to optimistic predictions that leptin could be a key to weight loss in humans (without the perceived unpleasantness of dieting and exercise). Although mutations in the human leptin gene and its receptor have been identified in a few humans with severe obesity (BMI >40), they both appear to be extremely rare. Clinical trials using recombinant leptin have demonstrated moderate weight loss in a subset of obese individuals. In addition, leptin participates in important interactions with other components of appetite control, such as neuropeptide Y and α-melanocyte–stimulating hormone and its receptor, the melanocortin-4 receptor (MC4R). Mutations in the gene that encodes MC4R have been found in 3% to 5% of severely obese individuals. Homozygosity for a DNA variant in the *FTO* gene (which is seen in 16% of Whites) has been associated with 40% and 70% increases in the risks of overweight and obesity, respectively. Recent evidence shows that the *FTO* variant is part of an enhancer that binds to the *IRX* gene, which is located 2 million base pairs away from *FTO* and is involved in regulation of fat mass. Identification of these human genes is leading to a better understanding of natural weight control in the human, and it could eventually lead to effective treatments for some cases of obesity.

Alzheimer Disease

Alzheimer disease (AD), which is responsible for 50% to 80% of cases of progressive cognitive impairment (dementia) among older adults, affects approximately 1 in 10 individuals older than 65 years of age and 1 in 3 individuals older than 85 years of age.[35]

Because of the aging of the population, the number of Americans with AD is predicted to increase substantially during the coming decade. AD is characterized by progressive dementia and memory

loss and by the formation of amyloid plaques and neurofibrillary tangles in the brain, particularly in the cerebral cortex and hippocampus. The plaques and tangles lead to progressive neuronal loss, and death usually occurs within 7 to 10 years after the first appearance of symptoms.

The risk of developing AD doubles in individuals who have an affected first-degree relative. Although most cases do not appear to be caused by single loci, approximately 10% follow an autosomal dominant mode of transmission. Approximately 5% of AD cases occur before age 65 and are considered early onset; these are much more likely to be an autosomal dominant inheritance.[36] AD is a genetically heterogeneous disorder. Approximately half of early-onset cases can be attributed to mutations in any of three genes, all of which affect amyloid-β deposition.[35] Two of the genes, presenilin 1 *(PSEN1)* and presenilin 2 *(PSEN2)*, are very similar to one another, and their protein products are involved in cleavage of the amyloid-β precursor protein (APP). When APP is not cleaved normally, a long form of it accumulates excessively and is deposited in the brain. This is thought to be a primary cause of AD. Mutations in *PSEN1* typically result in early-onset AD, with the first occurrence of symptoms in the fifth decade of life.

A small number of cases of early-onset AD are caused by mutations of the gene that encodes APP itself, which is located on chromosome 21. These mutations disrupt normal cleavage sites in APP, again leading to the accumulation of the longer protein product. It is interesting that this gene is present in three copies in trisomy 21 individuals, in which the extra gene copy leads to amyloid deposition and the occurrence of AD in those with Down syndrome (see Chapter 4). High-throughput DNA sequencing (techniques allowing the sequencing of massive amounts of DNA at once) studies have revealed an allele in APP that is protective against AD and may help to prevent cognitive decline.

An important risk factor for the more common late-onset form of AD is allelic variation in the apolipoprotein E *(APOE)* locus, which has three major alleles: *ε2*, *ε3*, and *ε4*. Studies conducted in diverse

populations have shown that persons who have one copy of the *ε4* allele are at least 2 to 5 times more likely to develop AD, whereas those with two copies of this allele are at least 5 to 10 times more likely to develop AD. The risk varies somewhat by population, with higher *ε4*-associated risks in Europeans and Japanese and relatively lower risks in Hispanics and Blacks. Despite the strong association between *ε4* and AD, approximately half of individuals who develop late-onset AD do not have a copy of the *ε4* allele, and many who are homozygous for *ε4* remain free of AD even at advanced age. The APOE protein product is not involved in cleavage of APP but instead appears to be associated with clearance of amyloid from the brain. Recent large-scale studies have revealed at least 20 additional genes are associated with AD.

Alcoholism

At some point, alcoholism (now formally termed alcohol use disorder) is diagnosed in approximately 10% of adult males and 3% to 5% of adult females in the United States. The national cost of alcoholism, in terms of lost productivity and direct medical costs, is approximately $250 billion per year.[37] More than 100 studies have shown that this disease clusters in families.[38] The risk of developing alcoholism among individuals with one affected parent is three to five times higher than for those with unaffected parents.

Most twin studies have yielded concordance rates for DZ twins less than 30% and concordance rates for MZ twins more than 60%. Adoption studies have shown that the offspring of an alcoholic parent, even when raised by nonalcoholic parents, have a fourfold increased risk of developing the disorder. To control for possible prenatal effects in an alcoholic mother, some studies have included only the offspring of alcoholic fathers. The results have remained the same. One study showed that the offspring of nonalcoholic parents, when reared by alcoholics, did *not* have an increased risk of developing alcoholism. These data argue that there may be genetic variants that predispose some people to alcoholism.

It has long been known that an individual's physiologic response to alcohol can be influenced by variation in the key enzymes responsible for alcohol metabolism: alcohol dehydrogenases (ADHs), which convert ethanol to acetaldehyde; and aldehyde dehydrogenases (ALDHs), which convert acetaldehyde to acetate. An allele of the *ALDH2* gene *(ALDH2*2)* results in excessive accumulation of acetaldehyde and thus in facial flushing, nausea, palpitations, and lightheadedness.[39] Because of these unpleasant effects, individuals who have the *ALDH2*2* allele are much less likely to become alcoholics. This "protective" allele is common in some Asian populations but is rare in other populations.

Several other genes are associated with susceptibility to alcohol addiction, including genes that encode components of gamma-aminobutyric acid (GABA) receptors. This finding is biologically plausible, because the GABA neurotransmitter system inhibits excitatory signals in neurons, exerting a calming effect. Alcohol has been shown to increase GABA release, and allelic variation in GABA receptor genes may modulate this effect.

It should be underscored that genes may increase one's *susceptibility* to alcoholism. Obviously, this is a disease that requires an environmental component, regardless of genetic constitution.

Psychiatric Disorders

The major psychiatric diseases, schizophrenia and bipolar disorder, have been the subjects of numerous genetic studies.[40] Twin, adoption, and family studies have shown that both disorders aggregate in families.

Schizophrenia

Schizophrenia is a severe emotional disorder characterized by delusions, hallucinations, retreat from reality, and bizarre, withdrawn, or inappropriate behavior. (Contrary to popular belief, schizophrenia is not a "split personality" disorder.) The estimated heritability of schizophrenia is up to 85%.[41] The risk of schizophrenia among relatives with one schizophrenic proband is eightfold. This

increases to 11-fold for relatives with two schizophrenic probands.[42] The lifetime risk for schizophrenia among offspring of one affected parent is approximately 8% to 10%, which is approximately 10 times higher than the risk in the general population.[43]

As one might expect, the empirical risks increase when more relatives are affected. For example, an individual with an affected sibling and an affected parent has a risk approaching 20% and an individual with two affected parents has a risk of nearly 50%. The risks decrease when the affected family member is a second- or third-degree relative. Details are given in Table 5.6. On inspection of Table 5.6, it may seem puzzling that the proportion of schizophrenic probands who have a schizophrenic parent is only approximately 5%, which is substantially lower than the risk for other first-degree relatives (e.g., siblings, affected parents and their offspring). This can be explained by the fact that people with schizophrenia are less likely to marry and produce children than are other individuals. Thus substantial selection against schizophrenia occurs in the population.

Table 5.6

Recurrence Risks for Relatives of Schizophrenic Probands

Relationship to Proband	Recurrence Risk (%)
Monozygotic twin	44.3
Dizygotic twin	12.1
Offspring	9.4
Sibling	7.3
Niece/nephew	2.7
Grandchild	2.8
First cousin	1.6
Spouse	1

NOTE: Figures are based on multiple studies of Western European populations.

Data from McGue M, Gottesman II, Rao DC. The analysis of schizophrenia family data. *Behavioral Genetics*, 1986;16(1):75–87.

Twin and adoption studies also indicate that genetic factors are likely to be involved in schizophrenia. Data pooled from five different twin studies show a 47% concordance rate for MZ twins, compared with a concordance rate of only 12% for DZ twins. When the offspring of a schizophrenic parent are adopted by normal parents, their risk of developing the disease is approximately 10%, which is approximately the same as the risk when raised by a schizophrenic biologic parent. Large-scale genetic studies have revealed more than 200 loci that are associated with risk of schizophrenia. The most significant of these associations implicates complement component genes (*C4A* and *C4B*) located in the MHC region. These genes are expressed in neurons and affect synaptic function and likely contribute to the decline in synaptic structures

observed in the brains of persons with schizophrenia. Other schizophrenia-associated genes encode components of the dopaminergic and glutamatergic neuronal signaling pathways. These findings are biologically plausible because the major therapeutic drugs used to treat schizophrenia block dopamine receptors.

Bipolar disorder

Bipolar disorder, also known as *manic-depressive disorder*, is a form of psychosis with extreme mood swings and emotional instability. The prevalence for bipolar type I in the United States is approximately 1%, but it rises to 5% to 10% among those with an affected first-degree relative.[44] Twin and family studies show that approximately 60% of the risk for bipolar disorder is attributable to genetic factors, whereas approximately 30% of the risk for unipolar disorder (major depression) is because of genetic factors.[45]

As with schizophrenia, large-scale studies have revealed more than 20 genes associated with susceptibility to bipolar disorder. Some of the best-replicated genetic studies implicate genes that encode voltage-gated calcium and sodium channels.[44] Ion-channel modulating drugs are frequently used as mood stabilizers, lending the genetic results functional plausibility. Many of the genes associated with bipolar disorder also are associated with schizophrenia.

Genetic studies of psychiatric disorders are especially challenging because these disorders are undoubtedly heterogeneous, reflecting the influence of numerous genetic and environmental factors. In addition, definition of the phenotype is not always straightforward, and it may change through time, significantly complicating genetic analysis.

Other Complex Disorders

The disorders discussed in this chapter represent some of the most common multifactorial disorders and those for which significant progress has been made in identifying genes. Many other

multifactorial disorders are being studied as well, and in some cases specific susceptibility genes have been identified. These include, for example, Parkinson disease, hearing loss, multiple sclerosis, amyotrophic lateral sclerosis, epilepsy, asthma, inflammatory bowel disease, and some forms of blindness.

Some General Principles and Conclusions

Some general principles can be deduced from the results obtained thus far on the genetics of complex disorders. First, the more strongly inherited forms of complex disorders generally have an earlier age of onset (e.g., breast cancer, AD, heart disease). Often these represent subsets of cases in which there is single-gene inheritance. Second, when laterality is a component, the bilateral forms are more likely to cluster strongly in families (e.g., breast cancer, CL/P). Third, although the sex-specific threshold model fits some of the complex disorders (e.g., pyloric stenosis, CL/P, autism, heart disease), it fails to fit others (e.g., type 1 diabetes).

A tendency exists, particularly among the lay public, to assume that the presence of a genetic component means that the course of a disease cannot be altered. *This is incorrect*. Most of the diseases discussed in this chapter have both genetic and environmental components. Thus lifestyle modification (e.g., diet, exercise, stress reduction) often can reduce risk significantly. Such modification may be especially important for individuals with a family history of a disease because they are likely to develop the disease earlier in life. For example, those with a family history of heart disease can often add many years of productive living with relatively minor lifestyle alterations. By targeting those who can benefit most from intervention, genetics helps to serve the goal of preventive medicine.

In addition, it should be stressed that the identification of a specific genetic lesion can lead to more effective prevention and treatment of the disease. Identification of mutations that cause autosomal dominant breast cancer may enable early screening and prevention of metastasis. Pinpointing a gene responsible for a neurotransmitter defect in a behavioral disorder such as

schizophrenia could lead to the development of more effective drug treatments. In some cases, such as those with familial hypercholesterolemia, targeted drug therapy or gene therapy may prove to be useful in treating the disease. It is important for healthcare practitioners to help individuals to understand these facts.

Although the genetics of common disorders is complex and often confusing, the community health effect of these diseases, together with the evidence for hereditary factors in their etiology, demands that genetic studies be pursued. Substantial progress is already being made. The next decade will undoubtedly witness many further advances in the understanding and treatment of these disorders.

Summary Review

Factors Influencing Incidence of Disease in Populations

1. The incidence rate is the number of new cases of a disease reported during a specific period (typically 1 year) divided by the number of individuals in the population.
2. The prevalence rate is the proportion of the population affected by a disease at a specific point in time. This rate and the incidence rate can be used to compare population variations in disease frequency.
3. Relative risk is a common measure of the effect of a specific risk factor. It is expressed as a ratio of the incidence rate of the disease among individuals exposed to a risk factor divided by the incidence of the disease among individuals *not* exposed to a risk factor.
4. Many factors can influence the risk of acquiring a common disease, such as cancer, diabetes, or hypertension. The factors can include age, gender, diet, exercise, and family history of the disease.

Principles of Multifactorial Inheritance

1. Traits in which variation is thought to be caused by the combined effects of multiple genes are polygenic.
2. The term *multifactorial* is used when environmental factors also are believed to cause variation in the trait.
3. Many quantitative traits (e.g., blood pressure) are multifactorial.
4. Because traits are caused by the additive effects of many genetic and environmental factors, they tend to follow a normal or bell-shaped distribution in populations.
5. Those diseases, however, that do not follow a bell-shaped distribution appear to be either present or absent in individuals. They do not follow the inheritance patterns of single-gene disease. Instead, such diseases may follow an underlying liability distribution. It is thought that a threshold of liability must be crossed before the disease is expressed.
6. Examples of diseases that correspond to the liability model include pyloric stenosis, neural tube defects, CL/P, and some forms of congenital heart disease.
7. Many of the common adult diseases, such as hypertension, coronary heart disease, stroke, diabetes mellitus (types 1 and 2), and some cancers, are caused by complex genetic and environmental factors and are thus multifactorial diseases.
8. For most multifactorial diseases, empirical risks (risks based on direct observation of data) have been derived.
9. In contrast to most single-gene diseases, recurrence risks for multifactorial diseases can change significantly from one population to another because gene frequencies, as well as environmental factors, can differ among populations.
10. Several criteria are used to define multifactorial inheritance: (a) the recurrence risk becomes higher if more than one family member is affected; (b) if the expression of the disease in a proband is more severe, the recurrence risk is higher; (c)

the recurrence risk is higher if the proband is of the less commonly affected sex; (d) the recurrence risk for the disease usually decreases rapidly in more remotely related relatives; and (e) if the prevalence of the disease in a population is f, the risk for offspring and siblings of probands is approximately $\sqrt{f}$.

Nature and Nurture: Disentangling the Effects of Genes and Environment

1. Family members share genes and a common environment; therefore resemblance in traits, such as high blood pressure, reflects both genetic and environmental factors (nature and nurture, respectively).
2. Few traits are influenced *only* by genes or *only* by environment. Most are influenced by both.
3. When a disease has a relatively larger genetic component, as in breast cancer, examination of family history should be emphasized in addition to lifestyle modification.
4. Two research strategies often are used to estimate the relative influence of genes and environment-lifestyle: twin studies and adoption studies.
5. MZ twins originate when the developing embryo divides to form two separate but identical embryos.
6. DZ twins are the result of a double ovulation followed by the fertilization of each egg by a different sperm.
7. If both members of a twin pair share a trait, they are said to be *concordant*. If they do not share the same trait, they are *discordant*.
8. Studies of adopted children also are used to estimate the genetic contribution to a multifactorial trait.
9. A genetic predisposition may interact with an environmental-lifestyle factor to increase the risk of disease; this is called a *gene-environment interaction*.

Genetics of Common Diseases

1. Congenital diseases are those present at birth. Most of these diseases are multifactorial in etiology.
2. Multifactorial diseases in adults include coronary heart disease, hypertension, breast cancer, colon cancer, diabetes mellitus, obesity, Alzheimer disease, alcoholism, schizophrenia, and bipolar affective disorder.
3. It is incorrect to assume that the presence of a genetic component means that the course of a disease cannot be altered—most diseases have *both* genetic and environmental aspects.

Future Directions, 199

Overview of Epigenetic Mechanisms

Humans exhibit an impressive diversity of physical and behavioral features. Much of this diversity is attributable to genetic variation. Another substantial contributor is "epigenetic" ("upon genetic") modification. Although the specific definition of *epigenetic* remains a topic of discussion among biologists,[1,2] it is generally used to describe nongenetic modifications that are heritable when a somatic

cell divides (mitotic inheritance), when gametes are produced (germline inheritance),[3] or both. For the purposes of this chapter, *epigenetics* is defined as the broad set of processes that modulate how a given set of genomic information gives rise to phenotype. Epigenetic mechanisms include chemical modifications to DNA and associated histones, and the production of small RNA molecules. Gene regulation by epigenetic processes can occur at the level of either transcription or translation.

Epigenetic modification is critical for fundamental processes of human development, including the differentiation of embryonic stem cells into specific cell types and the inactivation of one of the two X chromosomes in each cell of a genetic female. Some genes are said to be imprinted, meaning that their epigenetic modifications are always inherited such that it is always the allele from the father or from the mother, that is expressed in the offspring.

A variety of diseases can result from abnormal epigenetic states. Metabolic disease can occur when there is aberrant expression of both copies of a locus that is typically imprinted. Environmental stressors can markedly increase the risk of aberrant epigenetic modification and are strongly associated with some cancers. Because of their increasingly clear role in a wide range of pathologies, abnormal epigenetic states are currently a focus of both preventative efforts and pharmaceutical intervention.

Epigenetic Mechanisms

Currently known epigenetic marks (Fig. 6.1) include:

1. **DNA methylation**, which occurs through the attachment of a methyl group (CH_3) to C5 of a cytosine. In the somatic cells of adults, methylation typically occurs only at cytosines that are followed by a guanine base-site known as a **"CpG dinucleotide"** (Fig. 6.2). The fraction of CpG dinucleotides that are methylated is variable across the genome. In human embryonic stem cells, methylation also can occur at cytosines outside of the CpG context. Dense DNA methylation of a

given region of DNA is typically coincident with hypoacetylation (decrease of functional group acetyl) of the histone proteins around which the DNA is wound (see "Histone modification" later). Together, DNA methylation and histone hypoacetylation tend to be associated with **transcriptional silencing**, with the exclusion of transcription factors. Binding of **transcription factors** is required for production of messenger RNAs (mRNAs), which are then transcribed to form protein (see Chapter 4). Marks that are associated with the exclusion of transcription factors typically indicate suppression of expression of the encoded protein.

DNA methylation plays a prominent role in both human development and disease. For example, in each cell of a normal human female, one of the two X chromosomes is silenced by dense methylation and associated molecular marks, whereas the other X chromosome is transcriptionally active and largely devoid of methylation (see Chapter 4). Dense methylation is characteristic of regions that are **heterochromatic**, meaning that the DNA is tightly bound into a condensed state and is not actively transcribed. During **gastrulation** (early embryonic development), there is epigenetic inactivation of one of the two X chromosomes in each cell of a human female, either the X chromosome inherited from her mother or the X chromosome inherited from her father. The determination of which chromosome is to be silenced occurs at random and independently in each of the cells present at this stage of development; the silent state of that chromosome is inherited by all subsequent copies. If a female's two X chromosomes carry different alleles at a given locus, random X inactivation can lead to somatic mosaicism, wherein the alleles active in two different cells can confer two very different traits. Striking examples include the patchy coloration of calico cats and *anhidrotic ectodermal dysplasia*,[4] a condition characterized by patchy presence and

absence of sweat glands in the skin of human females who have one X chromosome bearing a normal allele and one X chromosome bearing a mutant allele at the X-encoded locus. Because of the somatic mosaicism that arises through random inactivation of the X chromosome, females tend to have less severe phenotypes than do males for a variety of X-linked disorders, including color blindness and fragile X syndrome.

Aberrant DNA methylation, either the presence of dense methylation where it is typically absent or absence of methylation where it is typically present, is associated with misregulation of tumor-suppressor genes and oncogenes. Specific alterations to DNA methylation states are a common feature of several human cancers, including those of the colon,[5] breast,[6] and ovaries.[7] Profiling these changes can be useful for cancer diagnosis[8] and for assessing disease prognosis.[9,10] Methods now in development focus on using cell-free DNA and are collected from blood draws to screen individuals for atypical methylation patterns associated with specific cancers. These developments raise the prospect of simultaneous screening for cancers across multiple different tissues (Box 6.1).[11]

2. **DNA hydroxymethylation** is most often observed in cells that are undergoing epigenetic transition. DNA hydroxymethylation differs from DNA methylation, in that it is a hydroxymethyl group, rather than methyl group, that is affixed to the C5 of cytosine. Until recently, considerable uncertainty surrounded the question of how genomic regions, dense in DNA methylation, undergo methylation loss during periods of epigenetic transition. In 2011, Wossidlo et al.[12] found that genome-wide declines in DNA methylation in early murine zygotes occur in concert with genome-wide increases in DNA hydroxymethylation. They also found that this loss of methylation and parallel gain in hydroxymethylation were obliterated in zygotes deficient in

the Tet3 enzyme. These results helped to establish that the Tet enzymes can convert DNA methylation into hydroxymethylation. Abnormally low levels of hydroxymethylation in fetal tissue have been linked to neural tube defects[13] and to disease severity in multiple myeloma.[14] Like DNA methylation, DNA hydroxymethylation is under active investigation as a possible target for early detection of cancer using cell-free DNA.[15]

3. **Histone modifications** are chemical changes to the histone proteins around which DNA is coiled and include histone acetylation and deacetylation. **Histones** are proteins that facilitate compaction of genomic DNA by coiling into the nucleus of a cell, much like how a spool helps to organize a long piece of thread for storage in a small space. Chemical modification of histones in a region of DNA can either upregulate or downregulate nearby gene expression by increasing or decreasing the tightness of the interaction between DNA and histones, thus modulating the extent to which DNA is accessible to transcription factors. DNA in association with histones is referred to as "chromatin." At any given time, various regions of chromatin are typically in one of two forms: *euchromatin*, an open state in which most or all nearby genes are transcriptionally active, or *heterochromatin*, a closed state in which most or all nearby genes are transcriptionally inactive.
   Chromatin structure plays a critical role in determining the developmental potential of a given cell lineage and can undergo dramatic changes during organismal development. Chromatin states differ substantially between embryonic stem cells, which are poised to give rise to all the different cell types that comprise an individual, and terminally differentiated cells, which are committed to a specific developmental path. The fraction of DNA that is in the heterochromatic state increases as cells differentiate. This is

consistent with the decrease in the fraction of the genome that is transcriptionally active when a cell lineage transitions from pluripotency into a terminally differentiated somatic lineage.[16] Mutations in genes that encode histone proteins can render cells refractory to differentiation signals,[17] and specific mutations are useful for assessing disease prognosis in children with aggressive gliomas.[18]

In contrast to most other cell types, including oocytes, sperm cells express not histones but **protamines**, which are evolutionarily derived from histones. Protamines, encoded by just two genes in the human genome,[19] enable sperm DNA to wind into an even more compact state than does the histone-bound DNA in somatic cells. This tight compaction improves the hydrodynamic features of the sperm head, facilitating its movement. Expression of protamine-encoding gene can be modulated by some dietary factors,[20] hinting at connections between environment and male fertility.

4. **Noncoding RNAs (ncRNAs)** play an important role in regulating a wide variety of cellular processes, including RNA splicing and DNA replication.[21] Of relevance to gene regulation are the hairpin-shaped **microRNAs (miRNAs)**, which are encoded by DNA sequences of approximately 22 nucleotides, typically within the introns of genes or in noncoding DNA located between genes. In contrast to DNA methylation and histone modification, both of which principally impacted gene expression at the level of transcription, miRNAs typically modulate the stability and translational efficiency of existing mRNAs encoded at other loci. Interaction between miRNAs and mRNAs targeted for degradation is typically mediated by regions of partial sequence complementarity. As a result, miRNAs can at once be specific enough so that they do not bind to *all* the mRNAs in a cell and general enough to regulate many different mRNA sequences. miRNAs also directly modulate translation by impairing ribosomal function. miRNAs

regulate diverse signaling pathways; those that stimulate cancer development and progression are called **oncomirs**. For example, miRNAs have been linked to carcinogenesis because they alter the activity of oncogenes and tumor-suppressor genes.

FIG. 6.2 **CpG site.**
A CpG site is the 5′-C-phosphate-G-3′ sequ-ence of nucleotides, shown on one DNA strand *(yellow)*. On the reverse DNA strand *(blue)*, the complementary 5′-CpG-3′ site is shown. A C-G base-pairing between the two strands is also shown *(right)*. (From Moini J, Avgeropoulos NG, Samsam M. Li–Fraumeni syndrome. *Epidemiol Brain Spinal Tumors*. 2021;367–377. https://doi.org/10.1016/b978-0-12-821736-8.00010-8.

An illustration depicts the one entwined double-helix structures of D N A of 5 prime and 3 prime sequences followed by a C p G dinucleotide. The complimentary codons on D N A strand 5 prime is C P G and 3 prime is G P C.

Box 6.1

Cancer of Ovary and Breast Can Arise Through Epigenetic Silencing of Tumor-Suppressor Gene *BRCA1*

Inherited mutations in the coding region of the *BRCA1* and *BRCA2* genes are known to increase risk of breast, ovarian, and prostate cancer. However, such mutations cannot explain all cases of breast cancer. Many families have a high incidence of breast cancer but no known pathogenic variants in the coding regions of the *BRCA1* gene. Researchers sought to identify *epimutations* (errors in epigenetic gene repression) that could potentially account for breast cancer in these families.

Evans et al. used bisulfite sequencing to examine the promoter region of the *BRAC1* or *BRCA2* genes in 49 women who had breast or ovarian cancer but did not have mutations in the coding regions of either gene. Abnormal, dense DNA methylation in the *BRCA1* promoter was found in two of these women. Both women also had a single mutation in the promoter of the gene. Examination of DNA from other women in the families of these women revealed that the point mutation was strongly associated with DNA methylation and transcriptional silencing of the *BRCA1* gene.

In conclusion, point mutations in the promoter region of the *BRCA1* gene can increase the probability of dense methylation. This dense methylation can lead to gene inactivation, indicating that epigenetic mechanisms driven by noncoding mutations can lead to breast cancer through loss of *BRCA1* function.

Inherited BRCA1 epimutation as a novel cause of breast and ovarian cancer. 2018. https://doi.org/10.1101/246934; Evans DGR, van Veen EM, Byers HJ, et al. A dominantly inherited 5′ UTR variant causing methylation-associated silencing of BRCA1 as a cause of breast and ovarian cancer. *Am J Human Genet*. 2018;103:213–220.

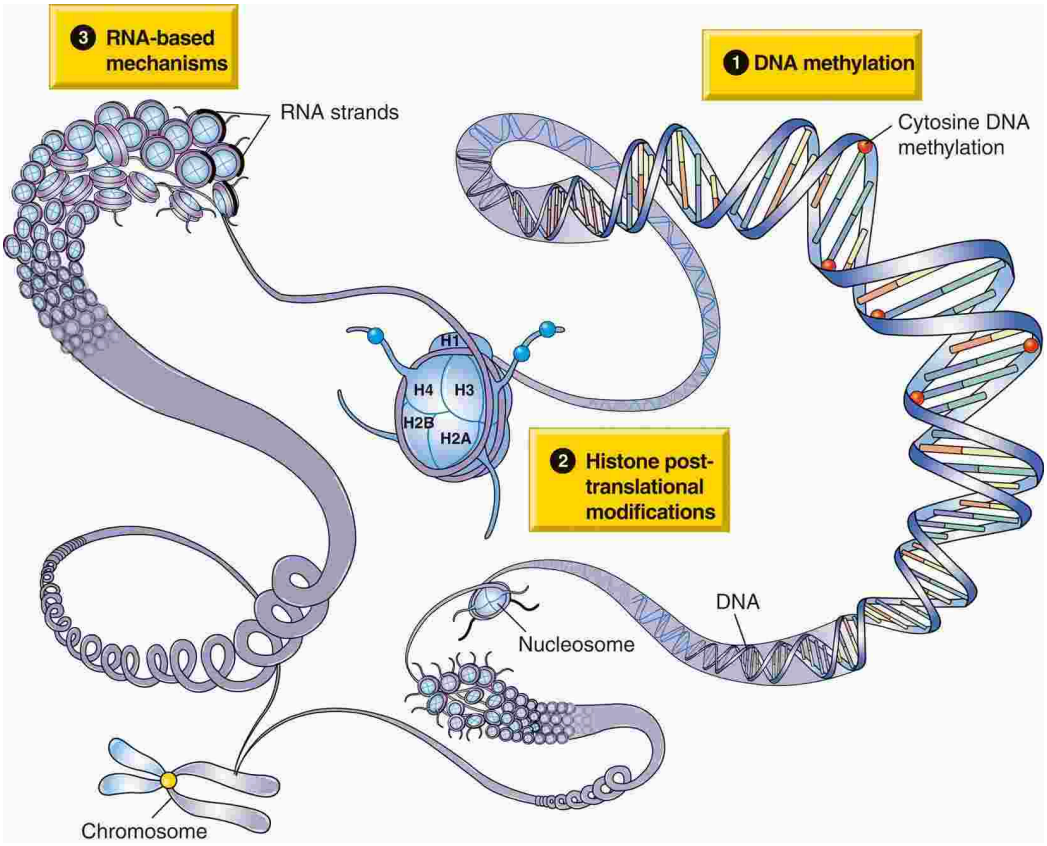

FIG. 6.1 Three Types of Epigenetic Processes. Investigators are studying three epigenetic mechanisms: *(1)* DNA methylation. *(2)* Histone modifications. *(3)* RNA-based mechanisms. See text for discussion.

An illustration of D N A condensing into chromosome depicts the three fundamental mechanisms of epigenetic gene as follows: 1. D N A methylation. 2. Histone post-translational modifications. 3. R N A-based mechanisms. The labels shown are as follows: R N A strands, cytosine D N A methylation, D N A, nucleosome, and chromosome.

Three Types of Epigenetic Processes

Epigenetics and Human Development

Each of the cells in the very early embryo has the potential to give rise to a somatic cell of any type. These **embryonic stem cells** are said to be *totipotent* ("possessing all powers"). A key process in early development is the differential epigenetic modification of specific DNA nucleotide sequences in these embryonic stem cells, which ultimately leads to the differential gene-expression profiles that characterize the various differentiated somatic cell types. These early modifications ensure that specific genes are expressed only in the cells and tissue types in which their gene products typically function (e.g., factor VIII expression primarily in hepatocytes, or dopamine receptor expression in neurons).

Epigenetic modifications that arise during early development ensure that specific genes are expressed only in the cells and tissue types in which their gene products normally function. Only a small percentage of genes, termed **housekeeping genes**, are ubiquitously expressed across cell types, escaping epigenetic silencing to remain transcriptionally active in all or nearly all cell types. Housekeeping genes include those encoding histones, DNA and RNA polymerases, and ribosomal RNA genes.

How do embryonic stem cells achieve epigenetic states typical of totipotency and can give rise to all the diverse cell types that comprise a fully developed organism? One hypothesis is that early embryogenesis (the 10 or so days just after fertilization) is characterized by rapid fluctuation in genome-wide DNA methylation densities. Fertilization triggers a global loss of DNA methylation at most loci in both the oocyte-contributed and the sperm-contributed genomes. This loss of methylation is accomplished in part by suppression of the DNA methyltransferases, the enzymes that add methyl groups to DNA. Methylation is not directly copied by the DNA replication process. Instead, immediately following replication, the methyltransferases read the pattern of methylation on the parent DNA strand and use that

information to determine which daughter-strand cytosines should be methylated. As embryonic cell division proceeds in the absence of DNA methyltransferases, cell division continues, eventually yielding cells that have nearly all their loci in unmethylated, transcriptionally active states. Around the time of implantation in the uterus, the DNA methyltransferases become active again, permitting establishment of the cell lineage–specific marks required for the establishment of organ systems.

Genomic Imprinting

A baby inherits two copies of each autosomal gene: one from its mother and one from its father. For a large subset of these genes, expression is **biallelic**, meaning that both the maternal and the paternal inherited copies contribute to offspring phenotype. For another, smaller subset of these genes, expression is stochastically **monoallelic**, meaning that the maternal copy is randomly chosen for inactivation in some somatic cells and the paternal copy is randomly chosen for inactivation in other somatic cells. For a third and smaller subset of autosomes (approximately 1%), either the maternal copy or the paternal copy is **imprinted**, meaning that either the copy inherited through the sperm or the copy inherited through the egg is inactivated and remains in this inactive state in all of the somatic cells of the individual.[22]

The subset of genes that are subject to imprinting is highly enriched for loci that are relevant to organismal growth. The *genetic conflict hypothesis*[23] was developed as a potential explanation for this pattern. Although both the mother and father benefit genetically from the birth and survival of offspring, their interests are not entirely aligned. Because a mother makes a large physiologic investment in each child, it is in her evolutionary best interest to limit the flow of energetic resources to any given offspring, to maintain her physiologic capacity to bear subsequent children. By contrast, it is in the best interest of the father for his child to extract maximum resources from the mother because his own future fecundity (fertility) is not contingent on the sustained fecundity of

the mother. In general, imprinting of maternally inherited genes tends to reduce offspring size, whereas imprinting of paternally inherited genes tends to increase offspring size. One hallmark of imprinting-associated disease is that the phenotype of affected individuals is critically dependent on whether the mutation is inherited from the mother or from the father.

A well-known disease example of imprinting is associated with a deletion of approximately 4 million base (Mb) pairs of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests **Prader-Willi syndrome**, whose features include short stature, hypotonia, small hands and feet, obesity, mild to moderate intellectual disability, and hypogonadism (Fig. 6.3A). The same 4-Mb deletion, when inherited from the mother, causes **Angelman syndrome**, which is characterized by severe intellectual disability, seizures, and an ataxic gait (see Fig. 6.3B). These diseases are each observed in approximately 1 of every 10,000 to 30,000 live births; chromosome deletions are responsible for approximately 70% of cases of both diseases.[24] The deletions that cause Prader-Willi and Angelman syndromes are indistinguishable at the DNA sequence level and affect the same group of genes.

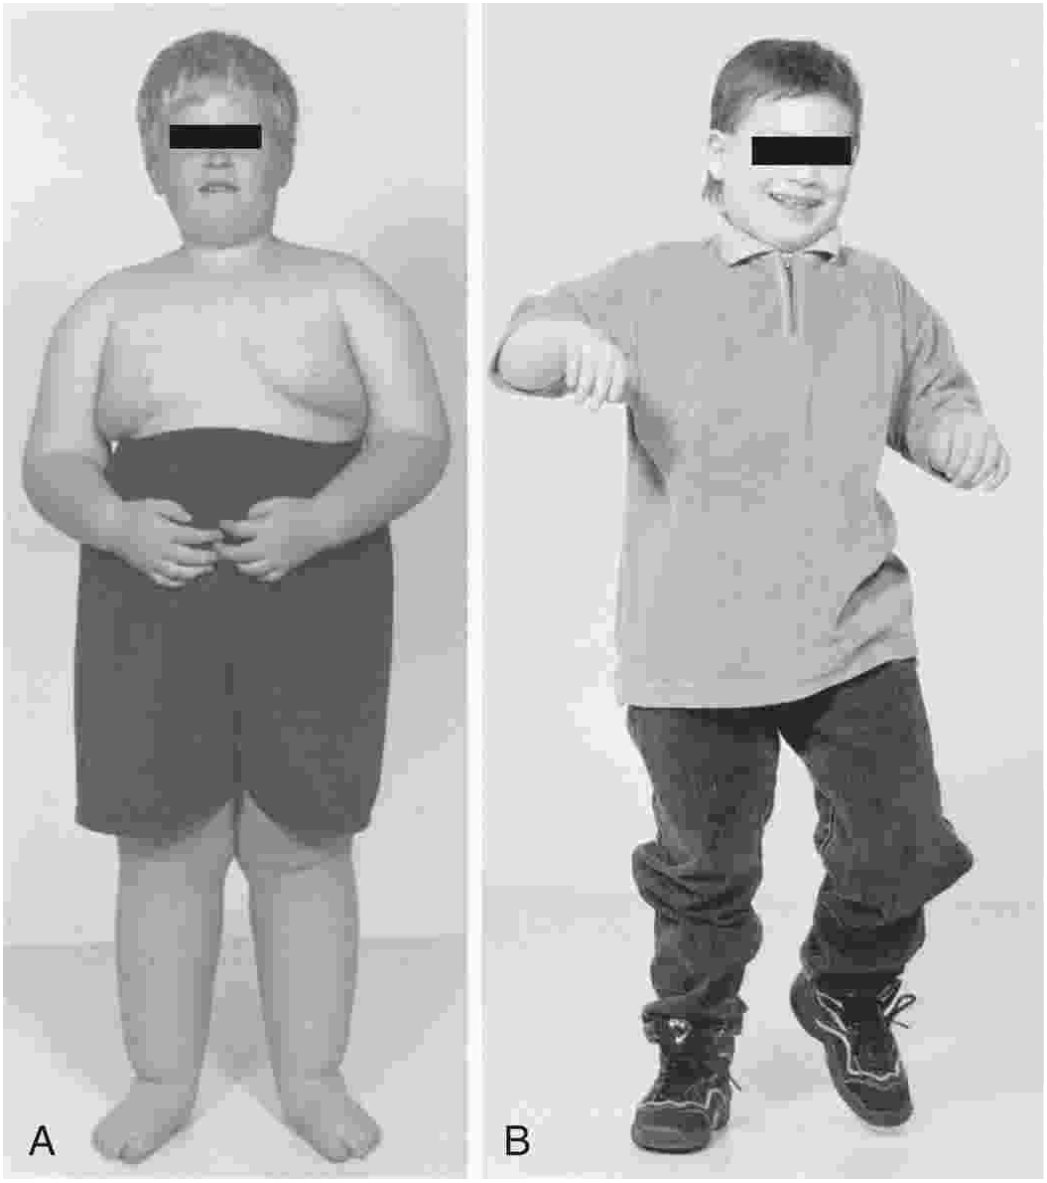

FIG. 6.3 Prader-Willi and Angelman Syndromes.
(A) A child with Prader-Willi syndrome (truncal obesity, small hands and feet, inverted V-shaped upper lip). **(B)** A child with Angelman syndrome (characteristic posture, ataxic gait, bouts of uncontrolled laughter). (From Jorde LB, Carey JC, Bamshad MJ. *Medical Genetics*. 4th ed. Philadelphia: Mosby; 2010.)

Prader-Willi and Angelman Syndromes

For several decades, it was unclear how the same deletion could produce such disparate results in different individuals. Further analysis showed that the 4-Mb deletion (the *critical region*) contains several genes that are normally transcribed only on the copy of chromosome 15 that is inherited from the father.[25]

These genes are transcriptionally inactive (imprinted) on the copy of chromosome 15 inherited from the mother. Similarly, other genes in the critical region are transcriptionally active only on the chromosome copy inherited from the mother and are inactive on the chromosome inherited from the father. Thus several genes in this region are normally active on only one chromosome copy. If the single active copy of one of these genes is lost because of a chromosome deletion, then no gene product is produced resulting in disease.

Prader-Willi Syndrome Pedigrees

Molecular analysis has revealed much about genes in this critical region of chromosome 15.[25] The gene responsible for Angelman syndrome encodes a ligase involved in protein degradation during brain development (consistent with the intellectual disability and ataxia observed in this disorder). In brain tissue, this gene is active only on the chromosome copy inherited from the mother. Consequently, for this gene a maternally transmitted deletion removes the single active copy. Several genes in the critical region are associated with Prader-Willi syndrome, and they are transcribed only on the chromosome transmitted by the father. A paternally transmitted deletion removes the only active copies of these genes producing the features of Prader-Willi syndrome (Fig. 6.4).

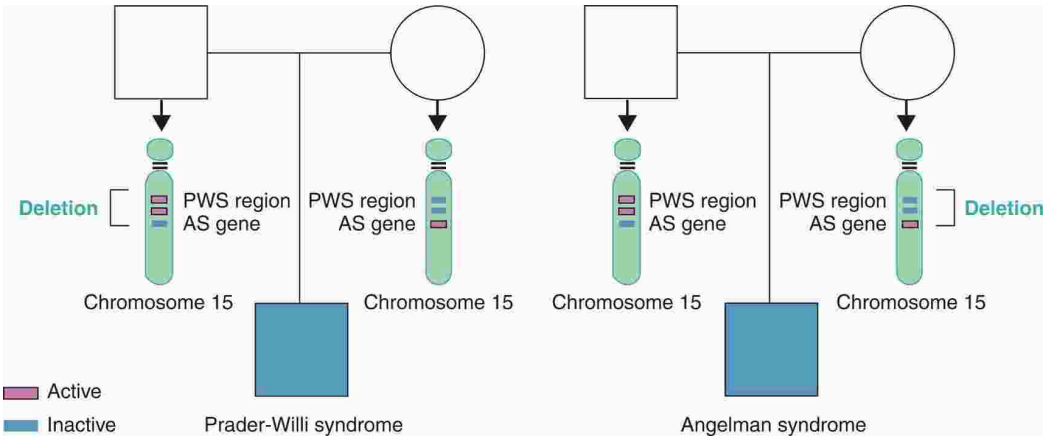

FIG. 6.4 Prader-Willi Syndrome Pedigrees. These pedigrees illustrate the inheritance patterns of Prader-Willi syndrome, which can be caused by a 4-million base pair (Mb) deletion of chromosome 15q when inherited from the father. In contrast, Angelman syndrome can be caused by the same deletion but only when it is inherited from the mother. The reason for this difference is that different genes in this region are normally imprinted (inactivated) in the copies of 15q transmitted by the mother and the father. (From Jorde LB, Carey JC, Bamshad MJ. *Medical Genetics*. 4th ed. Philadelphia; Mosby; 2010.)

Two pedigree charts, A and B, illustrate the inheritance pattern of Prader-Willi syndrome and Angelman syndrome. Pedigree chart A shows a square labeled deletion of chromosome 15 in P W S region with two active and one inactive A S gene, mates with a circle labeled P W S region with two inactive and one active A S gene results in solid square labeled Prader-Willi syndrome. Pedigree chart B shows a square labeled P W S region with

two active and one inactive A S gene, mates with circle labeled deletion of chromosome 15 in P W S region with two inactive and one active A S gene results in solid square labeled Angelman syndrome.

Beckwith-Wiedemann Syndrome

Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an increased predisposition to cancer. **Beckwith-Wiedemann syndrome** is usually identifiable at birth because of large size for gestational age, neonatal hypoglycemia, a large tongue, creases on the ear lobe, and omphalocele (birth defect of infant intestines). Children with Beckwith-Wiedemann syndrome have an increased risk of developing Wilms tumor or hepatoblastoma. Both tumors can be treated effectively if they are detected early; thus screening at regular intervals is an important part of management.[26] Some children with Beckwith-Wiedemann syndrome also develop asymmetric overgrowth of a limb or one side of the face or trunk (hemihyperplasia) (Fig. 6.5). As with Angelman syndrome, a minority of Beckwith-Wiedemann syndrome cases (approximately 20% to 30%) are caused by the inheritance of two copies of a chromosome from the father and no copy of the chromosome from the mother (**uniparental disomy**, in this case affecting chromosome 11). Several genes on the short arm of chromosome 11 are imprinted on either the paternally or maternally transmitted chromosome. These genes are found in two separate, differentially methylated regions (DMRs). In DMR1, the gene that encodes insulin-like growth factor 2 *(IGF2)* is inactive on the maternally transmitted chromosome but active on the paternally transmitted chromosome. Thus a normal individual has only one active copy of *IGF2*. When two copies of the paternal chromosome are inherited (i.e., paternal uniparental disomy) or there is loss of imprinting on the maternal copy of *IGF2*, an active *IGF2* gene is present in double dose. These changes

produce increased levels of IGF2 during fetal development contributing to the overgrowth features of Beckwith-Wiedemann syndrome. Note that, in contrast to Prader-Willi and Angelman syndromes, which are produced by a missing gene product, Beckwith-Wiedemann syndrome is caused, in part, by overexpression of a gene product.

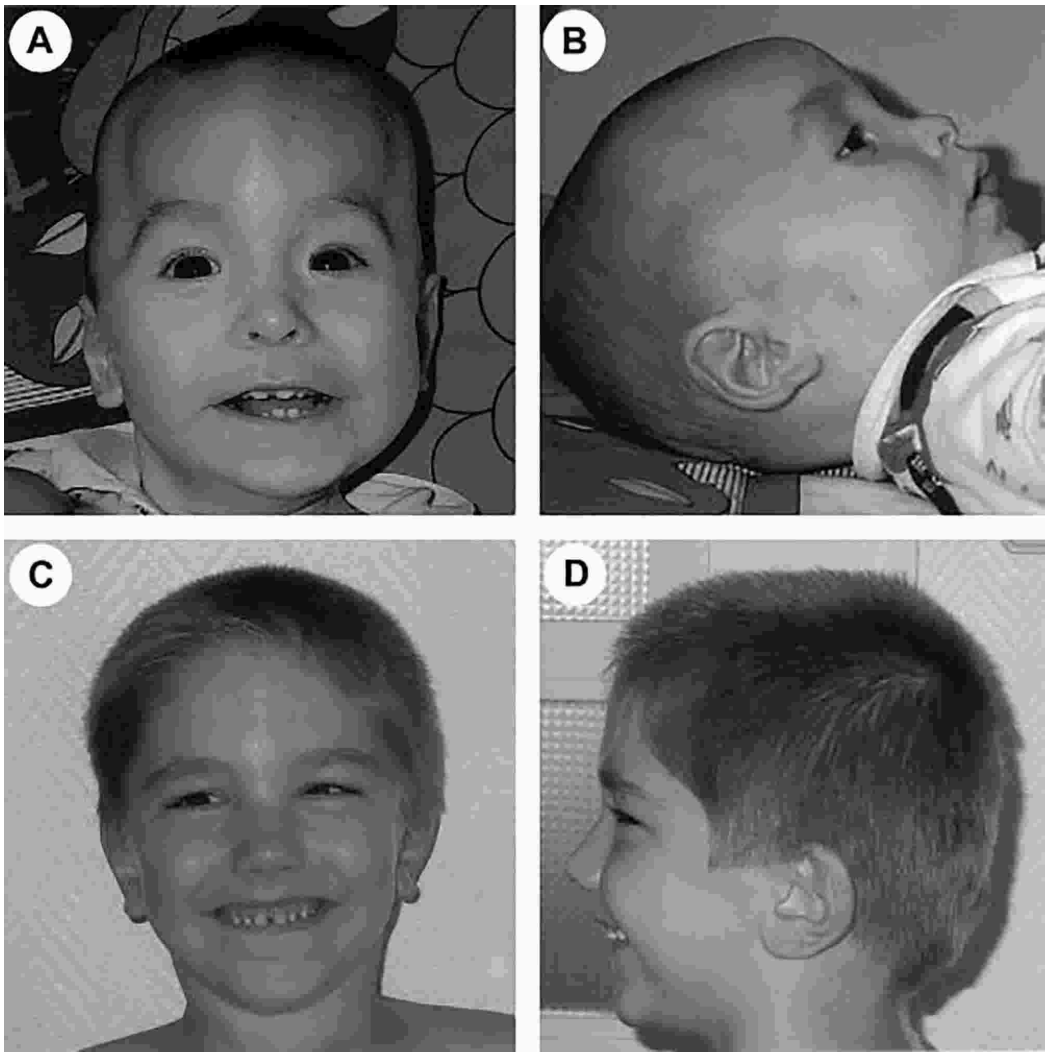

FIG. 6.5 Beckwith-Wiedemann Syndrome. Facial features of individuals with Beckwith-Wiedemann Syndrome (BWS). **A** and **B**, Frontal and lateral views of 1-year-old who had craniostensosis from a 1-bp NSD1 deletion. The Frontal bossing and antimongoloid slant of the palpebral fissure are not typical of BWS. **C** and **D**, Frontal and lateral views of a 4-year-old child with BWS who had a 4-bp NSD1 deletion. (From Baujat G, Rio M, Rossignol S, et al. Paradoxical NSD1 mutations in Beckwith-Wiedemann syndrome and 11p15 anomalies in Sotos syndrome. *Am J Hum Genet*. 2004;74[4]:715–720.)

Four photos, A through D, show the facial features of an infant and child with Beckwith-Wiedemann Syndrome. Photo A shows the closeup of an infantâ€™s anterior profile with Beckwith-Wiedemann Syndrome. Photo B shows the closeup of an infantâ€™s lateral profile with Beckwith-Wiedemann Syndrome. Photo C shows the closeup of a boyâ€™s anterior profile with Beckwith-Wiedemann Syndrome demonstrating an asymmetric face. Photo D shows the closeup of a boyâ€™s lateral profile with Beckwith-Wiedemann Syndrome.

Russell-Silver Syndrome

Russell-Silver syndrome is characterized by growth retardation; proportionate short stature; leg length discrepancy; and a small, triangular-shaped face (Fig. 6.6). Approximately one-third of Russell-Silver syndrome cases are caused by imprinting abnormalities of chromosome 11p15.5 that led to downregulation of IGF2 and therefore diminished growth. Another 10% of cases of Russell-Silver syndrome are caused by maternal uniparental disomy. Thus upregulation or extra copies of active IGF2 causes overgrowth in Beckwith-Wiedemann syndrome, whereas downregulation of IGF2 causes the diminished growth seen in Russell-Silver syndrome.[27]

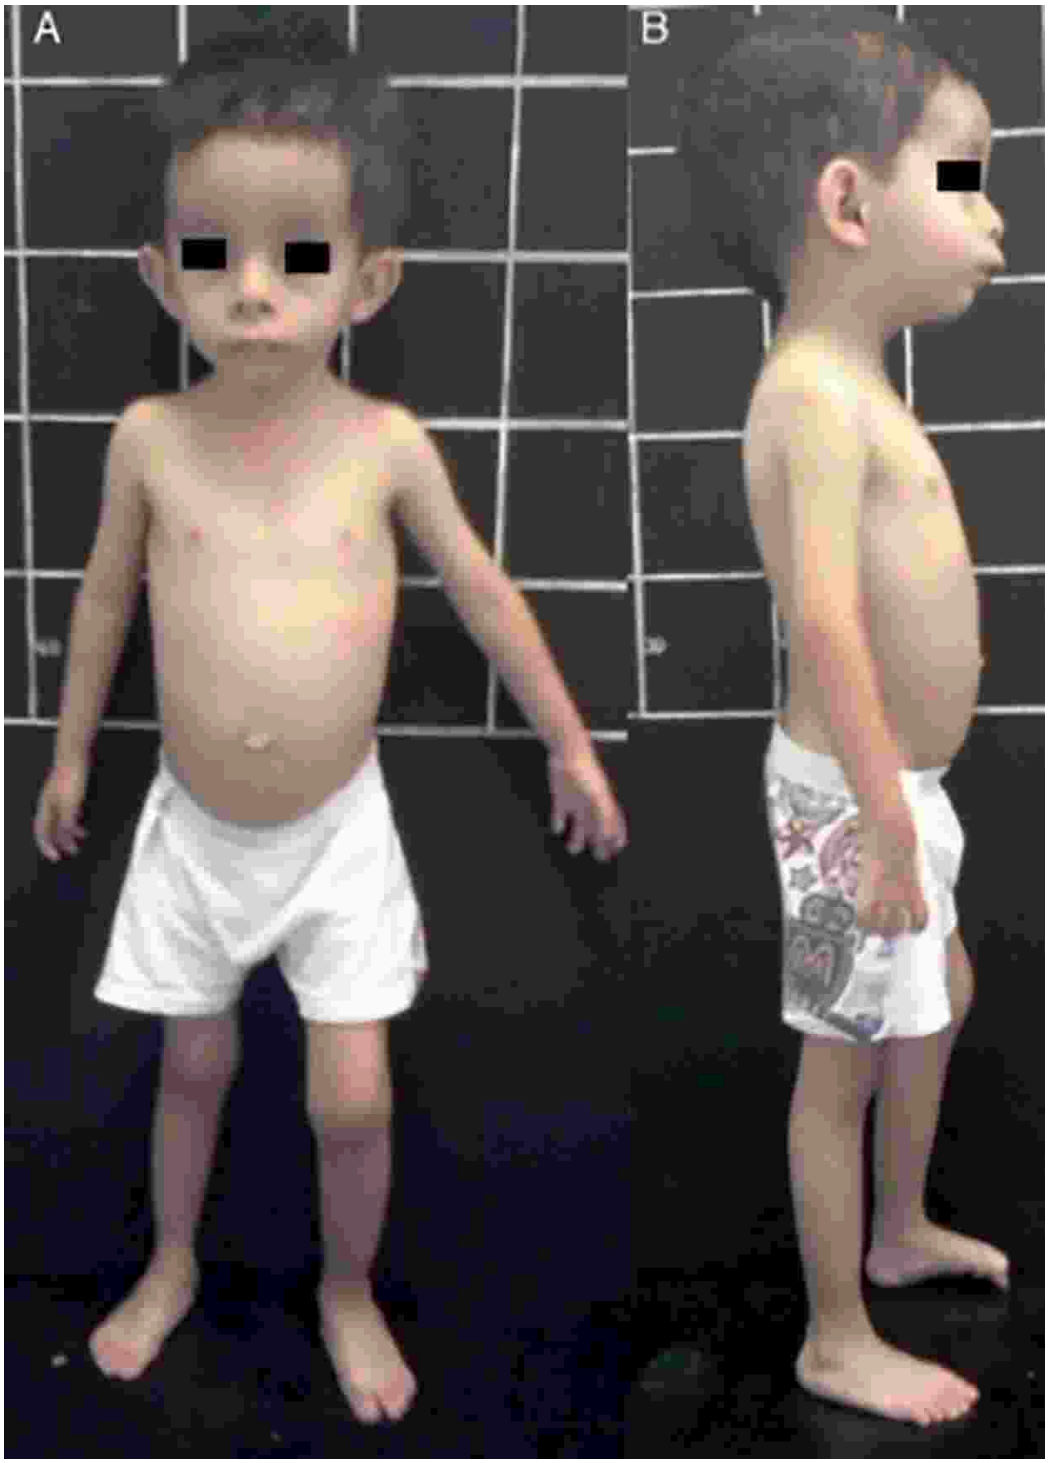

FIG. 6.6 Russell-Silverman Syndrome.
Child with Russell-Silverman Syndrome. **A**, Front view. **B**, Lateral view. Note hemihypertrophy with asymmetry, relative macrocephaly, triangular facies, prominent upper jaw, and an undersized

lower jaw. (From Galaz-Montoya CI, García-Delgado C, Cervantes-Peredo A, et al. Clinical profile of a cohort of Silver-Russell syndrome patients followed at the Hospital Infantil de México Federico Gómez from 1998 to 2012. *Bol Med Hosp Infant Mex*. 2014;71[4]:218–226.)

Two photos, A and B, show the features of a child with Russell-Silverman syndrome. Photo A shows the anterior profile of a child with Russell-Silverman syndrome. Photo B shows the lateral profile of a child with Russell-Silverman syndrome.

Epigenetics in Development and Mental Health

Several lines of evidence suggest a role for epigenetic abnormalities in disorders of development.

Epigenetics and Ethanol Exposure in Utero

The impact of ethanol exposure in utero on skeletal and neural development was first reported in 1973[28] and led to broad awareness of fetal alcohol syndrome (see Chapter 2). Only recently did population-based and molecular-level studies begin to clarify the epigenetic signals that mediate these impacts via both genome-wide and locus-specific mechanisms. The DNA methylation status of specific CpG sites differs between children with and without fetal alcohol spectrum disorder. The epigenetic impacts of ethanol exposure may extend to adulthood, with large cohort studies indicating changes in global[29] and site-specific methylation[30] as candidate markers of high level of alcohol consumption.

Epigenetics and Mental Health

Several emerging lines of evidence indicate an association between altered epigenetic states and mental health. Methylation profiles at genes associated with social behavior differ between women with anorexia nervosa and normal, age-matched controls.[31]

Individuals with posttraumatic stress disorder (PTSD) are reported to have changes in the methylation states of four cytosines within an immune-regulatory locus,[32] offering a potential explanation for the earlier finding of immune hyperactivation in affected individuals.[33] Many studies indicate an impact of adverse events during childhood on methylation profiles in adulthood (See Emerging Science Box: Parsing Apart Contributions of Genotype and Childhood Adversity to Methylation States in Adulthood).[34] Genomic regions may vary in the timing of their greatest sensitivity to the environment, with some reports indicating that adversity before age three has the greatest impact.[35] An ongoing challenge for studies linking environment to mental health is to determine whether observed epigenetic alterations play a mechanistic role in the etiology of cognitive syndromes or whether information on this link is considered principally for suggesting biomarkers potentially useful for diagnosis.

Emerging Science Box

Parsing Apart Contributions of Genotype and Childhood Adversity to Methylation States in Adulthood

Although some studies have suggested that epigenetic mechanisms may mediate the long-term health effects of adversity in early life (reviewed in Kundakovic and Champagne, 2015), results have been highly variable across studies. Cazmara and colleagues (2021) sought to address these complexities directly by quantifying the relative contributions of genotype and early-life adversity to methylation states in blood and saliva samples taken

from individuals of a range of ages. Exposure to childhood adversity was assessed through retrospective surveys. The study finds little evidence of a direct role for childhood adversity in shaping methylation states at any age. However, the authors detected evidence of a role for interactions between genotype and childhood adversity in explaining methylation states later in life. The finding that some genotypes could heighten the potential for adverse experiences early in life will yield epigenetic outcomes could help to explain inconsistent outcomes across studies in which genotype was not measured, or not considered in data analysis.

Data from Czamara D, et al. Combined effects of genotype and childhood adversity shape variability of DNA methylation across age. *Transl Psychiatry*. 2021;11(1):88; Kundakovic M, et al. Early-life experience, epigenetics, and the developing brain. *Neuropsychopharmacology*. 2015;40(1):141–153.

Fragile X Syndrome: A Genetic/Epigenetic Syndrome

In some diseases, both genetic and epigenetic factors contribute to the origin of abnormal phenotypes. For example, several abnormal phenotypes can arise in individuals with mutations at the **fragile X** locus, *FMR1*. The most common genetic abnormality at *FMR1* involves expansion in the number of cytosine-guanine (CG) dinucleotide repeats in the gene promoter. Females who have CG repeats more than the approximate 35 that are typical at this locus are at risk for fragile X–associated primary ovarian insufficiency, characterized by an elevated risk of early menopause.[36] Males with moderate expansions are at risk of fragile X tremor ataxia syndrome (FXTAS), characterized by a late-onset intention tremor and mitochondrial dysfunction.[37] Psychiatric phenotypes in the absence of intention tremor have also been reported for males with a premutation allele.[38]

Individuals with 200 repeats are at risk of fragile X syndrome, characterized by reduced IQ and a set of behavioral abnormalities. Fragile X syndrome, which is characterized by cognitive impairment, results from abnormal epigenetic silencing of the *FMR1* locus via

accrual of dense methylation within the expanded CG repeat region (Fig. 6.7A); targeted demethylation is sufficient to restore transcriptional activity of the expanded allele in cultured neurons, suggesting a potential therapeutic path. Remarkably, although possession of a large CG repeat in the *FMR1* promoter dramatically increases the probability that an individual will have fragile X syndrome, the disease can be present in males who have the large repeat and absent in their male siblings who have inherited an allele of very similar size.[39] The difference can be explained in part by the observation that acquisition of methylation-based silencing at *FMR1* is stochastic, meaning that the presence of a large repeat increases the probability of the dense promoter methylation that could lead to gene silencing but does not guarantee it. It remains to be seen whether dietary or environmental features can modulate the probability that dense methylation at *FMR1* will accrue in individuals with the full-mutation allele. Facioscapulohumeral muscular dystrophy results from the converse process, wherein mutational contraction of the DUX4 locus results in loss of methylation and aberrant expression (see Fig. 6.7B).

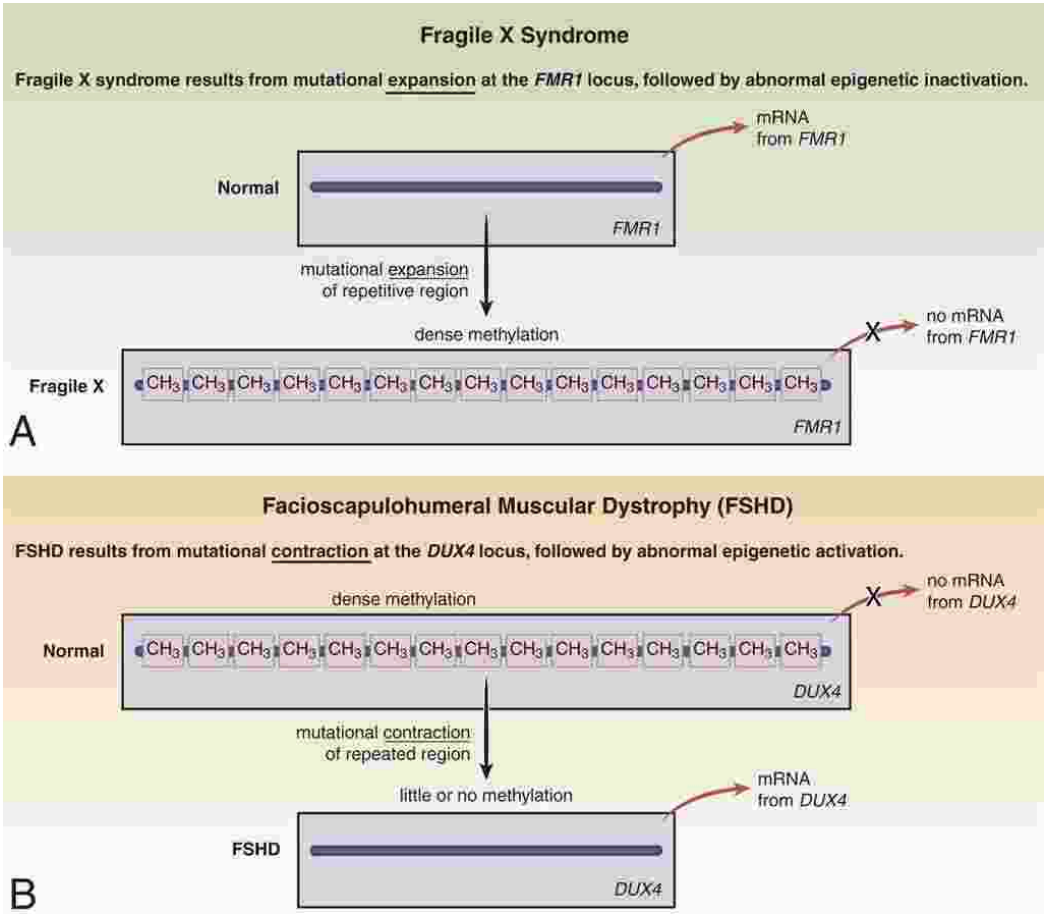

FIG. 6.7 Comparing the Molecular Mechanisms of Fragile X and Facioscapulohumeral Muscular Dystrophy. (A) *FMR1* in normal, expanded permutation, and full-mutation states. (B) *DUX4* in normal and contracted states.

Top panel A depicts the molecular mechanism of fragile X syndrome which shows the fragile X syndrome results from mutational expansion at the F M R 1 locus followed by abnormal epigenetic inactivation. Bottom panel B depicts the molecular mechanism of facioscapulohumeral muscular dystrophy which shows the facioscapulohumeral

muscular dystrophy results from mutational contraction at the D U X 4 locus, followed by abnormal epigenetic activation.

Exploring the Multigenerational Persistence of Epigenetic States

In some cases, epigenetic changes arising during an individual's lifetime may be transmitted through the germline, with the potential to impact gene expression in future generations.

Epigenetics and Nutrition

During the winter of 1943, millions of people in urban areas of the Netherlands suffered starvation conditions because of Nazi blockage of shipments of food from agricultural areas. When researchers sought to investigate how exposure to famine in utero had impacted individuals born in a historically prosperous country, they found individuals who suffered nutritional deprivation in utero were more likely to suffer from obesity and diabetes as adults than individuals in the Netherlands who had not experienced nutritional deprivation during gestation. There also seemed to be a transgenerational impact. The children of individuals who were in utero during the Dutch Hunger Winter were found to be significantly smaller than the children of those not impacted by the blockade. Other data sets reveal elevated risk of cardiovascular and metabolic disease for offspring of individuals exposed during early development to fluctuations in agricultural yields,[40] suggesting an intergenerational effect. More recent studies have also uncovered a relationship between exposures in utero and metabolic health in adulthood.[41,42]

The specific molecular mechanisms that mediate reported relationships between exposure to famine and disease risk in adulthood or in subsequent generations remain largely unknown.

From some animal models, it seems that the IGF2 gene is a possible target of epigenetic modifications arising through nutritional deprivation. Exposure in utero and through lactation to some chemicals (including bisphenol A, a constituent of plastics sometimes used in food preparation and storage) seems to lead to epigenetic modifications similar to those that arise through nutritional deprivation in early life (Box 6.2).[43]

Box 6.2

Epigenetics Could Explain Correlation Between Birth Month and Body Mass Index

It has long been observed that people conceived during cold times of the year tend to have lower body mass index (BMI) compared with people conceived during warmer times of the year. Sun et al. exposed male and female mice to cold temperatures before mating, then assessed the body mass and gene expression in their offspring. Their findings confirmed data from human populations. Offspring of male mice exposed to cold before mating tend to have larger amounts of brown adipose, a tissue with very high metabolic rate, as well as a lower overall probability of diet-induced obesity. Exposing female mice to cold before mating had no impact on brown adipose or obesity risk in their offspring. Exploration of DNA methylation in the sperm of cold-exposed male mice revealed methylation in the promoters of several genes involved in the production of brown adipose tissue.

In conclusion, the sperm of male mice exposed to cold have reduced methylation in several genes relevant to the development of brown adipose tissue by a yet unknown mechanism. The offspring of these cold-exposed males have higher expression of these genes, resulting in higher amounts of brown adipose tissue, higher metabolic rate, and lowering risk of diet-induced obesity.

Future work could focus on potential applications of cold exposure in the treatment or prevention of obesity.

Data from Sun W, Dong H, Becker AS, et al. Cold-induced epigenetic programming of the sperm enhances brown adipose tissue activity in offspring. *Nat Med*. 2018;24(9):1372–1383.

Epigenetics and Maternal Care

Mice and other rodents can exhibit two alternative styles of nursing behavior: frequent arched-back nursing, with a high level of licking and grooming behavior, and a style with infrequent arched-back nursing, with reduced licking and grooming behavior. A number of studies[44] have found that methylation states at the glucocorticoid receptor differ between mice exposed to these two different categories of maternal care. Because the glucocorticoid receptor is involved in a pathway that intensifies fearfulness and response to stress, these findings suggest that alteration to methylation states could help to explain the finding that exposure to stress early in life can modulate behavior in adulthood. These findings also highlight the concept that epigenetic processes can help store information about the environment and that the relevant epigenetic modifications can modulate behavior later in life.

Epigenetic Change Over the Lifespan

Twin Studies Provide Insights on Epigenetic Modification

Identical (monozygotic) twins, whose DNA sequences are essentially the same, offer a unique opportunity to isolate and examine the trajectory of epigenetic change over the lifespan. A recent study found that, as twins age, they exhibit increasingly substantial differences in methylation patterns of the DNA sequences of their somatic cells; these changes are often reflected in increasing numbers of phenotypic differences. Twins with significant lifestyle differences (e.g., smoking versus nonsmoking) tend to accumulate larger

numbers of differences in their methylation patterns. These results, along with findings that caloric restriction and other factors known to slow aging can also alter methylation states,[45] suggest that changes in epigenetic patterns may be an important part of the aging process (Fig. 6.8).

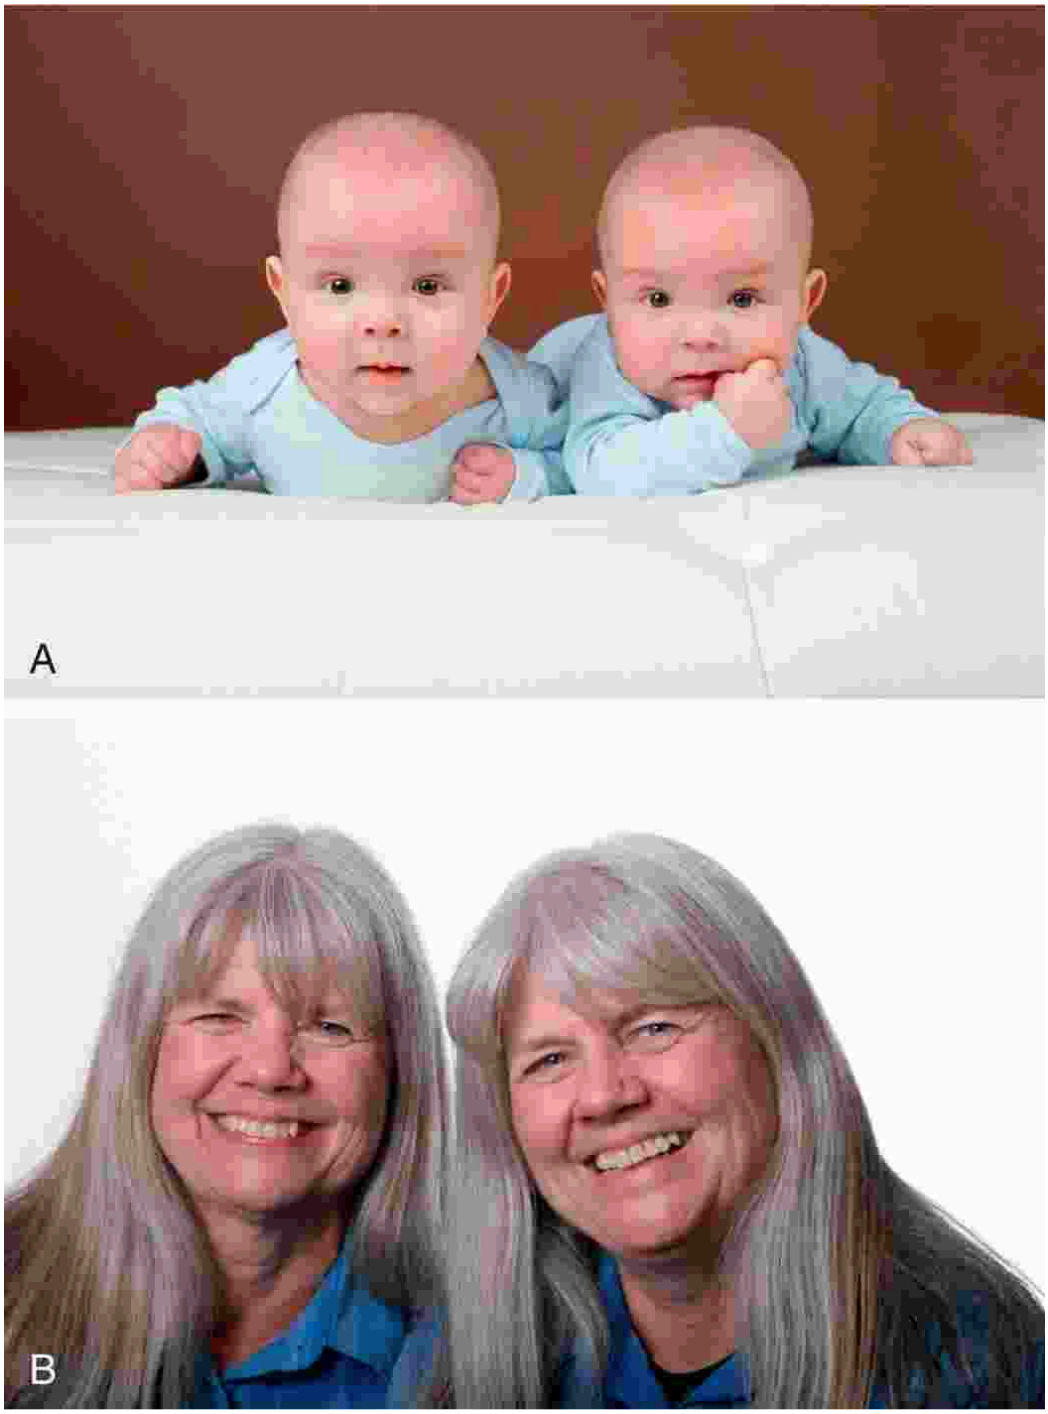

FIG. 6.8 Twins and Aging.
(A) Twins as babies look very much alike but **(B)** as adults have slight differences in appearance, possibly because of epigenetics. (A, vgm/Shutterstock. B, Stacey Bates/Shutterstock.)

The 2013 discovery of a set of approximately 350 CpG sites whose methylation status corresponds closely to an individual's age in years has inspired and enabled study of how specific environmental factors modulate the rate of biologic aging. For example, one recent study uncovered significant effects of vegetable consumption on the body mass index.[46]

Tools for Exploring Epigenetic States

Epigenetic information is not encoded DNA sequence. Therefore specialized methods must be used to detect and quantify it.

Detecting DNA Methylation in Populations of Molecules: Methyl-Sensitive Restriction Enzymes

Many restriction enzymes are sensitive to methylation and cleave DNA only at cytosines that are free of methylation. Clues to the overall level of methylation in DNA isolated from a given individual can be gathered by treating DNA with a methyl-sensitive enzyme and then comparing banding patterns for enzyme-treated and non–enzyme-treated samples.[47]

Detecting DNA Methylation in Single Molecules: Bisulfite Conversion

However, it is of interest to gather information about methylation on individual molecules. For example, among males who inherit a full-mutation fragile X allele, there is a strong correlation of the severity of the syndrome to the number of cells in which the fragile X allele is densely methylated.[39] To collect information on the methylation states of individual molecules, DNA can be subjected to bisulfite conversion prior to sequencing. Bisulfite treatment does not alter most nucleotides, including methylated cytosines, but deaminates unmethylated cytosines to uracil (Fig. 6.9).[48] Because uracil complements adenine, not guanine, methylated and unmethylated

cytosines can be distinguished in resulting sequence data if the reference nucleotide sequence is known. Either subcloning followed by Sanger sequencing, or next-generation sequencing can then be applied to ascertain the detailed methylation patterns of individual molecules.

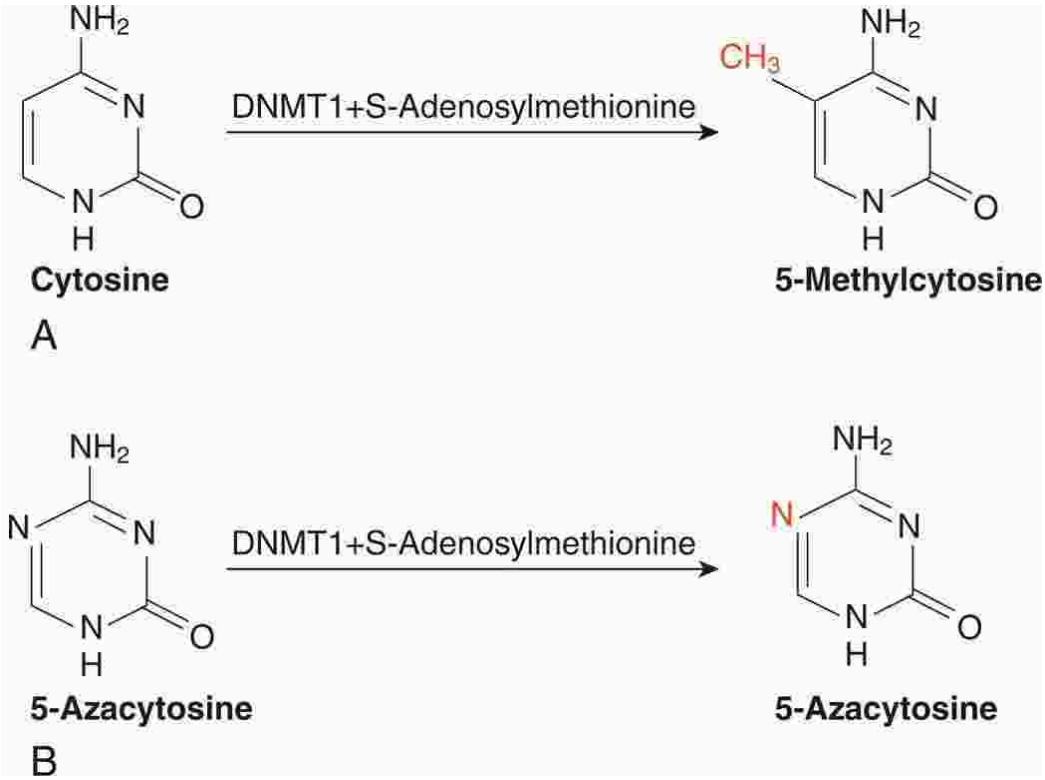

FIG. 6.9 5-Azacytosine as Demethylating Agent.

(A) Unmethy-lated cytosines in DNA are typically subject to the addition of methyl groups by DNA methyltransferase 1 (DNMT1), a DNA methyltransferase, using methyl groups supplied by the methyl donor S-adenosylmethionine. **(B)** In 5-azacytosine, the 5′ carbon of cytosine is replaced with a nitrogen. This chemical difference is sufficient both to block the addition of a methyl group and to confer irreversible binding to DNMT1. Incorporation of 5-azacytosine into DNA is therefore sufficient to drive passive loss of methylation from replicating DNA and thus to reactivate hypermethylated loci. 5-Azacytosine, bound to a sugar, can be integrated into DNA and has been administered with some success in treating epigenetic diseases that arise through hypermethylation of individual loci.

Two chemical equations, A and B, depict the methylation states of individual molecules subjected to bisulfite conversion. Top panel A shows cytosine is converted to 5-methylcytosine by addition of D N M T 1 and S-adenosylmethionine. The structure of cytosine comprises a six-membered ring. The carbon atoms at positions 1 and 3 are replaced by a nitrogen atom. The carbon atom in position 2 is attached to a carboxylic group and the carbon atom in position 6 is attached to the amine group. The structure of 5-Methylcytosine comprises a six-membered ring. The carbon atoms at positions 1 and 3 are replaced by a nitrogen atom. The carbon atom in position 2 is attached to a carboxylic group, the carbon atom in position 5 is attached to a methyl group and the carbon atom in position 6 is attached to the amine group. Bottom panel B shows 5-Azacytosine is converted to 5-azacytosine by the addition of D N M T 1 and S-adenosylmethionine. The structure of 5-Azacytosine comprises a six-membered ring. The carbon atoms at positions 1, 3, and 5 are replaced by a nitrogen atom. The carbon atom in position 2 is attached to a carboxylic group and the carbon atom in position 6 is attached to the amine group.

Detecting DNA Hydroxymethylation: Fluorescence Resonance Energy Transfer

Efforts to track the early-developmental transition from methylation to hydroxymethylation were initially hampered by the absence of a method to detect relative levels of DNA methylation and DNA hydroxymethylation within individual molecules. The introduction of Tet-assisted pyridine borane sequencing (TAPS) solves this problem. Like bisulfite treatment, TAPS involves a chemical conversion step but follows this step with enzyme-mediated C-to-T transition.

Identifying Histone-Modification States: Chromatin Immunoprecipitation

Information on the identity of DNA-bound proteins can provide important clues as to the activity states of individual regions. The goal of chromatin immunoprecipitation (ChIP) is to ascertain the sequences bound to specific proteins of interest. Broadly, this is achieved in six steps:

1. **Crosslink** DNA-bound proteins and the specific genomic regions to which they are attached. At this step, binding is not specific, meaning that all proteins, regardless of identity, are crosslinked to DNA.
2. **Shear** DNA, effectively lysing DNA regions that are not protein bound.
3. **Select** for proteins of interest, using an antibody specific to the protein of interest.
4. **Capture** protein-DNA complexes using a secondary antibody that can bind to the first; wash away any remaining, unbound DNA fragments.
5. **Remove** protein-DNA crosslinks and wash away proteins.
6. **Sequence** DNA fragments to profile the portion of genome that was bound by the protein of interest.

Detecting DNA Accessibility States: DNAse Hypersensitivity Testing

One of the hallmarks of transcriptionally active regions of the genome is sensitivity to cleavage by DNAses, enzymes that cleave DNA regions that are not protein bound. To identify these regions of active transcription, bulk DNA samples are initially treated with DNAses. Uncut regions can then be mapped to a reference genome sequence, and hypersensitive, transcriptionally active sites can be identified. DNAse hypersensitivity assays enable high-throughput data collection and comparison of chromatin-accessibility profiles across cell types and health and disease states.[49]

Detecting DNA Accessibility States in Single Molecules: Assay for Transposase-Accessible Chromatin

Like DNAse hypersensitivity testing, the recently introduced assay for transposase-accessible chromatin (ATAC-seq) is focused on identifying genomic regions whose "open" states suggest that they could be transcriptionally active.[50] However, in contrast to DNAse assays, under which transcriptionally active states are identified by their overall sensitivity to DNAse cleavage enzyme cleavage, ATAC-seq uses a transpose for which cleavage of accessible sites is followed immediately by specific ligation of a linker that bears barcodes that differ among cells. Genomic regions that have been ligated to adapters can then be isolated, amplified, and sequenced. As expected, chromatin activity states of specific genomic regions tend to be variable across tissues, and consistent across.[51]

Application of single-cell barcodes in ATAC-seq enables comparison of epigenomes across individual cells in a sample.[52] Using single-cell ATAC-seq, one group found that there is an unexpectedly high level of variation among the epigenetic states of individual intestinal lymphoid cells and that this variation is shaped by the microbiome.[53] This approach enables identification and

quantification of the relative abundance of different cell types, aiding, for example, in detecting gene-regulatory features of type II diabetes. Single-cell ATAC-seq can also provide high-resolution data on the evolution of epigenomic changes within a tumor.[54]

Detecting Overall Chromatin State on Individual Chromatin Fibers: Fiber-seq

Although bisulfite conversation, DNAse-hypersensitivity assays, and ATAC-seq can each provide invaluable information on genome-wide activity states, each of these methods chemically or enzymatically alters target molecules. The newly introduced Fiber-seq method[55] escapes these limitations by treating chromatin with a methyltransferase that adds methyl groups to adenines within regions of open chromatin. By applying sequencing technologies that can distinguish between methylated and unmethylated adenines, Fiber-seq yields paired, genetic and epigenetic data from individual molecules, raising the prospect for a molecule-level perspective on how somatic mutations impact gene expression.

Publicly Available Resources Enable Exploration of Epigenetic States at Genome Scale

One of the great steps of the genomics era is the emergence of public, online data repositories, for researchers to share their data, and enabling insights that might not be accessible from the work of an individual lab. In the case of epigenetics research, such publicly available datasets have provided unprecedented opportunities to compare epigenomic profiles over developmental time, and between tissues in disparate functional states.

The Encyclopedia of DNA Elements (ENCODE), a project supported by the National Human Genome Research Institute (NHGRI), was founded in 2003 and serves as an ever-growing repository of datasets that, collectively, help to discover drivers of genome activity across cell types and developmental stages.

Although the first phases of the project catalogued elements in human cells alone, recent phases have extended assays to model organisms, including mice,[56] offering the potential for features of genome regulation that contribute to unique human traits. One of the strengths of ENCODE is that it imposes a set of standards for data collection and analysis and requires both technical and biologic replication before a dataset can be made fully available to the public, ensuring reliability to a degree unattainable if data were instead collected by a large set of researchers, each imposing their own sets of standards and assumptions. The project has been especially successful in identifying conserved *cis*-regulation elements, genomic regions that control gene expression in humans and DNA sequence more similar across diverse species than expected by chance alone.

The vastness and diversity of the data freely available from ENCODE have enabled deep exploration of many developmental processes. For example, He et al. used ENCODE data to track changes in DNA methylation states within several different organs across embryonic development in mice.[57] In many cases, genomic regions transcriptionally active during embryonic development became epigenetically silenced shortly after birth, pointing to the existence of embryo-specific gene-expression profiles. He et al. also noted that many human diseases are associated with mutations in human homologs of murine regions active during development, underscoring the power of ENCODE data to help uncover the mechanisms of disease phenotypes.[57]

Epigenetics and Cancer

DNA Methylation and Cancer

Some of the most extensive evidence for the association of epigenetic modification with human disease comes from studies of cancer. Almost 30,000 research studies focusing on cancer genomics were published in 2020 alone (Fig. 6.10).[58] Tumor cells often exhibit genome-wide hypomethylation (decreased methylation), which can increase the activity of oncogenes (see Chapter 12).

Hypomethylation increases as tumors progress from benign neoplasms to malignancy. In addition, the promoter regions of tumor-suppressor genes are often hypermethylated, which decreases their rate of transcription and their ability to inhibit tumor formation. Hypermethylation of the promoter region of the *RB1* gene is often seen in retinoblastoma[59]; hypermethylation of the *BRCA1* gene is present in some cases of inherited breast cancer[60] (see Box 6.1 for data on epigenetics and breast cancer); and colon cancer cells often have the hypermethylation in the promoter region of the *MLH1* gene that encodes a protein that repairs DNA damage. When *MLH1* becomes inactive, DNA damage accumulates, giving rise to colon tumors.[61,62]

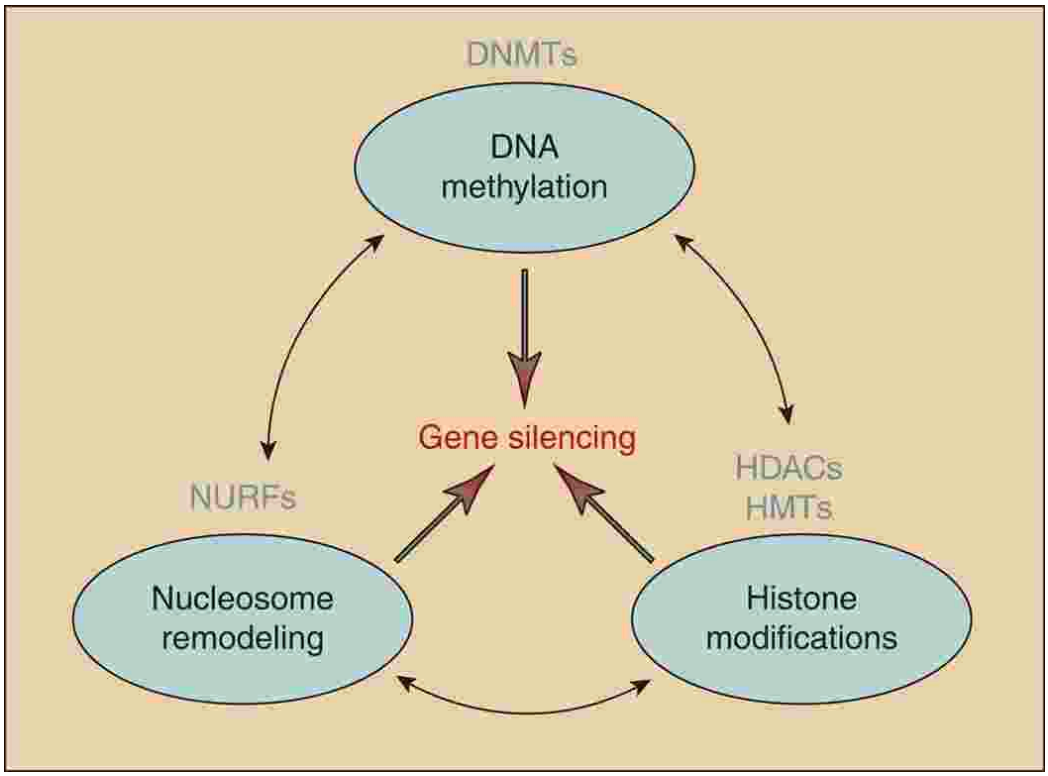

FIG. 6.10 Global Changes in Three Processes Relevant to Cancer.
Three processes—DNA cytosine methylation, histone modification, and nucleosomal remodeling—are intimately linked. Alterations in these processes result in permanent silencing of cancer-relevant genes. (From Jones PA, Baylin SB. The epigenomics of cancer. *Cell*. 2007;128[4]:683–692.)

An illustration depicts the three processes and alterations relevant to the global epigenomic alterations and cancers which shows the three processes D N A methylation, histone modifications, nucleosome remodeling are interlinked, and the alterations relevant to D N A methylation processes D N M Ts; histone modification processes H D A Cs

and H M Ts; Nucleosome remodeling processes N U R Fs resulting in gene silencing.

Importantly, the observation of perturbed DNA methylation states in tumors is not, itself, an indication that perturbation in DNA methylation is the proximate cause of cancer. However, as described later, the finding that many tumors have epigenetic abnormalities hints at exciting new opportunities for minimally invasive cancer screening and diagnosis.

Global Epigenomic Alterations and Cancer

A major feature of one form of inherited colon cancer (hereditary nonpolyposis colorectal cancer [HNPCC]) is the methylation of the promoter region of a gene, *MLH1*, whose protein product repairs damaged DNA. Inactivation of *MLH1*, a DNA mismatch repair enzyme, is associated with accrual of DNA damage, another common feature of colon tumors. Abnormal methylation of tumor-suppressor genes also is common in the progression of Barrett esophagus,[63] a condition in which the lining of the esophagus is replaced by cells that have features typically associated with the lower intestinal tract.

Epigenetic Screening for Cancer

The epigenetic abnormalities observed for a given tumor are often a defining feature of the tumor but cannot necessarily be inferred as the cause of disease. Regardless of the connection between the epigenetic abnormality and any cancer, the ability to screen for abnormal epigenetic states raises the possibility that epigenetic screening approaches could complement or even replace existing early-detection methods. In some cases, epigenetic screening could be done using bodily fluids, such as urine or sputum,[64] eliminating the need for the more invasive and costly strategies.

Misregulation of miRNAs in Cancer

Hypermethylation is seen in miRNA genes, which encode small (22 base pair) RNA molecules that bind to the ends of mRNAs, degrading them and preventing their translation. More than 1000 miRNA sequences have been identified in humans, and hypermethylation of specific subgroups of miRNAs is associated with tumorigenesis. When miRNA genes are methylated, their mRNA targets are overexpressed, sometimes leading to cancer.[65]

Emerging Strategies for the Treatment of Epigenetic Disease

Epigenetic modifications are potentially reversible: DNA can be demethylated, histones can be modified to change the transcriptional state of nearby DNA, and miRNA-encoding loci can be upregulated or downregulated. This raises the prospect for treating epigenetic disease with pharmaceutical agents that directly reverse the changes associated with the disease phenotype. In recent years, interventions involving all three types of epigenetic modulators (DNA methylation, histone modification, and miRNAs) have shown considerable promise for the treatment of disease.

DNA Demethylating Agents

5-Azacytidine has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome.[66] A cytosine analogue, 5-azacytidine, is incorporated into DNA opposite its complementary nucleotide, guanine. Chemical differences between 5-azacytidine and conventional cytosine cause it to achieve irreversible binding to the DNA methyltransferases. As a result, the administration of 5-azacytidine tends to reduce the density of DNA methylation,[67] offering prospects for reversing the aberrant accumulation of methylation at tumor-suppressor loci and even for activating an individual's own immune response against tumor cells.[68] Although 5-azacytidine can be an effective treatment for leukemia, it is

effective in only approximately half of individuals. Findings suggest that its benefits of demethylation by 5-azacytidine may be limited to individuals for whom mutations in TET2 have resulted in hypermethylation.[69]

Histone Deacetylase Inhibitors

The activity of the histone deacetylases (HDACs) increases chromatin compaction, decreasing transcriptional activity. In many cases, excessive activity of HDACs results in transcriptional inactivation of tumor-suppressor genes, leading ultimately to the development of tumors. Treatment with HDAC inhibitors, either alone or in combination with other drugs, is a promising strategy for cancer treatment.[70]

miRNA Coding

A major challenge in developing drugs that modify epigenetic alterations is to target only the genes responsible for a specific cancer. Therapeutic approaches that use miRNA offer a potential solution to this problem because treatment can be targeted to individual loci using sequence characteristics of relevant RNA molecules.

Epigenetics and Covid-19

SARS-CoV-2, the virus that has caused the Covid-19 pandemic, depends primarily on two proteins for entry into human cells[71]: the ACE2 receptor and the TMPRSS2 serine protease. Because viral pathogens must enter cells to replicate, there is potential for epigenetic variation among cells, tissues, and individuals, resulting in differential expression of these two proteins, which impacts susceptibility to infection. For example, epigenetic mechanisms modulating ACE2 expression have been proposed to explain variation in Covid-19 susceptibility and severity across age groups

(Emerging Science Box: Vaccination History, Covid-19, and Epigenetics).[72]

Emerging Science Box

Vaccination History, Covid-19, and Epigenetics

Is there a role for vaccination history and epigenetic mechanisms in protecting against severe Covid-19? The Sars-CoV-2 pandemic has raised several biomedical mysteries. Among them, why do some people suffer severe illness, whereas others experience only mild symptoms or remain asymptomatic? Some emerging studies suggest a potential role for epigenetic mechanisms.

Severe cases of Covid-19 are reported to be less common in individuals who previously received the Bacillus Calmette–Guérin (BCG) vaccine against tuberculosis. In a separate study not focused on Covid-19, de Laval et al. found that both infection with some pathogens and certain vaccinations can leave an enduring impact on chromatin structures in myeloid progenitor cells. Moreover, severe Covid-19 is very rare in children, who typically receive several vaccinations in the first years of life.

Based on these observations, some scientists have proposed that vaccination may provide broad "training" for myeloid cells, priming them to respond effectively to other pathogens, including Sars-CoV-2. The potential value of BCG vaccination in preventing severe Covid-19 and the search for possible epigenetic mediators remains active topics of investigation.

Data from de Laval B, et al. C/EBPβ-dependent epigenetic memory induces trained immunity in hematopoietic stem cells. *Cell Stem Cell*. 2020;26:793–793; Mehta NS, et al. SARS-CoV-2 (COVID-19): what do we know about children? A systematic review. *Clin Infect Dis*. 2020;71:2469–2479; Rivas MN, et al. Trained innate immunity, epigenetics, and Covid-19. *N Engl J Med*. 2020;383:1078–1080.

Epigenetic Modification of mRNA

Recently, there is renewed focus on yet another layer of epigenetic modification: changes to mRNA molecules.[73] Depending on tissue context, the attachment of methyl groups to the adenines within a given mRNA molecule can variously inhibit its use in protein synthesis or inhibit cellular differentiation. Recent findings indicate that excessive methylation of RNA molecules is a feature of some leukemias, wherein tumors develop from cells that do not proceed along normal differentiation trajectories. These findings suggest that drugs that inhibit aberrant accumulation of methylation on mRNA molecules could offer a promising strategy for treating leukemia.[74] Epigenetic modifications to mRNA are also reported to modulate memory formation[75,76] by impacting the probability that an individual RNA molecule will guide protein synthesis without changing the amino acid sequence of the resulting protein.

Future Directions

Epigenetic information is essential to fundamental processes, such as human development and memory formation. Ongoing work is untangling the complex interactions among genetic, epigenetic, and environmental factors in determining human phenotypes and developing new strategies that monitor and modify epigenetic information to diagnose and treat human disease.

The human body is continually exposed to a large variety of toxic substances, physical trauma, and infectious agents (viruses, bacteria, fungi, and parasites) that can cause damage to cells and tissues. Damage can also come from within, such as with cancers. In response, the human body has developed a highly sophisticated system of interactive immune defense mechanisms. *Innate immunity* refers to defense mechanisms that are present at birth and provide the initial nonspecific response to invasion and injury. *Adaptive immunity* refers to immunity that develops over the lifetime of the individual and provides long-term protection against specific invaders.

Innate Immunity

The human body has several ways to protect itself from injury and infection. Innate immunity includes natural barriers and inflammation. Innate barriers form the first

line of defense at the body's surfaces. They serve to prevent damage by the environment and thwart infection by pathogenic microorganisms. If these barriers are breached, the second line of defense, the inflammatory response, is activated to protect the body from further injury, fight infection, and promote healing. The third line of defense, adaptive immunity (also known as acquired or specific immunity), is induced through a slower and more specific process and targets particular invaders and diseased tissues for the purpose of eradicating them. Adaptive immunity also involves "memory," which results in a more rapid response during future exposure to the same invader. Comparisons among defense mechanisms are described in Table 7.1.

Table 7.1

Overview of Human Defenses

Characteristics	Innate Immunity		Adaptive Immunity
	Barriers	Inflammatory Response	
Level of defense	First line of defense against infection and tissue injury	Second line of defense; occurs as response to tissue injury or infection (inflammatory response)	Third line of defense; initiated when innate immune system signals cells of adaptive immunity
Timing of defense	Constant	Immediate response	Delay between first exposure to antigen and maximal response; immediate against secondary exposure to same antigen
Specificity	Broadly specific	Nonspecific	Response is very specific toward target
Cells	Epithelial cells	Mast cells, granulocytes (neutrophils, eosinophils, basophils), monocytes/macrophages, natural killer (NK) cells, platelets, endothelial cells	T lymphocytes, B lymphocytes, macrophages, dendritic cells
Memory	No memory involved	No memory involved	Specific immunologic memory by T and B lymphocytes

Characteristics	Innate Immunity		Adaptive Immunity
	Barriers	Inflammatory Response	
Active molecules	Defensins, collectins, lactoferrin, bacterial toxins	Activation of complement, clotting factors, kinins, cytokines	Antibodies, complement, cytokines
Protection	Protection includes anatomic barriers (i.e., skin and mucous membranes), cells and secretory molecules (e.g., lysozymes, low pH of stomach and urine), and ciliary activity	Protection includes vascular responses, cellular components (e.g., mast cells, neutrophils, macrophages), secretory molecules or cytokines, and activation of plasma protein systems	Protection includes activated T and B lymphocytes, cytokines, and antibodies

While these defense mechanisms are essential for maintaining health and preventing disease, uncontrolled or chronic immune activation and inflammation play a role in virtually all diseases, including heart, lung, and kidney diseases; cancer; neurodegenerative disorders; and rheumatologic disease. The information presented in this chapter introduces the components and processes of innate immunity and sets the stage for Chapter 8, which presents an overview of adaptive immunity; Chapter 9, which discusses alterations in immunity; and Chapter 10, which reviews infection. Innate immunity in the newborn and changes associated with aging are reviewed in the Pediatric Considerations and Geriatric Considerations boxes at the end of the chapter.

First Line Of Defense: Physical and Biochemical Barriers and the Human Microbiome

Innate barriers form the first line of defense at the body's surfaces. These barriers can be physical, mechanical, and biochemical. Surface barriers also house a group of beneficial microorganisms known as the *normal microbiome* that protect us from pathogenic microorganisms.

Physical and Mechanical Barriers

Physical barriers offer considerable protection from tissue damage and infection. These barriers are comprised of tightly associated epithelial cells of the skin and of the linings of the gastrointestinal (GI), genitourinary, and respiratory tracts (Fig. 7.1). When pathogens attempt to penetrate such barriers, they may be removed by mechanical means. For example, microorganisms may be sloughed off with dead skin cells (which are then replaced). Epithelial cells of the upper respiratory tract can trap microorganisms through the production of mucus and remove them through the action of hair-like cilia, which move the mucus upward where it is expelled through coughing or sneezing. Invading microorganisms can be removed from the GI tract through vomiting or defecation and from the urinary tract through urination. Other protective mechanisms of innate barriers include the relatively low temperature present on the skin and the low pH found in the stomach and the vagina, both of which inhibit the growth of pathogenic microorganisms.

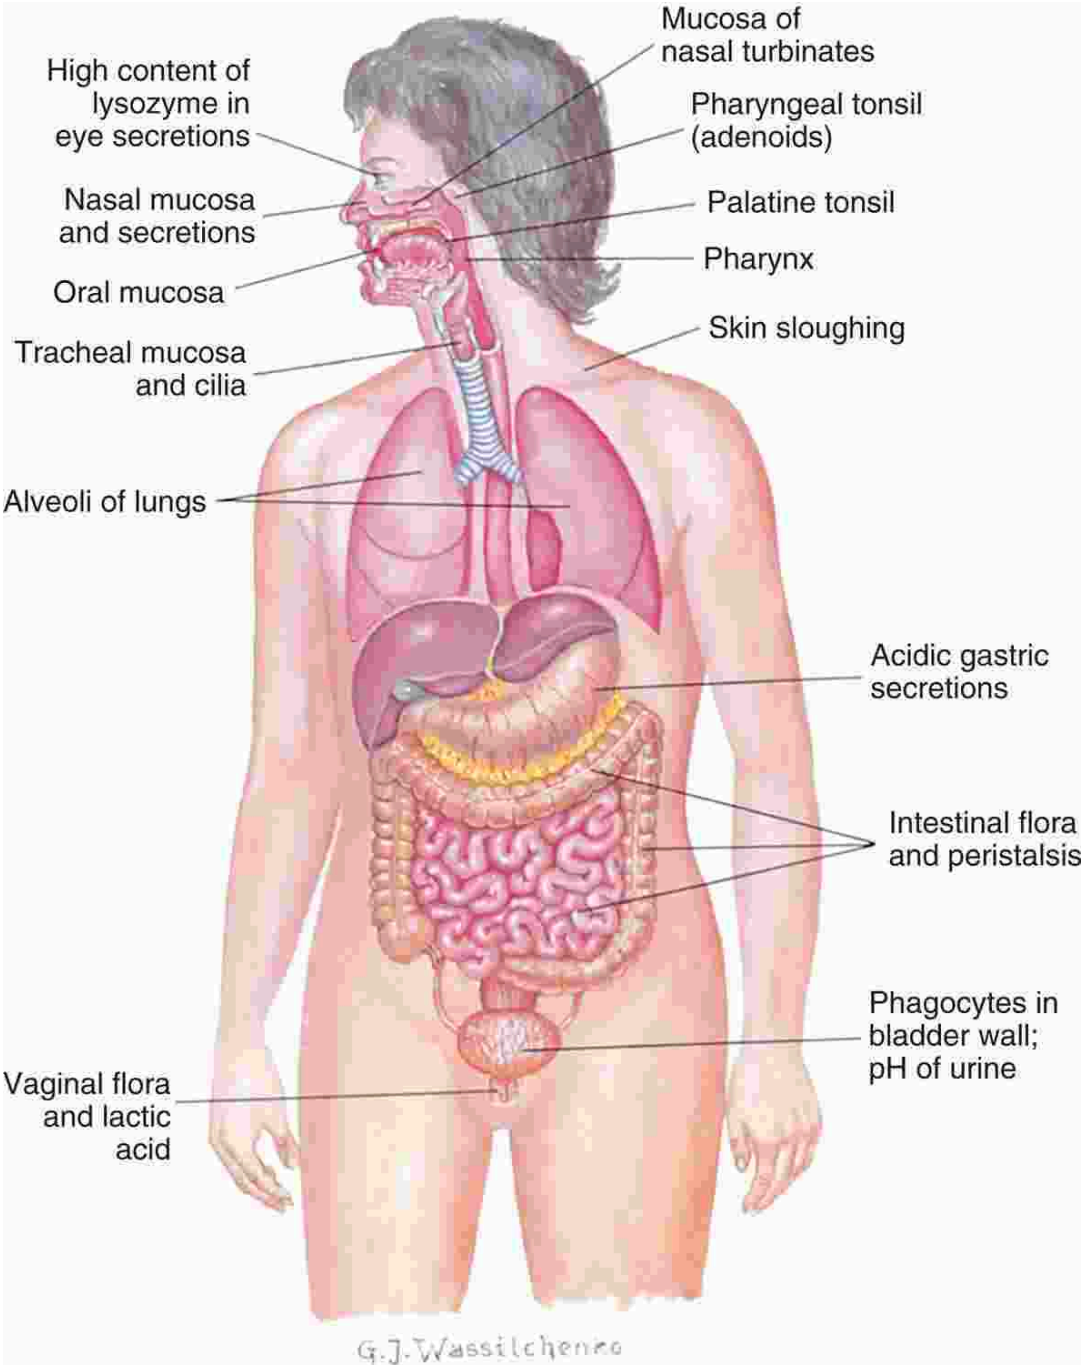

FIG. 7.1 Protection at Body Surfaces. (From Grimes, DE. *Infectious diseases*. St. Louis: Mosby; 1991.)

An illustration shows the anterior view of the internal organs in the human body. The following structures are labeled on the illustration, from the top to the bottom: high content lysozyme in eye secretions, nasal mucosa and secretions, mucosa of nasal

turbinate, pharyngeal tonsil (adenoids), oral mucosa, palatine tonsil, pharynx, tracheal mucosa and cilia, skin sloughing, alveoli of lungs, acidic gastric secretions, intestinal flora and peristalsis, phagocytes in bladder wall or p H of urine, and vaginal flora and lactic acid.

Biochemical Barriers

Epithelial surfaces also provide biochemical barriers by synthesizing and secreting substances meant to trap or destroy microorganisms (epithelial-derived chemicals). Mucus, perspiration, saliva, tears, and earwax are all examples of biochemical secretions that can trap and kill potential disease-causing microorganisms. Sebaceous glands in the skin secrete fatty acids and lactic acid, substances which kill bacteria and fungi. These secretions also create an acidic environment on the skin surface (pH 3 to pH 5) which is inhospitable to most bacteria.

Epithelial cell secretions contain antimicrobial peptides, substances that kill or inhibit the growth of disease-causing bacteria, fungi, and viruses. Defensins are antimicrobial peptides produced by neutrophils and epithelial cells that defend against bacterial infection by disrupting bacterial membranes. Collectins are soluble glycoproteins that facilitate the ability of macrophages to recognize and kill pathogenic microorganisms and can activate the complement system (see the Plasma Protein Systems and Inflammation section). They are produced by various organs, including the lungs (e.g., surfactant is a type of collectin).

The Normal Microbiome

The body's surfaces are colonized with an array of microorganisms, called the normal microbiome (previously referred to as normal flora). Molecular profiling of these microorganisms has shown that each individual has a unique suite of microbial strains that is acquired early in life, beginning in utero and continuing with exposure to the vaginal microbiome during birth.[1] With subsequent environmental exposures such as diet, antimicrobials, toxins, and animals, the composition of the microbiome diversifies. Changes in the microbial make-up of the infant microbiome can have lifelong impacts on health and disease.[2]

Body surfaces that have their own specialized microbiome include the skin; mucous membranes of the eye, nose, and mouth; upper and lower GI tracts; upper respiratory tract; urethra; and vagina. These surfaces are colonized by a combination of bacteria and fungi unique to the anatomic location and the particular individual (Fig. 7.2).

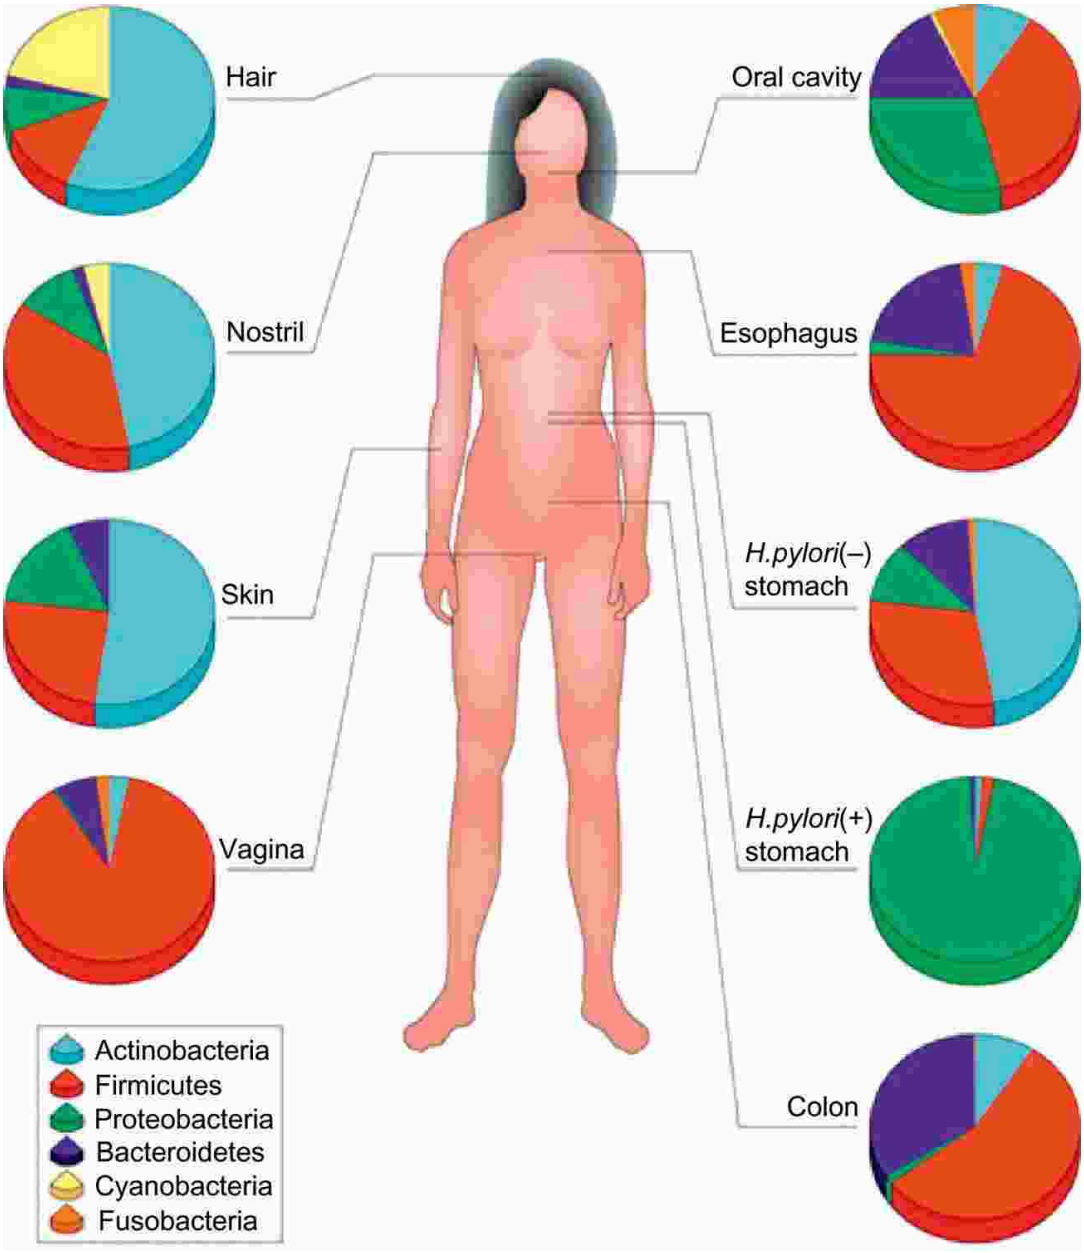

FIG. 7.2 The Human Microbiome.
Typical phylum-level composition of the human microbiota that vary at each site (From Cho I, Blaser MJ. The human microbiome: At the interface of health and disease. *Nature Reviews. Genetics*, 2012; 13:260–270.)

An illustration shows the anterior view of the human body and shows pie charts against its different parts for identifying the distribution of the human microbiome. The data from the illustration, in decreasing distribution of microbiome, for each

part are as follows. • Hair: Actinobacteria, cyanobacteria, firmicutes, proteobacteria, and Bacteroidetes. • Nostril: Actinobacteria, cyanobacteria, firmicutes, proteobacteria, and Bacteroidetes. • Oral cavity: Firmicutes, proteobacteria, Bacteroidetes, actinobacteria, fusobacteria. • Esophagus: Firmicutes, Bacteroidetes, actinobacteria, fusobacteria, and proteobacteria. • Skin: Actinobacteria, cyanobacteria, firmicutes, and proteobacteria. • H.pylori (negative), stomach: Actinobacteria, firmicutes, proteobacteria, Bacteroidetes, and fusobacteria. • H.pylori (positive), stomach: Proteobacteria, firmicutes, actinobacteria, and Bacteroidetes. • Colon: Firmicutes, Bacteroidetes, actinobacteria, and proteobacteria. • Vagina: Firmicutes, Bacteroidetes, actinobacteria, fusobacteria, and proteobacteria.

The microorganisms in the microbiome do not normally cause disease. The normal microbiome benefits the human body in a number of ways, and the human body provides an ideal environment for the microbiome to grow.[3] The interaction between host cells and the microbiome plays an essential role in fostering healthy innate and immune defense systems.[1,4,5]

Mechanisms by which the microbiome contributes to health and immunity include:

1. Produces enzymes which facilitate digestion of fatty acids and large polysaccharides
2. Synthesizes essential metabolites (e.g., vitamins K and B)
3. Releases antibacterial substances that are toxic to pathogenic microorganisms (e.g., ammonia, phenols, and indoles)
4. Competes with pathogens for nutrients and blocks attachment of the pathogens to the epithelium, an obligatory first step in the infectious process
5. Fosters healthy innate and adaptive immunity by inducing protective immune responses to pathogens, while at the same time maintaining regulatory pathways that support immune tolerance of innocuous microorganisms.

The health of the microbiome can be positively or negatively influenced by a wide range of environmental exposures (see Emerging Science Box: The Microbiome and Disease). For example, prolonged treatment with broad-spectrum antibiotics can

alter the normal microbiome, decreasing its protective activity and leading to an overgrowth of pathogenic microorganisms. In the intestine, for example, overgrowth of the yeast *Candida albicans* or the bacterium *Clostridioides difficile* (the cause of pseudomembranous colitis) may occur with antibiotic use. Some members of the normal bacterial microbiome are opportunistic pathogens—that is, they are harmless under normal conditions but can cause disease in immunocompromised individuals who lack the usual defense mechanisms. For example, *Pseudomonas aeruginosa* is a member of the normal microbiome of the skin, where it produces a toxin that protects the skin from infections caused by pathologic bacteria. With severe burns or critical illnesses in which the integrity of the skin and mucous membranes is compromised, *Pseudomonas* may enter the bloodstream and cause life-threatening systemic infections.

Emerging Science BoxThe Microbiome and Disease

The postulated mechanisms by which microbiome dysbiosis contributes to the development of disease are numerous and complex. The presence of microorganisms (especially in the gut) modulates both the induction and the suppression of local and systemic immune responses. In return, the host immune system fine-tunes the composition of the microbiome to maintain a beneficial symbiosis. When this symbiosis is altered, both innate and adaptive immunity are negatively impacted. With regard to innate immunity, neutrophils and macrophages engage in a constant "crosstalk" with the microbiome that modulates the inflammatory response. When dysbiosis occurs, these phagocytes become dysregulated leading to a chronic inflammatory state, which in turn can contribute to a large number of diseases. For example, early studies in Alzheimer disease suggest that changes in the microbiome can be linked to neuroinflammation and brain dysfunction. Communication between the microbiome and the body is impacted by environmental influences such as stress and diet. A high-fat diet leads to changes in the gut microbiome which in turn lead to inflammation and increased fat accumulation around viscera which is associated with atherosclerosis and diabetes. Dysbiosis in the gut also can result in the formation of toxic metabolites from food (e.g., phenylalanine) which contribute to cardiovascular disease risk. New studies indicate that the microbiome may be intentionally modulated to improve responses to treatment. For example, there is a great deal of optimism among researchers that altering the gut microbiome will prove an effective way of managing inflammatory bowel disease. Other studies suggest that altering the microbiome can improve the efficacy of hypertensive and psychiatric medications. To date, the most common techniques being used to alter the microbiome include probiotics, prebiotics, and fecal microbial transplantation (FMT).

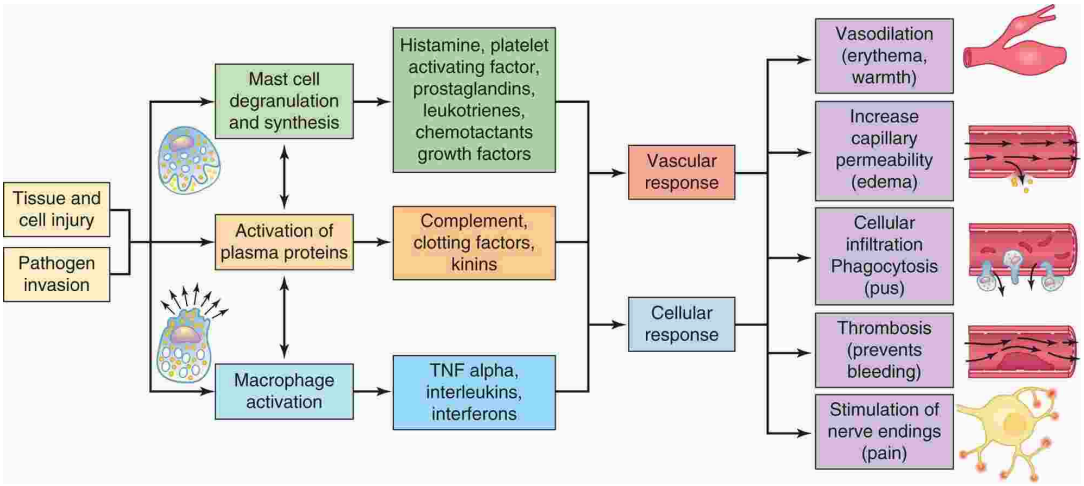
Connection between gut microbiome and the development of obesity. *European Journal of Clinical Microbiology and Infectious Diseases*; 38(11):1987–1998.

Epidemiologic studies have been used to associate negative changes in the microbiome (dysbiosis) with disease states (see Emerging Science Box: The Microbiome and Disease). Included in the long list of dysbiosis-associated diseases are mental health disorders, obesity, hypertension, heart failure, asthma, emphysema, rheumatologic conditions, diabetes, bowel disease, and cancer. Studies aimed at altering the microbiome for health promotion, disease prevention, and improved responses to treatment are ongoing.[1]

Second Line of Defense: Inflammation

Inflammation is a protective response that supports recovery from injury and disease. The inflammatory process is activated by virtually any injury to vascularized tissues. Triggers include infection and tissue damage (e.g., ischemia, trauma, chemical injury, foreign bodies, and immune reactions). When pathogen invasion or tissue damage occurs, inflammation is initiated by guardian cells (mast cells, macrophages, and dendritic cells) that are located near epithelial surfaces, in lymph nodes, and near blood vessels. Inflammatory mediators are released, causing both a vascular and a cellular response. The ultimate result of these responses is the migration of leukocytes, platelets, plasma proteins, and other biochemical mediators from the circulation into the nearby damaged tissue, where they can work together to destroy invaders, limit tissue injury, and promote healing. Algorithm 7.1 summarizes the process.



ALGORITHM 7.1 **Acute Inflammatory Response.**
Inflammation is usually initiated by cellular injury and may be complicated by infection. The inflammatory response involves mast cell degranulation, the activation of three plasma protein systems, and the activation of macrophages that release numerous cytokines. These systems are interdependent so that induction of one (e.g., mast cell degranulation) can result in the induction of the other two. The result is the development of the characteristic microscopic and clinical hallmarks of inflammation. *TNF alpha*, Tumor necrosis factor-alpha.

An illustrated flowchart tracks the process of acute inflammatory response. The data from the flowchart is as follows. Tissue and cell injury and pathogen invasion leads to the following three processes: 1. Mast cell degranulation and synthesis. 2. Activation of plasma proteins; also leads to the other two processes. 3. Macrophage activation. Conditions from process 1: histamine, platelet activating factor, prostaglandins, leukotrienes, and chemotactants growth factors. Conditions from process 2: complement, clotting factors, and kinins. Conditions from process 3: T N F alpha, interleukins, and interferons. All responses lead the following vascular and cellular responses: • Vasodilation (erythema, warmth). • Increase capillary permeability (edema). • Cellular infiltration phagocytosis (pus).

• Thrombosis (prevents bleeding). • Stimulation of nerve endings (pain).

The inflammatory response is characterized by the following:

1. The process occurs in vascularized tissues (i.e., tissues with a blood supply).
2. Activation is rapid (within seconds) after damage occurs.
3. The response includes chemical, vascular, and cellular components.
4. The response is nonspecific—that is, it takes place in approximately the same way regardless of the type of injury (stimulus) and whether or not the same stimulus has occurred in the past.

Inflammation, although producing pain and functional limitations in the affected individual, also results in numerous physiologic benefits. Protective functions of inflammation include the following:

1. *Prevention of infection and further damage caused by invading microorganisms:* Inflammatory exudates dilute the toxins produced by both bacteria and dying cells. The activation of plasma protein systems (e.g., complement and clotting systems) serves to contain and destroy invading microorganisms. The influx of phagocytes (neutrophils and macrophages) removes toxic cellular debris and pathogenic microorganisms, preventing them from further harming the body.
2. *Preparation of injury for healing and repair:* This involves removal of bacterial microorganisms, dead cells, and other physiologic debris through the epithelial channels and the lymphatic vessels that drain the region. Mechanisms of healing and repair are initiated.
3. *Facilitation of the development of adaptive immunity:* As fluid and cellular debris drain through the lymphatic vessels, lymphoid tissue and lymph nodes, microbial antigens encounter macrophages and lymphocytes concentrated in these areas. Adaptive immunity is initiated and helps fight off invaders and protect the body from future exposures to particular pathogens (see Chapter 8).

Plasma Protein Systems and Inflammation

Plasma protein systems are essential to an effective vascular and cellular inflammatory response (see Algorithm 7.1). There are three plasma protein systems that are especially important to innate immunity: the complement system, the clotting system, and the kinin system (Fig. 7.3). Although each system has a unique role in inflammation, all three systems have many similarities as well. Each system consists of multiple proteins and enzymes usually present in blood as inactive

forms. The proteins are activated early in inflammation by enzymes, which circulate as proenzymes until some form of tissue damage triggers the system initiating the sequence. Activation of the first components results in sequential activation of other components of the system, leading to a protective biologic function. This sequential activation is referred to as a cascade, hence the common terminology that references the complement cascade, the clotting cascade, or the kinin cascade.

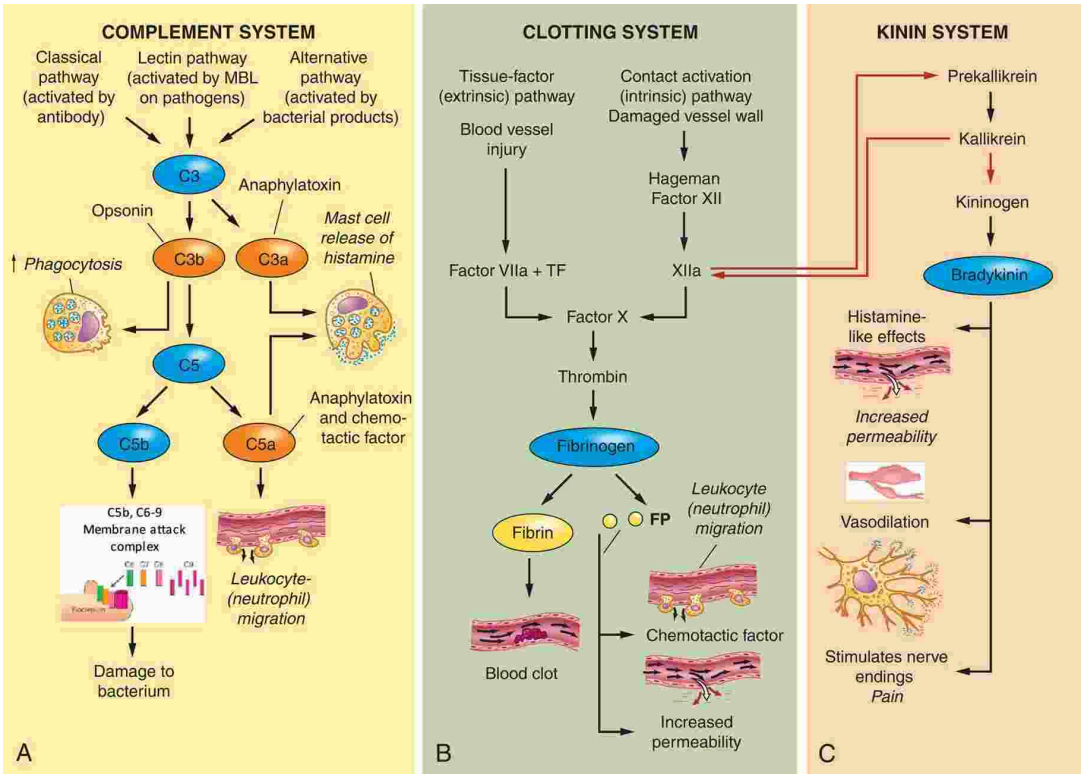


FIG. 7.3 Plasma Protein Systems in Inflammation: Complement, Clotting, and Kinin Systems.
Each plasma protein system consists of a family of proteins that are activated in sequence to create potent biologic effects. **(A)** The complement system can be activated by three mechanisms, each of which results in proteolytic activation of C3. The fragments of C3 activation, C3a and C3b, are major components of inflammation. C3a is a potent anaphylatoxin, which induces degranulation of mast cells. C3b can bind to the surface or cells, such as bacteria, and either serve as an opsonin for phagocytosis or proteolytically activate the next component of the complement cascade, C5. The smaller fragment of C5 activation is C5a, a powerful anaphylatoxin, and is also chemotactic for neutrophils, attracting them to the site of inflammation. The larger fragment, C5b, activates the components of the membrane attack complex (C5b–C9), which damage the bacterial membrane and kill the bacteria. **(B)** The clotting system can be activated by the tissue factor (extrinsic) pathway and the contact activation (intrinsic) pathway. All routes of clotting initiation lead to activation of factor X and thrombin. Thrombin is an enzyme that activates fibrinogen to form fibrin and small FPs. Fibrin comes together to form a clot, and the FPs are highly active as chemotactic factors and cause increased

vascular permeability. **(C)** Factor XIIa produced by the clotting system can also be activated by kallikrein of the kinin system *(red arrow)*. Prekallikrein is enzymatically converted to kininogen, which activates bradykinin. Bradykinin functions similar to histamine and increases vascular permeability. Bradykinin can also stimulate nerve endings to cause pain. *FP*, Fibrinopeptide; *MBL*, mannose binding lectin; *TF*, tissue factor.

Three illustrated panels, A, B, and C, demonstrate plasma protein systems in inflammation in complement system, clotting system, and kinin system, respectively. Panel A, complement system. Three mechanisms activate C 3: 1. Classical pathway (activated by antibody) 2. Lectin pathway (activated by M B L on pathogens) 3. Alternative pathway (activated by bacterial products) Activated C 3 results in two fragments: 1. C 3 a or anaphylatoxin. 2. C 3 b or opsonin. C 3 b can lead to increased phagocytosis or activate the component C 5, which produces two fragments: 1. C 5a or anaphylatoxin and chemotactic factor. 2. C 5 b. C 3 a and C 5 a can cause mast cell release of histamine. C 5 a can cause leukocyte (neutrophil migration). C 5 b and C 6 to C 9 can activate the membrane attack complex, causing damage to bacterium. Panel B, clotting system. There are two pathways to the activation of Factor X. 1. Tissue-factor (extrinsic) pathway. Blood vessel injury. Factor villa and T F. 2. Contact activation (intrinsic) pathway. Damaged vessel wall. Hageman factor 12. 12 a. Factor X activates thrombin and subsequently fibrinogen: 1. Fibrin. Blood clot. 2. F P. Chemotactic factor or leukocyte (neutrophil migration) and increased permeability. Panel C, kinin system. 1. Prekallikrein; also activated by 12 a. 2. Kallikrein; also activates 12 a. 3. Kininogen. 4. Bradykinin. 5. Histamine like effects. 6. Increased permeability. 7. Vasodilation. 8. Stimulates nerve endings, pain.

Complement System

The complement system intensifies or complements the capacity of cells of the innate and adaptive immune systems to clear pathogens and damaged cells and to activate inflammation.[6] Complement consists of a large number of proteins (sometimes called complement factors), which, together, constitute about 10% of the total circulating serum protein. Activation of the complement system initiates a cascade of proteolytic steps that result in the formation of several substances that can destroy pathogens directly or can eradicate pathogens through enhancing the activity of other components of the immune response.

The activation of C3 and C5, two important components of the complement cascade, results in the creation of several potent molecules critical to the immune response:

1. C3b—along with antibodies, serves as opsonins which coat the surface of bacteria increasing their susceptibility to phagocytosis by inflammatory cells (i.e., phagocytes [neutrophils and macrophages]).
2. C5a—functions as a chemotactic factor which serves as a form of chemical signaling that causes leukocytes to move to the area of inflammation.
3. C3a **and C5a**—sometimes called anaphylatoxins, induce rapid degranulation of mast cells to release histamine, a substance which induces vasodilation and increased capillary permeability.
4. Membrane attack complex (MAC)—composed of elements C6 through C9 and leads to bacterial destruction and tissue injury by creating pores in the outer membranes of cells or bacteria. These pores facilitate the infusion of water into the cells culminating in cellular death.

Three major pathways or cascades control the activation of complement (see Fig. 7.3A): the classical pathway, the alternative pathway, and the lectin pathway. The classical pathway is activated by antibodies, which are components of the adaptive immune system. Antibodies bind to antigens, which are typically proteins or carbohydrates produced by infectious microorganisms. Such antibodies activate the first complement component, C1, which, in turn, leads to the sequential activation of other components of the complement cascade, specifically C3 and C5, triggering inflammation.

The alternative pathway is activated directly by substances found on the surface of infectious microorganisms. These substances would include lipopolysaccharides (endotoxins) found on bacterial membranes and carbohydrates (zymosan) found on yeast cell walls. This pathway uses unique proteins (factor B, factor D, and properdin) to form a complex that sequentially activates the complement proteins C3 and C5. At this point, the process converges with the classical pathway. The alternative pathway provides a mechanism whereby the complement system can be activated in the absence of antibodies.

The lectin pathway, like the alternative pathway, is independent of antibodies and is activated by several plasma proteins, particularly mannose-binding lectin

(MBL). MBL binds to bacterial polysaccharides that contain the carbohydrate mannose and activates the complement cascade. Infectious agents that do not activate the alternative pathway may still be susceptible to the complement system through the lectin pathway.

In summary, the complement pathway or cascade is a sequential series of cellular events that serve as defense mechanisms for the body. It can be activated by at least three different pathways, resulting in one or more of four protective functions: *opsonization* (C3b), *anaphylatoxic activity* from mast cell degranulation (C3a, C5a), *leukocyte chemotaxis* (C5a), and *cell lysis* (C5b–C9; membrane attack complex). Because of this potent defense system, successful pathogens must develop mechanisms that resist complement activity in order to cause disease.[7]

While highly beneficial to host defense, the complement system can contribute to tissue damage in a wide range of acute and chronic inflammatory diseases (see Chapter 9). New therapies aimed at blocking complement are proving to be beneficial for a number of these conditions.[8]

Clotting

The clotting system (also known as the coagulation system) is a group of plasma proteins, which, when activated sequentially, form a blood clot which is a meshwork of fibrin strands and platelets. The clotting system can be activated by a variety of substances released during tissue injury or infection, such as collagen, enzymes, and bacterial toxins. Clots serve to plug damaged vessels and stop bleeding (hemostasis), trap microorganisms to prevent their spread to adjacent tissues, and provide a framework for future repair and healing. When the wall of a blood vessel is injured, two converging pathways lead to clot formation (see Fig. 7.3B):

1. The tissue factor (extrinsic) pathway is activated by tissue factor (TF), also called tissue thromboplastin, a substance released by damaged endothelial cells of the blood vessels. It reacts with activated factor VII (VIIa).
2. The contact activation (intrinsic) pathway is activated when vessel wall damage causes negatively charged subendothelial substances to come into contact with Hageman factor (factor XII) found in plasma.

Both pathways converge at factor X and thrombin. Thrombin activates fibrinogen to form fibrin. Fibrin, in turn, comes together to form a fibrin clot. The purposes of the fibrin clot are to:

1. Stop bleeding.
2. Help prevent the spread of inflammation and infection.
3. Keep the invader near the site of injury, thus maximizing the access of inflammatory cells and proteins.

4. Initiate the formation of two fibrinopeptides (A and B) that are released during the formation of fibrin and are chemotactic for neutrophils and increase vascular permeability.
5. Provide a framework for repair and healing.[9]

Platelets also play a crucial role in inflammation, including the secretion of immunoregulatory cytokines and the ability to bind infectious pathogens.[10] Additional details concerning the clotting system are discussed in Chapter 28.

Kinin System

The third plasma protein system, the kinin system (see Fig. 7.3C), interacts closely with the clotting system. Both the clotting and kinin systems can be initiated through activation of Hageman factor (factor XII), which, in turn, results in the formation of factor XIIa, also known as *prekallikrein activator*. Factor XIIa activates *prekallikrein*, the first component of the kinin system. The next product in the cascade is kallikrein, followed by *kininogen*, a precursor molecule, and then bradykinin, the final product of the kinin system. Bradykinin causes dilation of blood vessels. Bradykinin also acts in concert with prostaglandins to induce pain, trigger smooth muscle cell contraction (i.e., bronchoconstriction), and increase vascular permeability.

Control and Interaction of Plasma Protein Systems

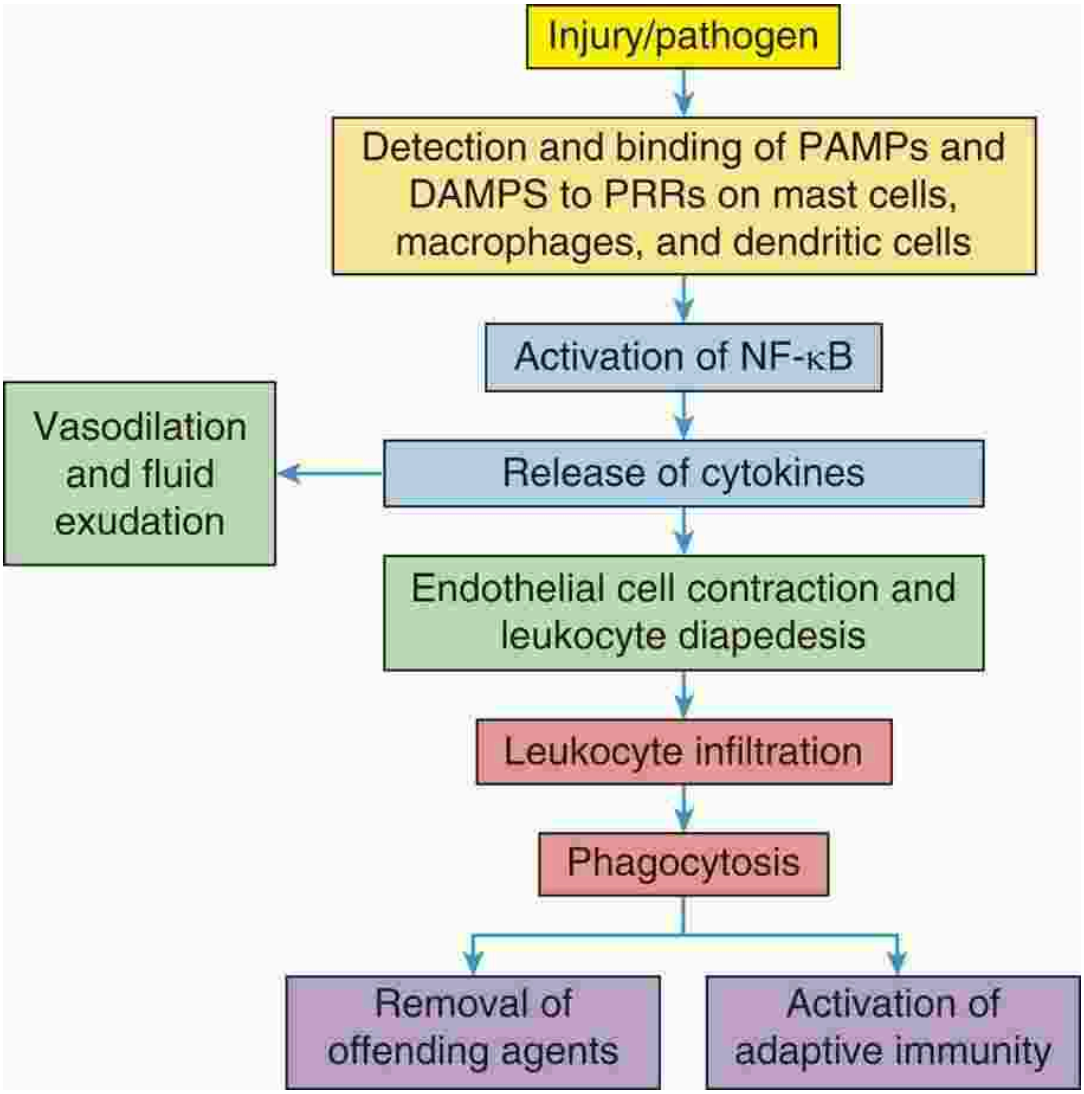
The three plasma protein systems are highly interactive. The activation of one system results in the production of a large number of biologically active substances that activate other systems. Tight regulation of these processes is essential for two reasons. First, the inflammatory process is critical for an individual's survival; therefore, efficient activation must occur regardless of the cause of tissue injury. The interaction among the three systems means that the entire inflammatory response may be activated regardless of which system initially triggers the sequence. Second, the biochemical mediators released during the inflammatory response are potent and potentially harmful to the individual. Their actions must be controlled and confined to injured or infected tissues.

Multiple mechanisms are available to regulate the plasma protein systems, activating or inactivating the reactions to maintain balance, and contain the inflammatory response. Plasma entering the tissues during inflammation contains enzymes that destroy the mediators of inflammation and downregulate the inflammatory response. These enzymes include protease inhibitors (e.g., C1-inhibitor) and carboxypeptidase, which inhibit the complement system; and kininase and histaminase, which inhibit the kinin system. The formation of clots activates a fibrinolytic system. This system serves to limit the size of the clot and degrade the clot after bleeding has ceased. In this system thrombin activates plasminogen, forming the enzyme plasmin, which degrades the fibrin polymers in clots and has been implicated in a wide range of inflammatory diseases.[11] Defects in these mechanisms can be genetic or acquired. For example, a genetic defect in the

protease C1 inhibitor (C1-inh) results in hereditary angioedema, a self-limiting edema of cutaneous and mucosal layers. Acquired defects in plasminogen activation and control, which is seen in severe infection, can result in widespread clotting.[12]

Initial Cellular Responders in Inflammation

Mast cells and macrophages can be thought of as guardian cells and are the primary cellular initiators of the inflammatory response (see Algorithm 7.1). Also present are dendritic cells which are a specialized type of macrophage that connects the innate and adaptive immune responses. These three types of cells reside near epithelial tissues, blood vessels, and lymphatics. They are equipped with receptors that allow them to detect pathogens and the cellular products of tissue damage (Algorithm 7.2).



ALGORITHM 7.2 Overview of the Sequence of Events in the Acute Inflammatory Response.
As a result of tissue injury or pathogen invasion, pattern recognition receptors *(PRRs)* on mast cells, macrophages, and dendritic cells are activated by binding to pathogen-associated molecular patterns *(PAMPs)* or damage-associated molecular patterns *(DAMPs)*. This leads to activation of NF-κB and the release of multiple cytokines that initiate vascular and cellular responses that work to bring immune cells to the area of injury/invasion, remove offending agents, activate adaptive immunity, and prepare the tissues for healing.

A flowchart provides an overview of the sequence of events in the acute inflammatory response. The sequence of events is as

follows. 1. Injury or pathogen. 2. Detection and binding of P A M Ps and D A M Ps to P R Rs on mast cells, macrophages, and dendritic cells. 3. Activation of N F sub negative k B. 4. Release of cytokines; Vasodilation and fluid exudation. 5. Endothelial cell contraction and leukocyte diapedesis. 6. Leukocyte infiltration. 7. Phagocytosis: Removal of offending agents and activation of adaptive immunity.

Cellular Receptors

Mast cells, macrophages, and dendritic cells have evolved a set of receptors referred to as pattern recognition receptors (PRRs) (Table 7.2). PRRs are generally expressed on cells in tissues near the body's surfaces (skin, respiratory tract, GI tract, genitourinary tract), where they monitor the environment for products of cellular damage and infectious microorganisms. PRRs can also be found on mucosal epithelial cells, neutrophils, and some lymphocytes. PRRs recognize two types of molecular patterns:

1. Pathogen-associated molecular patterns (PAMPs), which are molecules expressed by infectious agents either found on their surface or released as soluble molecules.
2. Damage-associated molecular patterns (DAMPs), which are products of cellular damage. Accordingly, cells of the innate immune system can respond to both sterile tissue damage (DAMPs) and septic tissue damage (PAMPs and DAMPs). It is estimated that at least 100 different PRRs are found on innate immune cells, rendering them capable of recognizing more than 1000 different molecules.

Table 7.2

Pattern Recognition Receptors

Receptors	Number of Receptors	What They Recognize	Where They Are Found
Toll-like receptors (TLRs)	10	PAMPs and DAMPs	Outer membrane of innate immune cells especially macrophages and dendritic cells
NOD-like receptors and NLR receptors	~22	PAMPs and DAMPs	Cytoplasm of innate immune cells
Scavenger receptors (including C-type lectin receptors (CLRs)	12	PAMPs, DAMPS, Cell membrane phospholipids	Outer membrane of phagocytes
Complement and Cytokine receptors[a]	Multiple	C3a, C3b, C5a, TNF-α, interleukins, interferons, chemotactic factors, prostaglandins, platelet activating factor, IL-10, TGF-β	Outer membrane of innate immune cells, platelets, epithelial cells, vascular smooth muscle

DAMP, Damage-associated molecular patterns; *IL-10*, interleukin-10; *NOD*, nucleotide oligomerization domain-like receptors; *NRL*, nucleotide-binding-like receptors; *PAMP*, pathogen-associated molecular patterns; *TGF-β*, transforming growth factor-beta; *TNF-α*, tumor necrosis factor-alpha).

[a]Complement and cytokine receptors are not true pattern recognition receptors but are essential for innate immune cell function

An important group of PRRs are Toll-like receptors (TLRs), which recognize a large variety of PAMPs located on the surface of microorganisms (e.g., bacterial lipopolysaccharide, peptidoglycans, lipoproteins, yeast zymosan, flagellin, bacterial or viral nucleic acid, and viral coat proteins). TLRs are expressed on the surface of many cells that have direct and early contact with potential pathogens. Such cells include mucosal epithelial cells, mast cells, macrophages, dendritic cells,

neutrophils, and lymphocytes. TLRs also are activated by oxidative stress, tissue injury, and damaged cellular contents (DAMPs). Activation of TLRs initiates a cascade of intracellular signaling pathways leading to the activation of nuclear factor-[kappa]B (NF-κB) in the cell nucleus.[13] NF-κB activation results in increased transcription and subsequent release of numerous inflammatory cytokines. Among these are tumor necrosis factor (TNF), interleukins, and interferons (IFNs) which play key roles in the inflammatory process, activation of the adaptive immune response, and the destruction of many pathogenic microorganisms (these cytokines are discussed in detail later in this chapter). Pathophysiologic changes in TLR stimulation and NF-κB activation have been implicated in numerous conditions such as neuroinflammation, heart disease, and cancer[13] (see Emerging Science Box: The Role of Toll-like Receptors [TLRs] and Nuclear Factor-kappaB [NF-κB] in Disease).[13]

Emerging Science BoxThe Role of Toll-like Receptors (TLRs) and Nuclear Factor-kappaB (NF-κB) in Disease

TLRs play a key role in the detection of invasion and tissue injury by immune cells. These receptors bind to a wide range of molecular patterns from pathogens (PAMPs) and damaged host cells (DAMPs). The subsequent steps in intracellular signaling and activation of NF-κB lead to the production of cytokines that are central to the inflammatory response and initiation of adaptive immunity. However, an uncontrolled inflammatory response may lead to a host of deleterious effects on cells and tissues. Changes in TLR binding and excessive NF-κB activity have been associated with a large number of inflammatory diseases affecting virtually every organ in the body. TLRs may detect byproducts of other pathophysiologic conditions leading to an exaggerated or misdirected immune response. For example, TLR binding to advanced glycation end-products (AGEs) produced in diabetes leads to widespread inflammatory injury to vascular tissues. Exaggerated NF-κB activation is linked to sepsis as well as acute and chronic diseases of the cardiovascular, neurologic, pulmonary, gastrointestinal, and renal systems. NF-κB activation is modulated by the nuclear peroxisome proliferator-activated receptor (PPAR) family which consists of three types of PPAR receptors (PPAR-α, β, and γ). These receptors are located on macrophages and lymphocytes as well as other tissues. Activation of PPAR pathways prevents excessive inflammation and tissue damage. Therapeutically, PPAR receptors are activated by nonsteroidal anti-inflammatory drugs (NSAIDs), thus reducing inflammatory symptoms. Other PPAR agonists that are currently in use include fibrates (treat dyslipidemia) and thiazolidinediones (treat diabetes). However, these medications have significant side effects. Dozens of new PPAR agonists to treat a wide range of conditions including biliary cirrhosis, Alzheimer disease, heart disease, renal disease, inflammatory bowel disease,

gout, cancer, and eye diseases are currently in clinical trials. Other therapeutic interventions that seek to modulate TLR and NF-κB activation are being explored.

Nucleotide-binding-like receptors (NLRs) (including nucleotide oligomerization domain–like [NOD-like] receptors) are cytoplasmic (intracellular) receptors in lymphocytes, macrophages, and dendritic cells. At least 23 NLRs have been identified in humans. They recognize intracellular microorganisms and damaged cells and initiate the production of proinflammatory mediators. NLRs also detect cells that are forming inflammasomes, which are large cytoplasmic complexes that activate cytokines. Inflammasomes are implicated in a wide variety of diseases including Coronavirus Disease 2019 (COVID-19) inflammatory lung damage.[14]

Scavenger receptors are membrane receptors primarily expressed on macrophages and are categorized into 12 classes.[15] They have multiple functions including the recognition and subsequent phagocytosis of bacterial pathogens and damaged cells. They also recognize soluble lipoproteins, such as high-density lipoprotein (HDL), low-density lipoprotein (LDL), and oxidized LDL, and have been implicated in atherosclerotic vascular diseases.[16] C-type lectin receptors (CLRs) are a type of scavenger receptor that binds to both PAMPs and DAMPs. There are many types of CLRs, such as macrophage mannose, Dectin 1 and 2, and mannose-binding lectin receptors. They are particularly important in recognizing fungal antigens and subsequent activation of innate immune cells.

Complement and cytokine receptors are found on many cells involved in the immune response, as well as on some epithelial cells. These are not true PRRs but are essential to innate immune cell function. Complement receptors recognize several fragments produced through activation of the complement system, particularly C3a, C5a, and C3b. This results in chemotaxis and activation of innate immune cells. Cytokine receptors recognize both proinflammatory and anti-inflammatory cytokines (these cytokines are discussed later in this chapter).

Mast Cells

Mast cells are significant and potent activators of the inflammatory response. They have abundant granules containing biochemical mediators, which are released in instances of pathogen invasion and tissue injury (Fig. 7.4). Mast cells are activated by PAMPs and DAMPs binding to PRRs, as well as by direct physical, chemical, and thermal injury. They also can be activated by components of the complement cascade and by immunoglobulin E (IgE) antibodies produced in allergies (see Chapter 9). Located in connective tissue and close to vessels, they can be found near the body's surfaces (skin, GI, and respiratory tract linings). A variety of stimuli associated with tissue injury can induce inflammation by triggering the release of potent soluble substances from mast cells. These substances are released in two ways:

1. *Degranulation*—release of preformed contents of mast cell granules
2. *Synthesis*—the new production and release of mediators in response to a stimulus

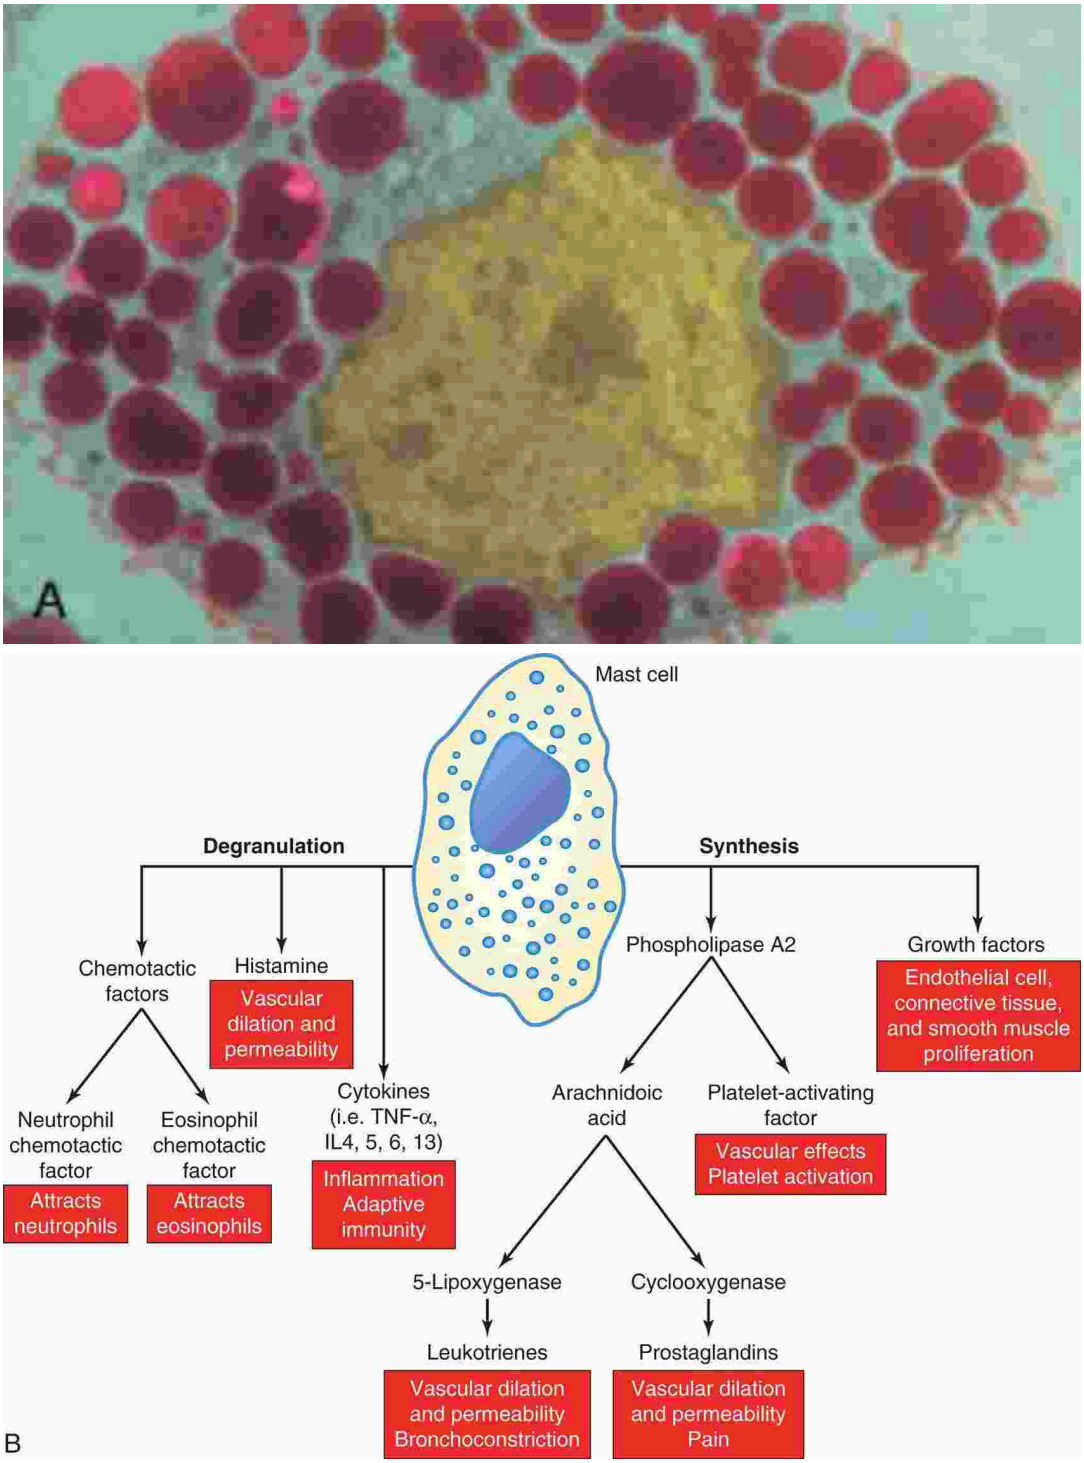

FIG. 7.4 Mast Cell Degranulation and Synthesis of Inflammatory Mediators.

(A) Colorized photomicrograph of mast cell; dense granules contain biologically active substances. Among these are histamine, which is a major initiator of vascular changes, and a variety of chemotactic factors. **(B)** Mast cell degranulation *(left)*

and synthesis *(right)*. Histamine and other biologically active substances are released immediately after stimulation of mast cells. Long-term responses are mediated by the synthesis and release of products of phospholipase A metabolism (leukotrienes, prostaglandins, and platelet-activating factor) and growth factors that promote tissue proliferation. *IL*, Interleukin; *TNF-α*, tumor necrosis factor-alpha. (A, From Roitt IM, Brostoff J, Male DK. *Immunology*, 3rd edition. St. Louis: Mosby, 1993.)

Panel A shows a colorized photomicrograph of a mast cell at the center surrounded densely by intracellular granules. Panel B shows flowchart tracking the degranulation and synthesis of a mast cell. Degranulation releases the following substances: 1. Chemotactic factors include neutrophil chemotactic factor that attracts neutrophils, and eosinophil chemotactic factor that attracts eosinophils. 2. Histamine causes vascular dilation and permeability. 3. Cytokines, for example, T N F alpha, I L 4, 5, 6, and 13, include inflammation and adaptive immunity. Synthesis releases the following substances: 1. Phospholipase A 2 includes arachidonic acid, and platelet-activating factor that causes vascular effects and platelet activation. Arachidonic acid, in turn, releases the following substances: 1. 5-lipoxygenase include leukotrienes that cause vascular dilation and permeability and bronchoconstriction, and cyclooxygenase include prostaglandins that cause vascular dilation and permeability, and pain. 2. Growth factors include endothelial cell, connective tissue, and smooth muscle proliferation.

Degranulation

Mast cells release biochemical mediators from their granules into the surrounding tissues within seconds of a stimulus. Substances within the granules include histamine, chemotactic factors, and cytokines. Their effects occur immediately.

Histamine is a small-molecular-weight molecule with potent effects on many other cells, particularly those that control the circulation. Histamine binds to *histamine receptors* (H1, H2, H3, and H4 receptors) on various cell surfaces. The binding of histamine to the *H1 receptor* is proinflammatory (Fig. 7.5). This causes a

rapid, temporary constriction of smooth muscle, along with dilation of the postcapillary venules. The net result of these two effects is increased blood flow within the microvasculature. H1 receptor binding also causes increased vascular permeability secondary to the retraction of endothelial cells lining the capillaries (opening the tight junctions between them), and increased leukocyte adherence to the endothelial walls. The H1 receptor also is present on smooth muscle cells within the bronchi. H1 stimulation results in bronchial smooth muscle contraction and bronchoconstriction often seen in asthma. Antihistamines are drugs that block the binding of histamine to the H1 receptor, resulting in decreased vascular effects. *H4 receptors* are highly expressed on mast cells where their stimulation is proinflammatory by promoting histamine and cytokine generation, and H4 receptor blockers are being developed in an effort to better treat many allergic and inflammatory disorders.[17] The role of histamine receptors and hypersensitivity is discussed in Chapter 9.

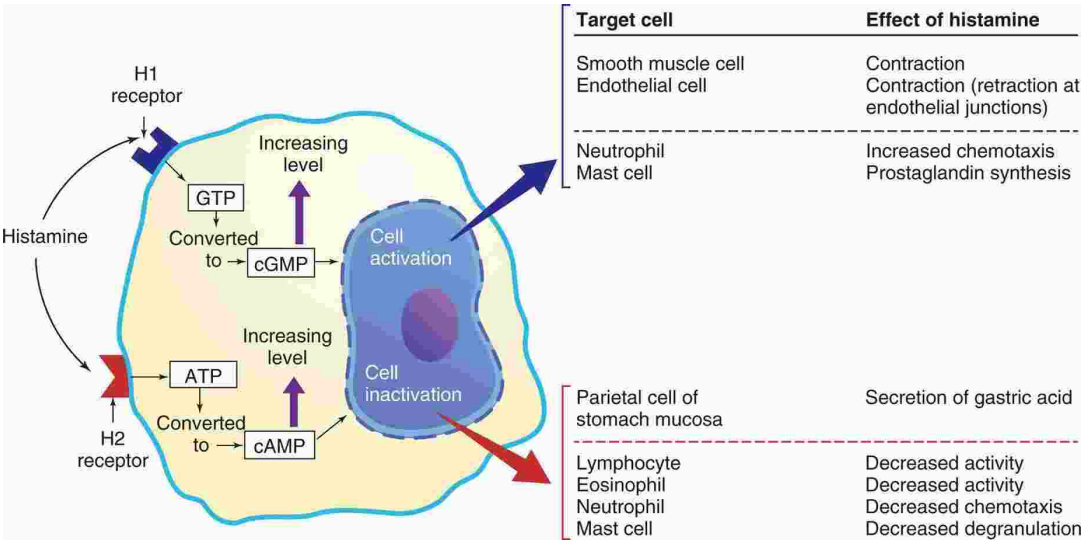

FIG. 7.5 Effects of Histamine Through H1 and H2 Receptors. The effects depend on *(1)* the density and affinity of H1 or H2 receptors on the target cell and *(2)* the identity of the target cell. *ATP*, Adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *GTP*, guanosine triphosphate.

An illustrated table summarizes the effects of histamine through H 1 and H 2 receptors. The illustration of a cell shows histamine being attracted to H 1 receptor and H 2 receptor. When bound to H 1 receptor, G T P is converted to c G M P, increasing its level and leading to cell activation. When bound to H 2 receptor, A T P is converted to c A M P, increasing its level and leading to cell inactivation. The table at the top identifies the target cell and lists the effect of histamine on the target cell. The data from the table for cell activation are as follows. • Smooth muscle cell: Contraction. • Endothelial cell: Contraction (retraction at endothelial junctions) • Neutrophil: Increased chemotaxis. • Mast cell: Prostaglandin synthesis. The data from the table for cell inactivation are as follows. • Parietal cell of stomach mucosa: secretion of gastric acid. • Lymphocyte: Decreased activity. • Eosinophil: Decreased activity. • Neutrophil: Decreased chemotaxis. • Mast cell: Decreased degranulation.

In contrast, histamine binding to the *H2 receptor* is generally anti-inflammatory because it results in the suppression of leukocyte function. Both H1 and H2 receptors are often present on the same immune cells where they may act in an antagonistic fashion. For example, stimulation of H1 receptors on neutrophils results in an augmentation of neutrophil chemotaxis, whereas stimulation of the H2 receptor results in its inhibition. The H2 receptor also is abundant on parietal cells of the stomach mucosa, where stimulation induces the secretion of gastric acid as part of the normal physiology of the stomach. *H3 receptors* inhibit the release of histamine and other neurotransmitters on neurons in the central nervous system. They are involved in blood–brain barrier function, and non-inflammatory processes including cognition, sleep, and regulation of food intake.[18] Research into the role of H3 receptors in health and disease are revealing potential uses treating neurodegeneration (Alzheimer and Parkinson disease), migraine, narcolepsy, and control of eating in obesity.[19]

Mast cell granules also contain chemotactic factors (chemokines). Chemotaxis is directional movement of cells along a chemical gradient formed by a chemotactic factor. Two important factors are neutrophil chemotactic factor (NCF) and eosinophil chemotactic factor of anaphylaxis (ECF-A). Neutrophils are the predominant cells that destroy bacteria in inflammation. Eosinophils help regulate the inflammatory response. Both cells are discussed in more detail later in this chapter.

Synthesis of mediators

Activated mast cells initiate synthesis of other mediators of inflammation. These mediators include leukotrienes, prostaglandins, platelet-activating factor and growth factors (see Fig. 7.4B).

1. Leukotrienes (slow-reacting substances of anaphylaxis [SRS-A]) are products of arachidonic acid. Arachidonic acid is released from mast cell membranes by intracellular phospholipase A2 which acts on membrane phospholipids. Leukotrienes are produced from arachidonic acid by the action of *lipoxygenase* and consist of several different subtypes (Fig. 7.6) Leukotrienes induce smooth muscle contraction (especially bronchoconstriction) and increased vascular permeability. Leukotrienes appear to be important in the later stages of the inflammatory response because they stimulate slower and more prolonged inflammatory responses than does the rapid-acting histamine.
2. Prostaglandins also are products of arachidonic acid. They cause increased vascular permeability, neutrophil chemotaxis, and pain. Pain results from the direct effects on nerves. Prostaglandins are long-chain, unsaturated fatty acids produced by the action of cyclooxygenase (COX). COX exists in two different forms: COX-1, which produces prostaglandins that activate platelets and protect the stomach lining, and COX-2, which activates

prostaglandins associated with inflammation (see Fig. 7.6). Aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit COX-1 and/or COX-2. They suppress inflammation and improve symptoms but have associated side effects. NSAIDs can cause GI tract bleeding, hypertension, renal dysfunction, and cardiovascular disease especially in older individuals who take them regularly for underlying conditions such as osteoarthritis.[20]

3. Platelet-activating factor (PAF) molecules are produced by neutrophils, monocytes, endothelial cells, mast cells, and platelets. The biologic activity of PAF is similar to that of leukotrienes. It causes increased vascular permeability, leukocyte adhesion to endothelial cells, and platelet activation (see Fig. 7.6).
4. Growth factors synthesized and released by mast cells include vascular endothelial growth factor (VEGF) which promotes endothelial cell proliferation, and platelet-derived growth factor (PDGF) which promotes connective tissue and smooth muscle proliferation (see Fig. 7.4B). These growth factors contribute to wound healing.

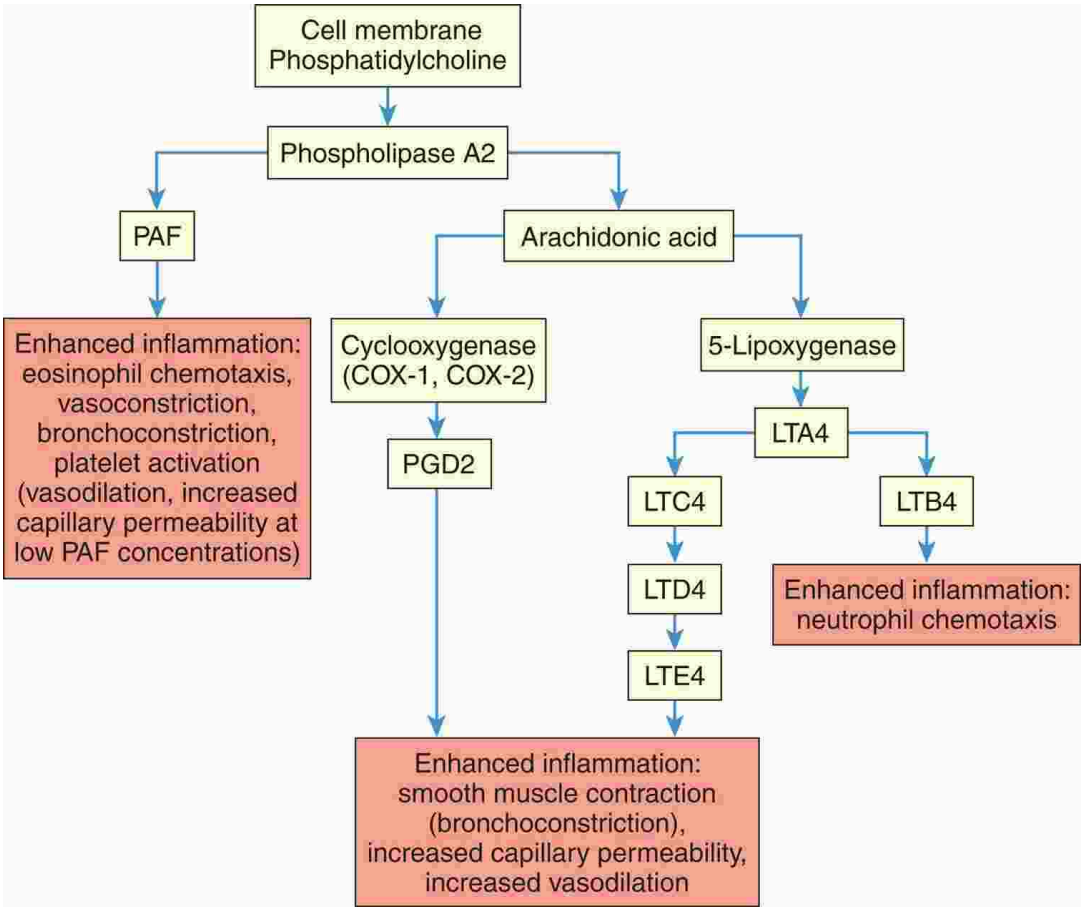

FIG. 7.6 Production of Lipid Vasoactive Substances by Mast Cells.
LTA4, LTC4, LTD4, LTE4, LTB4, Various leukotriene molecules; *PAF*, platelet-activating factor; *PGD2*, prostaglandin D2.

A flowchart tracks the production of lipid vasoactive substances by mast cells. The data from the flow chart is as follows. • Cell membrane phosphatidylcholine: phospholipase A 2. • Phospholipase A 2: P A F and arachidonic acid. • P A F: Enhanced inflammation. Eosinophil chemotaxis, vasoconstriction, bronchoconstriction, platelet activation (vasodilation, increased capillary permeability at low PAF concentrations). • Arachidonic acid: Cyclooxygenase and 5-Lipoxygenase. • Cyclooxygenase (C O X-1, C O X 2): P G D 2. Enhanced inflammation. Smooth muscle contraction (bronchoconstriction), increased capillary permeability,

increased vasodilation. • 5-lipoxygenase: L T A 4. • L T A 4: L T C 4 and L T B 4. • L T C 4: L T D 4. L T E 4. Enhanced inflammation. Smooth muscle contraction (bronchoconstriction), increased capillary permeability, increased vasodilation. • L T B 4: Enhanced inflammation. Neutrophil chemotaxis.

Macrophages

Macrophages are derived from circulating monocytes. As with other blood cell types, monocytes are produced in bone marrow and enter into the circulation. They migrate to tissues throughout the body where they transform to macrophages. These **tissue macrophages** have many different names depending on where they are located, including Kupffer cells (liver), alveolar macrophages (lungs), and microglia (brain) (see Table 28.3). Tissue macrophages are important initial mediators of the inflammatory response.

Macrophages and dendritic cells have an abundance of PRRs on their surface that can recognize a wide range of pathogens and molecules released from damaged tissues. PRR receptor binding to PAMPs and DAMPs results in intracellular communication leading to activation of NF-κB and the subsequent release of proinflammatory chemokines and cytokines. Chemokines (a type of cytokine) are members of a family of low-molecular-weight peptides that function primarily to induce leukocyte chemotaxis. They facilitate the movement of phagocytes from the blood stream through the vessel wall into the area of injury. Cytokines constitute a family of intercellular signaling molecules that are secreted, bind to specific membrane receptors, and regulate innate and adaptive immunity. Macrophages release both *proinflammatory* and *antiinflammatory* cytokines (Fig. 7.7). The most important proinflammatory cytokines secreted by macrophages are tumor necrosis factor-alpha (TNF-α), interleukins, and IFNs.

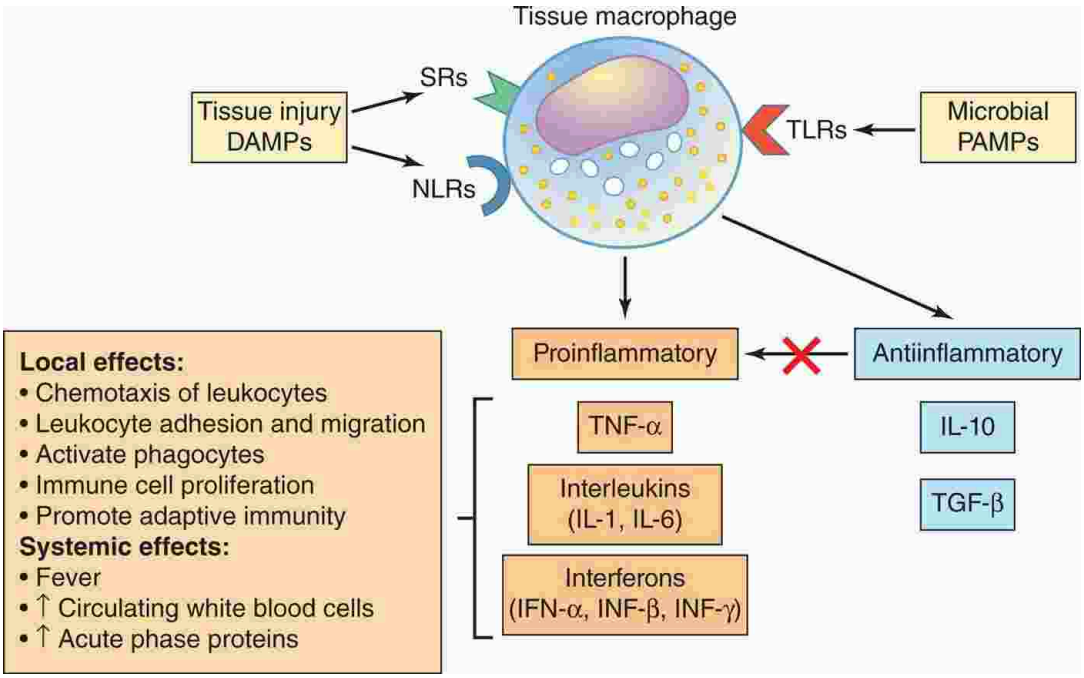

FIG. 7.7 Tissue Macrophage-Derived Cytokines.
When stimulated by pathogen invasion or tissue injury, macrophages release proinflammatory cytokines that have a wide range of local and systemic effects. Antiinflammatory cytokines are also released which limit the effects on inflammation. *DAMPs*, Damage-associated molecular patterns; *IFN*, interferon; *IL*, interleukin; *NLRs*, nucleotide-binding-like receptors; *PAMPs*, pathogen-associated molecular patterns; *SRs*, scavenger receptors; *TLRs*, Toll-like receptors; *TNF-α*, tumor necrosis factor alpha.

An illustrated flowchart summarizes the tissue macrophage-derived cytokines. Tissue macrophage is a result of S Rs and N L Rs from tissues injury D A M Ps and T L Rs from microbial P A M Ps, and it causes: • Proinflammatory: T N F-alpha, interleukins (I L-1, I L-6), interferons (I F N-alpha, I N F-beta, I N F-gamma). • Anti-inflammatory: Interleukins (I L-10), Interferons (T G F-beta). Local effects from proinflammation: • Chemotaxis of leukocytes. • Leukocyte adhesion and migration. • Activate phagocytes. • Immune cell proliferation. • Promote adaptive immunity. Systemic effects from proinflammation: •

Fever. • Increase in circulating white blood cells. • Increase in acute phase proteins.

Tumor necrosis factor-alpha

Tumor necrosis factor-alpha (TNF-α) is secreted primarily by activated macrophages, but is also released by mast cells, neutrophils, and lymphocytes. When PRRs on the surface of macrophages bind to PAMPs or DAMPs, NF-κB is activated and TNF-α is one of the most important proinflammatory cytokines that is then produced. It plays a role in promoting the innate response to virtually any injury or infection including chemotaxis and adherence of neutrophils, phagocytosis, and inflammatory and adaptive immune cell proliferation.[21] TNF-α has systemic effects, including the induction of fever, increased liver synthesis of inflammation-related serum proteins (acute phase proteins), muscle wasting (cachexia), and intravascular thrombosis. These effects can be deleterious in cases of severe or chronic infection and cancer. TNF-α contributes to the damaging effects of severe acute inflammatory conditions such as sepsis and to many chronic inflammatory diseases.

Interleukins

Interleukins (ILs) are produced predominantly by macrophages and lymphocytes in response to stimulation of PRRs or by cytokines secreted by other immune cells. More than 30 interleukins have been identified. Their effects include the following:

1. Regulation of cell adhesion molecules (CAMs), which are proteins that facilitate leukocyte binding with other cells or with the extracellular matrix
2. Attraction of leukocytes to a site of inflammation (chemotaxis)
3. Induction, proliferation, and maturation of leukocytes in bone marrow
4. General enhancement or suppression of inflammation and the adaptive immune response

Two major proinflammatory interleukins are interleukin-1 (IL-1) and interleukin-6 (IL-6). IL-1 is produced mainly by macrophages and activates monocytes, other macrophages, and lymphocytes, thereby enhancing both innate and adaptive immunity. It also acts as a growth factor for many cells. IL-1 is an endogenous pyrogen (fever-causing cytokine) which reacts with receptors on cells of the hypothalamus resulting in increased body temperature. IL-6 is produced by macrophages, lymphocytes, fibroblasts, and other cells. IL-6 directly induces hepatocytes in the liver to produce many of the proteins needed for inflammation (acute phase proteins). IL-6 also stimulates growth and differentiation of blood cells in the bone marrow and the growth of fibroblasts required for wound healing. IL-1 and IL-6 play important roles in numerous inflammatory diseases and infections,

and monoclonal antibodies that block these cytokines are used to treat many of them. For example, in severe COVID-19 infection, blockade of IL-1 and IL-6 resulted in decreased mortality.[22]

Interferons

Interferons (IFNs) are members of a family of cytokines that protect against viral infections and modulate the immune response. They are considered essential components of both innate and adaptive immunity. Type I IFNs (primarily IFN-α, IFN-β) are produced and released by virally infected cells. These IFNs do not kill viruses; rather they induce antiviral proteins in neighboring healthy cells. Type II IFN (IFN-γ) is produced primarily by lymphocytes. It activates macrophages and increases their capacity to detect and process invaders and abnormal cells so that they can be removed by the adaptive immune system.

Antiinflammatory cytokines

Some cytokines are antiinflammatory and diminish and control the inflammatory response. Two of the most important are IL-10 and TGF-β. Interleukin-10 (IL-10) is primarily produced by lymphocytes. It suppresses the activation and proliferation of other lymphocytes and limits the production of proinflammatory cytokines by macrophages. The result is a downregulation of both the inflammatory and the adaptive immune responses. Recent evidence suggests that IL-10 also may have proinflammatory effects in certain severe conditions such as Crohn disease and COVID-19.[23] Transforming growth factor-beta (TGF-β) is produced by many cells in response to inflammation. Its primary role in immunity is to suppress the activity of lymphocytes and downregulate the production of proinflammatory cytokines by macrophages.

Dendritic Cells

Dendritic cells can be considered a specialized type of macrophage derived from a common precursor stem cell in the bone marrow. Some, like macrophages, differentiate from circulating monocytes. They provide one of the major links between the innate and adaptive immune responses. They are located in tissues that have contact with the outside environment, e.g. the gut, respiratory tract, and skin. Like tissue macrophages, they recognize invaders with PRRs and phagocytose them. They are different from tissue macrophages in that they migrate from the tissues through lymphatic vessels to lymph nodes, where they present antigens from the phagocytosed invaders to T lymphocytes resulting in an adaptive immune response (see Chapter 8). Dendritic cells produce many of the same cytokines as macrophages.

The Vascular Response in Inflammation

After initiation by the plasma protein systems, mast cells, tissue macrophages, and dendritic cells, the inflammatory response has an almost immediate effect on blood vessels (see Algorithm 7.1). Inflammatory changes in the microcirculation (arterioles, capillaries, and venules) surrounding the site of an injury happen within seconds. They include the following processes:

1. Hemostasis (coagulation): Injury to blood vessels initiates the clotting cascade and activates platelets. Clotting slows blood flow, walls off injury, and provides a meshwork for healing.
2. Vasodilation: Arteriole and venule dilation increase the diameter of blood vessels, the volume of blood delivered to the injured site, and slows the velocity of blood flow. This action allows more time for the movement of fluids, chemicals, and cells into surrounding tissues, resulting in erythema (redness) and warmth in the area of injury.
3. Increased vascular permeability: Blood vessels become porous, secondary to retraction of endothelial cells, thus opening vascular tight junctions and enlarging the spaces between these cells. This results in exudation (the leaking of fluid and cells from vessels) and edema (tissue swelling from fluid leakage) of the area surrounding the injury.
4. Leukocyte cell adhesion: Leukocytes adhere to the inner walls of vessels, where they migrate through the enlarged spaces between endothelial cells and into the surrounding tissue (diapedesis). Accordingly, there is an influx of phagocytes (neutrophils and macrophages) to the injured tissue, where they target invaders and damaged cells.

Together, these vascular changes deliver leukocytes (particularly neutrophils and macrophages), plasma proteins, and other biochemical mediators to the site of injury. Chemical mediators activate pain fibers. Tissue injury, pain, and swelling contribute to loss of function.

Lymphatic vessels, which drain the extravascular fluid to lymph nodes, may become secondarily inflamed. The resulting lymphangitis (inflammation of lymph vessels) or lymphadenitis (inflammation of nodes) can present as enlarged and painful lymph nodes. For example, in an individual with a sore throat, the infected and inflamed pharynx can result in enlarged and painful lymph nodes, which are readily palpable in the neck region.

The Cellular Response in Inflammation

Once the inflammatory response has been initiated by plasma proteins, mast cells, tissue macrophages, and dendritic cells, other leukocytes move out of the blood vessels and travel quickly to the area of invasion or injury. Neutrophils are the most important phagocyte in the cellular response in inflammation and arrive early at the scene in large numbers where they begin the process of removing microorganisms

and cellular debris. Monocyte-derived macrophages play an essential role in removing debris and initiating the healing process. Both of these cell types function primarily through the process of phagocytosis.

Neutrophils

The neutrophil, or polymorphonuclear neutrophil (PMN), is a granulocyte named for its characteristic staining pattern as well as its multilobed nucleus. Neutrophils circulate in the blood in large numbers and are attracted to the area of injury by chemotactic factors, such as mast cell cytokines, chemokines, and complement. Neutrophils are the predominant phagocytes in early inflammation, arriving at the inflammatory site within 6 to 12 hours after the initial injury. The primary role of the neutrophil is to phagocytize pathogenic microbes and remove cellular debris and dead cells from lesions. The neutrophil is a mature cell incapable of division and is sensitive to the acidic environment found at inflammatory sites. Accordingly, it is short-lived and rapidly becomes a component of the purulent exudate (pus) removed from the body through the epithelium or drained from the infected site through the lymphatic system. They are present in sterile lesions, which drain "sterile pus," as well as in septic (nonsterile) lesions found in bacterial infections.

In addition to phagocytosis, neutrophils can form neutrophil extracellular traps (NETs) which are crucial in attacking pathogens. NETs are formed of material from cell nucleus breakdown (chromatin and histones) and neutrophil granules which contribute numerous enzymes that can degrade microorganisms. These enzymes include neutrophil elastase, myeloperoxidase, matrix metalloproteinases, and others.[24] NET formation usually leads to the destruction of the neutrophil. NETs may also contribute to tissue damage and autoimmune diseases.[25]

Monocyte-Derived Macrophages

Monocyte-derived macrophages are also essential phagocytes in inflammation. They begin appearing at the inflammatory site as soon as 24 hours after the initial neutrophil infiltration but do not arrive in large numbers until 3 to 7 days later. They are attracted by chemotactic factors released by the neutrophils that are already present at the site. Macrophage activation results in two subpopulations, M1 and M2 macrophages, each with specialized functions. *M1 macrophages* are proinflammatory and have bactericidal activity, promote adaptive immunity, and can attack cancer cells.[26]*M2 macrophages* are primarily involved in tissue healing and repair. Macrophages can survive and divide in the acidic environment of the inflammatory site and so are capable of conducting prolonged phagocytosis of microorganisms and damaged cells. They play an essential role in removing debris and promoting the formation of new blood vessels (angiogenesis) and secretion of growth factors that prepare the tissue for healing.[27]

Phagocytosis

Phagocytosis is the ingestion of microbes, foreign particles, or cell fragments. The two most important cells for phagocytizing pathogens or damaged cells are neutrophils and macrophages. Inflammatory cytokines and chemokines serve to activate these cells and through chemotactic factors cause them to move toward the area of injury. These cytokines also open the tight junctions between endothelial cells, creating spaces between them. Additionally, inflammation induces endothelial nitric oxide synthase (iNOS), increasing the amount of nitric oxide (NO) production. Effects of NO in inflammation include vasodilation and changes in inflammatory cell function.[28]

The first step in the migration of phagocytes to the area of invasion or injury starts when endothelial cells, monocytes, and neutrophils begin expressing new CAMs on their surfaces. The most important CAMs related to vascular inflammation are selectins, integrins, and intracellular adhesion molecules (ICAMs). These CAMs increase the adhesion, or stickiness, between phagocytes and endothelial cells in the walls of the capillaries. At first, the phagocytes roll down the endothelial surface. This is followed by tight binding to the endothelium in a process called margination, or pavementing (Fig. 7.8A). Other adhesion molecules such as platelet endothelial cell adhesion molecules (PECAMs) then are expressed leading to diapedesis or **emigration** of the cells through the openings between endothelial cells. The leukocytes digest the basement membrane and migrate into the surrounding tissues.[29] Monoclonal antibodies that block adhesion molecules are used to reduce inflammation in a variety of conditions including cancer (see Chapter 9).[30]

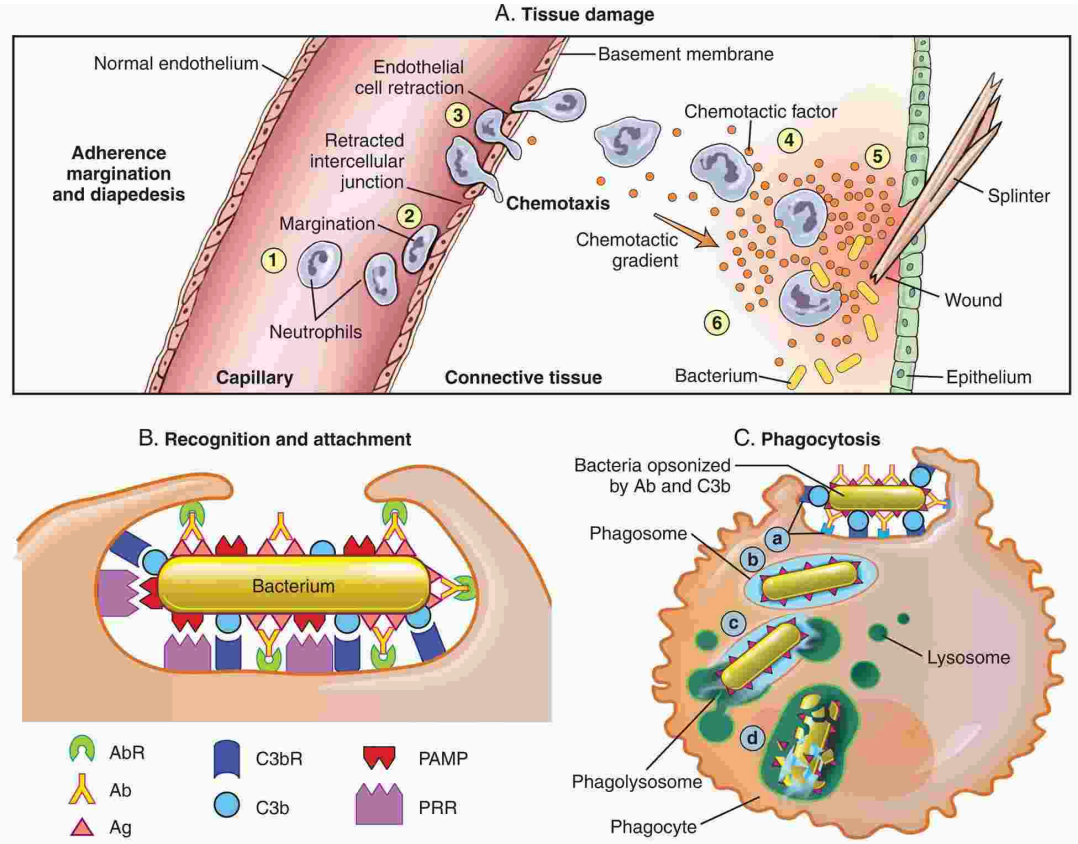

FIG. 7.8 Process of Phagocytosis.
The process that results in phagocytosis is characterized by three interrelated steps: adherence and diapedesis, tissue invasion by chemotaxis, and phagocytosis. **(A) Tissue damage**. *Adherence, margination, and diapedesis*: The primary phagocyte in the blood is the neutrophil, which usually moves freely within the vessel *(1)*. At sites of inflammation, neutrophils and endothelial cells respond to inflammatory cytokines by expressing adhesion molecules (selectins, integrins, and ICAMs). This causes the neutrophils to progressively develop increased adherence to the endothelium, leading to accumulation along the vessel wall (margination or pavementing) *(2)*. At sites of endothelial cell retraction, other adhesion molecules such as PECAMs allow the neutrophil to move through the vessel wall by means of diapedesis *(3)*. *Chemotaxis:* In the tissues, the neutrophil detects chemotactic factor gradients through surface receptors *(4)* and migrates toward higher concentrations of the factors *(5)*. The high concentration of chemotactic factors at the site of inflammation immobilizes the neutrophil *(6)*. **(B) Recognition and attachment**. Specific receptors are expressed on the surface of phagocytes that facilitate recognition and attachment to ligands found on the

surface of target invaders such as bacteria. **(C) Phagocytosis.** ***(a)*** Antibodies and complement serve to opsonize the surface of microorganisms which are then more easily recognized and bound to the surface of a phagocyte. ***(b)*** The microorganism is engulfed (ingested) into a phagocytic vacuole, or phagosome. ***(c)*** Lysosomes fuse with the phagosome, resulting in the formation of a phagolysosome. ***(d)*** The microorganism is killed and digested. *Ab*, Antibody; *AbR*, antibody receptor; *Ag*, antigen; *C3b*, complement component C3b; *C3bR*, complement C3b receptor; *PAMP*, pathogen-associated molecular pattern; *PRR*, pattern recognition receptor.

Three panels, A, B, and C, illustrate tissue damage, recognition and attachment, and phagocytosis, respectively. Top panel, tissue damage. An illustration shows a splinter punctured through the epithelium, causing a wound. A capillary with normal endothelium and a basement membrane contains white blood cells. Adherence margination and diapedesis of the blood cells is illustrated inside the capillary. 1. Neutrophils in the capillary. 2. Margination: cell moves closer to the endothelium. 3. Retracted intercellular junction: an open space between two endothelium cells. 4. Endothelial cell retraction: cell passe through the junction, chemotaxis. Bacterium from the site of the wound enters the connective tissue, which is combated by the white blood cells as a result of chemotactic gradient. Bottom left panel, recognition and attachment. An illustration shows a bacterium. Ligands and receptors binding to the ligands around the bacterium are as follows: • A g: A b R through A b. • C 3 b: C 3 b R. • P A M P: P R R. Bottom right panel, phagocytosis. An illustration shows bacterium being engulfed into the cell. The following structures in the cell are identified. • Bacteria opsonized by A b and C 3 b. • Phagosome. • Phagolysosome. • Phagocyte. • Lysosome.

Once inside the connective tissue in the perivascular space, phagocytes migrate to the inflammatory site by means of chemotaxis. They detect chemotactic factors (chemokines) in the environment through chemoreceptors on their plasma

membranes and migrate in the direction of highest concentration (see Fig. 7.8A). The most important chemotactic factors include bacterial products, complement fragments C3a and C5a, and chemokines. Neutrophils also respond to chemotactic factors released from mast cells (NCF). Monocyte-derived macrophages are attracted to monocyte chemotactic factor (MCF) that has already been released by neutrophils at the site of injury.

Phagocytosis at the inflammatory site involves four steps (see Fig. 7.8C):

1. Recognition and adherence of the phagocyte to its target through PRRs
2. Engulfment (ingestion or endocytosis) and formation of phagosomes
3. Fusion of the phagosome with lysosomal granules within the phagocyte
4. Destruction of the target

Most phagocytes can trap and engulf pathogens using their PRRs which recognize PAMPs on the microorganisms (see Fig. 7.8B). However, some pathogens such as encapsulated bacteria (see Chapter 10) are more difficult to engulf. Opsonization greatly enhances adherence of the phagocyte to the target microorganism or cell. Opsonins that coat the target bacteria or cell act as a "glue" tightening the affinity between the phagocyte and the target, making phagocytosis more effective. The most efficient opsonins are C3b of the complement system and antibodies produced during the adaptive immune response.

Engulfment (endocytosis) is a process whereby the microorganism is drawn into the interior of a phagocytic cell. Engulfment is carried out by small pseudopods that extend from the plasma membrane of the phagocyte to surround the target, forming an intracellular phagocytic vacuole, or phagosome. Upon formation of a phagosome, the lysosomes (containing destructive enzymes) converge, fuse with the phagosome, and discharge their contents to create a phagolysosome. Destruction of the target takes place within the phagolysosome. Destruction is accomplished by both oxygen-dependent and oxygen-independent mechanisms.

Oxygen-dependent killing mechanisms result from the production of toxic oxygen species (e.g., hydrogen peroxide, singlet oxygen, or hydroxyl radicals). Phagocytosis is accompanied by a burst of oxygen uptake by the phagocyte. Chemical mediators and other reactive oxygen species are highly damaging to bacteria.

Oxygen-independent mechanisms of microbial killing include (1) the acidic pH (3.5 to 4.0) of the phagolysosome, (2) cationic proteins that bind to and damage target cell membranes, (3) enzymatic attack of the microorganism's cell wall by lysozyme and other enzymes, and (4) inhibition of bacterial growth by lactoferrin binding of iron (iron is essential for bacterial growth). Throughout the process, these toxic substances are isolated within membrane-bound vesicles. This isolation protects the phagocyte from harm secondary to the phagocyte's own enzymes.

Several bacteria are resistant to destruction by phagocytes and can survive inside macrophages. Microorganisms, such as *Mycobacterium tuberculosis* (tuberculosis), *Mycobacterium leprae* (leprosy), *Salmonella typhi* (typhoid fever), *Brucella abortus*

(brucellosis), and *Listeria monocytogenes* (listeriosis), can remain dormant or multiply inside the phagolysosomes of macrophages.[31]

In addition to removing pathogens and damaged cells, phagocytes (especially macrophages) are responsible for removing cells that have completed their normal life cycle. For example, white blood cells and erythrocytes are programmed to live for only weeks or months. These dead cells number in the billions per day and must be recognized and removed from the body via phagocytosis.[32] Phagocytosis of a red blood cell is illustrated in Fig. 7.9.

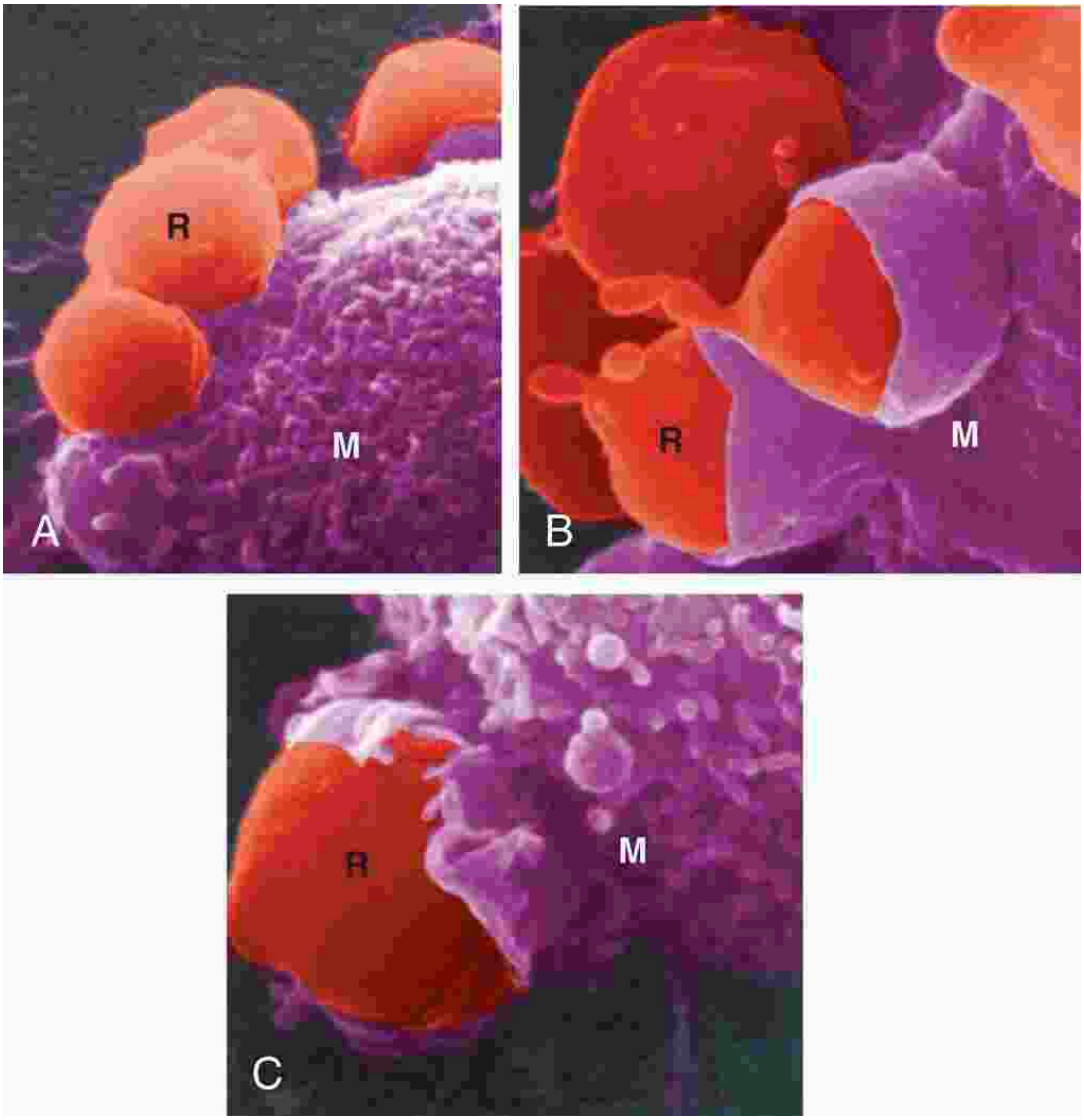

FIG. 7.9 Steps in Phagocytosis.
This scanning electron micrograph shows the progressive steps in phagocytosis. **(A)** Red blood cells *(R)* attach to the surface of a macrophage *(M)*. **(B)** Part of the macrophage *(M)* membrane starts to enclose the red cell *(R)*. **(C)** The red blood cells are almost totally engulfed by the macrophage. (From King DW, Fenoglio CM, Lefwitch JH. *General pathology: Principles and dynamics*. Philadelphia: Lea & Febiger; 1983.)

Dying phagocytes can cause tissue damage at the site of inflammation. When a phagocyte dies at an inflammatory site, it frequently lyses (breaks open), releasing its enzymatic contents into the tissue. These enzymes can cause inflammation-associated tissue destruction. The destructive effects of enzymes released by dying phagocytes are minimized by natural inhibitors found in blood. Examples of such inhibitors would include catalase, which breaks down hydrogen peroxide, and

alpha1-antitrypsin (α1-antitrypsin), a protease inhibitor produced by the liver. An inherited deficiency of α_1-antitrypsin, a disease known as alpha-1 antitrypsin deficiency, results in pulmonary emphysema secondary to chronic lung inflammation, even in nonsmokers (see Chapter 35).[33]

Other Cells of Inflammation

Another type of innate immune cell is the eosinophil. Although eosinophils are only mildly phagocytic, they serve as the body's primary defense against *parasites* and regulate *vascular mediators* released from mast cells. Lysosomal granules within the eosinophil contain enzymes that degrade vasoactive substances from mast cells, thus limiting and controlling the vascular effects of inflammation. Eosinophils also are important components of allergic conditions and can contribute to tissue damage; these effects are discussed in Chapter 9.

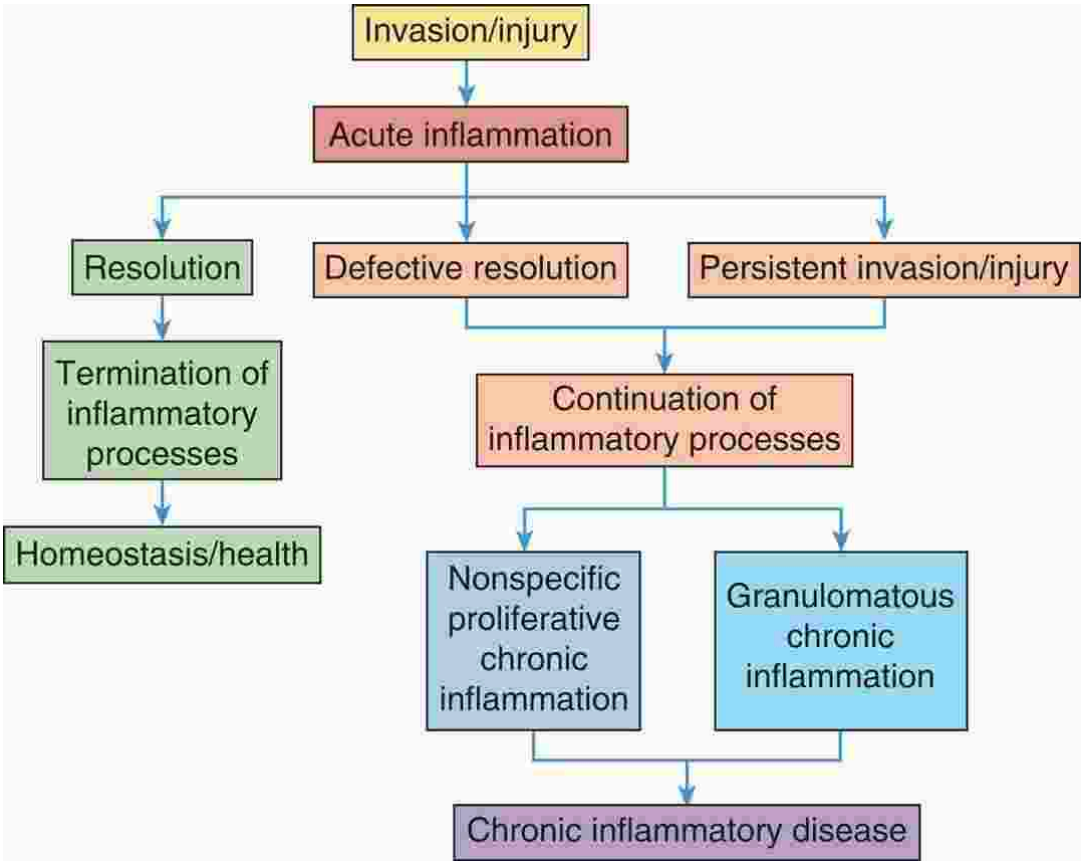
The basophil is the least prevalent granulocyte in the blood. It is similar to mast cells with respect to the contents of its granules. Basophilic granules also contain heparin, a naturally occurring anticoagulation product. Basophils release histamine which, as discussed previously, has potent vasoactive properties. Basophils are an important source of cytokines involved in the adaptive immune response, particularly responses associated with allergies and asthma.

Lymphocytes, another type of leukocyte, initiate specific, protective immune responses against pathogens and cancer. B lymphocytes produce antibodies, and T lymphocytes regulate other immune cells and kill viruses and cancer cells (see Chapter 8). Natural killer (NK) cells, a type of lymphocyte, eliminate virally infected and cancerous cells. NK cells have inhibitory and activating receptors that allow differentiation between infected or tumor cells and normal cells. If the NK cell binds to a target cell through activating receptors, it produces several cytokines and toxic molecules, which, in turn, kill the target cell. **Innate lymphoid cells (ILCs)** also are derived from lymphocyte precursors that reside near mucosal surfaces. There are three major groups of ILCs (ILC1s, ILC2s, and ILC3s) which contribute in different ways to preventing pathogen invasion and activating both the innate and adaptive immune responses (see Chapter 8).[34]

Acute and Chronic Inflammation

Inflammation can be divided into two phases: acute inflammation and chronic inflammation (Algorithm 7.3). The acute inflammatory response is self-limiting; it continues only until the threat to the body is eliminated. The process usually takes 8 to 10 days from onset of injury to healing. If the acute inflammatory response proves inadequate or does not resolve appropriately, chronic inflammation may develop and persist for weeks or months. The characteristics of the acute inflammatory response differ from those of a chronic response. Each phase involves different biochemical mediators and cells, all of which function in a coordinated

manner. Depending on the successful containment of tissue damage and infection, both the acute and chronic phases may eventually lead to healing.



ALGORITHM 7.3 **Chronic Inflammatory Response.** The acute inflammatory response to invasion or injury usually leads to resolution of the inciting event, reduction of inflammatory cytokines and cells, and restoration of tissue homeostasis and health. However, defects in the resolution process or persistent invasion and injury lead to chronic inflammatory damage to tissues and resultant disease.

A flowchart represents the chronic inflammatory response. The data from the flowchart are as follows from top to bottom. • Invasion or injury leads to acute inflammation. • Acute inflammation leads to resolution, defective resolution, and persistent invasion or injury. • Resolution leads to termination of inflammatory processes, which, in turn, leads to homeostasis or health. • Defective resolution and persistent invasion or injury leads to continuation of inflammatory processes. • Continuation of inflammatory processes leads to nonspecific proliferative

chronic inflammation and granulomatous chronic inflammation, which, in turn finally leads to chronic inflammatory disease.

Manifestations of Local and Systemic Acute Inflammation

The cells and plasma protein systems involved in the inflammatory response interact to produce the characteristic changes of inflammation, whether local or systemic. They also determine the duration of inflammation, either acute or chronic.

The classic or cardinal signs of the acute local inflammatory response were described in the first century by a Roman named Celsus. They include the following:

1. Rubor (redness, erythema)
2. Calor (heat)
3. Tumor (swelling)
4. Dolor (pain)
5. Functio laesa (loss of function)

Inflammatory exudates result from increased vascular permeability and the leakage of fluid into tissues. Exudates vary in composition, depending on the stage of inflammation, and, to a lesser extent, the triggering event. In early or mild inflammation, the exudate may be a serous exudate (watery) with very few plasma proteins or leukocytes (e.g., fluid in a blister). In more severe or advanced inflammation, the exudate may be a fibrinous exudate (thick and clotted) (e.g., the fluid exudates in the lungs of an individual with pericarditis). A purulent exudate (pus) is the accumulation of a large number of leukocytes, as occurs in bacterial infections (e.g., sputum in persons with pneumonia). A purulent exudate can also occur within walled-off lesions, known as cysts or abscesses. When bleeding occurs, the exudate is filled with erythrocytes and is described as a hemorrhagic exudate.

Systemic manifestations of acute inflammation include three primary systemic changes: fever, leukocytosis (a transient increase in the levels of circulating leukocytes), and increased levels of circulating plasma proteins. It is important to realize that individuals who are immunocompromised (e.g., those taking corticosteroids, chemotherapy agents, and antirejection medications) may not demonstrate these clinical manifestations, making it difficult to recognize acute infection or tissue injury.

Fever

Fever is partially induced by specific cytokines (e.g., TNF-α and IL-1) released from neutrophils and macrophages. These cytokines are known as endogenous pyrogens to differentiate them from pathogen-produced exogenous pyrogens (e.g., endotoxins produced by some bacteria). Pyrogens act directly on the hypothalamus,

the portion of the brain which controls the body's thermostat. A fever can be beneficial, as many microorganisms are sensitive to small increases in body temperature. For example, the microorganisms causing syphilis or gonococcal urethritis are highly sensitive to small increases in body temperature. However, fever may have harmful side effects when it enhances the body's susceptibility to endotoxins associated with severe bacterial infections.

Leukocytosis

Leukocytosis is an increase in the number of circulating white blood cells beyond the upper limit of normal (11,000/mL^3 in adults) (see Chapter 29). Inflammation stimulates the proliferation and release of granulocyte and monocyte precursors in bone marrow. The cells migrate into the systemic circulation resulting in both an increase in the total number of circulating leukocytes and an increased ratio of immature to mature cell forms. In particular, increased numbers of immature neutrophil forms such as band cells, metamyelocytes, and (rarely) myelocytes are released from the marrow into blood causing an abnormal complete blood count (CBC), a common laboratory analysis of blood cells. The differential count is a measure of the ratio or proportion of each of the various blood cell types circulating in the blood. An increase in the total number of white blood cells in combination with an abnormal differential count is a clue that there may be an ongoing infection.

Plasma Protein Synthesis

The hepatic synthesis of many plasma proteins is increased during inflammation. These proteins, which can be either pro-inflammatory or anti-inflammatory in nature, are referred to as acute-phase reactants (proteins). Acute-phase reactants reach maximal circulating levels within 10 to 40 hours after the onset of inflammation.

Laboratory tests that measure levels of acute-phase reactants are available. For example, an increase in blood levels of the acute-phase reactants fibrinogen is associated with an increased adhesiveness of erythrocytes. Erythrocytes adhere to one another under these circumstances, forming large clumps that are buoyant and slow to settle to the bottom of a test tube of blood. This results in an increased value for the laboratory test referred to as erythrocyte sedimentation rate (ESR) or, as it is more commonly known, the “sed rate.” Although this increased ESR is a nonspecific reaction, persons found to have an elevated ESR will likely have an inflammatory process going on somewhere within the body. Another common laboratory measure of inflammation is the **C-reactive protein (CRP)**, a laboratory measurement which also is increased during an inflammatory response. CRP is used to look for subclinical inflammation in individuals at risk for heart disease and to estimate the severity of certain infectious and autoimmune diseases.[35]

Chronic Inflammation

In its simplest terms, the difference between acute and chronic inflammation is duration. Chronic inflammation is slow, long-term inflammation lasting for prolonged periods of several months to years. It is characterized by low-grade persistent inflammatory changes that result in collateral damage to tissues.[36] Virtually all chronic diseases are characterized by a component of chronic inflammation. Although the cause of defective resolution and a persistent inflammatory response is often unknown, some common conditions associated with chronic inflammation include increasing age, cardiac and neurologic disorders, malignancy, autoimmune disorders, and chronic infection.

Chronic inflammation is most often thought to be preceded by an unsuccessful acute inflammatory response, although that initial insult may not have been recognized (see Algorithm 7.3). For example, if bacterial contamination or foreign objects (dirt, wood splinter, silica, glass, etc.) persist in a wound, the inflammatory response will be prolonged. Some microorganisms are resistant to killing by the acute inflammatory response or may produce toxins which damage tissue and cause persistent inflammation, even after the original microorganism is killed. Chronic inflammation also can occur as a result of defective resolution of acute inflammation, due to an inability to appropriately dampen the innate immune response.[37] Trained immunity in which innate immune cells remain hyperreactive to inflammatory stimuli may also play a role (see Emerging Science Box: Understanding the Causes of Chronic Inflammatory Disease).[38]

There are two major types of chronic inflammation (Fig. 7.10). *Nonspecific proliferative chronic inflammation* is characterized by the infiltration of lymphocytes and macrophages followed by a proliferation of fibroblasts, connective tissue, and epithelial cells. This often leads to scar or polyp formation. *Granulomatous chronic inflammation* occurs when macrophages and eosinophils attempt to wall off and isolate a foreign body or an infected area by forming a granuloma (Fig. 7.11). Infections caused by certain bacteria (tuberculosis, listeriosis, brucellosis), fungi (histoplasmosis, coccidioidomycosis), and parasites (leishmaniasis, schistosomiasis, toxoplasmosis) commonly result in granuloma formation. Many autoimmune conditions also are associated with granulomatous tissue changes.[39]

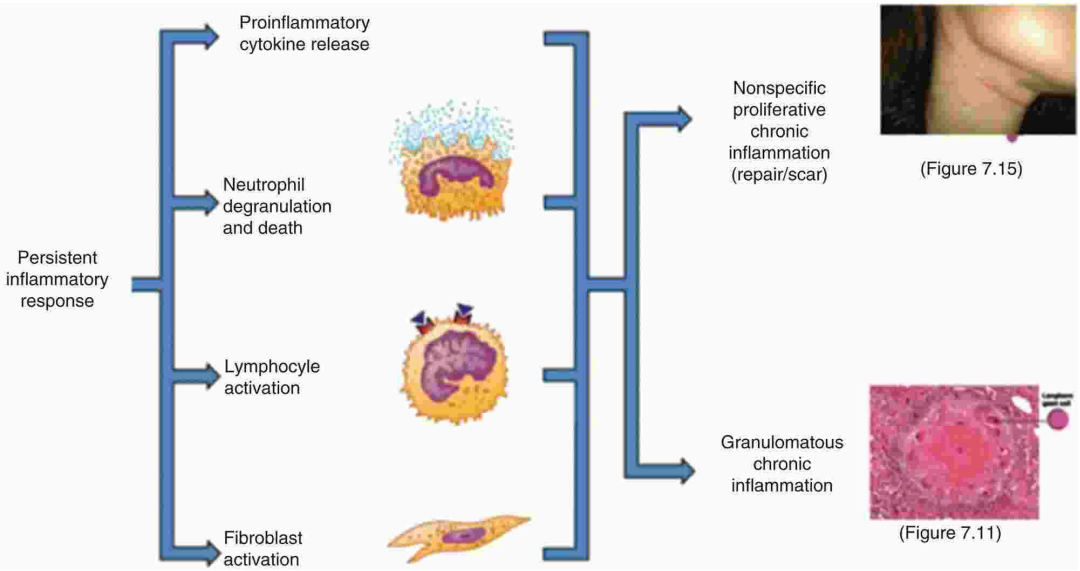


FIG. 7.10 Types of Chronic Inflammation.
Chronic inflammation is characterized by the persistence of many of the processes of acute inflammation. In addition, large amounts of neutrophil degranulation and death, the activation of lymphocytes, and the concurrent activation of fibroblasts result in the release of mediators that induce the infiltration of more lymphocytes and monocytes/macrophages leading to two types of chronic inflammatory outcomes.

An illustration identifies the types of chronic inflammation. Persistent inflammatory responses: • Proinflammatory cytokine release. • Neutrophil degranulation and death. • Lymphocyte activation. • Fibroblast activation. All responses lead to nonspecific proliferative chronic inflammation (repair or scar) and granulomatous chronic inflammation. A closeup of a hypertrophic scar shows a thin line of raised fibrous tissue running around the upper throat of a person. A photomicrograph of cells affected by tuberculous granuloma shows a smooth central area (amorphous caseous necrosis) and some pits indicating langhans giant cells, surrounded by epithelioid macrophage cells and lymphocytes.

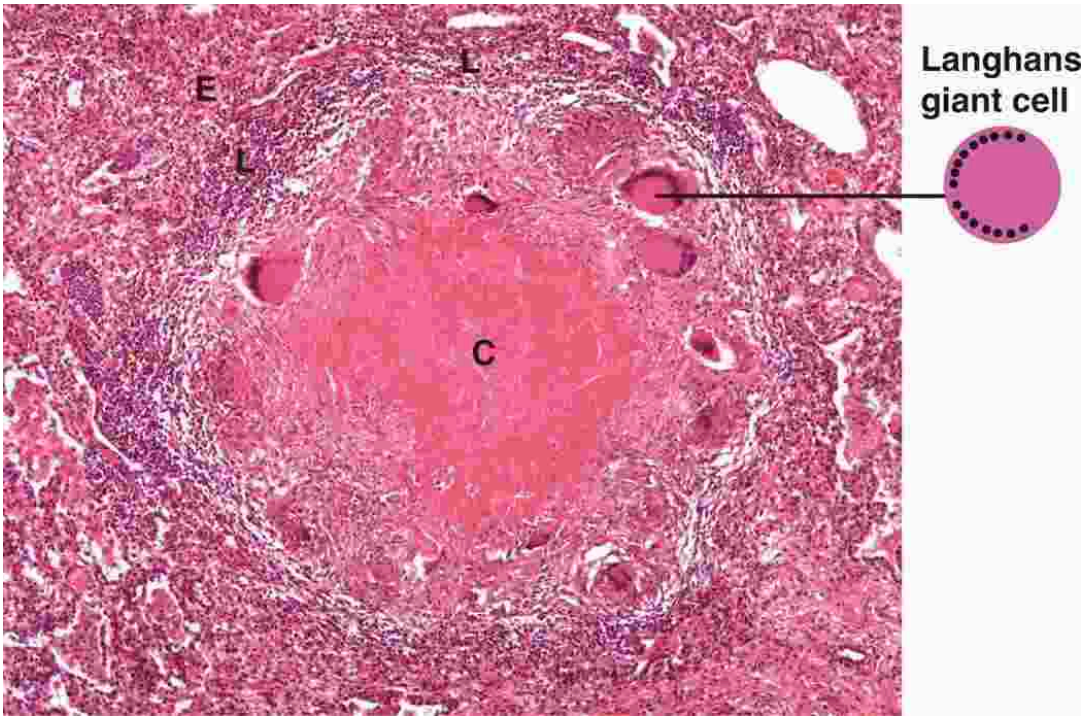

FIG. 7.11 Tuberculous Granuloma.
A central area of amorphous caseous necrosis *(C)* is surrounded by a zone of lymphocytes *(L)* and enlarged epithelioid macrophage cells *(E)*. Activated macrophages frequently fuse to form multinucleated cells (Langerhans giant cells). In tuberculoid granulomas the nuclei of the giant cells move to the cellular margins in a horseshoe-like formation. (From Kumar V, Abbas AK, Aster JC. *Robbins basic pathology*, 9th edition. Philadelphia: Saunders; 2013.)

A photomicrograph of cells affected by tuberculous granuloma shows a smooth central area (amorphous caseous necrosis) and some pits indicating langhans giant cells, surrounded by epithelioid macrophage cells and lymphocytes.

Granuloma formation is mediated by TNF-α and other proinflammatory cytokines. Macrophages are called to the area of persistent inflammation, where some differentiate into large epithelioid cells, which specialize in taking up debris and other small particles. Other macrophages fuse into multinucleated giant cells, which are active phagocytes, which can engulf particles larger than those that can be engulfed by a single

Emerging Science Box Understanding the Causes of Chronic Inflammatory Disease

Chronic inflammatory diseases such as myocardial infarction, stroke, cancer, diabetes, kidney failure, and autoimmune conditions cause more than half of all deaths in the world today. Although the cause of the persistent inflammatory response is often unknown, the most common triggers of chronic inflammation include chronic infections, physical inactivity, disrupted sleep, poor diet, obesity, microbiome dysbiosis, psychological stress, social isolation, and exposure to environmental toxins such as air pollutants (especially particulate matter), chemicals, and tobacco smoking. In addition, there is increasing evidence that maternal health during pregnancy can have a profound effect on the developing fetal immune system that may increase the risk for chronic inflammatory diseases later in life. Lack of adequate resolution of the acute inflammatory response is considered the primary underlying cause of chronic inflammation. Recent studies implicate trained immunity of the innate immune system in the development of chronic inflammatory conditions. Trained immunity describes the process by which innate immune cells are epigenetically and metabolically reprogrammed to remain hyperresponsive even after brief stimulation. For example, microorganisms and oxidized LDL are capable of inducing memory in macrophages. Trained immunity is thought to provide some protection against infectious diseases, but it can also contribute to chronic inflammation and the development of chronic inflammatory diseases such as atherosclerosis. Chronic inflammation in older individuals is thought to result in part from cellular senescence called inflammaging, a condition which is characterized by DNA damage, decreased cell proliferation, and increased secretion of pro-inflammatory cytokines. Many lifestyle changes recommended for specific chronic inflammatory disorders such as heart disease, cancer, and diabetes are thought to positively impact underlying inflammatory processes. For example, skeletal muscle releases small proteins called myokines during exercise which systemically reduces inflammation. A better understanding of how inflammation becomes chronic is leading to emerging ideas about how to better manage inflammatory conditions and prevent many common diseases.

macrophage. These two types of specialized cells form the center of the granuloma and are surrounded by lymphocytes. The granuloma itself is often encapsulated by fibrous deposits of collagen. It may become cartilaginous or even calcified by deposits of calcium carbonate and calcium phosphate.

The classic granuloma associated with tuberculosis is characterized by a wall of lymphocytes and epithelioid cells surrounding the mycobacteria. Death of cells within the granuloma results in the release of acids and enzymatic lysosomal contents from dead phagocytes forming a cheese-like proteinaceous center which consists of decaying tissue (caseous necrosis). In this inhospitable environment, the cellular debris is broken down into its basic constituents, forming a clear fluid within the granuloma (liquefaction necrosis). Eventually, this fluid diffuses out, leaving a hollow, thick-walled structure that has replaced normal tissue, resulting in the reduced lung function seen with tuberculosis infections.

Wound Healing

The most favorable outcome of inflammation is healing with a return to normal structure and function. Some destroyed tissues are capable of regeneration, a process where damaged tissue is replaced with healthy tissue of the original type. Regeneration occurs within the epithelia of the skin and intestines as well as in some organs, notably the liver. This restoration is an example of effective resolution of the acute inflammatory response.

Regeneration does not always follow inflammation and may not be possible when extensive damage has occurred and at sites where the original tissue is not capable of complete restoration of normal tissue structure. Where resolution is not possible, tissue repair occurs. Repair refers to the replacement of destroyed tissue with scar tissue. Scar tissue is composed primarily of collagen, a substance which fills in the lesion and restores tissue integrity and strength but cannot carry out the physiologic functions of the tissue it has replaced, resulting in loss of function.

A clean incision, such as a paper cut or a sutured surgical wound, heals primarily through the process of primary intention. Because this type of wound has minimal tissue loss and close apposition of the wound edges, healing can occur quickly (Fig. 7.12).

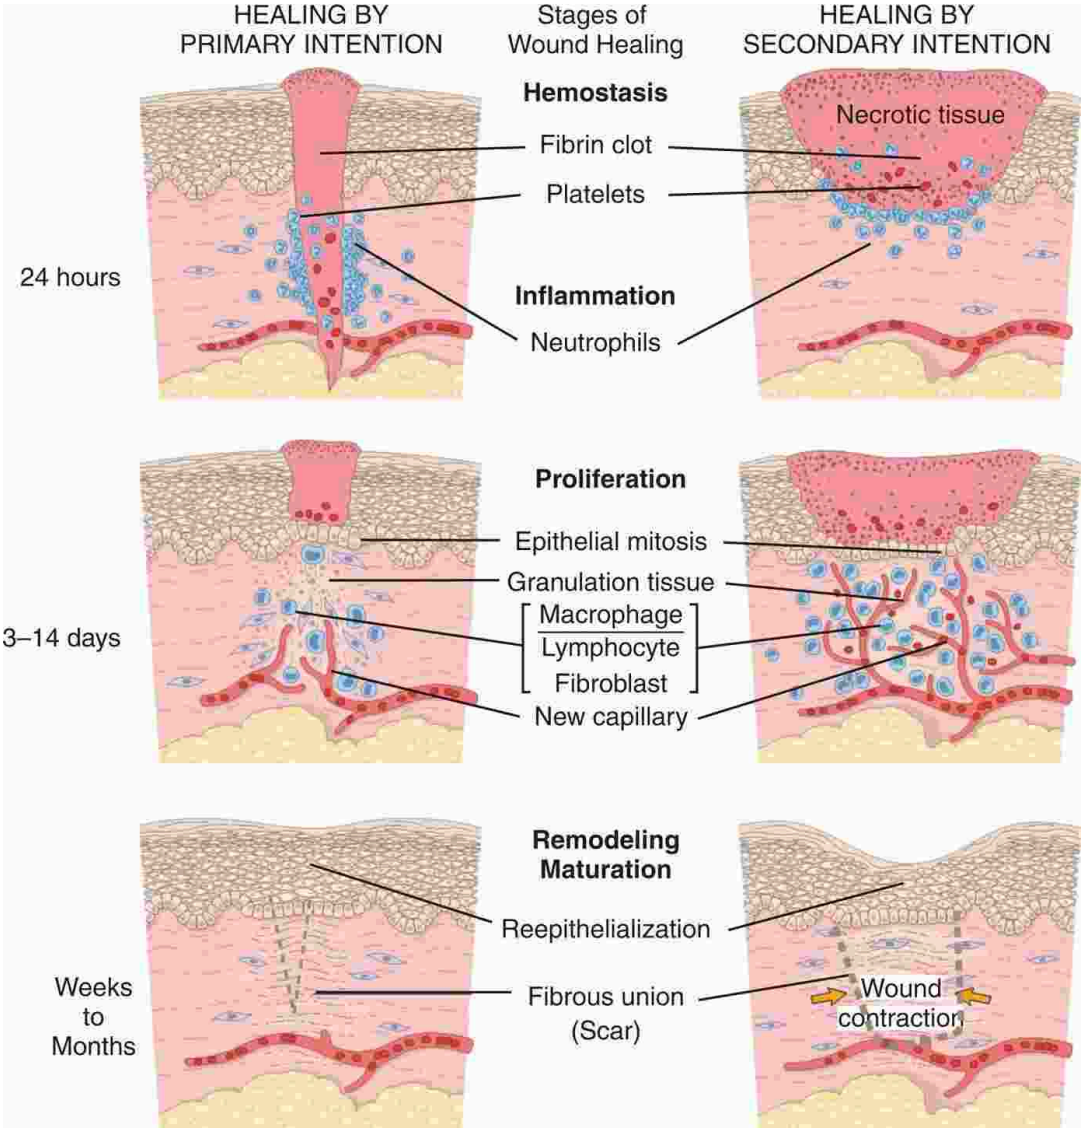

FIG. 7.12 Wound Healing by Primary and Secondary Intention and Stages of Wound Healing.
Phases of wound healing (coagulation, inflammation, proliferation/tissue formation, remodeling, and maturation) and steps in wound healing by primary intention *(left)* and secondary intention *(right)*. Note the large amounts of granulation tissue and wound contraction in healing by secondary intention. (From Roberts JR, Custalow CB. *Roberts and Hedges' clinical procedures in emergency medicine*, 6th edition. Philadelphia: Elsevier/Saunders; 2013.)

Three pairs of illustrations show wound healing by primary and secondary intention by stage. Top pair of illustrations, 24 hours. There are two stages of healing. 1, hemostasis. Platelets surround

the fibrin clot. 2, Inflammation. Neutrophils bind to the site of injury in healing by primary intention and the necrotic tissue in healing by secondary intention. Middle pair of illustrations, 3 days to 14 days. There is one stage of healing, proliferation. It involves epithelial mitosis, granulation tissue, macrophage, lymphocyte, fibroblast, and new capillary. Bottom pair of illustrations, weeks to months. There is one stage of healing, remodeling maturation. It involves reepithelialization and fibrous union (scar). In healing by secondary intention, the wound contracts.

Other wounds do not heal as readily. Healing of an open wound, such as a severe burn, requires a great deal of tissue replacement. In these cases, healing occurs through secondary intention (see Fig. 7.12). Healing by either primary or secondary intention may occur at different rates for different types of tissue injury.

Epidermal wounds that heal by secondary intention are not completely restored by healing. At best, repaired tissue regains 80% of its original tensile strength. In fibrous connective tissue, such as joints and ligaments, normal healing results in replacement of the original tissue with new tissue which does not exactly replicate the structure or function of the original. Some tissues heal without replacement of any functional cells as those cells are not capable of replication. For example, damage resulting from myocardial infarction heals with fibrous scar tissue rather than with cardiac muscle. Accordingly, cardiac function is not restored completely and the individual surviving the infarction will have varying amounts of impaired myocardial contractility and cardiac function depending on the size of the scar.

Wound healing occurs in four overlapping phases or stages: (1) *hemostasis (coagulation)*, (2) *inflammation*, (3) *proliferation with new tissue formation*, and (4) *remodeling and maturation* (Fig. 7.13).

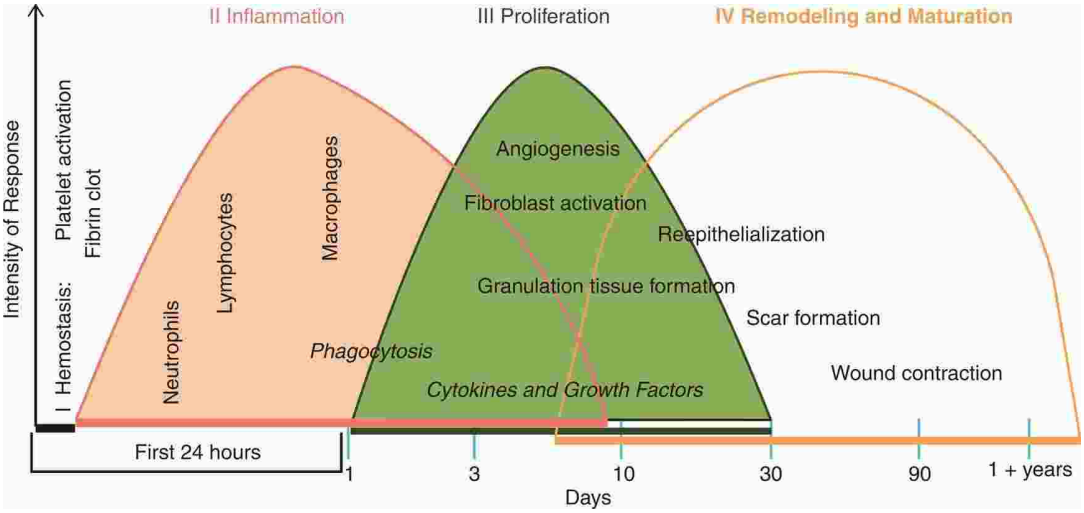

FIG. 7.13 Phases of Wound Healing and Time Course.

A graph plotting intensity of response over time period shows three curves representing the three phases of wound healing. The horizontal axis represents days: 1, 3, 10, 30, 90, and 1 plus years. There are four phases of wound healing. Phase 1, hemostasis. Occurs immediately and includes platelet activation and fibrin clot. Phase 2, inflammation or phagocytosis. The curve is very gently skewed to the left and spans about 9 days. It peaks through neutrophils, lymphocytes, and macrophages. Phase 3, proliferation or cytokines and growth factors. The curve is normal and spans between 1 day and 30 days. It involves angiogenesis, fibroblast activation, and granulation tissue formation. Phase 4, remodeling and maturation. The curve is wide with a broad peak and spans between 6 days and 1 plus years. It involves reepithelialization, scar formation, and wound contraction.

Phase I: Hemostasis (Coagulation)

Tissue injury damages capillaries and blood vessels and causes bleeding into the wound. Damage to blood vessels causes immediate vasoconstriction followed by vasodilation and initiates the coagulation cascade and activation of platelets. The fibrin mesh of the blood clot acts as a scaffold for cells that participate in healing.

Platelets contribute to clot formation. As the platelets degranulate, they release factors which cause increased capillary permeability and promote growth factors which initiate proliferation in undamaged cells. In addition to activation of clotting, there is activation of complement and kinins.

Phase II: Inflammation

The inflammatory phase begins within minutes. As has been described in detail previously, macrophages and mast cells release numerous vasoactive cytokines that increase blood flow to the wound and bring needed cells and proteins to the area of injury. DAMPs and chemokines released by injured cells recruit and activate inflammatory cells, especially neutrophils.[40] Neutrophils infiltrate the area of injury and initiate the process of clearing the wound of debris and bacteria. Lymphocytes initiate an adaptive immune response.

Phase III: Proliferation and New Tissue Formation

The proliferative phase begins 3 to 4 days after the injury and continues for as long as 2 weeks. The wound is sealed, and the fibrin clot is replaced by normal tissue or scar tissue during this phase. The proliferative phase is characterized by an invasion of macrophages. During this phase, both monocyte-derived and tissue macrophages are stimulated by a variety of cytokines to become M2 macrophages.[41] They clear debris, release numerous growth factors, recruit fibroblasts, and promote collagen synthesis and angiogenesis. Angiogenesis describes the process of the formation of new blood vessels and is one of the most important steps in wound healing. When blood vessels are injured, growth factors such as VGEF and PDGF secreted by M2 macrophages cause endothelial cells to sprout new capillaries. This brings nutrients and oxygen to the healing wound.[40]

The cleanup of the lesion, which also involves dissolution of fibrin clots (or scabs), is called debridement. After debridement, the remaining debris is drained away by blood and lymphatic vessels and the vascular dilation and permeability associated with early inflammation are reversed, thus preparing the lesion for either regeneration or repair. An important role for macrophages during this phase is the engulfment of neutrophils *(efferocytosis)* to clear them and promote resolution of inflammation.[40]

As wound healing progresses, granulation tissue grows into the wound from surrounding healthy connective tissue. It consists of invasive cells, new lymphatic vessels, and new capillaries, all derived from the analogous structures found in the surrounding healthy tissue. These components lend a red and granular appearance to the newly formed granulation tissue. Capillary buds sprout from vascular endothelial cells around the wound and extend into the débrided areas. Loops form when the young capillaries join (anastomose). The loops are more fragile and permeable than mature vessels, resulting in leakage of erythrocytes and

neutrophils. The erythrocytes are phagocytosed by macrophages, and the neutrophils assist in further debridement of the inflammatory lesion. Many of the new capillaries differentiate into larger vessels as repair continues, promoting influx of nutrients and removal of metabolic wastes. New lymphatic vessels also grow into the granulation tissue by a similar process.

Epithelialization is the process by which epithelial stem cells proliferate and grow into the wound from surrounding healthy tissue. Epithelial cells migrate under the clot or scab using matrix metalloproteinases to unravel the collagen. The migrating epithelial cells connect with similar cells from all sides of the wound and seal it. The epithelial cells remain active, undergoing differentiation to give rise to the various epidermal layers. Epithelialization of a skin wound can be hastened if the wound is kept moist, preventing the fibrin clot from becoming a scab.

Fibroblasts are important cells during healing because they secrete collagen and other connective tissue proteins. Fibroblasts deposit connective tissue proteins in debrided areas, about 6 days after they have entered a lesion. Collagen is the most abundant protein in the body. It contains high concentrations of the amino acids glycine, proline, and lysine, many of which are enzymatically modified during the healing process. Additionally, wound healing requires iron, ascorbic acid (vitamin C), and molecular oxygen (O_2). The absence of any of these components results in impaired wound healing. As healing progresses, collagen molecules form collagen fibrils which further modify to form collagen fibers. The complete process takes several months.

In granulation tissue, some fibroblasts transition into myofibroblasts, specialized cells responsible for wound contraction. Myofibroblasts have features of both smooth muscle cells and fibroblasts. Wound contraction occurs as extensions from the plasma membrane of myofibroblasts establish connections between neighboring cells. They anchor themselves to the wound bed then contract their fibers so as to exert tension on the neighboring cells. Wound contraction is necessary for closure of all wounds, especially those that heal by secondary intention. Contraction is noticeable 6 to 12 days after injury.

Phase IV: Remodeling and Maturation

Tissue remodeling and maturation are a process that begins several weeks after injury. Tissue regeneration and wound contraction continue in this phase during which there is a continuation of cellular differentiation, scar formation, and scar remodeling. The fibroblast is the major cell involved in tissue remodeling, where it functions to deposit collagen into an organized matrix. For wounds that heal by scarring, scar tissue is remodeled, and capillaries disappear, resulting in an avascular scar. Within 2 to 3 weeks after maturation has begun, the scar tissue has gained about two-thirds of its eventual maximal strength, which may be less than the strength prior to injury.

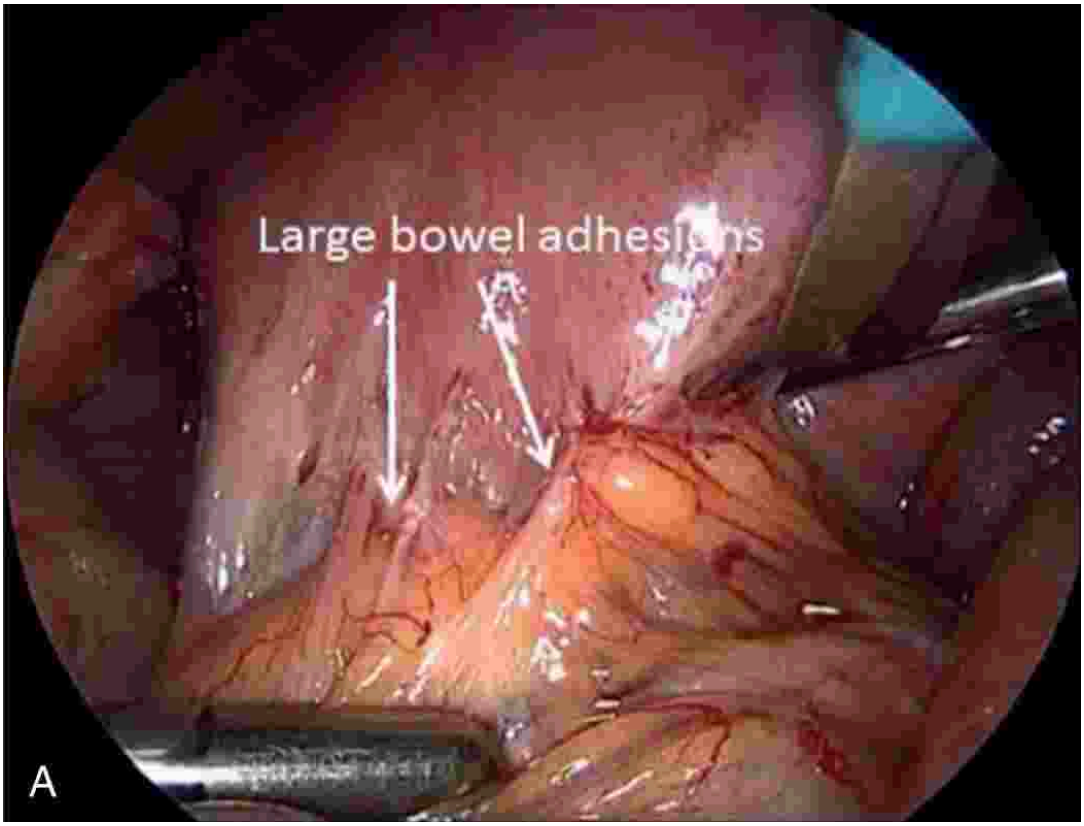
Dysfunctional Wound Healing

Dysfunctional wound healing and impaired epithelialization may occur during any phase of the healing process. The causes of dysfunctional wound healing include ischemia; excessive bleeding; excessive fibrin deposition; a predisposing disorder, such as diabetes mellitus; obesity; wound infection; inadequate nutrition; use of certain drugs; and tobacco smoking as well as history of keloid formation.

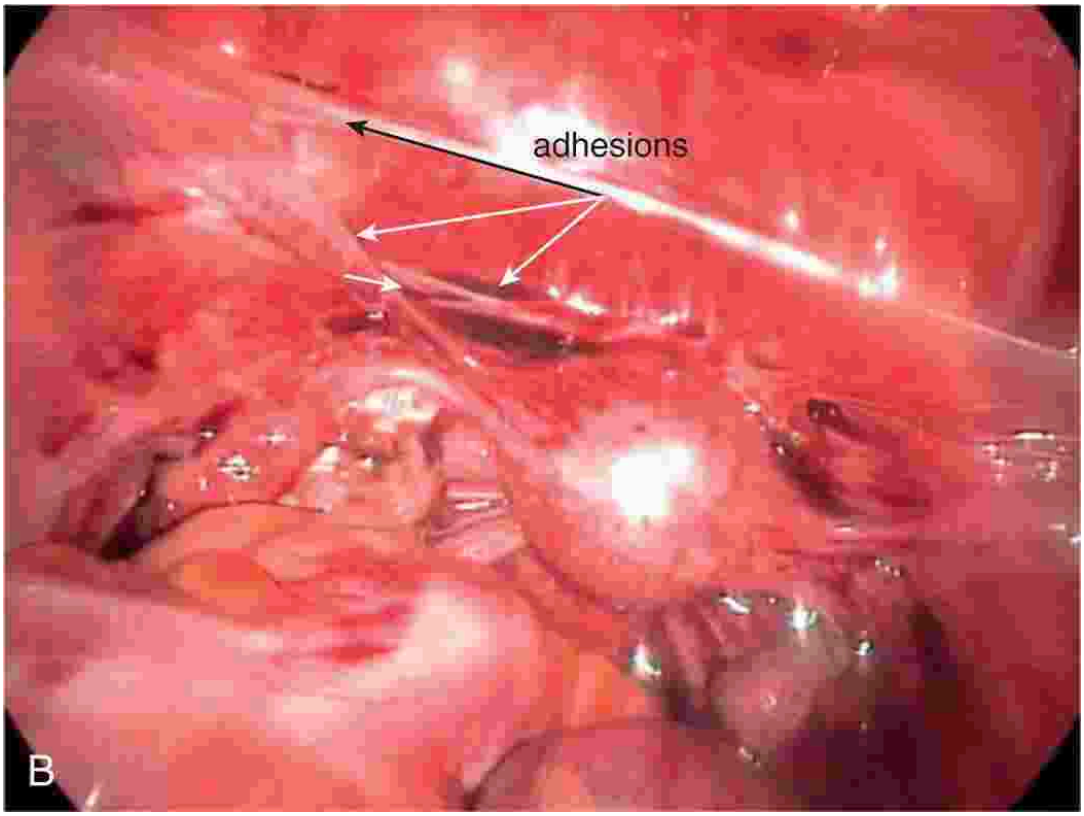
Ischemic (oxygen-deprived) *tissue* is susceptible to cellular death and infection, which prolongs inflammation and delays healing. Ischemia (both acute following injury as well as chronic) reduces energy production and impairs collagen synthesis as well as the tensile strength of regenerating connective tissue.

Excessive bleeding delays healing. Large clots increase the amount of space that granulation tissue must fill. Clots also serve as mechanical barriers to oxygen diffusion further amplified by tissue ischemia. Accumulated blood is an excellent growth medium for bacteria. Bacteria predispose the wound to infection and prolong inflammation through increased exudation and pus formation. Under normal conditions, vessels dilate, delivering inflammatory cells, nutrients, and oxygen to the site of injury. Decreased blood volume, associated with bleeding, inhibits inflammation secondary to vessel constriction.

Excessive fibrin deposition is detrimental to healing. Fibrin released in response to injury must eventually be reabsorbed to prevent the formation of fibrous adhesions. Adhesions that form in the pleural, pericardial, or abdominal cavities can bind together, forming fibrous bands. Such bands distort, impinge on, or strangulate the affected organs. An adhesion, so formed, may bind an organ to an adjacent organ resulting in both pain and/or impaired organ function (Fig. 7.14).



Large bowel adhesions
A



adhesions
B

FIG. 7.14 Fibrous Adhesions. Large bowel adhesion **(A)**. Uterine adhesion **(B)** and adhesions that extend from the liver to the inner lining (peritoneum) of the abdominal wall. (A, From Lee ETC, Wong FWS. Small bowel obstruction from barbed suture following laparoscopic myomectomy— A case report. *International Journal of Surgery Case Reports*, 2015; 16:146–149. https://doi.org/10.1016/j.ijscr.2015.09.039; B, From Burke C. Surgical adhesions: Implications for women's health: Part one of a two-part series. *Nursing for Women's Health*, 2012; 16(Supplement 1):S3–S11. https://doi.org/10.1111/j.1751-486X.2012.01707.x)

Closeup A shows the fused cells in large bowel adhesions. The fusion between the intestines and the abdominal wall causes the surrounding fibers and cells to stretch. The sites of large bowel adhesions are indicated by arrows. Closeup B shows the fused cells in uterine adhesion. Fibrous bands stretch between the uterine wall, the liver, and the abdominal wall. The sites of adhesions in the abdominal wall are indicated by arrows.

Obesity delays wound healing through impairing leukocyte function, which, in turn, predisposes the wound to infection, decreased growth factor production, and increases in proinflammatory cytokines. Additionally, there is a dysregulation of collagen synthesis and a decrease in angiogenesis.

Persons with *diabetes* are at risk for prolonged wound healing and wound infection, especially if they have persistent hyperglycemia. The causes of poor wound healing in diabetes are multifactorial and complex. Ischemia, hyperglycemia, infection, and decreased immune function all play a role [42] (see Emerging Science Box: Mechanisms of Impaired Wound Healing in Diabetes).

Emerging Science Box Mechanisms of Impaired Wound Healing in Diabetes

Diabetes is a complex metabolic disease that affects millions of people in the United States and worldwide. Many of these individuals will suffer from chronic wounds such as diabetic foot ulcers. The mechanisms that contribute to impaired wound healing in diabetes are the result of defects in immune function, cellular metabolism, and tissue integrity. The insulin resistance of persons with diabetes results in deficient glucose transport into many of the key cells involved in wound healing such as mast cells, macrophages, neutrophils, fibroblasts, lymphocytes, and epithelial cells. Cells require glucose to produce energy for physiologic functioning. Furthermore, hyperglycemia in diabetes suppresses macrophage function and prevents them from becoming effective M2

macrophages. Wounds in an individual with diabetes tend to be ischemic because of the prevalence of small-vessel diseases and impaired blood flow, along with glycosylation of hemoglobin that reduces oxygen release into tissues. Hypoxia-induced changes in nuclear function (e.g., microRNAs) reduce cellular proliferation and angiogenesis. The combination of these many factors results in a persistent pro-inflammatory state, decreased release of growth factors, increased risk for infection, and impairment of cellular and tissue function at every step in the healing process. While there are numerous treatment modalities in use and in development, good nutrition, exercise, and maintenance of normoglycemia remain central to improving wound healing in diabetes.

Data from Kalan LR, et al. The role of the microbiome in nonhealing diabetic wounds. *Annals of the New York Academy of Sciences*, 2019; 1435(1):79–92; Knipper JA, et al. Diabetes impedes the epigenetic switch of macrophages into repair mode. *Immunity*, 2019; 51(2):199–201; Morey M, et al. Laser capture microdissection on surgical tissues to identify aberrant gene expression in impaired wound healing in type 2 diabetes. *Journal of Visualized Experiments*, 2021; 167.

Wound infection is caused by the infiltration of pathogens into the injured or compromised tissues. Infection is promoted by the necrotic debris, low oxygen tension, and a decreased host immune response. Biofilms may form within the wound and prevent healing.[43] Biofilms are accumulations of microbes that adhere to the wound surface and secrete a matrix of polysaccharides that protect the pathogens from the immune response and from antibiotics (see Chapter 10). Such pathogens damage cells, stimulate the continued release of inflammatory mediators, consume nutrients, and delay wound healing.[43]

Optimal *nutrition* is important during all phases of healing because of the increased metabolic needs of the affected tissues. Hypoproteinemia with decreased levels of amino acids, such as arginine and glutamine, impairs fibroblast proliferation and collagen synthesis.[44] Prolonged lack of vitamins A and C, which are cofactors required for collagen synthesis, results in poorly formed connective tissue and significantly impaired healing. Other cofactors for collagen synthesis include iron, zinc, manganese, and copper. Accordingly, malnutrition results in an increased risk for wound infection, delayed healing, and reduced wound tensile strength.

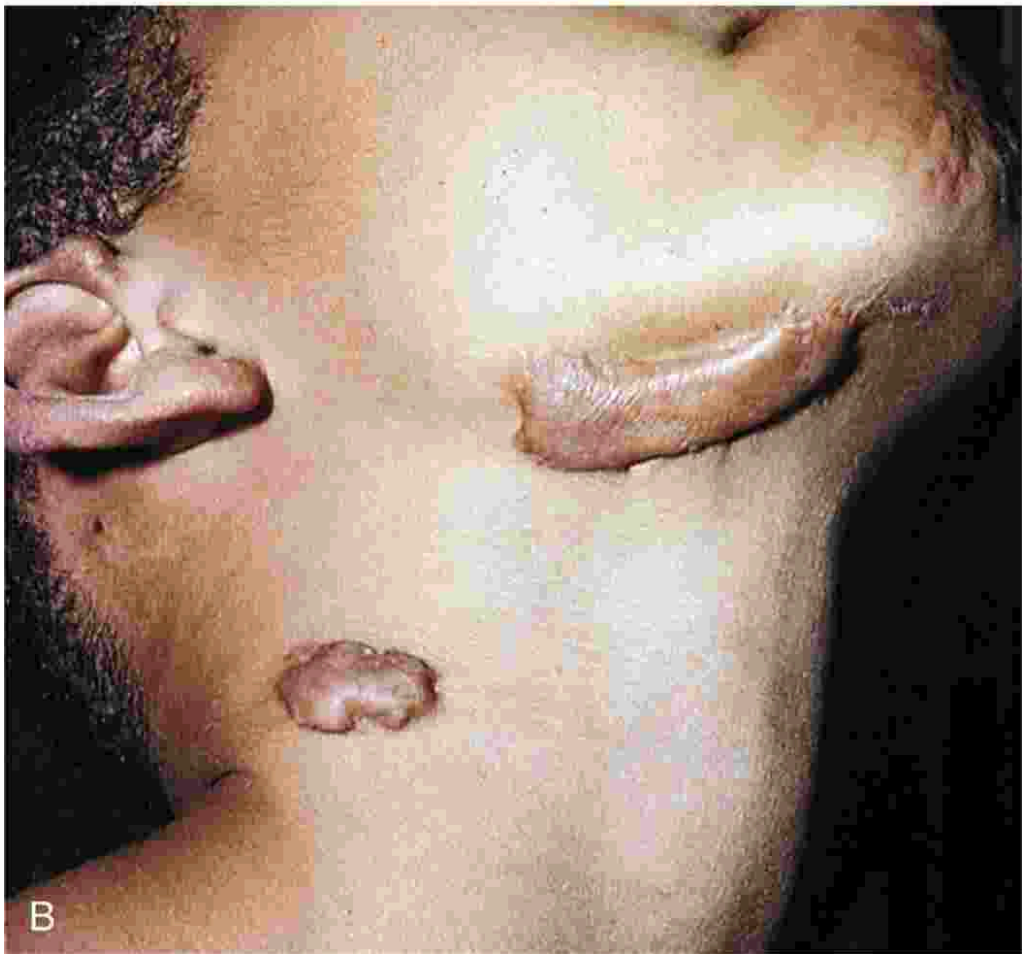
Medications associated with delayed or dysfunctional wound healing include antineoplastic (anticancer) agents, NSAIDs, and steroids. Antineoplastic agents slow cell division and inhibit angiogenesis. NSAIDs suppress acute inflammation and inhibit prostaglandin production, resulting in delayed wound healing,

especially healing involving bone tissue.[45] Corticosteroids (e.g., prednisone) disrupt wound healing by preventing macrophages from migrating to the site of injury and through inhibiting the release of both collagenase and plasminogen activator. Steroids also inhibit fibroblast migration into the wound during the proliferative phase, thus delaying epithelialization.

Toxic agents in *tobacco smoke* (carbon monoxide and hydrogen cyanide) delay wound healing. Nicotine is a potent vasoconstrictor that compromises wound healing by predisposing the tissue to ischemia and infection.

Dysfunctional collagen synthesis may involve excessive production of collagen, leading to a hypertrophic scar or keloid. Myofibroblasts release growth factors and inflammatory cytokines and contribute to excessive tissue contraction and extracellular matrix deposition.[46] A hypertrophic scar is raised but remains within the original boundaries of the wound. It tends to regress over time (Fig. 7.15A). A keloid is a raised scar that extends beyond the original boundaries of the wound, invading surrounding tissue. Keloids are fibrous lesions and are often characterized by pruritis, pain, and psychological discomfort.[40] They are likely to recur after surgical removal and treatment is often ineffective (see Fig. 7.15B). A familial tendency to keloid formation has been observed, with a greater incidence in persons with darker skin pigmentation, especially African Americans.

A



B

FIG. 7.15 Hypertrophic Scar and Keloid Scar Formation. Hypertrophic scar **(A)** and keloid scar **(B)** caused by excessive synthesis of collagen at suture sites. (A, From Flint PW, Haughey B, Lund V, et al. *Cummings otolaryngology: Head and neck surgery*, 6th edition. Philadelphia: Mosby; 2015; B, From Damjanov I, Linder J. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Closeup A is a hypertrophic scar that shows a thin line of raised fibrous tissue running around the upper throat of a person. Closeup B is a pair of keloid scars: one under a person's chin and the other at the base of the person's throat. Both scars are large, raised, discolored bumps on the skin surface.

Wound Disruption

Even after the healing process has occurred, wounds can be disrupted in a variety of ways that may reverse the healing process or negatively impact function. These complications are more likely if wound healing was dysfunctional.

Dehiscence

A potential complication of wounds that are closed with sutures is dehiscence, a scenario where the wound pulls apart at the suture line. Dehiscence generally occurs 5 to 12 days after suturing, at a time when collagen synthesis is at its peak. Approximately half of dehiscence occurrences are associated with wound infection. Other instances result from suture rupture caused by excessive strain. Adipose tissue is difficult to suture, increasing the risk of dehiscence in individuals who are obese. Wound dehiscence is usually heralded by increased serous drainage from the wound; there often is a perception by the individual that "something gave way." Prompt surgical attention is required.

Contracture

Wound contraction, necessary for healing, may become excessive where it results in an anatomic deformity or contracture of scar tissue. Burns of the skin are especially prone to contracture, particularly at joints with a resultant loss of joint function. Internal contractures include duodenal strictures, caused by dysfunctional healing of a peptic ulcer; esophageal strictures, caused by chemical burns, such as lye ingestion; or abdominal adhesions, caused by surgery, infection, or radiation. Contracture may occur in cirrhosis of the liver, where constricted vascular flow contributes to the development of portal hypertension and esophageal varices. Proper positioning, range-of-motion exercises, compression, and surgery are among

the strategies used to prevent or treat skin contractures. Internal contractures, such as those caused by fibrous adhesions between loops of bowel, cause pain or result in a loss of function and are released with surgery.

Pediatric Considerations

Innate Immunity in the Newborn Child

Neonates have transiently depressed immune function. In newborns, the innate immune response is limited in several ways. Complement levels are diminished. Neutrophils and monocytes are incapable of efficient chemotaxis due to decreased ability to express adhesion molecules and impaired margination and diapedesis. Furthermore, these phagocytes exhibit diminished expression of PRRs on their cell surfaces and have impaired ability to destroy microorganisms within phagolysosomes. As a result of these transient innate immune deficiencies, newborns are predisposed to infection, especially cutaneous abscesses caused by staphylococci or cutaneous candidiasis. In addition, newborns are predisposed to develop severe overwhelming sepsis and meningitis when infected by bacteria against which there are no circulating maternal antibodies. Factors that can enhance neonatal immunity include the establishment of a healthy gut microbiome through vaginal delivery and feeding via breast milk whenever possible.

Data from Collins A, Weitkamp JH, Wynn JL. Why are preterm newborns at increased risk of infection? *Archives of Disease in Childhood. Fetal and Neonatal Edition*, 2018; 103(4):F391–F394; Kumar SK, Bhat BV. Distinct mechanisms of the newborn innate immunity. *Immunology Letters*, 2016; 173:42–54; Tsafaras GP, Ntonsi P, Xanthou G. Advantages and limitations of the neonatal immune system. *Frontiers in Pediatrics*, 2020; 8:5; Yu JC, Khodadadi H, Malik A, et al. Innate immunity of neonates and infants. *Frontiers in Immunology*, 2018; 9:1759.

Geriatric Considerations

Innate Immunity in the Elderly

Immunity decreases with aging in a process called immunosenescence. Weakened innate antimicrobial responses put the elderly at increased risk for infection. Several cellular components of innate immunity are deficient in number (e.g., tissue macrophages) or have diminished activity (e.g., neutrophil chemotaxis, degranulation, and phagocytosis). One explanation for this diminished inflammatory cellular activity is an age-related decrease in expression and function of several, if not all, TLRs. NF-κB function is disordered, and there is decreased expression of adhesion molecules on immune cells. In addition, telomere dysfunction leads to immune cell senescence and death.

Paradoxically, elderly individuals are at increased risk for unopposed tissue inflammation called inflammaging. Levels of pro-inflammatory cytokines (e.g., TNF-α, IFN-γ, and IL-1) are elevated, along with higher levels of reactive oxygen species (oxidative stress). These factors contribute to the increased risk for chronic inflammatory diseases (e.g., heart disease and diabetes) that occurs with aging.

Other factors affect immunity and wound healing in the elderly. Because of impaired sensation or mobility and physiologic changes in the skin, older adults are at increased risk for sustaining various wounds. With aging, subcutaneous fat is lost, diminishing a layer of protection. Aging also alters the tissue microenvironment and macrophage function with changes in wound healing angiogenesis and fibrosis. Collagen fibers become thicker and a certain percentage of elastin is lost, further contributing to loss of protection. The regenerative capability of the skin is maintained with aging, but the epidermis undergoes age-associated changes that include atrophy of the underlying capillaries. The consequent decrease of perfusion makes older adults more susceptible than younger people to the adverse effects of hypoxia in the wound bed. Finally, aging fibroblasts may have a slower rate of proliferation, and therefore wound healing is attenuated.

Data from Fülöp T, Larbi A, Witkowski JM. Human inflammaging. *Gerontology*, 2019; 65:495–504; Duong L, Radley HG, Lee B, et al. Summary Review

Human Defense Mechanisms

1. Innate defenses are the first line of defense, are present at birth, and include the surface barriers skin and mucous membranes.
2. Inflammation is the second line of defense and is activated with injury or infectious disease.
3. Adaptive (acquired) immunity is the third line of defense, is specific to particular antigens, and has memory.

Innate Immunity

1. There are three layers of human defense: physiologic barriers, the inflammatory response, and adaptive (acquired) immunity.
2. Physical barriers are the first lines of defense functioning to prevent damage to the individual and thwart the entrance of pathogens. These barriers include the skin and mucous membranes.
3. Antibacterial peptides are found in mucous secretions, perspiration, saliva, tears, and other secretions. They provide a biochemical barrier against pathogenic microorganisms.
4. The skin, mucous membranes, and the lining of the gastrointestinal (GI) tract are colonized by commensal or mutualistic microorganisms called the microbiome. These microorganisms provide protection by releasing biochemical compounds which facilitate immune responses and prevent colonization by pathogens. Within the gut, they also facilitate digestion in the GI tract.
5. The second line of defense is the *inflammatory response*, a rapid and nonspecific protective response to cellular injury resulting from any cause. It can occur only in vascularized tissues.
6. Inflammation is mediated by three key plasma protein systems: the complement system, the clotting system, and the kinin system. The components of all three systems are a series of inactive proteins which are activated sequentially in the presence of tissue injury.
7. The complement system can be activated by antigen–antibody reactions (through the classical pathway) or by other products, especially bacterial polysaccharides (through the lectin pathway or the alternative pathway). The lectin and alternative pathways do not require antibody activation to recruit phagocytes, activate mast cells, and destroy pathogens.
8. The most biologically potent products of the complement system are C3b (opsonin), C3a (anaphylatoxin), and C5a (anaphylatoxin, chemotactic factor).
9. The clotting system stops bleeding, localizes microorganisms, and provides a meshwork for repair and healing.
10. Bradykinin is the most important product of the kinin system and causes vascular permeability, smooth muscle contraction, and pain.
11. Control of inflammation regulates inflammatory cells and enzymes and localizes the inflammatory response to the area of injury or infection.
12. Carboxypeptidase, histaminase, kinase, and C1 inhibitor are inactivating enzymes. The fibrinolytic system and plasmin facilitate clot degradation after bleeding is stopped.
13. Mast cells and macrophages are the most important cells for initiating the inflammatory response.
14. These cells express plasma membrane pattern recognition receptors (PRRs) which recognize molecules produced by infectious microorganisms. These molecules include pathogen-associated molecular patterns (PAMPs) and

damage-associated molecular patterns (DAMPs). Toll-like receptors (TLRs) are transmembrane receptors and nucleotide-binding-like receptors (NLR-like), and nucleotide oligomerization domain-like (NOD-like) receptors are cytoplasmic receptors. They are expressed by many inflammatory cells and recognize both PAMPs and DAMPs. Upon recognition, they promote the release of cytokines and inflammatory mediators, which, in turn, eliminate damaged cells and protect against invasion by microbes.

15. Mast cells are near epithelial surfaces and capillaries. Mast cells initiate inflammation by releasing biochemical mediators (histamine and chemotactic factors) from cytoplasmic granules. They also synthesize other mediators (prostaglandins, leukotrienes, and platelet-activating factor [PAF]) in response to stimuli. Basophils, found in blood, function in a manner that is similar to mast cells.
16. Histamine is the major vasoactive amine released from mast cells. It increases vascular permeability through dilation of capillaries and retraction of endothelial cells lining the capillaries.
17. Tissue macrophages use PRRs to identify microorganisms and molecules from damaged tissue, and then secrete many biochemical mediators (cytokines), which are responsible for activating other cells and regulating the inflammatory response. These cytokines include TNF-α, interleukins, interferons, and other molecules.
18. TNF-α is produced when PRR binding sends intracellular messengers to the nucleus of the macrophage which activates NF-κB. TNF-α has multiple pro-inflammatory effects including vascular effects, chemotaxis, cellular proliferation, and systemic inflammatory changes.
19. Interleukins are produced primarily by lymphocytes and macrophages. They activate the growth and differentiation of leukocytes and contribute to systemic inflammatory changes such as fever.
20. The most important proinflammatory interleukins are interleukin-1 (IL-1) and interleukin-6.
21. Interferons are produced by cells that are infected by viruses. Once released from infected cells, interferons can stimulate neighboring healthy cells to produce substances that prevent viral infection.
22. There are also anti-inflammatory cytokines such as TGF-β and IL-10 which downregulate the inflammatory response.
23. The vascular responses to inflammation are vasodilation, increased capillary permeability, and an accumulation of fluid and cells at the inflammatory site.
24. The cellular response to inflammation includes neutrophils, monocyte-derived macrophages, and other inflammatory cells.
25. The endothelial cells lining the circulatory system (vascular endothelium) regulate circulating components of the inflammatory system, maintaining normal blood flow. During inflammation, the endothelium expresses

receptors that stimulate leukocytes to exit the vessel. The endothelial cell body also retracts to allow fluid to pass into the tissues.

26. The polymorphonuclear neutrophil (PMN), the predominant phagocytic cell in the early inflammation, exits the circulation, through retracted endothelial junctions, by diapedesis. On exiting, it moves to the inflammatory site by chemotaxis.
27. The monocyte-derived macrophage, the predominant cell in the late inflammatory response, is highly phagocytic. Additionally, it is responsive to cytokines, which promote wound healing.
28. Phagocytosis is a multistep cellular process, which usually results in the destruction of pathogens and foreign debris. The steps include recognition and attachment, engulfment, formation of a phagosome, formation of a phagolysosome, and eventual destruction of the pathogen or foreign debris. Phagocytic cells engulf microorganisms, enclosing them within phagocytic vacuoles (phagolysosomes). The vacuoles contain toxins (especially metabolites of oxygen) and/or enzymes that kill and digest the microorganisms.
29. Opsonins are molecules which enhance phagocytosis by coating the antigen. This activity results in a stronger attraction between the microorganism and the phagocyte ("marking" the organism). It also enhances the affinity with which the phagocyte binds to the microorganism. Examples include antibodies and the complement component C3b.
30. Eosinophils release products that control the inflammatory response, and they are the principal cells that destroy parasitic organisms.
31. Other cells of innate immunity include dendritic cells which function as messengers between the innate and acquired (adaptive) immune systems, NK cells which detect certain invaders and cancer cells, and innate lymphoid cells which modulate many aspects of innate immunity.

Acute and Chronic Inflammation

1. *Acute inflammation* is self-limiting and usually resolves within 8 to 10 days.
2. *Local* manifestations of inflammation include the classic signs of redness, heat, swelling, pain, and loss of function. They are the result of vascular changes associated with the inflammatory process, including vasodilation and increased capillary permeability.
3. The principal *systemic effects* of inflammation are fever, leukocytosis (increased levels of circulating leukocytes), and an increase in plasma proteins, primarily the acute-phase reactants, IL-1, and IL-6.
4. *Chronic inflammation* is the persistence of the inflammatory response often contributing to tissue damage.
5. Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. It can take two forms, nonspecific proliferative chronic

inflammation and granulomatous chronic inflammation.
6. Nonspecific proliferative chronic inflammation occurs when the acute inflammatory response fails to eliminate the invader/injury or there is dysfunctional resolution of the acute inflammatory response.
7. *Granuloma* formation is a process wherein the body walls off and isolates certain infectious microorganisms or foreign bodies that could not be removed by acute inflammation. It serves to protect the body from further tissue damage.
8. Both forms of chronic inflammation can contribute to tissue dysfunction and organ damage and are the major causes of chronic disease.

Wound Healing

1. *Resolution* (regeneration) is the return of tissue to nearly normal structure and function. *Repair* is healing by scar tissue formation.
2. Resolution occurs when little tissue has been lost or where the injured tissue is capable of regeneration. This type of healing is called *healing by primary intention*.
3. Tissues that have sustained extensive damage or tissue types that are incapable of regeneration heal by repair, a process which results in the formation of a scar. This process is called *healing by secondary intention*.
4. Wound healing occurs in four overlapping phases; hemostasis, inflammation, proliferation with new tissue formation, and remodeling or maturation. Each of these phases is characterized by the complex interaction of multiple cells including platelets, neutrophils, macrophages fibroblasts, endothelial cells, and epithelial cells.
5. Dysfunctional wound healing can be secondary to ischemia, excessive bleeding, excessive fibrin deposition, predisposing disorders (e.g., diabetes mellitus), wound infection, inadequate nutrients, use of NSAIDs and steroids, or altered collagen synthesis.
6. *Dehiscence* is a disruption where the wound pulls apart at the suture line.
7. A *contracture* is a structural deformity caused by the excessive shortening of collagen in scar tissue.

Pediatric and Geriatric Considerations

1. Neonates often have transiently depressed inflammatory function, particularly decreased phagocyte chemotaxis and killing of microorganisms and limited complement activity.
2. Aging impairs the immune system due to a process called immunosenescence which causes impairment of cellular function in both immunity and wound healing.

3. Impaired wound healing in the aging population is multifactorial and includes changes in innate immunity, cellular metabolism, and tissue integrity.
4. The elderly are also at risk for excessive and disordered innate immune responses called inflammaging that contribute to many chronic diseases.

- Macrophages, 249

Immunologic Memory, 250

The third line of defense in the human body is adaptive (acquired) immunity, often called the immune response or immunity. Adaptive immunity consists of lymphocytes (Fig. 8.1) and serum proteins called *antibodies*. Once external barriers have been compromised, and inflammation has been activated (innate immunity; see Chapter 7), the adaptive immune response is

mobilized. Inflammation is the "first responder" that contains the initial injury and slows the spread of infection, whereas adaptive immunity *slowly* augments the initial defenses and promotes processes against reinfection.

Overview of Adaptive Immunity

Inflammation and adaptive immunity differ in several key ways. First, the components of innate immunity and inflammation are activated immediately after tissue damage. Adaptive immunity is *inducible;* the effectors of the immune response, lymphocytes, and antibodies, do not preexist in large numbers but are produced in response to infection or other abnormal molecules. Thus, adaptive immunity develops more slowly than inflammation.

Second, the inflammatory response is similar regardless of differences in the cause of tissue damage or whether the inflammatory site is sterile or contaminated with infectious microorganisms. The adaptive immune response is exquisitely *specific*. For example, the lymphocytes and antibodies induced in response to infection are extremely specific to the particular strain of the infecting microbe.

Third, the residual mediators of inflammation must be removed quickly to limit damage to surrounding healthy tissue and allow healing. The effectors of the adaptive immune response are *long-lived* and systemic, providing long-term protection against specific invaders.

Finally, the inflammatory responses to both recurrent tissue damage and infection are identical. The adaptive immune response has *memory*. For example, if reinfected with the same microbe, the adaptive immune system immediately produces protective lymphocytes and antibodies, thus providing long-term protection against infection.

Despite the differences, the innate and adaptive immune systems are highly interactive and complementary. Many components of innate resistance are necessary for the development of the adaptive immune response. Conversely, products of the adaptive immune response activate components of innate resistance. Thus, both systems are essential for complete protection against infectious disease.

The mechanisms underlying the adaptive immune response will be discussed in this chapter. As with Chapter 7, a complete description of all the important components and processes of an effective immune response would require far more space than available. Therefore, this chapter will focus on the basic concepts and the most important, or well-studied, mediators of the adaptive immune response.

The adaptive immune response has its own vocabulary. Antigens are the molecular targets of antibodies and lymphocytes. Antigens are generally small molecules (usually within proteins, carbohydrates, or lipids) found on the surface of microbes, infected cells, or abnormal tissues (this definition is expanded with immunologic diseases discussed in Chapter 9). In the fetus and throughout life, lymphocytes undergo extensive differentiation. Some lymphoid stem cells enter the thymus and differentiate into T lymphocytes (T cells, *T* refers to thymus-derived). In contrast, others enter specific regions of the bone marrow and differentiate into B lymphocytes (B cells, *B* refers to bone marrow derived) (Fig. 8.2). Each type of cell develops cell surface proteins that identify them as T or B cells. Both B and T cells also develop cell surface antigen receptors. These receptors are remarkable because an individual lymphocyte is programmed to recognize only one specific antigen.

It is estimated that before birth, each individual has produced a population of lymphocytes capable of recognizing as many as 10^{16} different antigens. This is called the generation of clonal diversity and refers to the process by which the extensive diversity of antigen receptors on B and T cells is established. During this process, self-reactive lymphocytes are also created but are then removed from the body via clonal deletion.

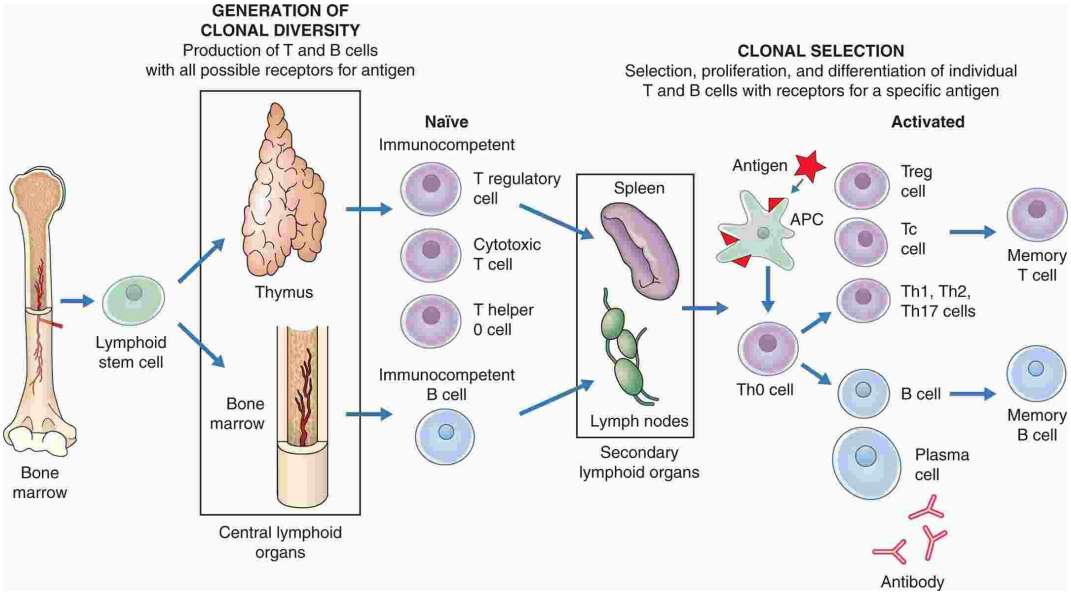

FIG. 8.2 Overview of the Adaptive Immune Response. Lymphoid stem cells from the bone marrow migrate to the central lymphoid organs (the thymus or regions of bone marrow). Cells that travel to the thymus undergo a series of differentiation stages resulting in several types of T cells (T helper [Th], T cytotoxic cells [Tc], and T regulatory cells [Treg]) each with its own unique antigen receptor (clonal diversity). B cells also undergo additional differentiation and gain an antigen-specific receptor in the bone marrow. These cells are "naïve," meaning that they have not yet encountered antigen. The cells enter the circulation and migrate to the secondary lymphoid organs (e.g., spleen and lymph nodes), where they establish residence in B and T cell-rich areas. When these cells are presented with a foreign antigen, they become activated and undergo additional cellular proliferation and differentiation (clonal selection). Th0 cells differentiate into three subtypes of cytokine-producing cells (Th1, Th2, Th17) that contribute to the further differentiation of Tc, Treg, and B cells. The result is an active cellular immunity or humoral immunity, or both. Cellular immunity is mediated by *effector* Tc cells that can kill targets. Treg cells regulate the immune response. Humoral immunity is conducted by B cells that have recognized antigen and differentiated into plasma cells that make antibodies to that antigen. Both T and B cells make memory cells that can produce a more rapid

adaptive immune response to a second challenge with the same antigen.

An illustration provides the mechanism of the adaptive immune response, which includes (1) generation of clonal diversity and (2) clonal selection. (1) Generation of clonal diversity involves migration of lymphoid stem cells from the bone marrow to the central lymphoid organs, that is, the thymus or bone marrow, which includes production of T and B cells with all possible receptors for antigen. Then, naïve immunocompetent cells differentiate to T regulatory cell, cytotoxic T cell, and T helper cell. The immunocompetent B cells also undergo differentiation. Spleen and lymph nodes are secondary lymphoid organs made of T regulatory cells and B cells, respectively. (2) Clonal selection involves selection, proliferation, and differentiation of individual T and B cells with receptors for a specific antigen. The antigen in A P C differentiates the cell to T h 0 cell. T h 0 cell differentiates to T reg cell, T c cell, T h 1, T h 2, or T h 17 cells, or B cell. T c cell becomes the memory T cell. B cell becomes the memory B cell. Antibodies in B cell differentiate into plasma cells.

B and T lymphocytes leaving the primary lymphoid organs (bone marrow and thymus) are immunocompetent (able to respond to antigens) but have not been exposed to antigen and thus are naïve. These cells enter the blood and lymphatic vessels and migrate to the systemic immune system's secondary lymphoid organs (e.g., lymph nodes, spleen) (Fig. 8.3A). Some take up residence in B cell and T cell-rich areas of those organs. Lymph nodes contain high concentrations of naïve B cells within follicles in the cortex and naïve T cells more centrally in the paracortex (Fig. 8.3B). Other lymphocytes reenter the circulation where approximately 60% to 70% of circulating lymphocytes are immunocompetent T cells, and 10% to 20% are immunocompetent B cells.

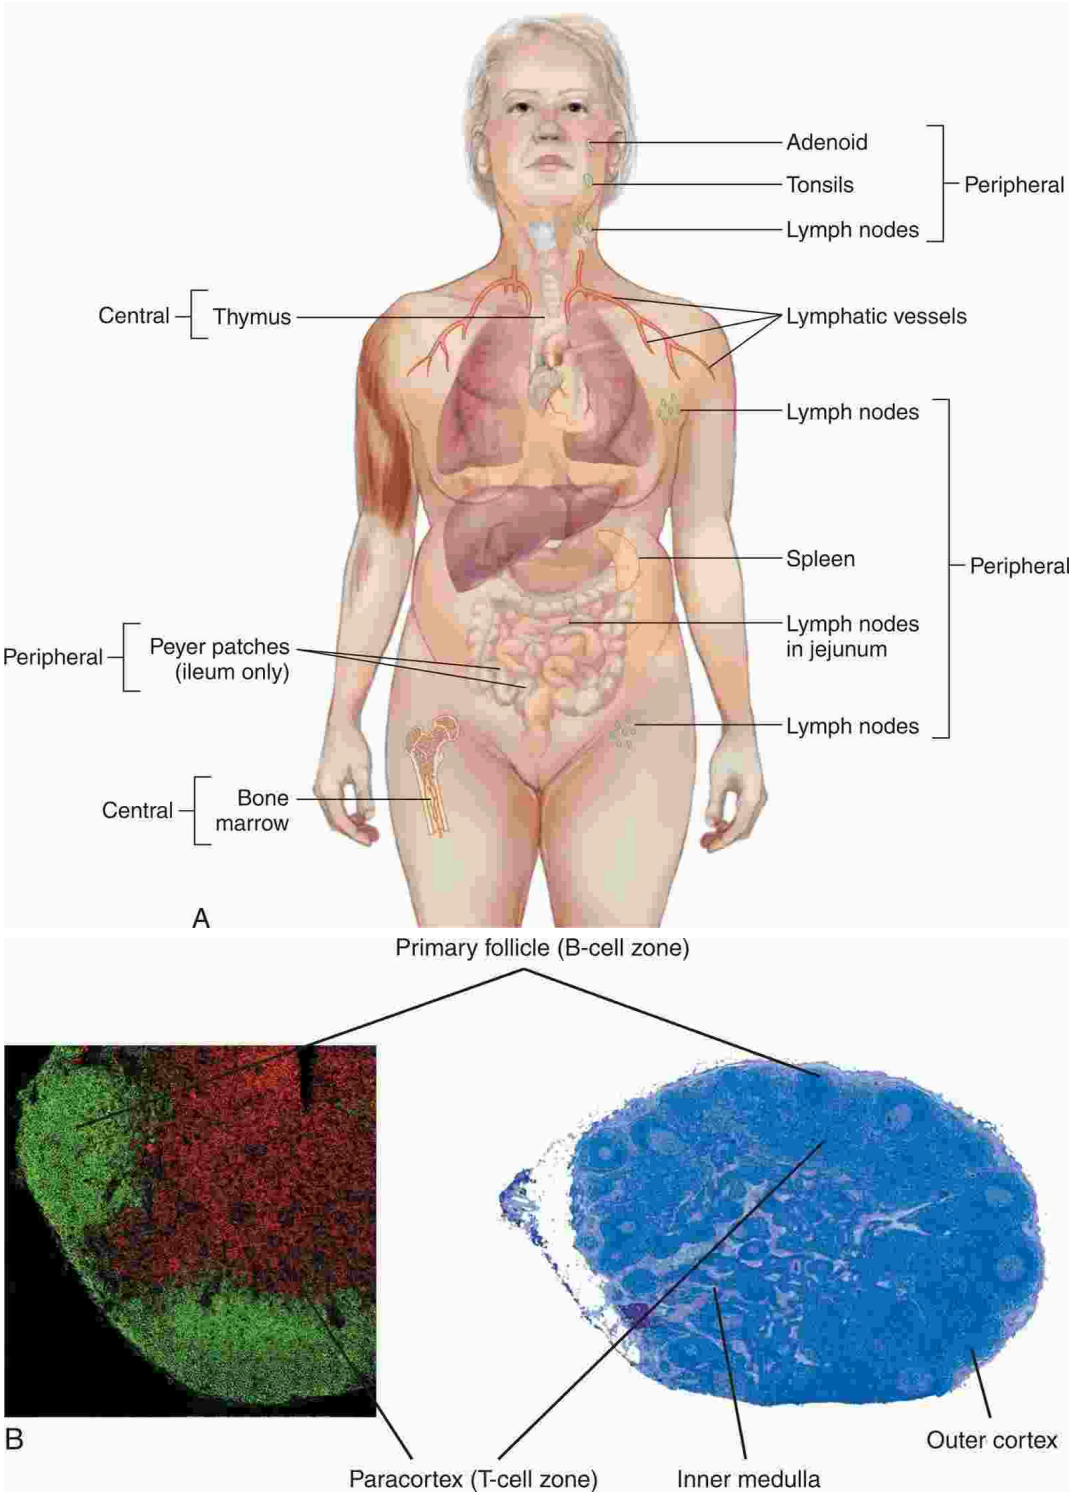

FIG. 8.3 Primary and Secondary Lymphoid Tissues. **(A)** Immature lymphocytes migrate through central (primary) lymphoid tissues: the bone marrow (central lymphoid tissue for B lymphocytes) and the thymus (central lymphoid tissue for T lymphocytes). Mature

lymphocytes later reside in the T and B lymphocyte–rich areas of the peripheral (secondary) lymphoid tissues. **(B)** Lymph nodes contain numerous B cells within cortical follicles and T cells within the paracortex. The lymph node medulla contains blood and lymphatic vessels.

Illustration A is the anterior view of a human with the internal organs highlighted. The following parts of the body are labeled in the illustration, from the top to the bottom: peripheral adenoid, peripheral tonsils, peripheral lymph nodes, central thymus, lymphatic vessels, peripheral lymph nodes near the armpits, peripheral spleen, peripheral lymph nodes in jejunum, peripheral lymph nodes on the upper thigh, peripheral Peyer patches (ileum only), and central bone marrow. Bottom left panel, B a photomicrograph, and bottom right panel, C an illustration, show a lymph node and label the following parts: primary follicle (B-cell zone) and paracortex (T-cell zone). The inner medulla and the outer cortex are also labeled on the illustration.

Induction of the adaptive immune response begins when exposure to an antigen occurs. This process begins with recognizing invaders by specialized antigen-presenting cells (APCs) (macrophages, dendritic cells, and B cells), which then *process* and *present* the antigen to lymphocytes. Thus begins a symphony of cellular interactions referred to as clonal selection involving:

- Intercellular communication through specific antigen receptors along with intercellular adhesion and costimulatory molecules
- Production and response to multiple cytokines
- Activation and regulation of the immune response by **T helper cells [Th cells]**
- Proliferation (clonal expansion) and differentiation of immunocompetent B and T cells into highly specialized effector cells (B cells developing into plasma cells that become factories to produce

antibodies and T cells developing into T cytotoxic (Tc) cells that can identify and kill a target cell.)
- Suppression of inappropriate immune responses (T regulatory cells [Treg cells])
- Differentiation of T and B cells into very long-lived memory cells that exist for decades or, in some cases, for the life of the individual
- Activation of memory cells if a second exposure occurs with the same antigen

Antibodies circulate in the blood and defend against extracellular antigens, such as microbes and microbial toxins. This is referred to as *humoral immune response* or humoral immunity. T cytotoxic cells (Tc cells) defend against intracellular pathogens (e.g., viruses) and abnormal cells, such as cancer cells. This is referred to as *cell-mediated immunity* or cellular immunity.

Antigens

The term antigen describes a molecule that can *bind with* antibodies or antigen receptors on B and T cells. Self-antigens are molecules found on healthy host cells. Non-self or foreign antigens are molecules that are generally not found on host cells. The healthy adaptive immune system can distinguish between self- and non-self antigens. When that ability is lost, autoimmune or hypersensitivity diseases can arise (see Chapter 9).

Exogenous antigens are extracellular non-self antigens that enter the body and circulate in blood and lymph. Common non-self exogenous antigens include infectious agents, allergens, and chemical agents (including some medications). Endogenous antigens are intracellular non-self antigens that have been generated when the cell has become abnormal because of injury, infection (e.g., viruses), or mutation of its DNA as occurs in cancer.

The ability of an antigen to induce an immune response is frequently related to the size of the antigen. In general, large molecules (those >10,000 daltons), such as proteins and polysaccharides, are the most immunogenic antigens. Many low-molecular-weight molecules can function as haptens; they are too small to induce an immune response by themselves but become immunogenic after combining with larger molecules that function as carriers for the hapten. For example, the widely used anticoagulant drug heparin can serve as a hapten by binding to a protein called platelet factor 4 (PF4) on the surface of platelets. When this occurs, antibodies may be produced that attack the heparin+PF4 complex and can destroy the platelets resulting in a common condition called *heparin-induced thrombocytopenia*. Similar conditions will be discussed in Chapter 9.

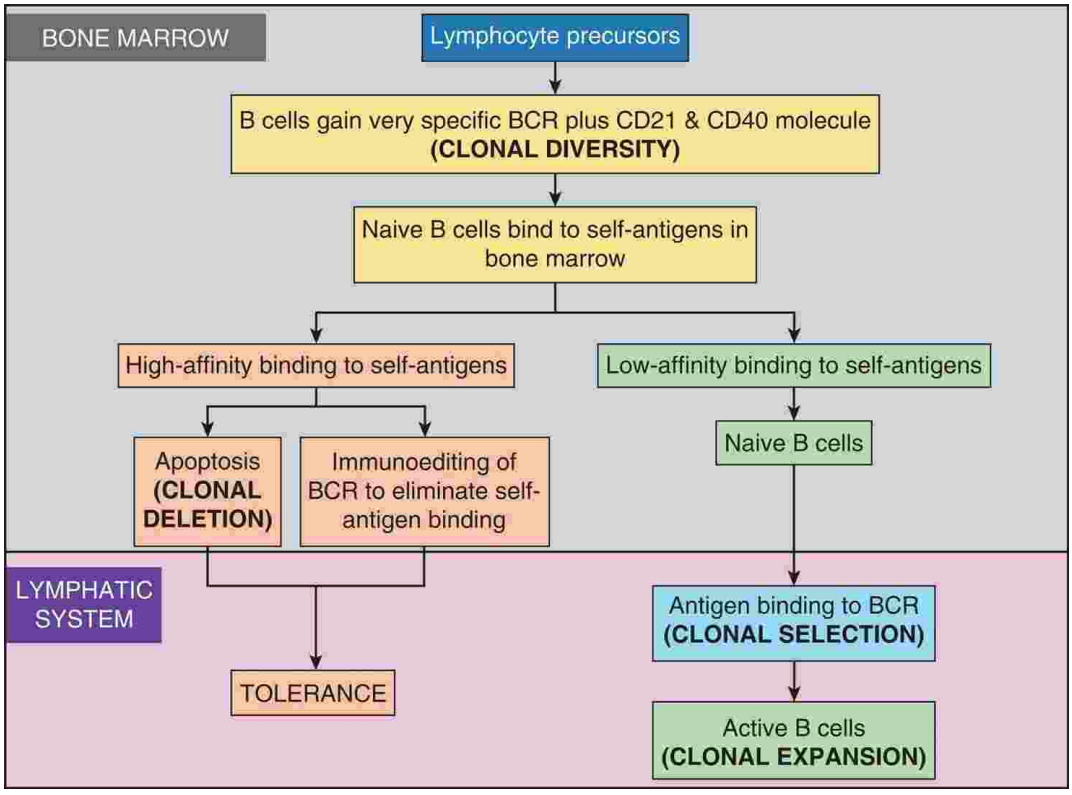
Lymphocytes of adaptive immunity have highly specialized receptors for antigens. This specificity means that most antigens will activate a relatively small number of cells. In contrast, a group of microbial molecules called superantigens (SAGs) can activate a large population of immune cells resulting in the overproduction of immune cytokines. The result can be severe disease and even shock and death. Some examples of SAGs are the bacterial toxins produced by *Staphylococcus aureus and Streptococcus pyogenes* (SAGs that cause toxic shock syndrome and food poisoning).

Lymphocyte Development

The primary cells involved in the adaptive immune response are T and B lymphocytes. T and B lymphocytes recognize antigens from invaders and abnormal tissues, differentiate into effector cells, and provide memory.

Development of B Lymphocytes

Lymphocyte stem cells destined to become B cells circulate through the specialized regions of bone marrow (the primary [central] lymphoid organs for B cells), where they are exposed to hormones and cytokines that induce proliferation and differentiation into B cells. As the stem cell begins to mature, it progressively develops a variety of necessary surface markers essential for the further differentiation and proliferation of the B cell. The next stage in development is the formation of the B-cell receptor (BCR) (Algorithm 8.1).



ALGORITHM 8.1 **Steps in B-Cell Development.**
Lymphocyte precursor cells that remain in the bone marrow each gain a very specific B-cell receptor (BCR) that can recognize a single antigen. The generation of millions of different lymphocytes, each with its own specific BCR, is called *clonal diversity*. These naïve B cells bind with self-antigens in the bone marrow. If they bind with high affinity to self-antigens, they either undergo apoptosis *(clonal deletion)* or undergo a process called immunoediting in which their BCRs are changed so that they no longer recognize self-antigens. This results in tolerance. If the B cells bind with only low affinity to self-antigens, then they move into the lymphatic system. If they encounter antigen to which they can bind their BCR *(clonal selection)*, they mature and proliferate to active B cells *(clonal expansion)*.

A flowchart tracks the steps in B cell development. The flowchart is divided in two sections: top, bone marrow, and bottom, lymphatic system. The steps in the top section are

as follows. • Lymphocyte precursors. • B cells gain very specific B C R plus C D 21 and C D 40 molecule (clonal diversity). • Naïve B cells bind to self-antigens in bone marrow. • High-affinity binding to self-antigens; low affinity binding to self-antigens. High-affinity binding to self-antigens: apoptosis (clonal deletion) and immunoediting of B C Rto eliminate self-antigen binding. This leads to tolerance in the lymphatic system. Low-affinity binding to self-antigens: naïve B cells. This leads to antigen binding to B C R (clonal selection) in the lymphatic system, which results in active B cells (clonal expansion) in the lymphatic system.

The B-cell receptor (BCR) is a complex of cell surface-bound antibodies and other molecules involved in intracellular signaling (Fig. 8.4). Its role is to recognize an antigen and communicate that information to the cell's nucleus. The BCRs in immunocompetent cells are membrane-associated immunoglobulin M (mIgM) with or without IgD (mIgD) antibodies with identical antigen-specificities.

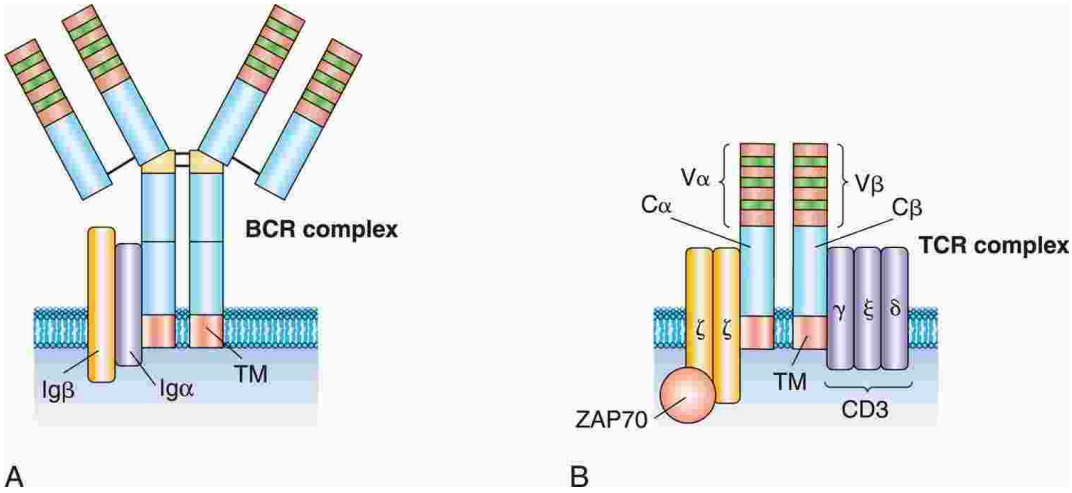


FIG. 8.4 B-cell Antigen Receptor and T-cell Antigen Receptor.

(A) The antigen receptor on the surface of B cells (B-cell receptor *[BCR]* complex) is a monomeric (single) antibody with a structure similar to that of circulating antibody, with an additional transmembrane region *(TM)* that anchors the molecule to the cell surface. The active BCR complex contains molecules (*Igα* and *Igβ*) responsible for intracellular signaling after the receptor has bound antigen. (B) The T-cell receptor *(TCR)* consists of an α- and a β-chain joined by a disulfide bond. Each chain consists of a constant region (*Cα* and *Cβ*) and a variable region (*Vα* and *Vβ*). Each variable region contains CDRs and FRs in a structure similar to that of antibody. The active TCR is associated with several molecules that are responsible for intracellular signaling after antigen binding. These include the CD3, which is a complex of γ (gamma), ε (epsilon); and δ (delta) subunits and a complex of two ζ (zeta) molecules. The ζ molecules are attached to a cytoplasmic protein kinase *(ZAP70)* that is critical to intracellular signaling.

Illustration A shows a cell with antigen receptors on the B C R complex, anchored by I g beta, I g alpha, and T M. Illustration B shows a cell with chains, V alpha C alpha and

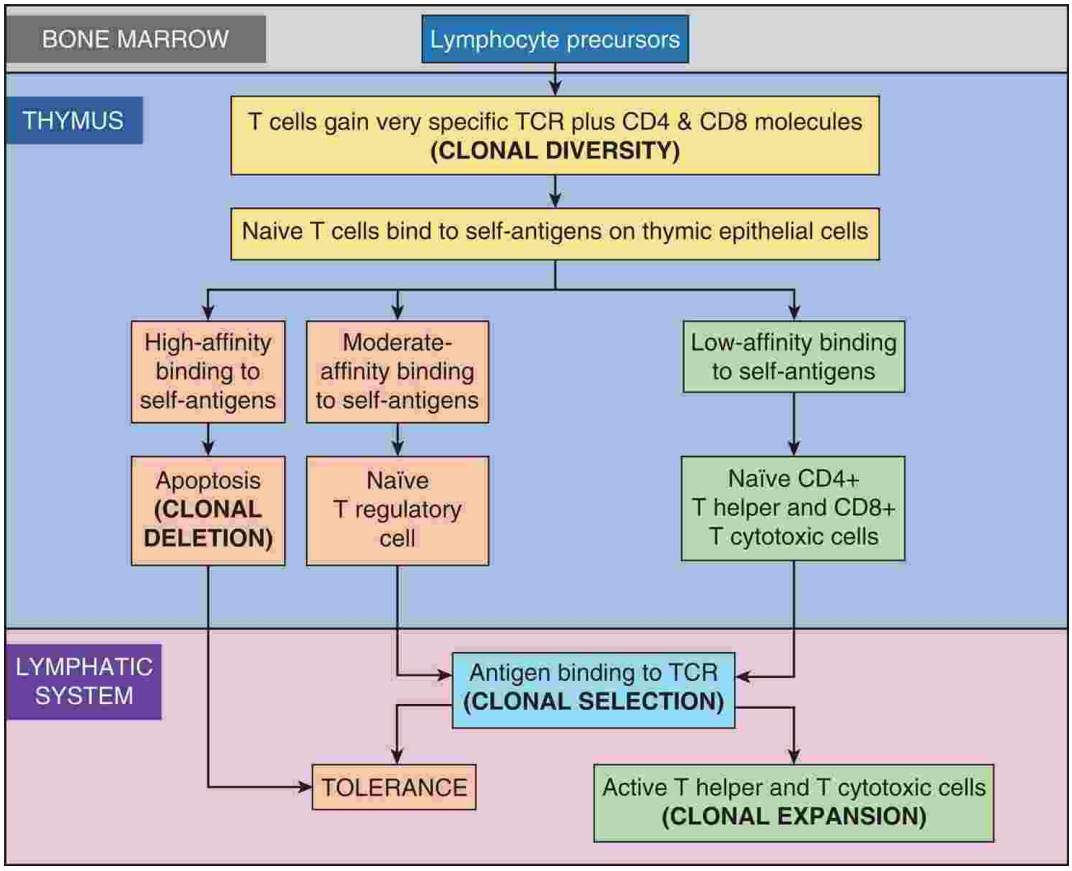
V beta C beta on the T C R complex, anchored by Z A P 70, T M, and C D 3.

The enormous repertoire of BCR specificities (clonal diversity) is made possible by rearranging existing deoxyribonucleic acid (DNA) during B cell development in the primary lymphoid organs, a process known as somatic recombination. Multiple loci in the DNA that encode for BCRs are recombined to generate receptors that collectively can recognize and bind to any possible antigen. A single lymphocyte will synthesize antibodies that can recognize the identical antigen as the BCR on that cell. (Antibody synthesis is discussed in the Humoral Immunity section.)

B-cell differentiation is also characterized by developing various important surface molecules that are markers for B cells. These include CD21 (a complement receptor) and CD40 (adhesion molecule required for later interactions with T cells). The designation "CD" refers to cluster of differentiation, specific cell-surface proteins that are assigned a unique number (e.g., CD21 and CD40).

Development of T Lymphocytes

The process of T-cell proliferation and differentiation is similar to that for B cells (Algorithm 8.2). Lymphoid stem cells travel from the bone marrow to the primary lymphoid organ for T-cell development, which is the thymus. In the thymus, these stem cells are exposed to thymic hormones and the cytokine interleukin 7 (IL-7) and are driven to undergo cell division and gain receptors (T-cell receptors [TCRs]) against the diversity of antigens the individual will encounter throughout life (clonal diversity).[1] They exit the thymus through the blood vessels and lymphatics as mature (immunocompetent) T cells with antigen-specific receptors on the cell surface and establish residence in secondary lymphoid organs.



ALGORITHM 8.2 Steps in T-Cell Development.
When lymphocyte precursor cells from the bone marrow travel to the thymus, they each gain a very specific T-cell receptor *(TCR)* that can recognize a single antigen (clonal diversity). T cells at this stage also gain both a CD4 and a CD8 molecule on their surface. These naïve T cells bind to self-antigens presented by thymic epithelial cells. If they bind tightly (high affinity), this indicates that they can attack the host's own tissues, and most are eliminated through apoptotic cell death (clonal deletion). A few of these T cells lose their CD8 molecule, gain a CD25 molecule, and become T regulatory cells. The clonal deletion of T cells or the induction of T regulatory cells results in immune system tolerance to self-antigens. If the naïve T cells instead bind with only low affinity to self-antigens, they either lose their CD8 molecule and become $CD4^+$ T helper cells or lose their CD4 molecule and become $CD8^+$ T cytotoxic cells. These naïve T cells then move into the lymphatic system where, if they encounter

antigen recognized by their TCRs, they are clonally selected to proliferate and become active immune cells (clonal expansion).

A flowchart tracks the steps in T cell development. The flowchart is divided in three sections: bone marrow, thymus, and lymphatic system. Lymphocyte precursors from the bone marrow travel to the thymus. In the thymus: • T cells gain very specific T C R plus C D 4 and C D 8 molecules (clonal diversity). • Naïve T cells bind to self-antigens on thymic epithelial cells. • High-affinity binding to self-antigens leads to apoptosis (clonal deletion). • Moderate-affinity binding to self-antigens leads to naïve T regulatory cell. • Low-affinity binding to self-antigens leads to naïve C D 4 plus, T helper and C D 8 plus, ot T cytotoxic cells. In the lymphatic system: • Naïve T regulatory cell and naïve C D 4 plus, T helper and C D 8 plus, or T cytotoxic cells lead to antigen binding to T C R (Clonal selection). • Clonal deletion from thymus and clonal selection in lymphatic system result in tolerance. • Clonal selection also results in active T helper and T cytotoxic cells (clonal expansion).

The most common TCR consists of two protein chains, α- and β-chains, each of which has a variable region, a constant region, and a complex of signaling molecules called CD3 (see Fig. 8.4). As with BCR generation, each T cell expresses only one type of TCR, and the diversity of TCRs generated through somatic recombination collectively can recognize and bind to any possible antigen.

Differentiation of T cells in the thymus also results in the expression of other essential surface molecules. Initially, proteins called CD4 and CD8 are concurrently expressed on the developing cells. As the cells mature, they retain either the CD4 molecule or the CD8 molecule, but not both. Those that retain the CD4 molecule develop into Th cells, whereas those that retain the

CD8 molecule become T cytotoxic (Tc) cells. Approximately 60% of immunocompetent T cells in the circulation express CD4, and 40% express CD8. A much smaller number of T cells express CD4 and CD25 and become T regulatory cells (Treg). The functions of Th, Tc, and Treg cells are discussed later in this chapter

As described in Chapter 7, innate lymphoid cells (ILCs) also are derived from lymphoid precursors and resemble T helper cells in their function but do not have TCRs and instead respond to nonspecific tissue injury. These cells are found near mucosal barriers and are organized into three major groups of ILCs (ILC1s, ILC2s, and ILC3s). Broadly, ILC1s promote cellular immunity, ILC2s promote humoral immunity, and ILC3s enhance epithelial barriers.[2]

Clonal Diversity, Clonal Deletion, Clonal Selection, and Clonal Expansion

As described previously in this chapter, clonal diversity occurs during the production of B cells and T cells in the primary lymphoid organs (Table 8.1). This process begins before birth and continues throughout life. Each B cell and T cell develops its own specific BCR or TCR, which can recognize only one antigen; yet taken together, the total population of lymphocytes can recognize almost any foreign antigen found in the environment that will be encountered throughout life. It is estimated that B and T cells can collectively recognize more than 10^{16} different antigenic determinants. Because there are so many potential antigens for which a single type of lymphocyte receptor is created, the body cannot sustain adequate numbers of all of the many millions of lymphocytes that might be needed.[3] Thus, the adaptive immune system is inducible, i.e., once an antigen is encountered by a particular lymphocyte (clonal selection), then many copies of that same lymphocyte are generated in order to adequately respond to that antigen (clonal expansion) (see Table 8.1). The lymphocytes that are produced move into the circulation as immunocompetent cells and migrate to the circulation and secondary lymphoid organs where they can provide a specific and long-lasting defense. This process takes time, so the adaptive immune response is slower than the innate immune response.

Table 8.1

Generation of Clonal Diversity, Clonal Deletion, Clonal Selection & Expansion

	Clonal Diversity	Clonal Deletion	Clonal Selection and Expansion
Purpose?	To produce large numbers of T and B lymphocytes with maximum diversity of antigen receptors	To remove self-reactive T and B lymphocytes	Select, expand, and differentiate clones of T and B cells against specific antigen
When does it occur?	In the fetus and throughout life	In the fetus and throughout life	Primarily after birth and throughout life
Where does it occur?	Central lymphoid organs: thymus for T cells, bone marrow for B cells	Central lymphoid organs: thymus for T cells, bone marrow for B cells	Peripheral lymphoid organs, including lymph nodes, spleen, and other lymphoid tissues
Is foreign antigen involved?	No	No	Yes, antigen determines which clones of cells will be selected
What tissues, hormones, or	Thymic hormones, IL-7, others	Thymic epithelial cells	Many cytokines produced by

	Clonal Diversity	Clonal Deletion	Clonal Selection and Expansion
cytokines are involved?			Th cells and APCs
Final product?	Immunocompetent T and B cells that can react with antigen but have not seen antigen (naïve) and migrate to secondary lymphoid organs	Promotes tolerance and prevents autoimmunity	Plasma cells that produce antibody, effector T cells that help (Th cells), kill targets (Tc cells) or regulate immune responses (Treg cells); memory B and T cells

	Clonal Diversity	Clonal Deletion	Clonal Selection and Expansion

APCs, Antigen-presenting cells; *IL*, interleukin; *Tc*, T cytotoxic cells; *Th*, T helper cells; *Treg cells*, T regulatory cells.

Tolerance refers to the ability of the adaptive immune system to remove or suppress adaptive immune responses to self-antigens or innocuous non-self-antigens (see Table 8.1). A lack of tolerance to self-antigens results in a wide range of disorders called autoimmune or hypersensitivity disorders. The process of generating tolerance occurs both centrally during the development of B and T lymphocytes or peripherally through activation of a specialized kind of T lymphocyte called a T reg. Central tolerance is achieved within the bone marrow for B lymphocytes and within the thymus for T lymphocytes. In both cases, developing lymphocytes that bind with high affinity to self-antigens within these organs are either killed (clonal deletion) or altered in such a way that they no longer will attack host tissues (see Algorithms 8.1 and 8.2). It is estimated that greater than 90% of developing B and T cells are eliminated in this way. Self-reactive B cells may instead undergo a change in the structure of their antigen receptors (BCRs) in a process called *immunoediting*, which renders them harmless to the host. Self-reactive T cells that bind to self-antigens in the thymus with moderate affinity do not undergo clonal deletion but rather gain other surface molecules and become T regulatory cells (Treg) that suppress the adaptive immune response and therefore prevent autoimmunity.[4] Treg cells can also be induced from circulating Th cells in response to excessive inflammation and autoimmunity in a process known as peripheral tolerance. Both types of Treg cells produce very high levels of immunosuppressive cytokines TGF-β and IL-10, which decrease T-cell activity. Enhancement of Treg activity is an emerging approach to the management of autoimmune diseases (see Chapter 9).[5,6]

Induction of the Immune Response

Induction of the adaptive immune response involves a complex interaction among antigen-presenting cells (APCs), lymphocytes, and cytokines. Most cells of the immune system cannot react directly with antigens. To initiate an effective immune response, most antigens must be *processed* and *presented* to the immune cells in a specific manner.

Antigen-Presenting Cells

Antigen presenting cells (APCs) are responsible for processing antigens and presenting them on their surface so that T lymphocytes can recognize them. The three major types of APCs are macrophages, dendritic cells, and B cells. Macrophages are phagocytes that are derived from circulating monocytes and reside in tissues, especially near epithelial surfaces. They detect both

pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) using their surface pattern recognition receptors (PRRs) (see Chapter 7). Dendritic cells are a specialized type of macrophage. There are three major types of dendritic cells: conventional, follicular, and plasmacytoid. Conventional dendritic cells are vital to adaptive immune responses because once they have recognized and phagocytosed antigens, they are capable of migrating to secondary lymph tissues (especially lymph nodes), where they can present those antigens to areas of highly concentrated lymphocytes (Fig. 8.5).[7] Follicular and plasmacytoid dendritic cells secrete multiple cytokines that influence B cell development. B lymphocytes are not phagocytes but can detect antigen with their surface receptors (BCRs) and endocytose BCR/antigen complexes.

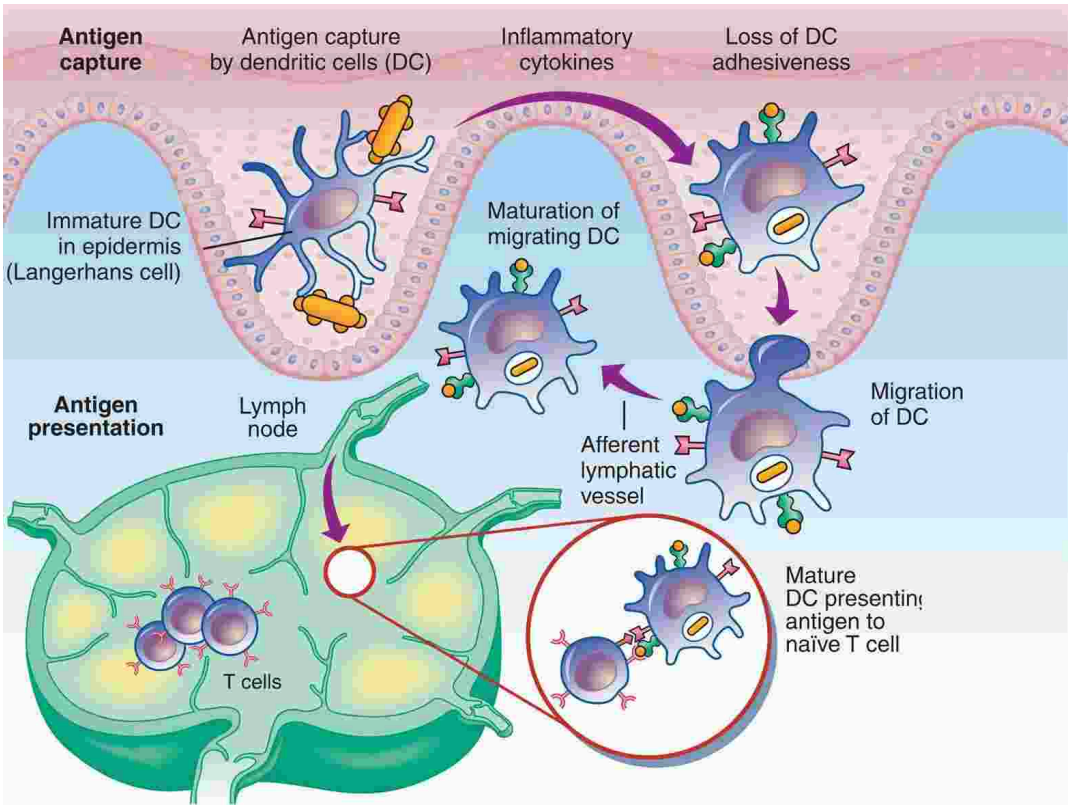

FIG. 8.5 The Role of the Dendritic Cell in Capturing Antigen.
Immature dendritic cells in the tissues encounter a phagocytose antigen, resulting in the production of inflammatory cytokines and a loss of adhesive interactions with neighboring cells. The maturing dendritic cell migrates through the lymphatic vessels to a regional lymph node, presenting the antigen to immunocompetent T cells to initiate the clonal selection process. (Redrawn from Kumar V, Abbas A, Fausto N. Robbins & Cotran pathologic basis of disease, 8th edition. Philadelphia: Saunders; 2010. McCance K, Huether S. Pathophysiology, 8th edition. St. Louis: Elsevier; 2019.)

An illustration shows the role of the dendritic cell in capturing antigen. The illustration is divided into two sections. Top section, antigen capture. The sequence of capture is as follows. • Immature D C in epidermis (Langerhans cell). • Antigen capture by dendritic cells (D C). • Inflammatory cytokines. • Loss of adhesiveness •

Migration of D C • Afferent lymphatic vessel. • Maturation of migrating D C. Bottom section, antigen presentation. The mature cell migrates to a lymph node, where the mature D C presents antigen to the naïve T cell.

Antigen Processing

Extracellular exogenous antigens that enter the body and circulate in blood and lymph are detected by macrophages and dendritic cells via their PRRs and are phagocytosed (see Chapter 7). Once the exogenous antigen is inside an APC, a complex series of intracellular processes leads to the enzymatic fragmentation of the antigen followed by assembly of an antigen molecule complex that is presented on the surface of the APC (Fig. 8.6). B cells recognize and capture exogenous antigens using their BCRs, endocytose BCR/antigen complexes, and then process them so the antigens can be presented on the surfaces of the B cells. Endogenous antigens generated when a cell has become infected by an intracellular microorganism (e.g., viruses) or mutation of its DNA (like occurs in cancer) also undergo antigen processing.

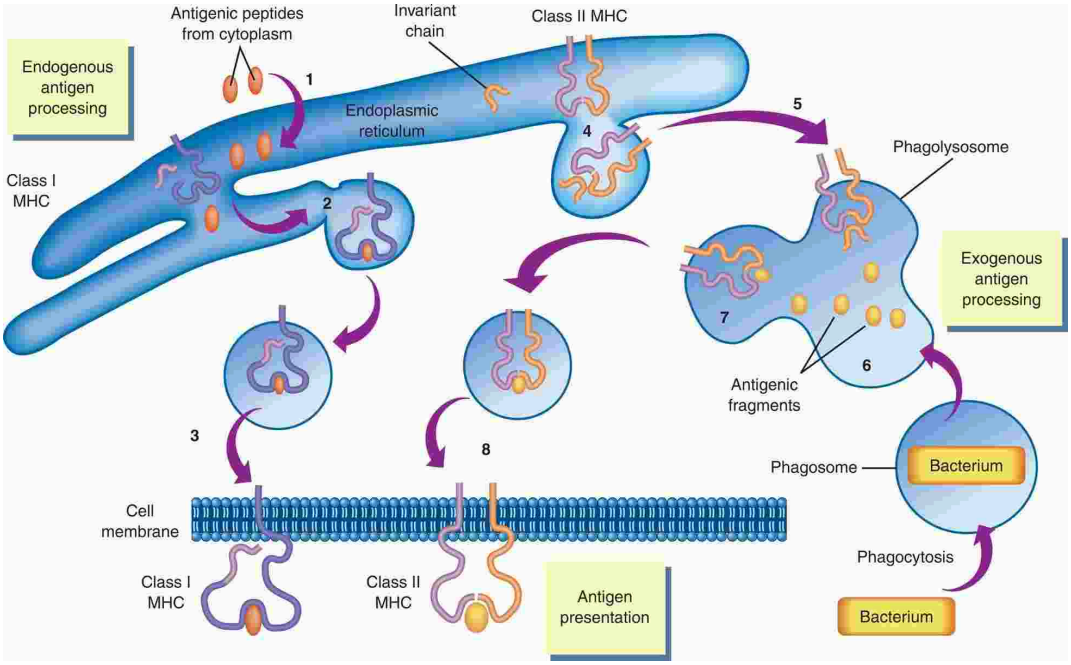

FIG. 8.6 Antigen Processing.
(1) Endogenous antigens (viruses, cancer) are transported into the endoplasmic reticulum (ER) where major histocompatibility complex (MHC) molecules are being assembled. ***(2)*** Endogenous antigen fragments bind to the α-chains of the MHC class I molecule. ***(3)*** The antigen/MHC class I complex is transported to the cell surface where it is presented to T cells. ***(4)*** The α- and β-chains of the MHC class II molecules are also being assembled in the ER. ***(5)*** The MHC class II molecule is transported to phagolysosomes where ***(6)*** exogenous antigenic fragments have been produced by phagocytosis. ***(7)*** The antigen fragments bind to the MHC class II molecule and ***(8)*** the antigen/MHC class II complex is transported to the cell surface where it is presented to T cells.

An illustration demonstrates endogenous antigen processing, exogenous antigen processing, and antigen presentation. Endogenous antigen processing. Antigenic peptides from the cytoplasm are transported to the endoplasmic reticulum, bind to the alpha chains, and

released to the cell surface through the cell membrane as class 1 M H C. Exogenous antigen processing. An invariant chain in the endoplasmic reticulum binds with class 2 M H C and is transported to phagolysosome. Phagocytosis of bacterium in phagosome releases antigenic fragments into the phagolysosome. The invariant chain in class 2 M H C is replaced with the antigenic fragments in the phagolysosome, which are then released to the cell surface through the cell membrane. Antigen presentation. Class 1 M H C and class 2 M H C in the cell surface.

Antigen Presentation

Antigen processing results in the presentation of antigens on the surface of APCs and abnormal cells by molecules of the major histocompatibility complex (MHC) (see Fig. 8.6). MHC molecules in humans also are called human leukocyte antigens (HLAs) when they are identified for organ transplantation (see Chapter 9). MHC molecules are glycoproteins found on the surface of all human cells except red blood cells. They are divided into two general classes, class I and class II, based on their molecular structure, distribution among cell populations, and function in antigen presentation. MHC I molecules are found on all nucleated cells. They are composed of a large alpha (α) chain along with a smaller chain called β_2-microglobulin that are coded for by gene complexes on chromosome 6 (HLA-A, HLA-B, HLA-C) (Fig. 8.7). MHC II molecules are found only on APCs and are composed of a different type of α- and β-chains that are coded for by another set of genes on chromosome 6 (HLA-DR, HLA-DP, HLA-DQ). In healthy tissues, these molecules identify cells as self, i.e., immune cells recognize MHC molecules on healthy host cells and do not attack them. Deleterious changes in the structure of MHC molecules can lead to autoimmune disorders and vulnerability to cancer and infection.[8,9] MHC genes are highly polymorphic; therefore, no two individuals (except identical twins) will have a complete set of identical MHC molecules. Transplantation of one person's cells into another person will result in an adaptive immune attack on the foreign tissue (rejection) (see Chapter 9).

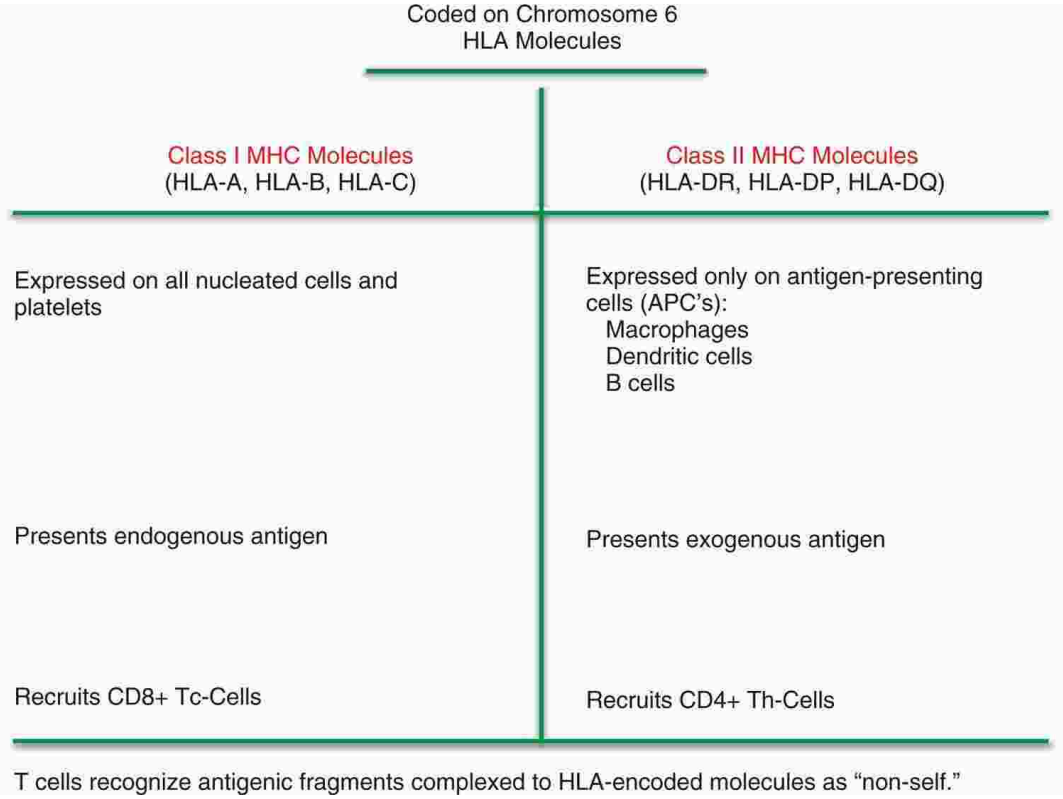

FIG. 8.7 Antigen-Presenting Molecules.
HLA-A, HLA-B, HLS-C, isotypes of class I MCH molecules; *HLA-DR, HLA-DP, HLA-DQ*, isotypes of class II MCH molecules.

A table classifies the antigen-presenting molecules coded on chromosome 6 H L A molecules. The table comprises two columns: Class 1 M H C molecules and class 2 M H C molecules. Class 1 M H C molecules: H L A-A, H L A-B, H L A-C. • Expressed on all nucleated cells and platelets. • Presents endogenous antigen. • Recruits C D 8 plus T c-cells. Class 2 M H C molecules: H L A-D R, H L A-D P, H L A-D Q. • Expressed only antigen-presenting cells (A P C's): Macrophages, dendritic cells, and B cells. • Presents exogenous antigen. • Recruits C D 4 plus T h-cells.

Because APCs have both MHC II and MHC I molecules on their surface, they can present antigens on both types of MHC molecules. In essence, antigen processing and presentation result in the creation of an antigen/MHC complex on the surface of the APC that makes it appear to T cells as foreign. T cells can only recognize antigens that are presented in this way. Antigens presented on MHC II molecules are recognized and bound by T helper cells, whereas antigens presented on MHC I molecules are recognized and bound by Tc cells.[10] B cells that have captured exogenous antigens preferentially present them on their MHC II molecules, thus primarily activating T helper cells. Because only APCs have MHC class II molecules, all other nucleated cells that have undergone intracellular infection or DNA mutation can only present antigen on MHC I molecules.

CD1 molecules on APCs also present antigen to immune cells. These molecules specialize in presenting lipid antigens found on some pathogens, particularly with bacteria of the *Mycobacterium* spp. (e.g., *Mycobacterium tuberculosis*).

In summary, the terms antigen processing and antigen presentation refer to how exogenous and endogenous antigens are cut up into small antigenic fragments and then presented to Tc cells (MCH I) or Th cells (MCH II). This interaction among APCs and subpopulations of T cells facilitates immune responses. When cells present antigen on MHC I, the primary response is the destruction of the presenting cell by Tc cells. When cells present antigen on MCH II Th cells are activated which modulate many elements of the adaptive immune response. Th cells support the differentiation of B cells into more effective antibody-producing cells (plasma cells). Th cells also promote Tc cell proliferation and function. Defects in any aspect of this cellular collaboration will lead to defects in cell-mediated immunity, humoral immunity, or both, depending on the specific defect (see Chapter 9).[11]

T-Helper Cells

To induce an optimal cellular or humoral immune response, APCs must present antigens to Th cells. When Th cells are first activated by antigen binding, they are often called Th0 cells. Depending on the antigen and signals from the APC, the Th0 cell further differentiates into three subtypes: T helper 1 (Th1), T helper 2 (Th2), and T helper 17 (Th17). Some Th cells become Treg cells.

T Helper Cell Activation

After an APC presents antigen held by the MHC class II molecules, activation of the Th0 cell requires six steps (Fig. 8.8):

1. The presented antigen is recognized and bound by the TCR on the Th0 cell.
2. Intercellular antigen binding is strengthened by the binding of the CD4 on the Th0 cell with the β_2 region of the MHC class II molecule.
3. The cytoplasmic portions of the TCR and CD4 molecules interact to activate intracellular signaling pathways.
4. Intercellular communication between the APC and Th cell through adhesion molecules and co-stimulatory signals further activates the Th0 cell, the most critical being the B7 protein on the APC and CD28 on the Th cell.
5. Interleukin-1 (IL-1) and interleukin-12 (IL-12) are secreted by the APC and provide additional signals to the Th0 cell.
6. IL-2 is secreted by the Th0 cell and acts in an autocrine (self-stimulating) fashion to induce further maturation and proliferation of the Th cell. Without IL-2 production, the Th0 cell cannot efficiently mature into a functional helper cell.

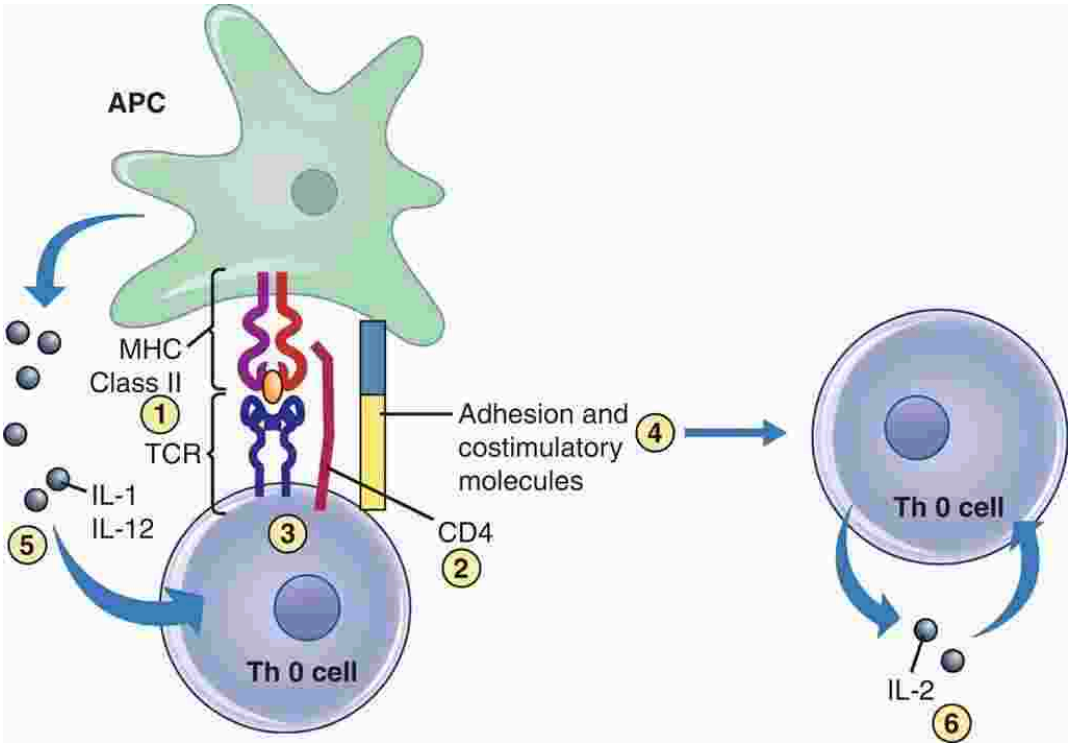

FIG. 8.8 **T helper (Th) Cell Activation.**
Once an antigen-presenting cell *(APC)* presents antigen on its major histocompatibility class II *(MHC II)* molecules, activation of a T helper 0 *(Th0)* cell requires six steps: ***(1)*** Binding of the T cell receptor *(TCR)* on the Th0 cell to the presented antigen; ***(2)*** Binding of the CD4 molecule on the Th0 cell to the β2 region of the MHC II molecule; ***(3)*** Activation of intracellular signaling pathways within the Th0 cell; ***(4)*** Intercellular adhesion and costimulatory molecules such as B7 on the APC and CD 28 on the Th0 cell provide intercellular communication; ***(5)*** Interleukins 1 and 12 (*IL-1* and *IL-12*) are secreted by the APC and provide additional signals to the Th0 cell; ***(6)*** Interleukin 2 (IL-2) is secreted by the Th0 cell and provides autocrine stimulation to induce further maturation and proliferation of the Th cell.

An illustration tracks the following six steps in T helper (T h) cell activation that involves an A P C and a T h 0 cell. (1) M H C class 2 binds to T C R. (2) C D 4 binds to T h 0 cell. (3) T h 0 cell is activated. (4) Adhesion and costimulatory

molecules communicated with the T h 0 cell. (5) I L-1 and I L-12 secreted by A P C activate the T h 0 cell further. (6) I L-2 is secreted by T h 0 cell.

T Helper Cell Function

Th cells are necessary for the development of most humoral and cellular immune responses. To provide effective immunity, activated Th0 cells undergo differentiation into one of several subsets: Th1, Th2, Th17, or Treg. (Fig. 8.9). The subset created in the greatest numbers depends on the intercellular communication from the APC to the Th0 cell (through interleukins and costimulatory molecules) and the predominant cytokines in the immediate environment. These subsets have different functions: Th1 cells preferentially support cell-mediated immunity, Th2 cells support humoral immunity, and Th17 cells support innate immunity and epithelial cell protection against invasion. Many antigens will produce excellent humoral and cell-mediated responses simultaneously. Treg cells secrete cytokines that suppress the immune system and promote tolerance (discussed previously in this chapter).

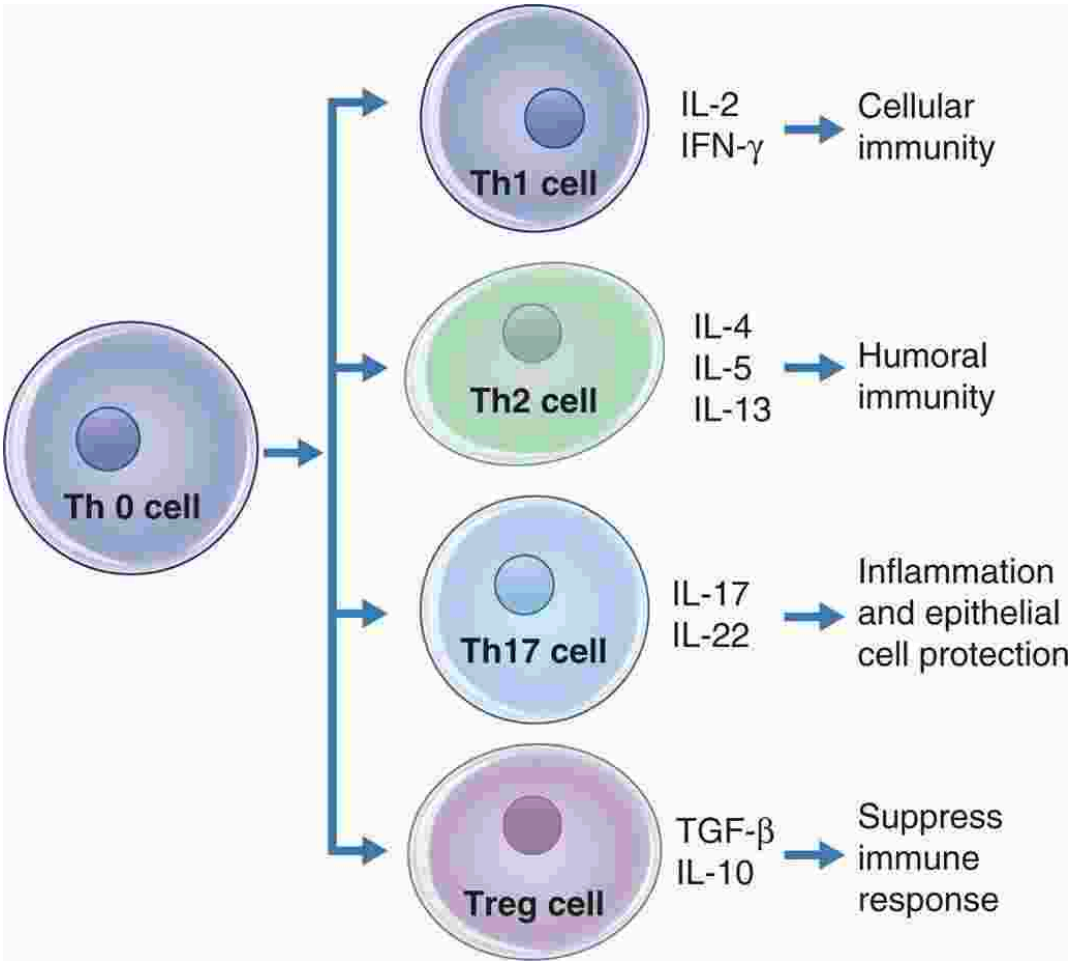

FIG. 8.9 Development of T helper (Th) Cell Subsets. Once T helper 0 *(Th0)* cells are activated, they undergo differentiation to become *Th1, Th2, Th17*, and T regulatory *(Treg)* cells. These Th subtypes are crucial to the development of effective cellular and humoral immune responses. Intercellular communication between the antigen-presenting cell and the Th0 cell and cytokines produced by the innate and adaptive immune systems determine which of the four subtypes will be created in the greatest numbers. Th1 cells secrete interferon-gamma *(IFN-γ)*, which promotes macrophage phagocytosis of invaders, and *IL-2*, which promotes differentiation of T-cytotoxic (Tc) cells leading to cellular immunity. Th2 cells produce *IL-4* and *IL-13*, which favor B-cell differentiation and humoral immunity. Th2 cells also produce *IL-5*, which stimulates eosinophils, a process important in fighting parasites and in causing allergic disease. Th17 cells

produce *IL-17* which stimulates cells of the innate immune system, thus increasing inflammation, and *IL-22*, which promotes epithelial cell protection. Treg cells produce immunosuppressive cytokines such as transforming growth factor-beta *(TGF-β)* and *IL-10*, which prevent the immune response from being excessive.

An illustrated flowchart tracks the development of T helper (T h) cell subsets. Initially, the T h 0 cell gets activated and differentiates into the following subsets: (1) T h 1 cell that includes I L-2 and I F N-gamma, which aid in cellular immunity, (2) T h 2 cell that includes I L-4, I L-5, and I L-13, which aid in hormonal immunity, (3) T h 17 cell that includes I L-17 and I L-22, which aid in inflammation and epithelial cell protection, and (4) T reg cell that includes T G F-beta and I L-10, which aid in immune response suppression.

Th1 cells

Th1 cells produce interferon-γ (IFN-γ). IFN-γ strongly activates macrophages to be better phagocytes. Th1 cells also produce IL-2, which supports the proliferation and activation of Tc cells. These processes promote the phagocytosis and cytotoxic killing of infected, cancerous, or damaged cells. In other words, Th1 cells primarily support cellular immunity.

Th2 cells

Th2 cells differentiate when extracellular antigens are presented by the APC, especially under the influence of IL-4 produced by other activated immune cells. Th2 cells support B cells proliferation and differentiation through IL-4 production, thus promoting humoral immunity. IL-13 produced by Th2 cells also supports humoral immunity. IL-5 also is produced by Th2 cells and promotes eosinophil proliferation and activation.

Th17 cells

Th17 cells primarily produce the cytokine IL-17. IL-17 stimulates the innate immune system and plays a crucial role in autoimmune disorders (see Emerging Science Box: IL-17 in Health and Disease). The presence of IL-17 causes an inflammatory reaction that is stronger and more prolonged than that provided by innate immune responses alone.[12] Th17 cells also produce IL-22 which helps maintain the integrity of epithelial barriers through the production of antimicrobial substances (defensins—see Chapter 7) and by promoting the repair of damaged epithelia.[13]

Emerging Science BoxIL-17 in Health and Disease

The cytokine IL-17 has many protective functions and is responsible for a wide range of inflammatory and autoimmune conditions. IL-17 is a family of 6 proteins (IL-17A—IL17F), of which IL-17A is most often linked to disease. In addition to T helper 17 (Th17) cells, IL-17A is produced by some T cytotoxic cells, natural killer cells, and innate lymphoid cells. IL-17A binds to receptors on innate immune cells such as neutrophils and macrophages and activates Nuclear Factor KappaB (NF-κB), which in turn induces the production of multiple proinflammatory cytokines (e.g., TNF-α, and IL-1), chemokines, and proteases. This effect is synergistic with other cytokines of the innate immune response and contributes to neutrophil and macrophage activation and function. Thus IL-17A is important to immune defense and wound healing. Unfortunately, IL-17A also has been shown to contribute to a wide range of conditions, including inflammatory rheumatologic, neurogenerative, pulmonary, cardiovascular, and ophthalmologic disorders, as well as cancer and other conditions as broad-ranging as periodontitis, type 1 diabetes, obesity, and pregnancy loss. Therapeutic blockade of IL-17A by monoclonal antibodies (e.g., secukinumab and Ixekizumab) effectively treats psoriasis, psoriatic arthritis, and ankylosing spondylitis; however, results have not been as promising for other IL-17-related conditions. Of increasing interest for new therapies is the discovery that Th17 cells can be induced by anti-inflammatory cytokines such as Transforming Growth Factor- Beta (TGF-β) to become Treg 17 cells that suppress the inflammatory response. IL-17F is also being recognized as a major contributor to chronic inflammatory diseases and monoclonal antibodies such as bimekizumab are being developed that can block both IL-17A and IL-17F.

Humoral Immunity

When a B cell matures in response to antigen exposure, it becomes a plasma cell capable of producing antibodies. These antibodies conduct the humoral immune response. The terms antibody and immunoglobulin (Ig) are frequently used interchangeably. However, the term *antibody* is used more frequently in health care settings.

B-Cell Activation

Cellular interactions between B cells and other components of adaptive immunity are required to produce an effective antibody response. B cells express surface immunoglobulin molecules that comprise the BCR (see Fig. 8.4). Unlike the TCR, which can only recognize processed and presented antigens, the BCRs on B cells can react with soluble antigens that have not been processed. When B cells bind to antigen, they can be activated to become antibody-producing plasma cells in two significant ways: (1) coactivation with Th cells by processing and presenting antigen (Fig. 8.10), or (2) through a T cell-independent mechanism (Fig. 8.11).

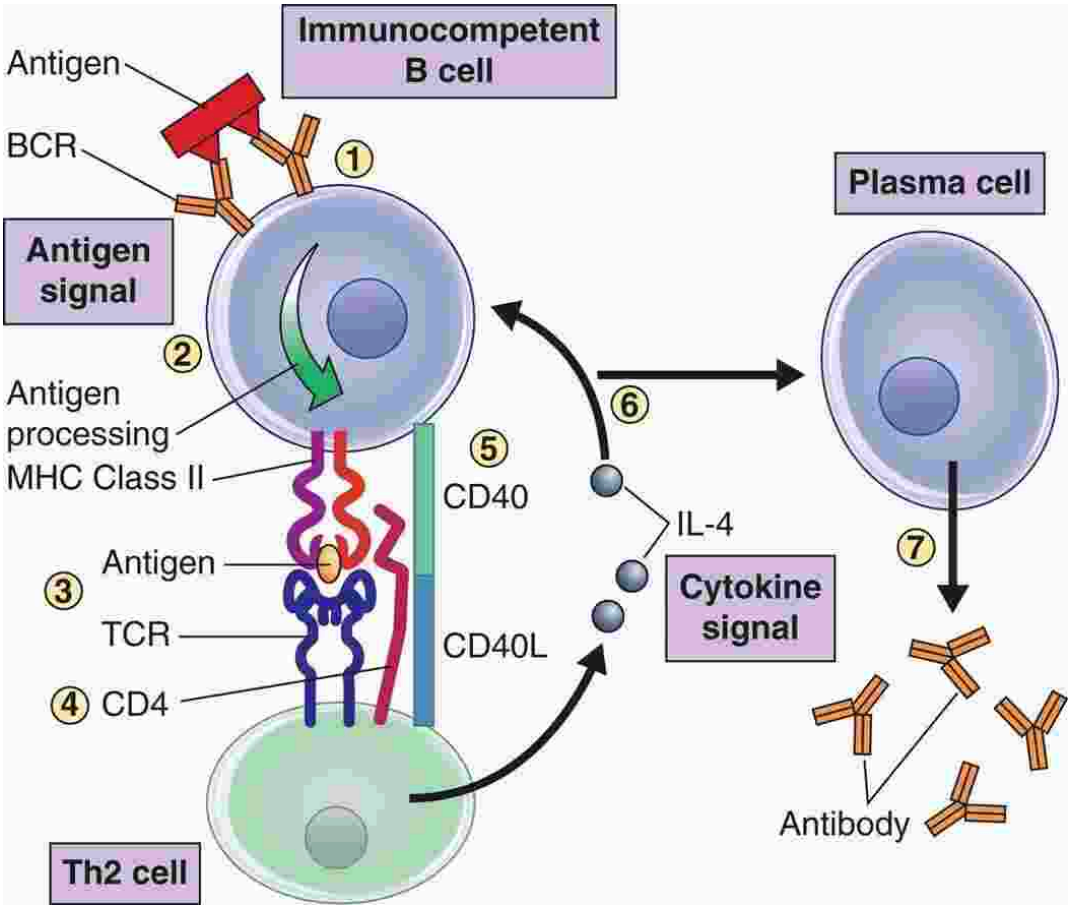

FIG. 8.10 B-Cell Activation.
Immunocompetent B cells undergo proliferation and differentiation into antibody-secreting plasma cells. Multiple signals are necessary ***(1)***. The B cell itself can directly bind soluble antigen through the B-cell receptor *(BCR)* and act as an antigen-processing cell. Antigen is internalized, processed ***(2)***, and presented to the T-cell receptor *(TCR)* on a T-helper 2 *(Th2)* cell by a major histocompatibility complex *(MHC)* II molecule ***(3)***. The CD4 molecule on the Th2 cell binds to the MHCII molecule on the B cell ***(4)***. The CD40 molecule on the B cell binds to the CD40 ligand (CD40L) on the Th2 cell providing a costimulatory signal between the cells ***(5)***. The Th2 cell cytokines provide a cytokine signal (e.g., interleukin-4 [IL-4]) that reacts with the B cell ***(6)***. The B cell differentiates into plasma cells that secrete antibody specific to the antigen ***(7)***.

An illustrated flowchart tracks the following seven stages in B-cell activation. (1) Immunocompetent B cell binds antigens, (2) antigen processing in M H C class 2, (3) antigen binds to T C R, (4) C D 4 binds to T h 2 cell, (5) C D 40 and C D 40 L generate cytokine signal, (6) I L-4 reacts the plasma cell, and (7) plasma cell secretes antibodies.

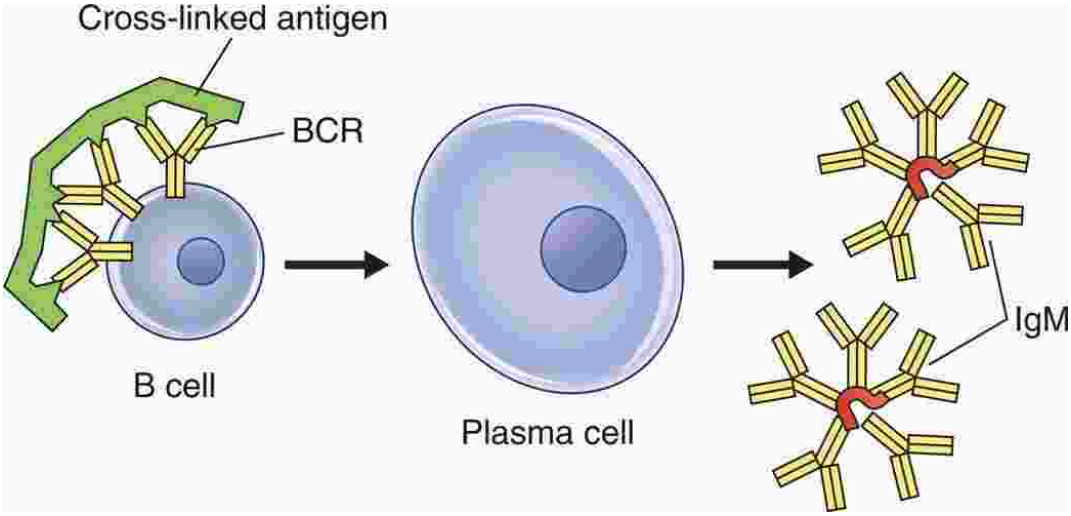

FIG. 8.11 Activation of a B Cell by a T Cell–Independent Antigen.
Antigens that can cross-link several B-cell receptors *(BCRs)* can directly induce the B cell to become an antibody-producing plasma cell. Because T-helper 2 cells do not participate, class switch does not occur, and the resultant antibody response is immunoglobulin M *(IgM)*.

An illustrated flowchart tracks the following stages in the activation of a B cell by a T cell-independent antigen. (1) Antigens cross-link B C R on a B cell, (2) B cell signals the plasma cell, and (3) plasma cell released cross-linked I g M.

Coactivation of B cells and Th cells is a multistep process. B cells preferentially present processed antigen on their MHC class II molecules and therefore activate Th cells.[14] The subsequent steps in Th0 cell are similar to those that occur when antigen is presented by APCs (see Fig. 8.8) in which the TCR binds to antigen, the CD4 on the Th0 cell binds to the MHC II molecule on the B cell, and there is intercellular communication via costimulatory molecules. The primary costimulatory molecules involved in Th cell and B cell coactivation are CD40 ligand on the Th cell and CD40 on the B cell (see Fig. 8.10). The Th0 cell is induced to become a Th2 cell, which secretes the Th2 cytokines, especially IL-4. IL-4 promotes B-cell proliferation and maturation into plasma cells. Plasma cells are activated B cells that produce antibodies capable of detecting the identical antigen as was bound by the BCR.

Although most antigens require B cells to interact with Th cells, a few antigens can bypass the need for cellular interactions and directly stimulate B-cell maturation and proliferation. These are called *T cell-independent antigens* (see Fig. 8.11). These antigens are mostly bacterial products that are large and can cross-link several BCRs. T cell-independent antigens usually induce plasma cells to secrete only IgM.

Molecular Structure and Classes of Antibodies

An antibody molecule consists of four polypeptide chains: two identical light (L) chains and two identical heavy (H) chains. The light and heavy chains are held together by noncovalent bonds and covalent disulfide linkages. There are three parts to an antibody molecule (Fig. 8.12). Two identical fragments can bind antigen and are termed antigen-binding fragments (Fab). The third fragment is termed the crystalline fragment (Fc).

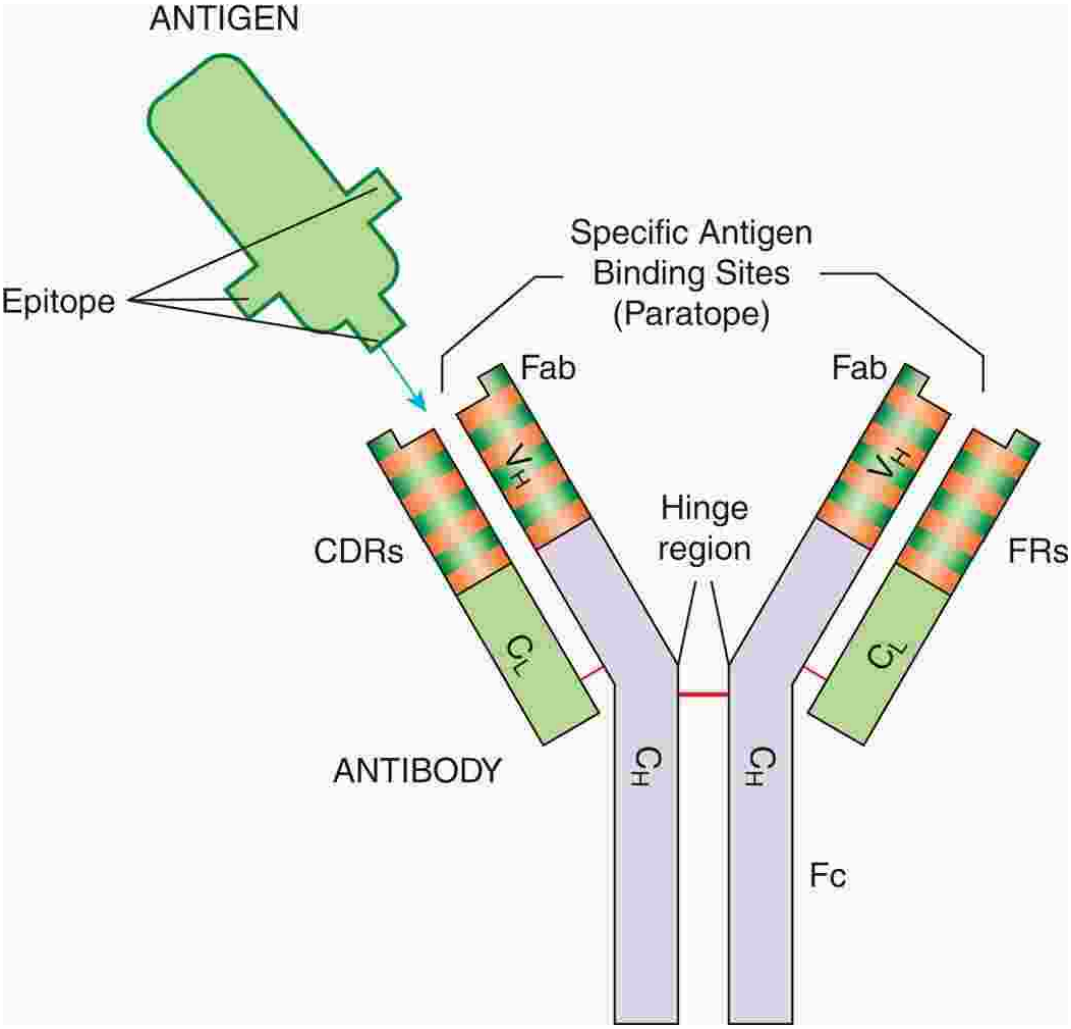

FIG. 8.12 Structure of Antibodies.
CDRs, Complementary determining regions; C_H, constant region heavy chain; C_L, constant region light chain; *Fab*, fragment antigen binding; *Fc*, crystalline fragment; *FRs*, framework regions V_H, variable region heavy chain; V_L, variable region light chain;. *Red lines* are disulfide linkages.

An illustration shows the structure of an antibody. The antibody is a Y-shaped structure with specific antigen biding sites (paratopes) at the head, a hinge region, and a tail, F c. Each paratope comprises two chains. The outer chain is made of C D Rs and C L. The inner chain is made of

V H and C H, where the C H extends into the tail. Epitopes on the antigen bind to the paratopes.

The Fab portions contain the recognition sites (receptors) for antigens and confer the molecule's specificity toward a particular antigen. The Fab portion on the antibody is sometimes referred to as the antigen-binding site or paratope. Its specificity for a particular antigen corresponds to the BCR on the B cell that produced the antibody. Because antigens are relatively small, a large molecule (e.g., protein, polysaccharide, nucleic acid) usually contains multiple and diverse antigens. The specific area of the antigen recognized by a particular antibody is called its antigenic determinant, or epitope. The antigen fits into the antigen-binding site of the antibody with the specificity of a key into a lock and is held there by noncovalent chemical interactions.

The antibody class is determined by the different amino acid sequences in the heavy chains that make up the Fc portion of the antibody. The Fc portion is responsible for most of the biologic functions of antibodies. There are five classes of antibodies (IgG, IgA, IgM, IgE, and IgD) characterized by differences in structure and function (Fig. 8.13). Both IgG and IgA have subclasses.

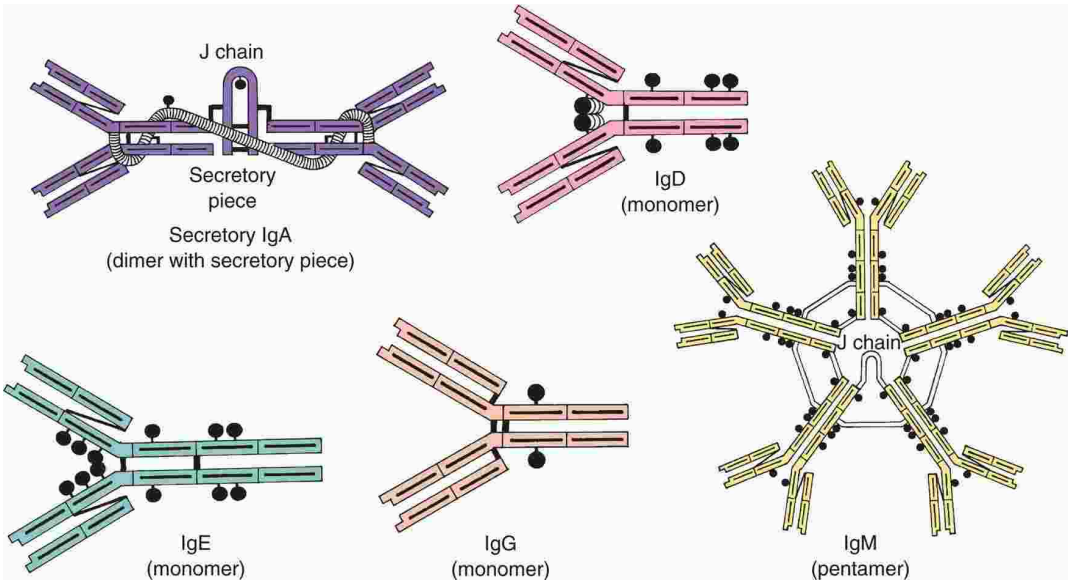

FIG. 8.13 Classes of Antibodies Secretory immunoglobulin A (IgA), IgD, IgE, IgG, and IgM.
The *black circles* attached to each molecule represent carbohydrate residues.

Five illustrations show the different classes of antibodies secretory immunoglobulins. The five classes are as follows. • Secretory I g A (dimer with secretory piece): Two Y-shaped antibodies are joined at their tails by a J chain, forming the secretory piece. • I g D (monomer): A single Y-shaped antibody with carbohydrate residues at the hinge and F Cs. • I g E (monomer): A single Y-shaped antibody with a longer tail. Carbohydrate residues are attached at the hinge and the tail. • I g G (monomer): A single Y-shaped antibody with minimum carbohydrate residues on the tail. • I g M (pentamer): A series of five Y-shaped antibodies joined at their tails by a J chain, in the shape of a regular pentagon. Carbohydrate residues are attached at the hinges, the tails, and the J chain.

IgG is the most abundant antibody class, constituting 80% to 85% of the antibodies in the blood and accounting for most of the protective activity against infections. During pregnancy, maternal IgG is transported across the placenta and protects the newborn child during the first 6 months of life.

IgM is the largest antibody and usually exists as a pentamer (a molecule consisting of five identical smaller molecules) that is stabilized by a J chain. It is the first antibody produced during the initial, or primary, response to antigens. IgM is usually synthesized early in neonatal life but may be increased as a response to infection in utero. mIgM serves as part of the BCR complex on B cells.

IgA is found in blood and bodily secretions as secretory IgA (subclass IgA2). Secretory IgA is a *dimer* consisting of two IgA2 molecules held together through a J chain and secretory piece. The secretory piece is attached to dimeric IgA during transportation through mucosal epithelial cells to protect against degradation by enzymes also found in secretions.

IgD functions as a part of the BCR antigen receptor on the surface of early B cells (mIgD).

IgE is normally at low concentrations in the circulation. It has specialized functions to mediate many common allergic responses (see Chapter 9) and defense against parasitic infections.

A significant component of B-cell maturation is class switch, which changes antibody production from one class to another (e.g., IgM to IgG). Antibody diversification through this process is essential for the immune system to produce protective humoral responses. B cells proliferate during the clonal selection process and develop into antibody-secreting plasma cells, which begin by secreting IgM. The plasma cell then can change the class of antibody it produces to IgG, IgA, or IgE. The antigenic specificity of the antibody remains unchanged. Thus, a B cell may produce a population of plasma cells capable of producing many different classes of antibodies against the same antigen. The type of antibody produced is under the control of Th cytokines. For instance, when the Th2 cytokines IL-4 and IL-13 are secreted in high amounts, they preferentially stimulate a class switch to IgE secretion.

Function of Antibodies

The chief function of antibodies is to protect against infection. The mechanism can be either *direct* (through the action of antibody alone) or *indirect* (requiring activation of other components of the innate immune response) (Fig. 8.14). Directly, antibodies can affect infectious agents or their

toxic products by neutralization (inactivating or blocking the binding of antigens to receptors). For instance, the influenza virus must attach to specific receptors on respiratory tract epithelial cells, and *Neisseria gonorrhoeae* (causes gonorrhea) must attach to specific sites on urogenital epithelial cells. Antibodies may protect the host by covering sites on the microorganism needed for attachment, thereby preventing infection. Vaccination with inactivated or attenuated (weakened) viruses can prevent many viral infections by inducing neutralizing antibody production. Antibodies can also protect against infection through agglutination (clumping insoluble particles in suspension) or precipitation (making a soluble antigen into an insoluble precipitate).

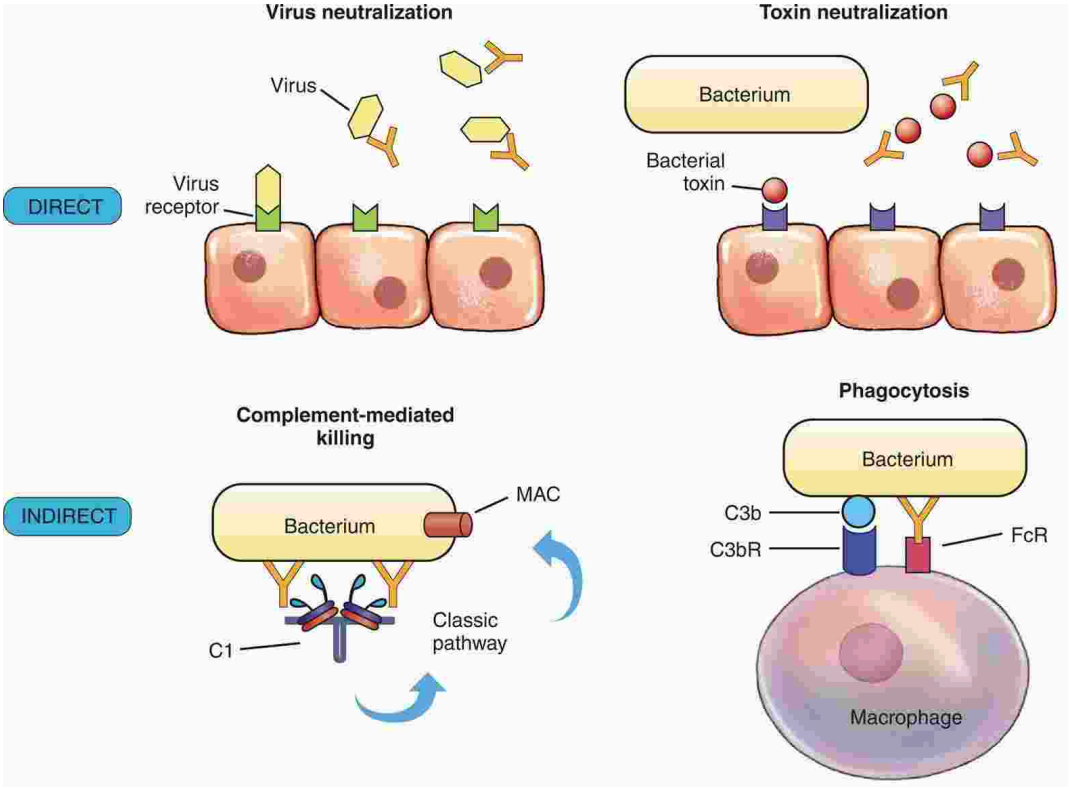

FIG. 8.14 Direct and Indirect Functions of Antibody. Protective activities of antibodies can be direct (through the action of antibody alone) or indirect (requiring activation of other components of the innate immune response, usually through the Fc region). *Direct* means include neutralizing viruses or bacterial toxins before they bind to receptors on the surface of the host's cells. *Indirect* means include activation of the classical complement pathway through C1, resulting in the formation of the membrane attack complex *(MAC)*, or increased phagocytosis of bacteria opsonized with antibody and complement components bound to appropriate surface receptors (*FcR* and *C3bR*), resulting in antibody-dependent cellular cytotoxicity (ADCC).

An illustration demonstrates direct and indirect functions of antibody. The direct function of the antibody involves virus neutralization and toxin neutralization. In both the cases, the antibody neutralizes the virus and toxin before they bind to the receptors. Thus, the viruses and bacterial

toxins do not bind to the host cell. The indirect function of antibody involves complement-mediated killing and phagocytosis. The former involves activation of classical pathway through C 1, resulting in the formation of an M A C on the bacterium. In the latter, C 3 b binds to the C 3 b R, while the antibody binds to F c R on the macrophage.

Some bacteria secrete toxins that harm individuals. For instance, bacterial toxins cause the symptoms of tetanus or diphtheria. Most toxins are proteins that bind to surface molecules on cells and damage those cells. Protective antibodies produced against the toxin, known as antitoxins, can bind to the toxins, prevent interaction with host cells, and neutralize their biologic effects.

Indirectly, antibodies activate components of innate immunity, including complement and phagocytes (see Fig. 8.14). Through the classical pathway, complement component C1 is activated by binding simultaneously to the Fc regions of two adjacent antibodies bound to a microbe, resulting in activation of the entire cascade and ultimate killing of the microbe by the complement membrane attack complex (see Chapter 7). In addition, phagocytic cells express receptors that bind the Fc portion of antibody; thus, antibody is an opsonin that facilitates phagocytosis of bacteria. IgM is the best complement-activating antibody, and IgG is the best opsonin. The process by which antibodies opsonize and connect antigens to phagocytic cells is called antibody-dependent cellular cytotoxicity (ADCC).

Immunoglobulin E

If IL-4 levels are moderate, B cells are stimulated to become plasma cells that secrete IgG. In individuals with parasitic infection or allergies, high levels of IL-4 result in plasma cell production of IgE. IgE is a special class of antibody that protects the individual from infection by large parasitic worms (helminths). When large multicellular parasites invade mucosal tissues, IgG, IgM, and IgA bind to the surface of parasites and activate both complement and ADCC. This response, however, does not significantly damage parasites. IgE initiates an inflammatory reaction that provides a more effective response to parasitic infection. Mast cells in the tissues have Fc epsilon receptors that bind the Fc portion of IgE molecules to the mast cell surface. Soluble antigen molecules from the parasite bind to the Fab portion of these IgE antibodies resulting in mast cell degranulation. Eosinophil chemotactic factor of

anaphylaxis (ECF-A) is released from the mast cells and attracts eosinophils from the circulation. Eosinophils contain granules whose contents include major basic protein, eosinophil cationic protein, eosinophil peroxidase, and eosinophil neurotoxin, each of which can damage infectious worms. Thus, elevated levels of IgE are commonly found in parasitic infection. The steps of this process are presented in Fig. 8.15.

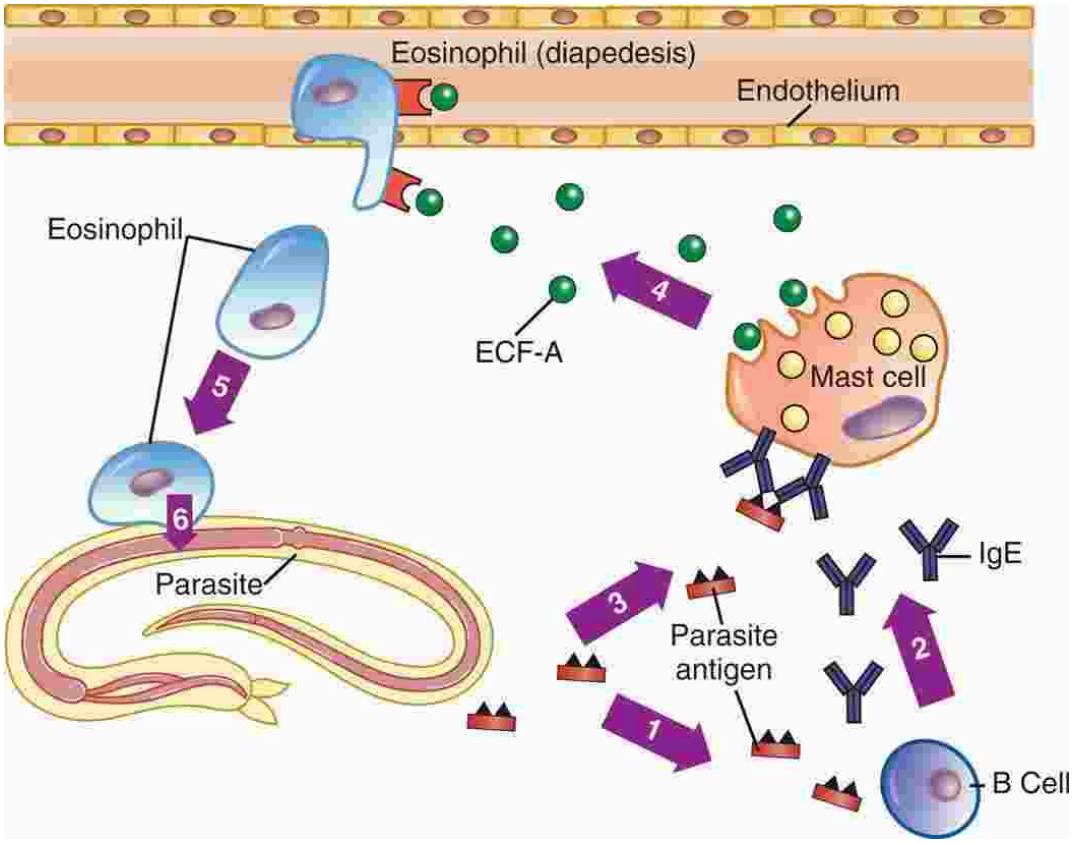

FIG. 8.15 Immunoglobulin E Function.
(1) Soluble antigens from a parasitic infection cause production of immunoglobulin E *(IgE)* antibody by B cells. ***(2)*** Secreted IgE binds to IgE-specific receptors on the mast cell. ***(3)*** Additional soluble parasite antigen cross-links the IgE on the mast cell surface, ***(4)*** leading to mast cell degranulation and release of many proinflammatory products, including eosinophil chemotactic factor of anaphylaxis (ECF-A). ***(5)*** ECF-A attracts eosinophils from the circulation. ***(6)*** The eosinophil attaches to the parasite's surface and releases potent lysosomal enzymes that damage microorganisms.

An illustrated flowchart tracks the immunoglobulin E function. The following structures are illustrated in the flowchart: Parasite antigens, B cell, I g E, mast cell, E C F-A, endothelium, eosinophil (diapedesis), and parasite.

When IgE is produced against relatively innocuous environmental antigens, it is also the primary cause of common allergies (e.g., hay fever, dust allergies, bee stings). Monoclonal antibodies are used to block the functions of IgE in individuals who have a severe allergy. The role of IgE in allergies is discussed in Chapter 9.

IgE is also capable of activating ADCC. Recent studies suggest that it may be possible to use IgE-mediated ADCC to increase the effectiveness of immune cells that invade tumors but are otherwise unable to detect and kill the cancer cells.[15]

Secretory Immune System

Immunocompetent lymphocytes migrate among secondary lymphoid organs and tissue as part of the systemic immune system. Another partially independent immune system protects the external surfaces of the body through lacrimal and salivary glands and a network of lymphoid tissues residing in the breasts, bronchi, intestines, and genitourinary tract known as mucosal-associated lymphoid tissues (MALTs). This system is called the secretory (mucosal) immune system (Fig. 8.16). Plasma cells in those sites secrete antibodies in bodily secretions, such as tears, sweat, saliva, mucus, and breast milk, to prevent pathogenic microorganisms from infecting and penetrating the body's surfaces.

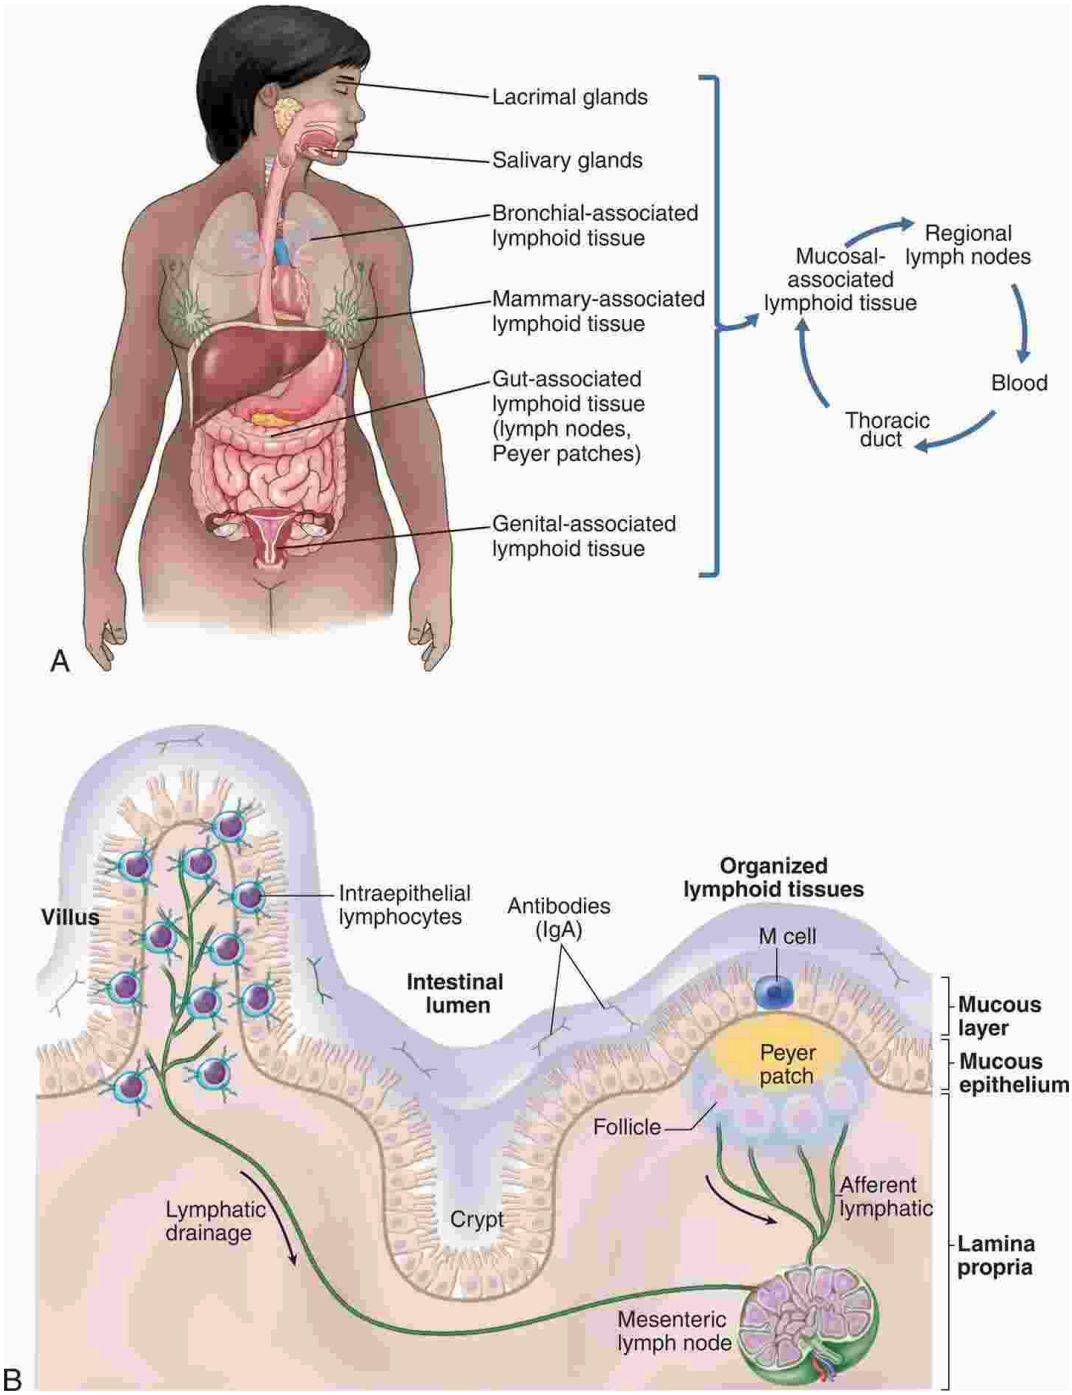

FIG. 8.16 Secretory Immune System.
(A) Lymphocytes from the mucosal-associated lymphoid tissues (MALTs) circulate throughout the body in a pattern separate from other lymphocytes. For example, lymphocytes from the gut-associated lymphoid tissue circulate through the regional lymph nodes, the thoracic duct, and the blood and return to other MALTs rather than

to lymphoid tissue of the systemic immune system. **(B)** Lymphoid tissue associated with mucous membranes is referred to as MALT.

Panel A is an illustration of the anterior view of a human, highlighting its internal organs. The following parts are labeled on the illustration, from the top to the bottom: lacrimal glands, salivary glands, bronchial-associated lymphoid tissue, mammary-associated lymphoid tissue, gut-associated lymphoid issue (lymph nodes, Peyer patches), and genital-associated lymphoid tissue. A cycle diagram linked to the illustration shows the following stages: mucosal-associated lymphoid tissue, regional lymph nodes, blood, and thoracic duct. Panel B is an illustration of the following layers of intestinal lumen, from the top to the bottom: mucous layer, mucous epithelium, and lamina propria. Antibodies (I g A) in the mucous layer bind to the intraepithelial lymphocytes, leading to lymphatic drainage. A sunken section on the mucous epithelium layer is labeled, crypt. An M cell is embedded between the epithelial cells with villi, above a Peyer patch surrounded by follicles. The follicles are linked through the afferent lymphatic to the mesenteric lymph node.

IgA is the dominant secretory immunoglobulin, although IgM and IgG also are present in secretions. The primary role of IgA is to prevent the attachment and invasion of pathogens through mucosal membranes, such as those of the gastrointestinal, pulmonary, and genitourinary tracts. Dimeric IgA antibodies are produced by plasma cells in the mucosa. Mucosal epithelium expresses a cell surface receptor that binds and internalizes IgA. The IgA, along with the epithelial receptor, is secreted as secretory IgA (sIgA). This sIgA protects against a variety of pathogens as well as helps to maintain a healthy microbiome in the gut.[16]

The lymphoid tissues of the secretory immune system are connected; thus, many foreign antigens in a mother's gastrointestinal tract (e.g., polio virus) induce the secretion of specific antibodies into breast milk. Colostral antibodies (i.e., those found in the colostrum of breast milk) may protect the nursing newborn against infectious disease agents that enter through the infant's gastrointestinal tract. Although colostral antibodies provide the newborn with passive immunity against gastrointestinal infections, they do not provide systemic immunity because the transport of these antibodies across the newborn's gut into the bloodstream is discontinued after the first 24 hours of life. Maternal antibodies that pass across the placenta into the fetus before birth provide passive systemic immunity.

Primary and Secondary Humoral Immune Responses

The immune response to antigen has classically been divided into two phases —primary and secondary responses. Although these two phases occur in cellular immune responses, this process is most easily demonstrated by measuring concentrations of circulating antibodies over time (Fig. 8.17). After a single initial exposure to most antigens, there is a latent period, or lag phase, during which clonal selection occurs. After approximately 5 to 7 days, IgM antibody is detected in the circulation. This is the primary immune response, typically characterized by IgM's initial production followed by IgG production against the same antigen. The quantity of IgG may be about equal to or less than the amount of IgM. The amount of antibody in a serum sample is frequently referred to as the titer; a higher titer indicates more antibodies. If no further exposure to the antigen occurs, the circulating antibody is catabolized (broken down), and titers fall. The individual's immune system, however, has been primed.

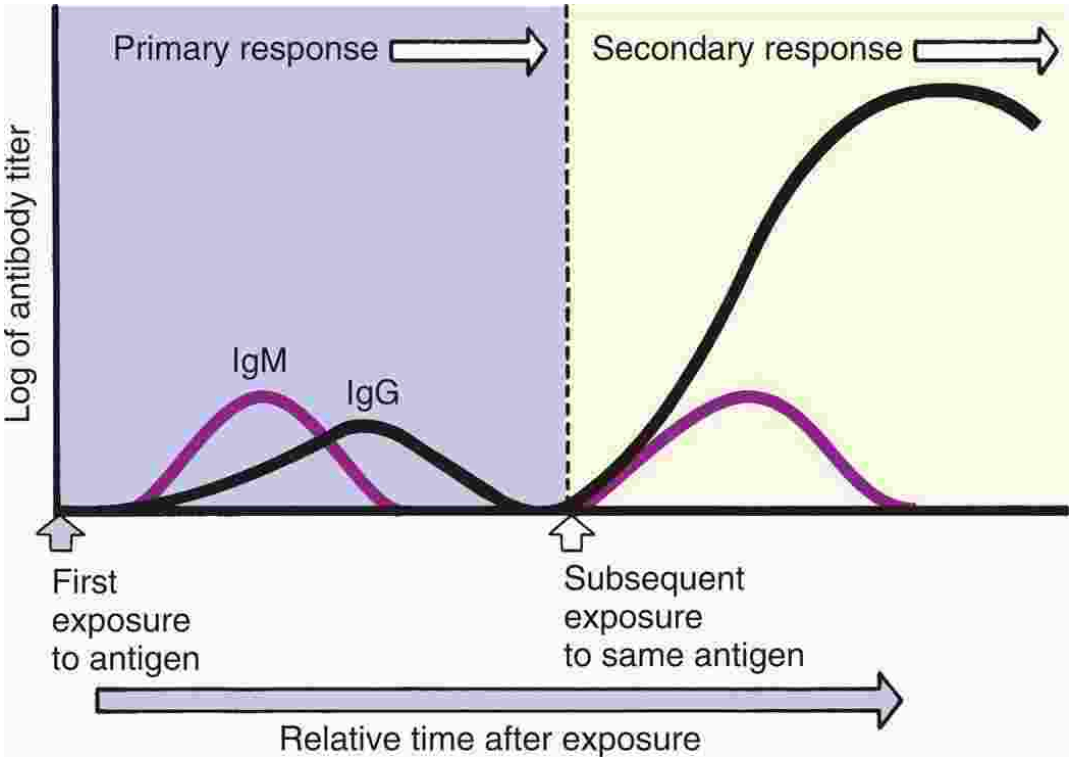

FIG. 8.17 Primary and Secondary Immune Responses. The initial administration of antigen induces a primary response during which immunoglobulin M *(IgM)* is initially produced, followed by immunoglobulin G *(IgG)*. Another administration of the antigen induces the secondary response in which IgM is transiently produced, and larger amounts of IgG are produced over a longer period.

A graph plots log of antibody titer against relative time after exposure. The horizontal axis marks to ticks: first exposure to antigen, at the origin, and subsequent exposure to same antigen, at the center of the axis. Primary response spans the distance between the origin and the center of the axis. Secondary response spans the distance beyond the center of the axis. I g M is a series of two, continuous, similar-looking waves, one in the primary response section and the other in the secondary response section. I g G is a series of two continuous waves. The wave in the primary response section is shorter and wider than the

corresponding I g M wave. The wave in the secondary response section is almost three times as tall as the corresponding I g M wave.

A second challenge by the same antigen results in the secondary immune response, characterized by the more rapid production of a larger amount of antibody compared with the primary response. The rapidity of the secondary immune response is the result of memory cells that are already differentiated. IgM may be transiently produced in the secondary response, but IgG production is increased considerably, making it the predominant antibody class. Natural infection (e.g., rubella) may result in measurable levels of protective IgG for the individual's life. Some vaccines (e.g., polio) also may produce extremely long-lived protection, although many vaccines require boosters at specified intervals.

Clinical Uses of Antibodies

Antibodies have many protective, diagnostic, and therapeutic uses in clinical settings (Table 8.2).[17] Because the secondary immune response takes time to develop, individuals with recent or potential exposure to a serious infectious agent may benefit from administering preformed antibody in a process termed passive immunity (passive acquired immunity). Examples include individuals exposed to an infectious agent without preexisting vaccine-induced immunity (e.g., hepatitis A virus or severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]). Antibodies also may be measured in the blood in individuals suspected of having an acute, chronic, or past infection (e.g., hepatitis B). The measurement of circulating antibody is also useful in diagnosing cancer, allergies, and autoimmune diseases (see Chapters 9 and 12). Passive treatment with antibodies is available for only a few infections (e.g., respiratory syncytial virus infection and SARS-CoV-2). However, it is now a common procedure to administer monoclonal antibodies to treat a wide variety of neoplastic, allergic, and autoimmune conditions (see Emerging Science Box: Monoclonal Antibodies).[18]

Emerging Science BoxMonoclonal Antibodies

Monoclonal antibodies (mAb) are produced in the laboratory from one B cell that has been cloned; thus, all the antibodies produced are of the same class, specificity, and function. The advantages of monoclonal antibodies are that (1) a single antibody of known antigenic specificity is generated

rather than a mixture of different antibodies; (2) monoclonal antibodies have a single, constant binding affinity; (3) monoclonal antibodies can be diluted to a constant titer (concentration in fluid) because the actual antibody concentration is known; and (4) the antibody can be easily purified. mAbs have been created and used to develop extremely specific and sensitive laboratory tests (e.g., home and laboratory pregnancy tests) and therapies. The therapeutic uses of mAbs have expanded exponentially over the past decade. The generic names of these drugs are usually easy to recognize because most end in the letters mAb. Current treatment options using mAbs are available for a wide variety of inflammatory, autoimmune, neurologic, vascular, and clotting disorders such as collagen vascular diseases (e.g., rheumatoid arthritis and systemic lupus erythematosus), asthma and allergy, inflammatory bowel disease, multiple sclerosis, migraine, atherosclerosis, and transplant rejection. One of the most exciting groups of mAbs in use today are those that block the ability of cancer cells to turn off immune cells that are trying to attack them (checkpoint inhibitors—see Chapter 12). Among the newest uses being explored for mAb is the treatment of anti-microbial resistant infections. Many more uses of mAb are being explored.

Cell-Mediated Immunity

Cell-mediated immunity (or cellular immunity) is conducted primarily by Tc cells. Natural killer cells and phagocytes (macrophages and neutrophils) also play a role. Cellular immunity most often destroys the target cell.

T-Cytotoxic Cells

Tc cells are activated when their TCRs detect foreign intracellular antigens presented on MHC I molecules. They attack infected and damaged cells and destroy them.

T Cytotoxic Cell Activation

The differentiation of immunocompetent T cells into effector Tc cells requires similar intercellular communications as described for Th cells. The Tc cell TCR recognizes antigen presented by MHC class I molecules on the surface of the APC and virus-infected or cancerous cells (Fig. 8.18). The Tc cell CD8 binds to the MHC class I molecule, which initiates cytoplasmic signaling

pathways that promote differentiation of the Tc cell. L-2 produced by Th1 cells and other cytokines activate receptors on the Tc cells resulting in proliferation and further differentiation into active Tc cells.[3]

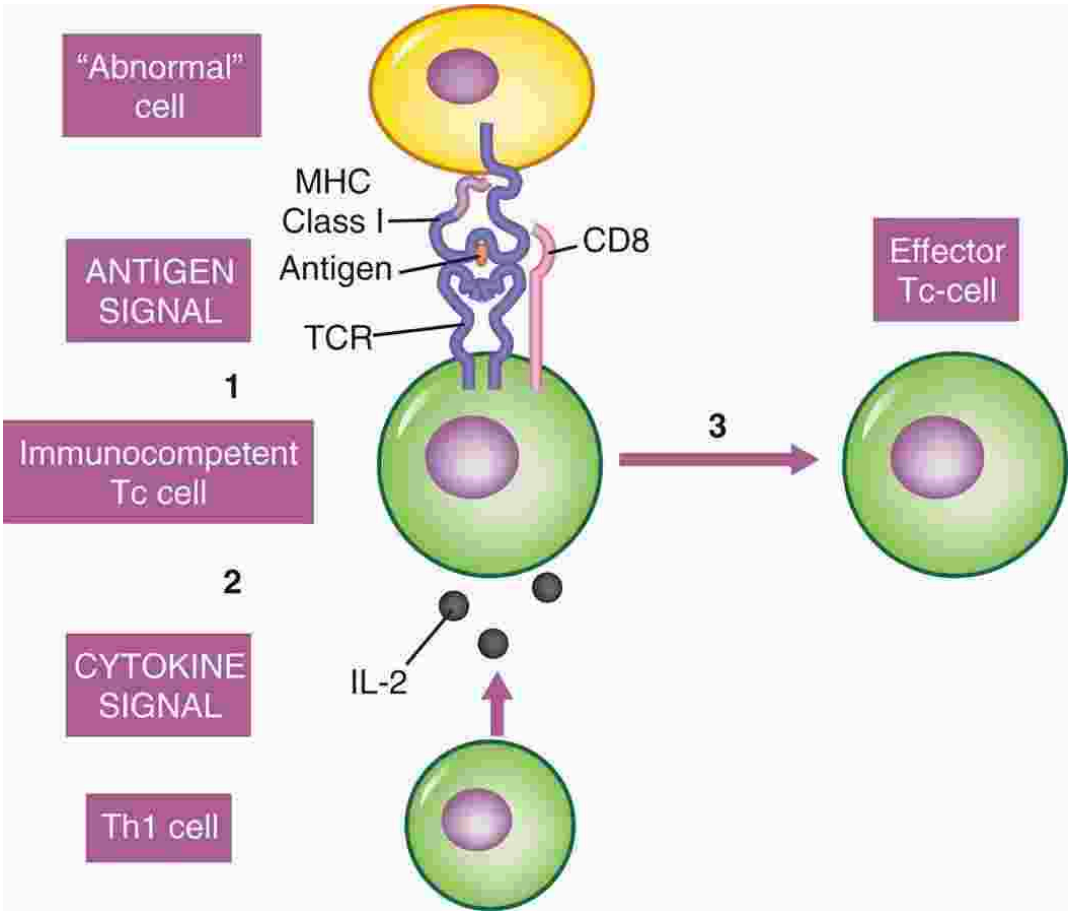

FIG. 8.18 T-Cytotoxic (Tc)-Cell Activation.
The immunocompetent Tc cell can react with antigen but cannot yet kill target cells. During clonal selection, this cell reacts with antigen presented by major histocompatibility complex class I (MHC I) molecules on the surface of a virally infected or cancerous *abnormal* cell. ***(1)*** The antigen–MHC I complex is recognized simultaneously by the T-cell receptor *(TCR)*, which binds to antigen, and CD8, which binds to the MHC I molecule. ***(2)*** A separate signal is provided by cytokines, particularly IL-2 from T-helper 1 *(Th1)* cells. ***(3)*** In response to these signals, the Tc cell develops into an effector Tc cell with the ability to kill abnormal cells.

An illustrated flowchart tracks the sequence of T-cytotoxic (T c)-cell activation. The illustration shows an abnormal cell. An antigen binds to the M H C class 1. T C R and C D 8

bind to the immunocompetent T c cell. T h 1 cell sends cytokine signals (I L-2), resulting in the effector T c-cell.

T Cytotoxic Cell Function

Tc cells are responsible for the cell-mediated destruction of abnormal cells, such as tumor cells or cells infected with viruses (Fig. 8.19). Tc cells form tight connections to the target cell through the action of adhesion molecules (integrins). Attachment to a target cell activates Tc killing mechanisms. The primary Tc killing mechanism is the release of perforins and granzymes from granules within the Tc cell. Perforins facilitate granzyme entry into the target cell. Granzyme B from Tc cells activates intracellular caspases in the target cell, which induces apoptosis. Tc cells also express a surface protein called Fas ligand. This protein binds to a receptor on the surface of the target cell, leading to caspase-mediated apoptosis. Cells that have undergone apoptosis are phagocytosed and removed from the body. Tc cells that have killed a target cell can detach and go on to kill other cells.

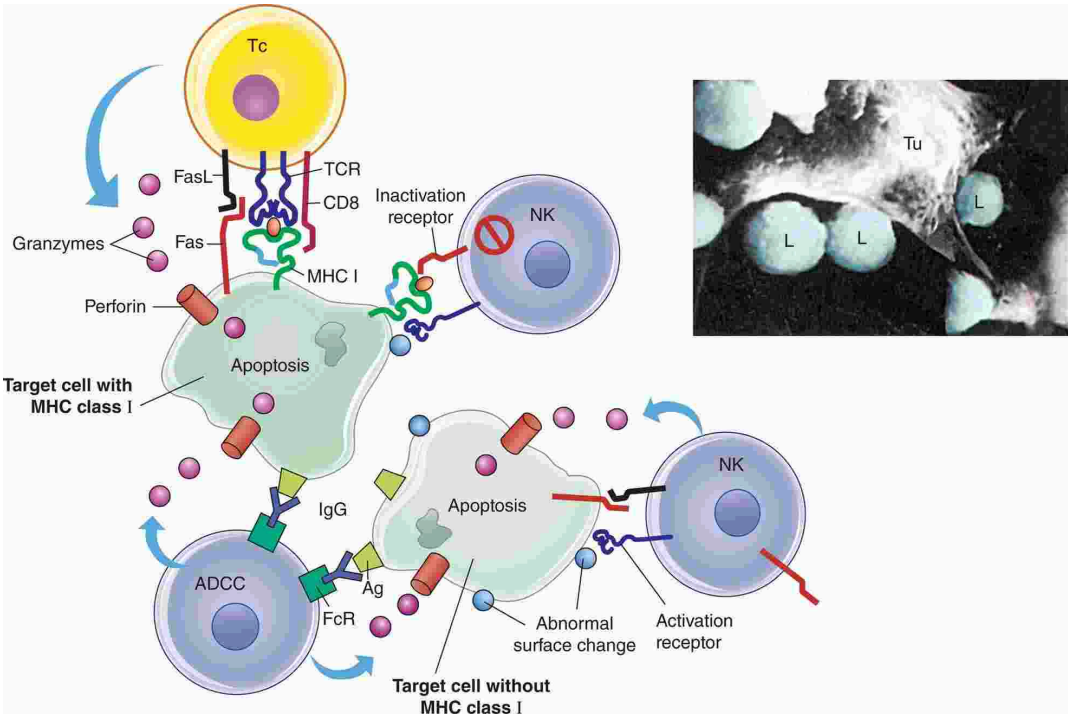

FIG. 8.19 Cellular Killing Mechanisms.
Several cells can kill abnormal (e.g., virally infected, cancerous) target cells. T-cytotoxic *(Tc)* cells recognized endogenous antigen presented by major histocompatibility complex *(MHC)* class I molecules *(cell on upper left)*. The intercellular interaction is enhanced through a variety of costimulatory adhesion molecules (not shown). The Tc cell mobilizes multiple killing mechanisms that induce apoptosis of the target cell. Tc cells contain granules that empty their contents into the target cell. These substances include perforin, which creates pores in the target cell, and granzymes which enter through these pores and induce apoptosis. Tc cells also provide stimulation of Fas molecules on the target cell surface by Fas ligand *(FasL)* on the Tc cell, which also induces apoptosis. Natural killer *(NK)* cells use the same mechanisms to kill target cells but do so through activation of non-MHC-dependent receptors that recognize abnormal surface changes on damaged, cancerous, or infected cells (*cell on bottom right*). NK cells specifically kill cancer cells that have down-regulated expression of surface MHC class I molecules. Target cells that express MHC class I molecules inactivate NK cells through various inactivation receptors *(cell on upper right)*.

Several cells, including macrophages and NK cells, can kill by antibody-dependent cell-mediated cytotoxicity *(ADCC)*. IgG antibody binds to foreign antigen on the target cell. Cells involved in ADCC *(cell on lower left)* bind IgG through Fc receptors *(FcRs)* and initiate killing. The insert is a scanning electron microscopic view of Tc cells *(L)* attacking a much larger tumor cell *(Tu)*. (*Insert* from Abbas A, Lichtman A. *Cellular and molecular immunology*, 5th edition. Philadelphia: Saunders; 2003.)

An illustration shows a T c cell, a target cell with M H C class 1, a target cell without M H C class 1, an A D C C, and two N K cells. Structures the binding the T c cell to the target cell with M H C class 1 are Fas L, T C R, C D 8, Fas, and M H C 1. There is an inactivation receptor between an N K cell and the target cell with M H C class 1. An I g G with F c R and A g binds the A D C C with both the target cells. Activation receptor from the second N K cell binds to the target cell without M H C class 1. Granzymes are released by the T c, A D C C, and N K cells. Abnormal surface change units surround the target cells. An accompanying photomicrograph shows a large tumor cell, T u, surrounded by T c cells, L.

Natural Killer Cells

Natural killer (NK) cells are a special group of lymphoid cells that are important components of both innate and adaptive immunity. They are similar to T cells but lack antigen-specific receptors. Instead, they express various cell surface activation receptors (see Fig. 8.19), which identify protein changes on the surface of cells infected with viruses or that have become cancerous. After attachment, the NK cell kills its target like that of Tc cells. Unlike Tc cells, NK cells lack CD8, and binding to MHC class I molecules results in the inactivation of the NK cell. Thus, if MHC class I antigen presentation has occurred, Tc cells provide the target cell killing. But in some

instances, a virus-infected or cancerous cell will "protect" itself from Tc cells by downregulating MHC class I molecule expression. In these instances, the lack of MHC class I inhibition allows NK cells to become activated and kill the target cell. Modified NK cells are being used in a variety of approaches to cancer immunotherapy.[19,20] NK cells and some macrophages can also specifically target abnormal cells by linking to antibodies that are bound to foreign antigens on these cells. NK cells express Fc receptors for IgG. If antigens on the infected or cancerous cell bind IgG, the NK cell can attach through Fc receptors and activate its standard killing mechanisms via ADCC (see Fig. 8.19).[21]

Macrophages

In addition to their vital roles in initiating innate and adaptive immune responses, macrophages are important effector cells of cell-mediated immunity. After binding to the presented antigen, Th1 cells adhere loosely to macrophages resulting in intercellular communication via costimulatory molecules such as CD40 and CD40 ligand (CD40L) (Fig. 8.20). The Th1 cells secrete interferon-γ (IFN-γ). IFN-γ induces the macrophages to become M1 macrophages which release proinflammatory cytokines and kill infected cells within their phagolysosomes (described in Chapter 7). Activated M1 macrophages also can contribute to a wide range of autoimmune conditions through a process called *delayed hypersensitivity*. (see Chapter 9)

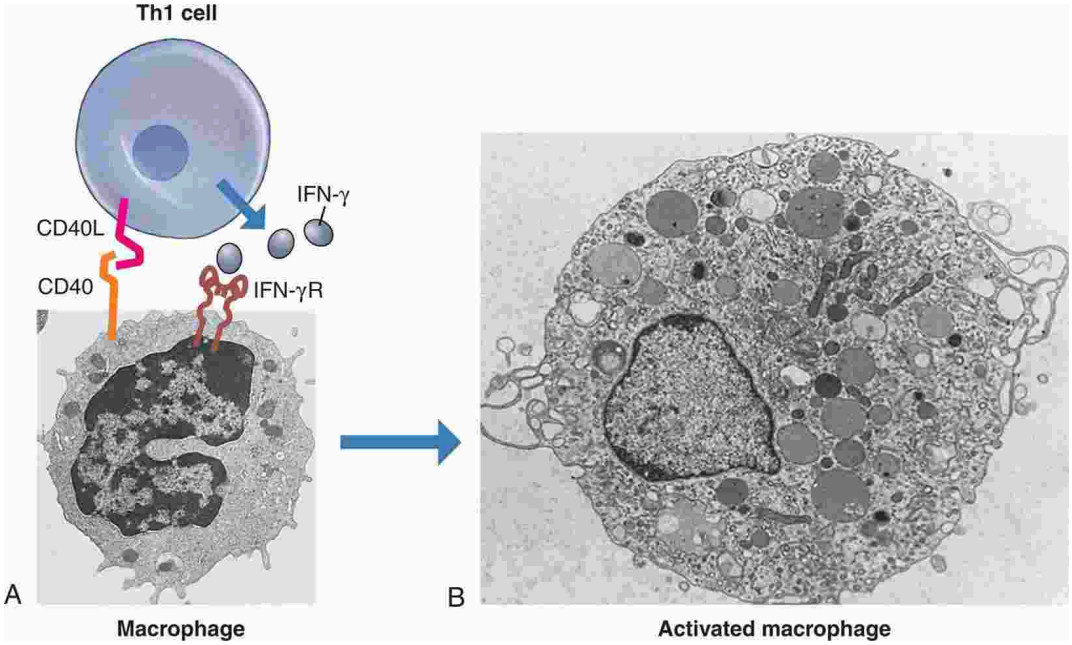

FIG. 8.20 Activation of a Macrophage by a T Cell. *Th1* cells produce cytokines that activate macrophages. Optimal macrophage activation also requires close contact among the cells, mediated by a variety of costimulatory molecules expressed on the surface of each cell (CD40L and CD40 shown here). *CD40L*, CD40 ligand; *IFN-γ*, interferon-gamma; *IFN-γR*, receptor for interferon-gamma. (Micrograph in [A] courtesy Dr. Noel Weidner, Department of Pathology, University of California, San Diego. [B] From Fawcett DW. Bloom and Fawcett: *A textbook of histology*, 12th edition. New York: Chapman & Hall; 1994. With kind permission of Springer Science and Business Media.)

Left panel, A. An illustration of a T h 1 cell and a photomicrograph of a macrophage are bound by C D 40 L and CD 40, respectively. I F N-gamma from the T h 1 cell are attracted to the I F N-gamma R, leading to activation of the macrophage. Right panel, B. A photomicrograph of an activated macrophage cell. Macrophage is located within tissue, showing the nucleus at the center left and numerous lysosomes and vesicles as dark spots scattered within the cytoplasm. Mitochondria as oval-shaped are present in

cell's cytoplasm. A slender finger-like extensions of the surface membrane are also present.

Immunologic Memory

During the activation (clonal selection) process, both B cells and T cells differentiate and proliferate into a large population of long-lived memory cells. Memory cells remain inactive until subsequent exposure to the same antigen. Upon re-exposure, these memory cells do not require the multiple cellular activation steps described previously and will therefore rapidly become new plasma cells or effector T cells. The establishment and maintenance of immunologic memory is complex and essential to host defenses (see Emerging Science Box: Immunologic Memory).[22]

Emerging Science BoxImmunologic Memory

Memory B and T cells can facilitate the generation of large numbers of effector Th, Tc, and antibody-producing plasma cells. This immunologic memory of the adaptive immune system is crucial to gaining more rapid and effective immune responses upon secondary exposures to invasion and injury. The processes that underlie immunologic memory are highly complex. For example, it is now known that there are several different types of T memory cells (T effector memory cells, T central memory cells, tissue T resident memory cells, and T stem cell memory cells). B-cell immunologic memory is also similarly complex, including the presence of different B memory cell morphologies (e.g., T-bet+ B cells) and long-lived effector plasma cells. Furthermore, these cells undergo multiple structural and functional adaptations over time (e.g., plasticity, priming, and exhaustion). The epigenetic and metabolic changes that control when and how these memory cells are maintained and activated are still being explored. To further complicate these processes, it is now known that cells of innate immunity such as monocytes, macrophages, natural killer cells, and innate lymphoid cells are also capable of immunologic memory. After exposure to an invader or injury, these cells undergo long-term changes in their metabolism and epigenetic programming, which changes their responses to secondary exposures. This type of innate immunologic memory is called “trained immunity.” Cutting-edge research is exploring techniques to modulate both adaptive and trained immunologic memory to achieve a better balance between immune attack and tolerance to

antigens. Therapeutic uses could include down-regulation of these processes for conditions characterized by excessive immunity such as autoimmune disorders or enhancement of these processes for conditions driven by inadequate immunity such as cancer and chronic infections.

Pediatric Considerations

Mechanisms of Self-Defense in the Newborn Child

The average human infant is immunologically immature at birth. Healthy development of the neonatal immune system is essential to long-term health. Although cell-mediated immunologic capabilities begin developing early in gestation and probably are entirely functional at birth, phagocytic activity, antibody production, and complement activity are clearly deficient. In the last trimester, the fetus appears capable of producing a primary immune response (almost entirely IgM) to in utero infections (e.g., cytomegalovirus, rubella virus, and *Toxoplasma gondii*) but is unable to produce a significant IgG response. Although some IgA can be detected, the capacity to produce IgA is underdeveloped.

To protect the child against infectious agents both in utero and during the first few postnatal months, a system of active transport facilitates the passage of maternal antibodies into the fetal circulation (Fig. 8.21). In the placenta, maternal and fetal blood are separated by a layer of specialized multinucleate cells termed *syncytiotrophoblasts*. Immunoglobulins are too large to diffuse across this cellular layer, so the trophoblastic cells actively transport immunoglobulins from the maternal to the fetal circulation. Active transport of maternal IgG is mediated by surface receptors specific to the Fc portion of free IgG but not for IgM, IgE, or IgA. In addition to

antibodies, maternal cytokines and cells are transferred in utero and influence the fetal immune system. Maternal vaccination has been promoted as a way of increasing the amount of antibody transferred to the fetus to protect the child after birth. This has decreased the antibody titers after newborn vaccination, but cellular immunity in the infant remains intact.

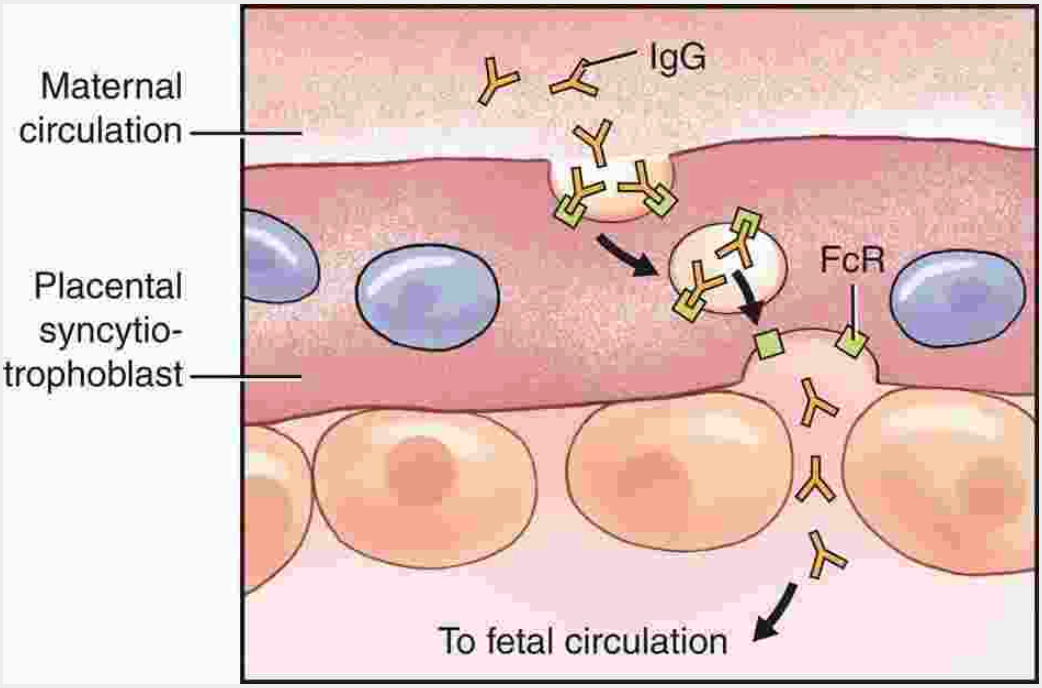

FIG. 8.21 Transport of IgG Across the Syncytiotrophoblast.
The human placenta is covered with a specialized multinucleated cell, the syncytiotrophoblast. Transport of maternal immunoglobulin G (IgG) across the syncytiotrophoblast and into the fetal circulation is an active process. Maternal IgG binds to Fc receptors on the surface of the syncytiotrophoblast and is internalized by the process of endocytosis. Receptors on the syncytiotrophoblast are specific for the Fc portion of IgG and do not bind other classes of immunoglobulins. Interaction of IgG with Fc receptors protects the antibody from lysosomal digestion during transport of the vacuole across the cell (i.e., transcytosis). On the fetal side of the syncytiotrophoblast, IgG is released by exocytosis (see Chapter 1). (From McCance K, Huether S. *Pathophysiology*, 8th edition. St. Louis: Elsevier; 2019.)

An illustration demonstrates the transport of I g G across the syncytiotrophoblast. The illustration shows three layers, from the top to the bottom: maternal circulation, placental syncytiotrophoblast, and fetal circulation. I g G

from the maternal circulation binds to the placental syncytiotrophoblast and is released through the F c R to the fetal circulation.

At birth, total IgG levels in the umbilical cord are near adult levels (Fig. 8.22). When the source of maternal antibodies is severed at birth, antibody titers in the newborn begin to drop as the maternal antibody is catabolized. Thus, antibody titers drop rapidly as the neonate's production of IgG is beginning to rise. The rate of catabolism is usually more rapid than the production rate so that the total immunoglobulin levels reach a minimum at 5–6 months in the typical child, occasionally causing transient hypogammaglobulinemia (insufficient quantities of circulating immunoglobulins). Many normal infants experience recurrent mild respiratory tract infections at this age.

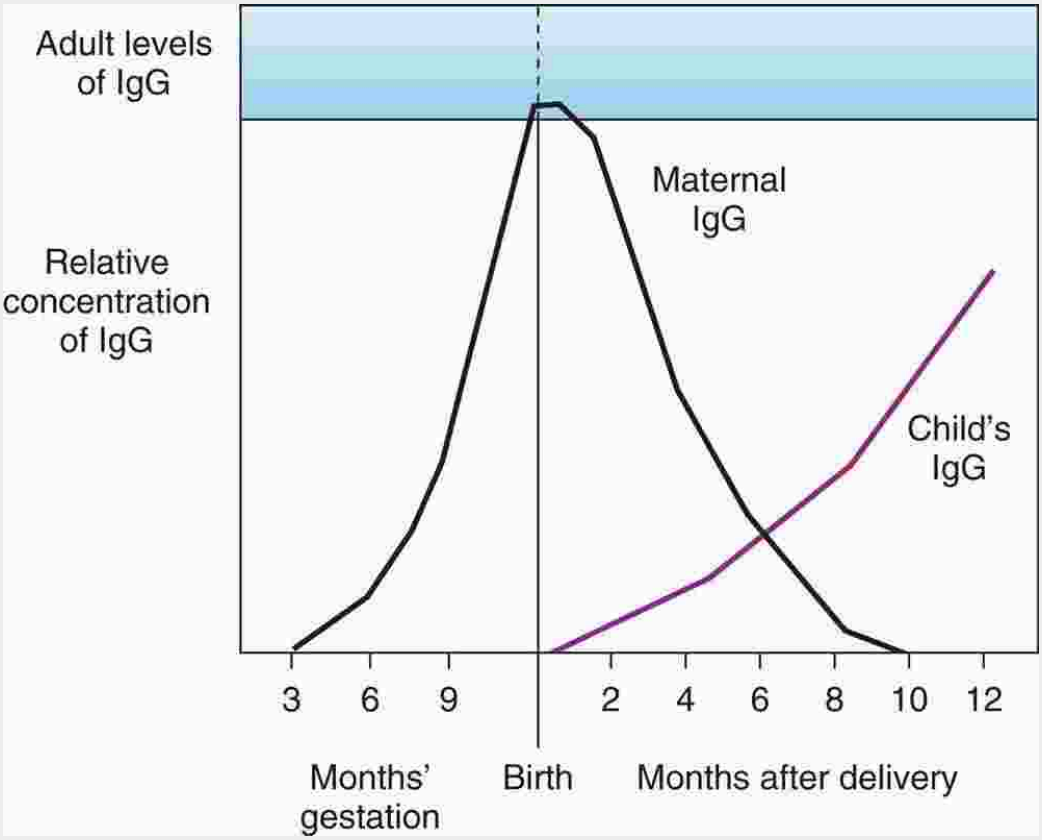

FIG. 8.22 Antibody Levels in Umbilical Cord Blood and Neonatal Circulation.
Early in gestation, maternal IgG begins crossing the placenta and enters the fetal circulation. At birth, the fetal circulation may contain nearly adult levels of IgG, which is almost exclusively from the maternal source. The fetal immune system can produce IgM and small amounts of IgA before birth (not shown). After delivery, maternal IgG is rapidly catabolized, and neonatal IgG production increases. (From McCance K, Huether S. *Pathophysiology*, 8th edition. St. Louis: Elsevier; 2019.)

A graph plots the concentration of I g G over a period. The horizonal axis shows three sections: months' gestation (3, 6, 9), birth, and months after delivery (2, 4, 6, 8, 10, 12). The vertical axis shows relative concentration of I g G with adult levels of I g G identified at the top. The maternal I g G is plotted as a curve that rises from 3 on the horizontal

axis to adult levels of I g G at birth and then falls to 10 on the horizontal axis. The child's I g G is a staggering upward slope from birth toward adult levels of I g G at 12 months after delivery.

Geriatric Considerations

Aging and Immune Function

Adaptive immune function decreases with age due to changes in both lymphocyte function and relative lymphocyte populations due to a process called *immunosenescence*. These changes render the older individual more susceptible to infectious disease and cancer and less able to respond to vaccination. The ability to respond to new antigens diminishes as the number of peripheral naïve T and B cells declines. The thymus, where T cells begin their development, reaches its maximum size at sexual maturity, and then undergoes involution until the thymus is only 15% of its maximum size by middle age. A decrease in thymic activity is accompanied by decreased production of thymic hormones, and the capacity to mediate T-cell differentiation decreases with this atrophy. The capacity for Th cells to produce IL-2 declines, yet there is a shift in the populations of T-cell subtypes, with Tc cells significantly outnumbering Th cells. This dysfunction is coupled with increased T cell senescence and exhaustion. B-cell function is altered with age, as shown by decreases in specific antibody production in response to antigenic challenge. A decline

in the number of circulating memory B cells is also observed. In the elderly, there is an increase in a subset of B cells called *age-associated B cells (ABCs)*. ABCs are paradoxically associated with the increased presentation of antigen, the release of cytokines, and secretion of antibodies; however, a significant proportion of these antibodies are autoantibodies and contribute to autoimmune disease. The combined effects of T and B lymphocyte dysfunction increase the risk for disease in the elderly. In addition, immune responses to vaccination are diminished, rendering older individuals more vulnerable to infections such as influenza and SARS-CoV-2 even in vaccinated individuals. In addition to these direct effects of aging on the adaptive immune system, the development of comorbidities in the elderly influences the immune response. Cardiovascular, pulmonary, renal, and hepatic diseases are associated with immune dysfunction, especially prevalent in the elderly.

Summary Review

Overview of Adaptive Immunity

1. Adaptive immunity is a state of protection, primarily against infectious agents, that differs from inflammation by being slower to develop, being more specific, and having memory that makes it much longer lived.

2. The adaptive immune response is most often initiated by cells of the innate system. These cells process and present portions of invading pathogens (i.e., antigens) to lymphocytes in peripheral lymphoid tissue.
3. The adaptive immune response is mediated by two types of lymphocytes—B lymphocytes and T lymphocytes. Each has distinct functions. B cells are responsible for humoral immunity that is mediated by circulating antibodies, whereas T cells are responsible for cell-mediated immunity, in which they kill targets directly or stimulate the activity of other leukocytes.
4. B and T lymphocytes leaving the primary lymphoid organs are immunocompetent but have not been exposed to antigen, thus are naïve.
5. Clonal selection with cellular proliferation and further differentiation of T and B cells into active effort cells of the adaptive immune system is initiated when exposure to an antigen occurs.

Antigens

1. Antigens are molecules that bind and react with components of the immune response, such as antibodies and receptors on B and T cells.
2. Common antigens include infectious agents, allergens, chemical agents, and abnormal molecules on the surface of cells.
3. Large molecules, such as proteins, polysaccharides, and nucleic acids, are most immunogenic. Thus, molecular size is a crucial factor for antigen immunogenicity.
4. Haptens are antigens too small to be immunogens by themselves but become immunogenic after combining with larger molecules.
5. The antigenic determinant, or epitope, is the precise chemical structure with which an antibody or B-cell/T-cell receptor (BCR/TCR) reacts.
6. Self-antigens are antigens on an individual's own cells. The individual's immune system does not usually recognize self-antigens as immunogenic, a condition known as *tolerance*.

Lymphocyte Development

1. The generation of clonal diversity results in the production of B and T lymphocytes with receptors against millions of antigens that possibly will be encountered in an individual's lifetime occurs in the fetus in

the primary lymphoid organs: the thymus for T cells and portions of bone marrow for B cells.

2. The generation of clonal diversity is the differentiation of lymphoid stem cells into B and T lymphocytes with specific BCRs and TCRs, respectively.
3. The enormous repertoire of BCR specificities is made possible by rearranging existing deoxyribonucleic acid (DNA) during B-cell development in the primary lymphoid organs, a process called *somatic recombination*.
4. Somatic rearrangement of the antibody variable regions will frequently result in a BCR that recognizes the individual's own antigens, which may result in attack on "self" antigens expressed on various tissue and organs. Many of these "autoreactive" B cells are eliminated in the bone marrow. Most of the developing B cells undergo apoptosis. This entire process is referred to as clonal deletion or central tolerance.
5. Treg cells are a diverse group of T cells that control the immune response, usually suppressing the response and maintaining tolerance against self-antigens. Treg cells produce very high levels of immunosuppressive cytokines, which induce tolerance.
6. The process of T-cell proliferation and differentiation is similar to that for B cells. The primary lymphoid organ for T-cell development is the thymus. Lymphoid stem cells travel through the thymus, where they gain a TCR, and receptors become immunocompetent. Self-reactive T cells undergo clonal deletion.
7. Proteins called *CD4* and *CD8* are expressed on the developing T cells. As the cell matures, it retains either the CD4 molecule or the CD8 molecule but not both. Eventually, CD4 cells develop into T-helper cells (Th cells), and CD 8 cells become T-cytotoxic cells (Tc cells). Other mature T cells include T-regulatory cells (Treg cells) and memory cells.
8. The generation of clonal diversity concludes when immunocompetent T and B cells migrate from the primary lymphoid organs into the circulation and secondary lymphoid organs to await antigen.

Induction of the Adaptive Immune Response

1. The induction of an immune response, or clonal selection, begins when antigen enters the individual's body and interacts with antigen-

presenting cells (APCs) (e.g., dendritic cells, macrophages, and B cells).
2. To induce an optimal cellular or humoral immune response, APCs must present antigens to Th cells. Antigen is processed in the APCs and presented on the cell surface by molecules of the major histocompatibility complex (MHC). The particular MHC molecule (class I or class II) that presents antigen determines which cell will respond to that antigen. Th cells require that the antigen be presented in a complex with MHC class II molecules. MHC class II molecules are found only on APCs. Tc cells require that the antigen be presented by MHC class I molecules.
3. The T cell binds to the presented antigen through the TCR and accessory molecules: CD4 or CD8. CD4 is found on Th cells and reacts specifically with MHC class II. CD8 is found on Tc cells and reacts specifically with MHC class I.
4. Further differentiation of these Th0 cells results in the formation of Th1 cells, which help Tc cells respond to antigen; Th2 cells, which help B cells develop into plasma cells; and Th17 cells, which help activate macrophages.

Humoral Immunity (Antibodies)

1. The humoral immune response consists of molecules (antibodies) produced by B cells. B cells are lymphocytes. B cells can detect antigen with their BCR molecules and differentiate into APCs that interact closely with Th cells.
2. Th cell activation by B cells results in the production of IL-4, which, along with costimulatory molecules CD40 and CD40L, activate the B cell to become an antibody-producing plasma cell.
3. B cells can also be activated to become antibody-producing plasma cells through a T-cell independent process.
4. A typical antibody molecule is constructed of two identical heavy chains and two identical light chains (either κ or λ) and has two Fab portions that bind antigen and an Fc portion that interacts with complement or receptors on cells.
5. Antibodies are plasma glycoproteins that can be classified by chemical structure and biologic activity as immunoglobulin G (IgG), IgM, IgA, IgE, or IgD.

6. The protective effects of antibodies may be *direct* through the action of antibody alone or *indirect*, requiring activation of other components of the innate immune response.
7. IgE is a special class of antibody produced against environmental antigens that are the primary cause of common allergies. It also protects the individual from infection by large parasitic worms (helminths).
8. The secretory immune system protects the external surfaces of the body through the secretion of antibodies in bodily secretions, such as tears, sweat, saliva, mucus, and breast milk. IgA is the dominant secretory immunoglobulin.

Cell-Mediated Immunity

1. The cells of cell-mediated immunity include Tc cells, NK cells, and macrophages. These cells kill damaged, cancerous, or infected cells,
2. Tc cells bind with antigen presented on the MHC I molecule on an APC. This, along with IL-2 from Th cells, activates the Tc cell.
3. Tc cell attachment to a target cell activates multiple killing mechanisms through which the target cell is induced to undergo apoptosis.
4. Natural killer (NK) cells are a special group of lymphoid cells that express various cell surface activation receptors that identify protein changes on the surface of cells infected with viruses or that have become cancerous. After attachment, the NK cell kills its target like that of Tc cells.
5. Macrophages are activated by interferon-γ (IFN-γ). From Th1 cells. Activated M1 macrophages secrete proinflammatory cytokines and kill infected cells within their phagolysosomes.

Immunologic Memory

1. When T and B cells are activated, they make long-lived copies of themselves called memory cells.
2. Upon re-exposure, these memory cells will rapidly become new plasma cells or effector T cells

Pediatric Considerations: Age-Related Factors Affecting Mechanisms of Self-Defense in the Newborn

Child

1. Neonates often have a transiently depressed inflammatory function, particularly neutrophil chemotaxis and alternative complement pathway activity.
2. The T cell-independent immune response is adequate in the fetus and neonate, but the T cell-dependent immune response develops slowly during the first 6 months of life.
3. Maternal IgG antibodies are transported across the placenta into the fetal blood and protect the neonate for the first 6 months, after which they are replaced by the child's own antibodies.

Geriatric Considerations: Age-Related Factors Affecting Mechanisms of Self-Defense in the Elderly

1. Elderly persons are at risk for impaired wound healing, usually because of chronic illnesses.
2. T-cell function declines, and the relative kind of T cells produced is altered in elderly persons.
3. Elderly individuals also develop impaired humoral immunity and are at risk for increased levels of circulating autoantibodies (antibodies against self-antigens).

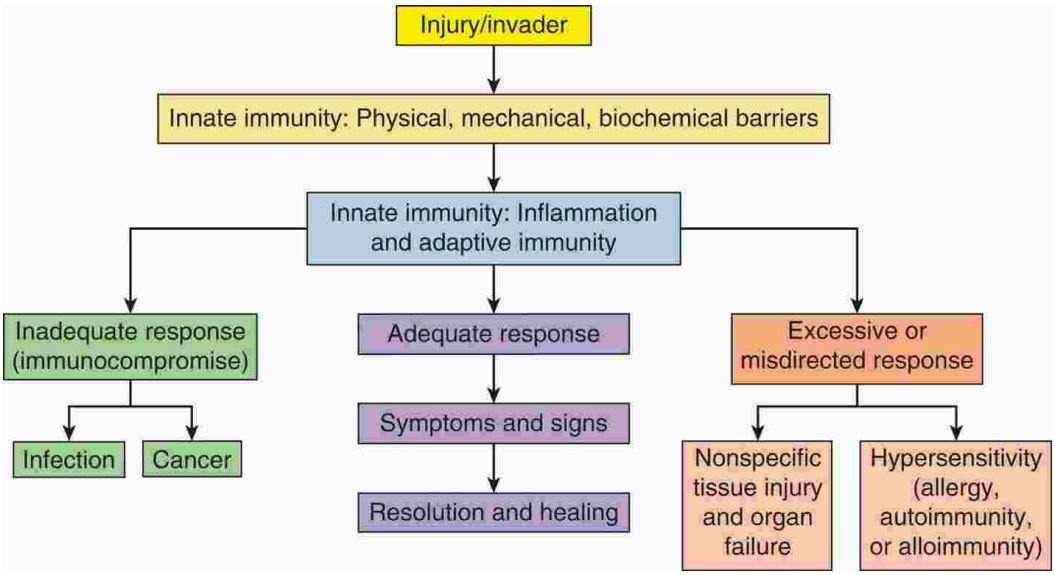
Innate and adaptive immunity serve to fight infection, remove diseased tissue, and promote healing. The innate immune system reacts quickly to virtually any form of injury or invasion primarily through the activation of inflammation. Adaptive immunity is a slower protective response system designed to recognize and remove antigens expressed by disease causing agents and to provide long-term immunity. These defensive systems are fine-tuned networks, but they are not perfect. There are two major categories of immune dysfunction: (1) excessive or misdirected responses, and (2) inadequate responses (immunocompromise) (Algorithm 9.1).



ALGORITHM 9.1 Overview of Immune Responses. Innate and adaptive immune defense mechanisms function to fight infection, remove diseased tissue, and promote healing. An adequate immune response often causes symptoms and signs such as pain, swelling, and redness but leads to resolution of injury and healing. However, immune responses may be excessive or misdirected, resulting in tissue injury which can be nonspecific or related to hypersensitivity reactions (e.g., allergy, autoimmunity, and alloimmunity). Immune responses may also be inadequate and result in systemic immunocompromise that may lead to overwhelming infection or cancer.

A flowchart provides an overview of immune responses. The data from the flowchart are as follows. 1. Injury or invader. Leads to 2. 2. Innate immunity: physical, mechanical, biochemical barriers. Leads to 3. 3. Innate immunity: inflammation and adaptive immunity. There are three responses at level 3: • Inadequate response (immunocompromise): Infection;

cancer. • Adequate response: Symptoms and signs; resolution and healing. • Excessive or misdirected response: nonspecific tissue injury and organ failure; hypersensitivity (allergy, autoimmunity, or alloimmunity).

http://evolve.elsevier.com/Rogers/pathophysiology/

Excessive or misdirected innate immunity is the cause of tissue damage in most acute and chronic diseases. For example, chronic inflammation of the blood vessels leads to atherosclerosis and heart disease. In chronic obstructive lung disease (COPD), inflammation destroys the architecture of lung tissue. An excessive innate immune response also can lead to systemic complications of acute injury or infection. In the case of severe infection, an uncontrolled systemic inflammatory response can lead to septic shock, failure of multiple organs, and death (see Chapter 48). Excessive inflammation like that seen in coronavirus disease 2019 (COVID-19) infection (see Chapter 10) results in overwhelming lung injury and respiratory failure.[1]

Excessive or misdirected adaptive immune responses result in what are called hypersensitivity reactions. These reactions may be (1) exaggerated against noninfectious environmental substances (allergy); (2) misdirected against the body's own cells (autoimmunity); or (3) directed against beneficial foreign issues, such as transfusions or transplants (alloimmunity). Several of these inappropriate responses can be serious or life-threatening.

Immune responses that are insufficient to protect the host against pathogens and abnormal or foreign cells (immune deficiency) may be the result of inherited or acquired immune defects. Immunocompromise often is caused by therapies aimed at treating other conditions such as cancer. This chapter will describe the mechanisms of hypersensitivity reactions with examples of allergy, autoimmunity, and alloimmunity. This will be followed by a summary of selected inherited and acquired immune deficiency diseases. Many other autoimmune and immune deficiency diseases are covered in detail in later chapters in this textbook.

Hypersensitivity Reactions

A hypersensitivity reaction is an altered immunologic response to an antigen that results in disease or damage to the individual. Hypersensitivity reactions can be classified by the immunologic mechanism that causes disease. These mechanisms have been divided into four distinct types: *type I* (immunoglobulin E [IgE]-mediated reactions), *type II* (tissue-specific reactions), *type III* (immune complex–mediated reactions), and *type IV* (cell-mediated reactions) (Table 9.1). The four mechanisms are interrelated, and in most hypersensitivity reactions, several mechanisms can be functioning simultaneously or sequentially.

Table 9.1

Immunologic Mechanisms of Hypersensitivity Reactions

Type	Name	Mechanism of Hypersensitivity	Clinical Examples
I	Immunoglobulin E (IgE)-mediated reaction	T helper 2 cells produce high levels of interleukin-4, leading to B-cell activation and subsequent plasma cell production of IgE antibody. IgE binds to mast cell receptors resulting in their immediate degranulation and release of histamine, leukotrienes, and other inflammatory mediators.	Allergic rhinitis, Asthma, Anaphylaxis
II	Tissue-specific reaction	Altered self-antigens on tissues are bound by autoantibodies resulting in tissue destruction by	Autoimmune hemolytic anemia, Heparin-induced thrombocytopenia, Graves disease, Myasthenia gravis

Type	Name	Mechanism of Hypersensitivity	Clinical Examples
		complement, macrophages, neutrophils, or natural killer cells. Some autoantibodies bind to hormone or neurotransmitter receptors causing decreased or increased receptor activation.	
III	Immune complex–mediated reaction	Antibodies are formed to circulating antigens resulting in the formation of immune complexes that deposit in tissues. These immune complexes activate complement and neutrophils resulting in tissue destruction.	Systemic lupus erythematosus, Raynaud phenomenon

Type	Name	Mechanism of Hypersensitivity	Clinical Examples
IV	Cell-mediated reaction	T helper 1 cells produce interferon gamma resulting in the activation of macrophages and T cytotoxic cells that attack the target cell through the release of destructive enzymes. In some cases, destruction of an invader is not possible, and granuloma formation walls it off from the rest of the body	Contact sensitivity to poison ivy and latex, Mycobacterial infection

Type	Name	Mechanism of Hypersensitivity	Clinical Examples
I	Immunoglobulin E (IgE)-mediated reaction	T helper 2 cells produce high levels of interleukin-4, leading to B-cell activation and subsequent plasma cell production of IgE antibody. IgE binds to mast cell receptors resulting in their immediate degranulation and release of histamine, leukotrienes, and other inflammatory mediators.	Allergic rhinitis, Asthma, Anaphylaxis
II	Tissue-specific reaction	Altered self-antigens on tissues are bound by autoantibodies resulting in tissue destruction by complement, macrophages, neutrophils, or natural killer cells. Some autoantibodies bind to hormone or neurotransmitter receptors causing decreased or increased receptor activation. IV	Cell-mediated reaction	T helper 1 cells produce interferon gamma resulting in the activation of macrophages and T cytotoxic cells that attack the target cell through the release of destructive enzymes. In some cases, destruction of an invader is not possible, and granuloma formation walls it off from the rest of the body	Contact sensitivity to poison ivy and latex, Mycobacterial infection

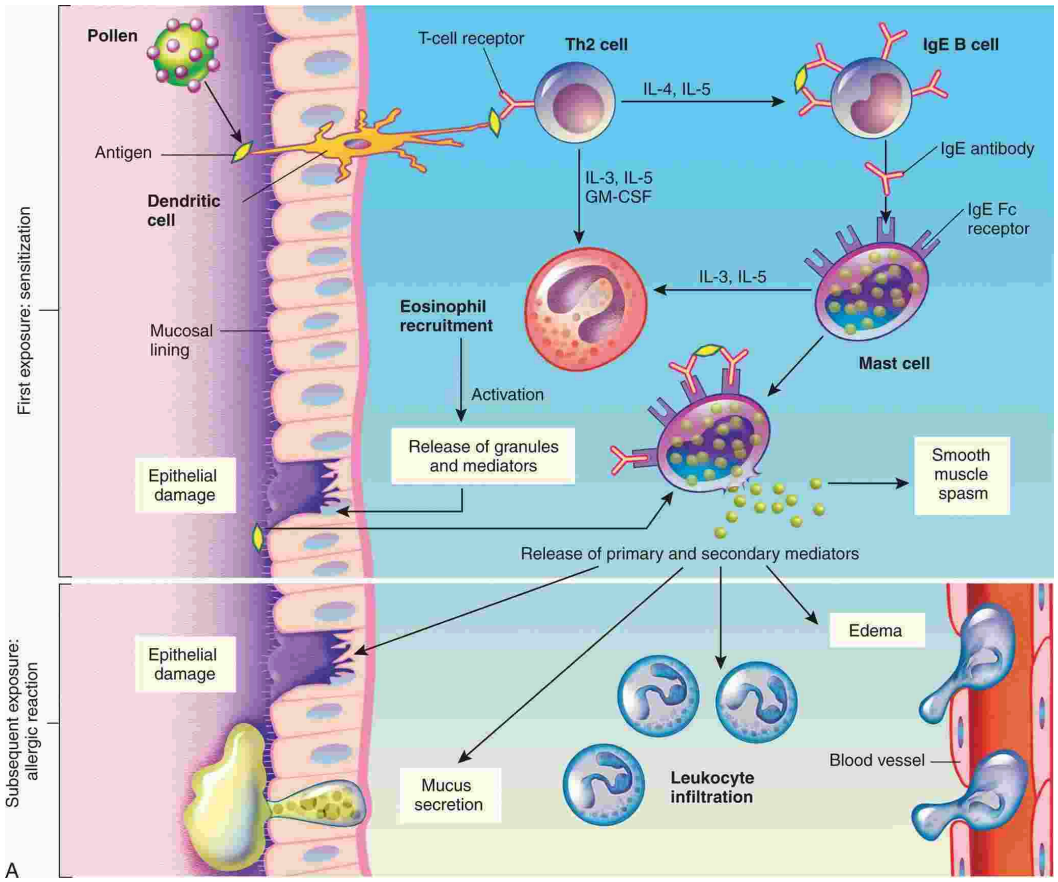
Immunologic Mechanisms of Hypersensitivity Reactions

Although the inflammatory responses of the innate immune system cause much of the tissue damage associated with hypersensitivity reactions, the mechanisms that initiate inflammation and tissue damage involve misdirected or excessive responses of the adaptive immune system. Hypersensitivity reactions are complicated, but an understanding of these mechanisms is essential to providing appropriate management of the many disorders that result from them.

Type I: IgE-Mediated Hypersensitivity Reactions

Type I hypersensitivity reactions are mediated by antigen-specific IgE and the products of tissue mast cells (Fig. 9.1). Most common allergic reactions are type I reactions against environmental antigens (e.g., pollen, bee venom, nuts, medications). Individuals who are genetically predisposed to this type of hypersensitivity generate an inappropriate IgE-mediated response to what would otherwise be an innocuous exposure. Most commonly, the term *allergy* indicates IgE-mediated reactions. However, some allergic reactions can be caused by other adaptive immune mechanisms, and IgE can contribute to some autoimmune and alloimmune diseases.



First exposure: sensitization
Pollen
T-cell receptor
Th2 cell
IgE B cell
IL-4, IL-5
Antigen
IgE antibody
Dendritic cell
IL-3, IL-5 GM-CSF
IgE Fc receptor
IL-3, IL-5
Eosinophil recruitment
Mucosal lining
Mast cell
Activation
Release of granules and mediators
Epithelial damage
Smooth muscle spasm
Release of primary and secondary mediators
Subsequent exposure: allergic reaction
Epithelial damage
Edema
Blood vessel
Mucus secretion
Leukocyte infiltration
A

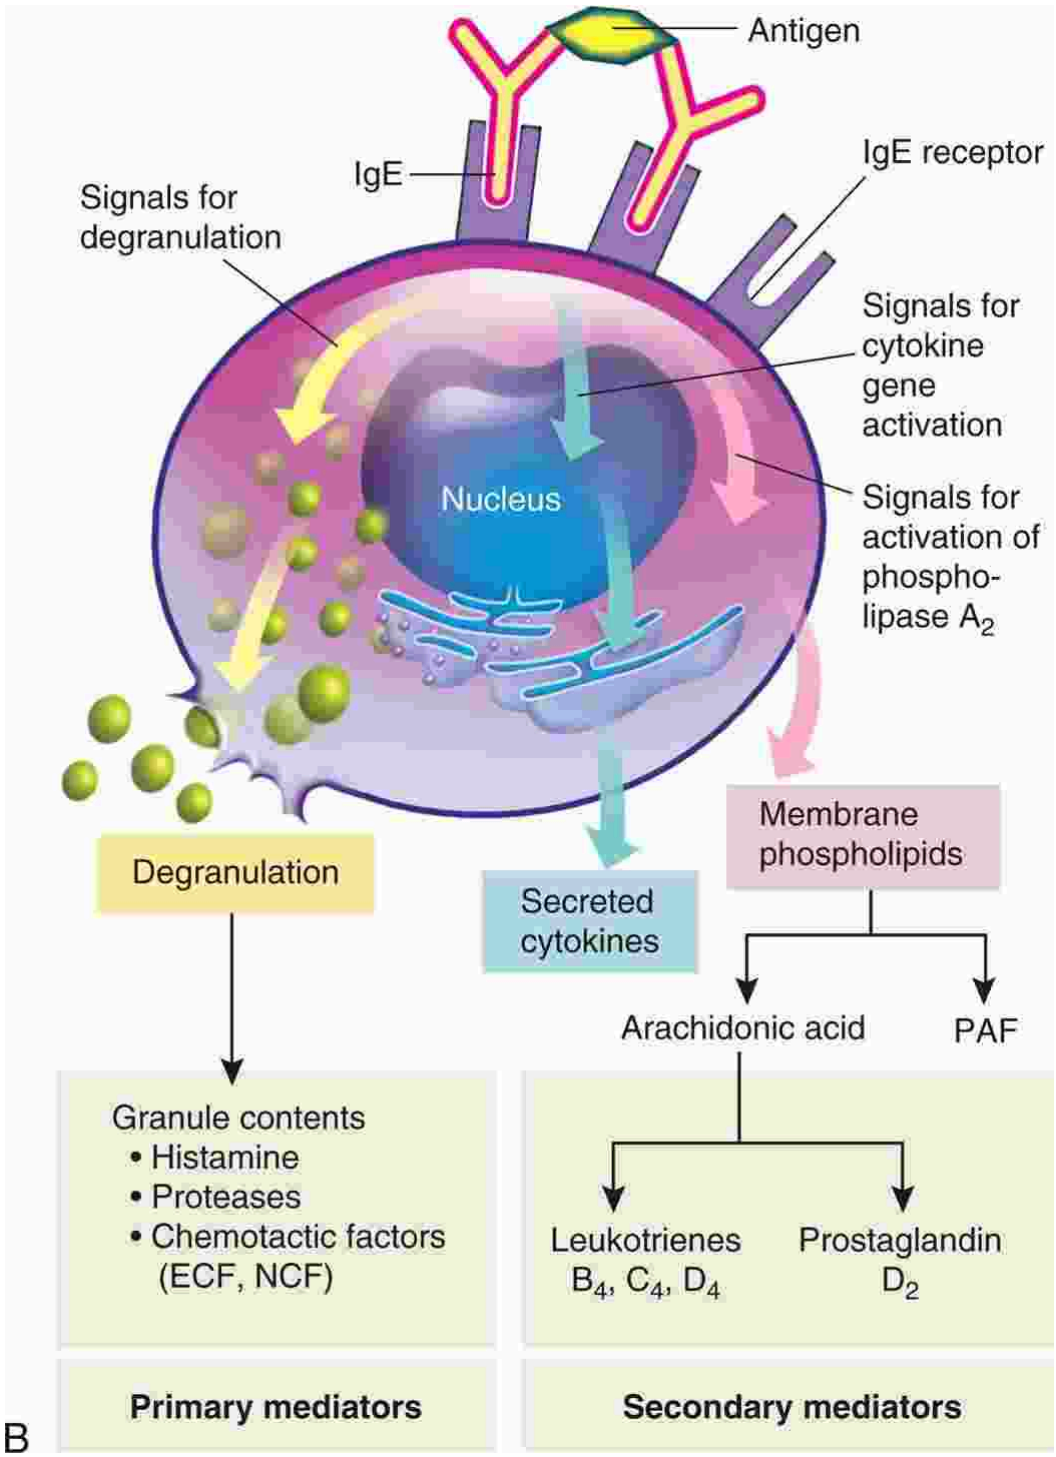


FIG. 9.1 Mechanism of Type I, Immunoglobulin E (IgE)-Mediated Reactions.
(A) Th2 cells are activated by antigen-presenting dendritic cells to produce cytokines, including IL-4 and IL-5. IL-5 attracts and promotes the survival of

eosinophils. High levels of IL-4 induce B cells to class-switch to IgE-producing plasma cells. The IgE coats the surface of the mast cell by binding with IgE-specific Fc receptors on the mast cell's plasma membrane (sensitization). Further exposure to the same allergen cross-links the surface-bound IgE and activates signals from the cytoplasmic portion of the IgE Fc receptors. These signals initiate two parallel and interdependent processes: mast cell degranulation and discharge of preformed mediators (e.g., histamine, chemotactic factors) and production of newly formed mediators such as leukotrienes and prostaglandins. Type I hypersensitivity reactions have two well-defined phases. On first exposure, there is an initial phase characterized by vasodilation, vascular leakage, and, depending on the location, smooth muscle spasm. Eosinophils contribute to mucosal epithelial cell damage. Subsequent exposures are characterized by infiltration of tissues with more eosinophils and with other inflammatory leukocytes resulting in prolonged epithelial cell damage and mucus secretion. Fig. 9.1, cont'd **(B)** Activation of mast cells leading to degranulation of preformed mediators (primary mediators) and synthesis of newly formed (de novo) mediators (secondary mediators). *ECF*, Eosinophilic chemotactic factor; *Fc*, fragment crystallizable; *Ig*, immunoglobulin; *IL*, interleukin; *NCF*, neutrophil chemotactic factor; *PAF*, platelet-activating factor; *Th*, T helper.

An illustration demonstrates the mechanism of type 1, immunoglobulin E (I g E)-mediated reaction. Top panel, first exposure: sensitization. The illustration shows a tissue with mucosal lining. Pollen generates

antigen that a dendritic cell transports through the epithelial layer and presents to the T-cell receptor on T h 2 cell, which leads to: • I L-4 and I L-5 present the antigen to the antibodies on the I g E B cell. • I L-3, I L-5, G M-C S F generate cytokine signals. I g E antibody from the I g E B cell binds to the I g E F c receptor in the mast cell, which leads to: • I L-3 and I L-5 recruit eosinophil and activates release of granules and mediators from the site of epithelial damage. • Smooth muscle spasm, releasing primary and secondary mediators. Eosinophil recruitment activates the release of granules and mediators at the site of epithelial damage. Antigen from this site binds to the antibodies on the I g E F c receptor of the mast cell, releasing primary and secondary mediators. Bottom panel, subsequent exposure: allergic reaction. Release of primary and secondary mediators leads to: • Epithelial damage. • Mucus secretion. • Leukocyte infiltration; enters the blood vessel. • Edema." "An illustration shows the activation of mast cells. The illustration shows 2 I g E antibodies bound to antigen through variable region and to the I g E receptor through F c region, sending the signal as follows: • Degranulation. • Cytokine gene activation leads to secretion of cytokines. • Activation of phospholipase A sub 2. Degranulation generates the following granule contents (primary mediators): • Histamine. • Proteases. • Chemotactic factors (E C F, N C F).

Membrane phospholipids produce arachidonic acid (secondary mediators) or P A F. Arachidonic acid can be: • Leukotrienes: B sub 4, C sub 4, and D sub 4. • Prostaglandin: D sub 2.

Mechanisms of type I, IgE-mediated hypersensitivity reactions

Type I hypersensitivity reactions require *sensitization* against a particular environmental antigen (**allergen**) that results in a primary immune response. The response occurs when the immune system first encounters an antigen (primary exposure) and forms antigen-specific memory B cells and T cells (immunologic memory). Disease symptoms appear after secondary exposure to the offending antigen when memory cells are rapidly activated against the same antigen (see Chapter 8). These reactions occur within minutes to a few hours after exposure to antigen and are termed **immediate hypersensitivity reactions**.

When allergens enter the body of a genetically predisposed individual, they are detected by dendritic cells and B cells, then undergo antigen processing and presentation (Fig. 9.1A). T helper (Th) cells are activated to produce large amounts of the Th2 cytokines, especially interleukin (IL)-4, IL-5, and IL-13. High levels of IL-4 and IL-13 cause B cells to proliferate and become plasma cells that produce antigen-specific IgE. IL-5 recruits and activates eosinophils, which contain granules full of enzymes that are especially damaging to the respiratory system (see Chapter 36). Other interleukins such as IL-9 and IL-33 also play a role in exacerbating type I hypersensitivity reactions.[2,3]

IgE has a relatively short life span in blood because it rapidly binds to Fc receptors (antibody receptors) on mast cells. The Fc receptors on mast cells specifically bind IgE that has not previously interacted with antigen. After a large amount of IgE has bound to the mast cells, an individual is considered *sensitized*. When there is a secondary or reexposure of a sensitized individual to the allergen, the IgE antibodies signal the mast cells to degranulate and release mediators.

Mast cells release a variety of cytokines (Fig. 9.1B). Histamine is the most potent preformed mediator of IgE-mediated hypersensitivity. Histamine acts immediately (within 15 to 30 minutes) and affects several key target cells. The tissues most commonly affected by type I responses contain large numbers of mast cells and are sensitive to the effects of histamine released from them. These tissues are found in the gastrointestinal tract, skin, and respiratory tract. Acting through histamine 1 (H1) receptors, histamine contracts bronchial smooth muscles (bronchial constriction), increases vascular permeability (edema), and causes vasodilation (increased blood flow) (see Chapter 7).

Mast cells also synthesize secondary mediators, such as leukotrienes, prostaglandins, and platelet activating factor, which act more slowly (within hours) and have effects similar to that of histamine (see Fig. 9.1B). These newly formed mediators also attract other immune cells (e.g., eosinophils, neutrophils, basophils, monocytes), activate kinins, and initiate the complement cascade with release of the anaphylatoxins C3a, C4a, and C5a (see Chapter 7). These mediators are responsible for a late phase reaction that sets in 2 to 24 hours later even without additional exposure to antigen and may last for several days. The overall effect of these cytokines is inflammation of affected tissues leading to vasodilation, mucous secretion, bronchoconstriction, and tissue injury.

Type II: Tissue-Specific Hypersensitivity Reactions

Type II hypersensitivities are generally immune reactions against a specific cell or tissue. Cells express a variety of antigens on their surfaces, some of which are called **tissue-specific antigens** because they are expressed on the membranes of only certain cells. For example, platelets have groups of antigens that are found on no other cells of the body. Environmental antigens (e.g., drugs or their metabolites) may bind to the plasma membranes of specific cells and function as **haptens**, making them targets of type II reactions. The three general mechanisms by which type II hypersensitivity reactions can affect cells are complement mediated lysis, antibody-dependent cellular cytotoxicity, and antireceptor antibodies (Fig. 9.2). Each mechanism begins with antibody binding to tissue-specific antigens or

antigens present on particular tissues. The symptoms of many type II diseases are determined by which tissue or organ expresses the particular antigen.

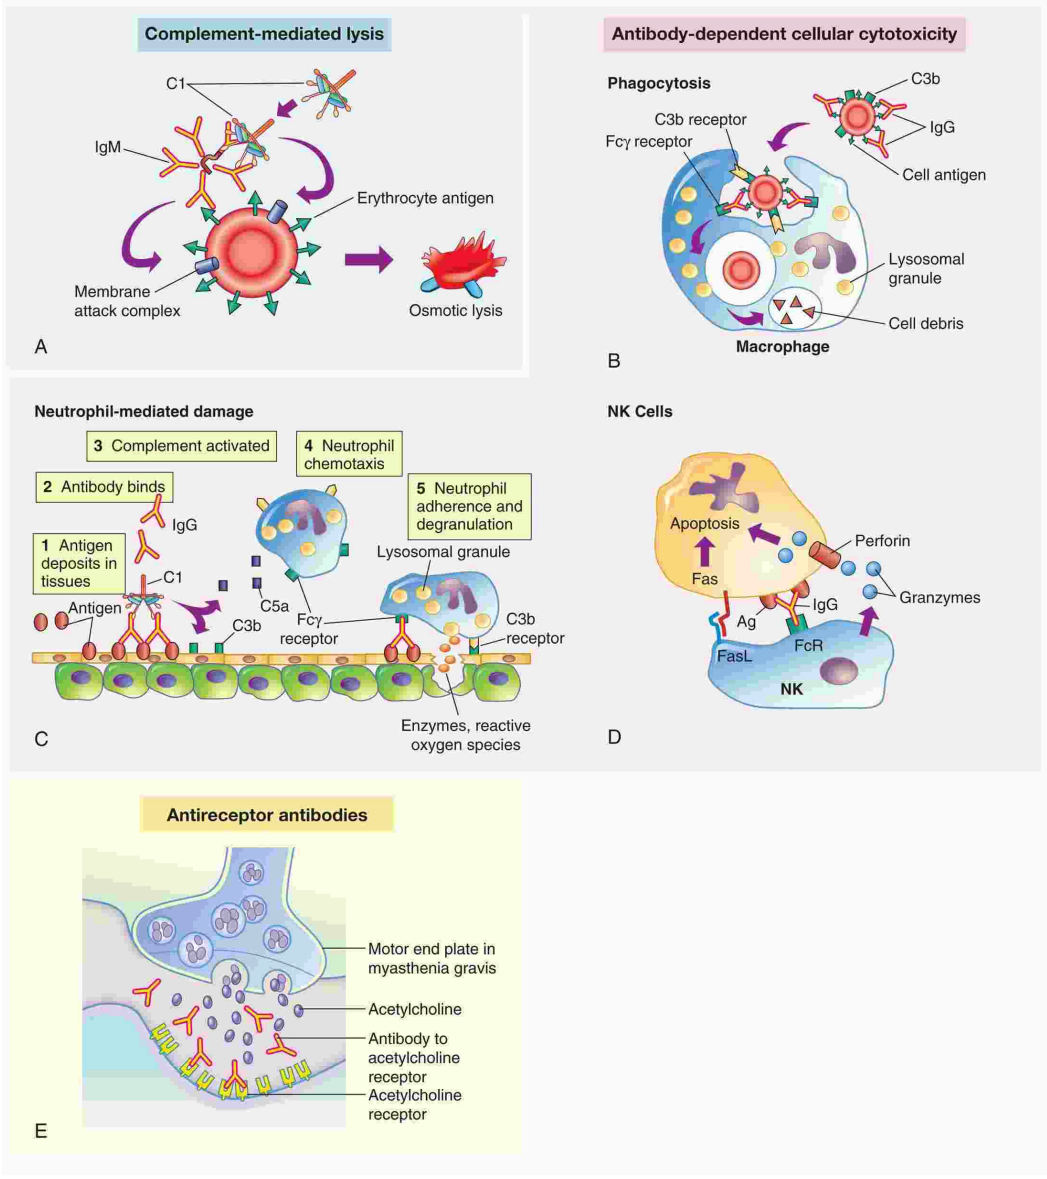

FIG. 9.2 Mechanisms of Type II, Tissue-Specific Reactions.

Antigens on the target cell bind with antibody and are destroyed or prevented from functioning by one of three mechanisms: *Complement-mediated lysis* **(A)** Complement binding to autoantibodies on a target cell (an erythrocyte target is illustrated here) results in destruction of the cell by the complement membrane attack complex. *Antibody-dependent cellular cytotoxicity* occurs through three processes: **(B)** Clearance (phagocytosis) by macrophages in

the tissue; **(C)** Neutrophil-mediated immune destruction; **(D)** Apoptosis of target cells by natural killer (NK) cells by the release of granzymes and perforin and by the interactions of Fas ligand. *Antireceptor antibodies***(E)** Modulation or blocking of the normal function of receptors by antireceptor antibody. This example of mechanism depicts myasthenia gravis in which acetylcholine receptor antibodies block acetylcholine from attaching to its receptors on the motor end plates of skeletal muscle, thereby impairing neuromuscular transmission and causing muscle weakness. *C1*, Complement component C1; *C3b*, complement fragment produced from C3, which acts as an opsonin; *C5a*, complement fragment produced from C5, which acts as a chemotactic factor for neutrophils; *Fcγ rece*ptor, cellular receptor for the Fc portion of IgG; *FcR*, Fc receptor.

Five illustrations, A, B, C, D, and E, demonstrate the mechanisms of type 2, tissue-specific reactions. Illustration A, complement-mediated lysis. An I g M binds C 1, leading to a membrane attack complex on a blood cell, releasing erythrocyte antigen, and resulting in osmotic lysis. Illustration B, antibody-dependent cellular cytotoxicity: phagocytosis. C 3 b is attached to the blood cell. I g G binds to the cell antigen. C 3 b receptor binds C 3 b and F c gamma receptor binds the I g G, producing lysosomal granules and cell debris in the macrophage. Illustration C, antibody-dependent cellular cytotoxicity: neutrophil-mediated damage. The illustration shows an epithelial layer and shows the following sequence of damage: • Antigen deposits in

tissues. • Antibody binds. • Complement activated: C 3 b and C 5 a. • Neutrophil chemotaxis: F c gamma receptor on the macrophage. • Neutrophil adherence and degranulation: release of lysosomal granules as enzymes, reactive oxygen species. Illustration D, antibody-dependent cellular cytotoxicity: N K cells. An N K cell comprises Fas L and F c R. Granzymes from the N K cell are attracted to the perforin of the apoptosis. I g G binds F c R in N K to A g in Apoptosis. Illustration E, antireceptor antibodies. The illustration shows the motor end plate in myasthenia gravis. Acetylcholine is released. Antibody to acetylcholine receptor binds to the acetylcholine receptor.

Mechanisms of type II, tissue-specific reactions

(1) *Complement-mediated lysis* occurs when antibodies (IgM or IgG) bound to tissue-specific antigens cause activation of the complement cascade through the classical pathway (Fig. 9.2A). Formation of the membrane attack complex (C5-9) damages the membrane and results in lysis of the cell. For example, erythrocytes are destroyed by complement-mediated lysis in individuals who have received mismatched transfused blood cells (see the section on Alloimmunity).

(2) *Antibody-dependent cell-mediated cytotoxicity (ADCC)* (Fig. 9.2B–D) occurs when antibodies bound to tissue-specific antigens activate macrophages, neutrophils, and natural killer (NK) cells, which attack the target cells. When antibodies activate complement, there is the deposition of C3b on the target cell surface. Receptors on macrophages and neutrophils recognize and bind these opsonins (antibody plus C3b) and increase phagocytosis of the target cell (see Fig. 9.2B). Toxic products

produced by neutrophils (lysozymes and toxic oxygen radicals) also cause tissue damage (Fig. 9.2C). ADCC also involves NK cells (Fig. 9.2D). Antibodies on the target cell are recognized by Fc receptors on NK cells, which release toxic substances that destroy the target cell. Examples of ADCC include autoimmune conditions in which autoantibodies are made against antigens on platelets or red blood cells causing them to be removed by phagocytes in the spleen.

(3) *Antireceptor antibodies* do not destroy the target cell but rather cause the cell to malfunction (Fig. 9.2E). These autoantibodies change the function of the target receptor by blocking, overstimulating, or destroying it. For example, in Graves disease, autoantibodies called thyroid-stimulating immunoglobulins (TSIs) bind to and activate receptors for thyroid-stimulating hormone (TSH) on thyroid gland cells. TSH normally stimulates thyroid hormone secretion but is under the control of feedback mechanisms. When TSIs bind to the TSH receptors, they stimulate the thyroid cells to overproduce thyroxine, thus producing symptoms of hyperthyroidism (see Chapter 22).

Type III: Immune Complex–Mediated Hypersensitivity Reactions

Type III hypersensitivity disease reactions are caused by antigen-antibody (immune) complexes that are formed in the circulation and are deposited in vessel walls or other tissues (Fig. 9.3). The primary difference between type II and type III mechanisms is that in type II hypersensitivity, antibody binds to antigen on the cell surface, whereas in type III, antibody binds to soluble antigen that was released into blood or body fluids.

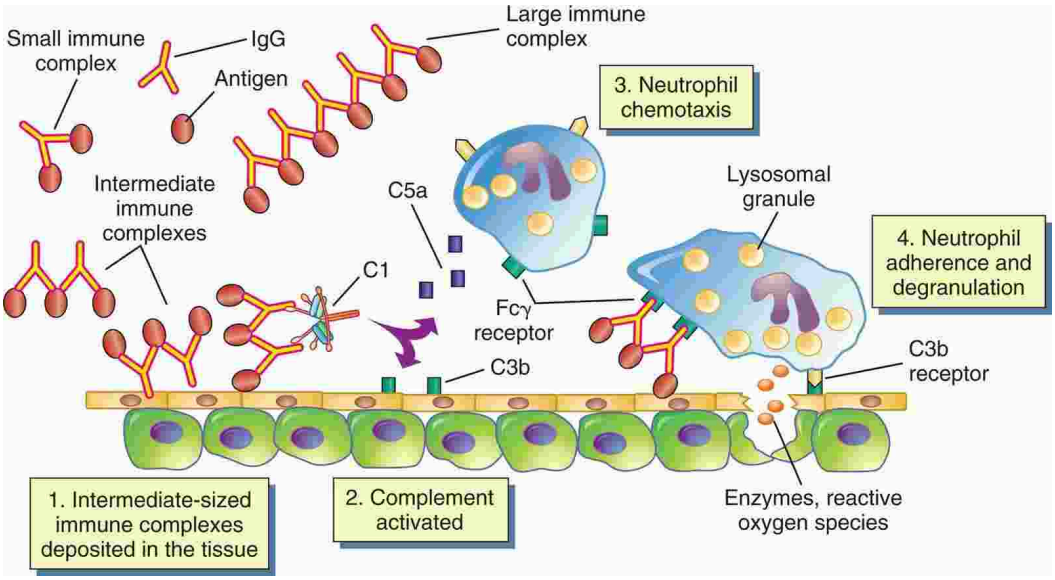

FIG. 9.3 Mechanism of Type III, Immune Complex–Mediated Reactions.
Immune complexes form in the blood from circulating antigen and antibody. Both small and large immune complexes are removed successfully from the circulation and do not cause tissue damage. Intermediate-sized complexes are deposited in certain target tissues in which the circulation is slow or filtration of blood occurs. The complexes activate the complement cascade through C1 and generate fragments, including C5a and C3b. C5a is chemotactic for neutrophils, which migrate into the inflamed area and attach to the IgG and C3b in the immune complexes. The neutrophils attempt unsuccessfully to phagocytose the tissue and, in the process, release a variety of degradative enzymes that destroy the healthy tissues. Fcγ receptor is the cellular receptor for the Fc portion of immunoglobulin G.

An illustration shows the mechanism of type 3, immune complex-mediated reactions. The illustration shows a I g G antibody and an antigen. A small

immune complex is a structure with two antigens, one each on the paratopes of the I g G. Intermediate immune complexes are pairs of antibodies with antigens on the paratopes. A large immune complex is a chain of multiple antibodies with antigens on the paratopes. The mechanism of reactions are as follows. 1. Intermediate-sized immune complexes deposited in the tissue. 2. Complement (C 1, C 5 a) activated. 3. Neutrophil chemotaxis (F c gamma receptor). 4. Neutrophil adherence and degranulation (lysosomal granules, C 3 b receptor): enzymes, reactive oxygen species.

Mechanisms of type III, immune-mediated hypersensitivity reactions

When antibodies bind to circulating antigens, immune complexes are then deposited in vascular tissues. Type III reactions are not organ specific and most commonly result in a vasculitis in the skin, kidney, or lungs. The harmful effects of immune complex deposition are caused by complement activation and by neutrophils attempting to phagocytose the immune complexes. During the attempted phagocytosis, large quantities of lysosomal enzymes are released into the inflammatory site instead of into phagolysosomes. The attraction of neutrophils and the subsequent release of lysosomal enzymes cause most of the resulting tissue damage. Two prototypic models of type III hypersensitivity help to explain the variety of diseases in this category. Serum sickness is a model of systemic type III hypersensitivities, and the *Arthus reaction* is a model of localized or cutaneous reactions.

Serum sickness–type reactions are caused by the formation of immune complexes in the blood and their subsequent generalized deposition in target tissues. A form of serum sickness is **Raynaud phenomenon**, a condition caused by the temperature-dependent

deposition of immune complexes in the capillary beds of the peripheral circulation. Certain immune complexes precipitate at temperatures less than normal body temperature, particularly in the tips of the fingers, toes, and nose, and are called **cryoglobulins**. The precipitates block the circulation and cause localized pallor and numbness, followed by cyanosis (a bluish tinge resulting from oxygen deprivation) and eventually gangrene if the circulation is not restored.

Arthus reaction is vasculitis caused by repeated local exposure to an antigen that reacts with preformed antibody and forms immune complexes in the walls of the local blood vessels. Symptoms of Arthus reaction begin within 1 hour of exposure and peak 6 to 12 hours later. The lesions are characterized by a typical inflammatory reaction, with increased vascular permeability, an accumulation of neutrophils, edema, hemorrhage, clotting, and tissue damage. For example, gluten-sensitive enteropathy (celiac disease) follows ingestion of antigen, usually gluten from wheat products (see Chapter 42). Allergic alveolitis (farmer lung disease, pigeon breeder disease) is Arthus-like acute hemorrhagic inflammation of the air sacs (alveoli) of the lungs, resulting from inhalation of fungal antigens, usually particles from moldy hay or pigeon feces (see Chapter 35).

Type IV: Cell-Mediated Hypersensitivity Reactions

Types I, II, and III hypersensitivity reactions are mediated by antibodies, whereas **type IV hypersensitivity** reactions are mediated by T lymphocytes and do not involve antibodies (Fig. 9.4). Type IV mechanisms occur through the presentation of antigens on major histocompatibility molecules (MHCs) to T cells. Th cells produce Th1 and Th17 cytokines. Th1 and Th17 cytokines recruit and activate macrophages and cytotoxic T lymphocytes (Tc cells) (see Chapter 8). Tc cells directly kill target cells. Macrophages release soluble factors, such as lysosomal enzymes and toxic reactive oxygen species. Together, these responses cause tissue damage. The response is delayed, occurring 24 to 72 hours after antigen reexposure, compared with an immediate type I reaction, which occurs within minutes. The response is delayed because of the time it takes for sensitized T cells to travel to the site of antigen reexposure and the time needed to produce

cytokines that activate other cells including macrophages (**delayed hypersensitivity**).

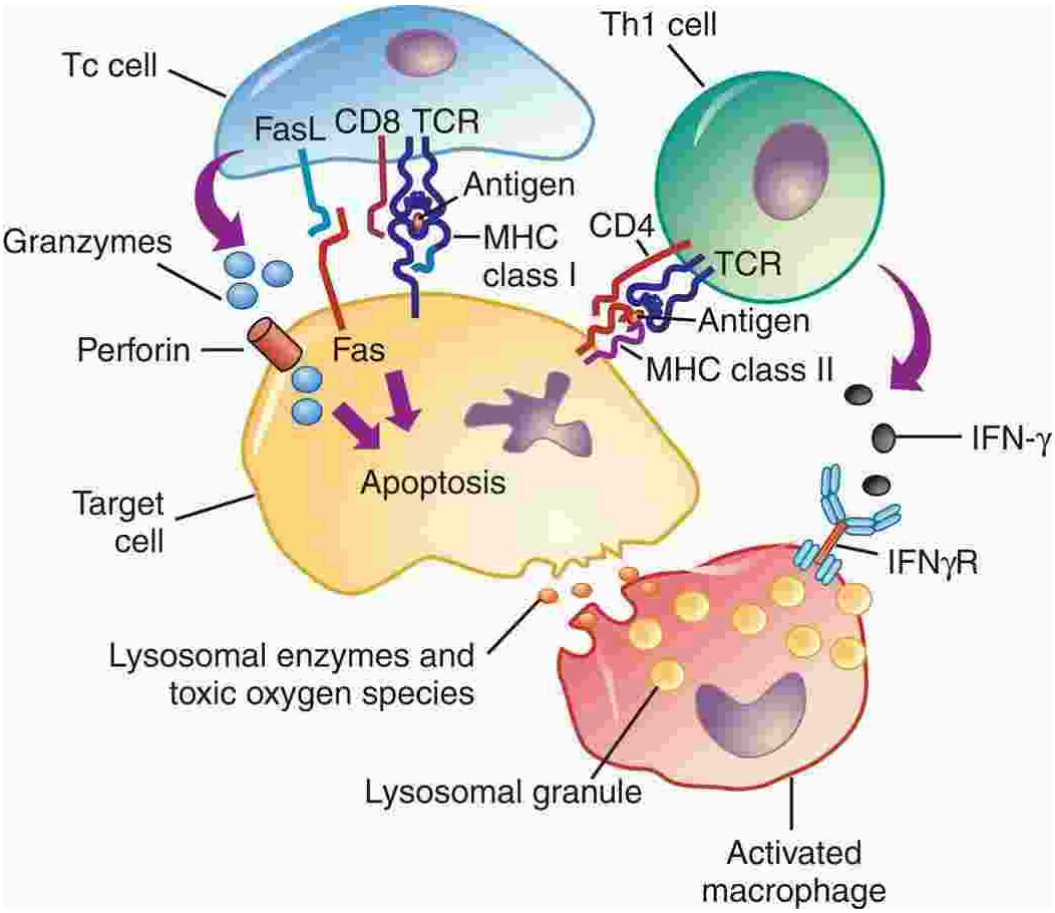

FIG. 9.4 Mechanism of Type IV, Cell-Mediated Reactions.

Antigens from target cells stimulate T cells to differentiate into T cytotoxic cells (Tc cells), which have direct cytotoxic activity through release of granzymes or the induction of apoptosis via Fas and Fas ligand binding. T helper cells (Th1) cells produce lymphokines (especially interferon-γ) that activate macrophages through specific receptors (e.g., IFN-γ receptor). The macrophages can attach to targets and release enzymes and reactive oxygen species that are responsible for most of the tissue destruction. *FasL*, Fas ligand; *IFN-γ*, interferon-γ; *IFN-γR*, interferon-γ receptor; *MCH*, major histocompatibility complex; *TCR*, T cell receptor.

An illustration shows the mechanism of type 4, cell-mediated reactions. The illustration shows a T c cell, a T h 1 cell, a target cell, and an activated macrophage. T C R on the T h 1 cell is bound to the target cell through M H C class 2 and C D 4. I F N-gamma from the T h 1 cell are attracted to the I F N gamma R. T C R on the T c cell is bound to the target cell through Fas L, Fas, C D 8, and M H C class 1. Granzymes from the T c cell are attracted to the perforin on the target cell. The target cell undergoes apoptosis, releasing lysosomal enzymes and toxic oxygen species. Lysosomal granules activate the macrophage.

In some cases, Tc cells and macrophages cannot kill or remove the offending agent. In these cases, they surround and contain the invader through the formation of a *granuloma* (see Chapter 7). The formation of multiple granulomas can lead to tissue damage and organ dysfunction.

Mechanisms of type IV cell-mediated hypersensitivity reactions

Clinical examples of type IV hypersensitivity reactions include graft rejection, reaction on the skin test for tuberculosis, and allergic reactions resulting from skin contact with some substances, such as poison ivy and metals. A type IV component also may be present in many autoimmune diseases. For example, T cells against type II collagen (a protein present in joint tissues) contribute to the destruction of joints in rheumatoid arthritis, and T cells against an antigen on the surface of pancreatic beta cells (the cell that normally produces insulin) are responsible for beta-cell destruction in insulin-dependent (type 1) diabetes mellitus.

In 1891, Ehrlich was the first to thoroughly describe type IV hypersensitivity reaction in the skin, leading to the development of a diagnostic skin test for tuberculosis. The reaction follows an intradermal injection of tuberculin antigen (purified protein derivative

[PPD]) into an individual who has latent or active tuberculosis and is therefore sensitized (has developed adaptive immune cells against tuberculosis antigen). After 24 to 72 hours the reaction site becomes infiltrated with T lymphocytes and macrophages, resulting in a clear hard center (**induration**) and a reddish surrounding area (**erythema**). The reaction is referred to as a positive skin test result (i.e., positive PPD) for tuberculosis infection.

Allergic type IV reactions are elicited by some environmental antigens that are haptens and become immunogenic after binding to larger (carrier) proteins in the individual. In allergic **contact dermatitis**, the carrier protein is in the skin. The best-known example is the reaction to poison ivy (Fig. 9.5). The antigen is a plant catechol, urushiol, which reacts with normal skin proteins and evokes a cell-mediated immune response. Skin reactions to industrial chemicals, cosmetics, detergents, clothing, food, metals, and topical medicines (e.g., penicillin) are elicited by the same mechanism. Contact dermatitis consists of lesions only at the site of contact with the allergen, as in metal allergy to jewelry.

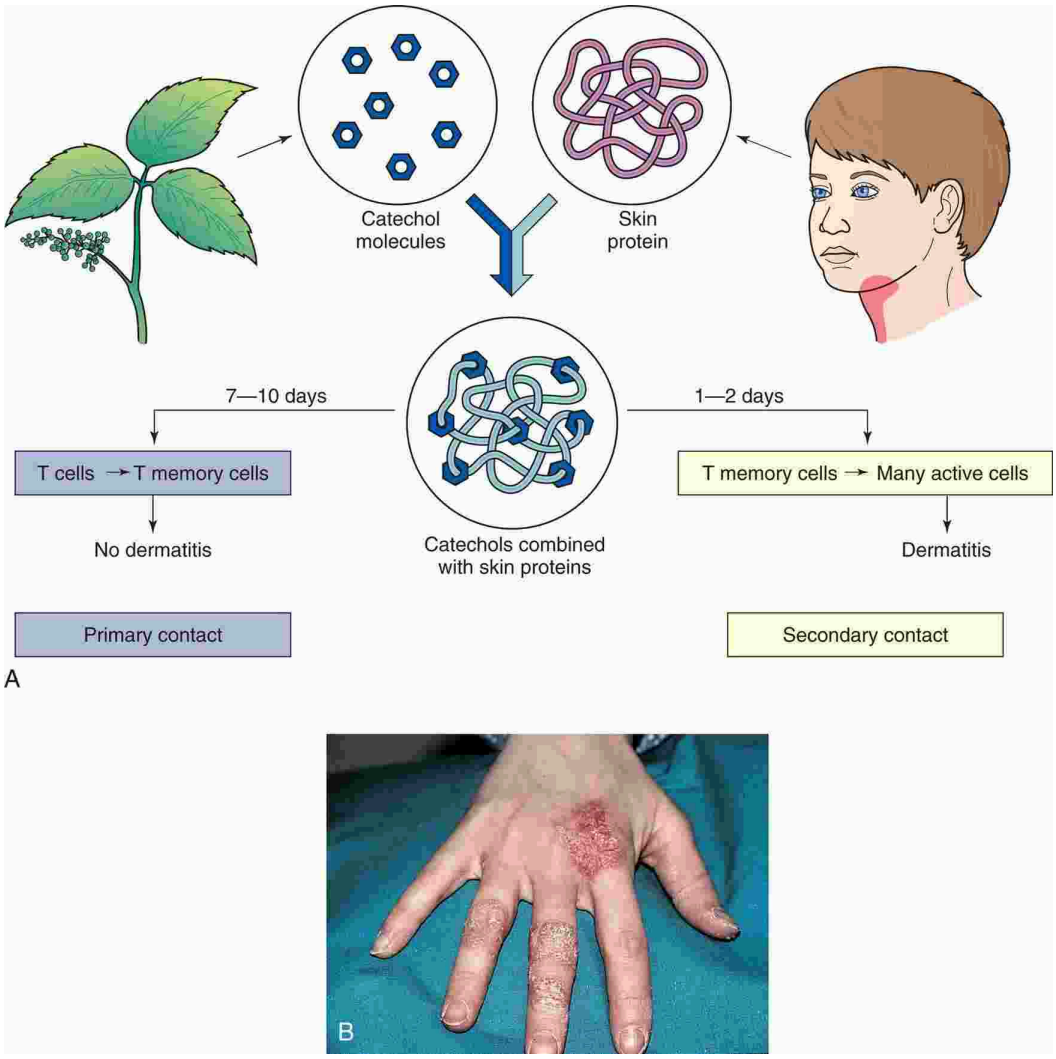

FIG. 9.5 Development of Allergic Contact Dermatitis.

(A) The development of type IV hypersensitivity to poison ivy. The first (primary) contact with allergen sensitizes (produces reactive T cells) the individual but does not produce a rash (dermatitis). Secondary contact activates a type IV cell-mediated reaction that causes dermatitis. **(B)** Contact dermatitis caused by a delayed hypersensitivity reaction leading to vesicles and scaling at the sites of contact. From Damjanov I, Linder J. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.

Top panel, A, is an illustrated flowchart showing the development of type 4 hypersensitivity to poison ivy. Catechol molecules from poison ivy combines with the skin proteins on humans. • 7 to 10 days: T cells to T memory cells, no dermatitis. Primary contact. • 1 to 2 days: T memory cells to many active cells, dermatitis. Secondary contact. Bottom panel, B, is a closeup of a hand affected by dermatitis. The skin appears dry and cracked on the fingers and on the surface below the index finger.

Antigenic Targets of Hypersensitivity Reactions

The four types of hypersensitivity reactions contribute to tissue damage and clinical diseases in a variety of ways. Often, several mechanisms of hypersensitivity are active at the same time. The three major types of hypersensitivity disorders are allergy, autoimmunity, and alloimmunity. The mechanisms that initiate the onset of hypersensitivity reactions are not completely understood. It is generally accepted that genetic and environmental agents are contributing factors.

Allergy

Allergy (atopy) refers to hypersensitivity to environmental antigens. These can include medicines, natural products (e.g., pollens, bee stings), infectious agents, and any other antigen that is not naturally found in the individual. Allergies are the most common hypersensitivity reactions. The majority of allergies are type I IgE-mediated reactions. These reactions usually lead to relatively mild symptoms such as rhinitis and sneezing. However, in some individuals, these reactions can be excessive and life-threatening (anaphylaxis). Antigens that cause allergic responses are called **allergens**. Typical allergens include pollens (e.g., ragweed), molds and

fungi (e.g., *Penicillium chrysogenum*), foods (e.g., milk, eggs, fish), animals (e.g., cat dander, dog dander), cigarette smoke, and components of house dust (e.g., fecal pellets of house mites). The most common forms of atopic disease are allergic rhinitis, bronchial asthma, anaphylaxis, and atopic dermatitis (eczema).

Genetic predisposition and environmental factors

Genes and environment interact in complex ways in individuals with type I hypersensitivity.[4] Certain individuals are genetically predisposed to develop type I IgE-mediated hypersensitivity and are called *atopic*. In families in which one parent has an allergy, allergies develop in approximately 40% of the offspring. If both parents have allergies, the incidence in the offspring may be as high as 80%. Atopic individuals tend to produce higher quantities of IgE and to have more Fc receptors for IgE on their mast cells. The airways and the skin of atopic individuals are also more responsive to a wide variety of both specific and nonspecific stimuli than are the airways and skin of individuals who are not atopic. Multiple genes have been associated with the atopic state, including polymorphisms in a large variety of cytokines that regulate IgE synthesis (e.g., IL-4, IL-13) and cellular receptors.

The environment has a significant impact on allergic disease. Diet, medications, and comorbidities impact the microbiome and the health of the adaptive immune system (see Emerging Science Box: The Microbiome and Food Allergy).[5] In genetically predisposed individuals, exposure to large quantities of allergens and irritants in the environment can trigger symptoms. The role of infection in allergic disease is complex and may be protective or may render organ systems such as the respiratory tract more vulnerable to allergic symptoms.

Emerging Science BoxThe Microbiome and Food Allergy

Last year, 6.5% of US children were reported to have a food allergy. Among the most common are allergies to nuts, peanuts, and shellfish. The mechanisms underlying food allergies remain unclear; however, several studies have found that dysbiosis in gut

microbiome plays an important role. Within the gastrointestinal tract, finely tuned mechanisms enable nutrients to be broken down and absorbed without causing an immune reaction to food antigens. Gut microorganisms may modify food antigens thus increasing or reducing their immunogenicity. They also influence the effectiveness of intestinal barriers to antigens and infectious agents. A healthy gut microbiome induces tolerance to food antigens through several mechanisms including the differentiation of T cells into T regulatory cells. Dysbiosis of the gut microbiome has been linked to activation of B cells and the production of immunoglobulin E antibodies in atopic individuals. Environmental factors that have been associated with gut microbiome dysbiosis and food allergy include a low-fiber/high-fat diet, antibiotics, lack of breastfeeding, and medications. A maternal diet rich in fruits and vegetables, fish, vitamin D-rich foods is associated with a healthier microbiome and a lower risk of allergic disease in their offspring. Dietary changes for children (including the early introduction of foods like peanuts) and adults as well as the use of prebiotics or probiotics are being evaluated to assess their impact on the gut microbiome and the incidence of fool allergies.

Clinical symptoms of allergy

The clinical manifestations of allergy are attributable mostly to the biologic effects of histamine. Tissues most commonly affected contain large numbers of mast cells and are sensitive to the effects of histamine released from them. These tissues are found in the gastrointestinal tract, skin, and upper and lower respiratory tracts (Fig. 9.6). The particular symptoms frequently reflect the main portal of entry for the allergen. For instance, pollens and other airborne allergens usually cause respiratory symptoms.

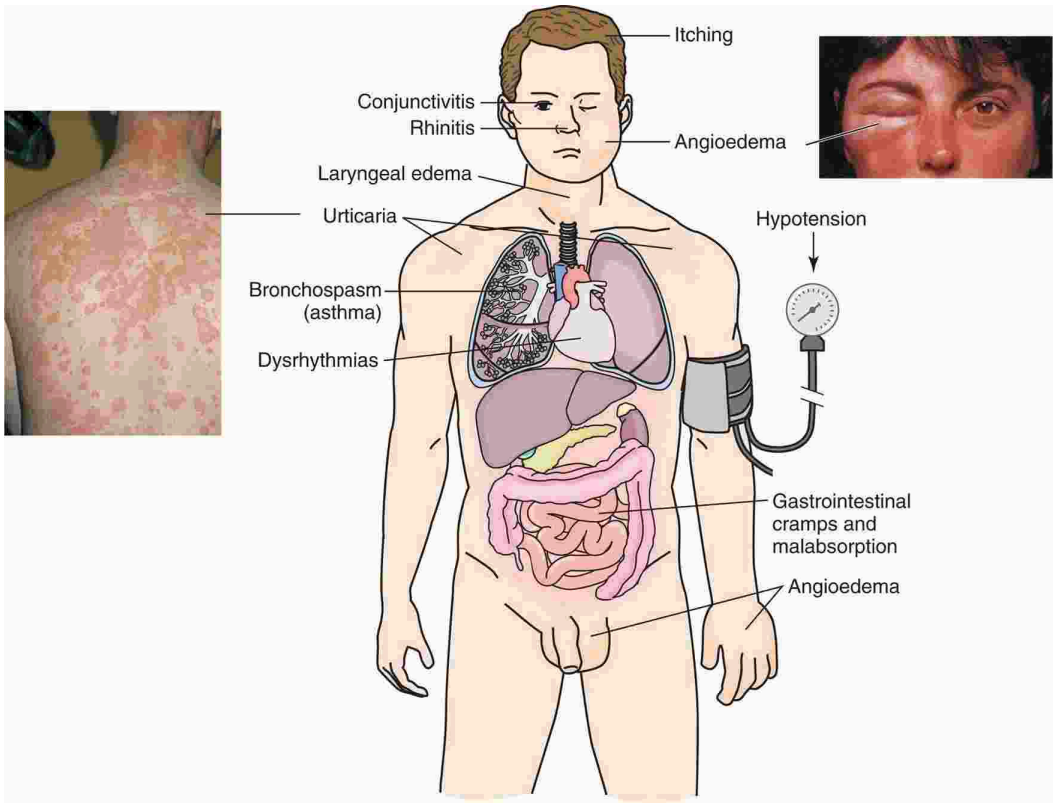

FIG. 9.6 Type I Hypersensitivity Reactions. Manifestations of allergic reactions as a result of type I hypersensitivity include pruritus, angioedema (swelling caused by exudation), edema of the larynx, urticaria (hives), bronchospasm (constriction of airways in the lungs), hypotension (low blood pressure), and dysrhythmias (irregular heartbeat) because of anaphylactic shock, and gastrointestinal cramping caused by inflammation of the gastrointestinal mucosa. Photographic inserts show a diffuse allergy-like eye and skin reaction on an individual. The skin lesions have raised edges and develop within minutes or hours, with resolution occurring after about 12 hours. (*Inserts* from Male D, Brostoff J, Roth D, et al. *Immunology*, 8th edition. St. Louis: Mosby; 2013.)

An illustration shows the anterior view of a human, with the internal organs highlighted. The following conditions are highlighted on the illustration: • Head: itching. • Eye: conjunctivitis. • Nose: rhinitis. • Cheek: angioedema (an accompanying closeup shows a person's eye swollen shut). • Neck: laryngeal edema. • Shoulders: urticaria (an accompanying closeup shows a person's shoulders and back, covered in welts). • Lungs: bronchospasm (asthma). • Heart: dysrhythmias. • Upper arm (attached with a blood pressure gauge): hypotension. • Intestines: gastrointestinal cramps and malabsorption. • Hands and genitalia: angioedema.

Effects of allergens on the mucosa of the eyes, nose, and respiratory tract include conjunctivitis (inflammation of the membranes covering the front of the eye and the lining the eyelids), rhinitis (inflammation of the mucous membranes of the nose), and asthma (constriction and swelling of the bronchi). Symptoms of all these conditions are caused by vasodilation, hypersecretion of mucus, edema, and swelling of the mucosa. Because the mucous membranes lining the respiratory tract (accessory sinuses, nasopharynx, and upper and lower respiratory tracts) are continuous, they are all adversely affected. The degree to which each is affected determines the symptoms of the disease. One of the most common type I reactions is asthma. It is presented in detail in Chapter 35. The central problem in asthma is obstruction of the large and small airways (bronchi) of the lower respiratory tract by bronchospasm (constriction of smooth muscle in airway walls), edema, and thick secretions. This leads to ventilatory insufficiency, wheezing, and difficult or labored breathing.

Urticaria, or hives, is a dermal (skin) manifestation of type I allergic reactions (see Fig. 9.6). The underlying mechanism is the localized

release of histamine and increased vascular permeability, resulting in limited areas of edema. Urticaria is characterized by white fluid-filled blisters (wheals) surrounded by areas of redness (flares). The wheal and flare reaction is usually accompanied by itching. Not all urticarial symptoms are caused by allergic (immunologic) reactions. Some, termed nonimmunologic urticaria, result from exposure to cold temperatures, emotional stress, medications, systemic diseases, hyperthyroidism, or malignancies (e.g., lymphomas).

Gastrointestinal allergies are caused primarily by allergens that enter through the mouth—usually foods or medicines. When food is the allergen, the active immunogen may be a product of food breakdown by digestive enzymes. Acute symptoms usually occur rapidly (frequently within minutes) and include vomiting, diarrhea, or abdominal pain. Prolonged or recurrent reactions may result in malabsorption or protein-losing enteropathy. Systemic symptoms may range from urticaria to life-threatening anaphylactic reactions. The most common food allergies are tree nuts, peanuts, milk, shellfish, and fish. The prevalence of food allergies is estimated at 3% to 10% of adults and 8% of children worldwide.[6] The most rapid and severe allergic reaction is **anaphylaxis**. Anaphylaxis occurs within minutes of reexposure to the antigen and can be either systemic (generalized) or cutaneous (localized). Symptoms of systemic anaphylaxis include pruritus, erythema, vomiting, abdominal cramps, diarrhea, and breathing difficulties, and the most severe reactions may include contraction of bronchial smooth muscle, edema of the throat, and decreased blood pressure that can lead to shock and death (see Chapter 48). Examples of systemic anaphylaxis are allergic reactions to antibiotics, bee stings, or peanuts.

Diagnosis and management of allergic reactions

Several tests are available to diagnose allergic reactions, including skin tests and measurement of IgE in the blood. Reactivity to a particular allergen may be tested by controlled administration of small doses of the suspected allergen or injection of an allergen into (intradermal) or onto (epicutaneous or prick test) the skin. If the individual is allergic to a particular allergen, a local wheal and flare reaction may occur within a few minutes at the site of injection. A variety of immunoassays can be

used can detect IgE antibodies in serum. These assays can be used to measure circulating levels of total IgE, or circulating levels of specific IgE antibodies against selected allergens.

If possible, avoidance of the allergen is the best method to limit allergic responses. Clinical **desensitization** to allergens can be achieved in some individuals. Minute quantities of the allergen are injected in increasing doses over a prolonged period. The procedure may reduce the severity of the allergic reaction in the treated individual.

Some type I allergic responses can be controlled by blocking histamine receptors with antihistamines. The effects of allergy on the respiratory system may require bronchodilators or medications that block leukotrienes (see Chapter 35). The most effective medications for allergic disease are the corticosteroids, which can be given by local administration (e.g., inhalers or topical ointments) or systemically to decrease tissue inflammation. For individuals with severe allergy, monoclonal antibodies that block IgE may be required (omalizumab). Other monoclonal antibodies that block IL-4 (dupilamab) and IL-5 (mepolizumab) are now available. In anaphylaxis, systemic administration of sympathomimetic medications such as epinephrine may be required to support the respiratory and cardiovascular systems (see Chapter 48).

Autoimmunity

Autoimmunity occurs when the immune system reacts against self-antigens to such a degree that autoantibodies or autoreactive T cells damage the individual's tissues. It is the result of a disturbance in the immunologic *tolerance* of self-antigens (see Chapter 8). This breakdown in tolerance is believed to occur in a genetically predisposed individual when there is some initiating event. Most often, the initiating event is unrecognized but is hypothesized to be an environmental factor such as infection or toxins, or some change in neurologic, endocrine, and/or immune status.

It is well established that autoimmune diseases can be familial. In familial cases, affected family members may not all have the same disease but rather may develop different autoimmune disorders. However, most autoimmune diseases appear as isolated events without a positive family history, and susceptibility for developing

such diseases appears to be linked to a combination of multiple genes and multifactorial. Genetic associations with particular autoimmune diseases have been identified for a variety of major histocompatibility complex (MHC) genes (see Chapter 8). Some associations are strong; others are more tenuous. Autoimmunity may result from changes in the way MHC molecules present antigen. These changes may cause an inappropriate or exaggerated response to environmental antigens such as microorganisms. A large variety of non-MHC genes also have been identified as risk factors for the development of specific autoimmune diseases. Most of these genes encode for inflammatory cytokines or costimulatory molecules found on the cell surface.

Tolerance is a state of immunologic control so that the individuals do not make a detrimental immune response against their own cells and tissues. *Central tolerance* occurs when autoreactive lymphocytes are either eliminated or suppressed in the primary lymphoid organs during differentiation of immature T or B lymphocytes (see Algorithm 8.1 and (8.2). *Peripheral tolerance* is maintained in the secondary lymphoid organs through the action of T regulatory (Treg) lymphocytes (see Chapter 8). Many autoimmune diseases display defects in either the number or the function of Treg cells in peripheral blood (see Emerging Science Box: T regulatory Cells and Autoimmunity).[7] In addition to Treg cells, dendritic cell processing and presentation of antigen are critical for the adaptive immune system to differentiate between self- and nonself-antigens. Defects in dendritic cell interaction with T cells have been linked to autoimmunity.[8]

In the vast majority of autoimmune diseases, the nature of the initiating event that results in a breakdown of tolerance is unclear.

Emerging Science BoxT Regulatory Cells and Autoimmunity

T regulatory cells (Tregs) are important for the induction and maintenance of peripheral tolerance and are key in preventing excessive immune responses and autoimmunity. It is believed that autoimmunity arises, at least in part, from a lack of peripheral tolerance associated with reduced Treg numbers or failure in their function. Tregs are differentiated in the thymus when T precursor

cells bind to self-antigens. Most of these self-reactive T cells will be clonally deleted, but some will instead be induced to become Treg which then migrate to the periphery. In addition, Tregs can be induced from T helper (Th) cells already in the periphery under inflammatory conditions. When Tregs recognize antigens, they release immunosuppressive cytokines such as interleukin (IL)-10 and transforming growth factor-beta (TGF-β). Recent studies have shown that Treg cells can be "unstable," meaning they have the ability to transform into other types of T cells under certain conditions (Treg plasticity). In autoimmune diseases, Tregs may become Th1, Th2, or Th17 cells, which promote cell-mediated and humoral immunity and inflammation rather than suppress it. These findings have led to the exploration of treatments for autoimmune diseases in which activated T cells that are attacking tissues are therapeutically induced to transform into Tregs, thus halting immune-mediated tissue damage. Tregs produced in the laboratory have been infused into individuals with severe autoimmune conditions such as graft-versus-host disease with promising results. These kinds of treatments might provide adequate tolerance without the use of immunosuppressive drugs that increase the risk of infection and cancer. Another potential use for Treg therapies is the prevention and management of transplant rejection in which Tregs would provide antigen-specific tolerance to the graft tissues without the need for systemic immunosuppression.

Antigen-specific therapeutic approaches for autoimmunity. *Nature Biotechnology*, 2019;37(3):238–251.

One of the most studied of these potential initiating events is the role of foreign antigens from infectious microorganisms causing **molecular mimicry**. Some antigens of infectious agents so closely resemble (mimic) a particular self-antigen that antibodies or T cells produced to protect against the infection also recognize the self-antigen as foreign (**cross-reactive antibody or T cell**). One example is rheumatic heart disease that may occur after a group A streptococcal sore throat. In this example, the M protein and group A carbohydrate in the streptococcal bacterial capsule mimic normal antigens in the heart valves resulting in the production of antibodies and T cells that damage the valves. Most potential associations between infection and autoimmunity are much less clear. For example, many researchers believe that there is a link between viral or bacterial infection and the onset of type 1 diabetes.[9] The link between infectious microorganisms and autoimmune disease continues to be investigated.

Women are far more likely to develop autoimmune disease than are men. Many theories have been proposed to explain this prevalence of autoimmunity in women. Many of the genes that code for immune function reside on the X chromosome. Although having two X chromosomes is protective against X-linked disorders (see Chapter 4), it has been proposed that hormonal changes during the life of a female individual may cause skewed activation of immune genes on X chromosomes.[10,11] Another hypothesis to explain the prevalence of autoimmunity in women is that a gene called VGLL3, which is more active in female than male skin cells, is overexpressed in women with autoimmune disease. This gene influences the function of several other genes involved in immune control.[12]

These kinds of initiating and contributing factors result in adaptive immune responses that are misdirected toward self-antigens. Self-directed immune responses often include a combination of hypersensitivity mechanisms II, II, and IV. The innate system is also activated with inflammatory damage to tissues.

Examples of Autoimmune Diseases

Many clinical disorders are associated with autoimmunity and are collectively referred to as **autoimmune diseases**. Table 9.2 provides a

list of a few of the many autoimmune diseases. Many of these and other autoimmune disorders will be discussed in later chapters of this textbook. In this chapter, we will discuss only two representative examples, heparin-induced thrombocytopenia (HIT) and systemic lupus erythematosus (SLE).

Table 9.2

Examples of Autoimmune Diseases

System Disease	Organ or Tissue	Probable Self-Antigen
Endocrine System		
Hyperthyroidism (Graves disease)	Thyroid gland	Receptors for thyroid-stimulating hormone
Hashimoto hypothyroidism	Thyroid gland	Thyroid cell surface antigens, thyroglobulin
Insulin-dependent diabetes	Pancreas	Islet cells, insulin, insulin receptors on pancreatic cells
Addison disease	Adrenal gland	Surface antigens on steroid-producing cells; microsomal antigens
Male infertility	Testis	Surface antigens on spermatozoa
Skin		
Pemphigus vulgaris	Skin	Intercellular substances in stratified squamous epithelium
Bullous pemphigoid	Skin	Basement membrane
Vitiligo	Skin	Surface antigens on melanocytes (melanin-producing cells)
Neuromuscular Tissue		

System Disease	Organ or Tissue	Probable Self-Antigen
Multiple sclerosis	Neural tissue	Surface antigens of nerve cells
Myasthenia gravis	Neuromuscular junction	Acetylcholine receptors; striations of skeletal and cardiac muscle
Rheumatic heart disease	Heart	Cardiac tissue antigens that cross-react with group A streptococcal antigen
Cardiomyopathy	Heart	Cardiac muscle
Gastrointestinal System		
Ulcerative colitis	Colon	Mucosal cells
Pernicious anemia	Stomach	Surface antigens of parietal cells; intrinsic factor
Primary biliary cirrhosis	Liver	Cells of bile duct
Chronic active hepatitis	Liver	Surface antigens of hepatocytes, nuclei, microsomes, smooth muscle
Eye		
Sjögren syndrome	Lacrimal gland	Antigens of lacrimal gland, salivary gland, thyroid, and nuclei of cells
Connective Tissue		
Ankylosing spondylitis	Joints	Sacroiliac and spinal apophyseal joint

System Disease	Organ or Tissue	Probable Self-Antigen
Rheumatoid arthritis	Joints	Collagen, immunoglobulin G (IgG)
Systemic lupus erythematosus	Multiple sites	Numerous antigens in nuclei, organelles, and extracellular matrix
Renal System		
Immune complex glomerulonephritis	Kidney	Numerous immune complexes deposited in glomerular vessels
Goodpasture syndrome	Kidney	Glomerular basement membrane
Hematologic System		
Idiopathic neutropenia	Neutrophil	Surface antigens on polymorphonuclear neutrophils
Idiopathic lymphopenia	Lymphocytes	Surface antigens on lymphocytes
Autoimmune hemolytic anemia	Erythrocytes	Surface antigens on erythrocytes
Autoimmune thrombocytopenic purpura	Platelets	Surface antigens on platelets
Respiratory System		
Goodpasture syndrome	Lung	Septal membrane of alveolus

System Disease	Organ or Tissue	Probable Self-Antigen
Endocrine System		
Hyperthyroidism (Graves disease)	Thyroid gland	Receptors for thyroid-stimulating hormone
Hashimoto hypothyroidism	Thyroid gland	Thyroid cell surface antigens, thyroglobulin
Insulin-dependent diabetes	Pancreas	Islet cells, insulin, insulin receptors on pancreatic cells
Addison disease	Adrenal gland	Surface antigens on steroid-producing cells; microsomal antigens
Male infertility	Testis	Surface antigens on spermatozoa
Skin		
Pemphigus vulgaris	Skin	Intercellular substances in stratified squamous epithelium
Bullous pemphigoid	Skin	Basement membrane
Vitiligo	Skin	Surface antigens on melanocytes (melanin-producing cells)
Neuromuscular Tissue		
Multiple sclerosis	Neural tissue	Surface antigens of nerve cells
Myasthenia gravis	Neuromuscular junction	Acetylcholine receptors; striations of skeletal and cardiac muscle
Rheumatic heart disease	Heart	Cardiac tissue antigens that cross-react with group A streptococcal antigen
Cardiomyopathy	Heart	Cardiac muscle
Gastrointestinal System		
Ulcerative colitis	Colon	Mucosal cells
Pernicious anemia	Stomach	Surface antigens of parietal cells; intrinsic factor
Primary biliary cirrhosis	Liver	Cells of bile duct
Chronic active hepatitis	Liver	Surface antigens of hepatocytes, nuclei, microsomes, smooth muscle
Eye		
Sjögren syndrome	Lacrimal gland	Antigens of lacrimal gland, salivary gland, thyroid, and nuclei of cells
Connective Tissue		
Ankylosing spondylitis	Joints	Sacroiliac and spinal apophyseal joint
Rheumatoid arthritis	Joints	Collagen, immunoglobulin G (IgG)
Systemic lupus erythematosus	Multiple sites	Numerous antigens in nuclei, organelles, and extracellular matrix
Renal System		
Immune complex glomerulonephritis	Kidney	Numerous immune complexes deposited in glomerular vessels
Goodpasture syndrome	Kidney	Glomerular basement membrane
Hematologic System		
Idiopathic neutropenia	Neutrophil	Surface antigens on polymorphonuclear neutrophils
Idiopathic lymphopenia	Lymphocytes	Surface antigens on lymphocytes
Autoimmune hemolytic anemia	Erythrocytes	Surface antigens on erythrocytes
Autoimmune thrombocytopenic purpura	Platelets	Surface antigens on platelets
Respiratory System		
Goodpasture syndrome	Lung	Septal membrane of alveolus

Autoimmune disease: Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a common complication associated with the use of the anticoagulant drug heparin (see Chapter 29). Heparin serves as a hapten and forms molecular complexes with the tissue-specific platelet antigen called platelet factor 4 (PF4). These

hapten/antigen complexes are then attacked by autoantibodies causing type II hypersensitivity. When these autoantibodies bind to the surface of platelets, they cause two problems. The first is that they destroy platelets, leading to thrombocytopenia and bleeding. The second is that the destroyed platelets release particles that activate thrombin, forming clots that can block blood vessels (thrombosis).[13]

Approximately 2% of individuals treated with heparin will develop clinically significant HIT.[14] To diagnose HIT, laboratory tests are done to document thrombocytopenia and/or thrombosis and to look for the presence of the autoantibodies. Management requires stopping heparin therapy and, if anticoagulation is still needed, substituting with a nonheparin anticoagulant.[13]

Autoimmune disease: Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is one of the most common, complex, and serious of the autoimmune disorders. It can affect any organ in the body. SLE is characterized by the production of a large variety of antibodies (autoantibodies) against self-antigens, including nucleic acids, erythrocytes, coagulation proteins, phospholipids, lymphocytes, platelets, and many other self-components. The most characteristic autoantibodies are against nucleic acids (e.g., single-stranded deoxyribonucleic acid [ssDNA], double-stranded DNA [dsDNS]), histones, ribonucleoproteins, and other nuclear materials. The blood normally contains many of these products of cellular turnover and breakdown. In SLE, autoantibodies react with the circulating antigen and form circulating immune complexes. The deposition of circulating DNA/anti-DNA complexes in the kidneys can cause severe kidney inflammation (Fig. 9.7). Similar reactions can occur in other systems, such as the brain, heart, spleen, lung, gastrointestinal tract, peritoneum, and skin. Thus many of the symptoms of SLE result from a type III hypersensitivity reaction and affect many systems. Other symptoms are related to type II hypersensitivity reactions and include destruction of red blood cells (anemia), lymphocytes (lymphopenia), and platelets (thrombocytopenia).

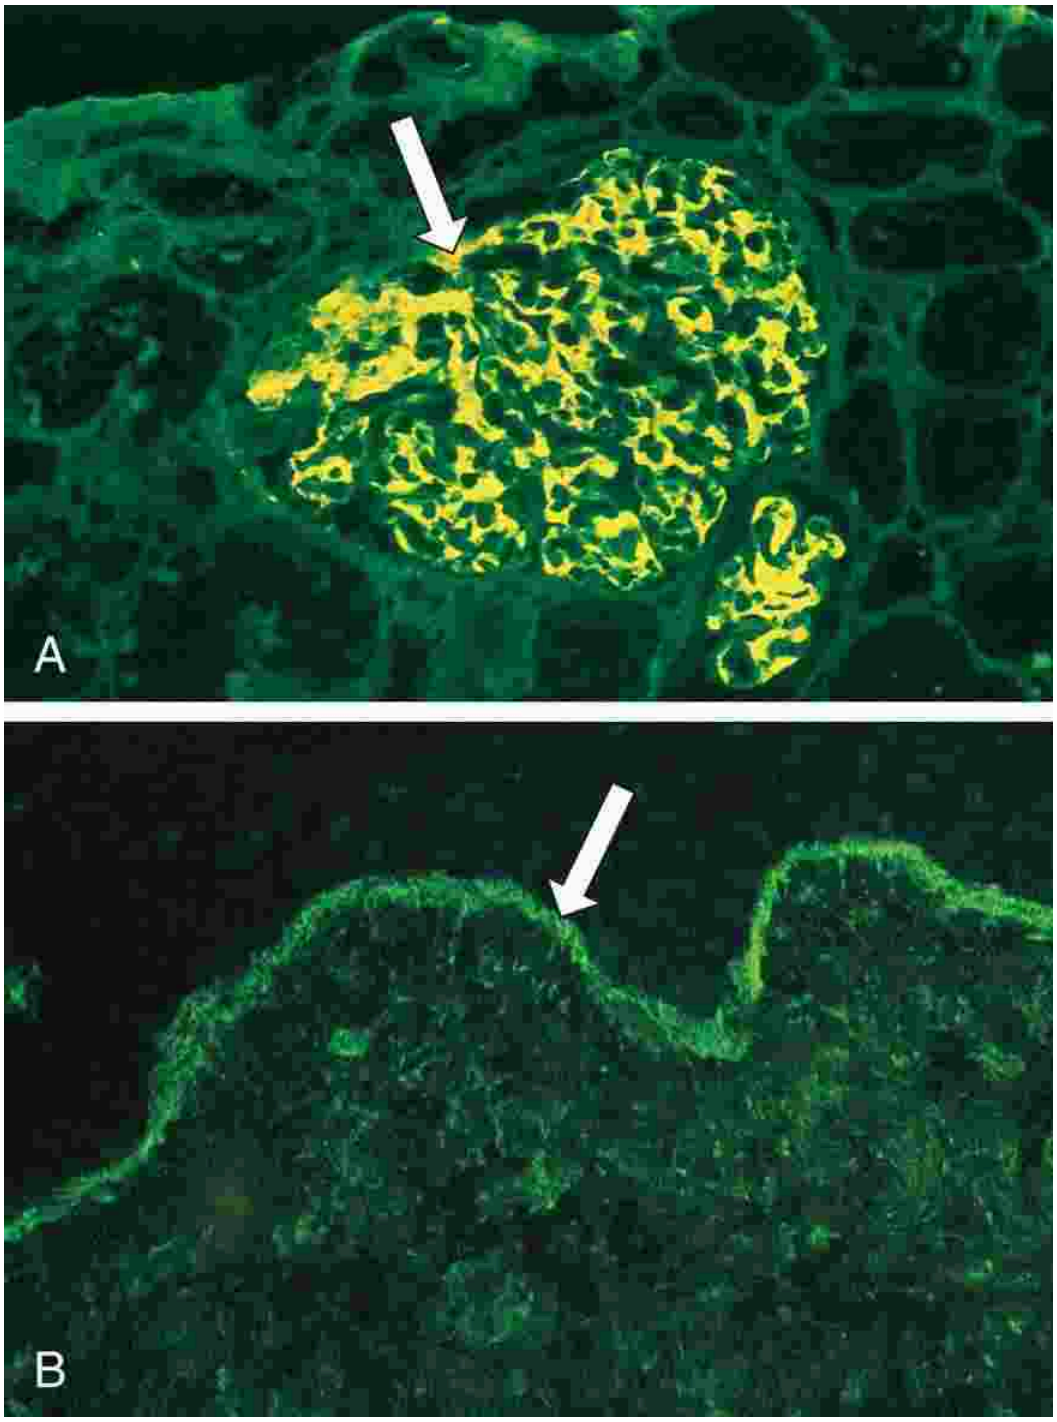

FIG. 9.7 Deposition of Immunoglobulin G (IgG) in the Kidney and Skin of Individuals With Lupus. These photographs of tissue were obtained from individuals with lupus and stained with fluorescent anti-IgG. **(A)** Section from a kidney showing a glomerulus with deposits of IgG (*arrow*, indicating

bright areas of staining). **(B)** Section of the skin showing deposition of IgG along the dermal-epidermal junction (*arrow*, indicating bright green staining). SLE, like most autoimmune diseases, occurs more often in women (approximately a 9:1 predominance of females), especially in the 20- to 40-year-old age group.[15] Blacks are affected more often compared with Whites (approximately an eightfold increased risk). Several genes have been identified that are associated with an increased risk for SLE, including changes in MHC molecular structure.[16,17] Environmental triggers (e.g., ultraviolet radiation exposure, smoking, medications, viruses such as Epstein-Barr virus [EBV], low vitamin D levels, environmental pollutants) and hormonal changes interplay with genetic predisposition in disease development and activity.[18] As in many autoimmune conditions, microbiome dysbiosis is thought to negatively impact adaptive immune responses in SLE.[19]

As with other autoimmune diseases, clinical manifestations of SLE may wax and wane; the individual may go through periods of remission and be relatively disease free until the onset of a *flare* (exacerbated disease activity). Clinical manifestations of SLE depend on organ systems involvement, including skin (rashes and photosensitivity), eyes (keratoconjunctivitis, scleritis, uveitis retinopathy), mucus membranes (ulcers), joints (arthralgias), linings of the viscera (serositis, pleuritis), kidney (proteinuria), blood (anemia), gut (abdominal pain, vasculitis, hepatobiliary disease), and the neurologic system (seizures or psychosis).[20] Lupus nephritis is common and carries a high risk for end-stage renal failure. Cardiovascular disease is common.[21] Fever also may be present. Classification of SLE is based on the type and severity of organ system damage along with measurement of antibodies and complement levels.[22]

Laboratory diagnosis is usually based on a positive antinuclear antibody (ANA) screening test. This is a very sensitive test, but a substantial number of false-positive results occur in healthy individuals and those with other diseases. Detection of ANAs is usually followed by one or more specific tests (e.g., antibodies against Smith antigen [Sm], and dsDNA).[20] Further diagnostic testing may be indicated such as urinalysis and serum C reactive protein and complement levels.

There is no cure for SLE or most other autoimmune diseases. Fatalities resulting from SLE are usually related to infection, organ failure, or cardiovascular disease. The goals of treatment are to control symptoms and prevent further damage by suppressing the autoimmune response. Ultraviolet light may initiate flares, and protection from sun exposure is helpful. Nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, reduce inflammation and relieve pain. Hydroxychloroquine is the preferred treatment for individuals with stable disease. Corticosteroids are often prescribed for flares and more serious active disease. Immunosuppressive drugs, (e.g., methotrexate, cyclophosphamide, azathioprine, tacrolimus, or mycophenolate mofetil) are used to treat severe symptoms. Immunotherapies focused on B-cell depletion (e.g., belimumab, rituximab) are used in selected individuals.[23] Many new biologic agents, such as anifrolumab (anti–type I interferon receptor antibody) and ustekinumab (antibody against IL-12/23 [p40]), are in clinical trials.[24]

Alloimmunity

Alloimmunity (isoimmunity) occurs when the immune system of one individual produces an immunologic reaction against tissues of another individual. **Alloantigens** (isoantigens) are nonself-antigens from members of the same species. No two individuals have exactly the same antigens on their tissues; therefore the introduction of one individual's tissues and cells into another will result in a strong immune response to the foreign antigens. Alloimmunity can be observed during immunologic reactions to blood transfusions, fetal tissues, or transplanted tissue.

Alloimmune disease: Transfusion reactions

Red blood cells (erythrocytes) express several important surface antigens, which are known collectively as the **blood group antigens** and can be targets of alloimmune reactions. More than 80 different red blood cell antigens are grouped into several dozen blood group systems. The most important of these, because they provoke the strongest humoral alloimmune response, are the ABO and Rh systems.

The **ABO blood group** consists of two major carbohydrate antigens, labeled A and B (Fig. 9.8), that are expressed on virtually all cells. These are codominant so that both A and B can be simultaneously expressed, resulting in an individual having any one of four different blood types. The erythrocytes of blood type A express the type A carbohydrate antigen, those with blood type B express the B antigen, those with blood type AB express both A and B antigens on the same cell, and those of blood type O express neither the A nor the B antigen. A person with type A blood also has circulating antibodies to the B carbohydrate antigen. If this person receives blood from a type AB or B individual, a severe transfusion reaction occurs, and the transfused erythrocytes are destroyed by agglutination or complement-mediated lysis. Similarly, a type B individual (whose blood contains anti-A antibodies) cannot receive blood from a type A or AB donor. Type O individuals, who have neither antigen but have both anti-A and anti-B antibodies, cannot accept blood from any of the other three types. These naturally occurring antibodies, called **isohemagglutinins**, are IgM antibodies developed early in life because of the presence of similar antigens expressed on naturally occurring bacteria in the intestinal tract.

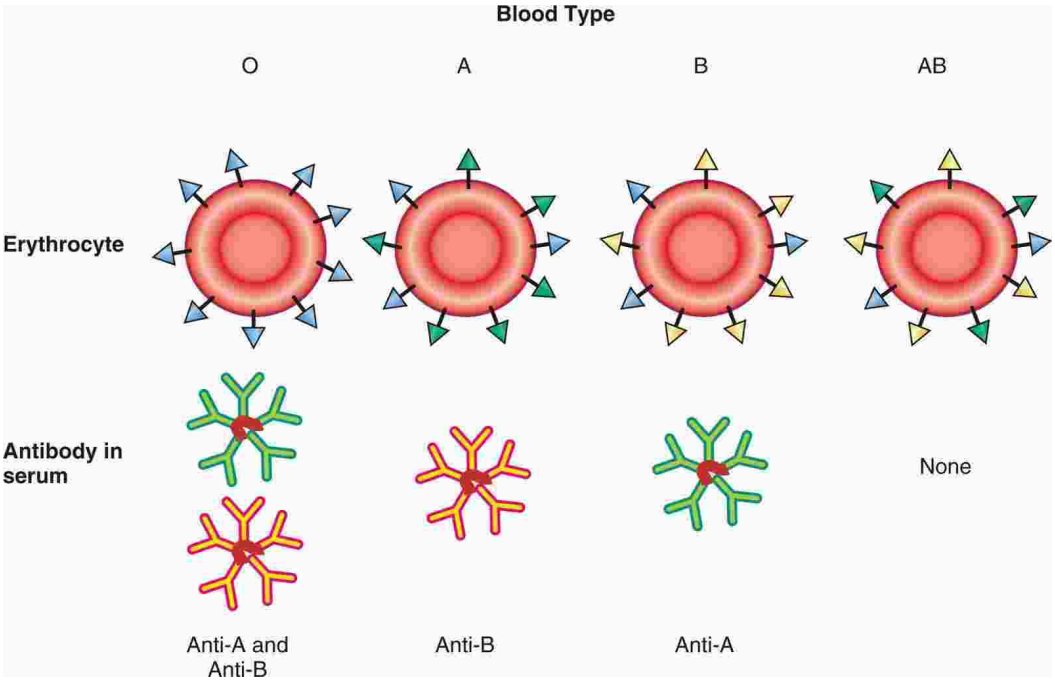

FIG. 9.8 ABO Blood Types.
This figure shows the relationship of antigens and antibodies associated with the ABO blood groups. The surfaces of erythrocytes of individuals with blood group O have a core carbohydrate that is present on cells of all ABO blood groups (H antigen, depicted in *blue*). The sera of blood group O individuals contain immunoglobulin M (IgM) antibodies against both A and B carbohydrates. In individuals of the blood group A, some of the H antigens have been modified into A antigens (depicted in *green*). The sera of these individuals have IgM antibodies against the B antigen. In individuals with blood group B, some of the H antigens have been modified into B antigens (depicted in *yellow*). These individuals have IgM antibodies against the A antigen in their sera. In individuals of the blood group AB, some of the H antigens have been modified into both the A and B antigens. These individuals do not have antibody to either A or B antigens.

A series of illustrations shows A B O blood types. The erythrocyte for O blood type comprises H antigen, and the antibody in serum comprises anti-A and anti-B. The erythrocyte for A blood type comprises A antigen and H antigen, and the antibody in serum comprises anti-B. The erythrocyte for B blood type comprises B antigen and H antigen, and the antibody in serum comprises anti-A. The erythrocyte for A B blood type comprises A antigen, B antigen, and H antigen, and the there are no antibody in serum.

Harmful transfusion reactions can be prevented by complete and careful ABO matching between donor and recipient. Because individuals with type O blood lack both types of antigens, they are considered **universal donors**—that is, anyone can accept their red blood cells. Similarly, type AB individuals are considered **universal recipients** because they lack both anti-A and anti-B antibodies and can be transfused with any ABO blood type.

Alloimmune disease: Hemolytic disease of the fetus and newborn

Hemolytic disease of the fetus and newborn (HDFN) (also known as erythroblastosis fetalis) is a condition in which maternal blood antigens do not match those of the fetus. This disorder usually results from incompatibility between maternal and fetal red blood cell (erythrocyte) Rho(D) antigens. The **Rh blood group** is a group of antigens expressed on red blood cells. This is the most diverse group of red blood cell antigens, consisting of at least 45 separate antigens, although only one is considered of major importance: the D antigen. Individuals who express the D antigen on their red blood cells are Rh positive, whereas individuals who do not express the D antigen are Rh negative. Approximately 85% of North Americans are Rh positive. Rh-negative individuals make IgG antibody to the D antigen (anti-D) if exposed to Rh-positive erythrocytes. In an Rh-negative mother whose fetus is Rh-

positive, antibodies from the mother cross the placenta and attack fetal erythrocytes. The attack induces severe anemia in the fetus (erythroblastosis fetalis) or in the newborn (erythroblastosis neonatorum). With each successive pregnancy with an Rh-positive fetus, the mother's immune system makes anti-D antibodies faster and in greater amounts. Diagnosis involves measurement of maternal antibodies and fetal testing. Prenatal and postnatal management may include intrauterine transfusions, exchange transfusions, intravenous immunoglobulin (IVIG), or plasmapheresis.[25] The occurrence of this particular form of the disease has decreased dramatically because of the use of prophylactic anti-D immunoglobulin (i.e., RhoGAM). Administration of anti-D antibody within a few days of exposure to RhD-positive erythrocytes prevents sensitization against the D antigen (see Chapter 30).

Alloimmune disease: Transplant rejection

Molecules of the **major histocompatibility complex (MHC)** were discussed in Chapter 8 as antigen-presenting molecules (see Figs. 8.6 and 8.7). MHC molecules also are a major target of transplant rejection. The human MHC molecules are also referred to as **human leukocyte antigens (HLAs)**, especially in the context of transplantation. The different MHC genetic loci are identified as class I: HLA-A, HLA-B, and HLA-C, and class II: HLA-DR, HLA-DQ, and HLA-DP (Fig. 9.9). Humans have two copies of each MHC locus (one inherited from each parent) that are codominant so that molecules encoded by each parent's genes are expressed on the surface of every cell, except erythrocytes. The tremendous number of possible alleles that can be expressed throughout the population makes it highly unlikely that any two unrelated individuals will have the same HLA antigens. This diversity of HLA molecules becomes clinically relevant during organ transplantation. The recipient of a transplant will mount an immune response against the foreign HLA antigens on the donor tissue, resulting in rejection. To minimize the chance of tissue rejection, the donor and recipient are tissue-typed to identify differences in HLA antigens prior to transplantation. The more similar the two individuals are in their HLA tissue type, the more likely it is that transplantation will be successful. The chance of finding a reasonably close match

among siblings is much higher than the general population, and, clearly, the most successful transplants would be between identical twins because they are nearly identical genetically.

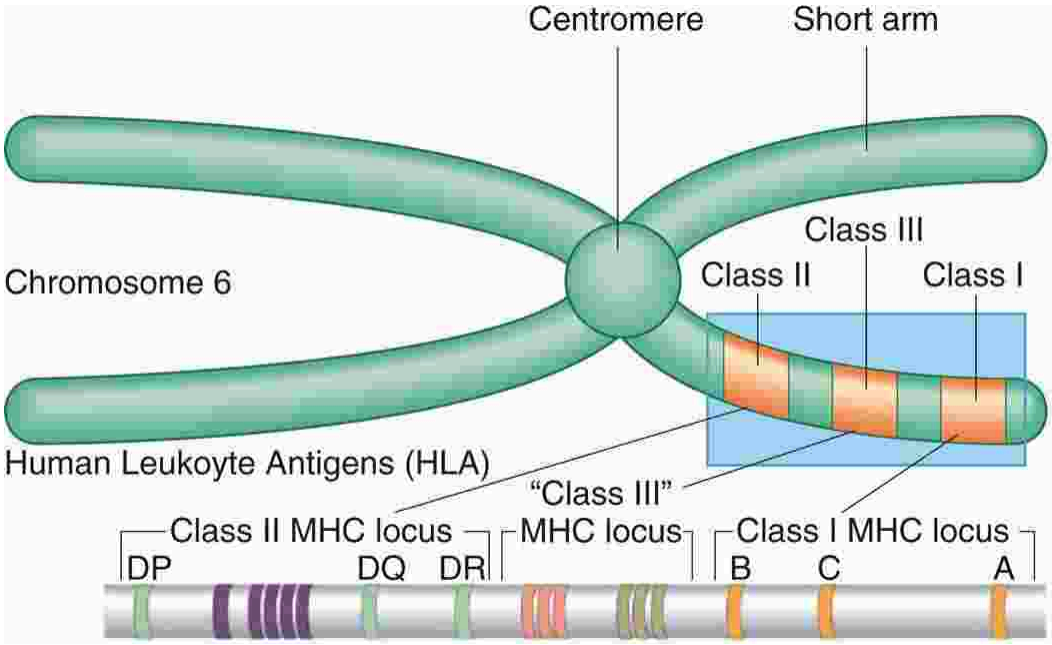

FIG. 9.9 Human Leukocyte Antigens (HLAs). The major histocompatibility complex *(MHC)* is located on the short arm of chromosome 6 and contains genes (genetic loci) that code for class I antigens (found mostly on nucleated cells), class II antigens (found mostly on dendritic cells, macrophages and B lymphocytes), and class III proteins (i.e., complement proteins and cytokines). From Peakman M, Vergani D. *Basic and clinical immunology*, 2nd edition. London: Churchill Livingstone; 2009 and Abbas AK, Lichtman AH, Pillai S. *Basic immunology*, 4th edition. St. Louis: Elsevier; 2014.

An illustration of chromosome 6 is labeled with the centromere and the short arms. The following protein classes are labeled on the short arm, from the outside toward the centromere: class 1, class 3, and class 2. The classification of the human leukocyte antigens (H L A) are as follows: • Class 1 M H C locus. From the right to

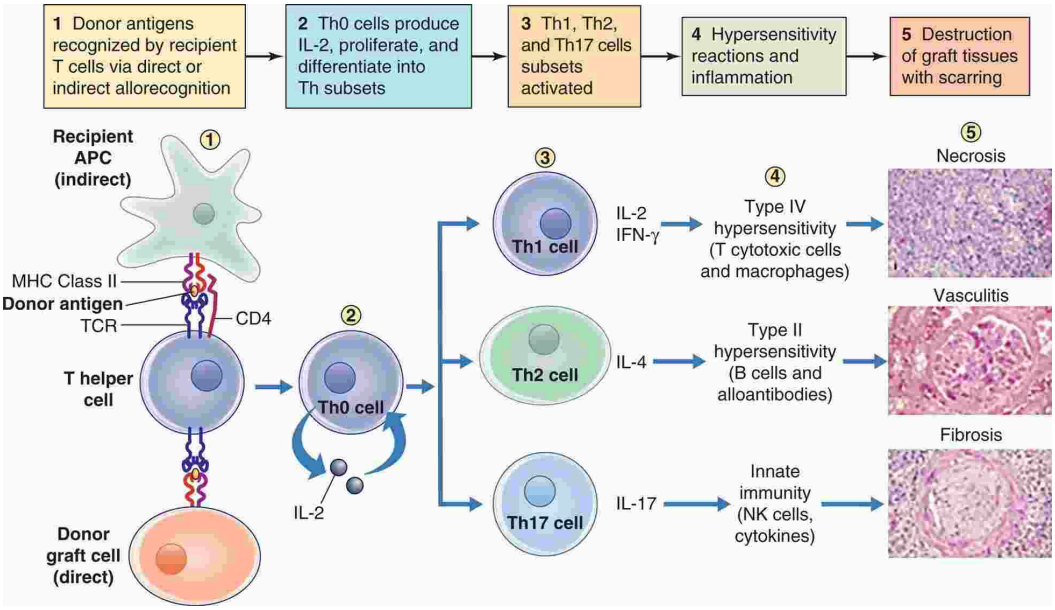
the left: A, C, B. • Class 3 M H C locus. • Class 2 M H C locus. From the right to the left: D R, D Q, and D P.

When donor tissue is transplanted into a recipient, the recipient's T cells recognize alloantigens in two different ways: (1) *direct* recognition of foreign HLA antigens, and (2) *indirect* recognition of donor peptides that are presented on recipient antigen-presenting cells (see Algorithm 9.1). Both processes result in the widespread activation and proliferation of Th cells. Th cells differentiate into several subtypes that produce numerous cytokines, including IL-2 and interferon (IFN)-γ (Th1 cells), IL-4 (Th2 cells), and IL-17 (Th17 cells) (see Chapter 8). These cytokines activate T cytotoxic cells, macrophages, NK cells, and B cells such that there is an intense cell-mediated and humoral attack on the graft tissue.

Transplant rejection may be classified as hyperacute, acute, or chronic, depending on the amount of time that elapses between transplantation and rejection and the mechanisms by which rejection occurs. **Hyperacute rejection** is immediate and rare. Hyperacute rejection occurs because of the presence of preexisting antibodies (type II hypersensitivity) to HLA antigens on the vascular endothelial cells in the grafted tissue. These preexisting antigens are usually found in individuals who have received multiple blood transfusions or previous transplants. When the circulation is reestablished to the grafted area, the graft may immediately turn white (the so-called white graft) instead of a normal pink color. Hyperacute rejection can be avoided by testing the recipient for preexisting antibodies prior to transplantation.

Acute rejection occurs within days to months after transplantation. This type of rejection occurs when the recipient develops an immune response against unmatched HLA antigens after transplantation. Both humoral and cell-mediated immune responses play a role (Algorithm 9.2). Direct and indirect recognition of alloantigens result in release of Th1, Th2, and Th17 cytokines. Alloantibodies are formed to graft blood vessels (type II hypersensitivity) which then activate complement, resulting in necrosis of graft vessels (vasculitis). Tc cells and macrophages are activated, resulting in direct lysis of graft cells and disruption of tissue architecture; this leads to graft dysfunction and

destruction (type IV hypersensitivity). NK cells and other components of innate immunity also play a role. The release of IL-2 is of particular importance in acute rejection; thus several antirejection medications target IL-2 synthesis or receptors (e.g., cyclosporin, tacrolimus, basiliximab). Other antirejection medications deplete T- and B-cell numbers, metabolism, and function (e.g., mycophenolate mofetil, rituximab, prednisone, azathioprine, belatacept), or block inflammatory cytokines such as IL-6 (e.g., tocilizumab). New methods for achieving graft tolerance include adoptive transfer of donor and recipient Treg cells and myeloid-derived suppressor cells.[26,27] Studies are exploring the potential for modifying the epigenetic profiles of immune cells and the use of messenger RNA (mRNA) in the prevention of graft rejection.[28] The choice of immunosuppressive medications is based on the type of organ being transplanted and the potential for recipient toxicity.



ALGORITHM 9.2 **Acute Graft Rejection.**

Acute graft rejection occurs days to months after transplantation. Recipient T helper (Th) cells recognize graft human leukocyte antigens (direct allorecognition) or donor antigens presented on recipient antigen-presenting cells (indirect allorecognition). These cells then secrete IL-2, proliferate, and differentiate into Th1, Th2, or Th17 cells. Th1 cells secrete IL-2 and IFN-γ which activate T cytotoxic cells and macrophages which participate in type IV hypersensitivity (cell-mediated immunity). Th2 cells secrete IL-4 which activate B cells to become alloantibody-producing plasma cells. Th17 cells secrete IL-17 which stimulates inflammation. These processes result in necrosis of graft cells, vasculitis of graft blood vessels, and fibrosis (scarring) of graft tissue. The end result is dysfunction and death of the transplanted organ. *IFN-γ*, Interferon-gamma; *IL*, interleukin; *MHC*, major histocompatability complex; *Th*, T helper; *TCR*, T cell receptor.

An illustration flowchart demonstrates acute graft rejection. There are five stages of rejection. 1. Donor antigens recognized by recipient T cells via direct or indirect allorecognition. Recipient A P C (indirect) and donor graft cell (direct) bind to the T helper cell through M H C class 2, donor antigen, T C R, and C D 4. 2. T h 0 cells produce I L-2, proliferate, and differentiate into T h subsets. 3. T h 1, T h2, and T h 17 cells subsets activated. 4. Hypersensitivity reactions and inflammation. 5. Destruction of graft tissue with scarring. The result of activation of the different cells are as follows: • T h 1 cell secretes I L-2, I F N-gamma. Type 4 hypersensitivity (T cytotoxic cells and macrophages) leads to necrosis. An accompanying photomicrograph shows dead cells. • T h 2 cell secretes I L-4. Type 2 hypersensitivity (B cells and alloantibodies) leads to vasculitis. An accompanying photomicrograph shows inflamed blood vessels. • T h 17 cell secretes I L-17. Innate immunity (N K cells, cytokines) leads to fibrosis. An accompanying photomicrograph shows a network of fibrous connective tissue.

Chronic rejection may occur after a period of months or years of normal function. It is characterized by slow, progressive organ failure. Chronic rejection occurs most often in recipients who were poorly matched to their donor, have comorbidities (e.g., diabetes, hypertension), received a graft that was in poor condition or was damaged during the transplantation procedure, or have required treatment for multiple acute rejection episodes.

Chronic rejection involves several mechanisms. A cell-mediated (type IV hypersensitivty) reaction against minor histocompatibility antigens on the grafted tissue contributes to persistent Tc-cell and phagocyte activation. Th17 cytokines trigger chronic inflammation. There also is binding of alloantibodies to donor graft MHC molecules, resulting in complement activation and tissue destruction (late antibody-mediated rejection).[29] These processes are subacute and slowly progressive, leading to graft fibrosis (scarring), dysfunction, and tissue death. Once chronic rejection is well established, there are few effective treatments, and it may be necessary to replace the graft with a new transplanted organ.

Deficiencies in Immunity

Immune deficiency is the failure of the immune or inflammatory response to function normally, resulting in increased susceptibility to infections and cancer. **Primary (congenital) immune deficiency** is caused by a genetic defect, whereas **secondary (acquired) immune deficiency** is caused by another condition, such as cancer, infection, or normal physiologic changes, such as aging. Acquired forms of immune deficiency are far more common than the congenital forms.

Initial Clinical Presentation

The clinical hallmark of immune deficiency is a tendency to develop unusual or recurrent, severe infections. The most severe primary immune deficiencies develop in children 2 years of age and younger. Potential immune deficiencies should be considered if the individual has experienced severe, documented bouts of pneumonia, otitis media, sinusitis (sinus infection), bronchitis, septicemia (blood infection), meningitis, or infections with opportunistic microorganisms (e.g., *Pneumocystis jiroveci*). Infections are generally recurrent, and multiple simultaneous infections are common. Invasive fungal infections are rare in healthy individuals and strongly indicate a defective immune system. Children frequently present with failure to thrive because of diarrhea and other chronic symptoms. A familial history of immune deficiency may be found in some types of primary deficiency.

The type of recurrent infections may indicate the type of immune defect. Deficiencies in T-cell immune responses are associated with recurrent infections caused by certain viruses (e.g., varicella zoster, cytomegalovirus [CMV]), fungi, yeasts (e.g., *Candida, Histoplasma*), or atypical microorganisms (e.g., *P. jiroveci*). B-cell deficiencies and phagocyte deficiencies are suggested if the individual has documented, recurrent infections with microorganisms that require opsonization (e.g., encapsulated bacteria, such as *Pneumococcus*) or those with viruses against which humoral immunity is normally effective (e.g., rubella virus). Some complement deficiencies resemble defects in antibody or phagocyte function, but others are associated with disseminated infections with bacteria of the genus *Neisseria* (*Neisseria meningitides* and *Neisseria gonorrhoeae*).

Primary (Congenital) Immune Deficiencies

Most primary immune deficiencies are the result of *single gene defects*. To date, 430 gene mutations are associated with immunodeficiency disorders.[30] In general, the mutations are sporadic and not inherited: a family history exists in only approximately 25% of individuals. The sporadic mutations occur before birth, but the onset of symptoms may be early or later, depending on the particular syndrome. In some instances, symptoms of immune deficiency appear within the first 2 years of life. Other immune deficiencies are slowly progressive, with the onset of symptoms appearing in the second or third decade of life.

The prevalence of primary immune deficiency diseases globally varies dramatically from country to country, and data are complicated by differences in diagnostic and reporting methods. The prevalence of diagnosed primary immune deficiency in North America is approximately 5 cases per 100,000 individuals; however, it is estimated that as many as 70% of cases are undiagnosed.[31] Many are subtle with minor deficiencies, but several result in major defects and lead to recurrent life-threatening infections. Sex distribution is approximately even, although some specific diseases have a male or female predominance. Primary immune deficiencies are classified into 10 groups, based on the principal component of the immune or inflammatory systems that is defective.[30] Of these 10 groups, the most

common disorders are included within combined immunodeficiencies (affecting both cellular and humoral immunity). These disorders may also be associated with syndromic features. The other classification groups include predominantly antibody deficiencies, diseases of immune dysregulation, defects in phagocyte number or function, defects in innate immunity, autoinflammatory disorders, complement defects, bone marrow failure, and phenocopies of inborn errors of immunity.[30] To provide a better understanding of the diversity and severity of primary immune deficiencies, a few select examples of each category will be discussed.

Combined Deficiencies

Combined deficiencies include the most life-threatening disorders and result from defects that directly affect the development of both T and B lymphocytes. The severity of each disorder depends on the degree to which B and T cells are affected.

Combined deficiencies wthout nonimmunologic abnormalities

Severe combined immunodeficiencies (SCIDs) are the most common combined deficiency without nonimmunologic abnormalities. Most often, it is inherited in an autosomal recessive pattern, or it may be X-linked.[32] There are at least 20 different forms of SCID, depending on how the underlying genetic defect affects lymphocyte development and function. T-cell differentiation is defective, and, depending on the type of SCID, B cells and NK cells also are affected.[32] Most individuals with SCIDs have few detectable lymphocytes or NK cells in the circulation and secondary lymphoid organs (spleen, lymph nodes). Immunoglobulin levels, especially IgM and IgA, are absent or greatly reduced. The most severe form of SCID is due to *reticular dysgenesis* in which a common stem cell fails to develop into mature immune cells. Most children with this form of SCID die in utero or soon after birth.

Several forms of SCID are caused by autosomal recessive enzymatic defects that result in the accumulation of toxic metabolites, and rapidly dividing cells, such as lymphocytes, are especially sensitive. For instance, deficiency of **adenosine deaminase (ADA deficiency)** results in the accumulation of toxic purines. Enzyme replacement therapy is

available for this form of SCID.[33] **X-linked SCID** results from a common defect in important IL receptors needed for lymphocyte maturation (e.g., IL-2, IL-4, IL-7, and others). Recent reports demonstrate the remarkable effectiveness of gene therapy in which a lentivirus is used as a vector to insert a normal copy of the IL-2 receptor (IL-2R) gene into a person's own hematopoietic stem cells.[34]

Even if nearly adequate numbers of B and T cells are produced, their cooperation may be defective. **Bare lymphocyte syndrome** is the form of SCID characterized by the inability of lymphocytes and macrophages to produce MHC class I or class II molecules. Without MHC molecules, antigen presentation and intercellular cooperation cannot occur effectively. Children with this deficiency develop serious, life-threatening infections and usually die before age 5 years.

A SCID newborn screening test is available and has been in use in the United States since 2008. After an abnormal screening, additional testing is needed to determine which type of SCID is present.[35] This approach has resulted in prompt treatment and higher survival rates and is now performed for all newborns in the United States. Hematopoietic stem cell transplantation is the standard treatment for infants with SCID; unfortunately, it is not universally effective and can be associated with serious complications such as graft-versus-host disease (GVHD). New gene therapies are emerging for several forms of SCID.[36]

Combined deficiencies with nonimmunologic abnormalities

Wiskott-Aldrich syndrome (WAS), an X-linked disorder characterized by the clinical triad of low platelet count (thrombocytopenia), eczema, and recurrent infections, is a condition in which IgM antibody production is greatly depressed. WAS results from a mutation of the *WAS* gene which causes defects in the WAS protein (WASP). WASP is required for normal differentiation of B cells and several other hematopoietic cell types. For example, defective WASP affects the actin cytoskeleton, which is important for platelet function. Immunodeficiencies include reduced antibody responses against antigens that primarily elicit an IgM response, such as polysaccharide antigens from bacterial cell walls (e.g., *Pseudomonas aeruginosa,*

Streptococcus pneumoniae, Haemophilus influenzae). Defective WASP also impacts neutrophil migration and function. Clinical manifestations include bleeding, eczematous rash, and recurrent infections (e.g., otitis media, pneumonia, herpes simplex, CMV). Autoimmune conditions (e.g., hemolytic anemia) are also common. Management includes IVIG or subcutaneous immunoglobulin (SQIG), stem cell transplantation, and gene therapy.[37]

Chromosome 22q11.2 deletion syndrome (DiGeorge syndrome or velocardiofacial syndrome) is another combined immunodeficiency with syndromic features. Chromosome 22q11.2 deletion is the most common microdeletion genetic syndrome in humans.[38] This mutation is associated with a wide spectrum of phenotypes even within families. The deletion of a particular gene, T-box transcription factor 1 (TBX1), is thought to be responsible for many of the syndrome's characteristic signs and symptoms. The TBX1 gene provides instructions for making a protein called T-box 1. The T-box 1 protein is necessary for the development of muscles and bones of the face and neck, aorta, and the thymus and parathyroid glands.[39] In most cases, hypoplasia of the thymus results in greatly decreased T-cell numbers and function. Immunocompromise with susceptibility to infection is complicated by a shift in Th-cell function to Th2 predominance resulting in allergies, as well as a reduction in Treg function resulting in autoimmune disorders. Cardiac and endocrine problems are also common. Defective development of the third and fourth pharyngeal pouches during embryonic development results in thymic defects and the absence of the parathyroid gland (causing inability to regulate calcium concentration). Low blood calcium levels cause the development of tetany or involuntary rigid muscular contraction. This syndrome frequently is associated with abnormal development of facial features that are controlled by the same embryonic pouches; these include low-set ears, fish-shaped mouth, and other altered features (Fig. 9.10). Loss of this gene may also contribute to behavioral problems such as schizophrenia and bipolar disorder. Dopaminergic neurons are also affected, leading to an increased risk for development of Parkinson disease later in life.[40] Management includes monitoring and intervention for hypoparathyroidism, heart defects, facial

abnormalities, infections, and neurologic complications. No specific treatment for the underlying condition is currently available.

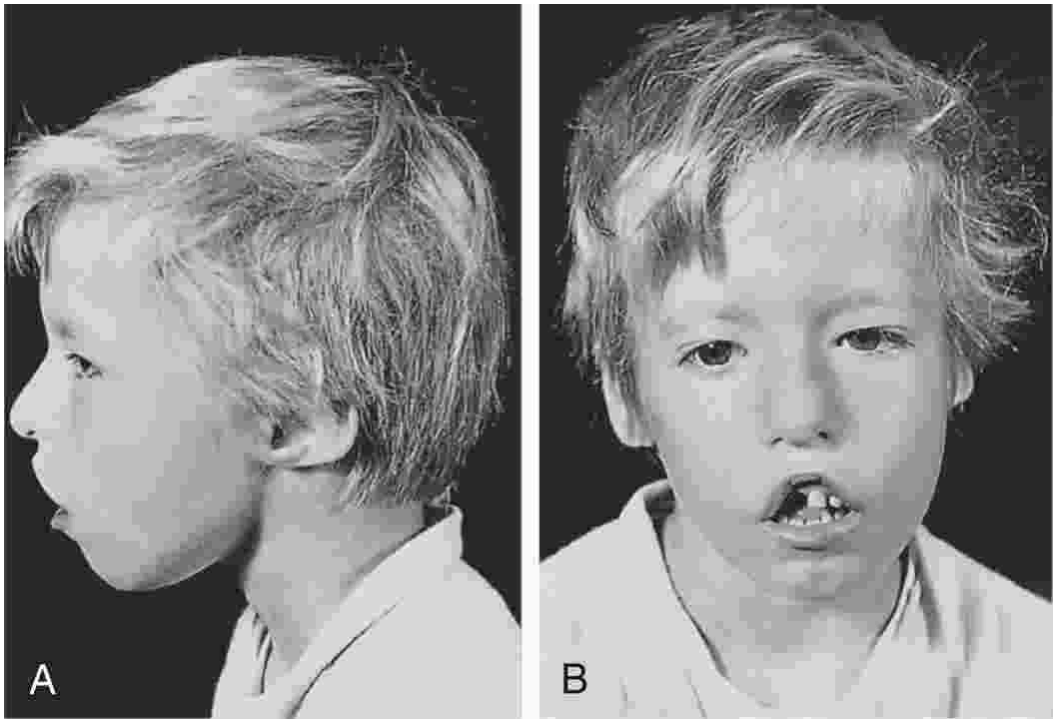


FIG. 9.10 Facial Anomalies Associated With Chromosome 22q11.2 deletion syndrome (DiGeorge Syndrome).
Note the wide-set eyes **(B)**, low-set ears **(A and B)**, shortened structure of the upper lip **(B)**, and underdeveloped chin **(A and B)**. From Male D, Brostoff J, Roth D, et al. *Immunology*, 8th edition. St. Louis: Mosby; 2013.

Predominantly Antibody Deficiencies

Predominantly antibody deficiencies result from defects in B-cell maturation or function and are the most common of immune deficiencies. T-cell immune responses are not affected in pure B-lymphocyte deficiencies. The results are lower levels of circulating immunoglobulins (**hypogammaglobulinemia**) or occasionally totally or nearly absent immunoglobulins (**agammaglobulinemia**).

Common variable immune deficiency

Common variable immunodeficiency (CVID) is the most common symptomatic primary immune deficiency, affecting up to 1 in 10,000 individuals.[41] There are two peak ages of onset, one before the age of 10 and another between 30 and 40 years of age. As the name implies, the presentation is very heterogeneous. It is characterized by hypogammaglobulinemia, but the particular class of antibody that is decreased varies. Although B-cell numbers are normal, most individuals have low amounts of IgG, which may or may not be accompanied by decreased levels of IgA and IgM. Multiple genetic defects in terminal differentiation of B lymphocytes may account for this condition, although the pathogenesis remains poorly understood.[42] Failure to produce sufficient immunoglobulins results in recurrent infections in 90% of individuals with CVID. Pneumonia caused by *S. pneumoniae* or *H. influenzae*, and infections with adenovirus, CMV, and varicella zoster are common.[41] Secondary complications include arthritis (infectious and noninfectious), gastrointestinal symptoms (malabsorption, chronic diarrhea), autoimmune disease (anemia, thrombocytopenia, endocrine diseases), and cancer (of the lymphoid system, skin, and gastrointestinal tract).[43] Interstitial lung disease is a significant cause of morbidity and mortality in CVID and is believed to be the result of dysregulated B-cell function.[44] Because of the heterogeneity of clinical features, diagnosis is difficult and may be delayed for several years. The advent of new diagnostic techniques will likely improve outcomes.[42]

Selective IgA deficiency

Some defects may involve a particular class of antibody, such as **selective IgA deficiency**, in which only IgA is suppressed. It is the most prevalent of the selective antibody deficiencies and is defined as a decreased serum IgA level lower than 7 mg/dL in individuals older than 4 years with normal levels of IgM and IgG in serum and exclusion of other causes of hypogammaglobulinemia. Selective IgA deficiency occurs in 1 in 700 to 1 in 400 individuals, and familial inheritance occurs in approximately 20% of cases. There is an increased incidence of common variable immune deficiency and transient

hypogammaglobulinemia of infancy among family members of those with selective IgA deficiency. It results from defects in the process of IgA class switch, production and secretion of IgA, and long-term survival of IgA-switched memory B cells and plasma cells.[45] Many individuals are asymptomatic, although others have a history of recurring sinus, joint, and pulmonary infections.[41] Some have gastrointestinal infection such as chronic intestinal candidiasis (infection with *C. albicans*). Complications of IgA deficiency include severe allergic disease and autoimmune diseases. Some individuals are at risk for life-threatening allergic reactions when they receive blood products that contain some IgA. This is thought to be due to IgG (or possibly IgE) anti-IgA antibodies, which may be found in some IgA-deficient individuals. Management includes treatment of infections and allergic reactions, but no specific treatment for this immunodeficiency is currently available.

IgG subclass deficiency

Deficiencies in certain subclasses of antibody, particularly IgG2 (**IgG subclass deficiency**), may result from a defect in switch to a particular subclass constant region. A reduced level of IgG2 results in an inability to adequately attack polysaccharide antigens on the surface of encapsulated bacteria. Low levels of IgG2 therefore are responsible for recurrent risk for pneumonias caused by these bacteria. Management with IVIG reduces the number of infections.[46]

Bruton agammaglobulinemia

Bruton agammaglobulinemia (X-linked agammaglobulinemia) is caused by blocked development of mature B cells in bone marrow. It results from mutations of genes responsible for the synthesis of Bruton tyrosine kinase (BTK). An absence of BTK causes absent precursor B-cell differentiation in the bone marrow and severe B-cell deficiency (<2%).[47] There is an associated inability to generate plasma cells and antibodies of all classes (panhypogammaglobulinemia). B-lineage cells in all organs are affected resulting in reduced sizes of lymph nodes and tonsils. Encapsulated bacterial infections are common. Nearly 85% of affected individuals develop infections early in life including otitis

media, skin infection, sepsis, sinusitis, acute gastroenteritis, cervical lymphadenitis, epididymitis, meningitis, osteomyelitis, urinary tract infection, and encephalitis. Treatment consists of replacement immunoglobulin and prophylactic antibiotics to prevent infections.

Immune Dysregulation

Primary immunodeficiencies categorized as immune dysregulation include disorders specific to Tc and NK cell function. This group of conditions is also characterized by autoimmune conditions as a result of alterations in tolerance.

Perforin deficiency results from a mutation in the perforin gene, the product of which is an important component of cellular killing by Tc and NK cells. Several other perforin deficiencies result from mutations in secretory vesicle function, including fusion with the cell membrane and other aspects of the process.

Chédiak-Higashi syndrome results from a defect in the movement of intracellular cytoplasmic granules and is caused by an autosomal recessive mutation in the lysosomal trafficking regulator (LYST) gene. Dysregulation of LYST function results in defects in lysosomal biogenesis.[48] As a result of these defects, the granules remain in the cytoplasm and form large aggregates that are readily apparent microscopically. Leukocytes from individuals with Chédiak-Higashi syndrome have decreased chemotaxis, granular fusion, and bacterial killing. Platelet granules also may be affected, resulting in prolonged bleeding, and partial albinism can occur because of defects in melanocyte granules. Affected children develop recurrent infections of the skin, respiratory tract, and mucous membranes, especially with gram-positive bacteria.

Autoimmune conditions associated with primary immunodeficiencies caused by immune dysregulation may result from abnormalities in Treg function. For example, mutations in IL-10 or its receptor IL-10R suppress the production or response to IL-10 (an immunosuppressive cytokine from Treg cells), resulting in excessive inflammation and an increased risk for early-onset inflammatory bowel disease, or recurrent respiratory disease. Lymphoproliferative disorders (adenopathy, splenomegaly, colitis) may also occur.[30]

Phagocyte Defects: Number, Function or Both

Phagocyte defects include inadequate numbers of phagocytes (e.g., **severe congenital neutropenia**) or defects in phagocyte function. These defects result in recurrent infections caused by a wide range of microorganisms that can infect lungs, skin, bones, and other organs.

Congenital neutropenia results from the inheritance of a large range of autosomal dominant, recessive, or X-linked mutations that result in lack of neutrophil maturation and function. Without adequate neutrophils, the innate immune response is severely impacted, particularly with regard to defense against microorganisms. Congenital neutropenia results in recurrent bacterial infections commensurate with the absolute count of neutrophil granulocytes in the circulation.[49] It is associated with several syndromic conditions, including oculocutaneous albinism, metabolic diseases, and bone marrow failure syndromes. Approximately 20% of people with severe congenital neutropenia develop certain cancerous conditions of the blood, particularly myelodysplastic syndrome or leukemia. Management includes in injections of granulocyte colony-stimulating factor and, in severe cases, bone marrow transplantation.

Primary autoimmune neutropenia (chronic benign neutropenia of childhood) is an idiopathic self-limiting condition affecting infants and toddlers. In most cases, mild to moderate decreases in neutrophil numbers resolve by early childhood without intervention. However, Black children have a 3.5 higher risk of having persistent neutropenia and may require treatment with granulocyte colony-stimulating factor.[50]

Chronic granulomatous disease (CGD) is a severe defect in the myeloperoxidase–hydrogen peroxide system (NADPH oxidase system)—a major means of bacterial destruction within the phagolysosome (see Chapter 7). Deficient production of hydrogen peroxide and other oxygen products needed for phagocytic killing results in recurrent severe pneumonias; tumor-like granulomata in the lungs, skin, and bones; and other infections with some opportunistic microorganisms, such as *Staphylococcus aureus*, *Serratia marcescens*, and *Aspergillus* species. These infections are characterized by recurrent episodes of cutaneous and organ abscess, pneumonia, and osteomyelitis. CGD is

also associated with other phagocytic defects, including decreased Toll-like receptor (TLR) recognition of pathogens, inability to form neutrophil extracellular traps, and hyperinflammatory states (see Chapter 7).[51]

Defects in Innate Immunity

Some immune deficiencies are characterized by a defect in the capacity to produce an immune response against a particular antigen. Innate immune cytokines such as interferons and ILs may be affected. Depending on the specific defect, there can be increased susceptibility to infection by mycobacteria, (e.g., tuberculosis), viruses (e.g., herpes simplex), bacteria, or fungi.[30] In **chronic mucocutaneous candidiasis**, interaction between the Th17 lymphocytes and macrophages is ineffective related to a specific infectious agent, *Candida albicans*. Thus the macrophage cannot be activated, and these individuals usually have mild to extremely severe recurrent *Candida* infections involving the mucous membranes and skin. Other defects in innate immunity include defects in TLRs and NK cells resulting in susceptibility to infections with mycobacteria, salmonella, and viruses (EBV, herpes, influenza viruses).

Autoinflammatory Disorders

Autoinflammatory disorders are characterized by abnormally high levels of inflammation secondary to mutations in genes that control inflammasome activation or in defects in cellular receptors of cytokines designed to decrease inflammation. These disorders are frequently related to diminished control of infections of epithelial surfaces. Vasculitis, inflammatory lung disorders, arthritis, inflammatory bowel disease, SLE, and other autoimmune conditions are common.[30]

Complement Deficiencies

Many complement deficiencies have been described. Every component of the complement cascade (see Chapter 7) may be affected.[30] C3 deficiency is the most severe defect because of its central role in the complement cascade. Loss of C3b results in an inability to opsonize, causing recurrent life-threatening infections with encapsulated bacteria

(e.g., *H. influenzae* and *S. pneumoniae*) at an early age. Deficiencies of any of the terminal components of the complement cascade (C5, C6, C7, C8, or C9 deficiencies) are associated with increased infections with only one group of bacteria—those of the genus *Neisseria* (*N. meningitides* or *N. gonorrhoeae*). *Neisseria* species usually cause localized infections (meningitis or gonorrhea), but terminal pathway defects result in a very high risk for systemic infections with atypical strains of these microorganisms. Management includes prompt treatment for infection. No specific treatments for complement deficiency are currently available.

Bone Marrow Failure

Some primary immune deficiencies result in failure of the bone marrow to produce hematopoietic cells, including those necessary for immune defense. One of the best described examples is **Fanconi anemia**. There are 22 different mutations that can cause Fanconi anemia (A-W); most are inherited in an autosomal recessive pattern.[30] These mutations result in dysfunction of some of the proteins involved in DNA replication, causing bone marrow failure. Severe anemia and life-threatening infections result. It is also associated with a significant risk of cancer.[52] Allogenic hematopoietic stem cell transplantation is curative for the bone marrow failure; however, those with malignant transformation prior to transplantation have a high rate of toxicity and transplant-related death.[53] Stem cell transplantation with lentiviral-mediated gene corrections is emerging as a potential cure for this condition.[54]

Phenocopies of Inborn Errors of Immunity

This group of conditions includes a wide variety of somatic mutations affecting T- or B-cell function, or the production of autoantibodies to inflammatory cytokines.[30] These abnormalities cause lymphoid changes such as splenomegaly and lymphadenopathy or may be associated with infections by mycobacteria, fungi, or staphylococci.

Evaluation of Those With Primary Immune Deficiency

The evaluation of primary immune deficiencies relies on next-generation sequencing methodology (exomes and genomes). These techniques have greatly improved genetic diagnosis with resulting improvements in care and genetic counseling.[55] In addition to genetic analysis, other evaluations include a complete blood count (CBC) with a differential. The CBC provides information on the numbers of red blood cells, white blood cells, and platelets, and the differential indicates the quantities of lymphocytes, granulocytes, and monocytes in blood. Quantitative determination of immunoglobulins (IgG, IgM, IgA) is a screening test for antibody production, and an assay for total complement (total hemolytic complement, CH_{50}) is useful if a complement defect is suspected.

Therapies for Primary Immune Deficiencies

The rapidly increasing knowledge of genetic, cellular, and molecular mechanisms that characterize primary immune deficiencies has fueled research into therapies aimed at specific immune defects.[56] As has been noted previously, some primary immune deficiencies can be successfully treated by replacing the missing component of the immune system. For example, individuals with B-cell deficiencies that cause hypogammaglobulinemia or agammaglobulinemia are usually treated by administration of IVIG, antibody-rich fractions prepared from plasma pooled from large numbers of donors. Administration of IVIG replaces the individual's antibodies temporarily; these antibodies have a half-life of 3 to 4 weeks. Thus individuals must be treated repeatedly to maintain a protective level of antibodies in blood.

Bone marrow transplants containing hematopoietic stem cells have been routinely used to treat SCID, WAS, and other primary immunodeficiencies.[57] However, individuals with SCID are at risk for **graft-versus-host disease (GVHD)**. This occurs if T cells in a transplanted graft (e.g., transfused blood, bone marrow transplants) are mature and therefore capable of cell-mediated immunity against the recipient's HLA. The primary targets for GVHD are the skin (e.g.,

rash, loss or increase of pigment, thickening of skin), liver (e.g., damage to bile duct, hepatomegaly), mouth (e.g., dry mouth, ulcers, infections), eyes (e.g., burning, irritation, dryness), and gastrointestinal tract (e.g., severe diarrhea), and the disease may lead to death from infections. The risk of GVHD can be diminished by removing mature T cells from tissue used to treat individuals with immune deficiencies. **Mesenchymal stem cells (MSCs)** are present in all adult tissues and may be useful in treating GVHD. MSCs have potent immunosuppressive properties. Several clinical trials have demonstrated complete suppression of GVHD in a large number of recipients of MSCs.[58]

Gene therapy involves the use of viral vectors to transfer healthy genes into stem cells that are then transplanted into affected individuals. This approach provides long-term replacement of specific immune factors. Gene therapy has become safer and more effective since new viral vectors (e.g., lentiviruses) are being used. Trials have verified immune reconstitution in individuals with ADA deficiency, X-linked SCID, CGD, WAS, and Fanconi anemia, and numerous clinical trials are underway for this form of treatment.[34,36,57,59,60]

Secondary (Acquired) Immune Deficiencies

Secondary, or acquired, immune and inflammatory deficiencies are far more common than primary deficiencies. These deficiencies are complications of other physiologic or pathophysiologic conditions (Box 9.1). Although secondary deficiencies are common, many are not clinically relevant. In many cases, the degree of the immune deficiency is relatively minor and without any apparent increased susceptibility to infection. Alternatively, the immune system may be substantially suppressed but only for a short duration, thus minimizing the incidence of clinically relevant infections. However, some secondary immune deficiencies (e.g., acquired immunodeficiency syndrome [AIDS] or immunosuppression by cancer) are severe and may result in recurrent life-threatening infections. Management usually consists of supportive care, prompt treatment of infections, and reversal of the underlying immunocompromising condition if possible.

Box 9.1

Some Conditions Known to Be Associated With Acquired Immunodeficiencies

Normal Physiologic Conditions

Pregnancy
Infancy
Aging

Psychological Stress

Emotional trauma
Eating disorders

Dietary Insufficiencies

Malnutrition caused by insufficient intake of large categories of nutrients, such as protein or calories
Insufficient intake of specific nutrients, such as vitamins, iron, or zinc

Infections

Congenital infections, such as rubella, cytomegalovirus, hepatitis B
Acquired infections, such as acquired immunodeficiency syndrome (AIDS)

Malignancies

Malignancies of lymphoid tissues, such as Hodgkin disease, acute or chronic leukemia, or myeloma
Malignancies of nonlymphoid tissues, such as sarcomas and carcinomas

Physical Trauma

Burns

Medical Treatments

Stress caused by surgery
Anesthesia
Immunosuppressive treatment with corticosteroids or antirejection drugs
Splenectomy
Cancer treatment with cytotoxic drugs or ionizing radiation

Other Diseases or Genetic Syndromes

Diabetes
Alcoholic cirrhosis
Sickle cell disease
Systemic lupus erythematosus (SLE)
Chromosome abnormalities, such as trisomy 21

Psychological Stress

The relationship between emotional stress and depressed immune function is an area of intense research, and the mechanisms linking them are now beginning to be understood. Many lymphoid organs are innervated and can be affected by nerve stimulation. In addition, lymphocytes have receptors for many hormones (e.g., sex hormones, neurotransmitters, and neuropeptides) and can respond to changing levels of these chemicals with increased or decreased function. For instance, stress-induced catecholamines affect the expression of adhesion molecules and the movement of lymphocytes among lymphoid organs. (Further discussion of the effects of stress on susceptibility to disease is the subject of Chapter 11.)

Physical Trauma

Major trauma results in a systemic inflammatory response that is paralleled by a compensatory antiinflammatory response syndrome (CARS). This results in a period of critical illness in during which there is persistent inflammatory and immunosuppressive responses.[61] Although the innate immune system is overactive, the adaptive immune system is suppressed. Antigen presentation by macrophages is reduced. Neutrophils and NK cells demonstrate decreased phagocytosis, cytokine production, and cytotoxic activity, as well as elevated rates of apoptosis.[62] Treg activity is increased. This immune suppression is associated with poor wound healing, infection, and multiple organ dysfunction.

Dietary Insufficiencies

Nutritional status can have a profound effect on immune function, and malnutrition is the predominant cause of secondary immune deficiencies worldwide. Severe deficits in protein or calorie (protein-calorie malnutrition) intake lead to immune deficiencies. Marasmus (deficiency in calories) and kwashiorkor (deficiency in protein but adequate calories) have similar outcomes. T cell–rich areas of primary (thymus) and secondary lymphoid tissue are greatly affected, resulting in impaired T-cell function. Antibody levels are normal, but neutrophil function (chemotaxis, phagocytosis, bacterial killing), complement levels, and NK activity are impaired, resulting in infections with microorganisms that are normally destroyed by opsonization and phagocytosis. Deficiencies in specific nutritional components such as zinc and vitamins may also contribute to T- and B-cell dysfunction. In hospitalized individuals with malnutrition, modifications in the gut microbiota and decreased functioning of the gut mucosal immune system result in increased nosocomial infections and mortality.[63]

Chronic Diseases

Chronic diseases of the cardiovascular, gastrointestinal, endocrine, and renal systems are commonly complicated by a secondary immune suppression. For example, diabetes results in altered glucose metabolism and suppresses many aspects of the immune and inflammatory responses, including phagocytosis and chemotaxis, and

lymphocyte proliferation.[64] Diminished T-cell memory for pathogens, impaired B-cell function, low levels of complement, and glycation of circulating antibodies are also found in those with uncontrolled diabetes.[65] Chronic heart failure is associated with poor nutrition, chronic inflammation, and adaptive immune dysfunction. Inflammatory bowel diseases, such as Crohn disease, ulcerative colitis, celiac disease, gastrointestinal infections, and cancer of the gastrointestinal tract are associated with decreased circulating levels of immunoglobulins.

Malignancies

Virtually all malignancies are complicated by immunosuppression, either through the effect of the disease itself on the body's defense mechanisms or as the result of treatment. Cancers cause both chronic inflammation and suppression of the adaptive immune system. For example, chronic inflammation releases growth factors such as vascular endothelial growth factor which causes the growth of new blood vessels (angiogenesis). At the same time, immunosuppressive macrophages and Treg cells are activated thus reducing the adaptive immune response to the tumor. Cancer cells are capable of protecting themselves by directly suppressing T lymphocytes that seek to destroy cancer cells (see Chapter 12). Cancer cells release metabolites and create a microenvironmental acidosis that hinder immune cell metabolism, proliferation, and functioning.[66] Late-stage malignancies result in generalized deficiency of the immune response and greatly increased susceptibility to developing life-threatening infections. Mechanisms include malnutrition, replacement of bone marrow by cancer cells, decreased NK and T lymphocyte function, and the release of soluble immunosuppressive chemicals. In fact, many people with malignancies die as a result of infections rather than of the direct effects of the tumor. Some malignancies (e.g., lymphomas, leukemias, plasmacytomas) present with an early and specific immune depression through a direct effect on B cells.

Immunosuppressive treatments

The list of medications that affect the immune response is ever increasing and includes anesthetics, analgesics, antithyroid medications, anticonvulsants, antihistamines, antimicrobial agents, antilymphocyte antibodies, and tranquilizers. The most profound immunosuppressive treatments are those that are intentionally used to suppress the immune system to manage immune-mediated disease, to treat malignancy, or to prevent rejection of transplanted tissues.

Corticosteroids are intentionally used to control hypersensitivity diseases (especially autoimmune disease) or to prevent rejection of transplants. They predominantly inhibit T-cell function, prevent lymphocyte proliferation, inhibit production of critical cytokines, and suppress monocyte/macrophage functions. These effects greatly increase an individual's susceptibility to infection.

Many drugs and other treatments such as radiation that are used to treat cancer (e.g., chemotherapeutic agents, irradiation) are not specific for cancer cells but are designed to attack cells at susceptible stages in their cell cycles. They attack rapidly proliferating cells, thus killing immune cells as well as malignant cells. Depending on the dose of chemotherapy and/or irradiation administered, the entire immune system may be depleted.

Antirejection drugs are used to prevent immune-mediated rejection of transplanted tissue. Although more targeted treatments are becoming available, most antirejection regimens cause generalized immune suppression and increase the likelihood of infection and cancer.[67] A careful therapeutic balance must be maintained between protecting the graft and preventing these complications.

Infections

Many infectious microorganisms successfully invade the human body using mechanisms for fighting off specific immune/inflammatory responses against themselves (discussed in Chapter 10). However, some infectious agents more broadly suppress the immune response. HIV is one of the few microorganisms that directly attacks the central processes involved in the development of an immune response (discussed in detail in Chapter 10). It infects and destroys $CD4^+$ Th cells, which are necessary to provide help for the maturation of both

plasma cells and Tc cells. Therefore HIV suppresses the immune response against itself and secondarily creates a generalized immune deficiency by suppressing the development of immune responses against other pathogens and opportunistic microorganisms.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection has been shown to decrease innate immune responses, including the production of interferon, which can contribute to a lack of adequate initiation of adaptive immunity.[67,68] Decreased innate immune responses to the virus have been linked to an increase in asymptomatic COVID-19, as well as an increase in severity in those with progressive disease.[69] T-cell activation may be delayed, leading to decreased early symptoms, but can contribute to morbidity and mortality.[70] Lymph nodes from individuals with COVID-19 were found to have a loss of germinal centers, and those remaining contained only one-third of normal T- and B-cell numbers.[67]

Several other viruses (e.g., measles; hepatitis B; and herpes viruses, such as EBV, CMV, and herpes simplex viruses) may suppress various components of the immune response. Measles virus can infect both B and T cells and macrophages. Infection may result in a transient lymphopenia and a suppressed T-cell response. Acute infections with herpes viruses also may transiently suppress the immune system. EBV not only infects B cells, but it also may suppress both $CD4^+$ and $CD8^+$ T cells and NK cells, although immunosuppression is generally not severe. Many viruses produce molecules similar in function to IL-10 that further contribute to immunosuppression. CMV infects mucosal epithelium and can infect macrophages where antigen processing and presentation may be impaired. Tumor viruses such as human papillomavirus (HPV) help to create a tumor microenvironment in which cancer cells are free to grow.[71]

Some fungal infections may suppress the immune response. In disseminated *C. albicans* infections, T-cell responses and neutrophil chemotaxis are suppressed to various degrees. Similar immunosuppression may be observed in individuals with disseminated histoplasmosis (infections with *Histoplasma capsulatum*). The most severe form of acute malaria (caused by the parasite *Plasmodium falciparum*) suppresses specific antibody responses against

protein and polysaccharide antigens by dysregulation of $CD4^+$ T-cell function and decreased IL-2 production.

Summary Review

Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

1. Inappropriate immune responses are exaggerated misdirected responses innocuous environmental antigens (allergy), the host's own tissues (autoimmunity), or beneficial foreign tissues (alloimmunity); or insufficient responses to protect the host (immune deficiency).
2. Allergy, autoimmunity, and alloimmunity are collectively known as hypersensitivity reactions.
3. Mechanisms of hypersensitivity are classified as type I (IgE-mediated) reactions, type II (tissue-specific) reactions, type III (immune complex–mediated) reactions, and type IV (cell-mediated) reactions.
4. Hypersensitivity reactions can be immediate (developing within minutes to a few hours) or delayed (developing within several hours or days).
5. Allergens are antigens that cause allergic responses.
6. Type I (IgE-mediated) hypersensitivity reactions are mediated through the binding of IgE to Fc receptors on mast cells and cross-linking of IgE by antigens that bind to the Fab portions of IgE. Cross-linking causes mast cell degranulation and the release of histamine (the most potent mediator) and other inflammatory substances.
7. Histamine, acting through the H1 receptor, contracts bronchial smooth muscles, causing bronchial constriction; increases vascular permeability, causing edema; and increases blood flow into the affected area, causing vasodilation. Histamine with H2 receptors results in increased gastric acid secretion and a decrease of histamine released from mast cells and basophils.

8. Type II (tissue-specific) hypersensitivity reactions are caused by five possible mechanisms: complement-mediated lysis, opsonization and phagocytosis, neutrophil-mediated tissue damage, antibody-dependent cell-mediated cytotoxicity, and modulation of cellular function.
9. Type III (immune complex–mediated) hypersensitivity reactions are caused by the formation of immune complexes that are deposited in target tissues, where they activate the complement cascade, generating chemotactic fragments that attract neutrophils into the inflammatory site. Neutrophils release lysosomal enzymes that result in tissue damage.
10. Immune complex disease can be a systemic reaction, such as serum sickness, or a localized response, such as the Arthus reaction.
11. Type IV (cell-mediated) hypersensitivity reactions are caused by cytotoxic T lymphocytes (Tc cells), lymphokine-producing Th1 cells and activated macrophages.
12. Typical allergens include pollen, molds and fungi, certain foods (milk, eggs, fish, peanuts), animals, certain drugs, cigarette smoke, and house dust.
13. Clinical manifestations of allergic reactions usually are confined to the areas of initial intake or contact with the allergen. Ingested allergens induce gastrointestinal symptoms, airborne allergens induce respiratory tract or skin manifestations, and contact allergens induce allergic responses at the site of contact.
14. Autoimmune diseases originate from the coincidence of an initiating event in a genetically predisposed individual leading to an autoimmune mechanism that affects specific target tissues or cells. Central tolerance develops during the embryonic period. Peripheral tolerance is maintained in secondary lymphoid organs by regulatory T lymphocytes or antigen-presenting dendritic cells.
15. Heparin-induced thrombocytopenia is a condition in which heparin molecules attach to proteins in the surface of platelets resulting in the formation of autoantibodies that destroy platelets (bleeding) and promote clotting (thrombosis).

16. Systemic lupus erythematosus (SLE) is a chronic, multisystem, inflammatory disease and is one of the most serious of the autoimmune disorders. SLE is characterized by the production of a large variety of autoantibodies.
17. Alloimmunity is the immune system's reaction against antigens on the tissues of other members of the same species.
18. Alloimmune disorders include transient neonatal disease, in which the maternal immune system becomes sensitized against antigens expressed by the fetus; transplant rejection; and transfusion reactions, in which the immune system of the recipient of an organ transplant or blood transfusion reacts against foreign antigens on the donor's cells.
19. Red blood cell antigens may be the targets of autoimmune or alloimmune reactions. The most important of these, because they provoke the strongest humoral immune response, are the ABO and Rh systems.
20. Antigens on fetal red blood cells (Rh) can cause maternal antibodies to cross the placenta and cause severe anemia in the fetus.
21. Hyperacute graft rejection (preexisting antibody) is immediate and rare, acute rejection is both antibody and cell mediated and occurs days to months after transplantation, and chronic rejection is caused by inflammatory damage to endothelial cells as a result of a weak cell-mediated reaction.

Deficiencies in Immunity

1. Disorders resulting from immune deficiency are the clinical sequelae of impaired function of components of the immune or inflammatory response, phagocytes, or complement.
2. Immune deficiency is the failure of mechanisms of self-defense to function in their normal capacity.
3. Immune deficiencies are either congenital (primary) or acquired (secondary). Primary immune deficiencies are caused by genetic defects that disrupt lymphocyte development, whereas

secondary immune deficiencies are secondary to disease or other physiologic alterations.

4. The clinical hallmark of immune deficiency is a propensity to unusual or recurrent severe infections. The type of infection usually reflects the immune system defect.
5. The most common infections in individuals with defects of the cell-mediated immune response are fungal and viral, whereas infections in individuals with defects of the humoral immune response or complement function are primarily bacterial.
6. Severe combined immunodeficiency is a total lack of T-cell function and a severe (either partial or total) lack of B-cell function. Other combined defects may result from deficiencies in antigen-presenting molecules (bare lymphocyte syndrome) or cytoskeletal proteins (WAS).
7. Chromosome 22q11.2 deletion syndrome (DiGeorge syndrome) is characterized by complete or partial lack of the thymus (resulting in depressed T-cell immunity) and the parathyroid glands (resulting in hypocalcemia) and the presence of cardiac anomalies.
8. Defects in B-cell function are diverse, ranging from a complete lack of the human bursal equivalent function, the lymphoid organs required for B-cell maturation (as in Bruton agammaglobulinemia), to deficiencies in a single class of immunoglobulins (e.g., selective IgA deficiency).
9. Defects in phagocyte function, which include insufficient numbers of phagocytes or defects of chemotaxis, phagocytosis, or killing, can result in recurrent life-threatening infections such as septicemia and disseminated pyogenic lesions.
10. Immune dysregulation disorders are characterized by abnormally high levels of inflammation secondary to mutations in control of inflammasome activation or in defects in cellular receptors of cytokines designed to decrease inflammation. These disorders are frequently related to diminished control of infections of epithelial surfaces.
11. Almost any portion of the complement cascade may be defective. The most severe defect is C3 deficiency, which results in recurrent life-threatening bacterial infections. Defects in

proteins of the membrane attack complex usually result in unusual, disseminated infections with bacteria of the *Neisseria* spp.

12. Bone marrow failure and somatic mutations in immune genes may also result in severe primary immunodeficiency states.
13. Primary immune deficiencies may sometimes be treated by replacement therapy. Deficient antibody production is treated by replacement of missing immunoglobulins with commercial gamma-globulin preparations. Lymphocyte deficiencies are treated with the replacement of host lymphocytes with bone marrow and stem cell transplants and gene therapies when available.
14. Acquired immunodeficiencies are caused by superimposed conditions, such as aging, malnutrition, infections, malignancies, physical or psychological trauma, environmental factors, some medical treatments, or other diseases chronic disease, or infections.

Antibiotic/Antimicrobial Resistance 304

Vaccines and Protection Against Infection 305
- Active Immunization 305
- Passive Immunotherapy 305

Modern health care has shown great progress in preventing and treating infectious diseases. However, infectious disease continues to be a threat to human health because of the emergence of previously unknown infections, the reemergence and spread of old infections that were thought to be under control, and the development of infectious agents that are resistant to multiple antibiotics. Deadly infections are not confined to developing nations, as the Coronavirus Disease 2019 (COVID-19) pandemic has made clear in recent years. Diseases, such as chronic hepatitis, human immunodeficiency virus (HIV) infection, bacterial and viral pneumonia, and foodborne infections remain major challenges in the United States. Most deaths related to infections occur in individuals whose immune systems are compromised (young children, the elderly, and those with chronic disease). The concepts and processes of infection are presented in this chapter. Specific infections are presented in Part Two of the book with the organ system chapters (i.e., infections that occur in the cardiovascular, pulmonary, genitourinary tract, gastrointestinal tract, and skin).

Microorganisms and Humans: A Dynamic Relationship

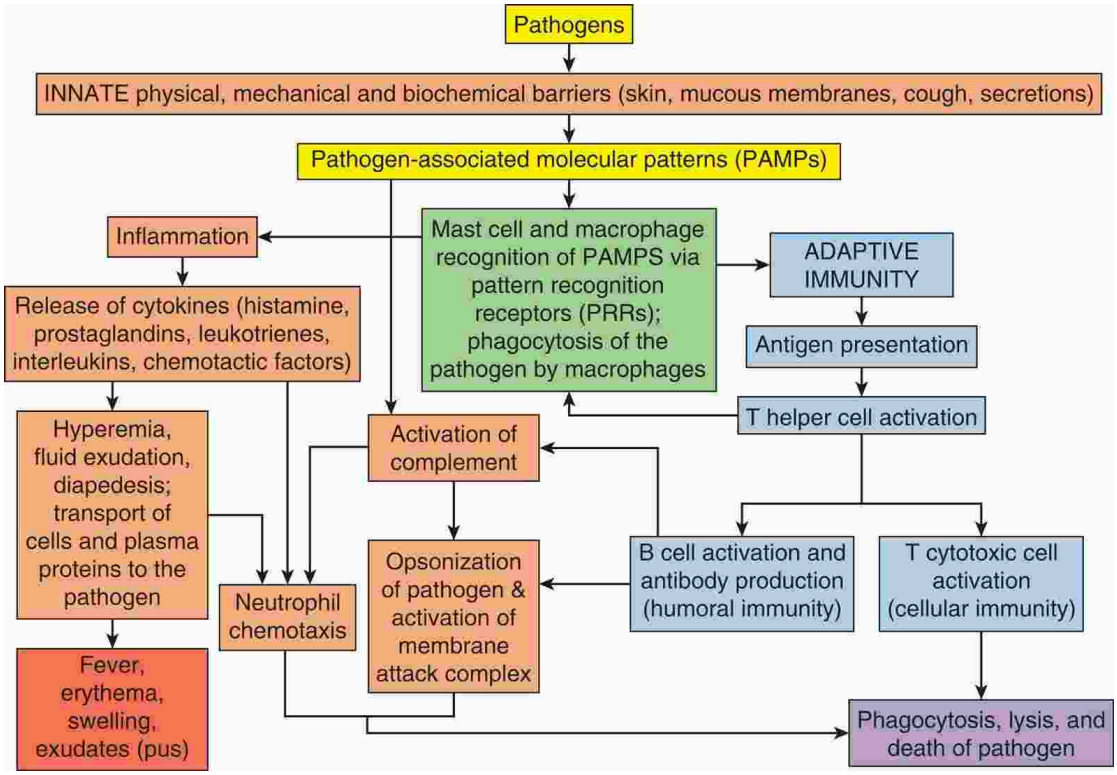
For many microorganisms, the human body is a hospitable site in which to grow and flourish because of sufficient nutrients and appropriate conditions of temperature and moisture. Only a small number of microorganisms are capable of causing disease. The relationship between humans and microorganisms is summarized in Box 10.1. Both host-related and microorganism-related factors influence the ability of microorganisms to become pathogenic and cause infection. The multiple layers of defense against pathogens are described in detail in Chapters 7 and 8 and are summarized in Algorithm 10.1.

Box 10.1

Relationships Between Humans and Microorganisms

Symbiosis: Benefits only the human; no harm to the microorganism
Mutualism: Benefits the human and the microorganism
Commensalism: Benefits only the microorganism; no harm to the human
Pathogenicity: Benefits the microorganism; harms the human

Opportunism: A situation in which benign microorganisms become pathogenic because of decreased human host resistance, increase in numbers, or translocation to other body sites.



ALGORITHM 10.1 **Host Defenses Against Pathogens.**
If pathogens breach the physical, mechanical, and biochemical barriers of innate immunity, mast cells and macrophages recognize pathogen-associated molecular patterns *(PAMPs)* via their pattern recognition receptors *(PRRs)*. The complement plasma protein system is activated by pathogen molecules via the alternative pathway. An inflammatory response is initiated during which numerous cytokines are released. Chemotactic factors call neutrophils to the area of invasion. The inflammatory vascular response (hyperemia, fluid exudation, and diapedesis of inflammatory cells) facilitates the transport of complement and cells to the area of invasion, as well as causes the symptoms and signs of infection. The adaptive immune system is activated and pathogen antigens are presented to Th cells. Th cells release a host of cytokines that activate B cells and T cytotoxic cells and contribute to further macrophage activation. Antibody production by B cells (plasma cells) activates complement via the classic pathway. Complement and antibodies work together to opsonize the pathogens and facilitate phagocytosis by neutrophils. In addition, the complement membrane attack complex directly lyses pathogens, and T cytotoxic cells are activated to kill intracellular pathogens.

A flowchart tracks the host defenses against pathogens. The sequence of defenses is as follows. • Pathogens. • Innate physical, mechanical, and biochemical barriers (skin, mucous membranes, cough, secretions). • Pathogen-associated molecular patterns (P A M Ps). P A M Ps lead to the following reactions. Reaction 1. Mast cell and macrophage recognition of P A M Ps via pattern recognition receptors (P R Rs); phagocytosis of the pathogen by macrophages. Reaction 2. Activation of complement. Reaction 1 leads to Reactions 3 and 4. Reaction 3. Inflammation. Reaction 4. Adaptive immunity.

Reaction 3 leads to Reactions 5: Release of cytokines (histamine, prostaglandins, leukotrienes, interleukins, chemotactic factors). Reaction 5 leads to Reactions 6 and 7. Reaction 6: Hyperemia, fluid exudation, diapedesis; transport of cells and plasma proteins to the pathogen. Reaction 7. Neutrophil chemotaxis. Reaction 6 leads to Reactions 7 and 8. Reaction 8. Fever, erythema, swelling, exudates (pus). Reaction 4 leads to Reaction 9: Antigen presentation. Reaction 9 leads to Reaction 10: T helper cell activation. Reaction 10 leads to Reactions 1, 11, and 12. Reaction 11. B cell activation and antibody production (humoral immunity). Reaction 12. T cytotoxic cell activation (cellular immunity). Reaction 11 leads to Reactions 2 and 13. Reaction 13. Opsonization of pathogen and activation of membrane attack complex. Reactions 7, 12, and 13 lead to Reaction 14: Phagocytosis, lysis, and death of pathogen.

Infectious diseases are caused by pathogenic microorganisms. There are many factors that influence the capacity of a microorganism to infect humans and cause disease. These factors include:

Communicability: The ability to spread from one individual to others and cause disease (e.g., severe acute respiratory coronavirus 2 [**SARS-CoV-2**], influenza, and measles viruses spread very easily; HIV is of lower communicability)
Immunogenicity: The ability to induce an immune response
Infectivity: The ability to invade and multiply in the host
Mechanism of action: How the microorganism damages tissue
Pathogenicity: The ability to produce disease—success depends on communicability, infectivity, extent of tissue damage, and virulence
Portal of entry: The route by which a microorganism infects the host (e.g., direct contact, inhalation, ingestion, or bites of an animal or insect)
Toxigenicity: The ability to produce soluble toxins or endotoxins, factors that greatly influence the degree of virulence
Virulence: The capacity to cause severe disease; for example, measles virus is of low virulence; rabies virus is highly virulent
ID50: The estimated number of organisms or virus particles required to produce infection in 50% of a population

The symbiotic microorganisms that make up the normal human microbiome (the resident microorganisms found in different parts of the body, including the skin, mouth, gastrointestinal tract, respiratory tract, and genital tract [see Chapter 7]) produce antibacterial factors that prevent pathogenic microorganisms from being able to colonize tissues, multiply, and invade.[1] Physical barriers (e.g., skin and lining of respiratory, intestinal and genital tracts) and the complex interaction of the microbiome and inflammatory and immune systems maintain this important relationship between host and resident microorganisms. When microorganisms in the microbiome cause infection because protective barriers are breached or defensive systems are weakened, they are referred to as *opportunistic microorganisms*. For example, alterations in the microbiome by antibiotics may allow local overgrowth of opportunistic microorganisms that can cause disease (e.g., *Clostridioides difficile, Candida albicans*). Individuals with primary or secondary immune deficiencies also may become infected with opportunistic microorganisms.

The Process of Infection

The process of infection includes encounter (contact) and transmission, colonization, invasion, dissemination, and cellular or tissue damage by the pathogenic microorganisms. There are several

different ways that an individual can encounter or come in contact with microorganisms. *Endogenous microorganisms* are already present in the body and part of the normal microbiome. *Exogenous microorganisms* are transmitted from an external source (e.g., contaminated water, food, or from another human, animals or insects).

Transmission of microorganisms can occur in several different ways:

Direct transmission occurs through direct contact with infections of another individual, such as the skin lesions of impetigo (*Staphylococcus aureus*) and STIs (see Chapter 27).

Indirect transmission: Occurs from contact with fomites, or from respiratory, fecal oral, or vector-borne transmission.

Fomites are inanimate objects that can become contaminated with infectious agents and serve as a mechanism for transfer between hosts (e.g., towels, toys, contact lenses). This is a common mechanism for the transmission of many types of infections and is the primary reason why frequent handwashing is an essential component of infection control.

Respiratory transmission may occur by means of several mechanisms. Coughing or sneezing creates a mist that can be inhaled from the air for considerable time. This mechanism readily transmits many viral diseases, including the common cold, influenza, and COVID-19. Infected individuals also may produce airborne droplets that settle on environmental surfaces. Other microorganisms such as fungi may be airborne by circulating air that carries microorganisms picked up from the soil, dried droppings, or other sites.

Fecal-oral transmission occurs when contaminated food or water is ingested. Examples include *Salmonella* (salmonella food poisoning), cholera, hepatitis A virus, *Giardia lamblia*, and many others that cause minor or major gastrointestinal diseases.

Vector-borne transmission most commonly occurs when an infectious agent undergoes part of its life cycle within an insect that feeds off the blood of infected animals or humans. The microorganism is then transmitted to other individuals through bites or stings (e.g, malaria [*Plasmodium* spp.]; Lyme disease [*Borrelia burgdorferi*]).

Horizontal transmission from one person to another through exposure to blood and body fluids (e.g., HIV, *Neisseria gonorrhoeae*); or zoonotic infections directly transmitted from animals (e.g., giardiasis, toxoplasmosis).

Vertical transmission from mother to child across the placenta (e.g., *Listeria monocytogenes*, cytomegalovirus [CMV]), during delivery from the birth canal (e.g., group B *Streptococcus, Escherichia coli, Chlamydia trachomatis*), or from breast milk (e.g., *S. aureus*).

Colonization is the ability of a pathogenic microorganism to survive and multiply on or within the human environment. *Adherence* is a part of the colonization process and helps protect the microorganism from removal by mechanical or other nonspecific forces, such as coughing of respiratory mucus. Adherence occurs between receptors on the microorganism and on the surface of cells. The specificity of these receptors results in localization of an infectious agent to particular sites, such as the confinement of common cold viruses to the respiratory tract.

Invasion or **penetration** is the ability of pathogens to cross surface barriers, including the skin and mucous membranes. This may involve penetration (e.g., mosquito bite) or a break in the integrity of the barrier (e.g., trauma). Normal protective barriers are described in Chapter 7. Other microorganisms are able to invade directly into cells.

Dissemination or spread of infection can occur by direct extension through surrounding tissue or through the blood or lymphatic vessels. **Tissue damage** or cellular alterations can occur directly by lysis caused during replication of the microorganism or the production of toxins, or indirectly as a result of an immune response with inflammation, swelling, scarring, or necrosis. The ability to damage tissues enhances the pathogenicity of the organism.

Stages of Infection

The clinical process of infection occurs in the following four distinct stages:

Incubation period: The period from initial exposure to the infectious agent and the onset of the first symptoms; during this time, the microorganisms have entered the individual, undergone initial colonization, and begun multiplying but are at insufficient numbers to cause symptoms. This period may last from several hours to years. The time between exposure and symptoms is often termed *clinical latency*. With some infections (e.g., HIV and varicella zoster infection), there is an acute symptomatic phase, followed by a latency period that can last months or even years.
Prodromal stage: The occurrence of initial symptoms, which are often mild and include a feeling of discomfort and tiredness; pathogens continue to multiply during this stage.
Invasion or acute illness period: The pathogen is multiplying rapidly, invading farther and affecting the tissues at the site of initial colonization as well as other areas; the immune and inflammatory responses have been triggered; symptoms may be specifically related to the pathogen or to the inflammatory response.
Convalescence: In most instances, the individual's immune and inflammatory systems successfully remove the infectious agent and symptoms decline; alternatively, the disease may be fatal or enter a latency phase with resolution of symptoms until pathogen reactivation at a later time.

Some infections are contagious well before symptoms begin. For example, during HIV infection, there is an acute phase where the individual may have very mild, non-specific symptoms, but the infection is very contagious. In other infections, such as hepatitis B, some individuals never develop symptoms yet can spread the infection to others. Many infections are contagious during all stages of infection, even well into convalescence.

Infectious Disease

Infectious disease may occur as isolated or recurrent events within individuals or populations. They sometimes are classified by their prevalence and spread within the community:

Endemic: Diseases with relatively high but constant rates of infection in a particular population. Many tropical infections are endemic to countries in the tropics.
Epidemic: The number of new infections in a particular population greatly exceeds the number usually observed
Pandemic: An epidemic that spreads over a large area, such as a continent or worldwide

Microorganisms are classified based on different morphologic characteristics and life cycles. However, groups of disease-causing microorganisms share many properties related to clinical disease, processes of infection, and evasion of human protective systems. Classes of pathogenic microorganisms and their characteristics are summarized in Table 10.1 and discussed in detail in the following sections.

Table 10.1

Classes of Microorganisms Infectious to Humans

Class	Size	Site of Reproduction	Example
Virus	20–300 nm	Intracellular	Human immunodeficiency virus, hepatitis A and B, chicken pox, measles, SARS-CoV-2
Bacteria	0.8–15 mcg	Skin	Staphylococcal wound infection
		Mucous membranes	Cholera
		Extracellular	Streptococcal pneumonia *Mycoplasma* pneumonia
		Intracellular	Tuberculosis, chlamydiasis
Fungi	2–200 mcg	Skin	Tinea pedis (athlete's foot)
		Mucous membranes	Candidiasis (e.g., thrush)
		Extracellular	Sporotrichosis
		Intracellular	Histoplasmosis
Protozoa	1–50 mm	Mucosal	Giardiasis
		Extracellular	African trypanosomiasis (sleeping sickness)
Helminths	3 mm to 10 m	Intracellular	Trichinosis
		Extracellular	Filariasis

Bacterial Infection

Bacteria are prokaryotes (lack a discrete nucleus), are relatively small, and are a common cause of disease (Fig. 10.1A). They can be aerobic or anaerobic and motile or immotile. Spherical bacteria are called *cocci*, rod-like forms are called *bacilli*, and spiral forms are termed *spirochetes*. Gram staining differentiates the microorganisms as gram-positive or gram-negative bacteria. Gram-positive bacteria have teichoic acid and peptidoglycan in their outer membranes, whereas gram-negative bacteria have lipopolysaccharide (LPS) in their outer membranes (Fig. 10.1B). LPS also is known as *endotoxin*. Gram-positive bacteria appear dark purple on Gram stain, whereas gram-negative appear light pink on Gram staining (Fig. 10.1C and D).

FIG. 10.1 General Structure of Bacteria.
(A) Major features of prokaryotes. Unlike a human cell, a prokaryote does not have nuclei and endoplasmic reticulum. Instead, it has a single chromosome and a cytoplasm rich in small ribosomes. A prokaryote also lacks mitochondria but has a complex cell membrane in which cellular respiration and energy production occurs. **(B)** Comparison of gram-positive and gram-negative bacterial cell walls. A gram-positive bacterium has a thick peptidoglycan layer that contains teichoic and lipoteichoic acids. A gram-negative bacterium has a thin peptidoglycan layer and an outer membrane that contains lipopolysaccharide, phospholipids, and proteins. The periplasmic space between the cytoplasmic and outer membranes contains transport, degradative, and cell wall synthetic proteins. **(C)** Example of a gram-positive (darkly stained microorganisms, *arrow*) group A *Streptococcus*. This microorganism consists of cocci that frequently form chains. **(D)** Example of a gram-negative (pink microorganisms, *arrow*) *Neisseria meningitidis* in cerebrospinal fluid. Neisseria form complexes of two cocci (diplococci). (A and B, From Murray PR, Rosenthal KS, Pfaller MA. *Medical microbiology*, 7th edition. Philadelphia: Saunders; 2013; C and D, From Murray PR, Rosenthal KS, Kobayashi GS, et al. *Medical microbiology*, 4th edition. St. Louis: Mosby; 2002.)

Top panel, A. An illustration of a prokaryote. The outer layer is labeled peptidoglycan, and below it lies the cell wall followed by a layer of cell membrane (site of cellular respiration). There is single supercoiled circular chromosome. Other structures in the cell are cytoplasm rich in 70S ribosomes and plasmid. A flagellum with a head and a tail has its head attached to the cell membrane. Middle panel, B. An illustration compares gram-positive and gram-negative bacterial cell walls. On the left, an illustration of a gram-positive bacterium cell comprises a cytoplasmic membrane and a cell wall. The cytoplasmic membrane is a bilipid layer with structural and enzymatic proteins. The following structures are identified on the cell wall: peptidoglycan, lipoteichoic acid, and teichoic acid. On the right, an illustration of a gram-negative bacterium cell comprises a cytoplasmic membrane, periplasmic space, and an outer membrane. Carrier proteins are attracted to the bilipid layer in the cytoplasmic membrane. The following structures are identified in the periplasmic space: peptidoglycan, nutrient-binding protein, and lipoprotein. The outer membrane is a single lipid layer with pore (porin protein). Bottom left panel, C. A photomicrograph of a gram-positive bacterium with long chains of cocci. Bottom right panel, D. A photomicrograph of a gram-negative bacterium with diplococci.

Bacteria can survive in an extracellular or intracellular environment. Extracellular bacteria use virulence mechanisms to proliferate in the body fluids of the extracellular environment. Intracellular bacteria can enter and survive in cells (including immune, epithelial, and endothelial cells). Intracellular microbes can persist for long periods (e.g., *C. trachomatis, Mycobacterium tuberculosis*, and *Mycobacterium leprae*) and cause disease by disrupting cellular structure and function.

Examples of human diseases caused by specific bacteria are listed in Table 10.2. **Bacteremia** occurs when bacteria are present in the blood. **Sepsis**, or **septicemia**, occurs when bacteria are growing in the blood and release large amounts of toxins causing clinical symptoms and signs.

Table 10.2

Examples of Common Bacterial Infections

Primary Site of Infection	Bacteria	Staining Characteristic	Disease (Primary)
Upper respiratory tract	*Corynebacterium diphtheriae*	Gram +	Diphtheria
	Streptococcus pyogenes (group A)	Gram +	Streptococcal pharyngitis
Lower respiratory tract	*Streptococcus pneumoniae*	Gram +	Pneumococcal pneumonia
	Mycoplasma pneumoniae	Immunofluorescent stain	Atypical pneumonia
	Chlamydophila pneumophila	Immunofluorescent stain	Atypical pneumonia
	Bordetella pertussis	Gram −	Whooping cough
	Legionella pneumophila	Gram −	Legionella pneumonia
	Mycobacterium tuberculosis	Ziehl–Neelsen stain	Tuberculosis
	Pseudomonas aeruginosa	Gram −	Pseudomonas pneumonia
Gastrointestinal tract	*Clostridium difficile*	Gram +	Pseudomembranous colitis
	Helicobacter pylori	Gram −	Gastritis and upper gastrointestinal ulcers
	Vibrio cholerae	Gram −	Infectious diarrhea
	Salmonella typhi	Gram −	Infectious diarrhea
	Clostridium botulinum	Gram +	Food poisoning
	Campylobacter jejuni	Gram −	Food poisoning
Urinary tract	*Escherichia coli*	Gram −	Cystitis and pyelonephritis
	Klebsiella pneumoniae	Gram −	Cystitis and pyelonephritis
	Proteus mirabilis	Gram −	Cystitis and pyelonephritis
Sexually transmitted infections	*Chlamydia trachomatis*	Immunofluorescent stain	Pelvic inflammatory disease
	Neisseria gonorrhoeae	Gram −	Gonorrhea
	Treponema pallidum	Gram −	Syphilis

Primary Site of Infection	Bacteria	Staining Characteristic	Disease (Primary)
Skin and wound infections	*Staphylococcus aureus*	Gram +	Cellulitis, wound and medical device infections
	Staphylococcus epidermidis	Gram +	Wound and medical device infections
	S. pyogenes	Gram +	Impetigo, erysipelas, cellulitis, fasciitis
Meninges	*Neisseria meningitidis*	Gram −	Meningitis
	Hemophilus influenza	Gram −	Meningitis
	Listeria monocytogenes	Gram +	Meningitis
Zoonotic infections	*Borrelia burgdorfer*	Gram −	Lyme disease
	Rickettsia rickettsii	Gram −	Rocky Mountain Spotted Fever

Mechanisms of Bacterial Invasion and Tissue Damage

Virulence factors that help bacteria cause infection include:

Pili (fimbria): Hair-like projections that express adhesion molecules to attach to cells and invade tissue and to connect one bacterium to another (Fig. 10.2)
Flagella: A rotary structure that provides motility and expresses adhesion molecules (see Fig. 10.1A)
Toxins: Poisonous substances that cause injury, such as exotoxins (direct injury), endotoxins (indirect injury)
Enzymes: Proteins that promote tissue invasion (e.g., proteases and lipases)
Capsules: An outer covering of the cell wall that prevents phagocytosis and resists host immunity
Biofilms: A matrix excreted by bacteria that protects them from immune cells and antibiotics

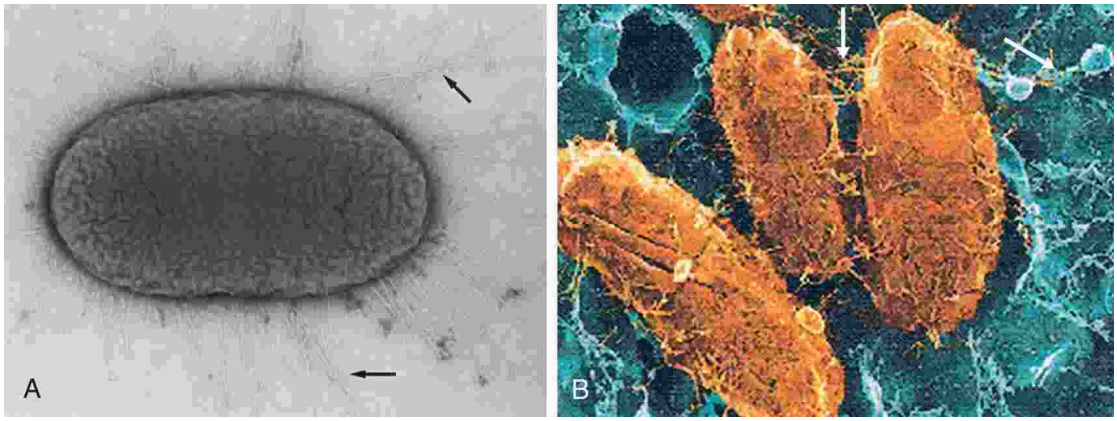

FIG. 10.2 Attachment of *Escherichia coli* Through Pili.
(A) Transmission electron micrograph showing pili *(arrows)* of pathogenic *E. coli*. **(B)** Scanning electron micrograph of *E. coli (orange)* attached by pili *(arrows)* to bladder epithelium *(blue)*. (A, Courtesy Eric Buckles and Paula J. Fernandes; B, Modified from Wein A, Kavoussi LR, Novick AC, et al. *Campbell-Walsh urology*, 9th edition. Philadelphia: Saunders; 2007.)

Left panel, A. An electron micrograph of an E. coli cell with pili anchored along the outer membrane of the cell. Right panel, B. An electron micrograph of three E. coli cells with pili anchored along the outer membrane of the cell that are attached to the bladder epithelium around the cells.

Many bacteria use toxins as virulence factors, including exotoxins and endotoxins. **Exotoxins** are secreted molecules, mostly protein enzymes. They directly injure cells by damaging cell membranes or by entering cells and changing their function. One of the most poisonous exotoxins is botulinum neurotoxin produced by *Clostridium botulinum*, which causes paralysis and respiratory compromise. Different strains of *S. aureus* are capable of producing a wide array of diseases, many of which result from exotoxins (Fig. 10.3). Some damage the cell membrane and others cause blood clots (coagulase); break down clots; cause separation of the epidermis, resulting in scalded skin syndrome (exfoliative toxins); secrete enzymes, which degrade lipids on the skin surface and facilitate abscess formation (lipases); produce enterotoxins, which cause food poisoning; or produce superantigens (a type of exotoxin), which stimulate a profound immune response.

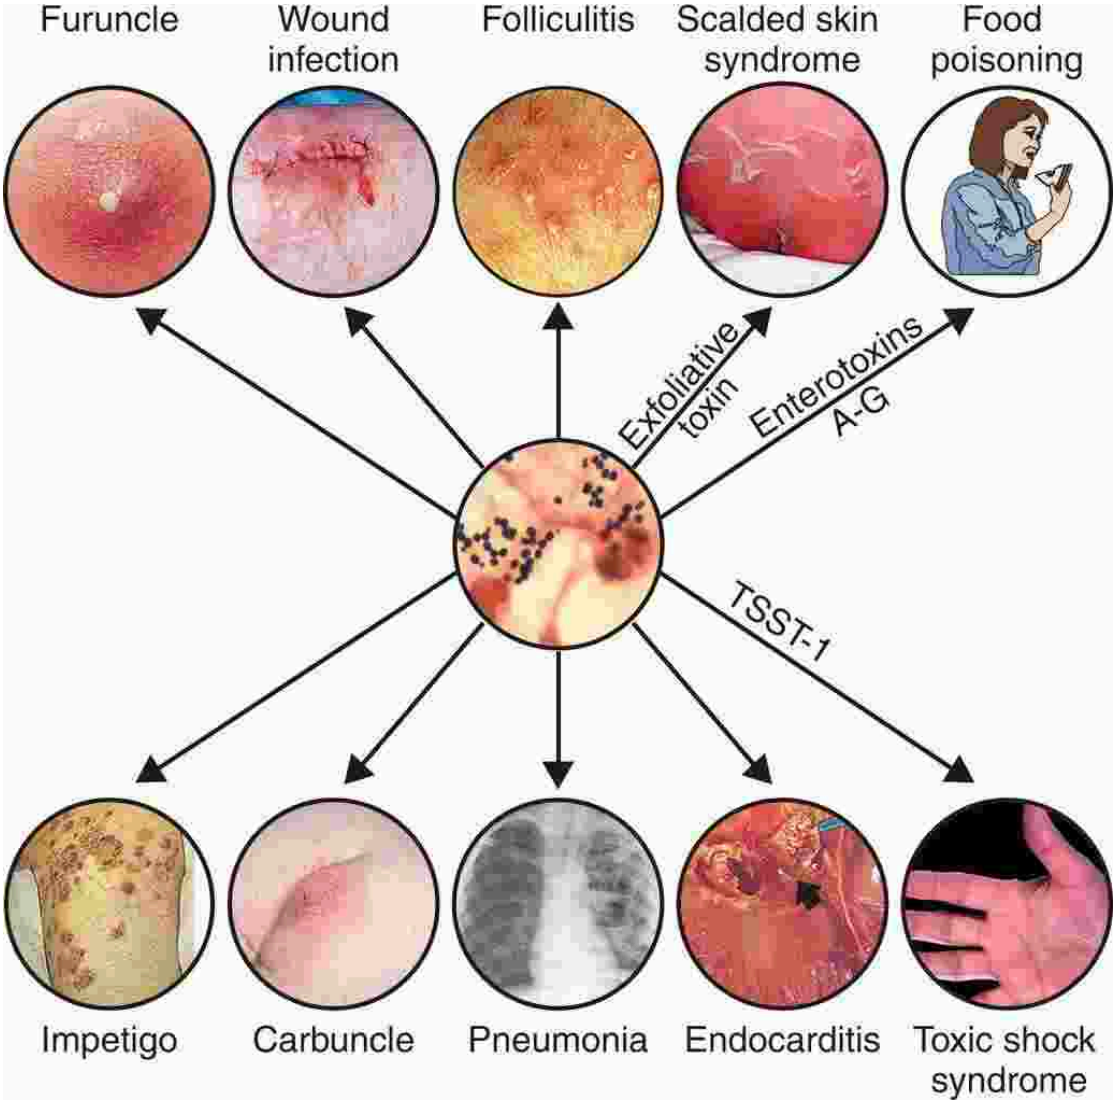

FIG. 10.3 ***Staphylococcus aureus*** **Infections.**
Different strains of *S. aureus* (gram-positive cocci) cause a variety of infections in different organ systems. The center photograph shows *S. aureus* in sputum from an individual with pneumonia. The particular infection may depend on the toxin produced: exfoliative toxin (scalded skin syndrome), enterotoxins A–G (food poisoning), or toxic shock syndrome toxin-1 (TSST-1). Toxic shock syndrome, carbuncle, impetigo, and wound infection photos: From Cohen J, Powderly WG. *Infectious diseases*, 3rd edition. St. Louis: Mosby; 2010. Folliculitis photo: From Goldman L, Ausiello D. *Cecil medicine*, 24th edition. Philadelphia: Saunders; 2012. Center photo and photos of food poisoning and endocarditis: From Kumar V, Abbas AK, Aster JC, et al. *Robbins and Cotran pathologic basis of disease*, 8th edition. Philadelphia: Saunders; 2010. Furuncle photo: From Long S, Pickering LK, Prober CG. *Principles and practice of pediatric infectious diseases*, 4th edition. Philadelphia: Saunders; 2012. Scalded skin syndrome and pneumonia photos: From Mandell G, Bennett JE, Dolin R. *Principles and practice of infectious diseases*, 7th edition. Philadelphia: Churchill Livingstone; 2010.

A series of photos identifies the different staphylococcus aureus infections. • Furuncle: a closeup of a boil on the skin surface. • Wound infection: A closeup of an infected skin cut. • Folliculitis: A closeup of multiple inflamed hair follicles

on the skin surface. • Scaled skin syndrome: A closeup of a blistered skin, caused as result of exfoliative toxin. • Food poisoning: An illustration shows a person eating a food item, caused a result of enterotoxins A-G. • Impetigo: A closeup of discolored sores on a child's arm. • Carbuncle: A closeup of a pus-filled bump of the skin surface. • Pneumonia: A radiograph of the chest shows white spots in the lings. • Endocarditis: A closeup of inflamed inner lining along the chambers and valves of the heart. • Toxic shock syndrome: A closeup of sunburn-like rashes on a person's palm, caused by T S S T-1.

Another type of toxin is endotoxin. Unlike secreted exotoxins, **endotoxin** (also called lipopolysaccharide) is contained in the cell walls of gram-negative bacteria and is released during lysis (or destruction) of the bacteria (see Fig. 10.1B). The innermost part of LPS, lipid A, is made of polysaccharides and fatty acids and is responsible for the substance's toxic effects. Endotoxin also may be released during bacterial growth or during treatment with antibiotics. At low levels, endotoxin initiates an effective innate immune response, including activation of inflammatory cells and complement (Fig. 10.4) (see Chapter 7). As the infection progresses, increasing amounts of endotoxin stimulate the release of inflammatory mediators such as tumor necrosis factor-α (TNF-α) interleukin- 1 (IL-1), IL-6, IL-8, nitric oxide, and platelet activating factor that produce fever and cause the local and systemic effects of inflammation (see Fig. 10.4). Once in the blood in high quantities, endotoxins cause the release of toxic levels of these cytokines that promote vasodilation (reduces blood pressure), decrease oxygen delivery to tissues, and may result in endotoxic shock (septic shock) (see Fig. 10.4) (see Chapter 48). Endotoxins also can activate the coagulation cascade, leading to the syndrome of disseminated (or diffuse) intravascular coagulation (see Chapter 29).

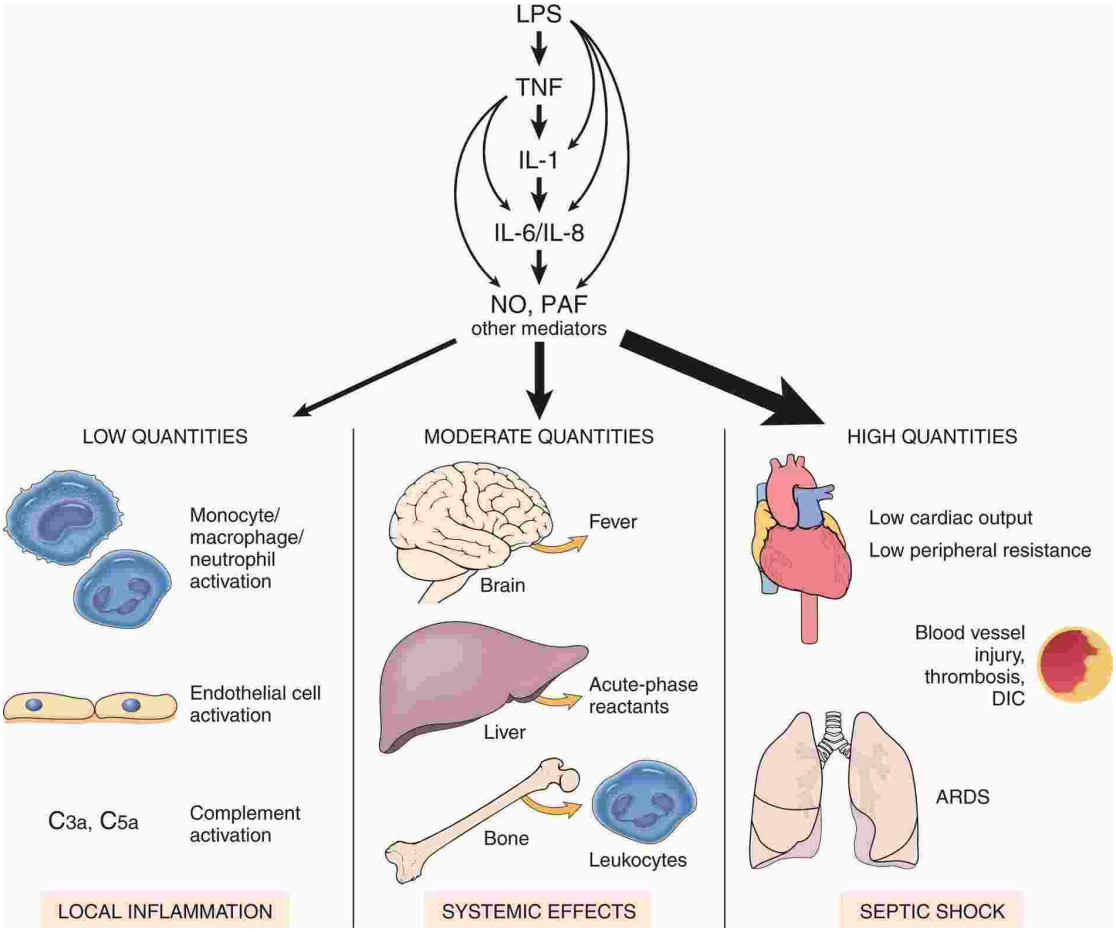

FIG. 10.4 The Many Effects of Lipopolysaccharide.
Bacterial endotoxin lipopolysaccharide *(LPS)* activates almost every aspect of inflammation. The release of LPS from gram-negative bacteria triggers successive waves of cytokine production, including tumor necrosis factor *(TNF)*, interleukin-1 *(IL-1)*, interleukin-6 *(IL-6)*, and interleukin-8 *(IL-8)*, and secondary mediators of inflammation, such as nitric oxide *(NO)* and platelet-activating factor *(PAF)*. At low levels of LPS the effect is local. Moderate levels of LPS cause more systemic inflammatory responses. High levels of LPS may lead to septic shock and death. *ARDS*, Acute respiratory distress syndrome; *DIC*, disseminated intravascular coagulation. (From Kumar V, Abbas A, Fausto N. *Robbins & Cotran pathologic basis of disease*, 7th edition. Philadelphia: Saunders; 2005; Modified from Abbas AK, Lichtman AH, Pober JS. *Cellular and molecular immunology*, 4th edition. Philadelphia: WB Saunders; 2000.)

An illustrated flowchart identifies the many effects of lipopolysaccharide. The release of L P S leads to the production of the following: • T N F. • I L-1. • I L-6 or I L-8. • N O, P A F. The effects of L P S based on quantities are as follows. • In low quantities, local inflammation is a result of monocyte or macrophage or neutrophil activation, endothelial cell activation, or complement activation (C 3 a, C 5 a). • In moderate quantities, systemic effects are a result of fever triggered in the brain, acute-phase reactants triggered in the liver, or leukocytes triggered in the bone. • In high quantities, septic shock is a result of low cardiac output or

low peripheral resistance in the heart; blood vessel injury, thrombosis, D I C; or A R D S in the lungs.

In addition to toxins, bacteria can release enzymes that promote infection and damage tissues and organs. Some of the most important bacterial enzymes are proteases, lipases, deoxyribonucleases (DNases), and hyaluronidase. These enzymes are not specific for any particular cell or cell receptor but facilitate spread of the microorganism by weakening the surrounding connective tissue to allow invasion. For example, kinases (e.g., streptokinase and staphylokinase) activate plasminogen to digest large clots that interfere with bacterial spread. In contrast, many staphylococcus species produce coagulase, an enzyme that produces clotting around the bacterium as a way of protecting itself. Many enzymes also will digest membranes of tissue cells leading to lysis and release of nutrients that are useful to the microorganisms.

While bacterial toxins and enzymes contribute to tissue injury, much of the damage caused by infections is secondary to the inflammatory and immune responses. Infectious microorganisms routinely initiate an immune and inflammatory response, including infiltrates of phagocytic cells and a wide variety of T cells, production of antibodies, and activation of plasma systems (complement, clotting) (see Chapters 7, 8, and 9). Cytokines and chemokines secreted by inflammatory and immune cells are designed to inhibit the proliferation and spread of infectious agents; however, most also are damaging to the surrounding tissue.

Bacterial Evasion of Immune and Inflammatory Defenses

In order for bacteria to invade, replicate, and cause disease, they must evade the inflammatory and immune defense mechanisms (see Algorithm 10.1). For example, some microorganisms produce proteases that digest components of the plasma systems (complement, clotting, fibrinolysis), immunoglobulins, cytokines, and antimicrobial peptides. Others produce leukocidins that lyse phagocytes. Table 10.3 provides other examples of mechanisms used by pathogens to resist the immune system.

Table 10.3

Examples of Mechanisms Used by Pathogens to Resist the Immune System

Mechanisms	Effect on Immunity	Example of Specific Microorganisms
Destroy or Block Component of Immune System		
Produce toxins	Kills phagocyte or interferes with chemotaxis Prevents phagocytosis by inhibiting fusion between phagosome and lysosomal granules	*Staphylococcus* *Streptococcus* *Mycobacterium tuberculosis*
Produce antioxidants (e.g., catalase, superoxide dismutase) Produce protease to digest immunoglobulin A (IgA)	Prevents killing by oxygen-dependent mechanisms Promotes bacterial attachment	*Mycobacterium* sp. *Salmonella typhi* *Neisseria gonorrhoeae* (urinary tract infection), *Haemophilus influenzae*, and *Streptococcus pneumoniae* (pneumonia)
Produce surface molecules that mimic Fc receptors and bind antibody	Prevents activation of complement system Prevents antibody functioning as opsonin	*Staphylococcus* Herpes simplex virus
Mimic Self-Antigens		
Produce surface antigens (e.g., M protein, red blood cell antigens) that are similar to self-antigens	Pathogen resembles individual's own tissue; in some individuals, antibodies can be formed against self-antigen, leading to hypersensitivity disease (e.g., antibody to M protein also reacts with cardiac tissue, causing rheumatic heart disease; antibody to red blood cell antigens can cause anemia)	Group A *Streptococcus* (M protein) *Mycoplasma pneumoniae* (red cell antigens)
Change Antigenic Profile		
Undergo mutation of antigens or activate genes that change surface molecules	Immune response delayed because of failure to recognize new antigen	Influenza virus Human immunodeficiency virus (HIV) Some parasites

Antiphagocytic capsules are expressed by most bacterial pathogens involved in pneumonia and meningitis (Fig. 10.5). **Capsules** are mostly polysaccharide, although proteins also may be capsular

components. Encapsulated bacteria are difficult for macrophages and neutrophils to phagocytose until they are opsonized by complement and antibodies, thus delaying the immune response to these microorganisms.[2] Examples include the thick polysaccharide covering of pneumococci *(S. pneumoniae)* and *Neisseria meningitidis*, the waxy capsule surrounding the tubercle bacillus *(M. tuberculosis)*, and the polysaccharide "slime" capsule of *Pseudomonas aeruginosa*.

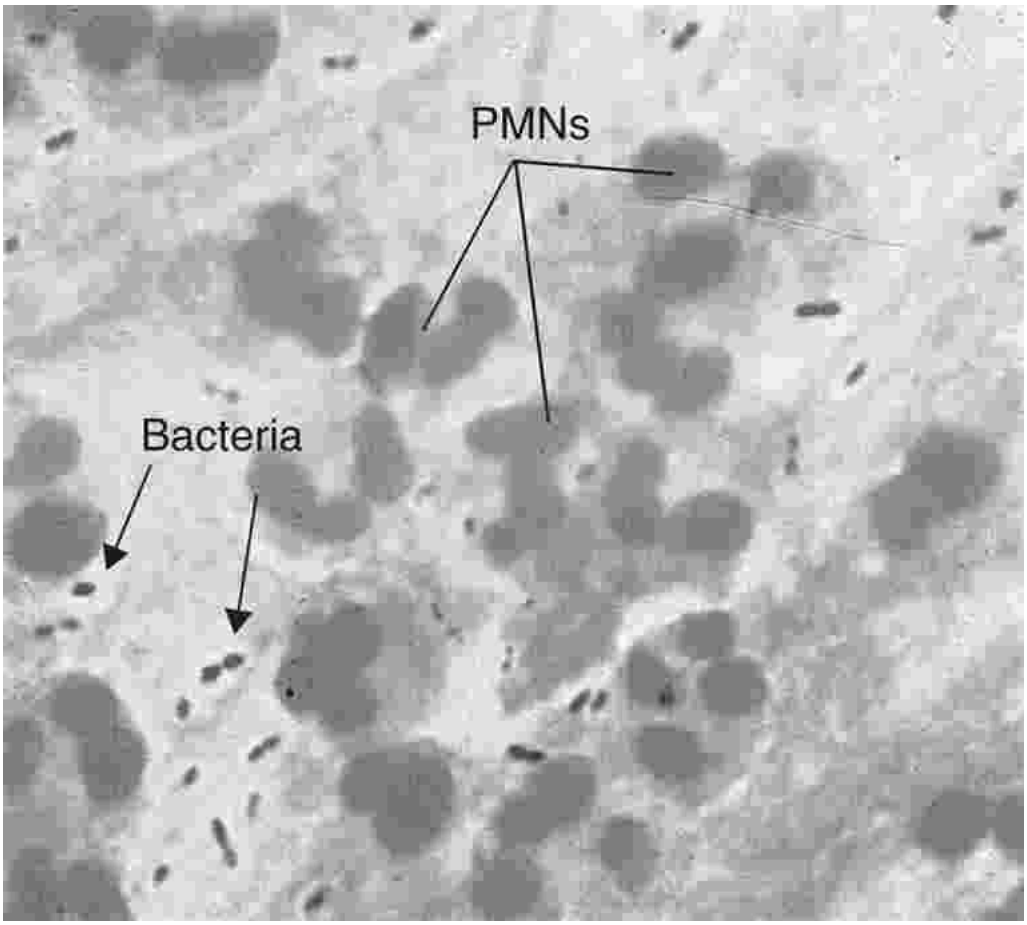

FIG. 10.5 Bacterial Capsules.
Bacterial Capsule. Gram stain of a sputum sample from an individual with pneumococcal pneumonia (×1000 magnification). The sputum is rich in polymorphonuclear *(PMN)* cells and slightly elongated, gram-positive cocci (*Streptococcus pneumoniae*). Clear areas *(arrows)* around the bacteria indicate capsules. (Modified from Mandell G, Bennett J, Dolin R. *Principles and practice of infectious diseases*, 7th edition. Philadelphia: Churchill Livingstone; 2010.)

Many bacteria are capable of developing increased virulence, antibiotic resistance, and other adaptive factors through a process called **horizontal gene transfer**. Bacteria can share segments of genetic material through bacteriophages or plasmids.[3] **Bacteriophages** are viruses that infect bacteria and can inject genetic material from one bacterium into another during their infectious process. **Plasmids** are small circular DNA molecules within bacteria that exist outside of chromosomes and can move from one microorganism to another through a process called conjugation. **Conjugation** is the process by which two bacteria fuse together via pili (see Fig. 10.2). Horizontal gene transfer occurs within and across species of bacteria and can create hybrid bacteria that demonstrate improved ability to infect and replicate, and to resist treatment.[3,4]

Another way microorganism overcome host defenses is by the formation of biofilms (Fig. 10.6). **Biofilms** consist of mixed species of microorganisms, including bacteria and fungi, immersed in a highly organized extracellular matrix of polysaccharides, nucleic acids, and proteins produced by the microorganisms. These biofilms become a multicellular community within a protective structure providing protection from external threats, including host defense mechanisms and antimicrobial treatment, making them difficult to eradicate. For example, there is increasing evidence that biofilm bacteria can skew T helper (Th) cell responses such that the immune response is unable to clear the bacteria.[5] Biofilms form on implanted medical devices (e.g., catheters, pacemakers, implanted heart valves, prosthetic joints, dentures). This type of biofilm most commonly is caused by *Staphylococcus epidermidis* and *S. aureus*, although biofilms formed by fungi and other bacteria such as *P. aeruginosa* may also occur.[6,7] Biofilms also occur on teeth, as well as on epithelial surfaces (e.g., persistent nasopharyngeal colonization with staphylococci; otitis media; diabetes-associated foot ulcers; infected burns; or pneumonia associated with cystic fibrosis). *C. difficile* forms biofilms in the gut, making gastrointestinal infection by this bacterium difficult to treat.[8] Biofilms are associated with chronic infections, especially in wounds where they contribute to poor wound healing.[9,10] Of great concern is the recognition that horizontal transfer of antibiotic resistance genes between bacterial is facilitated within biofilms.[11] Bacteria may be released from the surface of biofilms, potentially resulting in distant infections.

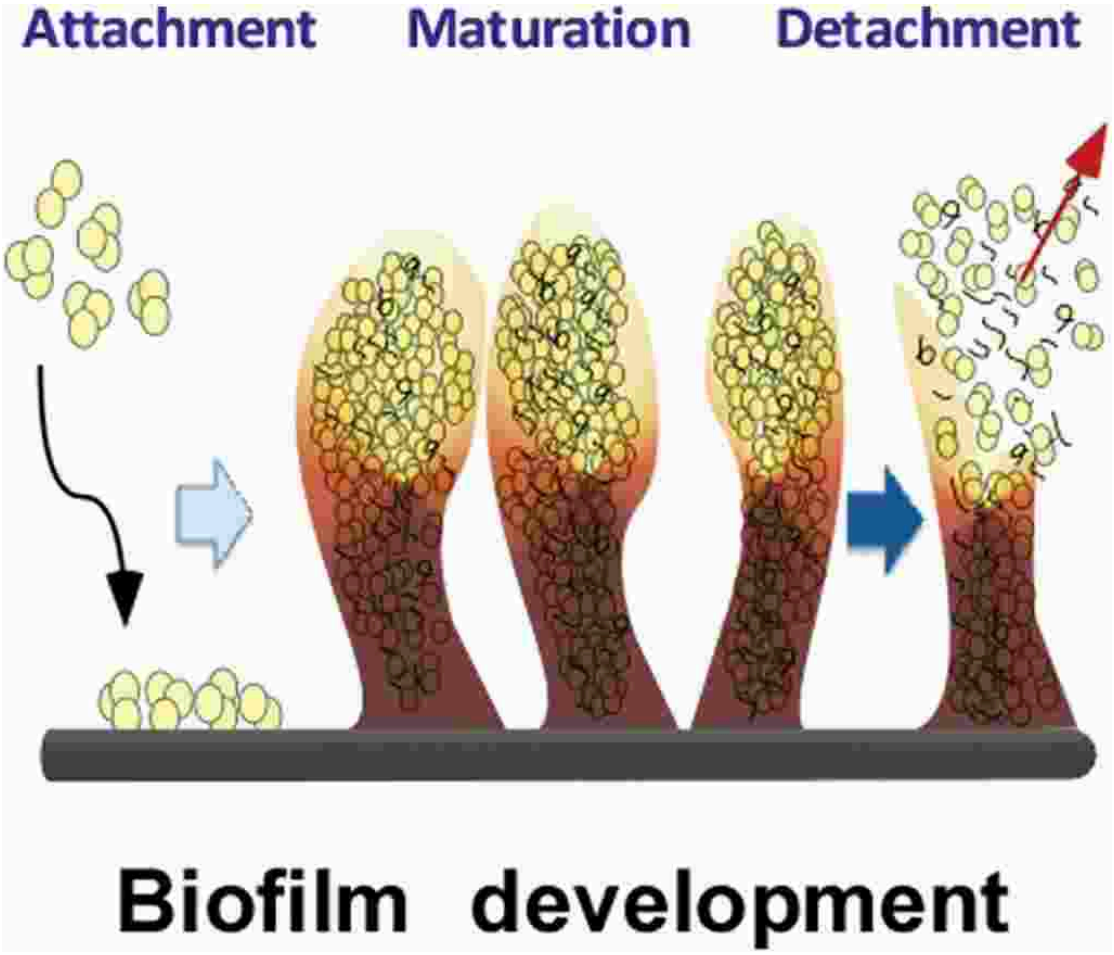

FIG. 10.6 Biofilm Development.
Biofilm formation occurs in three main steps: **(1)** microorganisms attach to an epithelial surface or medical device; **(2)** they proliferate and form the protective biofilm structure; and **(3)** they can detach and spread to other surfaces or the bloodstream. (From Joo HS, Otto M. Molecular basis of in vivo biofilm formation by bacterial pathogens. *Chemistry and Biology*, 2012;19(12):1503–1513.)

Viral Infection

Viral diseases are common and range in severity from the common cold to the acquired immunodeficiency syndrome (AIDS). Examples of human diseases caused by specific viruses are listed in Table 10.4 Viruses are extremely simple microorganisms that do not possess any of the metabolic organelles found in prokaryotes (e.g., bacteria) or eukaryotes (e.g., human cells). Viral replication depends on their ability to infect a permissive host cell. The basic viral structure (virion) consists of nucleic acid protected by a protein shell, the capsid. The viral genome can be double-stranded deoxyribonucleic acid (dsDNA), single-stranded DNA (ssDNA), double-stranded ribonucleic acid RNA (dsRNA), or single-stranded RNA (ssRNA). Many viruses also are surrounded by a protective envelope, which contains the viral proteins needed for attachment to host cells. Viruses also contain enzymes that drive viral replication. Viral pathogens directly destroy or damage cells as part of their replication in infected cells. Transmission is usually from one infected individual to an uninfected individual by aerosols of respiratory tract fluids, contact with infected blood or contaminated surfaces, sexual contact, transmission from an animal reservoir (zoonotic infection), or through a vector, such as mosquitoes.

Table 10.4

Examples of Human Diseases Caused by Specific Viruses

Baltimore Classification	Family	Virus	Envelope	Main Route of Transmission	Disease
dsDNA	Adenoviruses	Adenovirus	No	Droplet contact	Acute febrile pharyngitis
	Herpesviruses	Herpes simplex virus type 1 (HSV-1)	Yes	Direct contact with saliva or lesions	Lesions in mouth, pharynx, conjunctivitis
		Herpes simplex virus type 2 (HSV-2)	Yes	Sexually, contact with lesions during birth	Sores on labia, meningitis in children
		Herpes simplex virus type 8 (HSV-8)	Yes	Sexually, body fluids	Kaposi sarcoma
		Epstein-Barr virus (EBV)	Yes	Saliva	Mononucleosis, Burkitt lymphoma
		Cytomegalovirus (CMV)	Yes	Body fluids, mother's milk, transplacental	Mononucleosis, congenital infection
		Varicella-zoster virus (VZV)	Yes	Droplet contact	Chickenpox, shingles
ssDNA	Papovaviruses	Human papillomavirus (HPV)	No	Direct contact	Warts, cervical carcinoma
dsRNA	Reoviruses	Rotavirus	No	Fecal–oral	Severe diarrhea
ssRNA+	Picornaviruses	Coxsackievirus	No	Fecal–oral, droplet contact	Nonspecific febrile illness, conjunctivitis, meningitis
		Hepatitis A virus	No	Fecal–oral	Acute hepatitis
		Poliovirus	No	Fecal–oral	Poliomyelitis
		Rhinovirus	No	Droplet contact	Common cold
	Flaviviruses	Hepatitis C virus	Yes	Blood, sexually	Acute or chronic hepatitis, hepatocellular carcinoma
		Yellow fever virus	Yes	Mosquito vector	Yellow fever
		Dengue virus	Yes	Mosquito vector	Dengue fever

Baltimore Classification	Family	Virus	Envelope	Main Route of Transmission	Disease
		West Nile virus	Yes	Mosquito vector	Meningitis, encephalitis
	Togaviruses	Rubella virus	Yes	Droplet contact, transplacental	Acute or congenital rubella
	Coronaviruses	SARS-CoV-1, SARS-CoV-2	Yes	Droplets in aerosol or direct contact	Severe respiratory tract disease
	Caliciviruses	Norovirus	No	Fecal–oral	Gastroenteritis
ssRNA−	Orthomyxoviruses	Influenza virus	Yes	Droplet contact	Influenza
	Paramyxoviruses	Measles virus	Yes	Droplet contact	Measles
		Mumps virus	Yes	Droplet contact	Mumps
		Parainfluenza virus	Yes	Droplet contact	Croup, pneumonia, common cold
		Respiratory syncytial virus (RSV)	Yes	Droplet contact, hand-to-mouth	Pneumonia, influenza-like syndrome
	Rhabdoviruses	Rabies virus	Yes	Animal bite, droplet contact	Rabies
	Bunyaviruses	Hantavirus	Yes	Aerosolized animal fecal material	Viral hemorrhagic fever
	Filoviruses	Ebola virus	Yes	Direct contact with body fluids	Viral hemorrhagic fever
		Marburg virus	Yes	Direct contact with body fluids	Viral hemorrhagic fever
	Arenavirus	Lassa virus	Yes	Aerosolized animal fecal material	Viral hemorrhagic fever
ssRNA+ with RT	Retroviruses	HIV	Yes	Sexually, blood products	AIDS
dsDNA with RT	Hepadnaviruses	Hepatitis B virus	Yes	All body fluids	Acute or chronic hepatitis, hepatocellular carcinoma

AIDS, Acquired immunodeficiency syndrome; *DNA*, deoxyribonucleic acid; *ds*, double-stranded; *HIV*, human immunodeficiency virus; *RNA*, ribonucleic acid; *RT*, reverse transcriptase; *SARS*, severe acute respiratory syndrome; *ss*, single-stranded.

Viruses are obligatory intracellular microbes. Although classes of viruses differ in the ways they reproduce, they share common replicative steps (Fig. 10.7):

1. *Recognition* and *attachment* allow the virus to bind to a specific receptor on the target cell. The specificity of the virus-receptor attachment dictates the range of host cells that a particular virus will infect. Therefore, clinical symptoms reflect the damage to the specific type of infected cells (e.g., hepatitis A causes symptoms of liver failure; HIV infection results in destruction of CD4+ T cells and immunodeficiency).
2. *Penetration* into the cell most commonly occurs by endocytosis or membrane fusion.
3. *Uncoating* is the release of viral nucleic acid (genome) from the viral capsid by viral or host enzymes.
4. *Replication* is the synthesis of new DNA or RNA strands and messenger RNA (mRNA). Most DNA viruses (except poxviruses) replicate their genome in the nucleus where they use the host's transcriptase enzymes to produce messenger RNA (mRNA). Most RNA viruses (except influenza and HIV) replicate in the cytoplasm and directly make mRNA using viral polymerases.
5. *Translation* results in viral structural protein synthesis in the host cell endoplasmic reticulum and Golgi apparatus.
6. *Assembly* is the formation of new virions.
7. *Release* or shedding of new virions is by lysis of the cell, exocytosis of the viral particle, or budding from the cell membrane. A select group of viruses (e.g., HIV, herpesviruses, coronaviruses) retain a portion of the cell's plasma membrane when they bud from the surface of an infected cell providing added protection from immune processes.

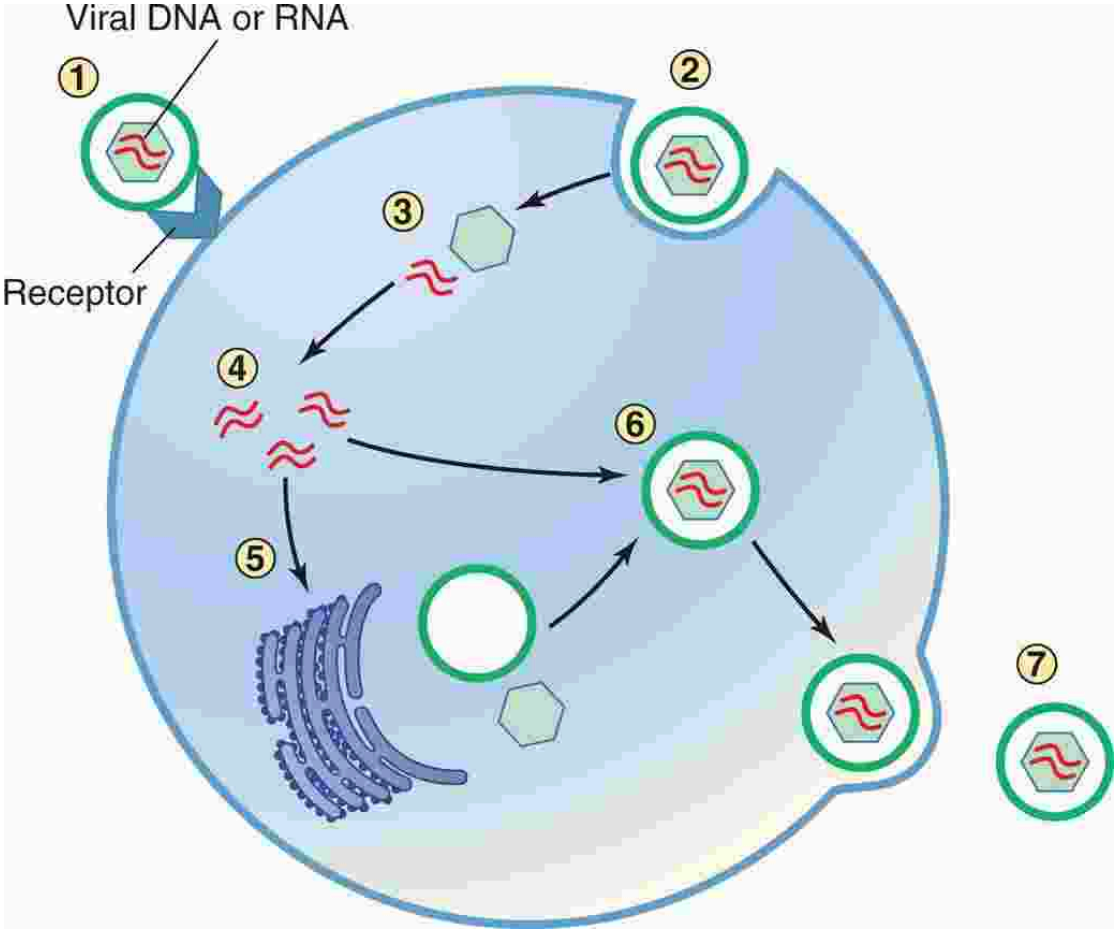

FIG. 10.7 Stages of Viral Infection of a Host Cell.
Viral life cycle includes several steps. ***(1)*** Recognition and attachment of the virus to a host receptor or cell wall molecule. ***(2)*** Penetration into the host cell by fusion or endocytosis. ***(3)*** Uncoating of the viral genome within the cell cytoplasm. ***(4)*** Replication of the viral genome using host or viral transcriptases and polymerases. ***(5)*** Translation with viral structural protein synthesis in the host cell endoplasmic reticulum and Golgi apparatus. ***(6)*** Assembly of the virus. ***(7)*** Release of the virus by budding or exocytosis, or by lysis of the host cell.

Mechanisms of Viral Invasion and Tissue Damage

The effects of a virus on an infected cell vary greatly and often result in destruction of the cell. These destructive processes can include cessation of DNA, RNA, and protein synthesis (e.g., herpesvirus); disruption of lysosomal membranes resulting in release of digestive lysosomal enzymes that can kill the cell (e.g., herpesvirus); fusion of host cells producing multinucleated giant cells (e.g., respiratory syncytial virus [RSV]); and alteration of the antigenic properties of the infected cell, causing the individual's immune system to attack the cell as if it were foreign (e.g., hepatitis B virus). Alternatively, there are viruses that cause transformation of host cells into cancerous cells, resulting in uninhibited and unregulated growth (e.g., human papillomavirus [HPV]; Epstein-Barr virus [EBV]), or promote secondary bacterial infection in tissues damaged by viruses (e.g., RSV and influenza viruses).

Viruses rarely produce toxins or other destructive products that cause tissue damage, and the severity of clinical symptoms is most often secondary to the level of inflammatory and immune cytokines produced in response to the infected cells. In most cases, the symptoms of viral infection (e.g., fever, aches, nausea) are generally mild, caused by the individual's own inflammatory response to infection,

and usually resolve in a relatively short time. However, more severe local cellular effects may result from destruction of infected cells by lymphocytes. For example, the dermal and ocular lesions of herpes simplex virus infection result from T cell–mediated cytotoxicity of epithelial cells. Hepatitis B causes immune-mediated destruction of infected liver cells causing liver failure and cirrhosis. Many viruses induce excessive production of proinflammatory cytokines and reactive oxygen species, all of which contribute to tissue damage. Severe systemic illness also can occur in viral infection resulting in significant morbidity and mortality (e.g., influenza pneumonia; COVID-19).

Viral Evasion of Immune and Inflammatory Defenses

Some viruses bypass intracellular defenses and hide within cells and away from normal inflammatory or immune responses in a process called *viral latency* (e.g., varicella zoster virus, HPV, and HIV). Varicella zoster virus (which causes chickenpox) will enter a latency phase and spread from mucosal and epidermal sites to remain dormant in the dorsal root ganglion. Later in life and in response to stimuli, such as stress, hormonal changes, or disease, the virus may exit latency and enter a productive cycle causing herpes zoster (shingles) or postherpetic neuralgia.

Viruses also can elude the immune system by making small changes to the genes that produce viral surface antigens, a process known as **antigenic variation**. **Antigenic drift** is a minor form of antigenic variation and results from mutations in the viral genome. For example, antigenic drift can lead to changes in the surface hemagglutinin (HA) and neuraminidase (NA) proteins that allow the influenza virus to attach to human cells. HA and NA also serve as specific antigens that can be detected by the adaptive immune system and allow the production of virus-specific antibodies. Vaccine protection gained from the previous year's infection does not necessarily protect against influenza in the following year because the HA and NA antigens undergo yearly change via antigenic drift.[12] A virus may undergo a sudden major antigenic variation known as **antigenic shift** (Fig. 10.8). Two or more different viruses combine to form a new strain having a mixture of surface antigens of the two or more original strains. For example, influenza A can infect humans, birds, and pigs. Antigenic shift occurs in pigs coinfected by a human and an avian strain of influenza. The genome is segmented into portions that undergo recombination during which the virus obtains a new HA or NA antigen. When an antigenic shift occurs, previous protection by vaccination may not exist, resulting in a major pandemic (an epidemic that spreads over a large area, such as a continent or worldwide) and much more severe disease. Such an event occurred in 2009 with the emergence of H1N1 influenza (“swine flu”). In an effort to improve vaccine effectiveness in the face of antigenic drift and antigenic shift, new methods for creating vaccines such as computationally optimized broadly reactive antigen (COBRA) and mRNA technologies have been developed.[13,14]

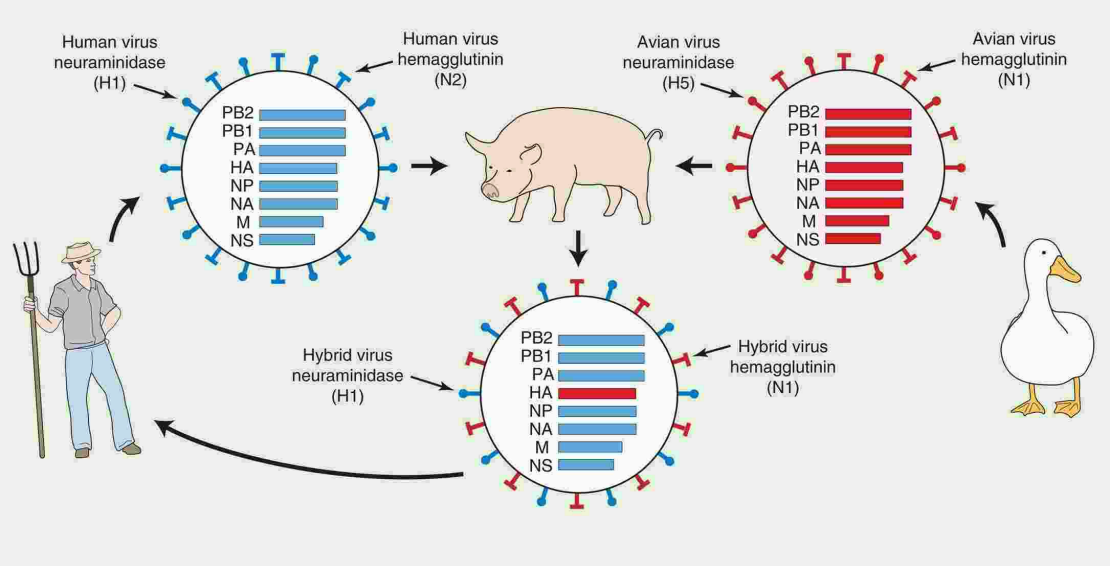

FIG. 10.8 Antigenic Shifts in Influenza Virus.
Antigenic shifts occur when viruses from two different species combine to create a new virus. In this figure, a human influenza virus *(blue)* and an avian influenza virus *(red)* coinfect a species that is permissive for both. Each virus contains single-stranded RNA that codes for eight important viral components including hemagglutinin *(HA)* and neuraminidase *(NA)* which are important for viral attachment to host cells. Different strains of influenza virus are designated by the molecular components of HA and NA—in this case the human virus is H1N2 and the avian virus is H5N1. When these viruses coinfect the permissive host (pig), their RNA strands mix, thus producing a hybrid virus, H1N1. This hybrid virus may cause more serious infection because there is likely to be less residual human immunity that normally provides partial protection against more common influenza infections.

An illustration demonstrates the antigenic shifts in influenza virus. Human virus neuraminidase (H 1) and human virus hemagglutinin (N 2), in humans, combine to form a cell which includes the following: P B 2, P B 1, P A, H A, N P, N A, M, and N S. Avian virus neuraminidase (H 5) and avian virus hemagglutinin (N 1), in ducks, combine to form a cell which includes the following: P B 2, P B 1, P A, H A, N P, N A, M and N S. The hybrid cell infects humans. It is a combination of hybrid virus neuraminidase (H 1) and hybrid virus hemagglutinin (N 1), in pigs, which includes the following: P B 2, P B 1, P A, H A, N P, N A, M and N S.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

The **human immunodeficiency virus (HIV)** is the cause of a severe secondary immune deficiency called **acquired immunodeficiency syndrome (AIDS)**. AIDS is responsible for millions of deaths worldwide, with sub-Saharan Africa suffering the highest number of deaths. At the end of 2020, it is estimated that globally there were an estimated 37.7 million people living with HIV, over two thirds of whom are in the WHO African Region.[15] Despite these staggering numbers, the incidence and mortality of HIV has declined around the world due to increasing availability of diagnostic and treatment options. In the United States, there are over 1 million Americans who are living with HIV, and 36,801 new cases were

diagnosed in 2019.[16] Although new infection rates are declining or stable in most racial and ethnic groups, the incidences of new infections increased by over 30% in American Indian and Alaska Native populations between 2015 and 2019.[16]

There are two types of HIV: HIV-1 (the most common [95% of HIV infections]) and HIV-2 (less common and less infectious). The discussion in this chapter is confined to HIV-1 and will be referred to as "HIV." There are four genotypes of HIV: M (Main), N (Non-M), O (Outlier), and P.[17] Most HIV is of the M genotype, which is further is divided into nine clades (subtypes), designated A–D, F–H, J, and K.[18] Different regions of the world have a predominance of one or more types of HIV. Globally, HIV clade C is the most prevalent, comprising 46% of global infections, and is the dominant subtype in Southern Africa and India. It is postulated that this high prevalence is due to the fact that subtype C has a lower replication capacity and is associated with a slower disease progression allowing more asymptomatic individuals to spread the disease before they know they are infected.[17] HIV clade B is the most common subtype in the United States, Western Europe, and Central and South America.

Transmission of HIV

The most common route of transmission worldwide is through heterosexual activity. However, in the United States almost 70% of new HIV infections occur among gay and bisexual men.[19] Other routes of transmission include blood or blood products, intravenous drug use, and maternal–child transmission before or during birth. Worldwide, women constitute more than half of those living with HIV/AIDS. Hundreds of thousands of cases of HIV/AIDS have been reported in children who contracted the virus from their mothers across the placenta, through contact with infected blood during delivery, or through the milk during breastfeeding.

Host genetic factors influence the transmission of HIV. Individuals with certain gene polymorphisms of their CXCR4 or CCR5 coreceptor molecules (see HIV Replication) are less likely to become infected.[17] In fact, individuals who are homozygous for the Δ32 mutation of the CCR5 coreceptor are immune to the virus. Other host factors that influence the transmission of HIV are related the viral load of the source of the infection and to the effectiveness of immune function in the exposed individual.

HIV replication

HIV is a member of a family of viruses called *retroviruses*. HIV carries its genetic information in the form of two identical copies of ssRNA contained in a capsid constructed of viral capsid protein p24. The capsid is encased in an envelope. The envelope displays glycoprotein 120 (gp120) on its surface connected to a transmembrane glycoprotein 41 (gp41) (Fig. 10.9). The genome of HIV codes for its structure (e.g., *gag*, *env*) as well as the viral enzymes reverse transcriptase, integrase, and protease *(pol, int, pro)*. Some HIV genes code for proteins that affect host immune responses to the virus (e.g., *nef*).[20] Other HIV genes code for infectivity, replicative rates, viral assembly, and release *(tat, tax, rex, rev, vif, vpu, vpr)*.

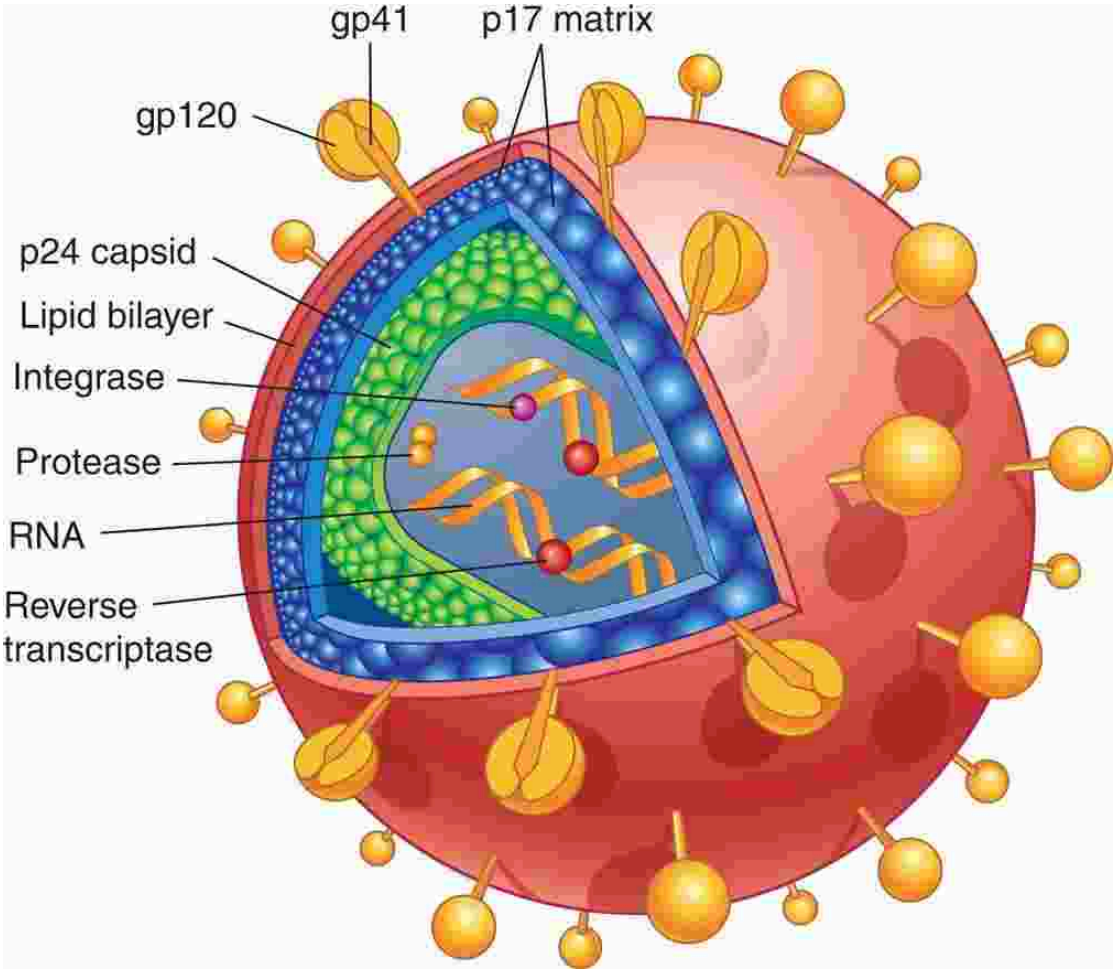

FIG. 10.9 Human Immunodeficiency Virus-1 (HIV-1) Structure.
The HIV-1 virion consists of a core of two identical strands of viral ribonucleic acid *(RNA)* molecules of viral enzymes (reverse transcriptase [RT], protease [PR], integrase [IN]) enveloped in a core capsid structure consisting primarily of the structural viral protein p24. The capsid is further encased in a matrix consisting primarily of viral protein p17. The outer surface is an envelope consisting of the plasma membrane of the cell from which the virus budded (lipid bilayer) and two viral glycoproteins: a transmembrane glycoprotein, gp41, and a noncovalently attached surface glycoprotein, gp120 (site of viral attachment). (Modified from Kumar V, Abbas AK, Fausto N, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Saunders; 2021.)

A cutaway illustration of the human immunodeficiency virus-1 (H I V-1) shows and labels the following structures, from the outside to the inside: g p 120, g p 41, lipid bilayer, p 17 matrix, p 24 capsid, protease, R N A, integrase, and reverse transcriptase.

After transmission from one person to another, HIV replication begins with attachment to the target cell (Fig. 10.10). The virus first attaches to macrophages and to dendritic cells, which then carry the virus into the lymph nodes where it can infect its primary target cell, the Th lymphocyte (see Chapter 8). For both dendritic cells and Th cells, the process of viral attachment begins with the binding of gp120 to

CD4 molecules present on the surface of these cells. Further viral attachment requires binding to chemokine coreceptors. The coreceptor on macrophages and dendritic cells is CCR5. On Th cells, the coreceptor is CXCR4. Fusion of the virus to the cellular membrane requires that the gp120/CD4 molecule complex undergoes conformational changes that allow the transmembrane gp41 to fuse with the target cell. At this point, the viral envelope and the cellular membrane are fully fused and the viral capsid is released into the target cell cytoplasm. A group of antiretroviral medications are used to block these steps in viral attachment and fusion (see Fig. 10.10). Once the virus has been released into the target cell cytoplasm, the viral enzyme HIV reverse transcriptase converts RNA into dsDNA. Using a second viral enzyme, HIV integrase, the new DNA is inserted into the infected cell's genetic material. If the cell is activated, transcription and translation of the viral information are initiated, resulting in the production of a long strand of viral components which is then processed by the viral enzyme HIV protease. Antiretroviral medications have been developed that prevent the action of all three HIV enzymes (see Fig. 10.10). Assembly of the virus occurs at the host cell plasma membrane.

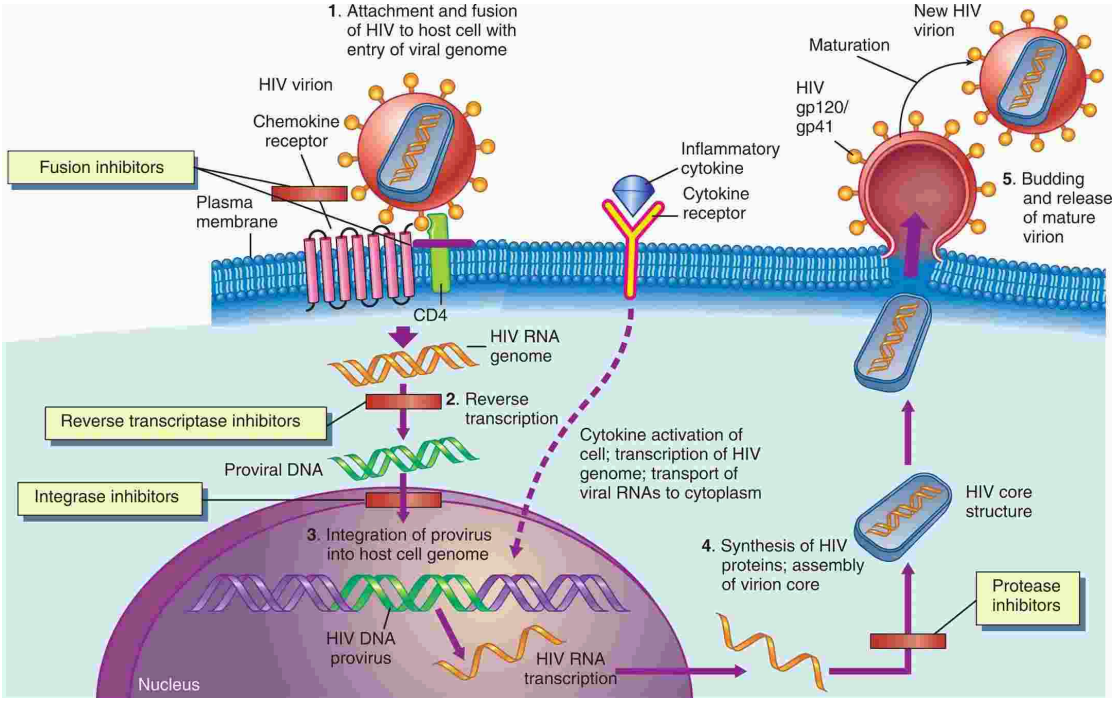

FIG. 10.10 Human Immunodeficiency Virus-1 (HIV-1) Life Cycle and Sites of Drug Intervention.
The HIV virion consists of a core of two identical strands of viral ribonucleic acid *(RNA)* enveloped in a protein capsid with viral glycoproteins gp41 and gp120 on its surface (envelope). ***(1)*** HIV infection begins when a virion attaches to CD4 and the chemokine co-receptor CCR5 on macrophages or dendritic cells, and to CD4 and the chemokine co-receptor CXCR4 on T-helper cells. Conformational changes in the gp120/CD4 complex allow for fusion of the virus to the cell membrane and entry into a cell where it uncoats. ***(2)*** The viral enzyme reverse transcriptase causes reverse transcription of viral RNA into deoxyribonucleic acid *[DNA]*. ***(3)*** The viral enzyme integrase inserts the DNA into the host cell chromosomes. When the host cell is activated by cytokines, viral mRNA travels into the cytoplasm. ***(4)*** Translation results in synthesis of HIV proteins, which are then divided into viral components by the viral enzyme protease. ***(5)*** The virus reassembles and buds from the cell. The HIV life cycle is susceptible to blockage at several sites (see the text for further information), including attachment and fusion inhibitors, reverse transcriptase inhibitors, integrase inhibitors, and protease inhibitors. Modified from Kumar V, Abbas AK, Fausto N, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Saunders; 2021.

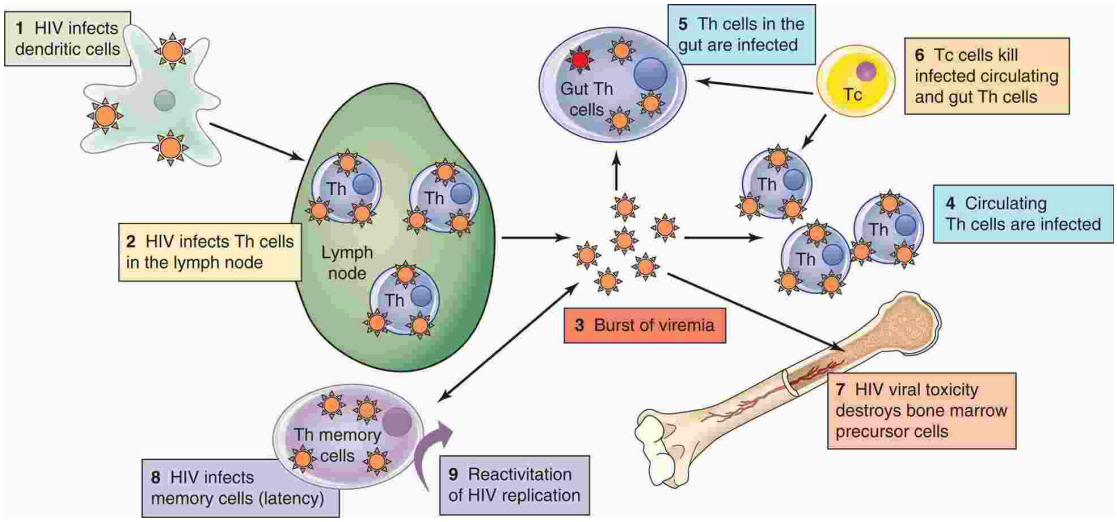
An illustration shows the lifecycle of human immunodeficiency virus-1 (H I V-1) and identifies the sites of drug intervention. The lifecycle of the H I V-1 is as follows. 1. Attachment and fusion of H I V to host cell with entry of viral genome. The H I V virion with chemokine receptors binds to the C D 4 and passes through the fusion inhibitors on the plasma membrane. 2. Reverse transcription. The H I V R N A genome passes through the reverse transcriptase inhibitors, resulting in a proviral D N A. 3. Integration of provirus into host cell genome. The proviral D N A passes through integrase inhibitors, resulting in an H I V D N A provirus in the nucleus, which then undergoes H I V R N A

transcription. 4. Synthesis of H I V proteins; assembly of virion core. The H I V R N A passes through protease inhibitors, forming the H I V core structure. 5. Budding and release of mature virion. g p 120 and g p 41 on the H I V help the H I V core structure mature into a new H I V virion. Inflammatory cytokine binds to the cytokine receptor embedded in the plasma membrane. Cytokine activation of cell; transcription of H I V genome; transport of viral R N As to cytoplasm generates the H I V D N A provirus.

The final step in the HIV lifecycle is the formation and release of new virions. As the virus buds, it takes some of the host cell membrane with it, making the virus less vulnerable to adaptive immune attack. Host cell membrane proteins that have been incorporated into the viral envelope are biologically active and can impact infectivity and viral pathogenesis.[21] Viruses that have budded from one host cell then travel through the body to infect other host cells. There is mounting evidence that direct intercellular transmission of HIV also occurs when infected cells are phagocytosed by healthy immune cells, or through the uptake of extracellular vesicles (exosomes) released by infected cells.[22,23] This cell-to-cell transmission of virus may play an important role in HIV infecting Th memory cells that form reservoirs for latent HIV infection.

HIV pathogenesis

Macrophages and dendritic cells are the first cells to be infected with HIV after exposure. Infected dendritic cells travel to the lymph node where the virus can infect numerous Th cells (Algorithm 10.2). Rapid HIV replication leads to a burst of virus into the bloodstream (viremia) and is often associated with flu-like symptoms (acute HIV). As more and more circulating Th cells become infected, they become the primary factories for further HIV replication. HIV also preferentially infects Th cells in gut lymphoid tissues.[24] T cytotoxic (Tc) cells become activated and kill virally infected Th cells in the circulation and in the gut (see Algorithm 10.2). In fact, Tc memory cells for HIV come to reside permanently in the gut and provide a sustained immune response to infected Th cells in intestinal lymphoid tissue.[25] While the killing of infected Th cells is essential for suppressing HIV replication, this process causes the destruction of billions of Th cells each day. The bone marrow is capable of producing large numbers of Th cells to replace those that are killed; thus, Th cell numbers remain relatively stable for some years in the untreated individual. However, later in the course of infection, the ability of the bone marrow to generate healthy Th cells diminishes, and there is a decline in both circulating and gut Th cells resulting in systemic immunocompromise and AIDS (Fig. 10.11). HIV also infects bone marrow precursor cells, hastening the decline in Th cell numbers (see Algorithm 10.2). HIV infects Th memory cells and can remain latent as a provirus in those cells for years. Many of these viral reservoir cells are located in mucosal tissues and the gut.[26] When infected memory cells are activated by exposure to new infections, reactivation of HIV replication leads to new bursts of viremia and accelerated Th cell infection (see Algorithm 10.2).[27] HIV can also infect macrophages and dendritic cells in the central nervous system, liver, adipose tissue, skin, and genital tract.[28] These cells also serve as a reservoir for latent HIV infection.



ALGORITHM 10.2 **Pathogenesis of Human Immunodeficiency Virus Infection (HIV).**
(1) Dendritic cells that populate mucosal surfaces are often the first cells to be infected with HIV. ***(2)*** Infected dendritic cells travel to the lymph node where the virus can infect numerous T helper (Th cells). ***(3)*** Viral replication occurs at a rapid rate, resulting in a burst of viremia. ***(4)*** Circulating Th cells are infected, greatly accelerating HIV replication. ***(5)*** HIV infects gut Th cells. ***(6)*** T cytotoxic (Tc) cells kill virally infected Th cells leading to a decline in circulating and gut Th cells. ***(7)*** HIV infects bone marrow precursor cells, hastening the decline in immunity. ***(8)*** HIV infects Th memory cells and can remain latent in those cells for years. ***(9)*** Memory cell reactivation by exposure to pathogens results in reactivation of HIV replication.

An illustration shows the pathogenesis of human immunodeficiency virus infection (H I V). The sequence of pathogenesis is as follows. 1. H I V infects dendritic cells. 2. H I V infects T h cells in the lymph node. 3. Burst of viremia. 4. Circulating T h cells are infected. 5. T h cells in the gut are infected. 6. T c cells kill infected circulating and gut T h cells. 7. H I V viral toxicity destroys bone marrow precursor cells. 8. H I V infects memory cells (latency). 9. Reactivation of H I V replication.

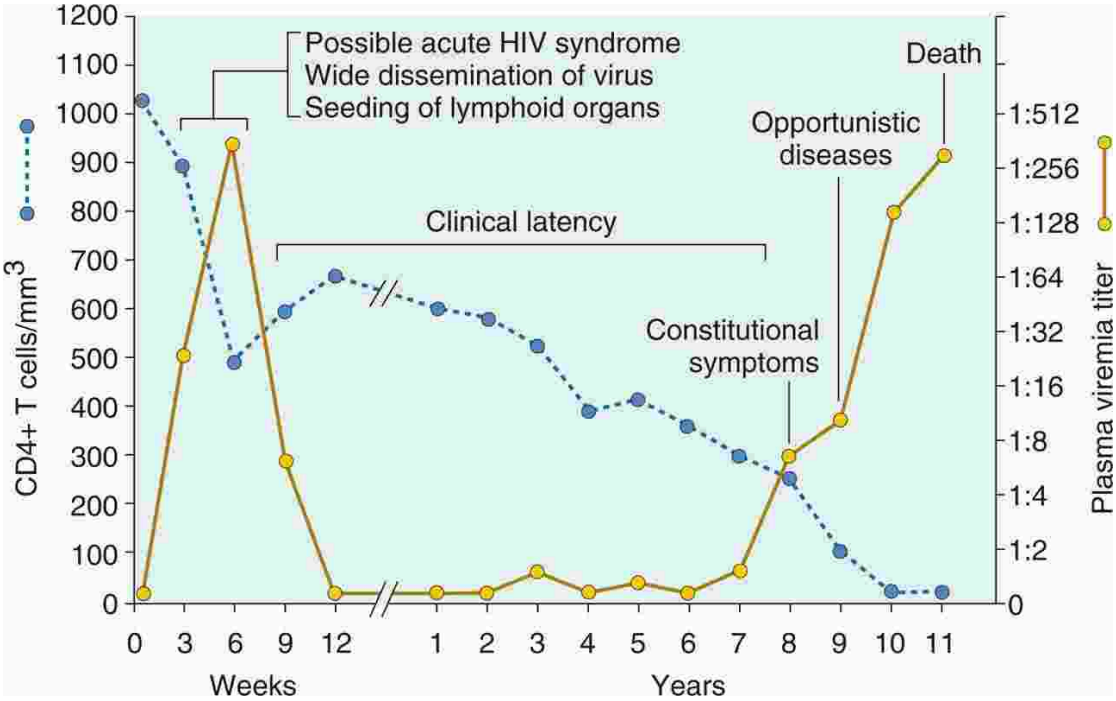


FIG. 10.11 Typical Progression From Human Immunodeficiency Virus *(HIV)* Infection to Acquired Immunodeficiency Syndrome (AIDS) in Untreated Persons.

Clinical progression begins within weeks after infection; the person may experience symptoms of acute HIV syndrome. During this early period, the virus progressively infects T cells and other cells and spreads to the lymphoid organs, with a sharp decrease in the number of circulating CD4+ T cells. During a period of clinical latency, the virus replicates and T-cell destruction continues, although the person is generally asymptomatic. The individual may develop HIV-related disease (constitutional symptoms)—a variety of symptoms of acute viral infection that do not involve opportunistic infections or malignancies. When the number of CD4+ cells is critically suppressed, the individual becomes susceptible to a variety of opportunistic infections and cancers with a diagnosis of AIDS. The length of time for progression from HIV infection to AIDS may vary considerably from person to person. (Redrawn from Fauci AS, Lane HC. Human immunodeficiency virus disease: AIDS and related conditions. In A. S. Fauci, E. Braunwald, K. J. Isselbacher, et al. [Eds.]. *Harrison's principles of internal medicine*, 14th edition. New York: McGraw-Hill; Saunders; 1998.)

A dual-axis line chart plots the typical progression from human immunodeficiency virus (H I V) infection to acquired immunodeficiency syndrome (AIDS) over a period. The horizontal axis shows weeks (0, 3, 6, 9, 12) and years (1 through 11). The vertical axis on the left shows C D plus T cells per cubic meter and ranges from 0 to 1200, in increments of 100. The vertical axis on the right shows plasma viremia tier in ratios from 0 through 1 to 512, in doubling increments. The distribution of the horizontal graph segments is as follows. • 3 weeks to 6 weeks: Possible acute H I V syndrome. Wide dissemination of virus. Seeding of lymphoid organs. • 9 weeks to 7 years: Clinical latency. The curve for C D 4 plus T cells declines staggeringly, passing

through the following approximate points: (1020, 0 weeks), (900, 3 weeks), (500, 6 weeks), (600, 9 weeks), (700, 12 weeks), (600, 1 year), (590, 2 years), (550, 3 years), (400, 4 years), (450, 5 years), (390, 6 years), (350, 7 years), (300, 8 years), (150, 9 years), (negligible, 10 years), and (negligible, 11 years). The curve for the plasma viremia titer shoots to a peak at 6 weeks, falls and is almost negligible between 12 weeks and 7 years, before leading to death at 11 years. The approximate data from the graph are as follows: • 0 weeks: negligible. • 3 weeks: ratio 1 to 16. • 6 weeks: ration 1 to 256. • 9 weeks: ratio 1 to 4. • 12 weeks to 7 years: negligible to under ratio 1 to 1. • 8 years, constitutional symptoms: ratio 1 to 6. • 9 years, opportunistic diseases: ratio 1 to 8. • 10 years: ratio 1 to 128. • 11 years, death: ratio 1 to 256.

The effects of HIV on the body extend beyond immune suppression. Chronic inflammation, recurrent opportunistic infections, and changes in the gut microbiome contribute to long-term effects on organ function. For example, HIV infection can impact alveolar cells and alter the production of surfactant proteins contributing to chronic lung disease.[29] Metabolic perturbations in Th cells and macrophages (immunometabolism) such as changes in glycolysis, fatty acid oxidation, and amino acid metabolism, persist despite therapy.[30] Direct viral toxicity to the gut mucosa leads to translocation of bacterial products from the intestines into the blood stream. These antigens, along with associated changes in the gut microbiome (dysbiosis) contribute systemic chronic inflammation.[31] People living with HIV demonstrate epigenetic age acceleration and carry an increased burden of age-related comorbidities (cardiovascular disease, cancer, cognitive impairment, osteoporosis, and frailty) hypothesized to be the result of immunosenescence and chronic inflammation that persist despite successful treatment.[32]

Clinical manifestations of HIV infection

According to the CDC, there are three stages of HIV infection:

1. **Acute HIV** begins 2 to 4 weeks after infection and is associated with flu-like symptoms or may be asymptomatic. It is during this time that the virus initially infects long-lived cells such as Th memory cells and the central nervous system.[33] Viral titers in the blood are high and the individual is highly contagious. Viral antigens can be measured in the blood during this stage.
2. **Clinical latency** (chronic HIV infection) is the period during which the virus continues to replicate, but the bone marrow is able to replace infected cells and immune defenses decline very slowly. This period may last for 10 to 11 years in untreated individuals or may last for decades if antiretroviral therapy (ART) is successful in keeping viral titers low. Individuals are often asymptomatic or have low level infections such as thrush. Some individuals fail to achieve latency and progress quickly and are known as rapid progressors. A more rapid progression in a newly infected individual may be correlated with a high source partner viral load at the time of transmission. A small number of HIV-infected individuals remain in clinical latency for an extended period and are known as long-term nonprogressors (LTNPs), although most of these individuals eventually develop symptoms without treatment. Elite controllers are HIV infected individuals in whom no disease progression can be detected for a very long time despite not receiving antiretroviral treatment. In fact, some maintain undetectable levels of virus and stable immunologic parameters for more than 25 years after infection. Low viral replication rates and highly effective immune responses have been documented in these individuals.[34]
3. **Acquired immunodeficiency syndrome (AIDS)** occurs when significant immune compromise develops. This is defined when Th cell numbers decline below 200 cells/mm or when opportunistic infections or certain cancers occur (Box 10.2). The rate at which AIDS progresses is related to the rate in decline of Th cells and the rate of increase in serum viral titers (see Fig.

10.11). Clinical manifestations include the signs and symptoms related to AIDS-defining infections, cancers, and neurologic (neuroinflammation; encephalopathy) or metabolic (wasting) complications (Fig. 10.12). Side-effects from antiviral medications are also common.

Box 10.2

AIDS-Defining Opportunistic Infections and Neoplasms

Infections

Protozoal and Helminthic Infections

Cryptosporidiosis or isosporiasis (enteritis)
Pneumocystosis (pneumonia or disseminated infection)
Toxoplasmosis (pneumonia or CNS infection)

Fungal Infections

Candidiasis (esophageal, tracheal, or pulmonary)
Coccidioidomycosis (disseminated)
Cryptococcosis (CNS infection)
Histoplasmosis (disseminated)

Bacterial Infections

Mycobacteriosis ("atypical," e.g., *Mycobacterium avium-intracellulare*, disseminated or extrapulmonary
Mycobacterium tuberculosis, disseminated or extrapulmonary)
Nocardiosis (pneumonia, meningitis, disseminated)
Salmonella infections (septicemia, recurrent)

Viral Infections

Cytomegalovirus (pulmonary, intestinal, retinitis, or CNS)
Herpes simplex virus (localized or disseminated)
Progressive multifocal leukoencephalopathy
Varicella-zoster virus (localized or disseminated)

Neoplasms

Invasive cancer of the uterine cervix
Kaposi sarcoma
Non-Hodgkin lymphomas (Burkitt, immunoblastic)
Primary lymphoma of brain

AIDS, Acquired immunodeficiency syndrome; *CNS*, Central nervous system; *HIV*, human immunodeficiency virus.

Diagnosis and management of HIV infection

In 2021, the World Health Organization (WHO) released new guidelines on HIV prevention, testing, treatment, service delivery and monitoring.[35] These guidelines provide guidance on management of HIV along the continuum of care including prevention, testing, ARV regimens, treatment monitoring,

the management of comorbidities, palliative care and pain management. Current CDC recommendations indicate that screening for HIV infection in all health care settings should be performed routinely for all persons 13 to 64 years of age after the individual is notified orally or in writing that testing will be performed unless the individual declines (known as *opt-out screening*). Screening also is recommended for men who have sex with men (MSM), pregnant women, and those with other sexually transmitted diseases (STDs) or tuberculosis (TB).[36] The CDC also recommends that clinicians screen asymptomatic sexually active MSM at least annually.[37]

HIV is diagnosed by the simultaneous measurement of both antibodies against HIV and HIV antigens in blood. If positive, these tests are confirmed by HIV DNA (nucleic acid tests [NATs]). The amount of virus in the blood (viral load) and the Th cell count are used to determine what is called the "set point," which describes the severity of infection and the level of risk for rapid progression to AIDS.

HIV prevention includes avoidance of HIV risk behaviors (e.g., unprotected sex, needle-sharing), adherence to antiretroviral treatment by infected individuals, and pre- and post-exposure prophylaxis with antiretroviral medications.[38] Advances in pre-exposure prophylaxis are emerging, including long-acting formulations of ART (cabotegravir) and insertable vaginal rings that release ART over 30 days. Monoclonal antibody treatment to prevent HIV is also being explored.[39] While vaccine development remains challenging, reports are emerging from early trials that describe the development of promising new vaccines.[40]

HIV/AIDS treatment guidelines are published by the National Institutes of Health (NIH) and are revised frequently as new antiretroviral medications are approved.[41] ART should be initiated as soon as possible after HIV infection is diagnosed. Approved HIV medications are classified by mechanism of action: **chemokine receptor inhibitors** (CCR5 antagonist prevents viral attachment), **HIV fusion inhibitors** (prevent CD4-gp 120 conformational changes during binding), **reverse transcriptase inhibitors** (nucleoside and nonnucleoside inhibitors of reverse transcriptase), **HIV integrase inhibitors** (inhibitors of viral integration into host genome), and **HIV protease inhibitors** (inhibitors of the proteases HIV uses for assembly of new virus) (see Fig. 8.12). The current regimen for the treatment of HIV infection is a combination of drugs, termed **antiretroviral therapy (ART)**. Current ART protocols indicate that individuals who are being treated for the first time should be given a combination of two synergist drugs from different classes.[41] Specific regimens (e.g., timing of drug administration, doses, drug combinations) are adapted on the basis of the age of the individual, secondary clinical symptoms (renal or hepatic insufficiency), CD4+ T-cell levels, viral load, presence of coinfections, preexisting cardiac risk factors, past history of treatment failure, ART drug resistance, and other parameters. Significant side effects from ART may occur and can result in reduced adherence with recurrence of disease progression and viral infectivity in some individuals. In January 2021, a long-acting formulation (cabotegravir and rilpivirine) given once per month via intramuscular injection was FDA approved with the goal of increasing adherence to treatment.[42]

The prevalence of HIV variants resistant to antiretroviral therapies is increasing. Resistance testing in an individual prior to starting ART is done routinely. Resistant strains may be found even in individuals when they are first diagnosed with HIV infection.[43] In 2018, the U.S. Food and Drug Administration (FDA) approved the first humanized monoclonal antibody called iblaizumab-uiyk for the treatment of multidrug-resistant HIV. This antibody blocks the conformational change of gp120 required for viral fusion with host cells and has been found to be effective in lowering HIV titers and improving immune function.[44] Several new drugs are in clinical trials including new monoclonal antibody treatments.[45] Unfortunately, drug therapy for HIV is not curative because the virus incorporates into the genetic material of the host, particularly CD4+ T memory cells. Additionally, HIV may persist in organs where the antiviral drugs are not as effective, such as the central nervous system (CNS). Therefore, ART must continue for the lifetime of the individual. Many new HIV treatments are being explored in an attempt to eliminate persistent HIV infection (see Emerging Science Box: Future Treatments for HIV Infection).

Emerging Science BoxFuture Treatments for HIV Infection

Anti-retroviral therapies (ARTs) for HIV/AIDS can effectively suppress virus replication in active T helper (Th) cells, and infected individuals can lead relatively healthy lives so long as treatment

continues. However, ART is not curative, and if discontinued, there is a rapid re-emergence of virus from latent provirus reservoirs such as T memory cells. Numerous approaches designed to eliminate HIV from these reservoirs are currently under investigation. One approach is the use of bone marrow transplantation with CCR5 and CXCR4-modified hematopoietic stem cells. To date, two HIV infected individuals who underwent allogeneic bone marrow transplantation for other conditions received lymphoid stem cells that lacked the CCR5 chemokine co-receptor needed for HIV fusion with macrophage and dendritic cell membranes. HIV that cannot enter host cells cannot replicate and, therefore, are not able to cause infection. It is believed that these two individuals have been cured of their HIV infection. However, bone marrow transplantation is associated with significant morbidity and mortality, therefore is unlikely to become a feasible approach to treating HIV infection in the near future. Another approach involves improving immune responses to HIV through genetic modification of T cytotoxic (Tc) cells. This can be accomplished through the use of viral vectors or nanotechnology to insert DNA into host Tc cells. The goal is the formation of new chimeric antigen receptors on Tc cells that can better recognize the virus (CAR-T Cell therapy). Because HIV mutates rapidly to evade the antigen-specific receptors on native Tc cells, CAR-T cell therapy includes the creation of numerous receptors that can recognize multiple HIV antigens. CAR-T cell approaches can also be used to alter the CD4 molecule on T helper cells, potentially rendering them resistant to HIV gp120 binding. A recent B cells are also targeted by emerging gene therapies. Vectored passive immunity is the delivery of synthetic genes that code for protective antibodies or antiviral proteins. Vectors such as attenuated viruses and plasmids deliver genetic material that produces neutralizing antibodies or antibodies capable of mediating antibody-dependent cellular cytotoxicity for HIV infected cells. Yet another approach is called "Shock and Kill" in which latency-reversing agents (e.g., histone deacetylases, protein kinase modulators) are used to reactivate latent HIV. As HIV begins to replicate, immunotherapies, and aggressive antiviral treatment are introduced to kill the newly-exposed viruses. A major barrier is that current methods that reactivate HIV also promote global T-cell activation, which can result in a life-threatening complication known as cytokine release syndrome. "Lock and Block" strategies involve the use of latency-promoting agents that prevent HIV transcription (e.g. tat inhibitors, epigenetic methylating agents) or damage the HIV genome (use of CRISPER/Cas9 s gene editing), thus keeping HIV in a provirus state. To date, neither shock and kill nor lock and block have been found to be adequately safe or effective in humans, but studies continue. Finally, there are ongoing efforts to create more effective monoclonal broadly neutralizing antibodies (bNAbs) that could prevent cell-to-cell transmission of HIV and better recognize and kill infected cells that contain latent virus.

In spite of the challenges, progress in global treatment outcomes for HIV and AIDS has been substantial. By the end of 2020, globally 73% of adults and 54% of children living with HIV were receiving lifelong ART. Between 2000 and 2019, new HIV infections fell by 39% and HIV-related deaths fell by 51%, with 15.3 million lives saved due to ART.[15]

Severe Acute Respiratory Syndrome Coronavirus -2 and Coronavirus Disease 2019

An outbreak of pneumonia in Wuhan, China in December 2019 led to the identification of the **severe acute respiratory syndrome coronavirus -2 (SARS-CoV-2)**. The virus has distinctive spikes on its surface making it look like a solar corona, thus its name (Fig. 10.13A). It is postulated that the virus originated in bats and may have been transferred to humans through exposure to an unidentified animal vector.[46] Genomic studies have identified related coronaviruses in bats in China, Cambodia, Thailand, and Laos.[47] A global pandemic called **coronavirus disease-2019 (COVID-19)** ensued, with human-to-human transmission resulting in hundreds of millions of cases worldwide and millions of deaths. According to the World Health Organization, the United States leads the world in the number of coronavirus cases and deaths, followed by India and Brazil.[48] Although this is the third major coronavirus-related serious illness to appear in the last 20 years (SARS in 2003 and Middle Eastern respiratory syndrome [MERS] in 2012), it is by far the most widespread.

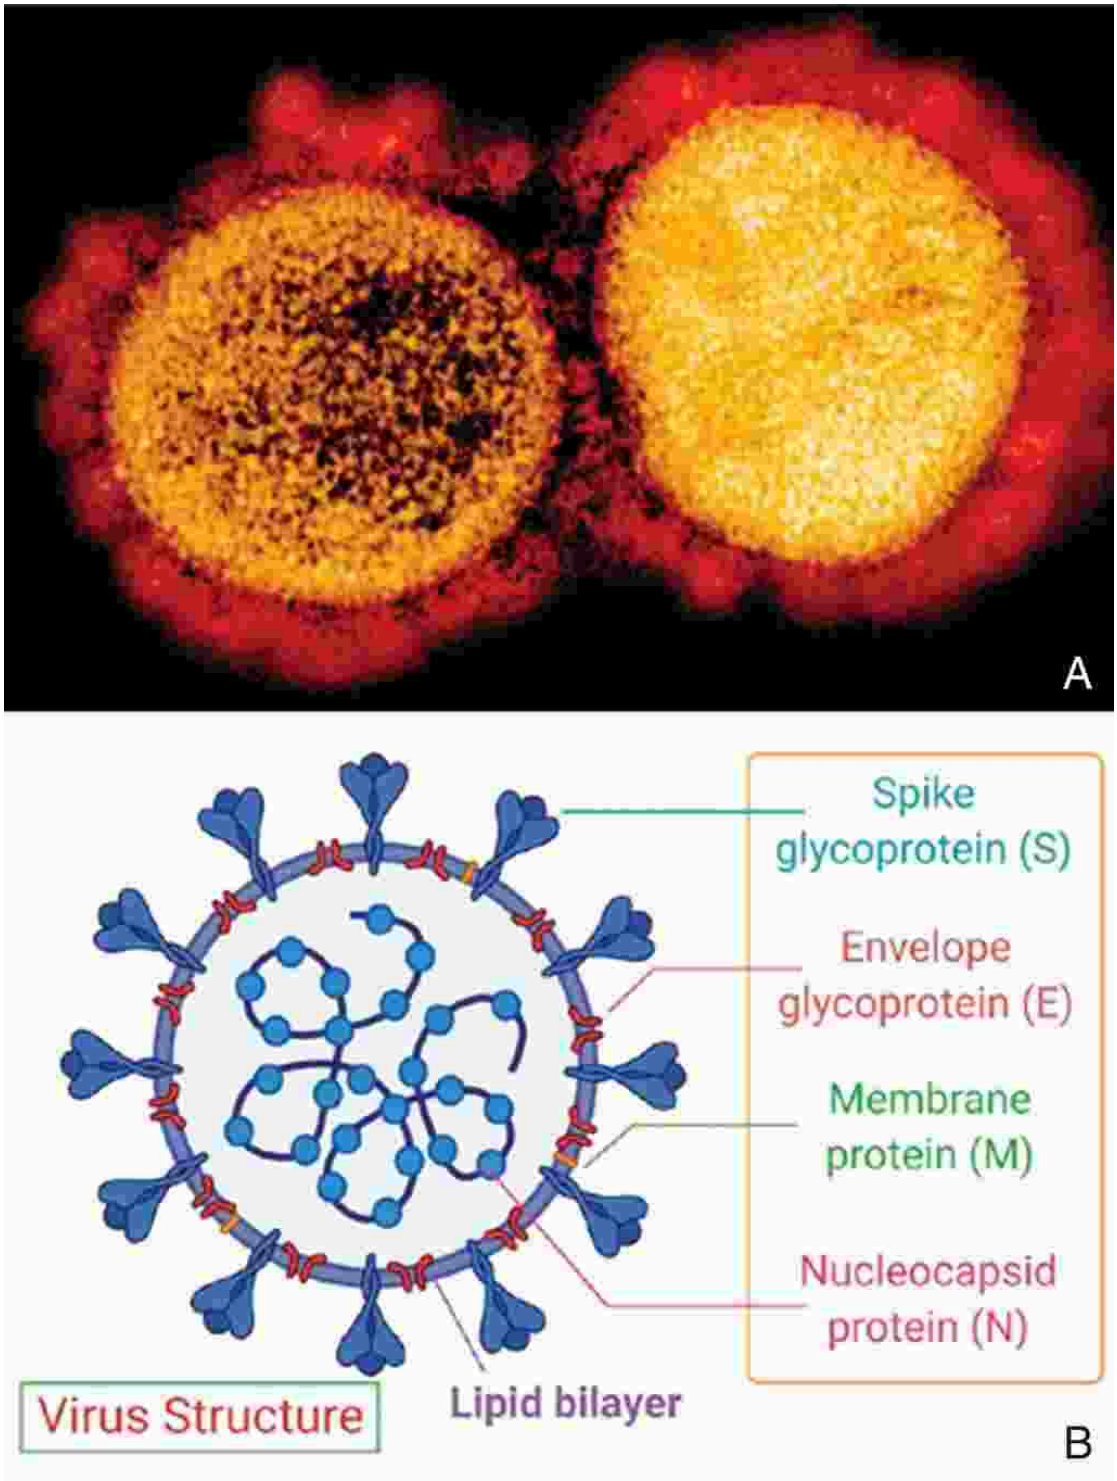

FIG. 10.13 Structure of SAR-CoV-2e.
(A) Transmission electron micrograph of SARS-CoV-2 virus particles, isolated from an individual. Image captured and color-enhanced at the NIAID Integrated Research Facility (IRF) in Fort Detrick, Maryland. **(B)** SARS-CoV-2 contains 4 major structureal proteins. A, (From Jha NK, Jeyaraman M, Rachamalla M, et al. Current understanding of novel coronavirus: Molecular pathogenesis, diagnosis, and treatment approaches. *Immuno* 2021;1:30–66. https://www.mdpi.com/2673-5601/1/1/4.)

Photomicrograph A shows two cells of SARS-CoV-2 virus. Illustration B shows the structure of the virus and is labeled with the following parts: spike glycoprotein (S), envelope glycoprotein (E), membrane protein (M), nucleocapsid protein (N), and lipid bilayer.

Transmission

SARS-CoV-2 has been detected at the highest levels in human sputum, pharyngeal swabs, and feces. It is transmitted most easily between infected persons via droplets released during cough, sneezing, or talking.[49] It is believed that transmission of the virus from infected individuals who remain completely asymptomatic is relatively rare; however, presymptomatic transmission is thought to be a major contributor to the spread of SARS-CoV-2.[50] During the 3 to 7 days between infection and symptoms, shedding of virus can be high from the respiratory tract, but infected individuals do not realize they are ill. Viral shedding peaks during early symptomatic illness (3-5 days after symptom onset) and declines below that which is readily transmissible approximately 5 to 7 days after the onset of symptoms in most individuals.[51]

The risk of transmission is greatest in indoor environments with poor ventilation and close contact (less than 6 ft) with infected individuals. Although the virus can be detected on non-porous surfaces for days to weeks, transmission of the virus from surfaces to hands and then to mouth, nose, or eyes is inefficient, and the risk of developing infection from contacting infected surfaces (fomites) is believed to be less than 1 in 10,000 exposures.[49] Viral mutations have led to the emergence of variants that have increased infectivity. These variants include the B.1.1.7 (alpha) variant that emerged in the United Kingdom, the B.1.1.351 (beta) variant that emerged in South Africa, and the B.1.1.33 (P.1) variant that emerged in Brazil. In 2021, two new variants emerged. The B.1.617.2 (delta) variant and the B.1.1.529 (omicron) variants have been found to have increased infectivity compared to previous forms of the virus and have been the cause of surges in new infections worldwide.[52,53] More new variants are emerging.

Pathogenesis

SARS-CoV-2 is a β coronavirus that consists of ssRNA and four major structural proteins: the spike (S) protein, nucleocapsid (N) protein, membrane (M) protein, and the envelope (E) protein (Fig. 10.13B).

Infection begins as the virus targets nasal and bronchial epithelial cells and pneumocytes. Other cells susceptible to infection include intestinal, cardiac, olfactory, bile duct, testicular, thyroid, pancreatic, adrenal, and pituitary cells.[54] The steps in the viral life cycle are the same as for many other viruses: (1) attachment; (2) fusion; (3) uncoating; (4) replication of the viral genome; (5) viral structural synthesis in the endoplasmic reticulum and golgi apparatus; (6) assembly; and (7) release (see Fig. 10.7).[55] Attachment of the virus occurs via its spike protein. The SARS-CoV-2 spike is a transmembrane glycoprotein composed of a receptor-binding domain and two subunits (S1 and S2). During attachment, the receptor-binding portion of the spike protein binds with high affinity to the membrane-bound form of angiotensin-converting enzyme 2 (ACE2) on human cells. ACE2 is highly expressed in lung, brain, and fat, and to a lesser extent in heart, kidney, pancreas, and intestine.[56] After attachment, the ACE 2 receptor and the S1 and S2 spike protein subunits undergo structural rearrangement. A transmembrane serine protease expressed on the target cell causes cleavage of the S protein subunits, stabilizing viral fusion with the host cell. SARS-CoV-2 is unusual in that it has a *furin cleavage site* at the S1/S2 boundary. Scientists are looking to this site as a potential target for antiviral drug therapy.[55] Following fusion, replication of the virus begins.

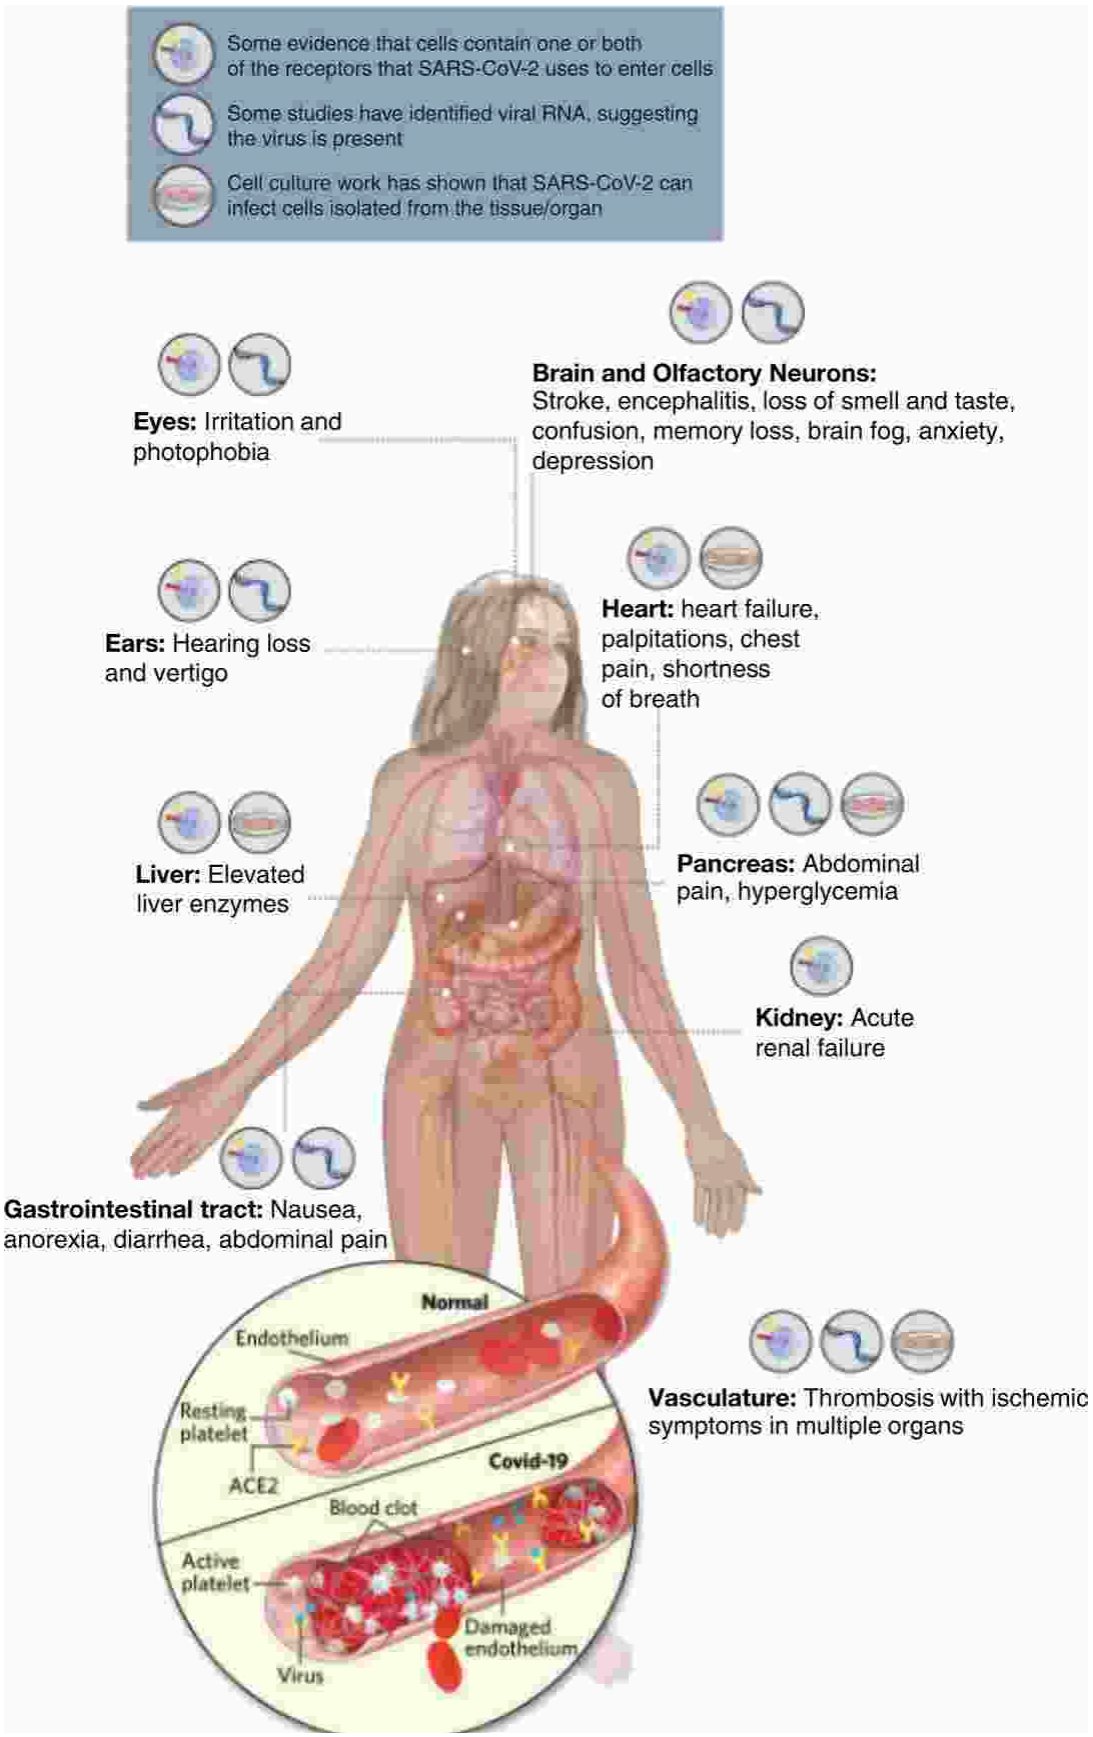
The pathophysiologic mechanisms of acute COVID-19 include endothelial damage and microvascular injury, immune system dysregulation with stimulation of a hyperinflammatory state, hypercoagulability with resultant thromboses, and maladaptation of the ACE2 pathway.[54] It primarily is the host response, rather than the virulence of the virus, that determines the progression and severity

of COVID-19.[57] There is evidence that the virus can evade the triggering of early innate responses, especially the release of type I and type III interferons.[56] This allows for unopposed viral replication and slows the initiation of the adaptive immune response. Once infection is established, a powerful inflammatory response is initiated, sometimes progressing to a "cytokine storm" in which numerous interleukins (Il-1, IL-6, IL-8, IL-17), TNFα, and other inflammatory cytokines are produced at high levels.[56] This hyperinflammatory response causes increased permeability of vascular and epithelial membranes, edema, and tissue necrosis, especially in lung tissue.[54] As the disease progresses, neutrophil and natural killer cell dysfunction develops, and the virus is effective in killing T cells—which can result in a profound lymphopenia.[57]

Multiple organs may be affected, most commonly severe inflammation of lung tissue resulting in an acute respiratory distress syndrome (ARDS)-like condition (see Chapter 35). In addition, the hyperinflammatory response causes endothelial injury, microangiopathic changes, and platelet activation, giving rise to a hypercoagulable state that resembles disseminated intravascular coagulation (DIC) but is characterized by clotting without bleeding.[54] The virus causes inflammatory and immune changes in the myocardium, contributing to cardiomyocyte death. Neuroinflammation is common with damage to both the brain parenchyma and cerebral vasculature. Acute kidney injury may occur, especially in critically ill individuals, resulting in COVID-19-associated nephropathy (COVAN) characterized by acute tubular necrosis, which is followed by glomerulosclerosis in some persons.

Clinical Manifestations

The average incubation period for COVID-19 is thought to be approximately 6 days from exposure to symptoms onset. It is estimated that about 25% of all cases remain asymptomatic.[58] Most infected individuals have only mild symptoms; however, elderly individuals and those with underlying medical conditions—such as cardiovascular disease, diabetes, and cancer—are at risk for severe disease and death. Many organ systems may be affected (Fig. 10.14). The most common symptoms are fever, cough, shortness of breath, myalgias, and fatigue. Loss of smell and taste is also common (see Chapter 16Emerging Science Box: Loss of Taste and Smell in SARS-CoV-2-Positive Patients). Some individuals also exhibit non-respiratory symptoms resulting from neurologic, cardiac, endocrine, hepatic and renal injury. Thrombotic complications are common and are linked to an increased risk for stroke and venous thromboembolism. Respiratory failure and septic shock are the primary causes of mortality. Most individuals recover within 3 to 4 weeks after infection. However, it is estimated that nearly one-third of affected persons have persistent symptoms lasting for many weeks and even months. This prolonged syndrome is called post-acute COVID-19 or "long COVID" (see Emerging Science Box: Post-Acute COVID-19).



Some evidence that cells contain one or both of the receptors that SARS-CoV-2 uses to enter cells
Some studies have identified viral RNA, suggesting the virus is present
Cell culture work has shown that SARS-CoV-2 can infect cells isolated from the tissue/organ
Brain and Olfactory Neurons: Stroke, encephalitis, loss of smell and taste, confusion, memory loss, brain fog, anxiety, depression
Eyes: Irritation and photophobia
Ears: Hearing loss and vertigo
Heart: heart failure, palpitations, chest pain, shortness of breath
Liver: Elevated liver enzymes
Pancreas: Abdominal pain, hyperglycemia
Kidney: Acute renal failure
Gastrointestinal tract: Nausea, anorexia, diarrhea, abdominal pain
Normal
Endothelium
Resting platelet
ACE2
Covid-19
Blood clot
Active platelet
Damaged endothelium
Virus
Vasculature: Thrombosis with ischemic symptoms in multiple organs

FIG. 10.14 Clinical Manifestations of Acute COVID 19.
Acute Covid-19 affects multiple organs in the body, including the neurologic, cardiac, renal, gastrointestinal, and endocrine systems. Widespread thrombosis can result in ischemic damage to multiple organs. (Adapted from The Scientist. SARS-CoV-2's Wide-Ranging Effects on the Body. September 2021. https://www.the-scientist.com/features/sars-cov-2-s-wide-ranging-effects-on-the-body-69109.)

An illustration shows the anterior view of a human with the internal organs highlighted. The illustration is labeled with the clinical manifestations of acute COVID 19: • Brain and olfactory neurons: stroke, encephalitis, loss of smell and taste, confusion, memory loss, brain fog, anxiety, and depression. • Eyes: irritation and photophobia. • Heart: heart failure, palpitations, chest pain, shortness of breath. • Liver: elevated liver enzymes. • Pancreas: abdominal pain, hyperglycemia. • Kidney: acute renal failure. • Gastrointestinal tract: nausea, anorexia, diarrhea, abdominal pain. • Vasculature: thrombosis with ischemic symptoms in multiple organs. An accompanying illustration compares a normal blood vessel and that affected by COVID 19. The normal vessel is made of an endothelium layer and comprises resting platelets and A C E 2 along with the blood cells. The affected vessel highlights a damaged epithelium, blood clot, active platelet, and virus.

Evaluation and Treatment

Testing for COVID-19 is indicated for individuals with appropriate symptoms, known exposures, or who are required to be tested for community or employment purposes. Two types of viral tests are used: nucleic

Emerging Science BoxPost-Acute COVID-19

Post-acute COVID-19 (long COVID; long haulers) is considered the continuation of COVID-19 symptoms or complications after 3–4 weeks post-acute infection, although a consensus definition remains to be developed. It is estimated that nearly half of those infected with SARS-CoV-2 develop some post-acute symptoms within 12 months after the acute infection. It can occur in those after hospital discharge and in individuals who suffered only mild-moderate acute illness. Continued viral toxicity, microvascular injury, immune system dysregulation, and persistent hyperinflammatory state. Underlying comorbidities, deconditioning, and recurrent infections also may play a role. Fatigue and dyspnea are the most common persistent symptoms, occurring in 50%–75% of individuals at 2–3 months, and persisting 6 months after acute illness in approximately 25% of individuals. Dyspnea is attributed to a reduction in diffusion capacity in the lung, with approximately 50% of individuals in one study having persistent ground-glass abnormalities seen on high-resolution computed tomography of the chest at 6 months. Neuorolgic disorders constitute the second most common sequelae. Persistent neuroinflammation is associated with cognitive and behavioral changes, with many individuals complaining of decreased memory and ability to concentrate. Muscular weakness, joint pain, anxiety, hair loss, and sleep disturbances also are common. The risk of thromboembolic events is also increased. Overall quality of life measures are significantly reduced. Compounding these symptoms are the potential sequelae of critical illness that occur in those hospitalized for COVID-19, including worsening abnormalities in physical, cognitive and psychiatric health after critical illness. Experts currently recommend that all individuals with acute COVID-19 be screened for symptoms and respiratory, psychiatric and thromboembolic sequelae at 4–6 weeks and

again at 12 weeks after discharge, with the initiation of appropriate diagnostic and holistic therapeutic interventions when indicated.

Data from Chopra V, et al. Sixty-day outcomes among patients hospitalized with COVID-19. *Annals of Internal Medicine*, 2020; https://doi.org/10.7326/M20-5661. Epub ahead of print; Goff D, et al. acid amplification tests (NAATs) and antigen tests. Serologic tests can confirm the presence of the virus in the nasopharynx and sputum and can detect the development of antibodies after infection. Laboratory findings include decreased lymphocytes in the blood, elevated levels of inflammatory cytokines and D-dimer, and bilateral lung infiltrates on computed tomography.

For individuals with mild to moderate COVID-19 who do not require hospitalization, NIH guidelines recommend the use of monoclonal antibodies that target the spike protein of the virus including bamlanivimab plus etesevimab or casirivimab plus imdevimab or sotrovimab to reduce the risk for disease progression.[59] Management guidelines for severe acute COVID-19 recommend isolation, oxygen, mechanical ventilation if needed, and anticoagulation. The antiviral remdesivir is used to decrease the time to recovery for hospitalized individuals. Dexamethasone is recommended for those requiring supplemental oxygen. NIH guidelines also recommend the administration of monoclonal antibodies that block inflammatory cytokines (e.g. janus kinase and IL-6) including baricitinib or tocilizumab or sarilumab for the treatment severe disease.[59] Additionally, several different blood-derived products and immunomodulators are under investigation for the management of COVID-19 including immune sera (convalescent serum).[60] Oral medications such as molnupiravir have been found to reduce the risk of hospitalization if taken early in the course of symptomatic infection.[61] The list of potential therapies is growing as new discoveries are made.

Several different vaccines have been developed globally to prevent SARS-CoV-2 infection. Two of these use an mRNA backbone carrying the spike protein sequence and are created in the laboratory. These mRNA constructs use the host cells' own translation machinery to make harmless pieces of viral spike proteins that elicit an immune response to the virus. These two vaccines have been found to have over 95% efficacy in preventing infection, and so far appear to be effective against SARS-CoV-2 variants.[62] Other vaccines use more conventional technologies such as adenovirus vector vaccines. It is still unknown whether prolonged immunity to the virus can be achieved, and booster immunizations are recommended. The effectiveness of all of these vaccines will need to be retested as new variants emerge.

Fungal Infection

Fungi are relatively large eukaryotic microorganisms with thick walls that have one of two basic structures: single-celled yeasts (spheres) or multicellular molds (filaments or hyphae) (Fig. 10.15). Some fungi can exist in either form called **dimorphic fungi**. They usually reproduce by simple division or budding. The cell walls of fungi are rigid and multilayered and composed of polysaccharides different from the peptidoglycans of bacteria. The lack of peptidoglycans allows fungi to resist the action of bacterial cell wall inhibitors, such as penicillin and cephalosporin. Molds are aerobic and yeasts are facultative anaerobes, which can adapt to anaerobic conditions.

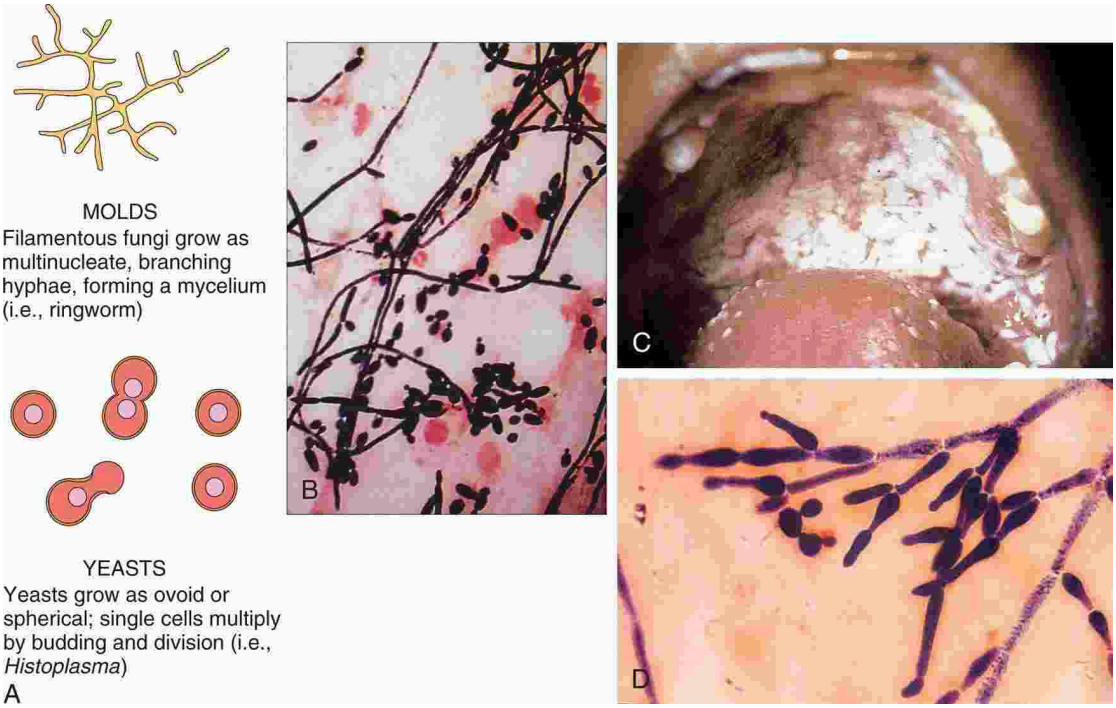

FIG. 10.15 Morphology of Fungi.
(A) Fungi may occur in either mold or yeast forms, or they may be dimorphic. **(B)** Photograph showing *Candida albicans* with both the mycelial and the yeast forms. **(C)** Oral infection with *C. albicans* (candidiasis, i.e., thrush). **(D)** Gram staining of sputum showing that clinical isolates of *C. albicans* present as chains of elongated budding yeasts (×1000). (A and B, From Goering R, et al. *Mims' medical microbiology*, 5th edition. London: Saunders; 2013. C, From McPherson R, Pincus M. *Henry's clinical diagnosis and management by laboratory methods*, 22nd edition. Philadelphia: Saunders; 2012; D, Courtesy Dr. Stephen Raffanti.)

Illustration A compares the structures of molds and yeasts. Molds are filamentous fungi that grow as multinucleate, branching hyphae, forming a mycelium (i.e., a ringworm). Yeasts grow as ovoid or spherical. They are single cells that multiply by budding and division (i.e., histoplasma). Closeup B shows long filamentous structures and single cells of Candida albicans. Closeup C shows yeast on the upper palate and tongue of a person. Closeup D shows chains of yeast cells.

Phagocytes and T lymphocytes are important in controlling fungi. There is increasing evidence that the phagocytes of the innate immune system are capable of trained innate immunity toward fungi, thus serious fungal infection is most common in individuals who have a compromised innate immune system (see Chapter 9).[63] Low white blood cell counts promote fungal infection, and infection control is particularly important for individuals who are immunosuppressed because of diseases such as cancer or AIDS, or because of treatment with immunosuppressive drugs such as chemotherapeutic agents, transplant rejection medications, or corticosteroids.

By mechanisms similar to those described for bacteria, pathogenic fungal infections damage tissue directly by secretion of enzymes and indirectly by initiation of an inflammatory response. Several toxins secreted by molds in the environment cause disease without fungal infection. Mycotoxins are produced

by molds that grow on nuts, beans, and grains. Ingestion of these toxins affect muscle coordination, causes tremors, and may be fatal. Other fungal toxins may cause cancer, for example aflatoxins produced by some *Aspergillus* species are especially carcinogenic.

Infections caused by fungi are called **mycoses**. Common pathogenic fungi are summarized in Table 10.5. Mycoses can be superficial, deep, or opportunistic. Superficial mycoses occur on or near skin or mucous membranes and usually produce mild and superficial disease. Fungi that invade the skin, hair, or nails are known as dermatophytes. The diseases they produce are called tineas (ringworm), for example, tinea capitis (scalp), tinea pedis (feet), and tinea cruris (groin). Chapter 46 discusses the various skin disorders caused by fungi.

Table 10.5

Examples of Human Diseases Caused by Fungi

Primary Site of Infection	Fungus	Disease (Primary)	Symptoms
Superficial (no tissue invasion, little inflammation)	*Malassezia furfur*	Tinea versicolor, seborrheic dermatitis, dandruff	Red rash on body
Cutaneous (no tissue invasion, inflammatory response)	*Trichophyton mentagrophytes; Trichophyton rubrum*	Tinea pedis; Tinea cruris	Scaling, rash, fissures, pruritus
	Candida albicans	Cutaneous candidiasis	Pruritic lesions in skin, mucous membranes
Subcutaneous (tissue invasion)	*Sporothrix schenckii*	Sporotrichosis	Ulcers or abscesses on skin and other organ systems
Systemic (dimorphic; causes disease in healthy individuals)	*Coccidioides immitis*	Coccidioidomycosis	Valley fever, flulike symptoms
	Histoplasma capsulatum	Histoplasmosis	Flu-like symptoms, disseminates to lungs and other organs
	Blastomyces dermatitidis	Blastomycosis	Flulike symptoms, chest pains
Systemic (opportunistic)	*Aspergillus fumigatus, Aspergillus flavus*	Aspergillosis	Invasive to lungs and other organs
	Pneumocystis jirovecii	Pneumocystis pneumonia (PJP)	Pneumonia
	Cryptococcus neoformans	Cryptococcosis	Pneumonia-like illness, skin lesions, disseminates to brain, meningitis
	Candidia albicans	Systemic candidiasis	Sepsis, endocarditis, meningitis

C. albicans is the most common cause of fungal infections in humans. It is an opportunistic yeast that is a commensal inhabitant in the normal microbiome of many healthy individuals, residing in the skin, gastrointestinal tract, mouth, and vagina. *C. albicans* is normally under the control of local defense mechanisms, including members of the microbiome that produce antifungal agents. In healthy individuals, antibiotic therapy can negatively impact the microbiome causing overgrowth of Candida, resulting in localized infection, such as vaginitis or oropharyngeal infection (thrush).

In immunocompromised individuals (particularly those with diminished levels of neutrophils [neutropenia]), disseminated infection may occur. *C. albicans* is the most common fungal species to cause infection in people with cancer (particularly acute leukemia and other hematologic cancers), transplantation (bone marrow and solid organ), and HIV/AIDS. Invasive candidiasis is the fourth most common healthcare-associated bloodstream infection and is commonly associated with iatrogenic immunocompromise, critical illness, and the use of indwelling catheters and intravenous lines in intensive care units (ICUs).[64] Prophylaxis with antifungal agents for individuals with hematologic disease or undergoing stem cell transplantation reduces the risk for invasive infection.[65] Disseminated candidiasis may involve deep infections of several internal organs, including abscesses in the kidney, brain, liver, and heart, and is characterized by persistent or recurrent fever, shock-like symptoms (hypotension, tachycardia), and DIC. The mortality rate among individuals with septic or disseminated candidiasis is about 30%. Diagnosis of candidiasis requires culture of the organisms and serologic tests. Management requires systemic antifungal medications and supportive measures. Unfortunately, most systemic antifungal drugs are associated with significant toxicity and resistance.[66] A new species of Candida *(Candida auris)* emerged in Asia in 2009 and has since spread across five continents. Multidrug-resistant strains have been identified with increased mortality (30% to 60%) in healthcare settings.[67]

In individuals with or without immunocompromise, an important fungal pathogen is *Aspergillus fumigatus*. Aspergillosis of the lungs and sinuses causes an allergic disease that results in asthma-like symptoms. In some individuals, A*spergillus* can form a fungus ball in the lung known as an aspergilloma. It can also cause a systemic illness called invasive pulmonary aspergillosis (IPA), which can occur in up to 15% of individuals who are being treated for lung disease in the ICU.[68] It also commonly affects individuals with cystic fibrosis. Aspergillosis has emerged as an important and serious complication of COVID-19.[69] Invasive aspergillosis requires systemic antifungal treatment. Strains resistant to antifungal treatment are increasing in prevalence.[70]

Another very important fungal pathogen in immunocompromised individuals is *Pneumocystis jerovicii* (previously *Pneumocystis carinii*). Pneumocystis pneumonia occurs most commonly in individuals with iatrogenic immunocompromise (antirejection medications, corticosteroids, cancer treatment), AIDS, autoimmune disorders, and critical illness including COVID-19. It can also complicate chronic lung disease. Human host-to-host transmission occurs via inhalation of spores and the fungus is tropic for lung tissue.[71] It can cause serious respiratory compromise, and mortality rates are high in those individuals who require hospitalization.[72] Diagnosis relies on silver staining and serologic testing of expectorated sputum or of lung tissue obtained at biopsy. *P. jirovecii* is resistant to amphotericin B and other antifungals (azoles).[71] Treatment consists of trimethoprim/sulfamethoxazole or alternative antimicrobials for those individuals who are intolerant of sulfa-containing antibiotics. At-risk individuals may receive chemoprophylaxis to prevent *P. jirovecii* pneumonia, especially those whose respiratory tracts are already colonized with this microorganism.[73]

Parasitic Infection

Parasitic microorganisms establish a relationship in which the parasite benefits at the expense of the other species. Parasites range from a unicellular protozoan to large worms. Parasitic worms (helminths) include intestinal and tissue nematodes (e.g., hookworm, roundworm), flukes (e.g., liver fluke, lung fluke), and tapeworms. A protozoan is a eukaryotic, unicellular microorganism with a nucleus and cytoplasm. Pathogenic protozoa include sporozoan (e.g., *Plasmodium falciparum* which causes malaria*)*, amebae (e.g., *Entamoeba histolytica*, which causes amoebic dysentery), and flagellates (e.g., *G. lamblia*, which causes diarrhea). Important parasites of humans are listed in Table 10.6.

Table 10.6

Examples of Human Diseases Caused by Parasites

Category	Subgroup	Species	Disease	Organs Affected/Symptoms
Protozoa	Ameboid	*Entamoeba histolytica*	Amebiasis	Dysentery, liver abscess
	Flagellate	*Giardia lamblia*	Giardiasis	Diarrhea
		Trichomonas vaginalis	Trichomoniasis	Inflammation of reproductive organs
		Trypanosoma cruzi, Trypanosoma brucei	Chagas disease: African sleeping sickness	Generalized, blood and lymph nodes, progressing to cardiac and central nervous system
	Ciliate	*Balantidium coli*	Balantidiasis	Small intestines, invasion of colon, diarrhea
	Sporozoa (nonmotile)	*Cryptosporidium parvum*	Cryptosporidiosis	Intestine, diarrhea
		Plasmodium spp.	Malaria	Blood, liver
		Toxoplasma gondii	Toxoplasmosis	Intestine, eyes, blood, heart, liver
Helminths	Flukes (trematodes)	*Fasciola hepatica*	Fasciolosis	Liver destruction
		Schistosoma mansoni	Schistosomiasis	Blood, diarrhea, bladder, generalized symptoms
	Tapeworms (cestodes)	*Taenia solium*	Pork tapeworm	Encysts in muscle, brain, liver
	Roundworms (nematodes)	*Ascaris lumbricoides*	Ascariasis	Intestinal obstruction, bile duct obstruction
		Necator americanus (hookworm)	Hookworm disease	Intestinal parasite
		Trichinella spiralis	Trichinosis	Intestine, diarrhea, muscle, CNS, death
		Enterobius vermicularis (pinworm)	Pinworm infection	Intestines

Water and food can be contaminated with protozoal parasites (e.g., *E. histolytica, G. lamblia*). Many protozoan parasites are transmitted through vectors. Important vectors for parasites include the tsetse fly, sand fleas, and mosquitoes. The tsetse fly can transmit the parasites Trypanosoma cruzi (causes Chagas disease and Trypanosoma brucei (causes sleeping sickness). Sand fleas can carry Leishmania species from infected dogs to people causing skin sores, infection of viscera, and the mucosa of the nose, mouth and throat (Leishmaniasis). The Zika virus is transmitted by mosquitoes and causes fever, rash, headache, conjunctivitis, and musculoskeletal discomfort. Of greatest concern is that it can be passed

from a pregnant mother to her fetus and cause birth defects. Transmission of *Plasmodium* is through the bite of an infected female *Anopheles* mosquito, in which the parasite grows in the salivary gland.

There are several types of *Plasmodium* species that can cause malaria (Fig. 10.16). The most common is *P. falciparum. Plasmodium* replication occurs in erythrocytes and results in the release of additional parasites that infect other erythrocytes. Periodic (48 to 72 hours) lysis of the erythrocytes results in anemia and induction of cytokines (e.g., TNF-β, interferon-gamma [IFN-γ], IL-1) that provoke fever, chills, sweating, headache, muscle pains, and vomiting. Most of the tissue damage caused by parasites is secondary to the release of enzymes that help invasion by destroying surrounding extracellular matrix and tissue. Profound anemia and pulmonary edema may occur. Neurologic complications may result from infected red blood cells adhering to endothelium in capillaries of the brain. Left untreated, malaria can result in serious illness and death. Antimalarial drugs are effective in many individuals, but relapses and antimicrobial resistance are common.[74] The world's first malaria vaccine, called Mosquirix, was endorsed by the WHO in fall 2021. It has an efficacy of about 50 percent against severe malaria in the first year. Although protection drops rapidly over the 3 years after full inoculation, it is estimated that in high prevalence areas it could prevent 116, 480 cases of clinical malaria and 484 deaths per 100,000 children vaccinated.[75] Malaria diagnosis and treatment is guided by the 2021 World Health Organization Guidelines.[76] Diagnosis rests on recognition of likely exposures, symptoms, and parasitological testing. Rapid diagnostic tests are available. Individuals who present with symptoms of malaria and a positive parasitological test but with no features of severe malaria are treated with a 3-day course of artemisinin-based combination therapy, whereas recurrent or severe malaria requires multiple medications and more prolonged treatment regimens.[76]

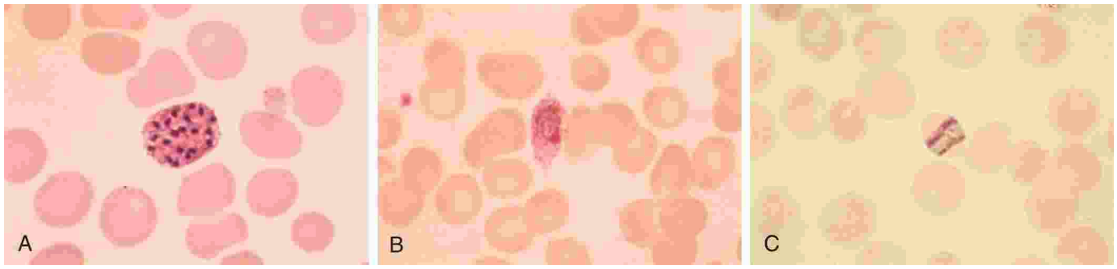

FIG. 10.16 Malaria.
Malaria Giemsa-stained smears. **(A)** *Plasmodium vivax* schizont. **(B)** *Plasmodium ovale* trophozoite. **(C)** Characteristic band from trophozoite of *Plasmodium malariae* containing intracellular pigment hemozoin. (From Kliegman R, et al. *Nelson textbook of pediatrics*, 20th edition. St. Louis: Saunders; 2016.)

Three photomicrographs, A, B, and C, show malarial cells. Left panel, A. A circular cluster of tiny chromatins and cytoplasm. Middle panel, B. An ovular cluster of larger chromatins in cytoplasm. Right panel, C. A band of compact cytoplasm.

The most common parasitic infections in the United States are *Toxoplasma gondii* and *Trichomonas vaginalis. T. gondii* can be found colonizing up to 30% to 50% of non-immunocompromised asymptomatic individuals.[77] The innate immune system is primarily responsible for keeping the organism in check in healthy individuals. Toxoplasmosis occurs in immunocompromised individuals such as those with AIDS or hematologic malignancies. It typically results in central nervous system infection including encephalitis and abscesses.[78] Ocular infections can occur in infants. Treatment with combinations of antimicrobials that block the folate pathway of parasite metabolism is indicated, but may be associated with significant serious adverse outcomes.[77]*T. vaginalis* is a common sexually

transmitted infection (see Chapter 27). It causes genitourinary infections is linked to an increased risk for premature delivery for pregnant women.

Antibiotic/Antimicrobial Resistance

Some antibacterial antibiotics are *bactericidal* (kill the microorganism), whereas others are *bacteriostatic* (inhibit growth until the microorganism is destroyed by the individual's own protective mechanisms). The mechanisms of action of most antibiotics are (1) inhibition of the function or production of the cell wall/membrane, (2) prevention of protein synthesis, (3) blockage of DNA replication, or (4) interference with folic acid metabolism (Table 10.7). Because viruses use the enzymes of the host's cells, there has been less success in developing antivirals.

Table 10.7

Mechanisms of Action of Commonly-Used Antimicrobials

Mechanism of Action	Agents
Inhibits synthesis of cell wall	Penicillins, cephalosporins, monobactams, carbapenems, vancomycin, bacitracin, cycloserine, fosfomycin
Cell membrane inhibitors	Amphotericin, ketoconazole, polymycin
Damages cytoplasmic membrane	Polymyxins, polyene antifungals, imidazoles
Alters metabolism of nucleic acid	Quinolones, rifampin, nitrofurans, nitroimidazoles
Inhibits protein synthesis	Aminoglycosides, tetracyclines, chloramphenicol, macrolides, clindamycin, spectinomycin
Inhibits folic acid synthesis (needed for protein synthesis)	Sulfonamides, trimethoprim
Alters energy metabolism	Trimethoprim, dapsone, isoniazid

Adapted from Visovsky CG, Zambroski CH, Holser S. *Introduction to clinical pharmacology*, 9th edition. St. Louis: Elsevier; 2019.

Antibiotic-resistant infections to one or multiple antibiotics are growing in number and severity.[79,80]. The CDC's publication "Antibiotic Resistance Threats in the United States, 2019 (2019 AR Threats Report)" states that more than 2.8 million antibiotic-resistant infections occur in the United States each year and more than 35,000 people die as a result. This report lists 18 pathogens sorted into "Urgent Threats," "Serious Threats," and "Concerning Threats."[81] Much of this resistance results from of a combination of factors such as antibiotic overuse, lack of compliance, antimicrobial use in agriculture, and the development of new strains of pathogens.[82]

Many infections once considered routine and easily treatable are now resistant to most currently available antibiotics. Important examples include **methicillin-resistant S. aureus [MRSA]** and *Streptococcus pneumoniae*, which causes pneumonia, meningitis, and acute otitis media (middle ear infection). Of interest, additionally, there are major increases in resistant *Enterococcus* (sepsis, wound infection, urinary tract infection), *P. aeruginosa* (burn infection, sepsis), and *M. tuberculosis*(tuberculosis). Antimicrobial-resistant strains of fungi and parasites are also increasing.

Microbes can use various mechanisms to resist or inactivate antibiotics (Fig. 10.17). The type of antibiotic affected by these resistance mechanisms is primarily determined by how the drug enters the microorganism or its mechanisms of action. For example, an enzyme called *beta-lactamase*, which is produced by most *S. aureus* species, prevents the action of penicillin on the microorganismal cell wall. Other antibiotics, such as fluoroquinolones and macrolides, are rendered ineffective by multiple resistance mechanisms. Many potential new approaches to antimicrobial resistance are being explored.

Examples include antimicrobial peptides, monoclonal antibodies, bacteriophages, stem cells, liposomes, and new vaccines.[83]

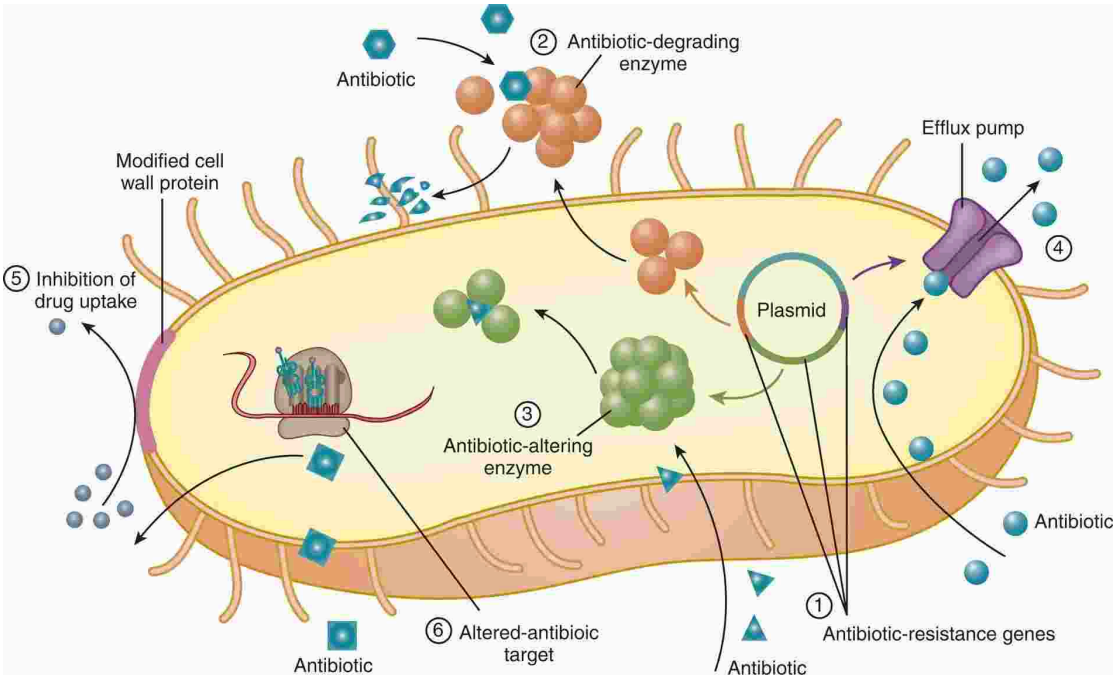

FIG. 10.17 Mechanisms of Antibiotic Resistance.
Mechanisms of antibiotic resistance include the following: ***(1)*** Resistance genes that are spread within the bacterial community by horizontal gene transfer to other generations of microbes. ***(2)*** Antibiotics are degraded by enzymes released from the microbe. ***(3)*** Antibiotics are altered by enzymes within the microbe. ***(4)*** Antibiotics are ejected from inside the microbe by efflux pumps in the cell membrane. ***(5)*** The cell wall can be modified to prevent antibiotic binding or uptake. ***(6)*** Modification of the cellular target of the antibiotic.

An illustration shows a cross-section of a cell with a modified cell wall protein. The mechanism of antibiotic resistance is as follows. 1. Antibiotic-resistance genes in plasmid. 2. Antibiotic-degrading enzymes released by plasmid. 3. Antibiotic-altering enzyme released by plasmid. 4. Antibiotics released through the efflux pump. 5. Inhibition of drug uptake at the site of modified cell wall protein. 6. Altered-antibiotic target.

Vaccines and Protection Against Infection

Active Immunization

Recovery from an infection generally results in the strongest resistance to a future infection with the same microbe. **Vaccines** are biologic preparations of antigens that, when administered, stimulate production of protective antibodies or cellular immunity against a specific pathogen without causing potentially life-threatening disease. There are several types of vaccines. Some use live-attenuated (rendered unable to cause disease) or inactivated (killed) microorganisms (e.g., measles, influenza).

Others use portions of the microbe and are called subunit, recombinant, peptide, polysaccharide, capsid, or conjugate vaccines (e.g., Hepatitis B, Pneumococcus). Toxoid vaccines use parts of the microbial toxin (e.g., diphtheria, tetanus). Recently, nucleic acid vaccines that include pieces of pathogen DNA or RNA are being developed, often using a recombinant vector vaccine to expose the individual's immune system to the pathogen (e.g., Zika, SARS-CoV-2). Most recently, mRNA vaccines for COVID-19 have been developed and have been shown to have high levels of efficacy.[62] This type of vaccine has been in development for decades and are expected to be developed for many other infectious (including HIV) and non-infectious diseases such as cancer.[84]

The purpose of **vaccination** is to induce long-lasting protective immune responses under safe conditions. The primary immune response from vaccination is generally short lived; therefore, booster injections are used to push the immune response through multiple secondary responses that result in large numbers of memory cells and sustained protective levels of antibody or T cells, or both (see Chapter 8). In the United States the CDC provides updated vaccine schedules, which are available at www.cdc.gov/vaccines/schedules/index.html.

Passive Immunotherapy

Passive immunotherapy is a form of countermeasure against pathogens in which preformed antibodies are given to the individual. Passive immunotherapy with human immunoglobulin has been approved for several infections, including hepatitis A and hepatitis B. Treatment of potential rabies infection after a bite combines passive and active immunization. Individuals who have been bitten receive passive immunization with monoclonal antibody to slow further viral proliferation, followed by active immunization via multiple injections with a killed viral vaccine to induce greater protective immunity. Monoclonal antibodies are now being used as prophylaxis to protect high risk individuals from certain infections (e.g., RSV, Ebola).[85] Monoclonal antibodies are also used to treat individuals infected with SARS-CoV-2.[59] With the increase in antibiotic-resistant microorganisms, the development of new vaccines for old diseases is needed.

Summary Review

Microorganisms and Humans: A Dynamic Relationship

1. Infectious disease is a significant cause of morbidity and mortality in the United States and worldwide.
2. Pathogens have unique characteristics that influence their ability to overcome body defense mechanisms and cause disease.
3. The process of infection includes encounter and transmission, colonization, invasion, dissemination, and cellular or tissue damage by the pathogenic microorganisms.
4. There are four distinct stages of infection: incubation period, prodromal stage, invasion or acute illness stage, and convalescence.

Infectious Disease

1. Bacteria have virulence factors that promote their ability to cause infection and cell injury, including pili, flagella, capsules, enzymes, competition for iron, and toxins.
2. Bacteria produce exotoxins or endotoxins. Exotoxins are enzymes that can damage the plasma membranes of host cells or can inactivate enzymes critical to protein synthesis, and endotoxins activate the inflammatory response and produce fever.
3. Septicemia results from the proliferation of bacteria in blood. Toxins released by bloodborne bacteria cause the release of vasoactive enzymes that increase the permeability of blood vessels. Leakage from vessels causes hypotension that can result in septic shock.
4. Viruses are intracellular parasites. They enter host cells and use their metabolic processes to proliferate and cause disease.

5. Viral replication includes seven steps: recognition and attachment, penetration, uncoating, replication, translation, assembly, and release.
6. Viruses that have invaded host cells may decrease protein synthesis; disrupt lysosomal membranes; form inclusion bodies, where synthesis of viral nucleic acids is occurring; fuse with host cells to produce giant cells; alter antigenic properties of the host cell; transform host cells into cancerous cells; and promote bacterial infection.
7. Viruses can elude the immune system by making small changes to the genes that produce viral surface antigens, a process known as *antigenic variation*.
8. SARS-Cov-2 is a novel coronavirus that emerged in fall 2019 causing a severe respiratory illness pandemic in 2020. New and emerging viral infections pose global threats.
9. HIV is a blood-borne pathogen present in body fluids with typical routes of transmission: blood or blood products, intravenous drug abuse, heterosexual and homosexual activity, and maternal-child transmission before or during birth.
10. The primary surface receptor on HIV is the envelope glycoprotein gp120, which binds to the CD4 molecule found mostly on the surface of T-helper cells. Viral binding with chemokine coreceptors CXCR4 on T helper cells and CCR5 on macrophages and dendritic cells is essential for viral fusion to the target cell membrane.
11. HIV is a member of the retrovirus family, which carries genetic information in the form of RNA. An enzyme, reverse transcriptase (RT), converts RNA into a double-stranded DNA. Another enzyme, an integrase, inserts the new DNA into the infected cell's genetic material. On activation, translation of the viral information may be initiated, forming new virions, resulting in lysis and death of the infected cell, and shedding infectious HIV particles.
12. HIV infects macrophages, dendritic cells, and circulating Th cells. It also infects T helper cells in the gut. T helper memory cells serve as reservoirs for HIV infection that persist for life, even in those who are treated with antiretroviral drugs.
13. The major immunologic finding in AIDS is a decrease in the number of CD4+ Th cells resulting in decreasing immune competence.
14. AIDS is characterized by immunocompromise and the development of opportunistic infections and cancers.
15. The COVID-19 pandemic is caused by infection with SARS-CoV-2 which has caused serious illness and death for millions of people worldwide.
16. SARS-CoV-2 is spread primarily by respiratory droplets produced when infected individuals cough, sneeze, or talk.
17. SARS-CoV-2 attaches to respiratory epithelial cells via its spike protein. Upon entering the cell, it sets of an immunologic response that can escalate to a cytokine storm which may cause severe lung disease and death.
18. Diseases caused by fungi are called *mycoses*, and fungi occur in two forms: yeasts (spheres) and molds (filaments or hyphae).
19. Dermatophytes are fungi that infect skin, hair, and nails with diseases, such as ringworm and athlete's foot.
20. *Candida albicans* is the most common cause of fungal infections in humans. Other important fungal pathogens include *Aspergillus fumigatus* and *Pneumocystis jiroveci*.
21. Parasitic microorganisms range from unicellular protozoa to large worms. Although less common in the United States, parasites and protozoa are common causes of infection worldwide.
22. Parasitic and protozoal infections are rarely transmitted from human to human. Infection mainly spreads through vectors (e.g., through mosquito bites) or through contaminated water.
23. *Plasmodium falciparum* is the most common cause of malaria.
24. *Toxoplasma gondii* and *Trichomonas vaginalis* are the two most common parasitic infections in the United States.

Antibiotic/Antimicrobial Resistance

Pathogens can use various mechanisms to resist the effects of antibiotics, including transmission of resistance genes to new generations of bacteria, enzyme degradation of the antibiotic, ejection of the antibiotic from the pathogen, modification of the cell wall to prevent binding or uptake of the antibiotic, or modification of the target of the antibiotic.

Vaccines and Protection Against Infection

1. Vaccines are biologic preparations of antigens that, when administered, stimulate production of protective antibodies or cellular immunity against a specific pathogen.
2. Passive immunotherapy is the administration of preformed antibodies for protection against a specific pathogen, such as hepatitis A and B or rabies.

- Negative Effects of Chronic Stress in Adolescents and Adults, 323

Coping and Intervention Strategies, 324
- Staying on the Good Side of the Stress Spectrum, 324
- Effects of Exercise, 324
- Mindfulness Therapy, 326

Stress is broadly defined as a perceived or anticipated threat that disrupts a person's well-being, or **homeostasis**, and exceeds the individual's capacity to meet the demands. The demands can be physical in nature (e.g., exposure cold temperatures, moving heavy equipment) or psychological (e.g., rush to meet exam deadlines, attempting to complete multiple job assignments). In everyday life, the term *stress* is commonly used to describe negative thoughts and uncontrolled feelings. Experiences that cannot be easily reconciled and threaten one's sense of security are considered

stressful, and the random and constant external and internal challenges are called **stressors**.[1,2] Stressful events perceived as especially threatening, chaotic, and chronic are personal, such as loss of a family member, loss of job security, cancer diagnosis, physical abuse, social neglect, or feelings of social discrimination. The National Institute of Mental Health further defines *stress* in terms of how the brain responds to a demand by activating the neuroendocrine hypothalamic-pituitary-adrenal (HPA) system, including the autonomic nervous system (ANS) and the immune system (IS). Importantly, chronic stress-induced activation of these physiologic systems has the potential to compromise recovery from stress and predispose the individual to engage in a wide range of unhealthy coping strategies, such as foregoing sleep, eating high-calorie comfort foods, and withdrawing from physical activity. Continued engagement in these unhealthy behavioral activities is linked to a number of serious illnesses, such as hypertension, depression, diabetes, and obesity. This chapter discusses the role played by the body and brain in relation to psychosocial and emotional stressors that promote the onset and progression of human diseases.

Background and General Concepts of Stress

Early Years of Stress Biology

Walter B. Cannon used the term *stress* in both a physiologic and a psychological sense as early as 1914 and coined the term *fight-or-flight response* to describe the body's preparation to deal with threat.[3] He applied the engineering concepts of stress and strain in a physiologic context and believed that emotional stimuli also were capable of causing stress. The physiologic reactions to stress included increased heart rate and blood supply of oxygen and glucose to muscles and the brain, elevated respiration, dilation of pupils, and inhibition of gastric secretions. It should be noted the “fight-or-flight” response involving the brain's perception of threat and rapid release of hormones is adaptive in protection from harm. Only when we overreact and cannot reconcile chronic threats will we become susceptible to the development of physical and mental disorders.

The concept of stress was further advanced by Hans Selye and discussed in terms of a chemical or physical change (i.e., physiologic stress, in response either to the external environment or within the body itself).[4]**Physiologic stress** involves (1) enlargement of the adrenal gland, (2)

decreased lymphocyte levels in blood from damage to lymphatic structures of the IS, and (3) development of bleeding ulcers in the stomach and duodenal lining. Selye concluded that physiologic stress will impair the ability of the organism to resist future stressors and represented the hallmark pattern of a nonspecific stress response that was labeled **general adaptation syndrome (GAS)**.

GAS involves three successive stages: the alarm, the resistance or adaptation, and the exhaustion stages. The **alarm stage** is the emergency reaction that prepares the body to fight or flee from threat. This stage involves the secretion of hormones and catecholamines (CAs) to support physiologic/metabolic activity (Figs. 11.1 and 11.2) and boosts the IS to thwart infection and disease. The ensuing **resistance** or **adaptation stage** requires continued mobilization of the body's resources, such as cortisol and adrenaline, to cope and overcome a sustained challenge. However, prolonged use of these resources may weaken the IS and increase the risk of developing diseases. The **exhaustion stage** (currently described as allostatic overload; discussed later) occurs when the body's physiologic resources are depleted and the IS no longer is able to cope with the stressor. The body now becomes vulnerable to psychosomatic and physical diseases, and mental disorders (**diseases of adaptation**). That is, when stress continues unabated, body organs, such as the heart and kidney, may no longer function normally, and disease may develop followed by premature death.

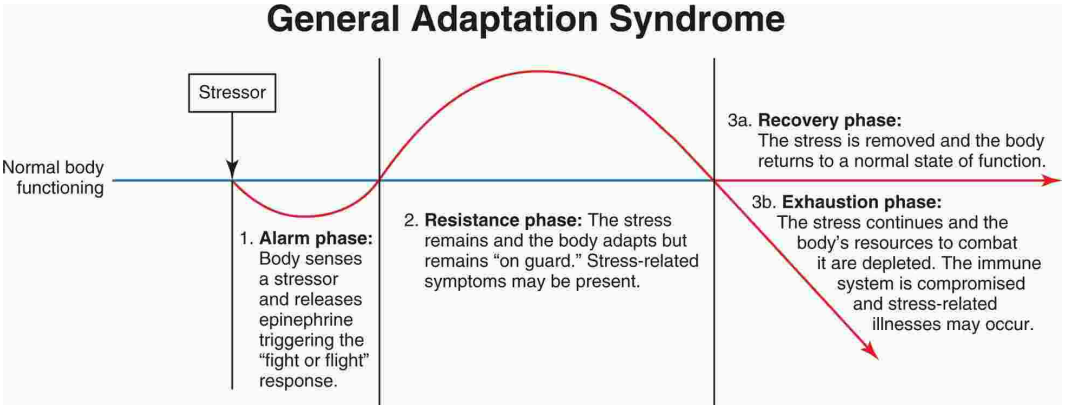

FIG. 11.1 The General Adaptation Syndrome.
Hans Selye describes three phases of the body's physiologic response to stress that involve the alarm phase, the resistance phase, and the exhaustion stage. (From Bonewit-West K, Hunt S. *Today's medical assistant*, 4th edition. St. Louis: Elsevier; 2021.)

A graph plots the general adaptation syndrome. The horizontal axis represents normal body functioning. There is no vertical axis. There are three segments along the horizontal axis. A continuous, solid line is traced from the first segment to the end of the third segment. 1. Alarm phase. Body senses a stressor and releases epinephrine triggering the fight or flight response. The curve is a small and U-shaped, spanning the first segment of the horizontal axis. 2. Resistance phase. The stress remains and the body adapts but remains on guard. Stress-related symptoms may be present. The curve is wide and inverted U-shaped, spanning the second segment of the horizontal axis. 3a. Recovery phase. The stress is removed and the body return to a normal state of function. The curve flatlines along the horizontal axis. 3b. Exhaustion phase. The stress continues and the body's resources to combat it are depleted. The immune system is compromised, and

stress-related illness may occur. The curve falls linearly below the horizontal axis in the third segment.

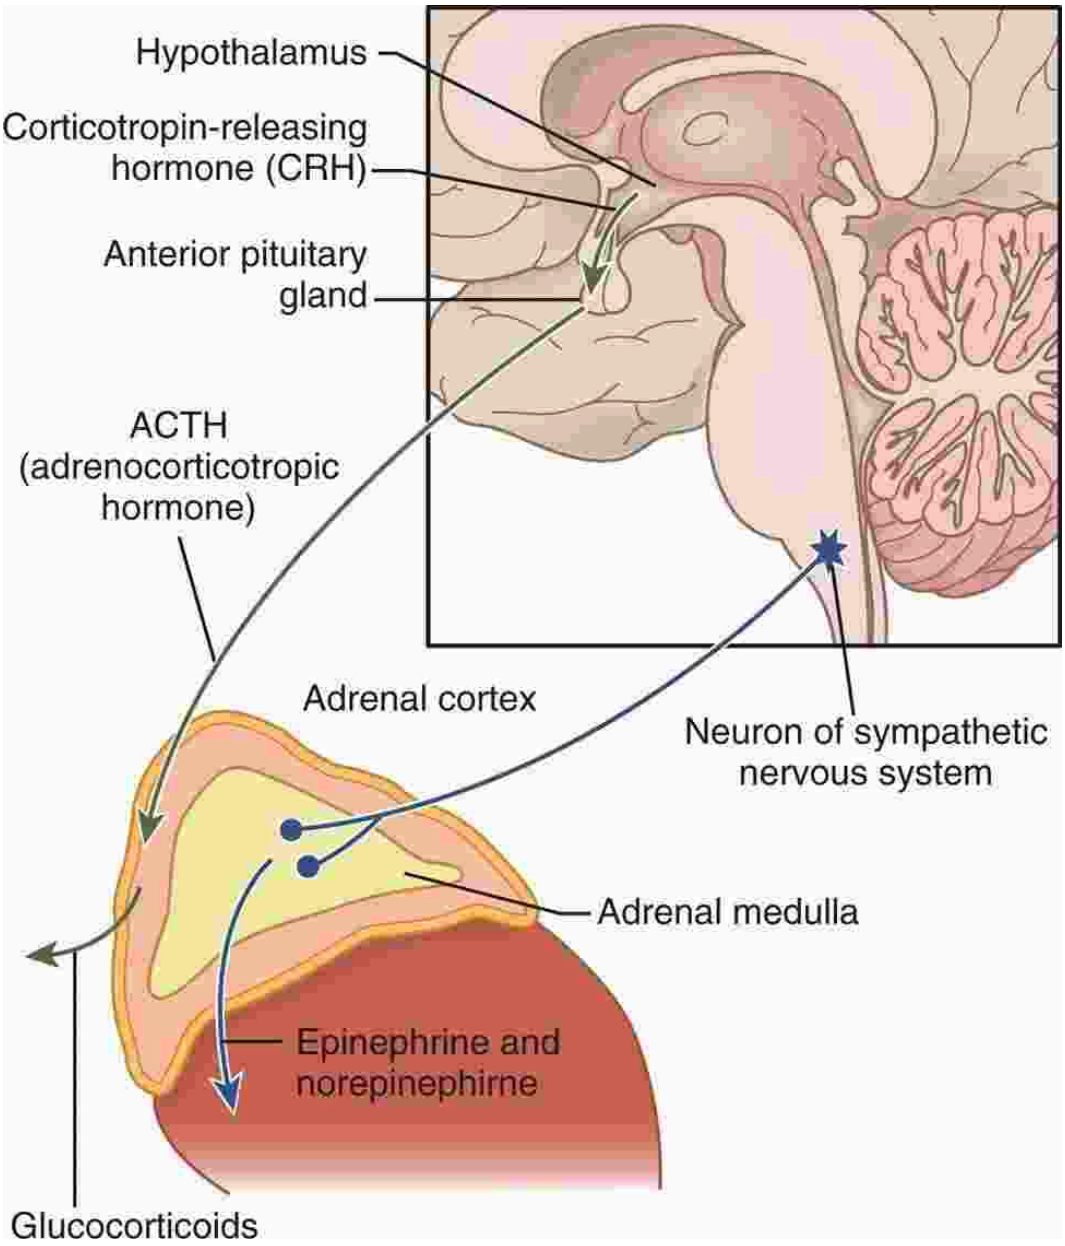

FIG. 11.2 The Alarm Reaction.
The alarm reaction includes increased secretion of glucocorticoids (cortisol) by the adrenal cortex and increased secretion of epinephrine and small amounts of norepinephrine from the adrenal medulla. *ACTH*, Adrenocorticotropic hormone. (Adapted from Patton KT, Thibodeau GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

An illustration shows the left lateral cross-section of the human brain and the adrenal cortex and adrenal medulla. The following parts of the brain are labeled: hypothalamus, corticotropin-releasing hormone (C R H), anterior pituitary gland, and neuron of sympathetic nervous system. Adrenal cortex releases glucocorticoids. Neuron of sympathetic nervous system triggers the adrenal medulla. The adrenal medulla secretes epinephrine and norepinephrine.

More recent studies have shown that a number of psychological factors, such as the degree of discomfort, unpleasantness, or suddenness of an unanticipated stimulus, are capable of activating the stress response. In fact, psychological stressors are as effective as physical stressors in activating adrenal hormone secretion. Psychological stressors can elicit a reactive or anticipatory stress response. For example, a routine medical examination involving no physical stressor may, nonetheless, elicit a **reactive physiologic response**, such as accelerated heart rate and dry mouth. **Anticipatory responses** can be generated by the fear of a potential encounter with a dangerous, unconditioned stimulus (e.g., a predator) or in conditioned situations when a person learns that a specific event is associated with an aversive outcome. A child with a history of parental abuse may show a physiologic stress response in anticipation of further abuse when that parent enters the room. Another well-known example of a conditioned emotional response is the recall of intense fear memories in posttraumatic stress disorder (PTSD). Military veterans and survivors of extreme natural disasters, car accidents, physical assaults, or rape show intense conditioned fear and debilitating responses that are triggered by sounds, odors, visual images, or other stimuli associated with the traumatic event.

It should be noted not all stress has negative health consequences. **Eustress** is a term to describe positive stress. For example, getting a new job, buying a new house, and meeting new friends are stressful situations that generate excitement, induce motivation, and focus energy to become successful. The challenge to gain self-control and self-esteem is considered positive stress.

Modern Overview of Stress: Allostasis and Allostatic Overload

The emerging link between stress and disease became the basis of the concept of **allostasis**, introduced by Sterling and Eyer (Fig. 11.3).[5] This concept refers to "stability through change" and differs from the "fixed homeostasis model" in which physiologic regulation revolves around a narrow set point range. For example, after exposure to a challenging stressor, heighted physiologic secretion of stress hormones (e.g., cortisol) is expected to return to basal levels. By contrast, allostasis involves a dynamic adaptation with the brain continuously monitoring many parameters in anticipation of what the HPA and the ANS system must do to meet future challenges. In other words, the brain modulates neurophysiologic systems in anticipation of future stressful situations and continuously adjusts its normal operating range (e.g., hormone secretion) rather than returning to basal hormone levels. Different parts of the brain's limbic system respond to different types of stress (see Fig. 11.3).[6] This adaptive strategy is thought to support coping with an unpredictable stressful environment.

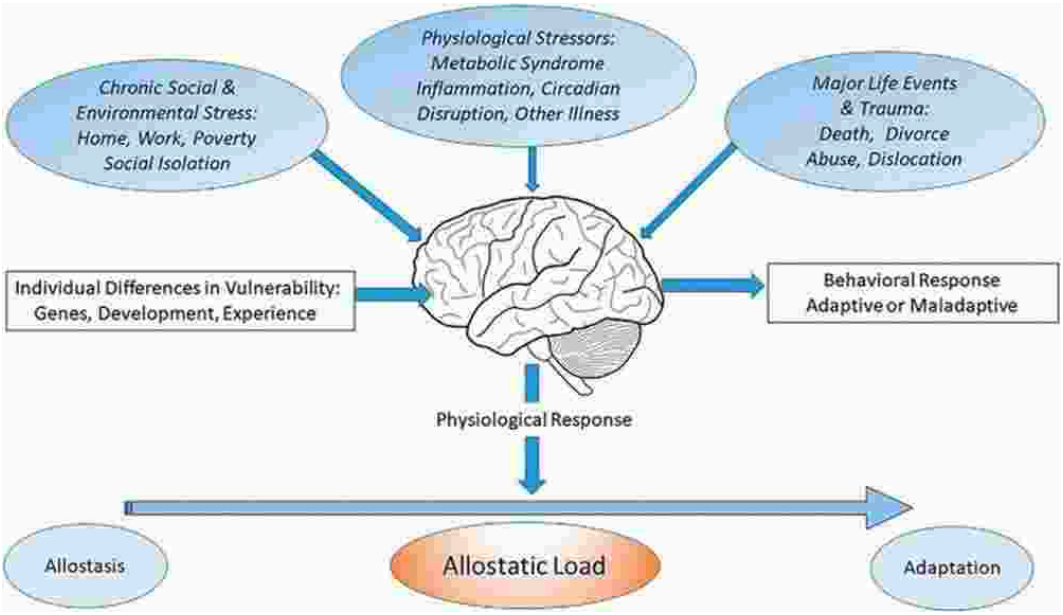

FIG. 11.3 Physiologic and Behavioral Stress Responses and Allostatic Load.
The brain is a primary organ that perceives and responds to what is stressful to an individual. The major function of cortisol and other mediators of allostasis is to promote adaptation. However, overuse and/or dysregulation among the mediators of allostasis lead to allostatic load (or overload) and accelerate disease processes such as cardiovascular disease, diabetes, and affective disorders. Three limbic brain regions are noted. (From McEwen BS, Akil H. Revisiting the stress concept: Implications for affective disorders. *Journal of Neuroscience Research*, 2020;40(1):12–21.)

An illustration shows the physiologic and behavioral stress responses and allostatic load. The illustration shows individual differences in vulnerability (genes, development, experience) affecting the following stressors: • Chronic social and environmental stress; home, work, poverty; social isolation. • Physiological stressors: metabolic syndrome; inflammation, circadian disruption, other illness. • Major life events and trauma:

death, divorce, abuse, and dislocation. The physiological response to the stressors is an allostatic load between allostasis and adaptation. The behavioral response is either adaptive or maladaptive.

Physiologic and Behavioral Stress Responses

Allostatic load is an index of the cumulative wear and tear on the body caused by repeated activation of multiple physiologic systems over time in response to environmental demands in an effort to maintain internal equilibrium.[7] Chronic activation of regulatory systems has the potential to tax the body and brain and lead to the emergence of diseases and disorders. **Allostatic overload** is the term used to describe chronic overactivation of adaptive regulatory physiologic systems that may lead to pathophysiology and onset of disease.[1,2] Situations that can contribute to allostatic overload include exposure to frequent stressors that cause repeated physiologic arousal, lack of adaptation to stressors, inability to shut off the stress response, and an allostatic response that is not sufficient to deal with the stressor.[7] In short, frequent and longer exposures to stress accelerate the wear and tear on the body and brain.

Allostasis and allostatic overload are highly individualized. An event or situation considered normal in one person may be stressful to another as a result of genetic, environmental (or both), or experiential factors. For example, some studies have shown that low socioeconomic status (SES), ethnicity, gender dysphoria, sexual orientation, and aging are associated with high levels of allostatic load.[7] The brain plays a key role in perceiving stress and determines when we have reached allostatic overload. Thus psychological or uncontrollable stress is increasingly recognized both as a precipitating factor for some diseases as well as a contributor that worsens symptoms in behavioral (e.g., anxiety), physiologic (e.g., chronic pain, asthma), or metabolic disorders (e.g., obesity, type 2 diabetes).[1,2] In addition, stress disrupts the biologic process of sleep and growth and reproductive functions. In the United States, chronic exposure to toxic, allostatic overload is a contributing factor underlying early mortality.[8] The susceptibility to stress varies from person to person, and factors related to susceptibility include coping style, type of personality, social support,

mental health, immune function, and other factors.[9] Examples of stress-related diseases and conditions can be found in Table 11.1.

Table 11.1

Examples of Stress-Related Diseases and Conditions

Target Organ or System	Disease or Condition	Target Organ or System	Disease or Condition
Cardiovascular system	Coronary artery disease	Gastrointestinal system	Ulcer

The Stress Systems

The perception or anticipation of a threat activates three major physiologic stress systems: the HPA axis; the sympathetic nervous system (SNS); and the IS. Acute activation of these stress-related systems modulates a broad range of mediators on the body and brain to protect and meet the physiologic and behavioral demands of the stressor to facilitate recovery (Fig. 11.4). For example, stress-induced activation of the SNS and the HPA axis triggers the release of hormones (e.g., epinephrine, cortisol), which rapidly mobilizes resources necessary to prepare the body and brain for

"fight-or-flight" responses to threat. In addition, both stress systems send signals to the IS to release cytokines, the mediators of inflammatory processes, such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor-α (TNF-α).[10] The acute release of these sympathetic, neuroendocrine, and immune mediators has profound effects on supporting immune functions, adaptive behavior, physiologic actions, cognitive ability, and mental health.[11,12]

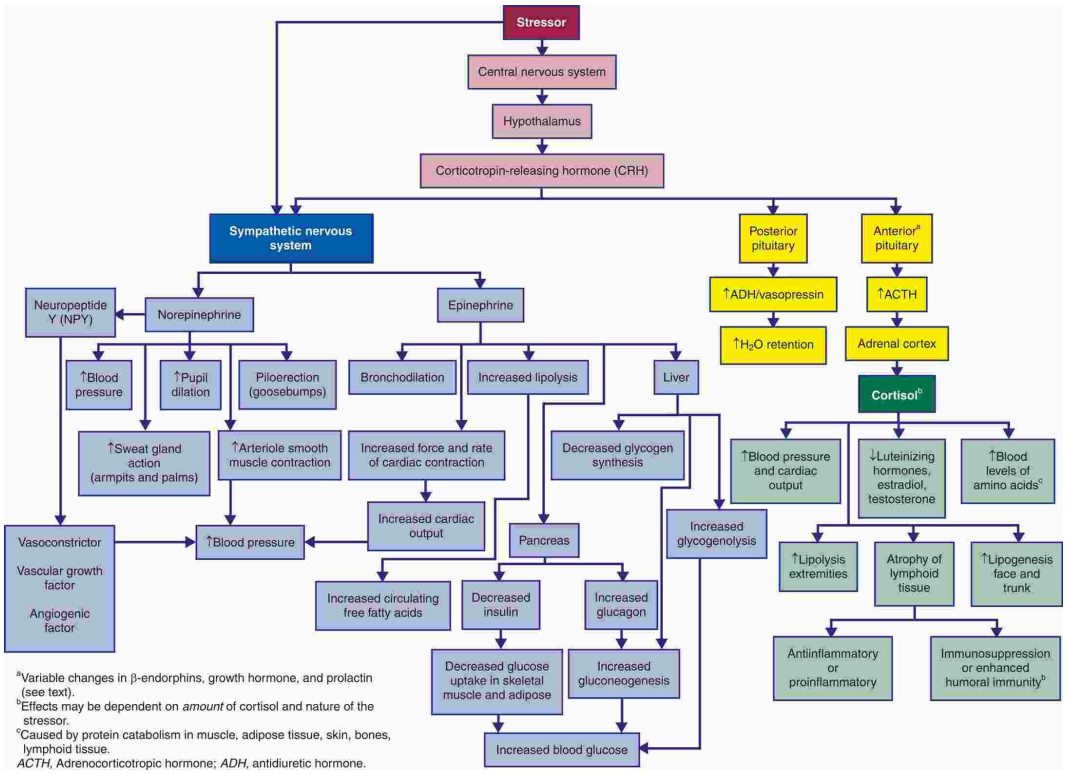

FIG. 11.4 The Stress Response.

Stress activates the brain, endocrine, and immune systems to defend the individual from threat. Stress-induced physiologic responses involve the sympathetic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. The sympathetic nervous system is responsible for rapid fight-or-flight responses. Through the release of catecholamines, namely epinephrine and norepinephrine, a cascade of events occurs to prepare the body for rapid mobilization and metabolic changes, including heart rate acceleration, dilation of pupils and bronchi, liver glucose release, and other adaptive functions. Systemic vasoconstriction and elevated blood pressure are accompanied by vasodilation and increased blood flow through arteries that supply striated muscle. Engagement of the HPA system and secretion of cortisol plays key roles in supporting the diverse effects of catecholamines, suppression of the immune-inflammatory response, delayed wound healing, and modulation of the reproductive hormone system. The physiologic responses to stress have

significance in the clinical setting as chronic stress and the accompanying pathophysiology can lead to a wide range of disease and disorders in the body and brain.

A hierarchy chart represents the stress response. A stressor impacts the following: • Central nervous system; hypothalamus; corticotropin-releasing hormone (C R H). • Sympathetic nervous system. The C R H impacts the following: • Sympathetic nervous system. • Posterior pituitary. • Anterior pituitary. The sympathetic nervous system releases: • Norepinephrine • Epinephrine Norepinephrine generates the following responses: • Neuropeptide Y (N P Y), which impacts the vasoconstrictor, vascular growth factor, and angiogenic factor. • Increased blood pressure. • Increased sweat gland action (armpits and palms). • Increased pupil dilation. • Increased arteriole smooth muscle contraction. • Piloerection (goosebumps). Epinephrine generates the following responses: • Bronchodilation. • Increased force and rate of cardiac contraction, leading to increased cardiac output. • Increased lipolysis, leading to increased circulating free fatty acids. • Pancreas: decreased insulin, leading to decreased glucose uptake in skeletal muscle and adipose; increased glucagon, leading to increased gluconeogenesis. Increased blood glucose. • Liver: decreased glycogen synthesis; increased glucogenesis; increased glycogenolysis, leading to increased blood glucose. Posterior pituitary generates the following response: • Increased A D H or vasopressin. • Increased water retention. Anterior pituitary generates the following responses: • Increased A C T H. • Adrenal cortex. •

Cortisol. Cortisol results in the following responses: • Increased blood pressure and cardiac output. • Decreased luteinizing hormones, estradiol, testosterone. • Increased blood levels of amino acids. • Increased lipolysis extremities. • Atrophy of lymphoid tissue: anti-inflammatory or proinflammatory; immunosuppression or enhanced humoral immunity. • Increased lipogenesis face and trunk.

***

Adaptive Roles of Stress Systems

Allostatic overload occurs when these protective physiologic regulatory systems are taxed by chronic, persistent exposure to threat and no longer able to adapt to the demands of the current and new stressors. Key physiologic changes involved in allostatic overload include exaggerated secretion of adrenal cortisol, CAs from the SNS, and proinflammatory cytokines that may initiate gene expression changes with widespread effects on neurobiologic structures and processes (Fig. 11.5). Brain regions, including the hippocampus, amygdala, and prefrontal cortex, may undergo structural remodeling that alters connections between brain cells and consequently influences both the structure and function of brain circuits underlying adaptive behavioral, cognitive, and physiologic responses. Brain alterations may impact our ability to process information that promote beneficial coping strategies and instead increase the risk of developing mental illness and cognitive impairments.[6] Becoming "stressed out," or allostatic overload, may lead to sleep deprivation; elevated evening cortisol secretion; heightened insulin and blood glucose levels; increased blood pressure; reduced parasympathetic activity; increased levels of proinflammatory cytokines; and increased secretion of the hormone ghrelin (primarily by cells of the stomach and pancreas), which promotes appetite. To summarize, allostatic overload points to the damaging effects of chronic stress on mediating many disease processes.

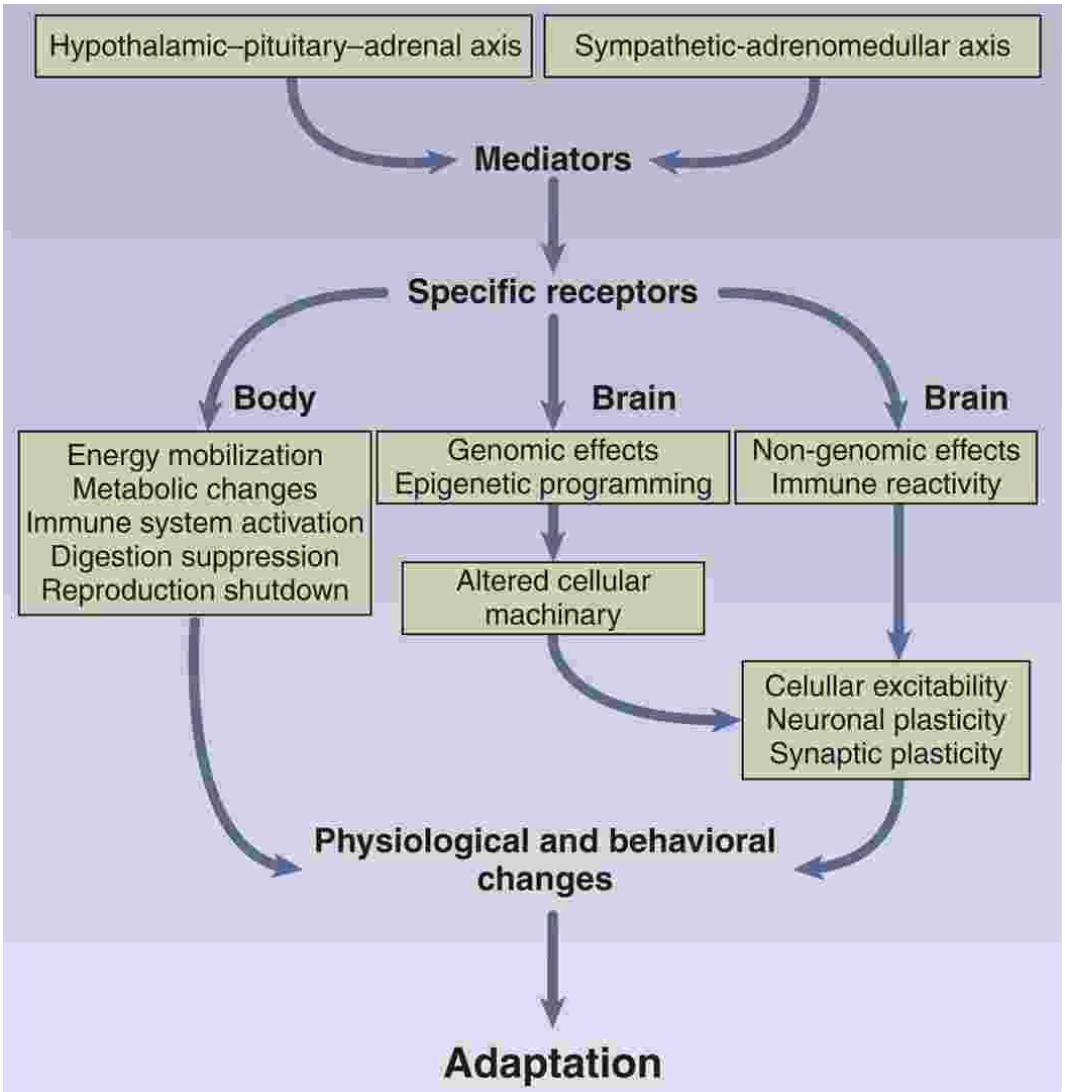

FIG. 11.5 Adaptive Roles of Stress Systems.
In response to stress, the hypothalamus activates the pituitary and adrenal cortex to secrete the glucocorticoid hormone cortisol. The hypothalamus also activates the sympathetic nervous system to release the catecholamines epinephrine and norepinephrine from the adrenal medulla and from nerve endings in the periphery. Together, the glucocorticoids and catecholamines prepare the body and brain for action and protect and keep the individual from harm with the accompanying activation of the immune system. See text for further details. (Adapted from Godoy LD, Rossignoli MT, Delfino-Pereira P, et al. A comprehensive overview on stress

neurobiology: basic concepts and clinical implications. *Frontiers in Behavioral Neuroscience*, 2018;12:127.)

A flowchart tracks the adaptive roles of stress systems. Hypothalamic-pituitary-adrenal axis and sympathetic-adrenomedullar axis are the mediators that impact specific receptors: • Body: Energy mobilization; metabolic changes; immune system activation; digestion suppression; reproduction shutdown. • Brain: Genomic effects; epigenetic programming; altered cellular machinery; cellular excitability, neuronal plasticity, synaptic plasticity. • Brain: Non-genomic effects; immune reactivity; cellular excitability, neuronal plasticity, synaptic plasticity. Responses to specific receptors are physiological and behavioral changes that lead to adaptation.

Regulation of the Hypothalamic-Pituitary-Adrenal Axis

An essential feature of the stress hormone system is the regulation of the **hypothalamic-pituitary-adrenal (HPA) axis** (Fig. 11.6). Stress activates the hypothalamus to secrete **corticotropin-releasing hormone (CRH)**, which binds to receptors on anterior pituitary cells, which, in turn, produce **adrenocorticotropic hormone (ACTH)**. ACTH is then released into the bloodstream and transported to the adrenal glands located on the top of the kidneys. After binding to receptors on the cortex of the adrenal glands, the **glucocorticoid (GC) hormone**, primarily cortisol, is released and reaches all tissues, including the brain.[6,13]

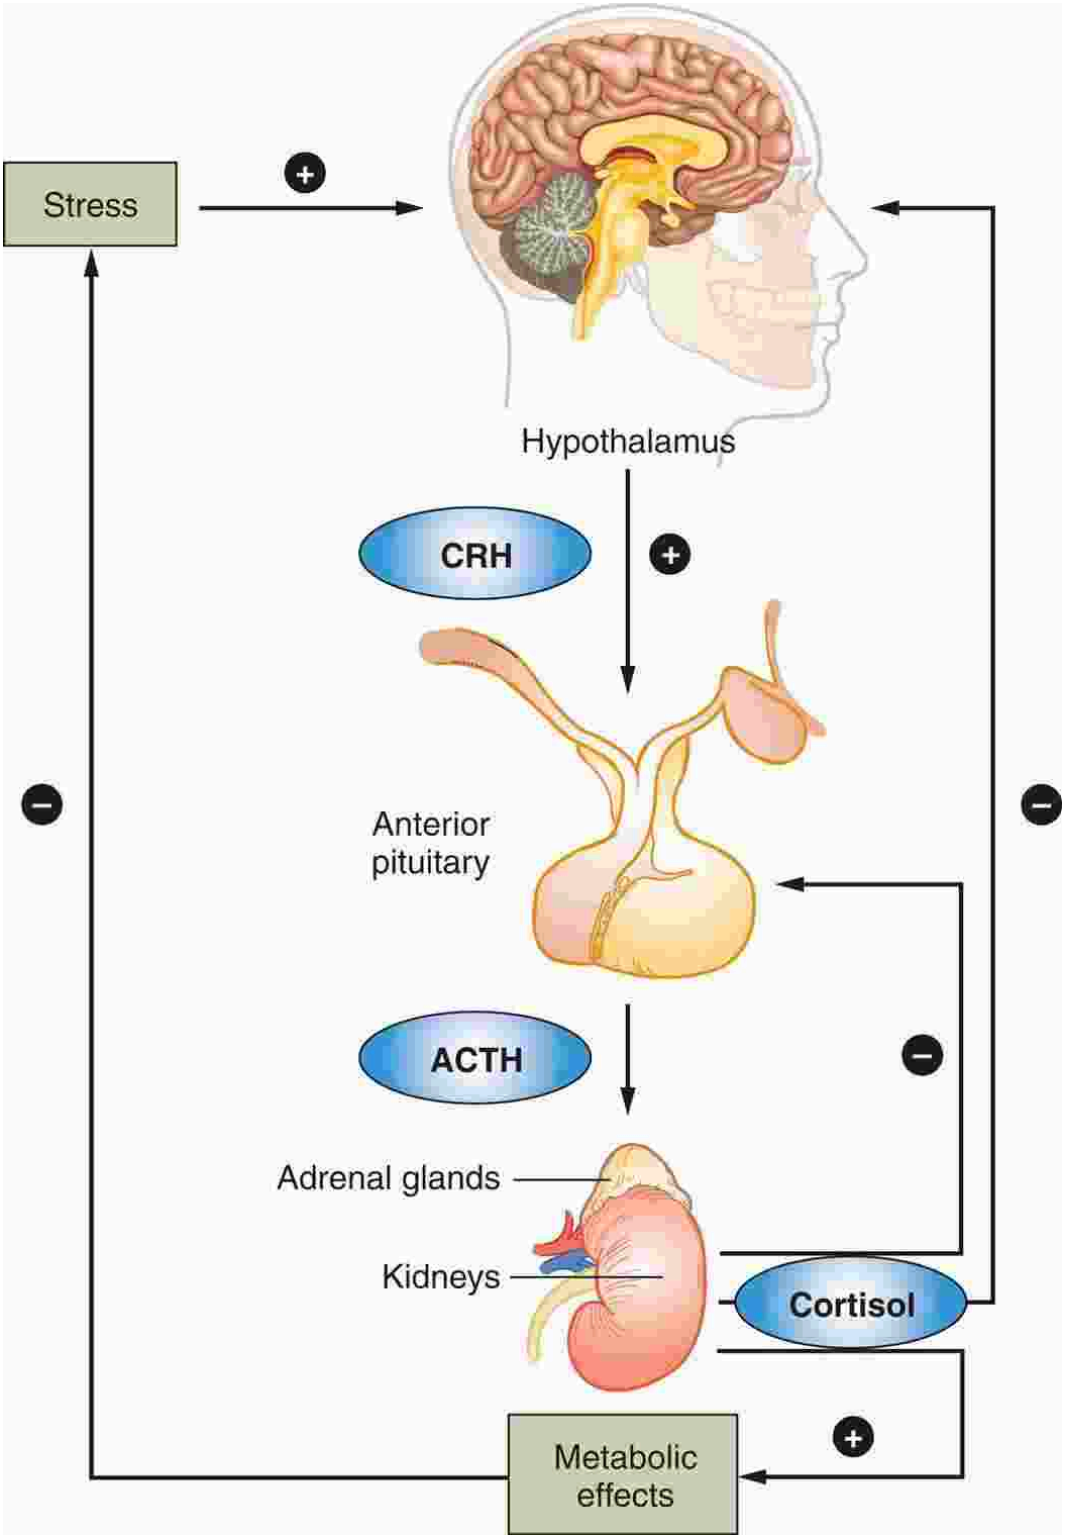

FIG. 11.6 Hypothalamic-Pituitary-Adrenal Axis.
The response to stress begins in the brain. The hypothalamus is the control center in the brain for many hormones, including corticotropin-releasing hormone

(CRH), adrenocorticotropic hormone *(ACTH)*, and glucocorticoids (cortisol).

A key aspect of the HPA axis is the negative feedback loops that inhibit further secretion of cortisol. Feedback loops between cortical and subcortical regions work together to return cortisol to allostatic levels that prevent cellular damage in the brain. Understanding the links between stress and HPA cortisol secretion are beginning to offer many insights into stress-related illnesses and health outcomes. Notably, stressors can exert lasting effects on an organism's physiology and on the HPA axis through GC signaling that activates the mineralocorticoid receptor and the **glucocorticoid receptor (GR)**. Stressor characteristics, including stressor duration, intensity, type, and context, have the potential to alter the regulation of the HPA axis and secretion of GCs.[6] Dysregulation of the HPA axis can be programmed in an age- and sex-dependent manner; these programming effects are linked with susceptibility to psychiatric and age-related diseases in both human studies and animal models. Furthermore, human and animal research shows that stress and GCs may induce long-lasting alterations in epigenetic modifications and changes in DNA methylation.[14,15]

Physiologic Effects of Cortisol

Cortisol reacts with numerous intracellular GRs (Table 11.2) to exert diverse biologic actions (see Chapter 21). Cortisol regulates many functions, including arousal, cognition, mood, sleep, metabolism, maintenance of cardiovascular tone, the immune and antiinflammatory responses, and growth and reproduction.

Table 11.2

Physiologic Effects of Cortisol

Functions Affected	Physiologic Effects
Carbohydrate and lipid metabolism	Diminishes peripheral uptake and utilization of glucose; promotes gluconeogenesis in liver metabolism cells; enhances gluconeogenic response to other hormones; promotes lipolysis in adipose tissue
Protein metabolism	Increases protein synthesis in liver and decreases protein synthesis (including immunoglobulin synthesis) in muscle, lymphoid tissue, adipose tissue, skin, and bone; increases plasma level of amino acids; stimulates deamination in liver
Antiinflammatory effects (systemic effects)	High levels of cortisol used in drug therapy suppress inflammatory response and inhibit proinflammatory activity of many growth factors and cytokines; however, over time some individuals may develop tolerance to glucocorticoids, causing an increased susceptibility to both inflammatory and autoimmune diseases
Proinflammatory effects (possible local effects)	Cortisol levels released during stress response may increase proinflammatory effects
Lipid metabolism	Lipolysis in extremities and lipogenesis in face and trunk
Immune effects	*Treatment* levels of glucocorticoids are immunosuppressive; thus they are valuable agents used in numerous diseases/conditions; T cell or innate immune system is particularly affected by these larger doses of glucocorticoids, with suppression of T helper cell 1 (Th1) function or innate

Functions Affected	Physiologic Effects
	immunity; *stress* can cause a different pattern of immune response; these nontherapeutic levels can suppress innate (Th1) and increase adaptive (Th2) immunity—the so-called Th2 shift; several factors influence this complex physiology and include long-term adaptations, reproductive hormones (i.e., overall, androgens suppress and estrogens stimulate immune responses), defects of the hypothalamic-pituitary-adrenal axis, histamine-generated responses, and acute versus chronic stress; thus stress seems to cause a Th2 shift *systemically*, whereas *locally*, under certain conditions, it can induce proinflammatory activities and by these mechanisms may influence onset or course of infections, autoimmune/inflammatory, allergic, and neoplastic diseases
Digestive function	Promotes gastric secretion
Urinary function	Enhances excretion of calcium
Connective tissue function	Decreases proliferation of fibroblasts in connective tissue (thus delaying healing)
Muscle function	Maintains normal contractility and maximal work output for skeletal and cardiac muscle
Bone function	Decreases bone formation
Vascular system/myocardial function	Maintains normal blood pressure; permits increased responsiveness of arterioles to constrictive action of adrenergic stimulation; optimizes myocardial performance
Central nervous system function	Somehow modulates perceptual and emotional functioning; essential for normal arousal and initiation of daytime activity

Functions Affected	Physiologic Effects
Possible synergism with estrogen in pregnancy?	May suppress maternal immune system to prevent rejection of fetus

Cortisol plays a key role in mobilizing substances needed for cellular metabolism and stimulates gluconeogenesis or the formation of glucose from noncarbohydrate sources, such as amino acids or free fatty acids in the liver. In addition, cortisol enhances the elevation of blood glucose levels that is promoted by other hormones, such as epinephrine, glucagon, and growth hormone. The effects of cortisol are considered to be permissive for the actions of other hormones. Cortisol also inhibits the uptake and oxidation of glucose by many body cells. Overall, the cortisol-induced increase in carbohydrate metabolism serves to energize the body to cope with the stressor.

Cortisol has anabolic effects on protein metabolism by increasing the rate of protein synthesis and ribonucleic acid (RNA) in the liver, and this effect is countered by cortisol's catabolic effect on protein stores in other tissues. Protein catabolism acts to increase levels of circulating amino acids; therefore chronic exposure to excess cortisol can severely deplete protein stores in muscle, bone, connective tissue, and skin.

Another important adaptive function of acute stress-induced cortisol secretion is to induce an antiinflammatory state to contain an inflammatory immune response. Cortisol also promotes resolution and repair by facilitating the actions of the GR, namely, the transcription of genetic material (through deoxyribonucleic acid [DNA] binding) within leukocytes. Because GRs are widely expressed, they influence virtually all immune cells. The adaptiveness or destructiveness of cortisol-induced effects may depend on the intensity, type, and duration of the stressor; the tissue involved; and the subsequent concentration and length of cortisol exposure.

Pathophysiologic Effects of Chronic Cortisol

Dysregulation of the HPA axis, especially chronic elevation of cortisol, is linked to a wide variety of disorders, including obesity, sleep deprivation, lipid abnormalities, hypertension, diabetes, atherosclerosis, and loss of bone density.[16] High HPA axis reactivity to stress, along with increased peripheral tissue sensitivity to GCs, is associated with the severity of coronary artery disease. Heightened stress-induced cortisol levels also

promote gastric secretion in the stomach and intestines, potentially causing gastric ulcers, which may account for the gastrointestinal ulceration observed by Selye. Furthermore, GCs contribute to the development of metabolic syndrome and the pathogenesis of obesity by directly causing insulin resistance and influencing genetic variations that predispose to obesity.[17,18] Chronic stress-induced secretion of GCs stimulates food intake and increases fat storage. As obesity develops, inflammatory cytokine levels increase, as do lipoproteins and free fatty acids (Fig. 11.7). The resulting low-grade inflammation is associated with an increased risk for diabetes, heart disease, cancer, disability, and early death (see Chapter 23).

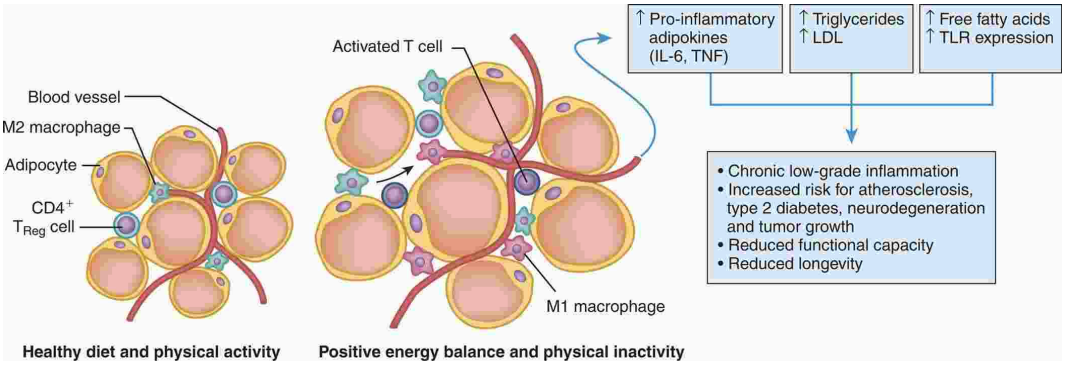

FIG. 11.7 Obesity: Adipocytes and Inflammation. People who consume a healthy diet and engage in physical activity have small adipocytes accompanied by antiinflammatory immune cells (e.g., M2-type macrophages and CD4+ T regulatory *[Treg]* cells). In contrast, positive energy balance and physical inactivity increases adipose tissue size with proinflammatory M1 macrophages that release proinflammatory adipokines (e.g., tumor necrosis factor *[TNF]*, interleukin-6 *[IL-6]*, C-reactive protein). Levels of triglycerides, low density lipoprotein (LDL), and free fatty acids are elevated, along with increased expression of toll-like receptors (TLR) on the surface of inflammatory cells. This low-grade inflammatory state accompanied by sedentary behavior, as well as stress, poor diet, etc., increases the risk of developing insulin resistance, colon cancer, breast cancer, atherosclerosis, depression, and neurodegeneration (e.g., Parkinson disease, Alzheimer disease). Notably, regular engagement in physical activity has anti-inflammatory effects that lessen the onset of many disease conditions. (From Gleeson M, Bishop NC, Stensel DJ, et al. The anti-inflammatory effects of exercise: Mechanisms and implications for the prevention and treatment of disease. *Nature reviews. Immunology*, 2011;11(9):607–615.)

An illustration shows the structure of cells with healthy diet and physical activity and with positive energy balance and physical inactivity. Left, healthy diet and physical activity. The illustration shows a cluster of

healthy cells embedding the following structures: blood vessel, M 2 macrophage, adipocyte, and C D 4 plus T reg cell. Right, positive energy balance and physical inactivity. The illustration shows a cluster of obese cells embedding blood vessel, activated T cell, and M 1 macrophage. Increased pro-inflammatory adipokines (I L-6, T N F), increased triglycerides and increased L D L, and increased free fatty acids and increased T L R expression result in the following responses: • Chronic low-grade inflammation. • Increased risk for atherosclerosis, type 2 diabetes, neurodegeneration, and tumor growth. • Reduced functional capacity. • Reduced longevity.

In the brain, GCs bind to hippocampal GRs and may lead to temporary dendritic shrinkage and loss of spines, and chronic elevations in GCs may initiate cell death and inhibit neurogenesis.[19] Because GRs support the HPA negative feedback effects of cortisol, chronic stress-induced disruption of hippocampal GRs may compromise the negative feedback system and facilitate excess GC secretion. This elevated, stress-induced increase in cortisol is linked to suppressed synaptic function, reduced neuroplasticity, and neural damage.[6] Chronic stress in the medial prefrontal cortex may shrink the dendrites, which may induce cognitive rigidity or inflexibility. Furthermore, the effects of chronic stress on the prefrontal cortex are linked to age-related loss of resilience, impaired memory, and impairment in fear memory extinction.[20]

Notably, not all stress-related disorders are associated with elevated cortisol levels. **Posttraumatic stress disorder (PTSD)**, involving exposure to a life-threatening trauma, induces a unique neurobiologic alteration in the HPA axis. For example, some people with PTSD are reported to show low urinary cortisol levels. The reduction in cortisol may reflect an adaptation of the body to protect itself from the deleterious effects of chronic, elevated GC secretion. However, GR sensitivity is increased and feedback to the HPA may be altered.[21] In other brain regions such the amygdala, animal models show that acute stressors cause an increase in spine density and

chronic stress leads to the expansion of dendrites in anxiety and in PTSD-like behavior. In addition, prolonged stress in the orbitofrontal cortex expands dendrites, which increases startle and vigilance. Other studies have shown that high GC levels during critical illness and trauma may help to prevent the development of PTSD.[22] The physiologic effects of other hormones, organs, and tissues involved in the stress response are summarized in Table 11.3.

Table 11.3

Other Hormones that Influence the Stress Response

Hormone	Source	Action
β-Endorphins (endogenous opiates)	Pituitary and hypothalamus	• Activates endorphin (opiate) receptors on peripheral sensory nerves, leading to pain relief or analgesia • Hemorrhage increases levels to inhibit blood pressure or delay compensatory changes that would increase blood pressure
Growth hormone (GH, somatotropin)	Anterior pituitary gland	• Affects protein, lipid, and carbohydrate metabolism • Counters effects of insulin • Involved in tissue repair • May participate in growth and function of immune system • Levels increase after variety of stressful stimuli (cardiac catheterization, electroshock therapy, gastroscopy, surgery, fever, physical exercise) • Increased levels associated with psychological

Hormone	Source	Action
		stimuli (taking examinations, viewing violent or sexually arousing films, participating in certain psychological performance tests) • Prolonged stress (chronic stress) suppresses growth hormone
Prolactin	Anterior pituitary gland; numerous extrapituitary tissue sites	• Increases in response to many stressful stimuli (including such procedures as gastroscopy, proctoscopy, pelvic examination, and surgery); increased for in situ breast cancer • Requires more intense stimuli than those leading to increases in catecholamine or cortisol levels • Levels show little change after exercise
Oxytocin	Hypothalamus	• Promotes bonding and social attachment • In animals associated with reduced hypothalamic-pituitary-adrenal (HPA)

Hormone	Source	Action
		activation levels and reduced anxiety

Hormone	Source	Action
Testosterone	Leydig cells in testes	• Regulates male secondary sex characteristics and libido • Levels decrease after stressful stimuli (anesthesia, surgery, marathon running, mountain climbing) • Decreased by psychological stimuli; however, some data indicate that psychological stress associated with competition (e.g., pistol shooting) increases both testosterone and cortisol levels, especially in athletes older than 45 years of age • Markedly reduced in individuals with respiratory failure, burns, and congestive heart failure • Decreased levels occur during aging and are associated with lowered cortisol responsiveness to stress-induced inflammation
Estrogen	Ovaries	

Hormone	Source	Action
		• Works in concert with oxytocin, exerting calming effect during stressful situations
Melatonin	Produced by pineal gland	• Increases during stress response; release is suppressed by light and increased in dark; receptors have been identified on lymphoid cells, possibly higher density of receptors on T cells than on B cells; suppression of lymphocyte function by trauma was reversed by melatonin
Somatostatin (SOM)	Produced by sensory nerve terminals found in and released from lymphoid cells and hypothalamus	• Natural killer (NK) cell function and immunoglobulin synthesis decreased by SOM; growth hormone secretion decreased by SOM
Vasoactive intestinal peptide (VIP)	Found in neurons of central nervous system (CNS) and in peripheral nerves	• VIP increases during stress; VIP-containing nerves are located in both primary and secondary lymphoid tissues, around blood vessels, and in gastrointestinal tract; VIP

Hormone	Source	Action
		receptors are on both T and B cells; VIP may influence lymphocyte maturation; cytokine production by T cells is modified by VIP; B-cell and antibody production is influenced by VIP
Calcitonin gene–related peptide (CGRP)	Found in spinal cord motor neurons and in sensory neurons near dendritic cells of skin and in primary and secondary lymphoid tissues	• CGRP receptors are present on T and B lymphocytes; thus it is likely that CGRP can modulate immune function; CGRP may enhance acute inflammatory response because it is vasodilator; maturation of immune B lymphocytes is inhibited by CGRP; interleukin-1 is inhibited by CGRP, which is important for activation of T cells; it has been shown to interfere with lymphocyte activation
Neuropeptide Y (NPY)	Present in neurons of CNS and in neurons throughout body; colocalized in nerve terminals in lymphatic tissues with norepinephrine	• Lymphocytes have receptors for NPY and thus may modulate their function; several lines of evidence suggest that NPY is neurotransmitter and neurohormone involved in stress

Hormone	Source	Action
		response; increased levels of NPY occur in plasma in response to severe or prolonged stress; may be responsible for stress-induced regional vasoconstriction (splanchnic, coronary, and cerebral); may also increase platelet aggregation. May be important in preventing depression.
Substance P (SP)	Produced by neuropeptide classified as tachykinin (increases heart rate subsequent to lowering blood pressure) found in brain, as well as nerves innervating secondary lymphoid tissues	• SP increases in response to stress; receptors for SP are found on membranes of both T and B cells, mononuclear phagocytic cells, and mast cells; proinflammatory activity induces release of histamine from mast cells during stress response; causes smooth muscle contraction, causes macrophages and T cells to release cytokines, and increases antibody production

Hormone	Source	Action
β-Endorphins (endogenous opiates)	Pituitary and hypothalamus	• Activates endorphin (opiate) receptors on peripheral sensory nerves, leading to pain relief or analgesia • Hemorrhage increases levels to inhibit blood pressure or delay compensatory changes that would increase blood pressure
Growth hormone (GH, somatotropin)	Anterior pituitary gland	• Affects protein, lipid, and carbohydrate metabolism • Counters effects of insulin • Involved in tissue repair • May participate in growth and function of immune system • Levels increase after variety of stressful stimuli (cardiac catheterization, electroshock therapy, gastroscopy, surgery, fever, physical exercise) • Increased levels associated with psychological stimuli (taking examinations, viewing violent or sexually arousing films, participating in certain psychological performance tests) • Prolonged stress (chronic stress) suppresses growth hormone
Prolactin	Anterior pituitary gland; numerous extrapituitary tissue sites	• Increases in response to many stressful stimuli (including such procedures as gastroscopy, proctoscopy, pelvic examination, and surgery); increased for in situ breast cancer • Requires more intense stimuli than those leading to increases in catecholamine or cortisol levels • Levels show little change after exercise
Oxytocin	Hypothalamus	• Promotes bonding and social attachment • In animals associated with reduced hypothalamic-pituitary-adrenal (HPA) activation levels and reduced anxiety
Testosterone	Leydig cells in testes	• Regulates male secondary sex characteristics and libido • Levels decrease after stressful stimuli (anesthesia, surgery, marathon running, mountain climbing) • Decreased by psychological stimuli; however, some data indicate that psychological stress associated with competition (e.g., pistol shooting) increases both testosterone and cortisol levels, especially in athletes older than 45 years of age • Markedly reduced in individuals with respiratory failure, burns, and congestive heart failure • Decreased levels occur during aging and are associated with lowered cortisol responsiveness to stress-induced inflammation
Estrogen	Ovaries	• Works in concert with oxytocin, exerting calming effect during stressful situations

Hormone	Source	Action
Substance P (SP)	Produced by neuropeptide classified as tachykinin (increases heart rate subsequent to lowering blood pressure) found in brain, as well as nerves innervating secondary lymphoid tissues	• SP increases in response to stress; receptors for SP are found on membranes of both T and B cells, mononuclear phagocytic cells, and mast cells; proinflammatory activity induces release of histamine from mast cells during stress response; causes smooth muscle contraction, causes macrophages and T cells to release cytokines, and increases antibody production

The Autonomic Nervous System

Sympathetic and Parasympathetic Nervous Systems

Activation of the SNS induces rapid release of **catecholamines (CAs)**, particularly norepinephrine, especially from sympathetic nerve terminals, and **epinephrine**, from the medulla of the adrenal gland. Sympathetic nerves also contain nonadrenergic mediators that amplify or antagonize the effects of adrenal CAs. CAs work in concert with the ANS to regulate the cardiovascular, pulmonary, hepatic, skeletal muscle, and ISs.

The parasympathetic system balances the SNS and thus also influences adaptation or maladaptation to stressful events. The parasympathetic system generally opposes the sympathetic system; for example, the parasympathetic nervous system slows the heart rate. The parasympathetic system also has antiinflammatory effects.

CAs stimulate two major classes of receptors: α-adrenergic receptors (α1 and α2) and β-adrenergic receptors (β1 and β2). Table 11.4 summarizes the actions of the two subclasses of adrenergic receptors. (A discussion of receptors can be found in Chapters 1, 15, and 21.) Epinephrine binds with and activates both α and β receptors, whereas norepinephrine binds primarily with α receptors.

Table 11.4

Physiologic Effects of Catecholamines

Organ/Tissue	Process or Result
Brain	Increased blood flow; increased glucose metabolism
Cardiovascular system	Increased rate and force of contraction
	Peripheral vasoconstriction
Pulmonary system	Bronchodilation
Skeletal muscle	Increased glycogenolysis
	Increased contraction
	Increased dilation of muscle vasculature
	Decreased glucose uptake and utilization (decreases insulin release)
Liver	Increased glucose production
	Increased glycogenolysis
Adipose tissue	Increased lipolysis
	Decreased glucose uptake
Skin	Decreased blood flow
Gastrointestinal and genitourinary tracts	Decreased protein synthesis
	Decreased smooth muscle contraction
	Increased renin release
	Increased gastrointestinal sphincter tone
Lymphoid tissue	Acute as well as chronic stress inhibits several components of innate immunity, particularly decreasing natural killer cells
Macrophages	Inhibit and stimulate macrophage activity

Organ/Tissue	Process or Result
	Depends on availability of type 1/proinflammatory cytokines, presence or absence of antigenic stressors, and peripheral corticotropin-releasing hormone (CRH)

Organ/Tissue	Process or Result
Brain	Increased blood flow; increased glucose metabolism
Cardiovascular system	Increased rate and force of contraction
	Peripheral vasoconstriction
Pulmonary system	Bronchodilation
Skeletal muscle	Increased glycogenolysis
	Increased contraction
	Increased dilation of muscle vasculature
	Decreased glucose uptake and utilization (decreases insulin release)
Liver	Increased glucose production
	Increased glycogenolysis
Adipose tissue	Increased lipolysis
	Decreased glucose uptake
Skin	Decreased blood flow
Gastrointestinal and genitourinary tracts	Decreased protein synthesis
	Decreased smooth muscle contraction
	Increased renin release
	Increased gastrointestinal sphincter tone
Lymphoid tissue	Acute as well as chronic stress inhibits several components of innate immunity, particularly decreasing natural killer cells
Macrophages	Inhibit and stimulate macrophage activity
	Depends on availability of type 1/proinflammatory cytokines, presence or absence of antigenic stressors, and peripheral corticotropin-releasing hormone (CRH)

Some of these responses require glucocorticoids (e.g., cortisol) for maximal activity (see text for explanation).

Data from Elenkov IJ, Chrousos GP. Stress hormones, proinflammatory and antiinflammatory cytokines, and autoimmunity. *Annals of the New York Academy of Sciences*, 2002;966:290–303; Granner DK. Hormones of the adrenal medulla. In Murray RK, et al., eds. *Harper's biochemistry*, 25th edition. New York: McGraw-Hill; 2000.

Epinephrine in the liver and skeletal muscles is rapidly metabolized. Epinephrine influences cardiac action by enhancing myocardial contractility (inotropic effect), increasing heart rate (chronotropic effect), and increasing venous return to the heart, ultimately increasing both cardiac output and blood pressure. Epinephrine dilates blood vessels to

allow greater oxygenation to skeletal muscles and also mobilizes free fatty acids and cholesterol.

CAs cannot cross the blood-brain barrier (BBB) and are synthesized and secreted in the brain to promote arousal, increase vigilance, facilitate anxiety, and other emotional responses.

Pathophysiologic Effects of Catecholamines

CA secretion increases proinflammatory cytokine production, which elevates heart rate and blood pressure and impairs wound healing. Chronic stress-induced release in norepinephrine contributes to the production of inflammatory leukocytes that adhere to vessel walls and promote the development of *plaque* (see Chapter 32).[23] Proteases released from these inflammatory leukocytes increase the risk of myocardial infarction and stroke by weakening the fibrous cap of the plaque, which can promote plaque rupture. In addition to a stress-induced risk of cardiovascular disease, the effects of stress on elevated inflammatory cytokine production also influence the onset of depression and autoimmune disorders and may facilitate functional decline that leads to frailty, disability, and untimely death. Stress-induced excessive levels of inflammatory cytokines during infection or inflammatory illness may activate a collection of nonspecific symptoms (e.g., fever, elevated HPA hormone secretion, loss of appetite, and loss of interests in physical and social activities) called the "sickness syndrome."[24] Finally, stress-induced CAs may promote tumor development by modulating the microenvironment.[25]

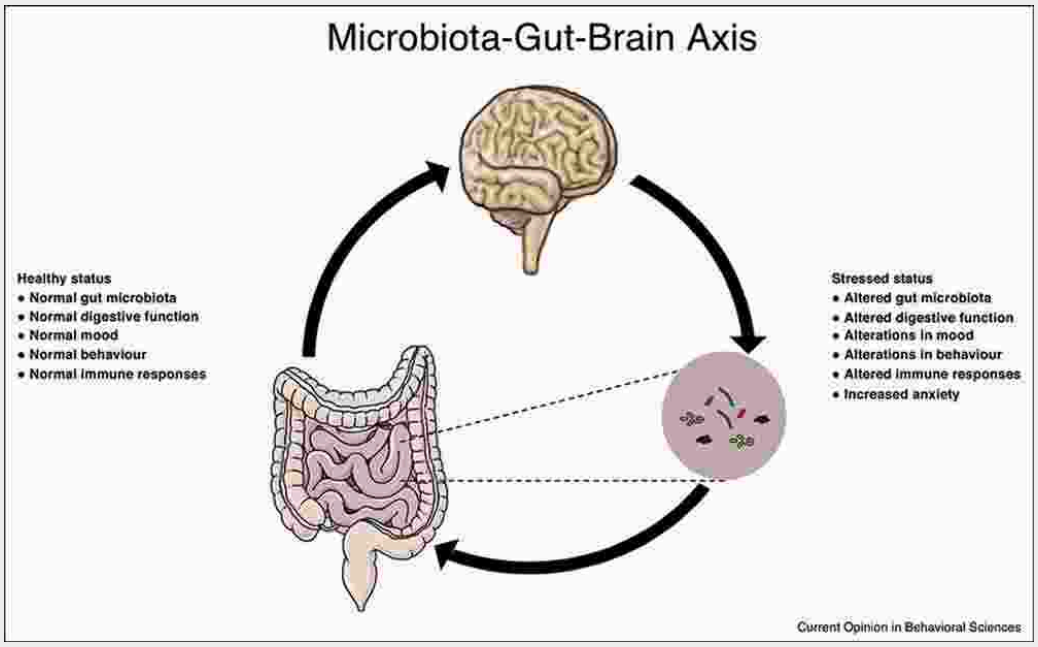
Role of the Immune System

The immune, nervous, and endocrine systems communicate through similar (and highly complex) pathways using hormones, neurotransmitters, neuropeptides, and immune cell products. Various components of IS responses are affected by neuroendocrine-produced factors involved in the stress reaction. Several pathways regulate communication among these systems (Fig. 11.8). The human gut microbiome also plays a role in stress and physiologic processes related to the immune response (see Emerging Science Box: The Gut Microbiota in Stress, Inflammation, and Disease).

Emerging Science Box The Gut Microbiota in Stress, Inflammation, and Disease

The human gut microbiota consists of trillions of bacteria and plays an important role in physiologic processes, including interactions with the host immune system and the brain. In addition, it plays a role in stress by modulating the intestinal barrier permeability and the gut-brain axis signaling through the vagal nerve, inflammatory molecules, endocrine molecules, and microbial metabolites.

A stable gut microbiota promotes normal gut physiology and contributes to appropriate physiologic functions along the microbiota-brain-gut axis to maintain the healthy status of the individual (see Figure below). Conversely, intestinal dysbiosis, or the imbalance in the gut microbial community, adversely impacts gut physiology leading to inappropriate brain-gut axis signaling and the progression to disease states. Examples of intestinal dysbiosis include *Clostridioides difficile* infection (infectious disease), inflammatory bowel disease (intestinal immune-mediated disease), obesity (metabolic disease), colorectal cancer, and autism spectrum disorder (neuropsychiatric disorder).



(Figure from Hollins SL, et al. Stress, microbiota, and immunity. *Current Opinion in Behavioral Sciences*, 2019;28:66–71. ISSN 2352–1546. https://doi.org/10.1016/j.cobeha.2019.01.015.)

An illustration represents the microbiota-gut-brain axis. The illustration a cycle connecting the gut, the brain, and the microbiome. The following statuses are classified as healthy: • Normal gut microbiota. • Normal digestive function. • Normal mood. • Normal behavior. • Normal immune responses. The following statuses are classified as unhealthy: • Altered gut microbiota. • Altered digestive function. • Alterations in mood. • Alterations in behavior. • Altered immune responses. • Increased anxiety.

The gut microbiota signals the brain through a number of pathways including regulating immune activity and proinflammatory cytokines that stimulate the hypothalamic-pituitary-adrenal (HPA) axis to produce corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol. The gut microbiota also can directly impact central

nervous system (CNS) immune activity through release of short-chain fatty acids (SCFAs), such as propionate, butyrate, and acetate, as well as tryptophan metabolites including kynurenic acid and quinolinic acid. Neuronal and spinal pathways, particularly afferent signaling from the vagus nerve, are critical in mediating the effect of the gut microbiota on brain function and behavior.

Good bacteria probiotics act to stabilize digestive pH, reduce inflammation, and increase neuroprotective molecules, such as brain-derived neurotrophic factor (BDNF). Impaired microbiota dysbiosis can induce neuroinflammation and reduce the expression of BDNF and N-methyl-D-aspartate receptor (NMDA) receptors, leading to cognitive impairment, mood disorders, and higher levels of amyloid beta formation.

A study in mice reported that stress worsens inflammation in the colon and the composition of the microbiome changes. Levels of SCFAs, which play a major role in maintaining normal gut and immune function by regulating colonic motility, blood flow, and gastrointestinal pH, were found to decrease when stress and the expression of the receptors also changed. Furthermore, when mice were stressed and infected with *Citrobacter rodentium*, a gram-negative bacterium that causes mild/moderate inflammation in the descending colon, colonic expression of the SCFA receptor GPR41 was positively associated with inflammatory cytokines and colonic histopathology scores. The results show that stress altered the microbiome, which in turn increased the level of colonic inflammation. This mouse model may have relevance to irritable bowel disease in humans.

Other research on the effects of stress on the gut lining examines how increased intestinal permeability plays a role in chronic diseases, such as celiac and Crohn disease. When the gut lining is compromised *(leaky gut)*, partially digested foods, bacteria, and toxins now penetrate the barrier and leak into the body and blood stream to trigger inflammation.

Another relevant study examined the effects social stress or marital discord on inflammatory markers associated with the leaky gut. They found that men and women who engage in hostile behavior toward each other had high serum levels of lipopolysaccharide-binding protein (LPB), which indicates the presence of bacteria in the blood. The leaky gut LPB was even greater in participants who were particularly hostile to their spouse and with a history of depression or another mood disorder. Furthermore, a strong relationship was found between LPB and C-

reactive protein, a primary marker of inflammation. Individuals with the highest LBP had 79% higher levels of C-reactive protein compared to people who were not in hostile marital relationships. Of note, depressed people also may have a history of cardiovascular disease, metabolic syndrome, and/or diabetes. The results now demonstrate a link between marital discord and the leaky gut pathway leading to a proinflammatory state with implications on mental and physical health.

FIG. 11.8 Neurophysiologic Pathways Linking Perceived Threat to Inflammation.
Neurophysiologic pathways linking stress or threat-related neural activity in the amygdala, medial prefrontal cortex, and hippocampus with the hypothalamic-pituitary-adrenal *(HPA)* axis, the autonomic nervous system *(ANS)*, and immune cells that increase inflammation. Threat perception activates the HPA axis, leading to increased release of the glucocorticoid hormone cortisol from the adrenal glands *(broken lines)*. In addition, activation of the sympathetic arm of the ANS leads to increased release of the catecholamine epinephrine and norepinephrine *(solid lines)*. Cortisol and catecholamines bind to receptors on immune cells to increase synthesis and release of cytokines, including interleukin-1β *(IL-1β)*, interleukin-6 *(IL-6)*, and tumor necrosis factor-α *(TNF-α)*, which serve adaptive roles in protecting the body from disease. However, when chronic stress-induced cortisol secretion occurs, the glucocorticoid receptor *(GR)* becomes downregulated and limits the antiinflammatory effects of cortisol. In addition, the expression of proinflammatory genes is increasingly expressed that heighten the secretion of proinflammatory cytokines. Altogether these effects ultimately lead to elevated inflammation that increases the risk of disease. (From O'Donovan A, Slavichc GM, Epela ES, et al. Exaggerated neurobiological sensitivity to threat as a mechanism linking anxiety with increased risk for diseases of aging. *Neuroscience and Biobehavioral Reviews*, 2013;37:96–108.)

An illustration shows the neurophysiologic pathways linking perceived threat to inflammation. The illustration shows the right lateral view of the brain, labeling the following parts: amygdala, hypothalamus, hippocampus. Medial prefrontal cortex, and pituitary gland. When a threat is perceived H P A is activated, releasing cortisol from the adrenal glands. Additionally, A N S is activated,

releasing N E or epinephrine from the adrenal glands. N E, epinephrine, and cortisol are attracted to the G R embedded in the lipid bilayer of the immune cell. I L-1 beta, I L-6, and T N F-alpha are released from the immune cell. Protein in the D N A in the nucleus is labeled.

Effects of Acute and Chronic Stress on the Immune System

Stress-induced secretion of HPA hormones and CAs by the sympathetic branch of the ANS directly influences the IS. Immune cells have receptors for ACTH, CRH, endorphins, norepinephrine, growth hormone, steroids, and other products of the stress response. In addition, cholinergic, adrenergic, and peptidergic nerves innervate lymphoid organs, such as the thymus, spleen, lymph nodes, and bone marrow. Exposure to stress increases endogenous opiate secretion, which can modulate immune cell function.[26]

Lymphocytes also produce ACTH and endorphins in small amounts that influence the immune response in an autocrine (same cell stimulation) or paracrine (cell to cell) manner in ongoing immune and memory cytotoxic responses. The T-cell growth factor IL-2 can upregulate pituitary ACTH. Immune-derived cytokines have direct and indirect effects on HPA and adrenal cell functions. Thus the IS has an adaptive role as a signal organ to alert other systems of internally threatening stimuli (e.g., pathogens, infection, tissue damage, tumor cells). The release of immune inflammatory mediators (e.g., IL-6, TNF-β, interferon [IFN]) is triggered by bacterial or viral infections, cancer, tissue injury, and other stressors, which, in turn, initiate a stress response through the HPA pathway. Enhanced systemic production of these cytokines also induces other central nervous system (CNS) and behavior changes during an acute inflammatory infectious episode.

It is important to recognize that inflammation is considered to be beneficial in the short term by destroying pathogens and facilitating the healing process. However, chronic low-grade systemic inflammation characterized by prolonged secretion of proinflammatory cytokines is associated with cardiovascular disease, osteoporosis, arthritis, type 2 diabetes mellitus, chronic obstructive pulmonary disease (COPD), and diseases associated with aging (Fig. 11.9). Prolonged severe stress may lead

to enlargement of the adrenal gland with simultaneous involution of the thymus and lymph nodes. Chronic stress secretion of GCs impacts many immune cell functions, including decreased natural killer (NK) cell and T-cell cytotoxicity and impaired β-cell function. Thus prolonged secretion of cortisol is an important mechanism underlying stress-related immune structure alterations, suppression of the immune response, and chronic inflammation.[27]

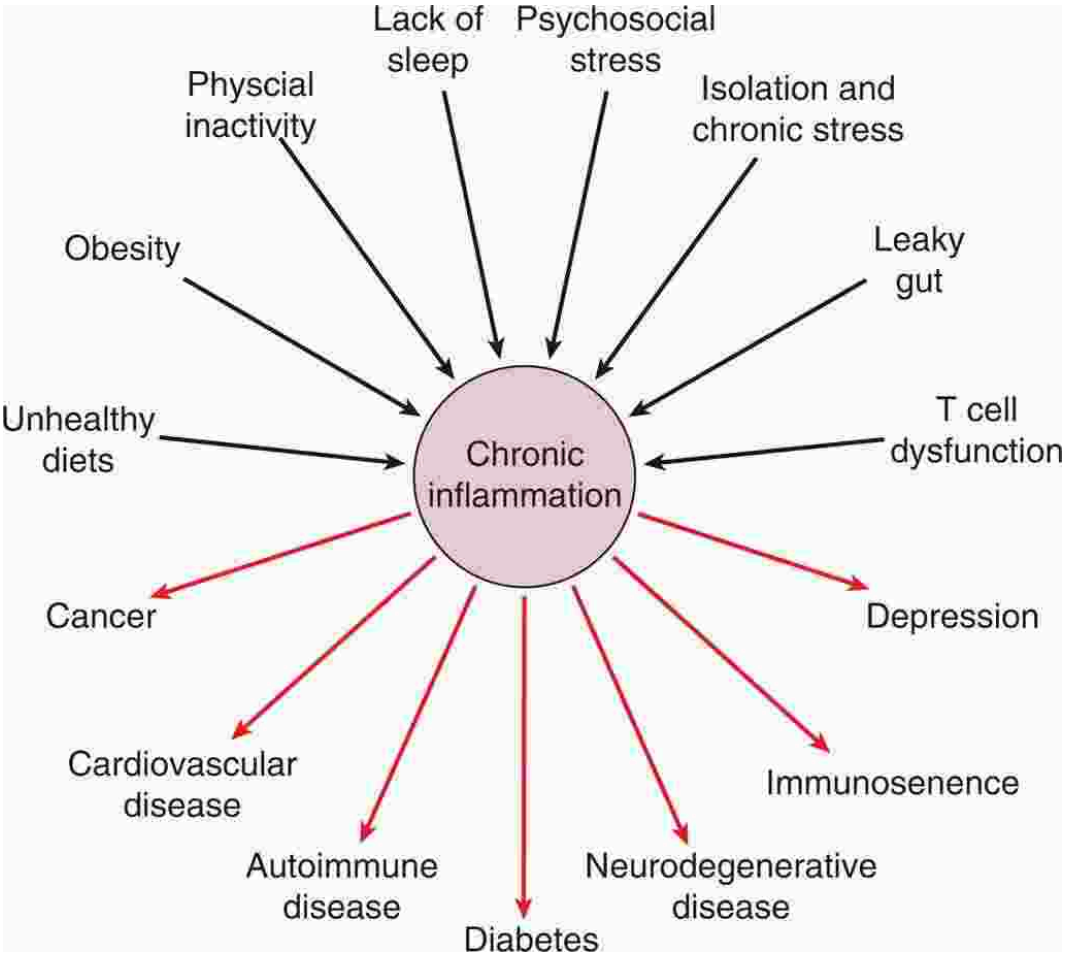

FIG. 11.9 The Broad Negative Health Effects of Inflammation on the Body and Brain.
Numerous factors, including unhealthy diets, obesity, physical inactivity, lack of sleep, stress, social isolation, leaky gut, and T-cell dysfunction, contribute to a chronic inflammatory state. Currently, chronic inflammation is recognized as a common underlying condition leading to pathology and a diverse set of illnesses, such as autoimmune disease, cancer, cardiovascular disease, neurodegenerative disease, diabetes, immunosenescence, and depression.

An illustration lists the stressors to and responses of chronic inflammation. Stressors: Unhealthy diets, obesity, physical inactivity, lack of sleep, psychosocial stress, isolation and chronic stress, leaky gut, and T cell

dysfunction. Responses: Cancer, cardiovascular disease, autoimmune disease, diabetes, neurodegenerative disease, immunosenescent, and depression.

The elevation in inflammation levels also stems from chronic stimulation of the SNS and the gradual downregulation of key antiinflammatory pathways, such as the HPA axis and the parasympathetic nervous system. Studies show that psychosocial stress-induced modulation of lymphoid and myeloid cells and chronic inflammation by cytokines, such as IL-6, are implicated in cancer progression, metastasis, and recurrence.

Stress-induced SNS release of CAs and activation of β-adrenergic receptor (β-AR) are implicated in primary tumor growth and metastasis and colonization of tumors in distant tissues.[25,28] For example, inflammatory factors such as IL-6 are regulated by β-AR signaling and increase in circulation after stressor exposure. IL-6 and associated gene polymorphisms of IL-6 are prognostic indicators of tumor progression, metastasis, and survival in human cancers. Peripheral immune cells which are responsive to β-AR signaling and secrete IL-6 and other regulatory factors reside within and around the tumor microenvironment and can promote or prevent malignant disease.[29] Inflammatory cell recruitment into the primary tumor microenvironment may serve as a biomarker for early detection of disease progression or serve as a prognostic indicator of therapeutic success and resolution of disease.

Microglia activation in the brain is an important component of neuroinflammation. Microglia are resident immune cells in the brain. If injury or infection occurs, the microglia play an active protective role in protecting the brain tissues. Microglia also are involved in the pruning and maintenance of synapses, trafficking of neurotransmitters, and phagocytosis or the removal of cell fragments and damaged cells. However, excessive stress and microglia activation that increase cytokine production may compromise the tightly controlled BBB and allow cytokines and leukocytes to enter the brain from the periphery.

The resultant inability to control inflammatory cells in the brain has the potential to impair adaptive brain functions. Stress-induced inflammation by microglia disrupts corticoamygdala and corticobasal ganglia neural circuits that balance positive and negative states, and predisposes people to negative thinking and to engage in self-medicating behaviors such as

smoking, drug use, and consumption of high-fat diets. Repetitive negative thinking has been linked to the development of dementia (see Emerging Science Box: Repetitive Negative Thinking is a Risk Factor for Alzheimer Disease). Depression has been linked to stress-induced inflammation.[11,12,30] This link may explain the high prevalence of depression in association with other chronic inflammatory conditions such as heart disease (see Emerging Science Box: Stress and Inflammation Are Causal Factors Linking Heart Disease with Depression).

Emerging Science BoxRepetitive Negative Thinking Is a Risk Factor for Alzheimer Disease

A recent observational study reported that repetitive negative thinking (RNT) is a potential risk factor for dementia. RNT is defined as a cognitive process that involves persistent worrying and ruminating thoughts. Previous research showed that depression and anxiety are risk factors for dementia and people diagnosed with depression and anxiety exhibit chronic negative thinking. However, the precise relationship between RNT and dementia was not clear. The current study demonstrated that people with high levels of RNT experiences were more likely to show both decline in global cognition and episodic memory within a 4-year period and aggregation of amyloid and tau deposits, the neuropathologic markers of Alzheimer disease.

The researchers suggest that RNT elevates stress factors such as high blood pressure which can contribute to onset of amyloid and tau deposition. In addition, the researchers propose that behavioral interventions known to reduce RNT, such as mindfulness therapy could be used to investigate its benefits on decreasing cognitive deficits and neuropathologic markers of Alzheimer disease.

Data from Marchant NL, et al. Repetitive negative thinking is associated with amyloid, tau, and cognitive decline. *Alzheimer's and Dementia*, 2020;16(7):1054–1064. https://doi.org/10.1002/alz.12116.

Emerging Science BoxStress and Inflammation are Causal Factors Linking Heart Disease with Depression

The association between heart disease and stress-induced depression is well known, but the underlying basis of these illnesses is unclear. Are people with heart disease more likely to develop depression, or are depressed people more likely to show an increased risk of heart disease? Are there similar genetic or environmental factors in people who develop heart disease and depression?

A recent study involving 367,703 unrelated, middle-aged participants of European ancestry found that the link between the two disorders could not be explained entirely by genetic factors. That is, a genetic risk score strongly associated with heart disease was not associated with depression. Instead, a Mendelian randomization analyses showed that triglycerides, interleukin-6 (IL-6), and C-reactive protein (CRP) were found in high levels in people with both heart disease and depression. IL-6 and CRP are both inflammation-related proteins occurring in response to various damaging stimuli, including smoking, infection, and stress. The findings suggest that stress-induced inflammation, a common biologic mechanism occurring in both the cardiovascular system and brain, is a causal risk factor linking comorbidity in depression and heart disease.

Data from Khandaker GM, et al. Shared mechanisms between coronary heart disease and depression: Findings from a large UK general population-based cohort. *Molecular Psychiatry*, 2020;25:1477–1486.

The Impact of Chronic Stress Across the life Span

The deleterious effects of chronic stress can foster pathophysiologic changes that impact health and disease across the life span. These negative effects may begin before birth and extend into the aging process later in life.

Negative Effects of Chronic Stress at an Early Age

Human brain development begins from the fetal period to the neonatal period, infancy, childhood, adolescence, and early adulthood. Throughout this developmental time span, the brain is undergoing a host of critical changes, such as cell proliferation, cell migration, differentiation, and eventual synaptic maturation, and neuronal connections and functioning. These dynamic changes in the development of stress-responsive systems and brain structures, including the amygdala, hippocampus, and prefrontal cortex, can be significantly impacted by the effects of early stress. Changes

in these systems may induce pathophysiologic, cognitive, motivational, emotional, and genetic alterations that become embedded and thus impact health and the risk of disease later in life.[19,31]

Many epidemiologic studies show that stress in women during pregnancy has the potential to adversely affect the early development of a child.[15] Prenatal stress also increases the incidence of spontaneous abortions, fetal malformations, and preterm birth and impairs the intellectual, language, and emotional development of a child. Other studies reported increased propensity to acquire cardiovascular and metabolic disorders in later life.[18] Prenatal stress is a predicator of low birth weight associated with a higher risk of depression during adolescence and adulthood.

Activation of the HPA axis and release of cortisol is suggested to be a major source mediating the negative effects of maternal stress on the fetus. High levels of stress-induced maternal cortisol secretion could cross the placental barrier and enter the fetus to alter brain development and the HPA axis.[31] Convincing data point to high maternal cortisol, a key biomarker of stress, during pregnancy with low birth weight. The consequences of cortisol-induced low birth weight have extended to disease risk in later life, including overweight/obesity, cardiovascular conditions (e.g., hypertension), and behavioral disorders attributed to altered brain structures and epigenetic modifications (i.e., changes in gene expression). Allostatic overload of elevated GC secretion in early life potentially compromises the well-being of the individual throughout life.

The fetus exposed to elevated levels of proinflammatory cytokines also is at risk of developing a range of neurodevelopmental disorders. Excessive exposure to proinflammatory cytokines has the potential to alter brain morphology in the prenatal period, which compromises cognitive functioning in late life. An example is maternal obesity during gestation, which produces an inflammatory state linked to offspring neurodevelopmental alterations that predict insulin resistance, an elevated body mass index (BMI), and increased risk of attention-deficit/hyperactivity disorder.[32]

The caregiving environment is believed to support and protect the child and buffer the potential effects of stress on altering the development of stress systems. However, allostatic overload or a chronic proinflammatory state induced by psychosocial stress in early life may promote dysregulation of the HPA and ANS and predispose an individual to show

increased hypervigilance to threat, poor emotional regulation, and increased health risk behaviors (e.g., poor dietary choices, risky behaviors). Childhood trauma involving physical, sexual, and emotional abuse or neglect is associated with psychiatric illnesses, including depression, anxiety, and PTSD, and with health problems, such as rheumatoid arthritis, cardiovascular disease, metabolic syndrome, and cancer. Studies have reported that exposure to childhood trauma was associated with elevated baseline levels of peripheral C-reactive protein (CRP), TNF-α, and the cytokine IL-6 in adulthood.[33,34] This chronic inflammatory state may be the culprit contributing to the development of both physical and mental disorders observed in adults exposed to childhood trauma.

A well-documented risk factor linked to chronic stress and poor health is low SES.[35] Families with low SES are exposed to a host of stressors, such as financial unpredictability, household chaos and violence, noisy neighborhood environment, and disruption of family routines, all of which contribute to an increase in stress for both parents and children. Socioeconomically disadvantaged young children exhibit elevated levels of cortisol and mental illness. Children living in lower-SES households and from racial/ethnic minorities also are at risk of age-related diseases widely linked to cardiometabolic morbidity and mortality.[36] Chronic childhood adversity–induced activation of the HPA axis affects GC metabolism and immune function, which predispose individuals to chronic inflammation, as indicated by elevations in IL-6, the proinflammatory CRP; fibrinogen; and other biomarkers associated with cardiometabolic disease.[34] Of further interest, people living below the poverty level and have low education exhibit CRP levels nearly twice the value in those living above the poverty level. Early life adversity and associated stress impacts brain development. For example, people who suffered from maltreatment in childhood show greater amygdala reactivity to threat. In addition, functional connectivity is altered between brain areas (i.e., amygdala) responsible for threat detection and connective brain areas (prefrontal cortex) responsible for cognitive regulation and coping to threat responses.[37] Childhood poverty is linked with deficits in executive function through stress-related structural changes in the prefrontal cortex.[38] Impairments in executive functioning may compromise the ability to manage psychosocial functions including social relationships, emotions, and ability to cope with stress. As a result, these cognitive impairments increase the risk for developing the symptoms of anxiety, depression, and other health-related problems.[39]

Depending on the temporal developmental periods when the child is exposed to stress, brain development may occur in different ways that affect cognitive and mental health issues. Exposure to negative stressful experiences, such as illness or parental separation, occurring from age 0 to 5 years was associated with faster maturation of the prefrontal cortex and amygdala during puberty. These parts of the brain are responsible for personality expression, decision-making, moderating social behavior, and expressing emotions. Thus, although early-life stress accelerates brain maturation during adolescence, the rapidly maturing brain may compromise the effects of adaptive developmental plasticity, which may lead to subsequent mental and physical disorders.

Telomeres are DNA-based caps located at the end of chromosomes. These end-caps protect genetic information and degradation during cell division. Telomeres shorten during repeated cell divisions over time and are an indication of biologic aging. Stress has a major influence on telomere shortening that can begin in utero by increasing early telomere damage. Maternal stress during pregnancy and childhood adversity are reported to impact telomere length during the periods of exposure as well as later in life.[40,41] Children who experienced cumulative exposures to violence, poverty, and traumatic life events showed significantly more telomere erosion prior to puberty, even after adjusting for confounding factors.[42]

Another consequence of childhood stress is an accelerated increase in BMI.[43] Stress triggers the secretion of the neurohormone ghrelin, which increases appetite, food-seeking behavior, and food-associated reward. Children exposed to chronic stress also are deficient in leptin, a hormone involved in the regulation of energy balance. The imbalance in physiologic factors that normally regulate body weight likely contributes to the onset of obesity in children. Exposure to maternal stress also may increase the risk of childhood overweight/obesity, which may be caused by epigenetic modifications (i.e., DNA methylations cause changes in gene expression).[44] In summary, exposure to early stress disrupts a number or adaptive regulatory systems in the body and brain which increases risk of disease in later life.

Negative Effects of Chronic Stress in Adolescents and Adults

Social or personal stress occurring at a later age may produce a different developmental trajectory. From age 14 to 17 years, adolescents who were ridiculed or disliked by their peers showed reduced gray matter volume in different parts of the brain, including the prefrontal cortex and the hippocampus, which is responsible for memory. In addition, gray matter volume of the anterior cingulate was reduced and may be related to the higher incidence in antisocial traits reported at these ages. Callous, unemotional behavior occurring at this time may be linked to the future development of psychopathy.[45]

Stress-induced developmental alterations in these neural circuits may sensitize the individual to thoughts or situations as threatening and increase the activation of stress systems and their negative consequences. Stress-induced structural changes in the prefrontal cortex may impair working memory, executive function, attention, self-awareness, and inhibitory or impulse control. Overtime, the growing child may be less likely to develop cognitive, behavioral, and self-regulatory control of emotions that enable them to manage and adapt to stress.

In adults, telomere shortening or attrition linked to biologic aging can be accelerated by a number of conditions associated with stress-induced inflammation. Adults who experienced childhood adversity or allostatic load exhibited higher inflammatory markers (IL-6, TNF-α) and shorter telomere length.[40] Shorter telomere length found in white blood cells reflects an increased risk of aging-related morbidity and mortality. Research showed that adults with telomeres in the shortest category had 25% greater early risk of death compared with those in the longest telomere category.[46]

A clear example of the effects of chronic psychosocial stress in adults is burnout, a syndrome associated with a number of negative consequences to workers' well-being and health. Uncontrolled work stress is a significant predictor of adverse physical consequences, including hypercholesterolemia, type 2 diabetes, coronary heart disease, and hospitalization caused by a cardiovascular disorder, musculoskeletal pain, changes in pain experiences, prolonged fatigue, headaches, gastrointestinal issues, respiratory problems, severe injuries, and early mortality at age younger than 45 years. Potential mechanisms contributing to burnout include dysregulation of the HPA axis and ANS, which are accompanied by impaired immune function and inflammation.[47] These interrelated stress systems increase the risk of adopting poor health choices (e.g., smoking,

lack of physical activity and sleep, bad eating habits) that make the individual vulnerable to infectious disease, such as flu-like illnesses, the common cold, and gastroenteritis.

Similar to burnout, social isolation and loneliness are becoming increasingly common in older people who are living longer and with reduced social interactions. Loneliness is associated with chronic stress that activates the hypothalamic-pituitary-adrenocortical axis and the SNS. Prolonged activation of these stress systems leads to GC resistance and compromises the IS to protect the body and brain, which increases the risk of many health issues, including heart disease, high blood pressure, diabetes, and dementia. Furthermore, loneliness increases the risks of morbidity and mortality similar to cardiovascular disease, smoking, obesity, depression, and cognitive decline. The World Health Organization recognizes the importance of social connections, and research points to a growing epidemic of loneliness in many countries, which can have serious health and economic effects in the years to come.[48,49]

Coping and Intervention Strategies

Coping is the process of managing stressful challenges that impact the individual's resources.[50] Coping responses may be adaptive or maladaptive, and the extent to which an individual responds to distress using effective positive coping strategies will determine the degree of successful moderation of the stress challenge (Fig. 11.10). Personality characteristics, such as academic achievement, motivation, optimism, and aggression are associated with differences in appraisal and response to stressors. These personality characteristics may facilitate or impede the efficacy of interventions for preventing disease and managing illness in a clinical setting.

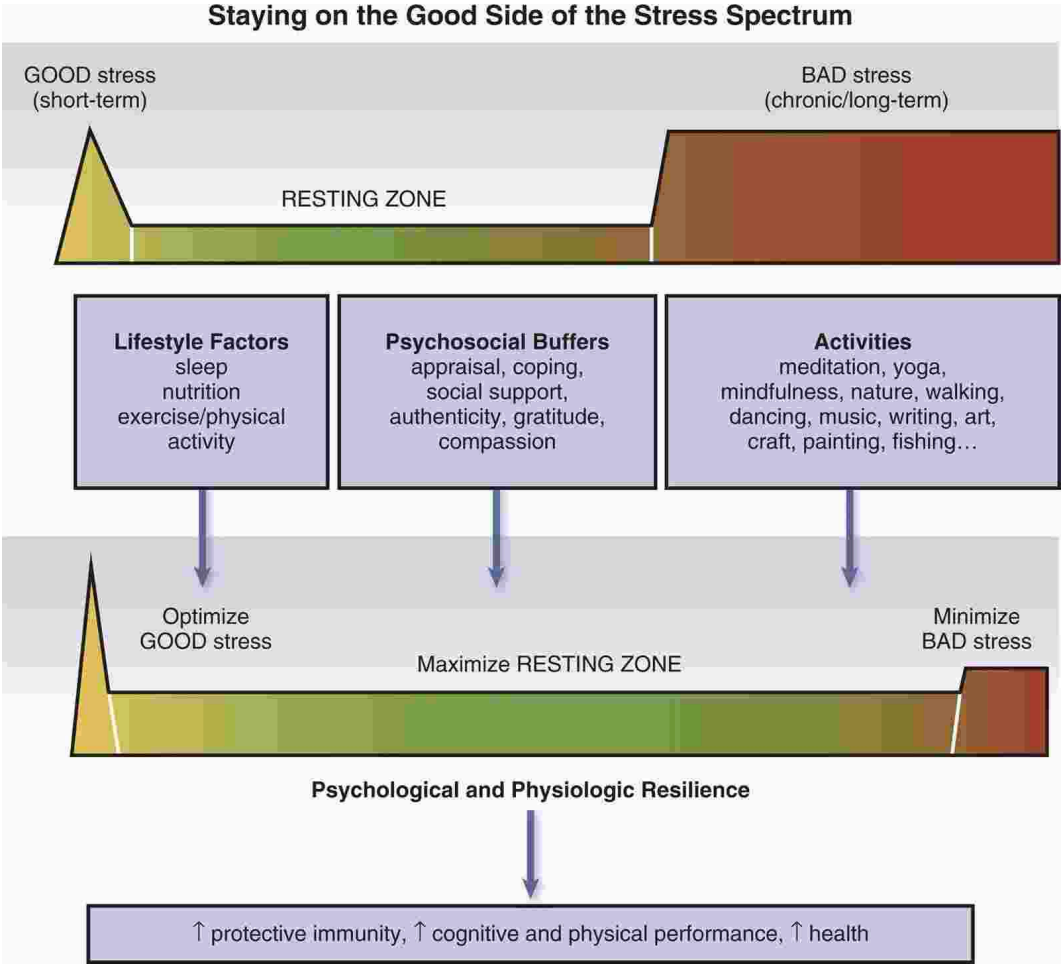

FIG. 11.10 Staying on the Good Side of the Stress Spectrum.

GOOD stress is shown on the left of the spectrum and involves a rapid biologic response to the stressor, followed by a rapid shutdown of the response upon cessation of the stressor. These responses support physiologic conditions that are likely to enhance protective immunity, cognitive and physical performance, and overall health. BAD stress, represented on the right of the spectrum, involves exposure to chronic or long-term biologic changes that are likely to result in dysregulation or suppression of immune function, a decrease in cognitive and physical performance, and an increased likelihood of disease. Short- and/or long-term stress is generally superimposed on a psychophysiologic RESTING ZONE of low/no stress that also represents a state of health

maintenance/restoration. To maintain health, one needs to optimize GOOD stress, maximize the RESTING ZONE, and minimize BAD stress. Achieving psychological and physiologic resilience involves a multipronged approach. Sleep of good quality and duration that helps one to feel rested in the morning, a moderate and healthy diet, and consistent and moderate exercise or physical activity are three LIFESTYLE FACTORS that are likely to enable one to stay on the “good” side of the stress spectrum. Effective appraisal and coping mechanisms, genuine gratitude, social support, and compassion toward others and oneself are likely to provide PSYCHOSOCIAL BUFFERS against bad stress and enable one to stay on the “good” side of the stress spectrum. In addition, depending on individual preferences, ACTIVITIES, such as meditation, yoga, being in nature, exercise/physical activity, music, art, craft, dance, or fishing, painting, may reduce BAD stress, extend the RESTING ZONE, and optimize GOOD stress. Such personal activities are likely to involve different strokes for different folks and need not always be meditative or reflective in nature.
(Adapted from Dhabhar FS, McEwen BS. Bidirectional effects of stress on immune function: Possible explanations for salubrious as well as harmful effects. In: Ader R, ed. *Psychoneuroimmunology*. Vol. IV. San Diego: Elsevier; 2007.)

An illustration represents the staying on the good side of the stress spectrum. Top spectrum. The illustration shows a small triangle on the left end of the spectrum, representing good stress (short-term). A flat section along the spectrum represents the resting zone. A lengthy, raised plateau on the right end of the spectrum represents bad stress (chronic or long-term). Three textboxes list the following factors, buffers, and activities. • Lifestyle factors: sleep, nutrition, exercise or physical activity. •

Psychosocial buffers: appraisal, coping, social support, authenticity, gratitude, and compassion. • Activities: meditation, yoga, mindfulness, nature, walking, dancing, music, writing, art, craft, painting, fishing, and so on. Middle spectrum. The illustration shows a tall, narrow triangle on the left end of the spectrum, representing good stress, optimized by lifestyle factors. A long, flat section along the spectrum represents the resting zone, maximized by psychosocial buffers. A small, raised platform on the right end of the spectrum represents bad stress, minimized by activities. Psychological and physiologic resilience leads to the following: • Increased protective immunity. • Increased cognitive and physical performance. • Increased health.

Staying on the Good Side of the Stress Spectrum

Maladaptive coping responses to stressors, such as increased smoking, decreased exercise and sleep, and poor diets provide an important pathway through which stressors influence the risk of disease. Constant disturbances of the sleep-wake cycle observed in many stressed people may exacerbate the pathophysiologic status of some individuals. Sleep deprivation and circadian disruption, even in young otherwise healthy individuals, have detrimental influences on respiratory and IS function. Sleep deprivation has been shown to cause chronic inflammation and is associated with diseases such as diabetes and atherosclerosis.[51]

Altered immune function, depression, hypertension, and many other disorders have been linked to repressive coping behaviors toward emotions and stress.[52] School teachers who devote long hours without reward and are unable to disengage from work-related tasks also are found to have lower innate immune responses. Coping strategies are especially beneficial when they are problem-focused and receive social support. Effective

interventions may result in greater stress resilience and improved psychological and physiologic outcomes.

Other important factors, such as social support and development of self-esteem, may mitigate the adverse effects of stress and confer resilience. Furthermore, the social environment may alter genes (i.e., epigenetics) which are expressed or suppressed to promote adaptation to stress or disease. For example, research in animals showed that maternal protective caregiving behavior may turn on genes that efficiently regulate the HPA stress response in offspring. The effects of the parental rearing environment found in animals also may extend to the human caregiving situation where children reared by highly attentive mothers showed lower stress-induced cortisol secretion to an inoculation procedure at the doctor's office than offspring of less-attentive mothers. Different parental rearing styles may impact how the developing child responds and copes to stress.[53]

Social support also can be beneficial for adults with limited education on how to care for themselves and for children who require caregiving attention. Teaching adults how to engage the child with problem-solving skills, planning, and emotional self-regulation in positive interactions offers a way to alleviate potential negative health effects of stress on the adult and child family members.

Effects of Exercise

Coping behaviors, such as regular physical activity, can significantly enhance mental well-being and lessen symptoms of depression and anxiety as effectively as psychotherapy.[54–56] The beneficial effects of exercise are found at all age groups—from adolescents to the elderly. Stress-induced imbalances in brain neurotransmitters are noted in people with depression, which is associated with negative emotions, such as increased anger, confusion, fatigue, tension, and reduced vigor. Animal and human studies further indicate that maternal exercise during pregnancy has the potential to strengthen the cardiac autonomic control of the fetus that could reduce the prevalence of age-related diseases and lead to an increase in quality of life and life span.

Impairments in serotonin neurotransmission are linked to depression, which can be treated with selective serotonin reuptake inhibitors (SSRIs) in some cases. This antidepressant drug increases the availability of brain serotonin by preventing its reuptake in the synapse. Blood levels of

serotonin are increased in aerobic exercise.[57] Increases in serotonin are correlated with a decrease in depression.

The positive effects of exercise on depression also may occur as a result of the ability of exercise to reduce inflammation.[58] Thus physical exercise may be improving the neuroimmune status observed in depression by reducing inflammation.

Another major benefit of exercise is to reduce the development of obesity, a major public health problem in the United States and across the world. Because people exposed to chronic stress often seek high-calorie comfort foods as a way to alleviate stress, they are at risk to develop obesity and diabetes, heart disease, metabolic disorders, liver disease, cancer, inflammatory disorders, mental illnesses, and premature death. Obesity leads to a chronic low-grade inflammatory state caused by increased production of proinflammatory cytokines (e.g., IL-1, IL-6, IL-17, and TNF) from adipocytes (fat cells) in adipose tissue (see Fig. 11.7). Coping with stress and obesity through exercise has the potential to reduce adipose tissue, attenuate serum proinflammatory cytokine levels, and create an antiinflammatory environment. The interplay between obesity, inflammation, and depression may be mediated through diet and exercise through the loss of adipose tissue and the restoration of adaptive immune and behavioral functions.[55,59]

Finally, another positive effect of exercise, especially aerobic exercise, is to enhance cognitive and brain functions. Exercise increases brain metabolism and brain structure and synaptic proteins, such as brain-derived neurotrophic factor (BDNF). Exercise-related BDNF levels have been linked to improvements in memory and hippocampal volumes.[60] Because the role of stress is linked to the development of cognitive and mental disorders, such as anxiety and depression, the positive effects of aerobic exercise on improving cognitive functions may be related to brain functions that are not compromised by stress.

Mindfulness Therapy

One type of cognitive therapy that is gaining increasing attention for the treatment of stress-related disorders is mindfulness therapy, which involves the personal monitoring of current experiences with acceptance; it is thought to dampen psychological and physiologic stress reactions, thereby limiting the cumulative impact of allostatic load or stress on health. Mindfulness therapy, such as mindfulness-based stress reduction (MBSR),

is effective in coping with various medical conditions, including chronic pain and depression, and attenuating the negative perception of stress. MBSR has been shown to reduce stress, anxiety, and depression among nurses.[61] Mindfulness training in adults with attention-deficit/hyperactivity disorder also improves neurocognitive deficits, such as attention deficit, and enhances emotional regulation and quality of life.

Mindfulness is believed to improve health by modulating[62] the HPA secretion of cortisol, a primary product of the neuroendocrine stress system, with pervasive effects throughout the body and brain. As discussed earlier, chronic stress-induced secretion of cortisol is involved in a wide range of mental and physiologic health functions. A major role of mindfulness appears to reduce cortisol and allostatic load.[62] The neural mechanisms or stress systems linked to mindfulness training interventions appear to involve the top-down prefrontal cortical regions that modulate connected neural sites, such as the amygdala and the subgenual anterior cingulate cortex, which are activated by stress and contribute to stress reactions. In stressed adults, mindfulness was found to increase the resting state of the stress-regulatory region of the dorsolateral prefrontal cortex and decreases stress-related regions between the amygdala and the subgenual anterior cingulate cortex. These brain changes were linked to a reduction in stress biomarkers (i.e., cortisol, circulating IL-6).[63]

Although the majority of mindfulness interventions have focused on adults, recent research has begun to examine the beneficial effects of mindfulness on at-risk children and adolescents.[64,65] These studies demonstrate that children and adolescents participating in mindfulness training showed improvement in their sleep and self-esteem, greater well-being, and reduction in depression and anxiety. These outcomes of mindfulness classes appear effective in mitigating the toxic effects of stress in youth. The intervention of mindfulness beginning at a young age has the potential to teach valuable coping skills in at-risk children that may lower their long-term burden of disease in adulthood.

In summary, the current understanding of the role of stress in modulating the complex interplay between the brain and the body is beginning to offer promising avenues of effective interventions for health and disease. Alterations in biomarkers of stress systems (e.g., cortisol, norepinephrine, proinflammatory cytokines) are revealing insights into potential targets to address their causal basis in disease and mental disorders. However, treatments for many stress-related diseases will likely

continue to be a major challenge. The young exposed to stress may have already undergone neuroanatomic, physiologic, and cognitive changes that are different from those in people exposed to stress in adulthood. The specific biologic changes induced by the length of stress exposure, the nature of the stressor, and the age, sex, and genetic makeup of individual are a few of a number of factors that complicate the treatment of this disease. The dynamic nature of stress on the individual and the subsequent occurrence of chronic diseases may require early stress reduction interventions that prevent or reduce the toxic effects of stress on the body and the brain.

Summary Review

Background and General Concepts of Stress

1. Stress is broadly defined as a perceived or anticipated threat that activates stress-related systems in the body and the brain (the stress response).
2. The term *fight-or-flight response* was coined by Walter Cannon to describe how the brain's perception of threat and rapid physiologic responses prepares the body to deal with threat.
3. Cannon's view was further developed by Hans Selye in 1946 by demonstrating that internal or external stressors could result in adrenal gland enlargement, immune alterations (increased leukocytes), and gastrointestinal manifestations (ulcers). These global physiologic responses, characterized by Selye, were labeled general adaptation syndrome (GAS).
4. GAS occurs in three stages: the alarm stage; the stage of resistance or adaptation; and the stage of exhaustion. The latter stage is now referred to as *allostatic overload*. Diseases of adaptation develop if the stage of resistance or adaptation does not restore homeostasis. Although important, this approach is now thought to be greatly oversimplified.
5. Stress research continued into the mid-1950s to show that psychological stressors are as effective as physical stressors in activating adrenal gland hormone secretion. Psychological stressors can be anticipatory and triggered by expectations of an upcoming negative event or can be reactive to a stressor. Both of these

psychological stressors are capable of eliciting a physiologic stress response.

6. The emerging link between stress and disease became the basis for the concept of allostasis (stability through change; monitoring the environment for adaptive response). This allostasis concept differs from a "fixed homeostasis model" (i.e., stress-induced heightened physiologic responses eventually returning to a narrow step point range) by involving a dynamic adaptation of the brain to constantly adjust its physiologic operating range to meet future anticipated demands. In other words, returning stress-induced hormone levels to prestress levels may not be the most adaptive strategy to cope with impending stressful encounters.
7. Chronic activation of regulatory stress systems has the potential to tax the body and the brain and lead to the emergence of diseases and disorders. In allostatic overload, chronic overactivation of adaptive regulatory physiologic systems may lead to pathophysiology and onset of disease.

The Stress Systems

1. The perception or anticipation of threat activates three major physiologic stress systems: (1) the hypothalamic–pituitary–adrenal (HPA) axis, (2) the sympathetic nervous system (SNS), and (3) the immune system (IS). Acute stress-induced activation of these stress systems modulates a broad range of mediators in the body and the brain to protect and meet the physiologic and behavioral demands of the stressor to facilitate recovery.
2. Key physiologic changes involved in allostatic overload include exaggerated or chronic secretion of adrenal cortisol, catecholamines from the sympathetic nervous system, and proinflammatory cytokines that may initiate gene expression changes with widespread effects on the body, and neurobiologic structures and processes.
3. Becoming "stressed out" by allostatic overload may lead to sleep deprivation, heightened insulin and blood glucose levels, increased blood pressure, and reduced parasympathetic activity. These physiologic consequences are often linked to insomnia, depression, chronic pain and fatigue syndromes, obesity, metabolic syndrome,

essential hypertension, type 2 diabetes, atherosclerosis and its cardiovascular consequences, osteoporosis, and autoimmune inflammatory and allergic disorders.

4. Activation of the HPA system involves sequential secretion of corticotropin-releasing hormone from the hypothalamus, which stimulates receptors in the anterior pituitary to secrete adrenocorticotropic hormone (ACTH), which, in turn, stimulates the adrenal cortex to secrete the glucocorticoid cortisol.
5. Cortisol secretion induced by acute stress binds to glucocorticoid receptors to activate diverse biologic actions throughout the body and the brain. The many adaptive functions include, but are not limited to, arousal, cognition, mood, metabolism, maintenance of cardiovascular tone, and effects on the immune system.
6. Cortisol's main effects involve metabolic processing by mobilizes glucose, amino acids, lipids, and fatty acids and delivers them to the bloodstream. As an example, anabolic effects of cortisol increase the rate of protein synthesis in the liver, whereas the catabolic effects of cortisol increase levels of amino acids, ultimately depleting protein stores in muscle, bone, skin, and connective tissue.
7. Chronic dysregulation of the HPA axis, especially abnormal elevated secretion of cortisol, is linked to a wide variety of disorders, including obesity, metabolic syndrome, sleep deprivation, lipid abnormalities, coronary heart disease, diabetes, atherosclerosis, and loss of bone density. In the brain, chronic glucocorticoid secretion may lead to cognitive impairments and emotional disorders, such as depression. For example, depression is accompanied by shrinkage of the hippocampus and the prefrontal cortex.
8. Activation of the autonomic nervous system (ANS) consists of sympathetic stimulation of the adrenal medulla and nerve endings to rapidly secrete catecholamines (norepinephrine, epinephrine).
9. Epinephrine exerts its chief effects on the cardiovascular system by increasing cardiac output and blood flow to the heart, brain, and skeletal muscles by dilating vessels that supply these organs. It also dilates the airways, thereby increasing delivery of oxygen to the bloodstream. Norepinephrine and epinephrine contribute to arteriolar vasoconstriction to other parts of the body raising blood pressure.

10. The parasympathetic nervous system balances or restrains the sympathetic system, resulting in slowed heart rates and antiinflammatory effects. During prolonged stress (allostatic overload), the parasympathetic system becomes less effective in opposing the sympathetic system.
11. Acute stress-induced secretion of HPA hormones and catecholamines (CAs) directly influences the immune system, which plays an adaptive role as a signal organ to alert other systems from internally threatening stimuli (e.g., infection, tissue damage, tumor cells). The release of immune inflammatory mediators (e.g., interleukin-6 [IL-6], tumor necrosis factor-β [TNF-β], interferon [IFN]) serves to protect the body from bacterial or viral infections, cancer, tissue injury, and other stressors.
12. Chronic stress induced by prolonged, intrusive, and/or negative thoughts may lead to pathophysiology of the immune system. Persistent secretion of proinflammatory cytokines and inflammation is linked to cardiovascular disease, osteoporosis, arthritis, type 2 diabetes mellitus, chronic obstructive pulmonary disease (COPD), and other diseases associated with aging.
13. Clear examples of the adverse effects of chronic psychosocial stress are burnout, a syndrome associated with a number of negative impacts on workers' well-being and health, as well as loneliness and social isolation. Mechanisms contributing to the effects of psychosocial stress include dysregulation of the HPA axis and the ANS which are accompanied by impaired immune function and inflammation.

Chronic Stress at an Early Age Increases the Risk of Developing Long-Lasting Pathophysiologic Alterations Linked to Poor Health and to Disease

1. Children exposed to prenatal or postnatal stressors increase the risk of developing long-lasting pathophysiologic alterations linked to poor health and to disease.
2. High levels of stress-induced maternal cortisol secretion could cross the placental barrier and enter the fetus to cause low birth weight and increase the risk of disease in later life, including obesity, cardiovascular conditions (e.g., hypertension), and behavioral

disorders (e.g., depression and attention-deficit/hyperactivity disorder).
3. Early exposure to psychosocial stressors (e.g., parental, sexual, or emotional abuse, low socioeconomic status [SES] or poverty) are linked to the development of dysregulated HPA and ANS leading to a chronic proinflammatory state that increases the risk of disease.
4. Early life stressors may impair brain systems that govern executive functions involved in attention, self-awareness, impulse control behavior that regulate emotions, and adaptive coping behavior.

Negative Effects of Stress on Telomere Length, Aging, and Disease

1. Telomeres are deoxyribonucleic acid (DNA)–based caps located at the end of chromosomes to protect genetic information and degradation during cell division.
2. Telomere shortening or attrition is linked to biologic aging and can be accelerated by a number of conditions associated with inflammation and oxidative stress. Shorter telomere length found in white blood cells reflects an increased risk of aging-related morbidity and mortality and is associated with a range of conditions in people with obesity, smoking, type 2 diabetes, and low SES.
3. Stress has a major role on telomere shortening that can begin in utero by increasing early telomere damage, inflammation, and greater rate of leukocyte division.
4. Studies showed that childhood psychosocial stress predicts telomere erosion and increased risk of developing depres-sion and metabolic disorders.

Coping and Intervention Strategies

1. Coping styles affect the ability of a person to handle stress. Personality characteristics, such as academic achievement, motivation, and optimism, increase the likelihood of successfully dealing with stress. In addition, people who engage in coping strategies that receive social support develop greater stress resilience and improved psychological and physiologic outcomes.

2. Maladaptive coping responses to stress, such as increased smoking, decreased exercise and sleep, and poor diets, are likely to alter adaptive immune functions and increase susceptibility to disease.
3. Engagement in exercise as a means of coping with stress has beneficial effects at all ages. Exercise has the potential to rebalance neurotransmitter effects that were altered by stress. Exercise also may improve the neuroimmune status (i.e., inflammation) by inhibiting the secretion of proinflammatory cytokines. Exercise increases brain metabolism that improves cognitive functions that could be compromised by chronic exposure to stress.
4. Another major benefit of exercise is to reduce obesity, a major contributor of the pathophysiology of diabetes, heart disease, metabolic disorders, liver disease, cancer, inflammatory disorders, mental illnesses, and premature death. Coping with stress and obesity by exercising reduces adipose tissue, attenuates serum proinflammatory cytokine levels, and creates an antiinflammatory environment.
5. Mindfulness therapy is increasingly used to reduce the chronic impact of allostatic load on health. This therapy involves monitoring current experiences with acceptance and is effective in coping with various medical conditions, including chronic pain, depression, and attenuating the negative perception of stress.
6. Mindfulness appears to improve health by modulating the stress-induced secretion of cortisol by the HPA and by dampening brain regions activated by stress that facilitate a range of stress reactions.
7. In children and adolescents experiencing chronic stress, mindfulness training can result in improvement in sleep, self-esteem, well-being, and reduction in depression and anxiety. Mindfulness teaches valuable coping skills that potentially reduce the likelihood of at-risk children developing chronic diseases in adulthood.

Cancer is a leading cause of suffering and death in the developed world. Intensive research has led to a significantly enhanced understanding of this complex and frightening disease. Experts now know that cancer is a collection of more than 100 different diseases, each caused by a specific and often unique age-related accumulation of genetic and epigenetic alterations. Environment, heredity, and behavior interact to modify the risk of developing cancer and the response to treatment. Improvements in treatment strategies and supportive care, coupled with new, often individualized therapies based on advances of the basic pathophysiology of malignancy, have contributed to an increasing number of effective options for these diverse, often lethal disorders collectively called *cancer*.

Cancer Terminology and Characteristics

Cancer is a collection of related diseases. The National Cancer Institute (NCI) of the National Institutes of Health (NIH) defines **cancer** as diseases in which "some of the body's cells begin to divide without stopping and spread into surrounding tissues."[1] The term *cancer* comes from the Latin translation of the Greek word for crab, *karkinoma*, which the physician Hippocrates used to describe the appendage-like projections extending from tumors into adjacent tissue. The word **tumor** originally referred to any swelling that is

caused by inflammation but is now generally reserved for describing a new growth, or **neoplasm**. Neoplasms result from an abnormal growth following uncontrolled proliferation serving no physiologic purpose. Not all tumors or neoplasms, however, are cancer. The term cancer refers to a *malignant* tumor and is not used to refer to *benign growths*, such as lipomas or hypertrophy of an organ.

Tumor Classification and Nomenclature

The careful evaluation of each cancer is important for many reasons. Different cancers will have different causes, different rates and patterns of progression, and different responses to treatment. The classification starts with knowing the tissue and organ of origin, the extent of distribution to other sites, and the microscopic appearance of the lesion. Increasingly, it also includes a detailed description of the critical genetic changes in the cancer.

Benign and Malignant

Tumors can be benign or malignant (cancerous). **Benign tumors** are usually encapsulated with connective tissue and contain fairly well-differentiated cells and well-organized surrounding supportive tissue called stroma (Fig. 12.1). They retain recognizable normal tissue structure and do not invade beyond their capsule, nor do they spread to regional lymph nodes or distant locations. Mitotic cells are rarely present during microscopic analysis. Benign tumors are generally named according to the tissues from which they arise with the suffix "-oma," which indicates a tumor or mass. For example, a benign tumor of the smooth muscle of the uterus is a *leiomyoma*, and a benign tumor of fat cells is a *lipoma*. Benign tumors can become extremely large and, depending on their location in the body, can cause morbidity or be life-threatening. For example, a benign meningioma at the base of the skull may cause symptoms by compressing adjacent normal brain tissue. Other benign tumors of endocrine organs can produce hormones, sometimes excessively.

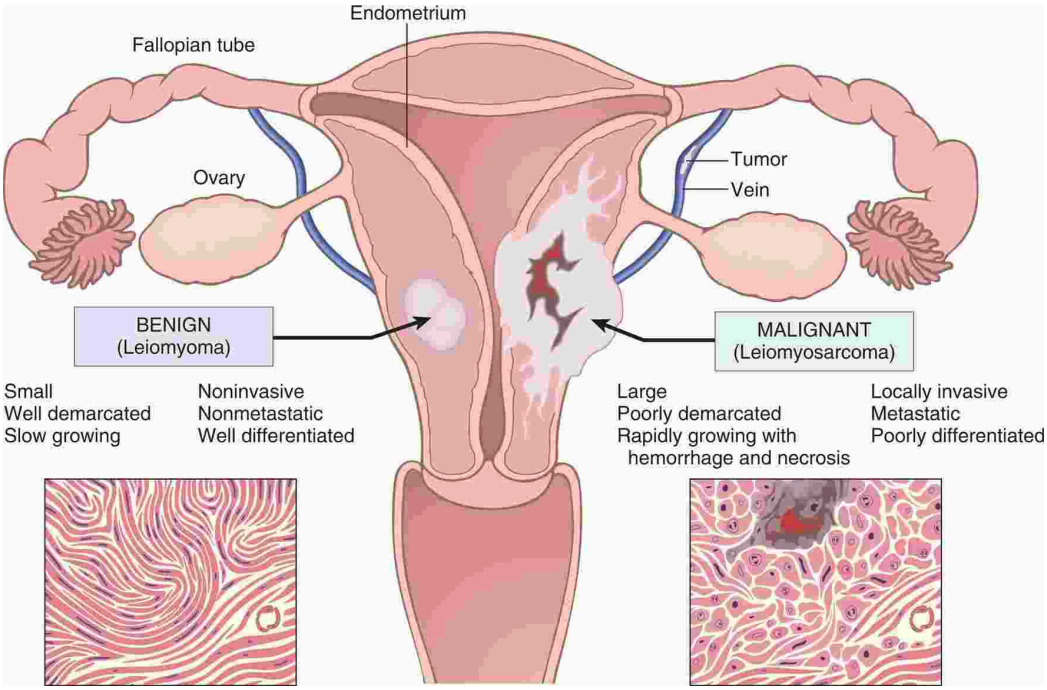

FIG. 12.1 Comparison Between a Benign Tumor and a Malignant Tumor of the Same Origin. From Kumar V, Abbas AK, Aster JC. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Saunders; 2021.

An illustration of a uterus compares a benign tumor and a malignant tumor. The following parts of the illustration are labeled: ovary, fallopian tube, endometrium, tumor and vein. A benign (leiomyoma) tumor is identified on the left. It is small, well demarcated, slow growing, noninvasive, nonmetastatic, and well differentiated. An accompanying illustration of the tumor shows long fibrous structures. A malignant (leiomyosarcoma) tumor is identified on the right. It is large, poorly demarcated, rapidly growing with hemorrhage and

necrosis, locally invasive, metastatic, and poorly differentiated. An accompanying illustration of the tumor shows a cluster of infected cells.

Some tumors initially described as benign can progress to cancer and then are referred to as **malignant tumors**, which are distinguished from benign tumors by more rapid growth rates and specific microscopic alterations, including loss of differentiation and absence of normal tissue organization (Fig. 12.2). One of the microscopic hallmarks of cancer cells is **anaplasia**, the loss of cellular differentiation. Malignant cells are also **pleomorphic**, with marked variability of size and shape. They often have large darkly stained nuclei, and mitotic cells are common. Malignant tumors may have a substantial amount of stroma, but it is disorganized, with loss of normal tissue structure. Malignant tumors lack a capsule and grow to invade nearby blood vessels, lymphatics, and surrounding structures. The most important and most deadly characteristic of malignant tumors is their ability to spread far beyond the tissue of origin, a process known as *metastasis*.

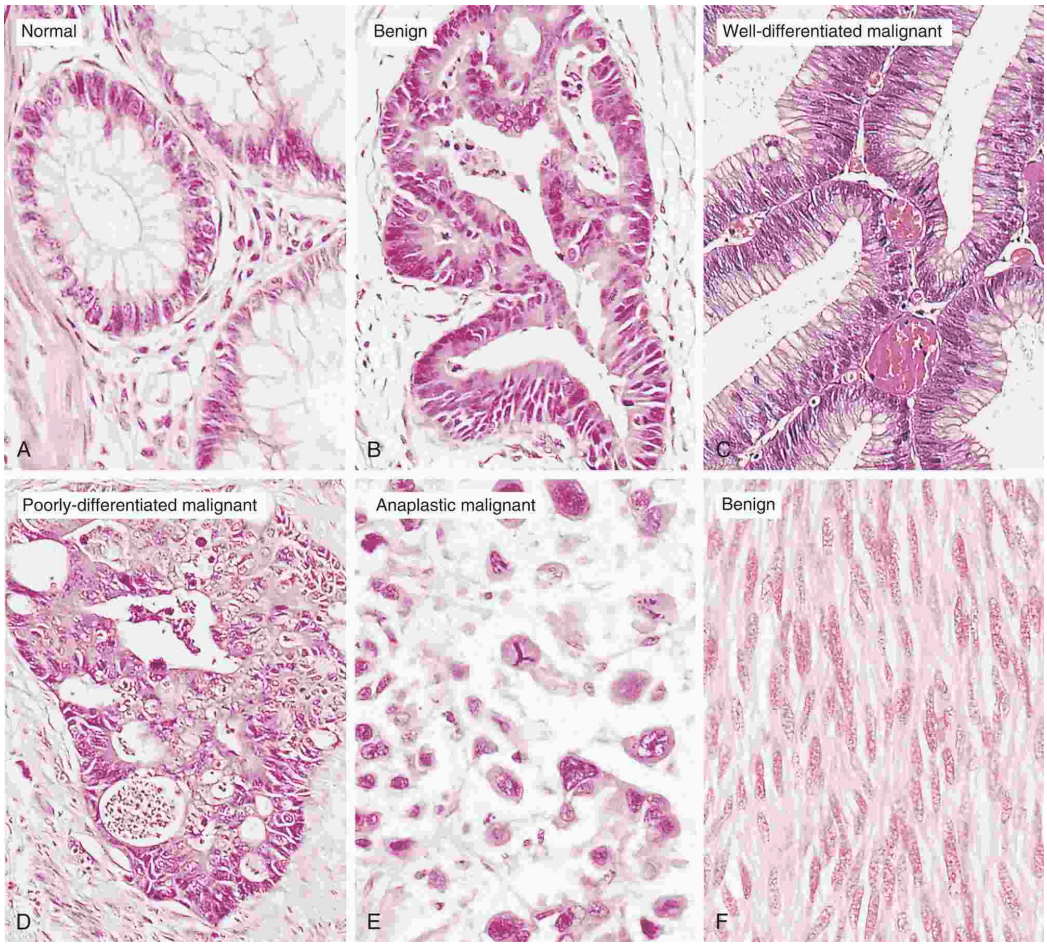

FIG. 12.2 Loss of Cellular and Tissue Differentiation During the Development of Cancer.

The cells of a benign neoplasm **(B)** resemble those of the normal colonic epithelium **(A)** in that they are columnar and have an orderly arrangement. Loss of some degree of differentiation is evident in that the neoplastic cells do not show much mucin vacuolization. Cells of the well-differentiated malignant neoplasm **(C)** of the colon have a haphazard arrangement, and although gland lumina are formed, they are architecturally abnormal and irregular. Nuclei vary in shape and size, especially when compared with those illustrated in A. Cells in the poorly differentiated malignant

neoplasm **(D)** have an even more haphazard arrangement, with very poor formation of gland lumina. Nuclei show greater variation in shape and size compared with the well-differentiated malignant neoplasm in C. Cells in anaplastic malignant neoplasms **(E)** bear no relation to the normal epithelium with no recognizable gland formation. Tremendous variation is found in the size of cells and their nuclei, with very intense staining (hyperchromatic nuclei). Not knowing the site of origin would make it impossible to classify this tumor by microscopic appearance alone. Well-differentiated tumors often resemble their cell of origin, as shown in the example of a benign tumor of smooth muscles **(F)**. From Stevens A, Lowe J. *Pathology*, 2nd edition. London: Mosby; 2000.

Unlike benign tumors, which are named related to the tissue of origin, cancers generally are named according to the cell type from which they originate. Cancers arising in epithelial tissue are called **carcinomas**, and if they arise from or ductal or glandular structures are named adenocarcinomas. Hence a malignant tumor arising from breast glandular tissue is a **mammary adenocarcinoma**; an example of a benign breast tumor is a fibroadenoma. Cancers arising from mesenchymal tissue (including connective tissue, muscle, and bone) usually have the suffix **sarcoma**. For example, malignant cancers of skeletal muscle are known as *rhabdomyosarcomas*. Cancers of lymphatic tissue are called **lymphomas**, whereas cancers of blood-forming cells are called **leukemias**. However, many cancers, such as Hodgkin disease and Ewing sarcoma, are named for historical reasons that do not follow this nomenclature convention.

Carcinoma in Situ

Carcinoma in situ (CIS) refers to preinvasive epithelial tumors of glandular or squamous cell origin. Cancers develop incrementally as they accumulate specific genetic lesions. Careful surveillance for

cancer often detects abnormal growths in epithelial tissues that have atypical cells and an increased proliferation rate compared with normal surrounding tissues. These early-stage cancers are localized to the epithelium and have not penetrated the local basement membrane or invaded the surrounding stroma. Based on these characteristics, they are not malignant though they are called CIS. CIS occurs in several sites, including the cervix, skin, oral cavity, esophagus, and bronchus. In glandular epithelium, in situ lesions occur in the stomach, endometrium, breast, and large bowel. In the breast, ductal carcinoma in situ (DCIS) fills the mammary ducts but has not progressed to local tissue invasion. DCIS lesions are readily treatable; however, the optimal therapeutic approach is controversial. CIS lesions can have one of the following three fates: (1) they can remain stable for a long time, (2) they can progress to invasive and metastatic cancers, or (3) they can regress and disappear. CIS can vary from low-grade to high-grade dysplasia, with the high-grade lesions having the highest likelihood of becoming invasive cancers. The time that such preinvasive lesions remain in situ before becoming invasive is unknown. Some carcinomas of the cervix appear as preinvasive lesions in situ for several years before they progress to invasive carcinoma and metastatic tumors (Fig. 12.3). Knowing the best treatment for low-grade CIS lesions is challenging because the proportion that progress to cancer versus the proportion that will never cause clinical problems is usually not known. Although most persons prefer removal of any CIS as opposed to “watchful waiting,” this topic continues to be a source of great debate.

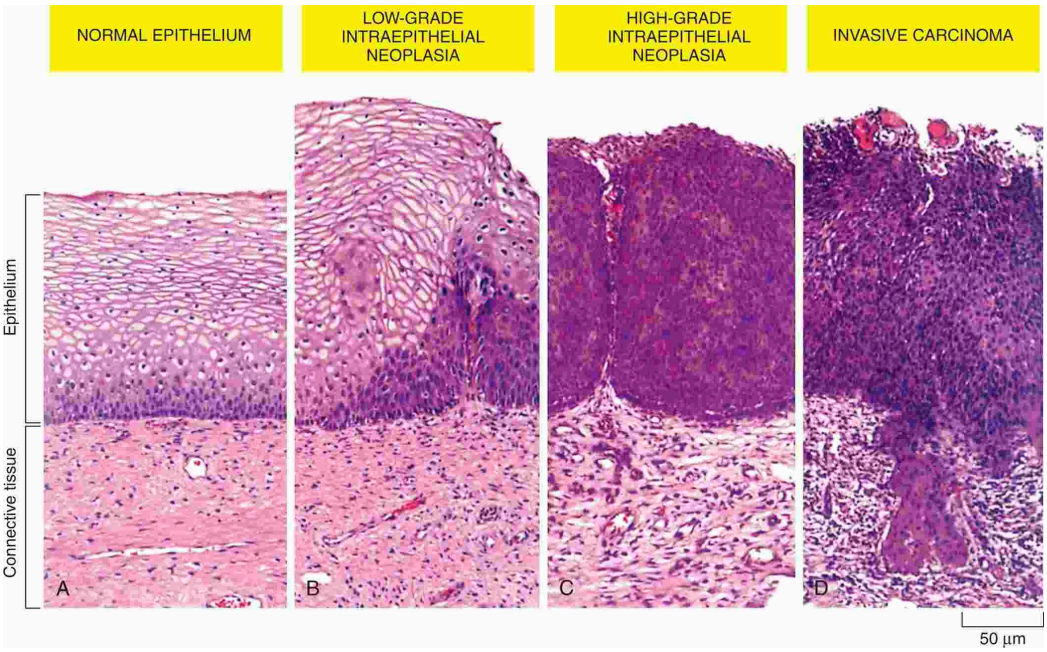

FIG. 12.3 Progression from Normal to Neoplasm in the Uterine Cervix.
A sequence of cellular and tissue changes progressing from low-grade to high-grade intraepithelial neoplasms (also called *carcinoma in situ*), and then to invasive cancer is seen often in the development of cancer. In this example of the early stages of cervical neoplastic changes, the presence of anaplastic cells and the loss of normal tissue architecture signify the development of cancer. The high rate of cell division and the presence of local mutagens and inflammatory mediators all contribute to the accumulation of genetic abnormalities that lead to cancer. (From Alberts B, Johnson A, Lewis J, et al. *Molecular biology of the cell*, 5th edition. New York: Garland; 2002.)

Four photomicrographs show progression of cancerous cells in the uterine cervix. Each micrograph shows two layers: an epithelium layer

above a layer connective tissue. A, normal epithelium. The illustration shows normal cells in both layers. B, low-grade intraepithelial neoplasia. The illustration shows an inflamed epithelial layer with some amount of infected cells. C, high-grade intraepithelial neoplasia. The epithelium is completely infected with numerous cancerous cells. The connective tissue layer is also degenerating. D, invasive carcinoma. The cancerous cells have passed from the epithelium to the connective tissue.

The Biology of Cancer Cells

In two seminal publications, Douglas Hanahan and Robert Weinberg[2,3] described what they considered the hallmarks of cancer. Both articles stimulated considerable discussion and, especially, debate. The original publication contained six hallmarks, but with time and new research findings, increased to eight hallmarks and two traits that enable cancer progression. Their analysis remains the leading overview of why a cell is malignant. The following discussion is organized in the context of those 10 hallmarks/enablers (Fig. 12.4). Two fundamental concepts are the foundation for understanding the biology of cancer: (1) cancer is a complex disease, and (2) the microenvironment of a tumor is a heterogeneous mixture of cells, both cancerous and benign.

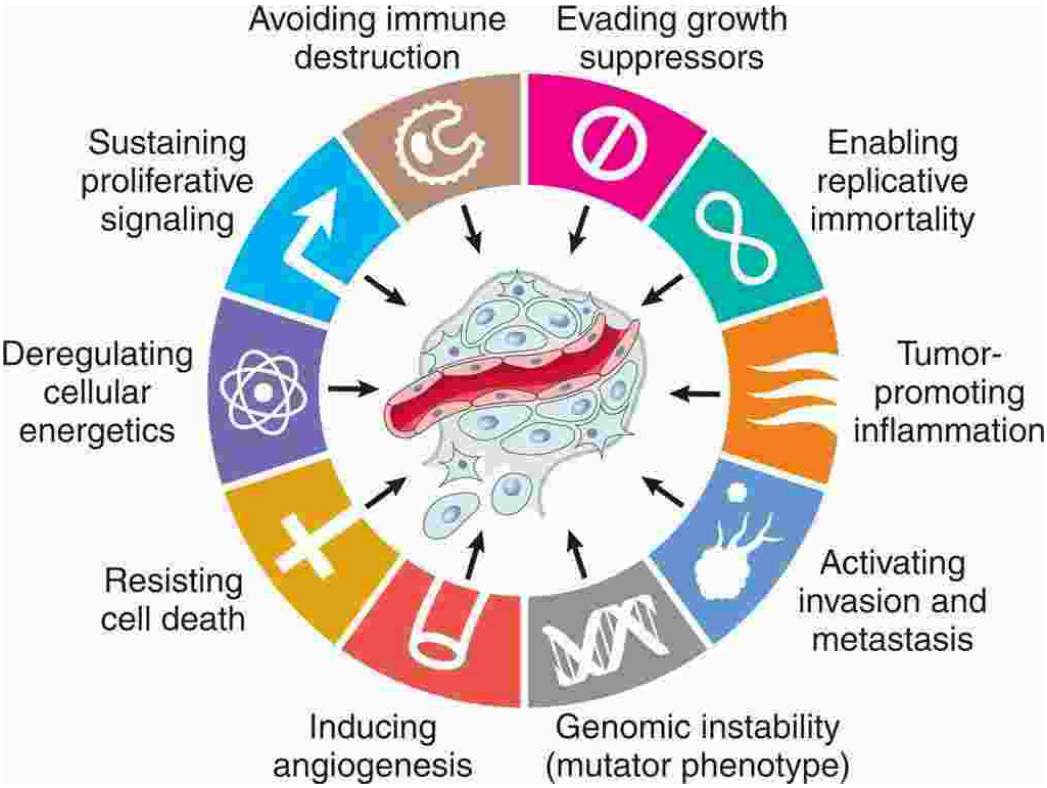

FIG. 12.4 **Hallmarks of Cancer.** Adapted from Hanahan D, Weinberg RA. Hallmarks of cancer: The next generation. *Cell*, 2011;144(5):646–674. Found in Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition, Philadelphia: Elsevier; 2021.

An illustration lists the hallmarks of cancer: • Evading growth suppressors. • Enabling replicative immortality. • Tumor-promoting inflammation. • Activating invasion and metastasis. • Genomic instability (mutator phenotype). • Inducing angiogenesis. • Resisting cell death. • Deregulating cellular energetics. • Sustaining proliferative signaling. • Avoiding immune destruction.

Cancer is a disease of cumulative genetic changes during aging. The fraction of individuals who develop cancer increases dramatically with age. Genetic changes involve mutational and epigenetic mechanisms. *Mutation* means an alteration in the DNA sequence affecting expression or function of a gene (Fig. 12.5; also see Chapter 4). Mutations include **point mutations** or a small-scale change in DNA, the alteration of one or more nucleotide base pairs. This type of change can have profound effects on the activity of resultant proteins. **Chromosome translocations** are large changes in chromosome structure in which a piece of one chromosome is translocated to another chromosome. **Gene amplification** is the result of repeated duplication of a region of a chromosome. Instead of the normal two copies of a gene, tens or even hundreds of copies are present. Epigenetic effects can alter gene expression indirectly and include **DNA methylation**, histone acetylation, or altered expression of **non-coding RNA** (see Chapter 6).[4]**Driver mutations** "drive" the progression of cancer. There are over 100 different driver mutations, although some are more critical than others, and a small number of these are present in an individual cancer. Not all mutations in cancer contribute to the malignant phenotype. Some are just random events, called **passenger mutations**, and are just along for the ride. After a critical number of driver mutations has occurred, a cell becomes cancerous. Unfortunately, the cancer cell has a selective advantage over its neighbors; its progeny can accumulate faster than its nonmutant neighbors. This advantage is known as **clonal proliferation** or **clonal expansion** (Fig.12.6). As a clone with mutations proliferates, it may become an early-stage tumor, for example, a CIS or a benign colonic polyp.

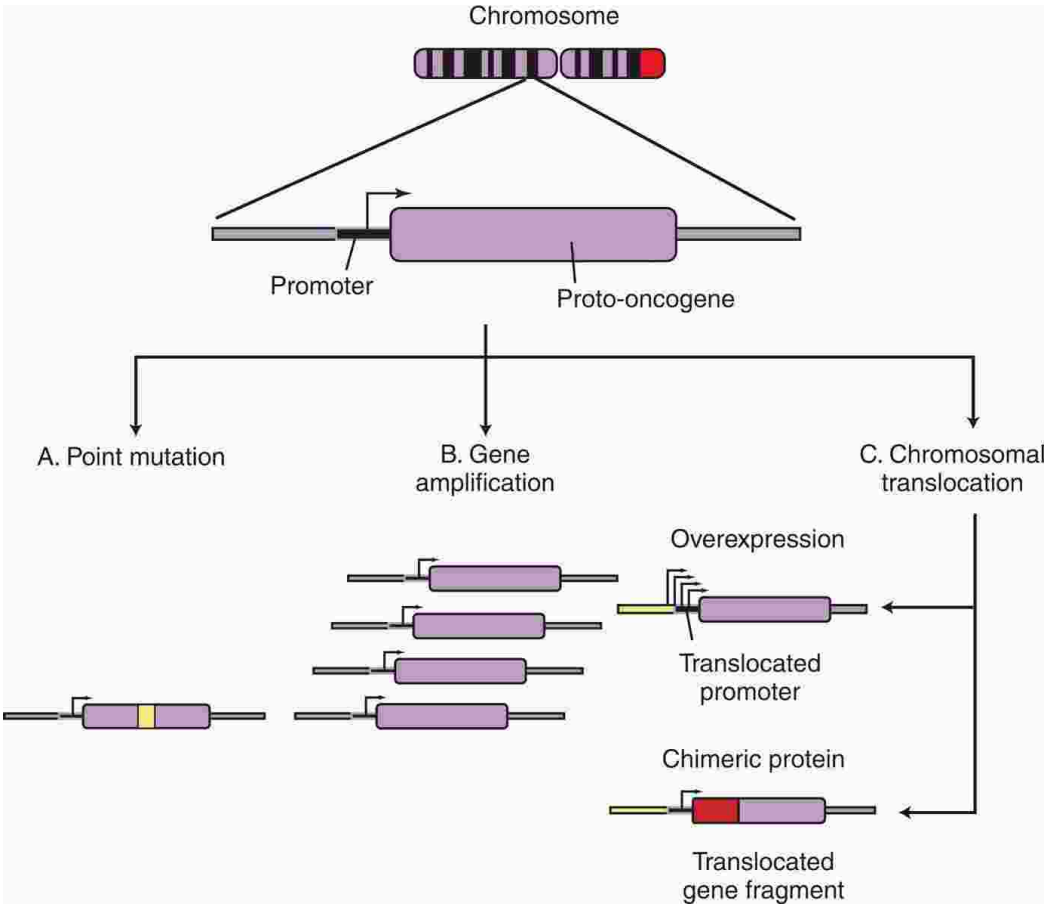

FIG. 12.5 Oncogene Activation Mechanisms. Cellular genes may become cancerous oncogenes as a result of **(A)** point mutations that alter one or a few nucleotide base pairs, causing the production of a protein that is activated as a result of the altered sequence (e.g., *ras*), **(B)** amplification of the cellular gene, resulting in higher levels of protein expression (e.g., N-myc in neuroblastoma), or **(C)** chromosomal translocations that either lead to the juxtaposition of a strong promoter, causing increased protein expression (c-myc in Burkitt lymphoma), or produce a novel fusion protein that is derived from gene fragments normally present on different chromosomes (BCR-ABL in chronic myeloid leukemia). (From Haber DA. Molecular

genetics of cancer. In *ACP Medicine*. Danbury, CT: WebMD; 2004.)

An illustration shows the mechanisms for oncogene activation. Chromosome comprises a promoter and a proto-oncogene which undergo one of three mechanisms: A. Point mutation. There is a single oncogene. B. Gene amplification. There are multiple oncogenes. C. Chromosomal translocation: overexpression in the translocated promoter; chimeric protein in the translocated gene fragment.

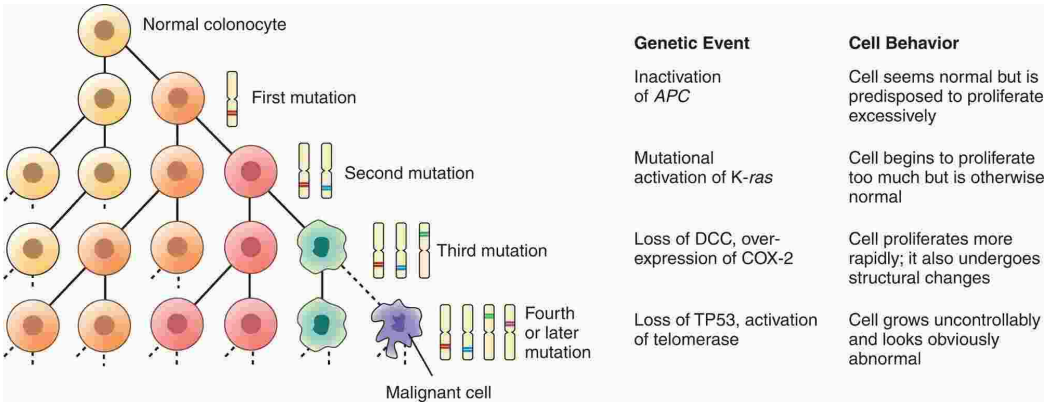

FIG. 12.6 Clonal Proliferation Model of Neoplastic Progression in the Colon. During clonal proliferation, progressively altered populations of colon cells (colonocytes) arise over time. As genetic and epigenetic changes occur, different subclones (indicated by different color cells) coexist for a time. Clones that grow the fastest out-compete other clones, producing even more malignant, and abnormal-appearing, growths. The sequential accumulation of mutations has been well studied in the progression from a normal colon cell to a benign intestinal polyp to a malignant colon cancer. One of the earliest mutations in colon cancer is loss of the tumor-suppressor gene *APC*. Additional mutations (often in the oncogene *RAS*), activation of COX-2, and loss of the tumor suppressors *DCC* and TP53 occur as the lesion progresses from a benign polyp to an invasive carcinoma. *APC*, Adenomatous polyposis coli; *COX-2*, cyclooxygenase-2; *DCC*, deleted in colon cancer; TP53, *p53* gene. Modified from Mendelsohn I, et al. *The molecular basis of cancer*, 2nd edition. Philadelphia: Saunders; 2001; and Kumar V, et al. *Basic pathology*, 6th edition. Philadelphia: Saunders; 1997.

An iterative illustration represents the clonal proliferation model of neoplastic progression in the colon. The illustration shows a normal colonocyte at the top. The subsequent mutations, genetic events, and cell behaviors are as follows. • First mutation. There two sub clones. A P C is inactivated. Cell seems normal but is predisposed to proliferate excessively. • Second mutation. Each clone has two sub clones. Mutational activation of K-Ras occurs. Cell begins to proliferate too much but is otherwise normal. • Third mutation. Each clone has two sub clones, with one cancerous cell. There is loss of D C C and overexpression of COX-2. Cell proliferates more rapidly; it also undergoes structural changes. • Fourth mutation or later. The clones of the cancerous cell are also cancerous. There is loss of T P 53 and activation of telomerase. Cell grows uncontrollably and looks obviously abnormal.

The increasingly rapid cell division and impaired DNA repair mechanisms of cancer cells result in a continuing accumulation of mutations throughout the progression to the most aggressive metastatic lesion. Thus, **malignant transformation**, the process by which a normal cell becomes a cancer cell, is directed by progressive accumulation of genetic changes that alter the basic nature of the cell and drive it to malignancy. The process of tumor development involves cancer cells with a heritable change that confers a survival advantage on them, enabling them to out-compete their neighbors. Each cancer cell may develop its own set of mutations resulting in a genomically *heterogeneous* mixture of cancer cells with subsets that

have accumulated more and more mutations that increase the cell's malignant potential, while other subsets of cancer cells that do not accumulate a critical set of mutations eventually lose the competition and die.[5] The degree of intratumor mutational heterogeneity may vary considerably among tumors. For instance, melanomas have a rather high degree of genetic homogeneity, whereas pancreatic cancers are more heterogeneous and appear to arise from independent mutational events in the pancreas.

The processes occurring during the development of cancer are, in many ways, analogous to wound healing (see Chapter 7). The initial proliferation of cancer cells and enlargement of the tumor elicit the synthesis of proinflammatory mediators by the cancer cells and adjacent nonmalignant cells. As with wound healing, mediators recruit inflammatory/immune cells (primarily T lymphocytes and macrophages, but also B cells and neutrophils) and cells normally associated with tissue repair (fibroblasts, adipocytes, mesenchymal stem cells, endothelial cells, and pericytes). These cells form the **stroma** (tumor microenvironment) that surrounds and infiltrates the tumor (Fig. 12.7).[6] In some conditions, stromal cells may make up 90% of the tumor mass. Extensive paracrine signaling among the stromal and cancer cells affects both populations; cancer cells increase proliferation and become more heterogeneous during tumor growth, and several populations of stromal cells undergo evolution to phenotypes that promote cancer progression and metastatic potential. **Intratumoral genetic heterogeneity** or diversity arises from ongoing proliferation and mutation.[7] Tumor-associated endothelial cells, fibroblasts, and inflammatory cells develop different and distinct gene expression profiles with unique cell surface molecules and patterns of secreted molecules. During this process, many cancer cells die, but the surviving cells are more aggressive, and many take on a metastatic phenotype.[7] Because continuing somatic mutations may be random, cancer cells in different regions of the tumor may be genetically diverse. Additionally, a population of cancer stem cells may arise, the origin of which is still unclear. Many of the hallmarks of cancer are

consequences of *cancer-stromal interactions* (discussed later in the chapter).

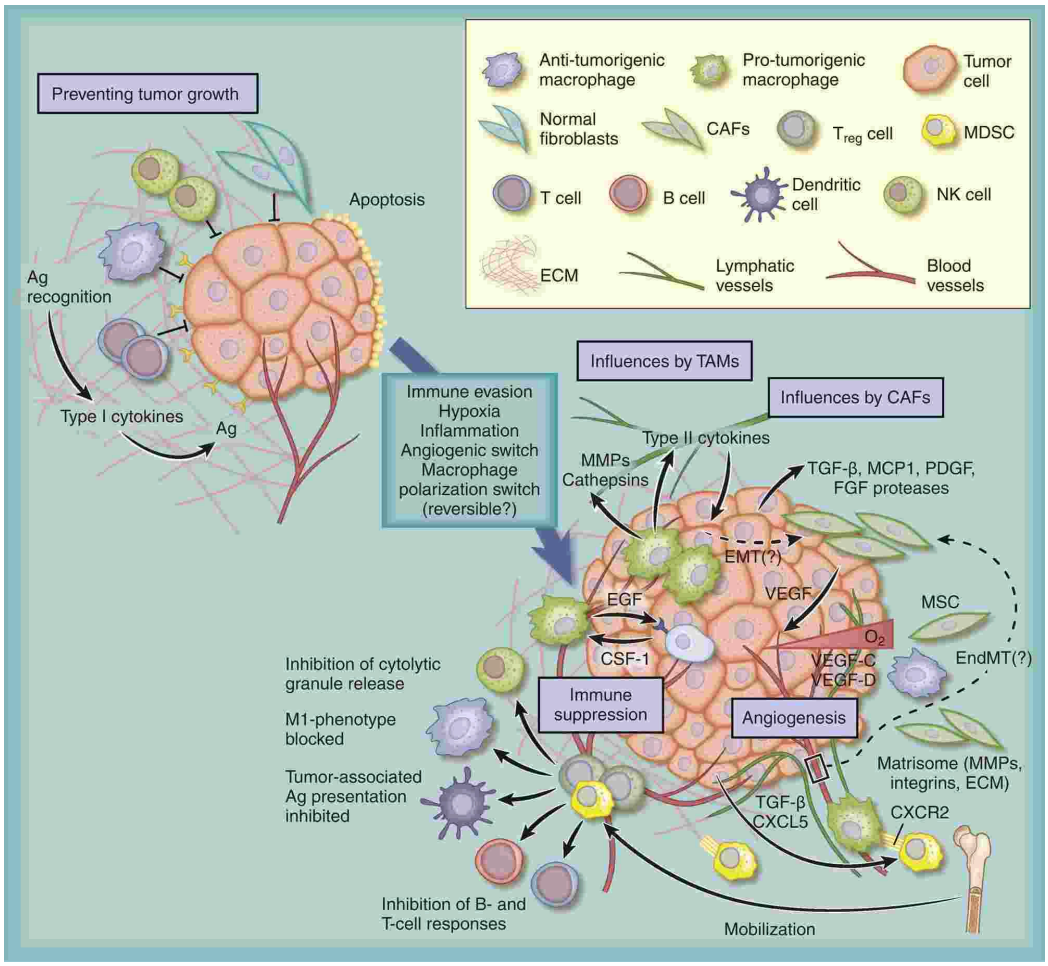

FIG. 12.7 Cancers Live in a Complex Microenvironment.

Cancer cells express tumor-specific antigens that ideally can be recognized by cells of the immune system and inflammatory systems (natural killer cells, antitumor M1 macrophages, T-cytotoxic cells) and destroyed by apoptosis or undergo growth suppression by type I cytokines. However, successful cancers produce a variety of cytokines and chemokines that are chemoattractants for stromal cells that infiltrate the tumor and undergo change to pro-tumor phenotypes. These include tumor-associated M2 macrophages *(TAMs)*, cancer-associated fibroblasts *(CAFs)*, mesenchymal stem cells *(MSCs)*, and immune

suppressor cells of T-cell origin (T-regulatory cells) and myeloid origin (myeloid-derived suppressor cells). Through multiple receptor-mediated interactions between other stromal cells and the cancer cells, the stromal cells, as well as the cancer cells, collectively produce a battery of additional cytokines (e.g., TGF-β, type II cytokines), chemokines (e.g., CXCL5), growth factors (e.g., VEGF, EGF, CSF-1, FGF, PDGF), and proteases (e.g., MMPs) and secrete components of the extracellular matrix *(ECM)*. The stromal reaction promotes tumor progression, including new blood vessel growth (angiogenesis), tumor cell proliferation and differentiation, suppression of immune rejection and tumor cell apoptosis, invasion, and commitment to metastasis. *CAF*, Cancer-associated fibroblast; *CSF-1*, colony-stimulating factor-1; *CXCL5*, C-X-C motif chemokine 5; *EGF*, epidermal growth factor; *FGF*, fibroblast growth factor; *MMP*, matrix metalloproteinase; *MSC*, mesenchymal stem cell; *NK*, natural killer cell; *PDGF*, platelet-derived growth factor; *TAM*, tumor-associated macrophage; *TGF-β*, tumor growth factor-beta; T_{reg}, T-regulatory cell; *VEGF*, vascular endothelial cell growth factor. Modified from Quail DF, Joyce JA. Microenvironmental regulation of tumor progression and metastasis. *Nature Medicine*, 2013;19(11):1423–1437.

An illustration shows how cancerous cells live in a complex microenvironment. Preventing tumor growth. There is a cluster of tumor cells on E C M. Normal fibroblasts, N K cells, anti-tumorigenic

macrophage, and T cells are attracted to the tumor cells. A g recognition releases type 1 cytokines which secrete A g, causing apoptosis. The cluster of cells undergoes immune evasion, hypoxia, inflammation, angiogenic switch, macrophage polarization switch (reversible?). A larger cluster of tumor cells on E C M undergoes the following: • Influences by T A Ms: M M Ps cathepsins and type 2 cytokines. • Influences by C A Fs: T G F-beta, M C P 1, P D G F, F G F proteases. • Angiogenesis: T G F-beta, C X C L 5, C X C R 2, matrisome (M M Ps, integrins, E C M), End M T, M S C, V E G F, V E G F-C, and V E G F-D. • Immune suppression: Bone marrow mobilization, inhibition of cytolytic granule release, M 1-phenotype blocked, tumor-associated A g presentation inhibited, inhibition of B- and T-cell responses, E G F, C S F-1.

Several of the hallmarks/enablers are primarily genomic alterations that initiate and maintain development of cancer. These will be discussed first and include sustained proliferative signaling, evading growth suppression, genomic instability, and replicative immortality (see Fig. 12.4). Other hallmarks/enablers are secondary to genomic change and include inducing angiogenesis and reprogramming energy metabolism. A third group, tumor resistance to destruction by the host's protective mechanisms, includes resistance to apoptotic cell death, tumor-promoting inflammation, and avoiding immune destruction. The last hallmark is the culmination of the previous nine: activating invasion and metastasis.

Genomic Hallmarks

Sustained Proliferative Signaling

The first and prime hallmark of cancer is uncontrolled cellular proliferation. Normal cells generally only enter proliferative phases in response to growth factors that bind to specific receptors on the cell surface. The cytoplasmic components of the receptors send signaling molecules that activate intracellular pathways leading to induction/activation of regulatory factors affecting DNA synthesis, entrance into the cell cycle, and changes in expression of other genes related to cell metabolism for optimal growth (Fig. 12.8). One example is initiation of proliferation by epidermal growth factor (EGF). EGF binds and cross-links two EGF receptors on the cell surface.[8] The cytoplasmic portions of the receptors are tyrosine kinases that attach phosphorus to tyrosine in neighboring proteins, including each other (autophosphorylation). Phosphorylation allows a bridging protein to link the EGF receptors to plasma membrane–associated inactive RAS. **RAS** is an acronym for "rat sarcoma," where it was found originally. EGF receptor activation and linkage by the bridging protein activates RAS via the replacement of guanine diphosphate (GDP) with guanine triphosphate (GTP). Activated RAS then initiates signaling pathways such as the **mitogen-activated protein kinase (MAPK) pathway** and the **phosphatidylinosityl-3-kinase (PI3K) pathway**. These signaling pathways phosphorylate other cytoplasmic proteins and affect activity and nuclear localization of transcription factors, such as **myelocytomatosis viral oncogene homolog (MYC)**, that govern the transcription of cell cycle regulators, such as cyclins, and entrance into cellular proliferation. PI3K also activates AK strain transforming (Akt) kinases and mammalian target of rapamycin (mTOR) proteins, which contribute to cell proliferation and growth. Proliferation can be discontinued through this pathway by decreased levels of growth factors in the environment or inactivation of signaling pathway components. These signaling pathways are inactivated by GTPase-activating proteins (GAPs), which inactivate RAS, and by phosphatase and tensin homologue (PTEN), which inactivates PI3K (see Fig.12.8).

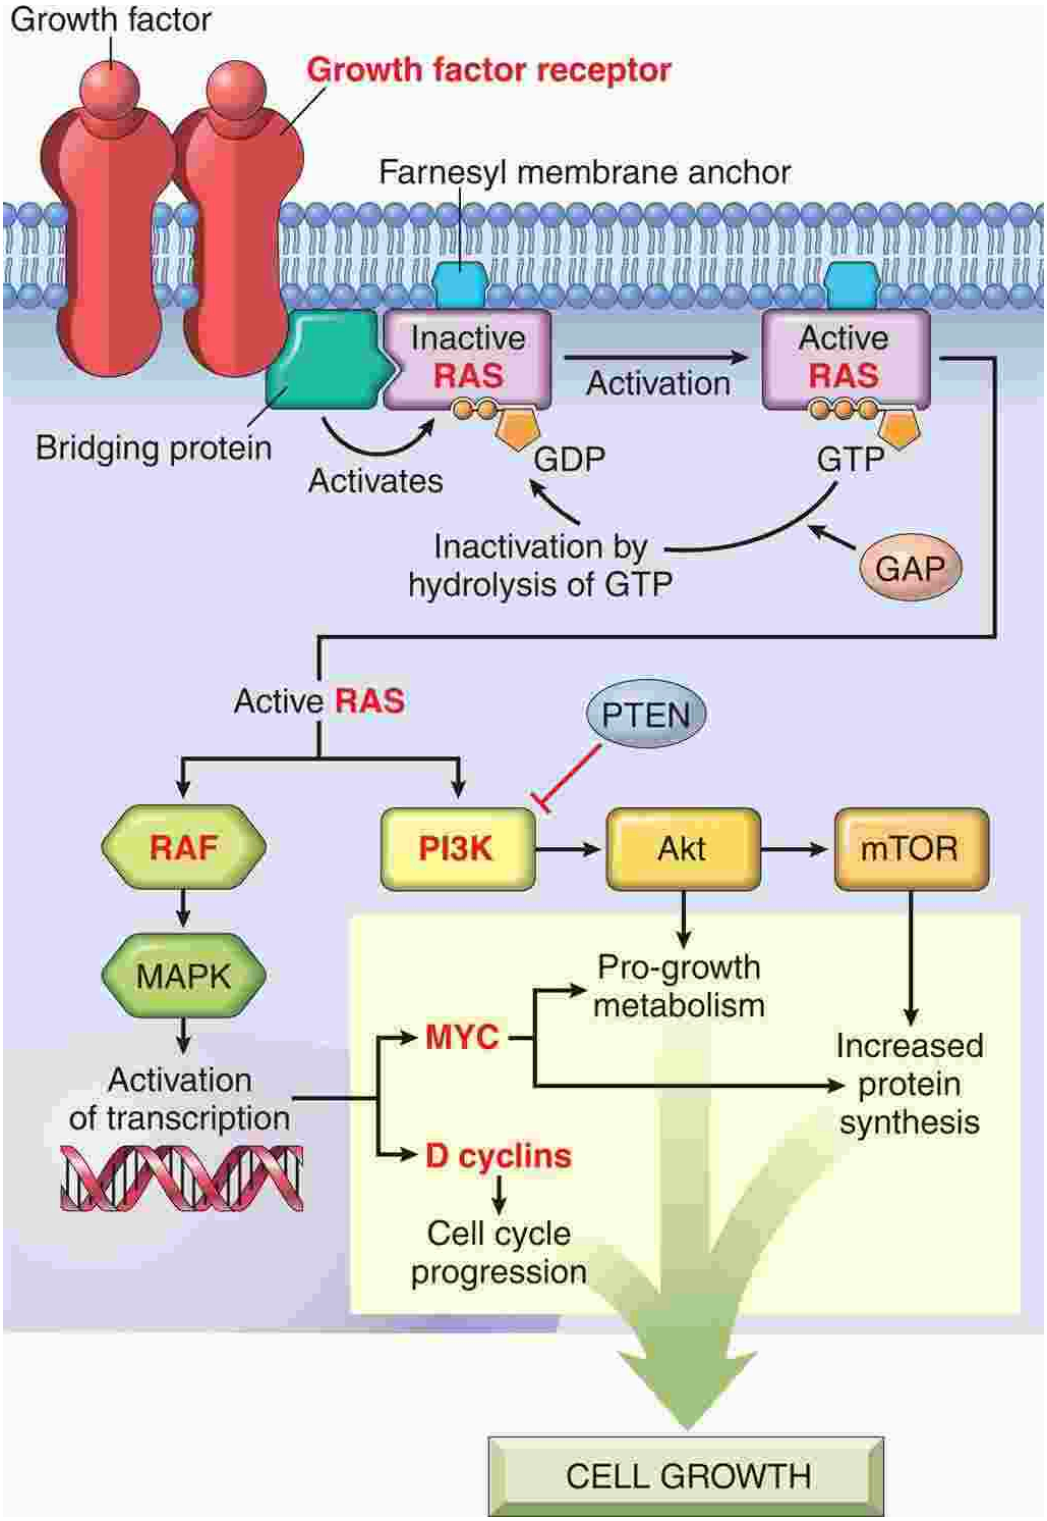

FIG. 12.8 Growth Factor Signaling Pathways in Cancer.

Growth factor receptors, RAS, PI3K, MYC, and D cyclins are oncoproteins that are activated by

mutations in various cancers. GTPase-activating proteins (GAPs) apply brakes to RAS activation, and phosphatase and tensin homologue (PTEN) serves the same function for PI3K. *Akt*, AK strain transforming kinases; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *MAPK*, mitogen-activated protein kinase; *PI3K*, phosphatidylinositide-3-kinase; *mTOR* mammalian target of rapamycin. From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition, Philadelphia: Elsevier; 2021.

An illustration shows growth factor signaling pathways in cancer. Growth factor binds to the growth factor receptor in the lipid bilayer. A bridging protein links the inactive R A S at the farnesyl membrane anchor along the inner lipid layer, activating it. G A P aid in the inactivation of G T P by hydrolysis. R A F and P I 3 K are activated by the active R A S. R A F activates M A P K, leading to activation of transcription. Transcriptions activates M Y C and D cyclins. M Y C leads to pro-growth metabolism. D cyclins lead to cell cycle progression. P I 3 K activates A k t, amplified by P T E N. A k T activates m T O R and pro-growth metabolism. m T O R increases protein synthesis. Cell cycle progression, pro-growth metabolism, and increased protein synthesis lead to cell growth.

The genes that encode components of receptor-mediated pathways designed to regulate normal cellular proliferation are collectively called **proto-oncogenes**. Cancerous cells characteristically express mutated or overexpressed proto-oncogenes, which are called **oncogenes**. Oncogenes are independent of normal regulatory mechanisms; thus, the cell is driven into a state of unregulated expression of proliferation signals and uncontrolled cell growth. Oncogenes can affect any portion of the growth factor pathways, such as described for EGF. For instance, most growth factors originate from neighboring cells, but some cancers acquire the ability to secrete growth factors that stimulate their own growth, a process known as **autocrine stimulation**. As described later in this chapter, noncancerous stromal cells within a tumor are frequently modified to benefit the cancer. In some instances, stromal cells produce excessive growth factors that drive the proliferation of cancer cells. Other cancers increase the expression of growth factor receptors (GFRs); for example, in breast cancer, production of the **human epidermal growth factor receptor 2 (HER2)**, also known as the epidermal growth factor receptor gene (ERBB2), is upregulated and is hyperresponsive to low levels of EGF. Some breast and lung cancers are treated by inhibitors of HER2 and other EGF receptors that block this pathway.[9]

Oncogenes may lead to constant activation of the signal cascade from the cell surface receptor to the nucleus. Up to a third of all cancers have an activating mutation in the RAS gene resulting in a continuous cell growth signal even when growth factors are missing (see Fig. 12.8). Other mutations in the EGF receptor pathway include excessive proliferation signaling by hyperactivation of the PI3 kinase.

Several types of genetic events can activate oncogenes. A point mutation that is frequently observed in lung cancer results in continuous activation of the EGF **receptor tyrosine kinase**. A point mutation in the *RAS* gene converts it from a regulated proto-oncogene to an unregulated oncogene. Activating point mutations in *RAS* are found in many cancers, especially pancreatic and colorectal

cancer. Specialized tests, such as direct DNA sequencing, can detect such point mutations in clinical samples, and new treatments are being developed that target cells with RAS mutations.[10]

Translocations can activate oncogenes by one of two distinct mechanisms (Fig. 12.9). First, a translocation can cause excess and inappropriate production of a proliferation factor. One of the best examples is the t(8;14) translocation found in many Burkitt lymphomas; t(8;14) designates a chromosome that has a piece of chromosome 8 fused to a piece of chromosome 14 (see Chapter 29). Burkitt lymphoma is an aggressive cancer of B lymphocytes. The **MYC proto-oncogene** found on chromosome 8 is normally activated at low levels in proliferating lymphocytes and is inactivated in mature lymphocytes. If the t(8;14) translocation occurs, the *MYC* gene is aberrantly placed under the control of a B-cell immunoglobulin gene *(IG)* present on chromosome 14. The *IG* gene is very active in maturing B lymphocytes. The t(8;14) translocation alters the control of *MYC;* its normal low-level expression is switched to high levels, as directed by an *IG* gene promoter. Hyperproduction of **MYC protein** drives proliferation and blocks differentiation.

FIG. 12.9 Examples of Chromosomal Translocations and Associated Oncogenes. See text for further explanation. From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition, Philadelphia: Elsevier; 2021.

Two illustration show chromosomal translocations and associated oncogenes. Top panel. The illustration shows two sets of chromosome pairs, 9 and 22, one normal and the other affected by chronic myelogenous leukemia. A B L oncogene from the normal chromosome 9 translocate to the B C R locus of the leukemic chromosome 22, generating an A B L-B C R hybrid gene. The hybrid gene leads to tyrosine kinase inhibited by tyrosine kinase inhibitor, resulting in the activation of growth factor signaling pathways. Bottom panel. The illustration shows two sets of chromosome pairs, 8 and 14, one normal and the other affected by Burkitt lymphoma. M Y C oncogene from the normal chromosome 8 translocate to the I G gene of the lymphoma chromosome 14, causing increased M Y C protein, which leads to increased expression of pro-growth genes.

Second, chromosome translocations can lead to production of novel proteins with growth-promoting properties. In chronic myeloid leukemia (CML), a specific chromosome translocation is almost always present (see Fig. 12.9). This translocation, t(9;22), was first identified in association with CML in Philadelphia in 1960 and is often referred to as the **Philadelphia chromosome**. Translocation

fuses two chromosomes in the middle of two different genes: *BCR* (breakpoint cluster region gene) on chromosome 9 and *ABL* (Abelson gene) on chromosome 22. The result is production of a BCR-ABL fusion protein containing the first half of BCR and the second half of ABL (a nonreceptor tyrosine kinase). BCR-ABL is an unregulated protein tyrosine kinase that promotes growth of myeloid cells. Imatinib, a drug that specifically targets this tyrosine kinase, represents the first successful chemotherapy targeted against the product of a specific oncogenic mutation.[9] Imatinib and related tyrosine kinase inhibitors (TKIs) are highly effective in the treatment of CML and, because of their specificity, lack the toxic side effects noted with nonspecific anticancer drugs. However, imatinib is not effective in cancers that do not have the t(9;22) translocation or related mutations. In modern personalized cancer therapy, knowledge of the specific genetic alteration can dictate the optimal drugs for the individual.

Oncogenes also may be activated by gene amplification (Fig. 12.10). Gene amplification results in increased expression of an oncogene, or in some cases drug resistance genes. The N-MYC oncogene, a member of the MYC family, is amplified in 25% of childhood neuroblastomas and confers a poor prognosis. The HER2 gene *(ERBB2)* is amplified in 20% of breast cancers.

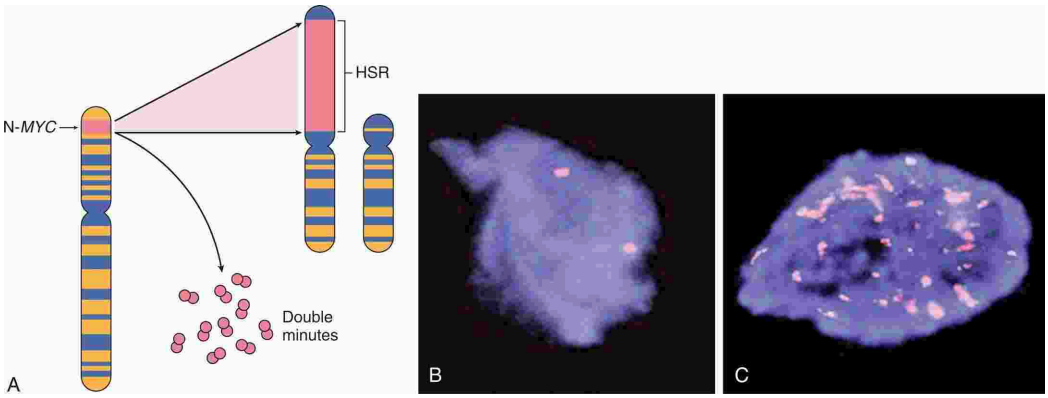

FIG. 12.10 N-Myc Gene Amplification in Neuroblastoma.
(A) The N-Myc gene is present on chromosome 2, becomes amplified, and is seen either as extra chromosomal double minutes or as a chromosomal homologous staining region. The N-Myc gene is detected in human neuroblastoma cells using a technique called FISH (fluorescent in situ hybridization). **(B)** A single pair of N-Myc genes is detected in normal cells and in low-grade neuroblastoma. **(C)** Multiple, amplified copies of the N-Myc gene are detected in some cases of neuroblastoma. Amplification of the N-Myc gene is strongly associated with a poor prognosis in childhood neuroblastoma. A, From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition, Philadelphia: Elsevier; 2021; B and C, Courtesy Arthur R. Brothman, PhD, FACMG, University of Utah School of Medicine, Salt Lake City, UT.

Illustration A is a chromosome that highlights the N-M Y C gene that amplifies to a H S R or double minutes. Photomicrograph B shows two pink N-M Y

C genes in a cell. Photomicrograph C shows multiple pink N-M Y C genes of varying sizes in the cell.

Evading Growth Suppressors

Uncontrolled cancer cell proliferation also is related to inactivation of tumor-suppressor genes. **Tumor-suppressor genes** normally regulate the cell cycle, inhibit proliferation resulting from growth signals, stop cell division when cells are damaged, and prevent mutations. Therefore, they also have been referred to as *anti-oncogenes*. Whereas oncogenes are activated in cancers, tumor suppressors must be *inactivated* to allow cancer to occur (Table 12.1 and Fig. 12.11). A single genetic event can activate an oncogene because it can act in a dominant manner in the cell. However, we have two copies of each tumor-suppressor gene, one from each parent. Both copies must be inactivated; thus, two mutations are necessary (homozygous mutations, also called loss of heterozygosity).

Table 12.1

Comparison of Cancer Gene Types

Gene Type	Normal Function	Mutation Effect
Caretaker	DNA and chromosome stability	Chromosome instability and increased rates of mutation
Dominant oncogenes[a]	Encode proteins that promote growth (e.g., growth factors)	Overexpression or amplification causes gain of function
Tumor suppressors (recessive oncogenes)	Encode proteins that inhibit proliferation and prevent or repair mutations	Requires loss of function of both alleles to increase cancer risk

[a]Nonmutant state referred to as proto-oncogene.

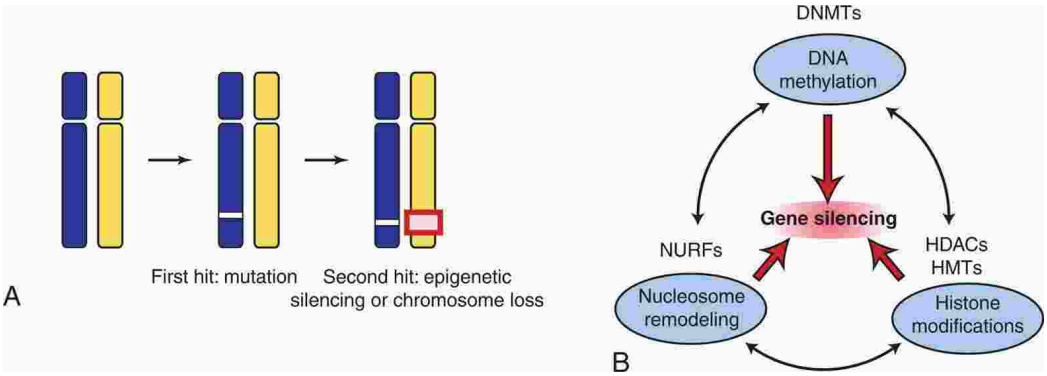

FIG. 12.11 Silencing Tumor-Suppressor Genes by Epigenetic Alterations.
Tumor-suppressor genes can be turned off by a variety of mechanisms. **(A)** In this example, the first hit is a point mutation in a tumor-suppressor gene *(white box)*, followed by either epigenetic silencing or chromosome loss of the second allele *(red box)*. **(B)** Genes can normally be silenced by a variety of interacting processes including DNA methylation, histone modifications, nucleosome remodeling, and microRNAs (not shown). Several cellular enzymes contribute to these modifications, including DNA methyltransferases *(DNMTs)*, histone deacetylases *(HDACs)*, histone methyltransferases *(HMTs)*, and complex nucleosomal remodeling factors *(NURFs)*. Gene silencing is essential for normal development and differentiation. B, Adapted from Jones PA, Baylin SB. The epigenomics of cancer. *Cell*, 2007;128:683–692.

Four illustrations, A, B, C, and D, demonstrate the silencing of tumor-suppressor genes by epigenetic alterations. Illustration A shows chromosome

mutations. Illustration B shows the cycle of gene silencing.

The most mutated gene in many human cancers is the **p53 tumor-suppressor gene (TP53)**. *TP53* missense mutations are the most common mutation in human cancers.[11] The protein p53 acts as a tumor suppressor, which means it regulates cell division by restricting cells from growing and dividing too fast or in an uncontrolled way; thus, it is called the *guardian of the genome*.[12] The p53 protein is in the nucleus of cells in the body and attaches directly to DNA. When DNA becomes damaged by such agents as toxic chemicals, radiation, or ultraviolet (UV) rays, the protein plays a critical role in whether the DNA will be repaired or the damaged cell with die from apoptosis.[12] If the DNA can be repaired, p53 activates other genes, **caretaker genes**, for repair. If the DNA cannot be repaired, p53 prevents the cell from dividing and signals it to undergo apoptosis.[12] From all these roles of p53, it assists in the prevention of tumors (Fig. 12.12). Many types of **cellular stress** (e.g., anoxia, oncogene expression, nuclear damage) produce intracellular signals (e.g., levels of nucleotides and glucose, degree of oxygenation, DNA damage, and other indicators of cellular abnormalities) detectable by p53. Typically, p53 is in an inactive complex with inhibitor molecules. Stress activates kinases that phosphorylate p53 into an active suppressor of cell division and activator of caretaker genes. Caretaker genes encode proteins involved in repairing damaged DNA, such as occurs with errors in DNA replication and mutations caused by numerous stressors. The p53 tumor suppressor protein is a DNA transcriptional regulator[13] and importantly, controls initiation of cellular **senescence** (cease dividing) or apoptosis and suppresses cell division until DNA repair is complete or other effects of stress are corrected. If not corrected, the cell enters senescence or apoptosis, thus preventing further DNA damage and mutations. Cellular senescence has been shown to exhibit both a tumor suppressor and an oncogenic effect.[14]

Senescence can promote cancer development by altering the cellular environment through a **senescence-associated secretory phenotype (SASP)**.[15] Early-stage senescence may protect cells from cancer transformation, but prolonged senescence often promotes cancer development.[15] Aberrant redox signaling assists senescence and carcinogenesis.[14] Loss of function of *TP53* or caretaker genes leads to increased mutation rates and cancer. *TP53* mutations in many cancers are linked to a poor prognosis.[13]**Li-Fraumeni syndrome** is a very rare inheritable loss-of-function mutation in *TP53* in one allele resulting in a 25-fold increase of developing malignancy at an early age (<50 years of age). These malignancies may include breast cancer, brain tumors, acute leukemia, soft tissue sarcomas, bone sarcoma, and adrenal cortical carcinoma.

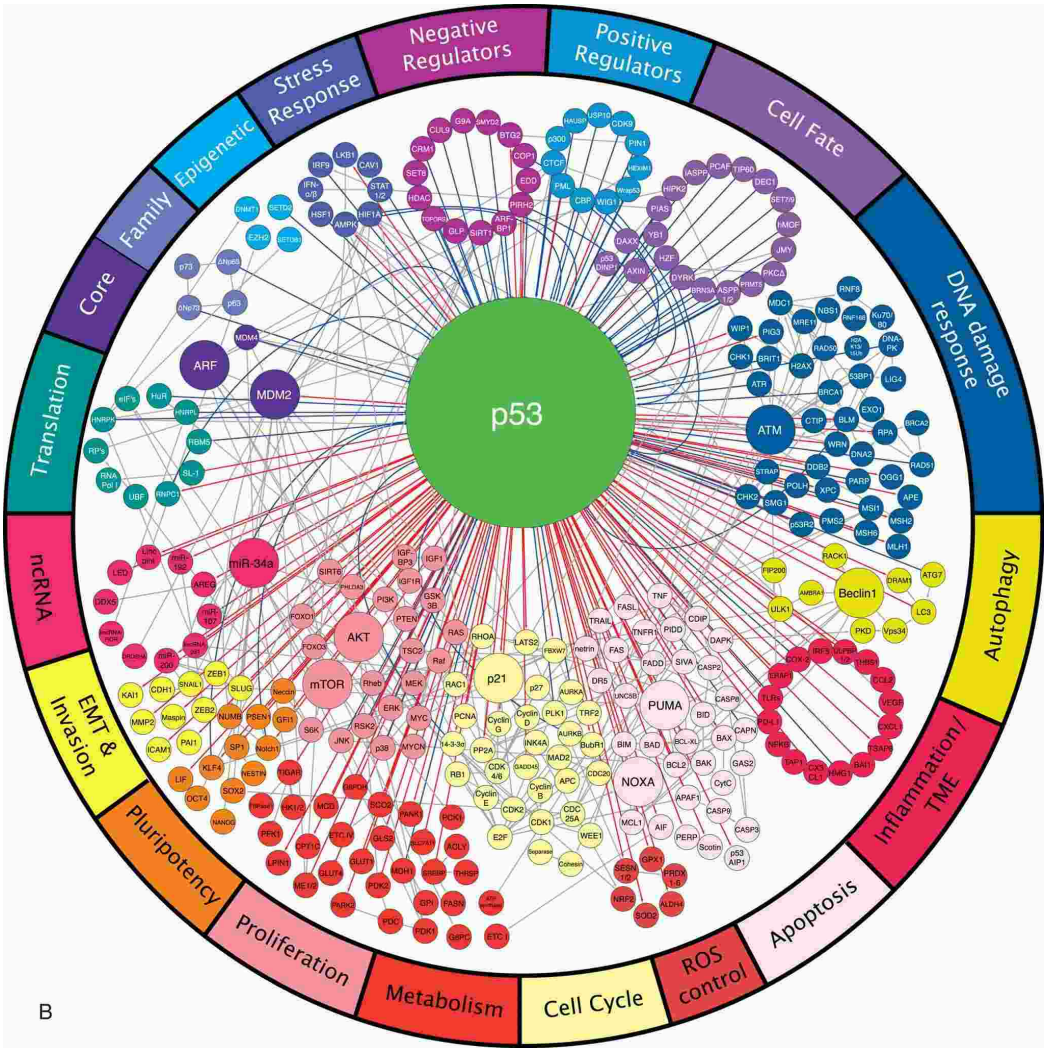

FIG. 12.12 The Role and Network of p53.
(A) The Role of p53 in Maintaining the Integrity of the Genome. Activation of normal p53 by DNA-damaging agents or by hypoxia leads to cell cycle arrest in G_1 by up-regulation of the cell cycle inhibitor p21 and induction of DNA repair transcriptional up-regulation of the cyclin-dependent kinase inhibitor *CDKN1A* (encoding the cyclin-dependent kinase inhibitor p21) and the *GADD45* genes. Successful repair of DNA allows cells to proceed with the cell cycle. If DNA repair fails, *p53* triggers either apoptosis or senescence. In cells with loss or mutation of the

p53 gene, DNA damage does not induce cell cycle arrest or DNA repair, and genetically damaged cells proliferate, giving rise eventually to malignant neoplasms. (From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition, Philadelphia: Elsevier; 2021.) **(B)** The p53 network is large and it controls many biological processes. Each node or circle represents a gene, and each line represents an interaction. Direct p53 inputs are indicated as blue lines and direct p53 outputs as red lines. P53 controls effector processes by activating multiple target genes. Although not shown here, the pathways are highly interconnected, and interactions are positive, negative, or modifying. Adapted from Data from Kastenhuber ER, Lowe SW. Putting p53 in context. *Cell*, 2017;170:1062–1078.

An illustrated flowchart shows the role and network of p 53. The data from the flowchart are as follows. Ionizing radiation of carcinogens mutagens leads to a normal cell (p 53 normal) or a cell with mutations or loss of p 53. Normal cell: D N A damage and oncogenic stress hypoxia lead to accumulation of p 53 that binds to D N A. Transcription dependent and independent effects on targets include the following: • Senescence: Normal cell. • P 21 (C D K inhibitor): G 1 arrest leading to successful repair, and thus normal cells. • D N A repair: G 1 arrest leading to successful (normal cells) or unsuccessful repair (apoptosis). • B A X: an apoptosis gene. • D N A

damage leads to p 53-dependent genes not being activated. No cell cycle arrest, no D N A repair, and no senescence lead to mutant cells. Expansion and additional mutations lead to a malignant tumor." "An illustration shows the p 53 network and represents genes that contribute to the following biological processes: • Positive regulators • Cell fate • D N A damage response • Autophagy • Inflammation or T M E • Apoptosis • R O S control • Cell cycle • Metabolism • Proliferation • Pluripotency • E M T and invasion • n c R N A • Translation • Core • Family • Epigenetic • Stress response • Negative regulators

Because inactivation of tumor-suppressor genes requires at least two mutations (one in each allele), a single **germ cell mutation** (sperm or egg) results in the transmission of cancer-causing genes from one generation to the next, producing families with a high risk for specific cancers. These inherited mutations that predispose to cancer are almost invariably in tumor-suppressor genes because only a single additional mutation in any other cell **(somatic cell mutation)** is needed to inactivate completely the tumor-suppressor gene (Table 12.2). Another way that tumor suppressor-genes can be inactivated is through **epigenetic silencing** or modulation of gene function (see Fig. 12.11 and Chapters 4, 6, and 13). Many cancers have increased methylation of DNA in the promoter region of tumor-suppressor genes. They also have associated changes in the modification of histones in the chromatin, often correlated with methylation of DNA. These changes alter the promoter regions of genes, leading to their **silencing** or altered gene expression.

Table 12.2

Some Familial Cancer Syndromes Caused by Loss of Tumor-Suppressor Gene Function

Syndrome	Gene
Retinoblastoma	*RB1*
Li-Fraumeni syndrome	*p53* (TP53)
Familial melanoma	$p16^{INK4a}$*(CDKN2A)*
Neurofibromatosis	*Neurofibromin (NF1)*
Familial adenomatous polyps	*APC*
Breast cancer	*BRCA1*

An example of increased risk for cancer that can be inherited is the familial form of retinoblastoma. The **retinoblastoma (*RB1*) gene** resides on chromosome 13, in a region referred to as q14 (13q14). *RB1* gene provides instructions for a protein called pRB.[16] It is responsible for monitoring antigrowth cellular signals and blocking activation of the growth/division phase in the cell cycle; thus *RB1* is a tumor suppressor gene and mutations in RB1 lead to persistent cell growth.[17] Most individuals with RB mutations have a subtle mutation, such as a point mutation, in one allele. The RB gene in the other chromosome may be inactivated through loss of the 13q14 region or epigenetic mechanisms. In the inherited form of retinoblastoma, a mutation in one *RB* allele is inherited so that only one additional mutation in the normal allele leads to cancer (see Table 12.2). RB is mutated in childhood retinoblastoma, and in some lung, breast, bladder, bone cancers (osteosarcoma), leukemias, and melanoma as well.[16] Approximately 40% of children with retinoblastoma have the inheritable form and most will develop tumors in both eyes (bilateral retinoblastoma) and are at increased

risk for a second primary cancer, such as a sarcoma or malignant melanoma.[18]

Other familial cancers with inheritable mutations in tumor-suppressor genes include Wilms tumor, a childhood cancer of the kidney (*WT1* gene), neurofibromatosis (*NF1* gene), and familial polyposis coli or adenomas of the colon (*APC* gene). Characterization of cancer-causing genes and other genetic factors helps identify individuals prone to developing cancer and contributes to understanding of sporadic cancers. Individuals known to carry mutations in tumor-suppressor genes are offered targeted cancer screening to facilitate early cancer detection and therapy.

Genomic Instability

Genomic instability is an increased tendency of alterations—mutability—in the genome during the life cycle of cells. Inherited and acquired mutations in caretaker genes that protect the integrity of the genome and DNA repair increase the level of genomic instability and risk for developing cancer.[19] Acquired mutations in "guardians of the genome," such as *TP53*, that detect DNA damage and activate repair mechanisms result in genomic instability and an increasing accumulation of mutations. Xeroderma pigmentosum is a defect in the repair of DNA pyrimidine dimers created by UV light that increases the risk for skin cancers. Hereditary nonpolyposis colorectal cancer results from an inherited defect in repairing DNA base pair mismatches that occur occasionally during DNA replication. Affected individuals have an increased rate of small insertions and deletions in DNA, leading to a high rate of colon and other cancers. Some inherited mutations threaten the integrity of entire chromosomes. Bloom syndrome, caused by mutations in a DNA helicase, presents with an increased risk of several forms of cancer, and those with Fanconi aplastic anemia, caused by loss of function for repairing DNA double-strand breaks, have a particularly increased risk of acute myelogenous leukemia. These examples are autosomal recessive disorders in which affected individuals demonstrate marked chromosomal instability. Genomic

instability also may result from increased epigenetic silencing or modulation of gene function discussed earlier (see Chapter 6).

Changes in gene regulation can affect not just single genes, but also entire intracellular signaling networks. Gene expression networks can be regulated by changes in **microRNAs (miRNAs or miRs)** and other non–coding RNAs (ncRNAs). miRNAs regulate gene expression by binding to target messenger RNA, thereby leading to repression or promotion of DNA translation. Through this process, miRNAs regulate cell differentiation, proliferation, apoptosis, autophagy, and stem cell maintenance.[20] miRNAs can be divided into those that promote cancer (oncogenic miRNAs or oncomirs), and those that prevent cancer (tumor suppressor miRNAs). **Oncomirs** promote multiple cancer pathways, including genomic instability, methylation patterns, immune dysfunction, tumor microenvironment, and drug resistance.[20]

Mutations in *BRCA1* and *BRCA2* (breast cancer 1 and 2, early-onset genes) are important clinically. Both are tumor-suppressors and caretaker genes that repair double-stranded DNA breaks. Inherited harmful mutations in *BRCA1* or *BRCA2* can occur from either a mother or father. Either gene with a high-risk mutation greatly increases the risk for a variety of tumors, especially breast cancer in both women and men, and ovarian or prostate cancers.[21] From a seminal paper, the average cumulative risk of developing breast cancer by age 70 years with a *BRCA1* mutation was 65%, and ovarian cancer was 39%.[22] The corresponding estimates for *BRCA2* mutation were 45% for breast cancer and 11% for ovarian cancer.[22] At-risk women are currently offered enhanced screening, prophylactic (risk-reducing) surgery, and chemoprevention.

In addition to specific gene mutations and abnormal epigenetic silencing, **chromosome instability (CIN)** also appears to be increased in malignant cells, resulting in a high rate of chromosome loss, as well as loss of heterozygosity and chromosome amplification. The underlying mechanism of this instability is not clear but may be caused by malfunctions in the cellular machinery

that regulates chromosome segregation at mitosis. CIN has been associated with resistance to cancer therapies in many cancers.[23]

Enabling Replication Immortality

A hallmark of cancer cells is their **immortality;** they seem to have an unlimited life span and will continue to divide for years under appropriate laboratory conditions. One of the most commonly used laboratory cell lines, **HeLa cells**, was derived from a cervical cancer specimen obtained in 1951 that continues to grow and divide in laboratories worldwide. Most normal cells are not immortal and can divide only a limited number of times (known as the *Hayflick limit*) before they either enter senescence (cease dividing) or enter crisis (apoptosis) and die. One major block to unlimited cell division (i.e., immortality) is the size of a specialized structure called the *telomere*. **Telomeres** are protective ends, or caps, of repeating hexanucleotides (six nucleotide units) on each chromosome and are placed and maintained by a specialized enzyme called **telomerase** (see Fig. 12.13). Telomerase is usually active only in germ cells (in ovaries and testes) and in stem cells. All other cells of the body lack telomerase activity. Thus, when non–germ cells begin to proliferate abnormally, their telomere caps shorten with each cell division. Short telomeres usually signal the cell to cease cell division. If the telomeres become critically small, the chromosomes become unstable and fragment, and the cells die.

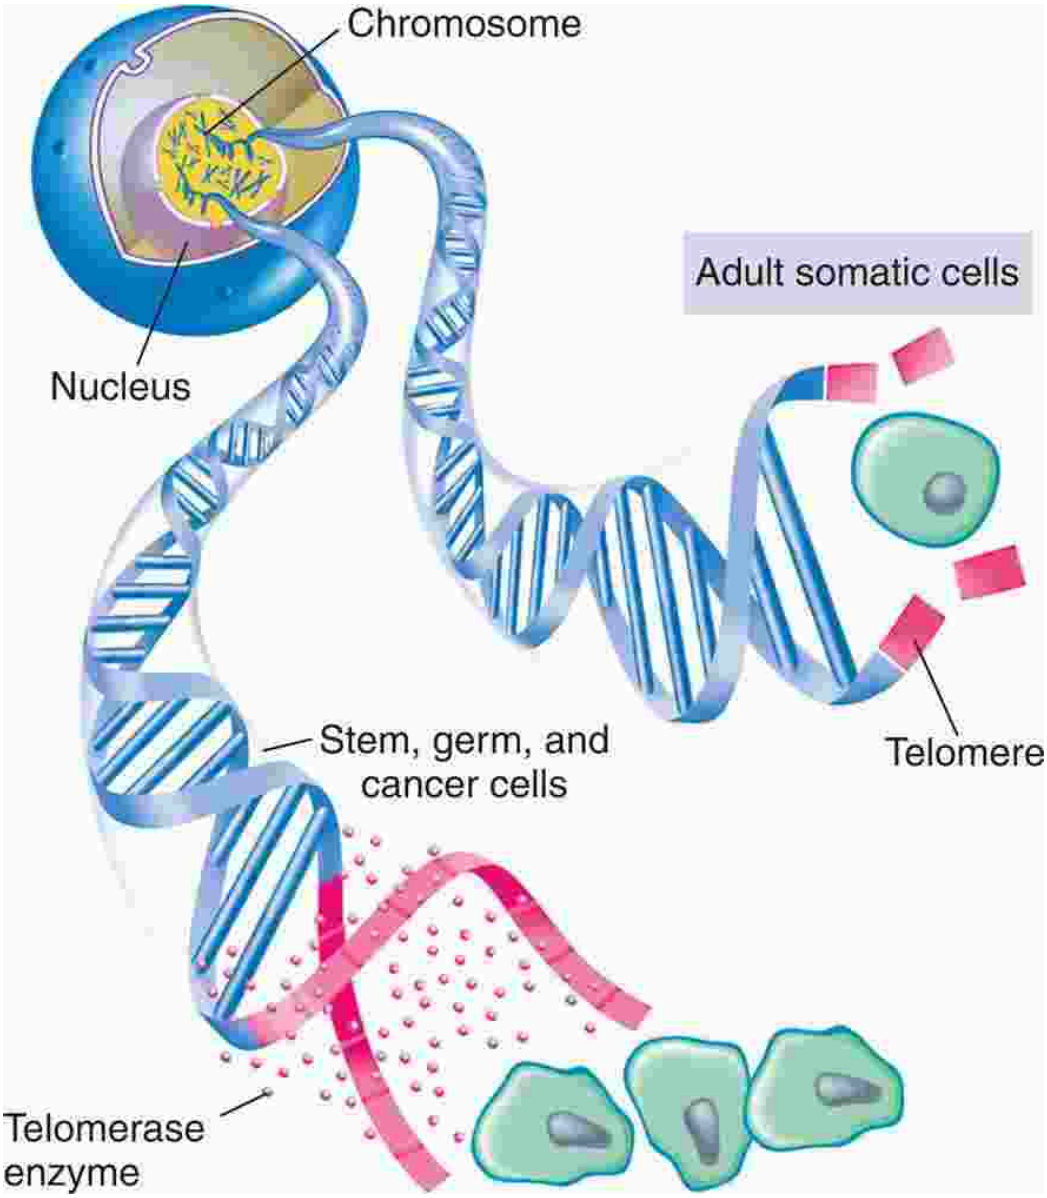

FIG. 12.13 Control of Immortality: Telomeres and Telomerase.
Normal adult somatic cells cannot divide indefinitely because the ends of their chromosomes are capped by telomeres. In the absence of the telomerase enzyme, telomeres become progressively shorter with each division until, when they are critically short, they signal to the cell to stop dividing. In germ cells, adult stem cells, and cancer cells, the telomerase gene is

"switched on," producing an enzyme that rebuilds the telomeres. Thus, like germ cells, the cancer cell becomes immortal and able to divide indefinitely without losing its telomeres.

An illustration demonstrates the control of immortality through telomeres and telomerase. The illustration shows a cutaway view of a cell with nucleus and chromosomes. Adult somatic cells in the D N A helical structures end with telomeres. Stern, germ, and cancer cells in the D N A helical structure lead to telomerase enzymes surrounding its end.

Cancer cells are very heterogeneous, and many cells die as the cancer develops. When they reach a critical age, most cancer cells reactivate telomerase to restore and maintain their telomeres, thereby allowing continuous division. Telomerase not only maintains telomere length, but it also affects DNA replication, cellular apoptosis, tumorigenesis, and resistance to therapy by cancer cells, including those of breast and cervical origin.[24] The trigger for re-expression of telomerase activity remains unclear; however, evidence is emerging that promotor mutations, genomic rearrangements, and epigenetic dysregulation of telomerase reverse transcriptase (TERT) are core steps.[24] Cancer cells move closer to immortality by upregulating telomerase and downregulating tumor suppressor genes. Telomerase activity is restored in about 90% of cancers and is an attractive therapeutic target.[25]

Cancer stem cells (CSCs) are a subpopulation of tumor cells that have replication immortality. They arise from tissue resident stem cells or develop from transformed differentiated cells. Transformation from differentiated cells into CSCs occurs through the activation of oncogenes, inactivation of tumor suppressor genes,

and re-expression of telomerase.[26] CSCs can change their appearance and function in response to the tumor microenvironment such that they drive cancer progression, serving as the cellular seeds for both tumor growth, metastases, and disease recurrence[27] (See section Activating Invasion and Metastasis). CSCs exist in a variety of tumor types such as leukemia, brain, breast, lung, and gastrointestinal (GI) cancers. Detection of CSCs is conducted via identification of surface protein markers and metabolic/functional properties. They often are highly resistant to traditional forms of cancer treatment. New therapies that target CSCs are being developed.[28]

Cellular Adaptations

Inducing Angiogenesis

An important component of wound healing is the process of establishing new blood vessels within the tissue undergoing repair (called **neovascularization** or **angiogenesis**). Access to a blood supply also is obligatory for the growth and spread of cancer. Without a blood supply to deliver oxygen and nutrients, growth of a tumor is limited to about a millimeter in diameter.

Angiogenic factors and **angiogenic inhibitors** typically control development of new vessels. In cancerous tumors, several mechanisms increase and maintain secretion of angiogenic factors by the cancer cells and prevent release of angiogenic inhibitors. **Hypoxia-inducible factor-1α (HIF-1α)**, an oxygen-sensitive transcription factor, is a primary regulator of angiogenesis in normal tissue; HIF-1α is stabilized under hypoxic conditions and induces expression of pro-angiogenic factors, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF).[29] Inactivation of tumor-suppressor genes (e.g., *p53*) or increased expression of oncogenes (e.g., *HER2*) leads to increased expression of HIF-1α–regulated angiogenic factors and increased vascularization. Increased expression of HIF-1α also is related to increased resistance to chemotherapy, increased tumor cell glycolysis, increased metastasis, and a poor prognosis. These effects may likely occur

through an autocrine mechanism by which VEGF activates tumor-associated VEGF receptors.

Other routes of angiogenic factor induction include mutations in cancer oncogenes (e.g., *RAS, MYC*) that increase transcription of VEGF by cancer cells. Most cells in the tumor microenvironment also secrete VEGF, including tumor-infiltrating monocytes, endothelial cells, adipocytes, and cancer-associated fibroblasts. Endogenous angiogenesis inhibitors, such as **thrombospondin-1 (TSP-1)**, typically bind to cellular surface receptors on inflammatory cells and negatively regulate angiogenesis in wound healing and tissue remodeling. The expression of angiogenesis inhibitors is under the control of p53, which is suppressed in cancer cells, thus diminishing the control of stromal inflammatory cell secretion of angiogenic factors.

Cancer cells and stromal cells may increase production of **matrix metalloproteinases (MMPs)** (e.g., MMP-9) (Fig. 12.14).[30] MMPs are zinc-dependent proteases that digest the surrounding extracellular matrix (ECM). The ECM contains stored latent (inactive) forms of some angiogenic factors (e.g., bFGF, transforming growth factor-beta [TGF-β]). MMPs activate the stored forms into functional angiogenic factors.

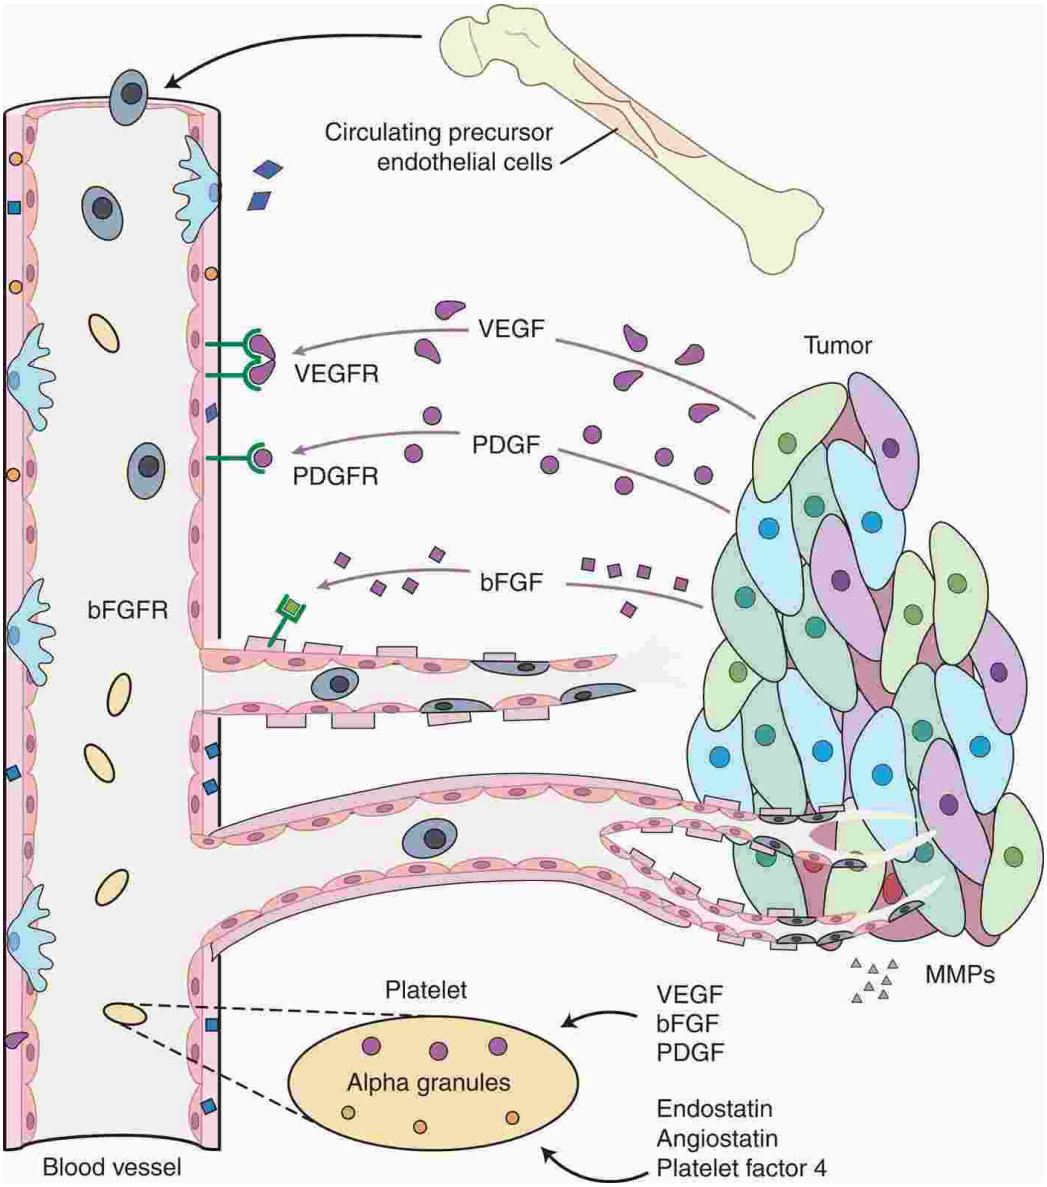

FIG. 12.14 Tumor-Induced Angiogenesis. Malignant tumors secrete angiogenic factors and tissue-remodeling matrix metalloproteinases *(MMPs)* that actively induce formation of new blood vessels. New blood vessels are formed from both local endothelial cells and circulating precursor cells recruited from the bone marrow. Circulating platelets can also release regulatory proteins into the tumor. *bFGF* and *bFGFR*, Basic fibroblast growth factor and its receptor,

respectively; *PDGF* and *PDGFR*, platelet-derived growth factor and its receptor, respectively; *VEGF* and *VEGFR*, vascular endothelial growth factor and its receptor, respectively. Adapted from Folkman J. Angiogenesis: An organizing principle for drug discovery? *Nature Review Drug Discovery*, 2007;6(4):273–286.

An illustration shows tumor-induced angiogenesis. The illustration shows a blood vessel with some branches. Circulating precursor endothelial cells from the bone marrow and alpha granules in the platelet flow through the vessel. Alpha granules include V E G F, b F G F, P D G F, endostatin, angiostatin, and platelet factor 4. One of the two branches of blood vessels is connected to a large tumor. Tumor secretes M M P s, V E G F, b F G F, P D G F which binds to their respective receptors.

The vessels formed within tumors differ from those in healthy tissue. They originate from endothelial sprouting from existing capillaries and irregular branching, rather than regular branching seen in healthy tissue. The interendothelial cell contact is less tight, so the vessels are more porous and prone to hemorrhage and allow passage of tumor cells into the vascular system. Another form of angiogenesis in tumors is called **vasculogenic mimicry**. Tumor cells form tubular structures like blood vessels that contain erythrocytes. These tubular tissues can attach to blood vessels to form a vascular network.[31]

Angiogenic inhibitors targeting VEGF signaling have been used to inhibit angiogenesis and diminish tumor growth.[32] Unfortunately, anti-VEGF therapies have not improved survival of individuals as much as was expected due to therapy resistance.[33,34] For example,

tumors may use alternative growth factors other than VEGF to activate angiogenesis or may revert to other ways of securing blood flow. New therapies to block angiogenesis are being explored.[33,35]

Reprogramming Energy Metabolism

Cancer cells live in a distinct environment from normal cells and have different nutritional requirements from nonproliferating cells (Box 12.1). The successful cancer cell divides rapidly, with the consequent requirement for the building blocks to construct new cells. Nonmalignant cells in the presence of adequate oxygen normally generate adenosine triphosphate (ATP) by mitochondrial oxidative phosphorylation (OXPHOS), generating 36 ATP molecules from each glucose molecule that is broken down to water and carbon dioxide. In the absence of sufficient oxygen (hypoxia), normal cells perform glycolysis, or the breakdown of glucose by enzymes (anaerobic glycolysis), generating only two ATP molecules per molecule of glucose with lactic acid and pyruvate as by-products.

Box 12.1

Cancer Metabolism

Reprogrammed metabolism is a hallmark of cancer. Reprogramming describes usual metabolic pathways that are enhanced or suppressed in tumor cells compared to benign tissues because of cancer mutations and/or other factors. Tumors reprogram pathways of nutrient obtainment and metabolism to meet the energetic, biosynthetic, and redox needs of tumor cells. An explosion of research in cancer metabolism is highlighting core principals. Cancer metabolic reprogramming has profound effects on gene expression, cellular differentiation, and the tumor microenvironment. Metabolic hallmarks of cancer metabolism include:

1. deregulated uptake of glucose and amino acids

2. grasping or opportunistic modes of nutrient acquisition
3. use of glycolysis/tricarboxylic acid (TCA) cycle intermediates for synthesis and nicotinamide adenine dinucleotide phosphate (NADPH) production
4. increased demand for nitrogen
5. alterations in metabolic-driven gene regulation and
6. metabolic interactions with microenvironment.

Most tumors display several of these hallmarks, but few display all six.

Understanding tumor metabolism is essential for determining treatment. Tumor cells adapt to nutrient-limited environments by inducing gene expression that secures adequate nutrients to sustain their metabolic demands. For example, acute lymphoblastic leukemia (ALL) cells are sensitive to the amino acid asparagine biosynthesis. ALL cells are responsive to asparagine depletion thus the use of the asparagine depletion enzyme L-asparaginase

Data from DeBerardins RJ, Chandel NS. Fundamentals of cancer metabolism. *Sci Adv*. 2016;2[5]:e1600200; Pavlova NN, Thompson CB. The Emerging Hallmarks of Cancer Metabolism. *Cell Metab*. 2016;23(1):27– 47.

Energy metabolism in cancer cells has received renewed attention and is deemed as important as other hallmark characteristics, such as sustained angiogenesis. In the 1920s, the emerging distinction between normal cells and cancer cells was first reported by Otto Warburg, termed the *Warburg effect*. The **Warburg effect** suggests that even in the presence of sufficient oxygen, cancer cells prefer to produce ATP through glycolysis instead of OXPHOS (Fig. 12.15).[9] Thus, the Warburg Effect is the use of glycolysis under normal oxygen conditions, hence the name **aerobic glycolysis**.[36] Although aerobic glycolysis was postulated to arise from cancer-specific mitochondrial dysfunction, it is now apparent that this is a highly regulated and beneficial adaptation for cancer cells. The shift from OXPHOS to glycolysis allows lactate and other products of

glycolysis to be used for the more efficient production of lipids, nucleosides, amino acids, and other molecular building blocks needed for rapid cell growth. Recent work, however, challenges the Warburg Effect because mitochondrial OXPHOS still contributes to overall ATP generation under normal conditions for certain cancer cells and reduces significantly in hypoxic environments. Perhaps more significantly, the Warburg Effect does not focus on the metabolic interactions between cancer cells and other components of the microenvironment.[37,38] Ongoing investigations involve glucose, amino acids, and possibly lactate dehydrogenase and their importance in cancer metabolism.

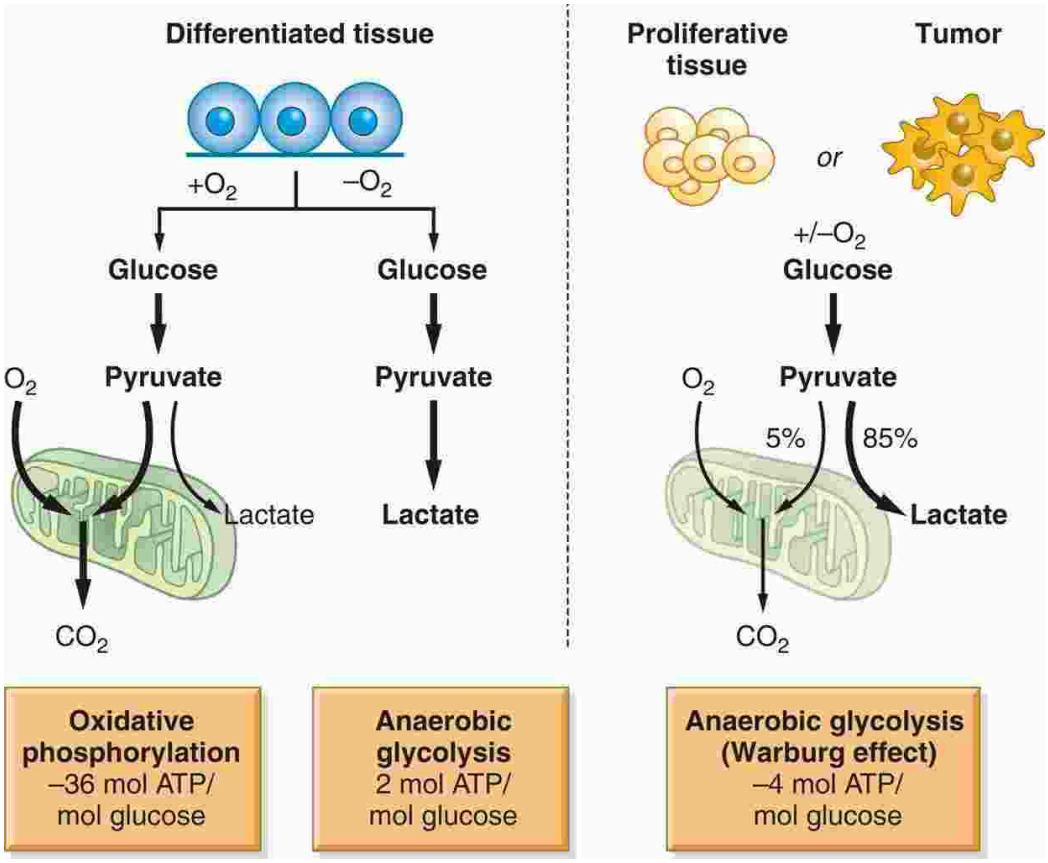

FIG. 12.15 Cancers Have Altered Metabolism. Normal tissues use oxidative phosphorylation (OXPHOS) to turn glucose into CO_2 and energy (in the form of ATP). Cancers take a different approach; even in the presence of oxygen, usually they do not use OXPHOS. Instead, they consume large quantities of glucose to make cellular building blocks, supporting rapid proliferation. *ATP*, Adenosine triphosphate. From Van der Heiden MG, Cantley LC, Thompson CB. Understanding the Warburg effect: The metabolic requirements of cell proliferation. *Science*, 2009;324:1029–1033.

An illustrated flowchart shows the altered mechanism of cancer cells. Oxidative

phosphorylation, minus 36 moles of A T P per mole of glucose: Differentiated tissues, in the presence of oxygen, turn to glucose, pyruvate, and lactate, releasing carbon dioxide. Anaerobic glycolysis, 2 moles of A T P per mol of glucose: Differentiated tissues in the absence of oxygen turn to glucose, pyruvate, and lactate. Anaerobic glycolysis (Warburg effect), minus 4 moles of A T P per mole of glucose: Proliferative tissue or tumor, in the presence or absence of oxygen, turns to glucose and pyruvate. 85 percent of pyruvate turns to lactate. 5 percent of pyruvate combines with oxygen to release carbon dioxide.

A new model, the **reverse Warburg effect**, may play a role in certain cancers.[39] Cancer cells may continue using the OXPHOS to generate large amounts of ATP. However, they also may manipulate the **cancer-associated fibroblasts (CAFs)** (see Fig. 12.18) perhaps by inducing oxidative stress to undergo aerobic glycolysis and secrete metabolites (e.g., lactate, pyruvate) that the cancer cells can use in the citric acid cycle (Krebs cycle) to feed OXPHOS and produce ATP.

A recent finding is that the mammalian/mechanistic target of rapamycin complex 1 (mTORC1) is a significant nutrient sensor and regulator of cellular metabolic processes.[40]

Clinically, the high glucose utilization of a cancer can be exploited for its detection. 18F-Fluorodeoxyglucose (FDG) is incorporated into cells in the same way as glucose, with two key differences. Because it is missing a key hydroxyl group, it cannot be broken down by glycolysis, and thus FDG accumulates in cells. Because it is tagged with F^{18}, it can be imaged by a positron emission tomography (PET) scan. Small metastatic tumor masses that are consuming huge

amounts of glucose can readily be detected with this imaging method (Fig. 12.16).

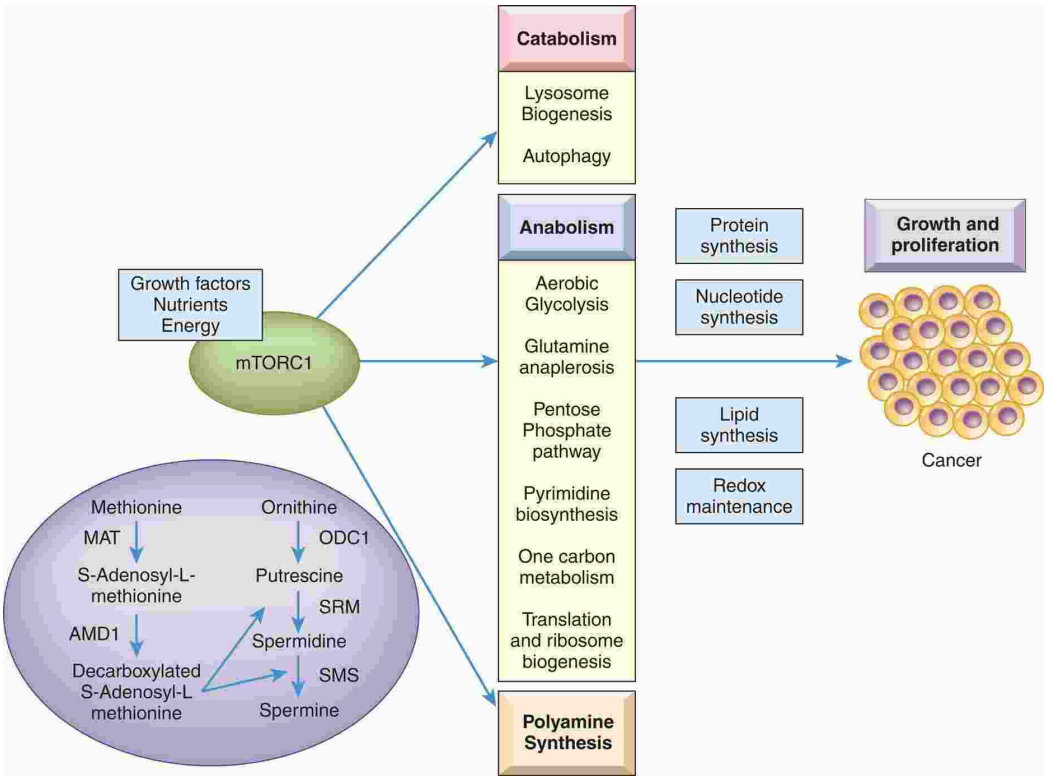

FIG. 12.16 Intense Glucose Requirement Aids in Diagnosis of Metastatic Non–Small Cell Lung Cancer.

This 54-year-old woman had a non–small cell lung cancer resected from the left upper lobe. Five years later, these studies were obtained. The positron emission tomography (PET) scan using 18-fluorodeoxyglucose (FDG) shows metastatic lesions in the brain, right shoulder, and mediastinal and cervical lymph nodes, as well as in the liver, left pelvis, and proximal femur. *PET whole-body image**(left)***: Representative coronal image from the whole-body FDG-PET/CT–fused image of the same person ***(right)***. The fused image consists of the computed tomography (CT) image with the metabolic information superimposed in color. The pattern of spread is most likely from the primary tumor to the large mediastinal lymph nodes, followed by lymphatic

spread to cervical nodes. Blood-borne dissemination produced the bone, brain, and liver metastases. Normally, only the heart, brain, and bladder show a strong signal in PET scans.
Images courtesy John Hoffman, MD, Huntsman Cancer Institute, Salt Lake.

A flowchart shows how intense glucose requirement aids in diagnosis of metastatic non-small cell lung cancer. Growth factors, nutrients, and energy in m T O R C 1 lead to the following. • Catabolism: lysosome biogenesis and autophagy. • Anabolism: aerobic glycolysis, glutamine anaplerosis, pentose phosphate pathway, pyrimidine biosynthesis, one carbon metabolism, and translation and ribosome biogenesis. • Polyamine synthesis. Protein synthesis, nucleotide synthesis, lipid synthesis, and redox maintenance after anabolism lead to growth and proliferation (cancer). Omithine with O D C 1 to putrescine; with S R M to spermidine; with S M S to spermine. Polyamine synthesis. Methionine with M A T to S-adenosyl-L-methionine; with A M D 1 to decarboxylated methionine; to putrescine or spermidine.

Resistance to Destruction

Resisting Apoptotic Cell Death

Programmed cell death **(apoptosis)** is a mechanism by which individual cells can self-destruct under conditions of tissue remodeling or as a protection against aberrant cell growth that may lead to malignancy. Two pathways may trigger apoptosis. The intrinsic pathway (mitochondrial pathway) monitors cellular stress. Cellular stress may include DNA damage, genomic instability, aberrant proliferation, loss of adhesion to ECM or to adjacent cells, and other causes and characteristics of abnormal cellular physiology. The extrinsic pathway is activated through a plasma membrane receptor complex linked to intracellular activators of apoptosis (known as the *death receptor*) (see Chapter 2) (Fig. 12.17).

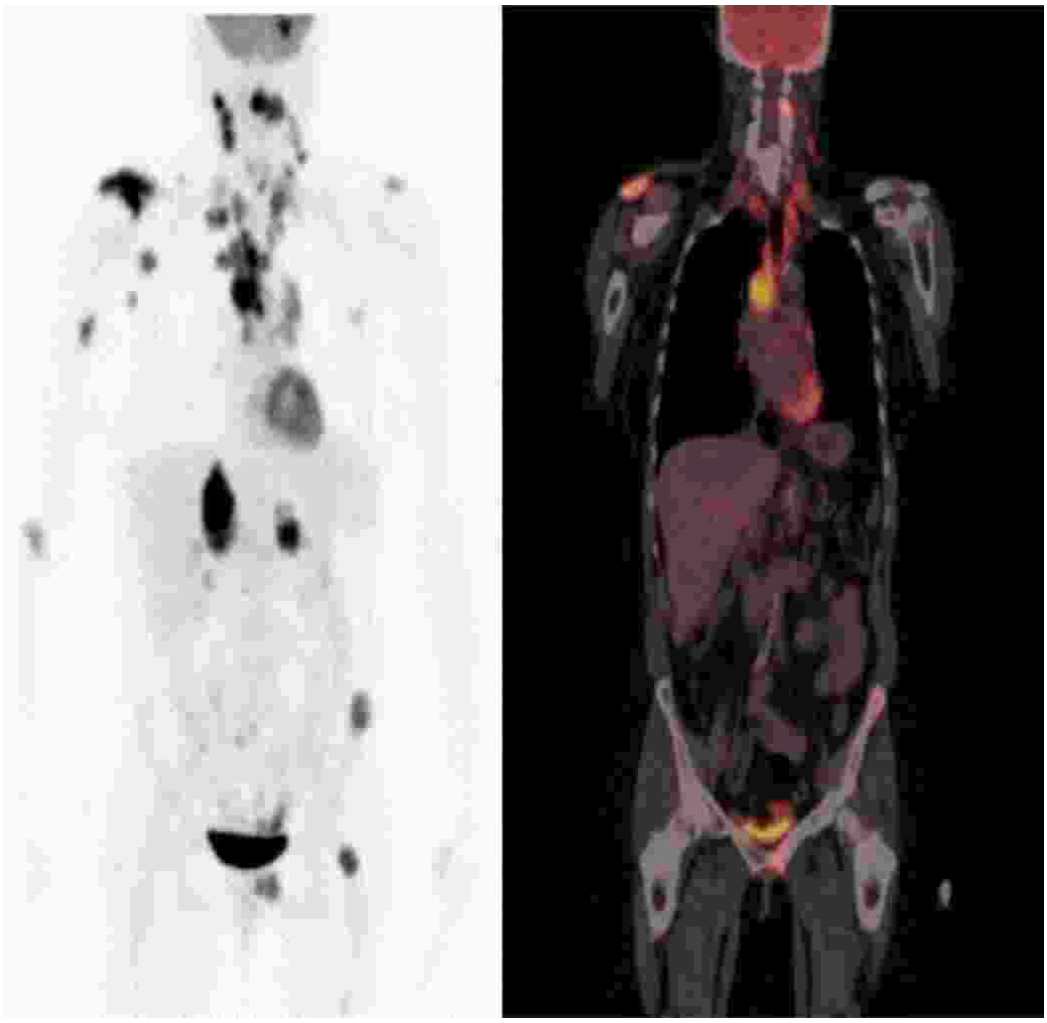

FIG. 12.17 Extrinsic and Intrinsic Pathways of Apoptosis and Mechanisms Used by Tumor Cells to Evade Cell Death.
(1) Loss of p53 through mutation leading to reduced function of proapoptotic factors, such as BAX. ***(2)*** Reduced egress of cytochrome *c* from mitochondria as a result of up-regulation of antiapoptotic factors, such as BCL-2. ***(3)*** Loss of apoptotic peptidase-activating factor 1 *(APAF-1)*. ***(4)*** Upregulation of inhibitors of apoptosis *(IAP)*. ***(5)*** Reduced CD 95. ***(6)*** Inactivation of death domain signaling complex (FADD). From Kumar V,

Abbas AK, Aster JC. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.

Apoptotic pathways are dysregulated in most cancers. Most commonly, loss-of-function mutations to the *TP53* gene suppress activation of apoptosis during DNA damage. The balance between pro- and anti-apoptotic molecules also can be affected by overexpression of anti-apoptotic molecules or diminished expression of anti-apoptotic molecules resulting from mutations. By whatever mechanism, or combination of mechanisms, successful cancers suppressed apoptotic pathways and increased resistance to cell death.

Tumor-Promoting Inflammation

The relationship between a cancer and the inflammatory system is complex. The inflammatory response contributes to the onset of cancer, and cancer is a cause of chronic systemic and local inflammation. Tumors can manipulate the inflammatory process in their local tumor microenvironment to benefit tumor progression and spread.[41] Cancer also causes systemic perturbations in both innate and adaptive immune processes that reduce the body's ability to fight the cancer (see Evading Immune Destruction section).

Chronic inflammation has been recognized for close to 150 years as being an important factor in the development of cancer. Chronic inflammations may result from many causes, for example, solar irradiation, asbestos exposure (mesothelioma), pancreatitis, and infection (Table 12.3). Additionally, some organs appear to be more susceptible to the oncogenic effects of chronic inflammation (e.g., the GI tract, prostate, thyroid gland). Individuals who have suffered with ulcerative colitis for 11 years or more have up to a 30-fold increase in the risk of developing colon cancer. Chronic viral hepatitis caused by hepatitis B virus (HBV) or hepatitis C virus (HCV) infection markedly increases the risk of liver cancer.

Table 12.3

Chronic Inflammatory Conditions and Infectious Agents Associated With Neoplasms

Inflammatory Conditions	Associated Neoplasm(s)
Inflammatory Conditions	
Asbestosis, silicosis	Mesothelioma, lung carcinoma
Bronchitis	Lung carcinoma
Cystitis, bladder inflammation	Bladder carcinoma
Gingivitis, lichen planus	Oral squamous cell carcinoma
Inflammatory bowel disease, Crohn disease, chronic ulcerative colitis	Colorectal carcinoma
Lichen sclerosus	Vulvar squamous cell carcinoma
Chronic pancreatitis, hereditary pancreatitis	Pancreatic carcinoma
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma
Sialadenitis	Salivary gland carcinoma
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma
Skin inflammation	Melanoma
Infectious Agent (Nonviral)	
Helicobacter pylori	Gastric adenocarcinoma, MALT lymphoma
Chronic bacterial cholecystitis	Gallbladder cancer

Inflammatory Conditions	Associated Neoplasm(s)
Schistosomiasis	Bladder, liver, rectal carcinoma; follicular lymphoma of spleen
Liver flukes	Cholangiocarcinoma
Infectious Agent (Viral)	
Human immunodeficiency virus type 1 (HIV-1)	Non-Hodgkin lymphoma, squamous cell carcinomas, Kaposi sarcoma
Hepatitis B and hepatitis C	Hepatocellular carcinoma
Epstein-Barr virus	B-cell non-Hodgkin lymphoma, Burkitt lymphoma, nasopharyngeal carcinoma
Kaposi sarcoma-associated herpesvirus (KSHV/HHV8)	Kaposi sarcoma
Human papilloma virus (HPV)-16, -18, -31, others	Cervical, anogenital warts
Human T-cell lymphotropic virus 1 (HTLV-1) Merkel cell polyomavirus	Adult T-cell leukemia/lymphoma Merkel cell carcinoma a rare skin cancer

Inflammatory Conditions	Associated Neoplasm(s)
Inflammatory Conditions	
Asbestosis, silicosis	Mesothelioma, lung carcinoma
Bronchitis	Lung carcinoma
Cystitis, bladder inflammation	Bladder carcinoma
Gingivitis, lichen planus	Oral squamous cell carcinoma
Inflammatory bowel disease, Crohn disease, chronic ulcerative colitis	Colorectal carcinoma
Lichen sclerosus	Vulvar squamous cell carcinoma
Chronic pancreatitis, hereditary pancreatitis	Pancreatic carcinoma
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma
Sialadenitis	Salivary gland carcinoma
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma
Skin inflammation	Melanoma
Infectious Agent (Nonviral)	
Helicobacter pylori	Gastric adenocarcinoma, MALT lymphoma
Chronic bacterial cholecystitis	Gallbladder cancer
Schistosomiasis	Bladder, liver, rectal carcinoma; follicular lymphoma of spleen
Liver flukes	Cholangiocarcinoma
Infectious Agent (Viral)	
Human immunodeficiency virus type 1 (HIV-1)	Non-Hodgkin lymphoma, squamous cell carcinomas, Kaposi sarcoma
Hepatitis B and hepatitis C	Hepatocellular carcinoma
Epstein-Barr virus	B-cell non-Hodgkin lymphoma, Burkitt lymphoma, nasopharyngeal carcinoma
Kaposi sarcoma-associated herpesvirus (KSHV/HHV8)	Kaposi sarcoma
Human papilloma virus (HPV)-16, -18, -31, others	Cervical, anogenital warts
Human T-cell lymphotropic virus 1 (HTLV-1)	Adult T-cell leukemia/lymphoma
Merkel cell polyomavirus	Merkel cell carcinoma a rare skin cancer

MALT, Mucosa-associated lymphoid tissue.

Modified from Kuper H, Adami HO, Trichopoulos D. Infections as a major preventable cause of human cancer. *Journal of Internal Medicine*, 2000;248(3):171–183. American Society for Microbiology. *The 7 Viruses That Cause Human Cancers* (see Table 12.3). Washington, DC: The American Society for Microbiology; 2019.

A specific example is the association between gastric inflammation induced by infection with the bacterium *Helicobacter pylori (H. pylori)* and the risk for gastric cancer. *H. pylori* is a bacterium that infects more than half of the world's population. Chronic infection with *H. pylori* is a significant cause of peptic ulcer disease and is strongly associated with gastric carcinoma, a leading cause of cancer deaths worldwide (see Chapter 41). It also is associated with a less common

cancer, gastric mucosa–associated lymphoid tissue (MALT) lymphomas. *H. pylori* infection is often acquired in childhood and disproportionately affects lower socioeconomic classes. Although most infections are asymptomatic, prolonged chronic inflammation, oxidative stress, and stimulation of GFRs may lead to increased gastric acid secretion, atrophic gastritis, and duodenal ulcers, or benign cellular proliferation that in 1% to 2% of individuals progress to dysplastic changes and finally gastric adenocarcinoma.[42] *H. pylori* infection can both directly and indirectly produce genetic and epigenetic changes in cells of infected stomachs, including mutations in *TP53* and alterations in the methylation of specific genes. Eradication of *H. pylori* from infected individuals before the development of dysplasia may prevent the development of cancer. However, there is no expert consensus on the value of population screening and treatment strategies. The MALT lymphomas associated with chronic *H. pylori* infections may depend on chronic inflammation and antigenic stimulation associated with infections, and therefore treatment with antibiotics may be useful even in cases of early lymphoma.[43]

Once cells with malignant phenotypes have developed, additional complex interactions occur between the tumor and the surrounding stroma and cells of the immune and inflammatory systems. Cancers disrupt the environment, initiate or enhance inflammation, and recruit local and distant cells (macrophages, lymphocytes, and other cellular components of inflammation). The acute inflammatory response is initially designed to eliminate infection but evolves to initiate and direct the healing process (see Chapter 7). Successful tumors appear capable of manipulating cells of the inflammatory response from a rejection response towards the phenotypes associated with wound healing and tissue regeneration; a process that includes induction in the damaged tissue of cellular proliferation, neovascularization, and local immune suppression.[41] These activities benefit cancer progression and increase resistance to chemotherapeutic agents.

One of the key cells that promote tumor survival is the **tumor-associated macrophage (TAM)**. Tumors commonly produce cytokines and chemokines that are chemotactic factors for monocytes/macrophages (e.g., colony-stimulating factor-1 [CSF1; also known as *macrophage colony–stimulating factor* or *M-CSF*], the chemokine ligand 2 [CCL2; also known as *monocyte chemotactic protein-1* or *MCP-1*]). Levels of CCL2 in human breast cancer and cancers of the esophagus are related to the degree of macrophage infiltration and progression of the tumor. Most tumors have large numbers of TAMs, whose presence frequently correlates with a worse prognosis.[44] Thus, monocytes are attracted from the blood and into the tumor, where they mature into macrophages. Monocytes can differentiate into several macrophage phenotypes (sometimes known as *plasticity* and *versatility*), depending on the conditions in the microenvironment. The classic proinflammatory macrophage (M1) is the primary macrophage in the acute inflammatory response and is responsible for removal and destruction of infectious agents. During healing, however, a different phenotype (M2) produces anti-inflammatory mediators to suppress ongoing inflammation and induce cellular proliferation, angiogenesis, and wound healing. TAMs appear to phenotypically mimic the M2 phenotype.

TAMs have diminished cytotoxic response and release a variety of immunosuppressive cytokines that block T-cytotoxic cell and natural killer (NK)-cell functions and promote tumor growth and spread.[44] TAMs secrete cellular growth factors (e.g., TGF-β and fibroblast growth factor-2 [FGF-2]) that favor tumor cell proliferation, angiogenesis, and tissue remodeling, similar to their activities in wound healing. They also secrete angiogenesis factors (e.g., VEGF) that induce neovascularization and matrix metalloproteinases (MMPs) that degrade intercellular matrix.[44] The overall effect is increased tumor growth, invasion of the blood vessels, increased oxygen to the tumor, and invasion through the degraded matrix into the local tissue.

Cancer-associated fibroblasts (CAFs) synthesize the ECM that surrounds and permeates the tumor (Fig. 12.18). Cytokines and growth factors stored in the matrix, as well as growth factors, metalloproteases, proteoglycans, and other molecules secreted by CAFs, contribute greatly to cancer progression, local spread, and metastasis (see Fig. 12.18.; Box 12.2: Cancer Associated Fibroblasts: Critical Facts).[45,46]Box 12.2 lists critical facts about the role and function of CAFs in cancer biology and tumor behavior. It is important to understand the significant roles of CAFs in clinical therapy. Several studies have documented how the number of CAFs or their function is linked to outcomes.[47–49] Much investigative activity is ongoing, with several clinical trials involving CAF-targeting agents in combination with existing therapies.[46] New methods are being developed to target fibroblasts specifically such as fibroblast activation protein (FAP) ligands coupled with cytotoxic drugs.[50] Clinical benefit might require targeting of CAF subtypes or reprogramming of CAFs to a normal fibroblast or an antitumorigenic CAF phenotype. Importantly, this requires the defining of CAF subtypes and their interrelationships.[46] The heterogeneity of CAFs, their functions, and possible changeability pose a challenge for the field, with preclinical studies suggesting that the non-specific targeting or deletion of stromal fibroblasts may not increase tumor control.[51,52] An example of making CAFs more normal is provided by the targeting of the vitamin D receptor in pancreatic cancer. Treatment with a vitamin D receptor ligand caused activated *stellate cells* (stellate cells are quiescent fibroblasts) to revert to a quiescent state and reduced disease aggressiveness.[53,54]

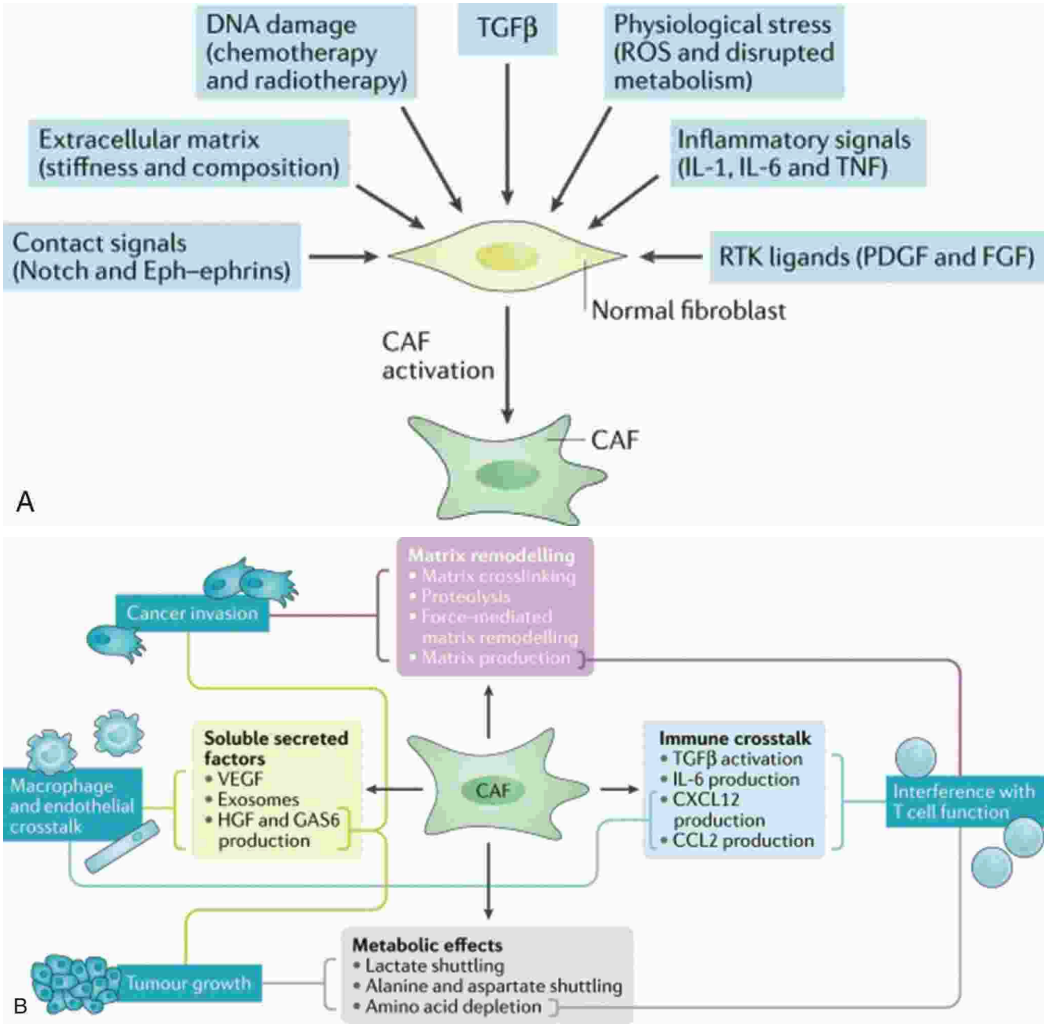

FIG. 12.18 Cancer Associated Fibroblasts. **(A)** Depicts several mechanisms of cancer associated fibroblast *(CAF)* activation. **(B)** Summary of CAF functions and corresponding mechanisms. *FGF*, Fibroblast growth factor; *HGF*, hepatocyte growth factor; *IL*, interleukin; *PDGF*, platelet-derived growth factor; *ROS*, reactive oxygen species; *TGF-β*, transforming growth factor-beta; *TNF*, tumor necrosis factor; *VEGF*, vascular endothelial growth factor. Data from Sahai E, Astsaturov I, Cukierman E, et al. A framework for advancing our understanding of cancer-associated fibroblasts. *Nature Reviews*. Cancer, 2020;20:174–186.

Two flowcharts, A and B, show cancer associated fibroblasts. Flowchart A. A normal fibroblast can undergo any of the following mechanisms, leading to C A F activation and thus C A F: • Contact signals (Notch and Eph-ephrin's). • Extracellular matrix (stiffness and composition). • D N A damage (chemotherapy and radiotherapy). • T G F-beta. • Physiological stress (R O S and disrupted metabolism). • Inflammatory signals (I L-1, I L-6, and T N F). • R T K ligands (P D G F and F G F). Flowchart B. The different C A F mechanisms are linked as follows. • Cancer invasion and interference with T cell function lead to matrix remodeling (matrix crosslinking, proteolysis, force-mediated matrix remodeling, and matrix production). • Macrophage and endothelial crosstalk and cancer invasion lead to soluble secreted factors (V E G F, exosomes, and H G F and G A S 6 production). • Interference with T cell function and macrophage and endothelial crosstalk lead to immune crosstalk (T G F-beta activation, I L-6 production, C X C L 12 production, and C C L 2 production). • Tumor growth and interference with T cell function lead to metabolic effects (lactate shuttling, alanine and aspartate shuttling, and amino acid depletion).

Box 12.2

Cancer Associated Fibroblasts: Critical Facts

- In normal development and physiology, fibroblasts are the main producers of connective tissue extracellular matrix (ECM)
- Their function changes with age
- Fibroblasts play a key role in tissue repair and are activated following tissue damage
- During wound healing they can produce transforming growth factor β (TGFβ)
- Following tissue injury, they crosstalk with adjacent epithelia and influence epithelial stem cell behavior
- Fibroblasts promote angiogenesis via vascular endothelial growth factor A (VEGA)
- They coordinate the function of the immune system via the production of chemokines and cytokines
- They play a functional role within the immune system; fibroblastic reticular cells (FRCs) within lymph nodes generate ECM conduits for the movement of potential antigens and serve migration "highways" for leukocytes
- Fibroblasts promote immune tolerance by the expression and presentation or normally tissue-restricted antigens
- Emerging is complex crosstalk between fibroblastic cells and epithelial cells in exocrine organs (such as, stellate cells are a distinctive type of fibroblast found in the liver and pancreas, they store lipid droplets and specific derivatives of retinoic acid
- Activation and quiescence of stellate cells is regulated by the vitamin D receptor, and deletion of which leads to spontaneous liver and pancreas fibrosis.

- Stellate cells play a broad role in metabolic homeostasis
- Fibroblasts play key roles in communicating with many other cell types in normal tissue homeostasis as well as repair
- Cancer associated CAFs may be the most effective cell within the tumor microenvironment at depositing and remodeling the ECM
- CAFs contribute to increased stiffness of tumor tissue and this triggers prosurvival and proproliferation signaling in cancer cells
- Increased mechanical stress can collapse blood vessels, leading to hypoxia, promoting more aggressive cancer phenotypes, and reducing drug delivery.
- Altered tissue mechanics may play a role in cancer development and premalignant disease; this is evidenced by the links between mammographic density and breast cancer incidence
- CAFs are a substantial source of growth factors, cytokines, and exosomes which, can promote tumor growth and regulate therapy responses. For example, fibroblast growth factor (FGF5), leukemia inhibitory factor (LIF), growth arrest-specific protein 6 (GAS6), TGF β, hepatocyte growth factor (HGF) promotes invasion and proliferative behavior in cancer cells.
- CAFs via cytokines and chemokines act on leukocytes, including CD+8 T cells, regulatory T (Treg) and macrophages, with both immunosuppressive and immunopromoting outcomes.
- Consensus from recent work is that the predominant effect of CAFs is immunosuppressive with IL-6, CXC-chemokine 9 (CXCL9) and TGFβ having well-established roles in reducing T cell responses.
- Antigen cross presentation by CAFs has been recently observed, and this may lead to CD+4 T cell activation and suppression of CD+8 T cells

- IL-6 may promote immunosuppression via systemic effects on metabolism
- Interference with the action of CXCL12 produced by CAFs promotes T cell mediated tumor control and targeting focal adhesion kinase (FAK) in cancer cells concomitantly reduces stromal fibroblast activation and the development of an immunosuppressive environment
- CAFs and cancer cells exchange metabolites and amino acids, which is an additional avenue by which stromal fibroblasts, interact with tumor cells
- Autophagy in stromal fibroblasts can generate alanine, which is used by pancreatic ductal adenocarcinoma (PDAC) cells to fuel the tricarboxylic acid (TCA) cycle.
- Metabolic dysregulation of CAFs is linked to altered immunoregulation, possibly through IL-6 production or depletion of immunomodulating amino acids.
- Both conventional DNA damaging chemotherapy and radiotherapy can trigger changes in CAF biology and fibrosis is a common late side effect of radiotherapy. Conventional chemotherapies, radiotherapy and target agents can promote the generation of CAFs, modulate their function, and lead to therapy resistance
- An appealing clinical strategy is to make CAFs more "normal," such as, targeting of the vitamin D receptor in pancreatic cancer. Treatment with vitamin D receptor ligand caused activated stellate cells (stellate cells are quiescent fibroblasts) to revert to a more quiescent state and reduced disease aggressiveness

Viruses and Cancer

Several viruses have been associated with human cancer; human papillomavirus (HPV), Epstein-Barr virus (EBV; also known as HHV4), Kaposi sarcoma herpesvirus (KSHV; also known as HHV8), hepatitis B and C viruses (HBV, HCV), and **Merkel cell polyomavirus** are associated with about 12% to 20% of all human cancers worldwide (see Table 12.3).[55] Cancer of the cervix and hepatocellular carcinoma account for approximately 80% of virus-linked cancer cases.

Virtually all cervical cancer is caused by infection with specific types of HPV, which infects basal skin cells and commonly causes warts. There are more than 120 HPV types, but only about 40 can infect human mucosal tissue, and only a few (HPV-16, -18, -31, and -45) are associated with the highest risk for developing cervical, anogenital, and penile cancer. Most HPV infection is handled effectively and rapidly by the immune system and does not cause cancer. Cancer is more common in people with prolonged infection with HPV (a decade or more), during which the viral DNA becomes integrated into the genomic DNA of the infected basal cell of the cervix and directs the persistent production of viral oncogenes. (see Chapter 25 and Box 27.5 for current CDC guidelines on HPV vaccine).

Chronic hepatitis B infections are common in parts of Asia and Sub-Saharan Africa and confer a 200-fold increased risk of developing liver cancer. Chronic hepatitis C infections have become increasingly recognized in Western countries. Up to 80% of liver cancer cases worldwide are associated with chronic hepatitis caused either by HBV or by HCV. About 60% of HBV-infected persons are unaware of their infection.[56] The initial infection with hepatitis B or C is not associated with cancer; instead, it is acquisition of a chronic viral hepatitis that markedly increases cancer risk. In both cases, it appears that a lifetime of chronic liver inflammation predisposes to the development of hepatocellular carcinoma. Widespread use of the HBV vaccine is expected to significantly decrease the incidence of chronic hepatitis B and hence hepatocellular carcinoma (see Chapter 41). So far, there is no vaccine for HCV;[57] however, effective

treatment of chronic infection is available and can prevent the development of hepatocellular carcinoma.[58]

For most other human tumor viruses, immunoprophylaxis is not yet available. EBV and HHV8 are members of the Herpesviridae family. More than 90% of adults have been infected with EBV, usually as children and without symptoms. EBV infection during adolescence may cause infectious mononucleosis. The virus infects B lymphocytes, stimulates their limited proliferation, and usually becomes latent throughout their lives. If the individual is immunosuppressed because of human immunodeficiency virus (HIV) infection or because of drugs given for an organ transplant, persistent EBV infection can lead to the development of B-cell lymphomas. EBV infection also is associated with Burkitt lymphoma in areas of endemic malaria and with nasopharyngeal carcinoma, a cancer endemic in Chinese populations in Southeast Asia. HHV8 is linked to the development of Kaposi sarcoma, a cancer that was once seen primarily in older men but now occurs in a markedly more virulent form in immunosuppressed individuals, especially those with acquired immunodeficiency syndrome (AIDS). HHV8 also has been linked to several rare lymphomas. **Human T-cell lymphotropic virus type 1 (HTLV-1)** is an oncogenic retrovirus linked to the development of adult T-cell leukemia and lymphoma (ATLL). HTLV is transmitted vertically (that is, inherited by children from infected parents) and horizontally (e.g., by breastfeeding, sexual intercourse, blood transfusions, and exposure to infected needles). Infection with HTLV may be asymptomatic, and only a small fraction of infected individuals progress to ATLL, often many years after acquiring the virus. Immunization has proven beneficial in preventing viral-induced cancers. **Merkel cell polyomavirus** is associated with a rare skin cancer or Merkle cell carcinoma.

Evading Immune Destruction

Based on the processes of adaptive immunity, cancer cells are abnormal and should be recognized and removed from the body (see Chapter 8). The *immune surveillance hypothesis* predicts that most

developing malignancies are suppressed by an efficient immune response against antigens found on cancer cells. **Tumor-specific antigens** are found only on cancer cells and include antigens from oncogenic viruses and altered glycoproteins and glycolipids (neoantigens). When present, tumor-specific antigens are processed by the tumor cell and presented on the cell surface by major histocompatibility complex (MHC) class I molecules and are targets of CD8+ T-cytotoxic cells (Tc cells) (Fig. 12.19) (see Chapter 8). NK cells recognize altered cell surface glycoproteins and glycolipids (see Chapter 7). Thus, cancer cells should be recognized as foreign and destroyed by the immune system. There is evidence to support the immune surveillance hypothesis, primarily based on the observance that individuals who are significantly immunosuppressed (e.g., after organ transplantation) have an increased risk for cancers of the skin, head and neck, lung, liver, and colon as well as lymphomas and leukemias. However, the incidence of these cancers in immunocompromised individuals is less than would be predicted if immune surveillance is highly effective. This discrepancy is the result of cancer cells having developed multiple mechanisms to evade the immune system including (1) absence of tumor-specific antigens, (2) lack of appropriate antigen processing and presentation and (3) production of immunosuppressive factors and activation of inhibitory molecules on immune cells (Fig. 12.20). As cancer cells proliferate, clonal development of immune-resistant variants arises. The link between these escape mechanisms and current cancer treatment is discussed in detail later in this chapter.

FIG. 12.19 Tumor Antigens and Induction of CD8+ Cytotoxic T cell Response.
Dendritic cells and macrophages in the tumor microenvironment ingest tumor cells or released tumor antigens and migrate to draining lymph nodes. Here, they present the antigens in the context of major histocompatibility complex (MHC) class II molecules and from the process called *cross-presentation*, from MHC class I molecules, enabling the tumor antigens to be recognized by naive CD8+ cytotoxic T lymphocytes *(CTLs)*. CTLs have the ability to kill tumor cells. From Kumar et al., 2021 modified from Abbas AK, Lichtman AH. *Cellular and molecular immunology*, 8th edition. Philadelphia: Elsevier; 2017.

An illustration shows the tumor antigens and induction of C D 8 plus cytotoxic T cell response. The illustration shows a tumor under a layer of tissue. Dendritic cells comprising phagocytosed tumor antigen pass through afferent lymphatic vessels, reaching the lymph node. Dendritic cell in the lymph node activates tumor antigen-specific C D 8 plus T cell. Tumor-specific C T L migrates to the tumor, killing the C T L in the tumor.

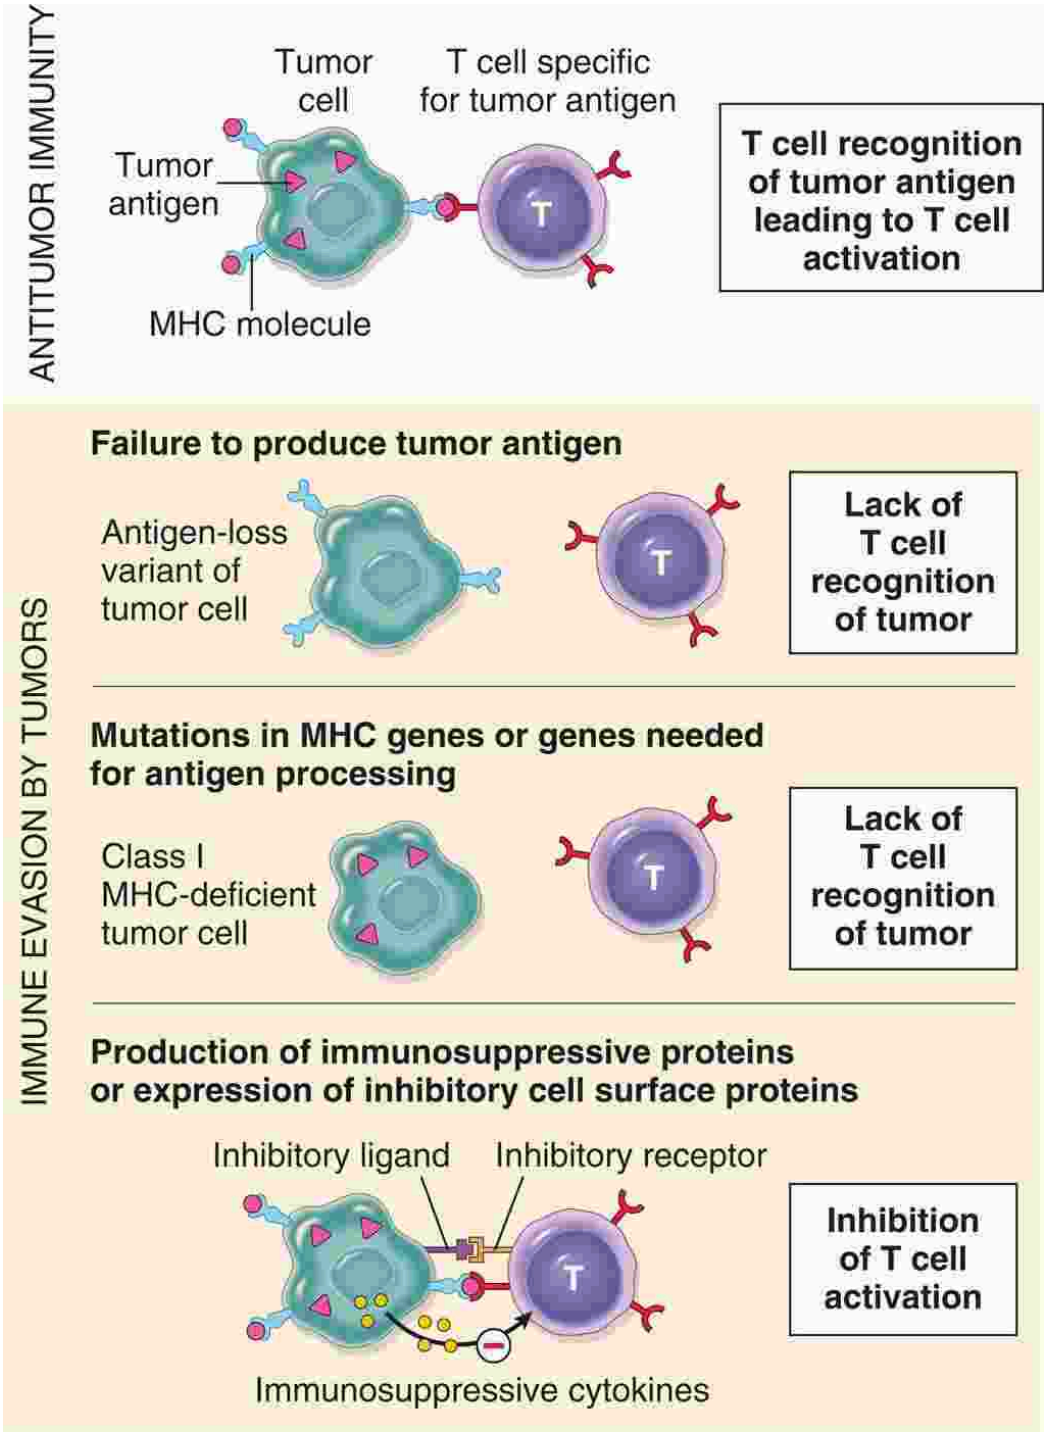

FIG. 12.20 Mechanisms by Which Tumor Cells Evade the Immune System.
Tumors may evade the immune response by losing expression of antigens or major histocompatibility complex *(MHC)* molecules or

by producing immunosuppressive cytokines or ligands for inhibitory receptors on T cells. From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.

An illustration shows antitumor immunity and immune evasion by tumors. Antitumor immunity. T cell recognition of tumor antigen leads to T cell activation. A tumor cell comprises tumor antigens and M H C molecules. A T cell specific for tumor antigen binds to the tumor cell. Immune evasion by tumors. There are three mechanisms. • Failure to produce tumor antigen. The illustration shows an antigen-loss variant of a tumor cell and a T cell, demonstrating lack of T cell recognition of tumor. • Mutations in M H C genes or genes needed for antigen processing. The illustration shows a class 1 M H C-deficient tumor cell and a T cell, demonstrating lack of T cell recognition of tumor. • Production of immunosuppressive proteins or expression of inhibitory cell surface proteins. The illustration shows a tumor cell with an inhibitory ligand bound to the inhibitory receptor of a T cell that negates immunosuppressive cytokines, demonstrating inhibition of T cell activation.

Although some cancer cells do express tumor-specific antigens that can be recognized by the immune system, most cancer cells do not, and those that do most often present antigens that are

undetectable by the immune system (see Fig. 12.20).[59] These cells can hide or mutate their surface antigens so that Tc and NK cells cannot recognize them. Tumor vaccination is a form of cancer treatment used to make the cancer cells antigenically detectable by the immune system.[60]

Even if the adaptive immune system is activated in the presence of a cancer, tumors are able to produce immunosuppressive factors that suppress or subvert the immune response (see Fig. 12.20). For example, many tumors have an abundance of **tumor-infiltrating lymphocytes (TILs)**. Although the immune cells frequently found in tumors were once thought to be futile attempts at an antitumor response; instead, it appears that cancers actively recruit an immune and stromal response to assist in remodeling of tissues, formation of new blood vessels, and promotion of metastasis. The predominant TILs are T-regulatory (Treg) cells.[41] Treg cells are CD4+ cells that differentiate under the control of specific cytokines, primarily TGF-β (see Chapter 8). The role of Treg cells during wound healing is to control or limit the immune response to protect the host's own tissues against autoimmune reactions. Their role in tumors is manipulated to prevent a destructive antitumor immune response and provide cytokines that facilitate tumor cell proliferation and spread.[61] Treg cells and TAMs, as well as other stromal cells, produce very high levels of TGF-β and interleukin-10 (IL-10). IL-10 is an immunosuppressive cytokine, which generally decreases T-helper cell 1 (Th1) and Th2 activity, suppresses antigen recognition and cell proliferation by Th cells, and suppresses the capacity of CD8+ T-cytotoxic (Tcyto) cells to recognize, proliferate, and kill tumor cells. The goal of current immunotherapy regimens is to reverse this relationship and facilitate T-cell–mediated cancer cell death (discussed later in this chapter). The release of immunosuppressive factors into the tumor microenvironment also increases resistance of the tumor to chemotherapy and radiotherapy. Increased levels of Treg cells in blood and lymph nodes and infiltrating the tumor correlate with poor outcomes in breast and GI tumors. In advanced non–small cell lung cancer, an elevated ratio of Treg to Tcyto cells is

related to a poor response to platinum-based chemotherapy. Immunosuppressive cytokines additionally lower the cancer cell's sensitivity to immune-mediated death (see Fig. 12.19). Adoptive T cell transfer is a cancer treatment in which lymphocytes are removed from the affected individual and activated or modified so that when they are reinfused, they attack the tumor.[62]

Immune cells have surface molecules whose purpose is to activate (co-stimulatory factors) or suppress (co-inhibitory factors) immune responses to antigens (see Chapter 8). Co-inhibitory molecules are often called immune *checkpoints*. Cancer cells may suppress T cells by binding to immune checkpoints, causing the lymphocyte to turn off its attack (see Fig. 12.20). An example is the checkpoint programed cell death receptor 1 (PD-1) binding with programmed cell death ligand-1 (PDL-1). Checkpoint inhibitors are a group of immunotherapy drugs that block this interaction, thus reactivating the immune cell to attack the tumor (see Immunotherapy section)[63]

With increasing heterogeneity of cells within the tumor, subpopulations of antigen-negative cancer cell variants may selectively outgrow more immune-sensitive cells. Variants may suppress the production of particular antigens or suppress levels of antigen-presenting MHC class I. Other cytokines appear to increase the cancer cells' resistance to apoptosis. For example, the Th2 cytokine IL-4 increases the resistance of thyroid cancer to chemotherapy; IL-6 produced by Th cells, adipocytes, and fibroblasts activates survival pathways in breast cancer leading to resistance to radiotherapy; and adipocytes enhance the transcription of the anti-apoptotic factor Bcl-2 in leukemia cells. Current chemotherapeutic regimens seek to kill as many cancer cells as possible so that there is less likelihood for the development of more resistant variants; however, toxicity of these treatments limits their effectiveness.

Activating Invasion and Metastasis

Metastasis is the spread of cancer cells from the site of the original tumor to distant tissues and organs through the body. Metastasis is a defining characteristic of cancer and is the main cause of death from

cancer. The process of metastases requires cancer cells to leave their primary site, circulate in the bloodstream, withstand pressure in the blood vessels, thrive in the new cellular surroundings, and escape "destruction" by immune cells.[64–66]

Biologic Processes of Metastasis

New paradigms in the study of metastasis have identified molecular underpinnings of the dissemination process.[64] An improved understanding of how the invading tumor cell interacts with other proteins and cells has elucidated new biological principles by which metastatic cells regulate their mobility and plasticity.[64] Unfortunately, communications with the tumor microenvironment allow invading cancer cells to conquer stromal challenges, settle, and colonize.[64] Characteristics are driven by genetics and epigenetic changes within the tumor cell itself and its microenvironment.[64] It is critical to understand these mechanisms of the metastatic process to develop successful treatment interventions. Hanahan and Weinberg identify that "activating invasion and metastasis" is a hallmark of cancer.[3] Invasion of close tissue and seeding at distant sites to form metastases remains a "key" feature of cancer malignancy (Fig. 12.21).

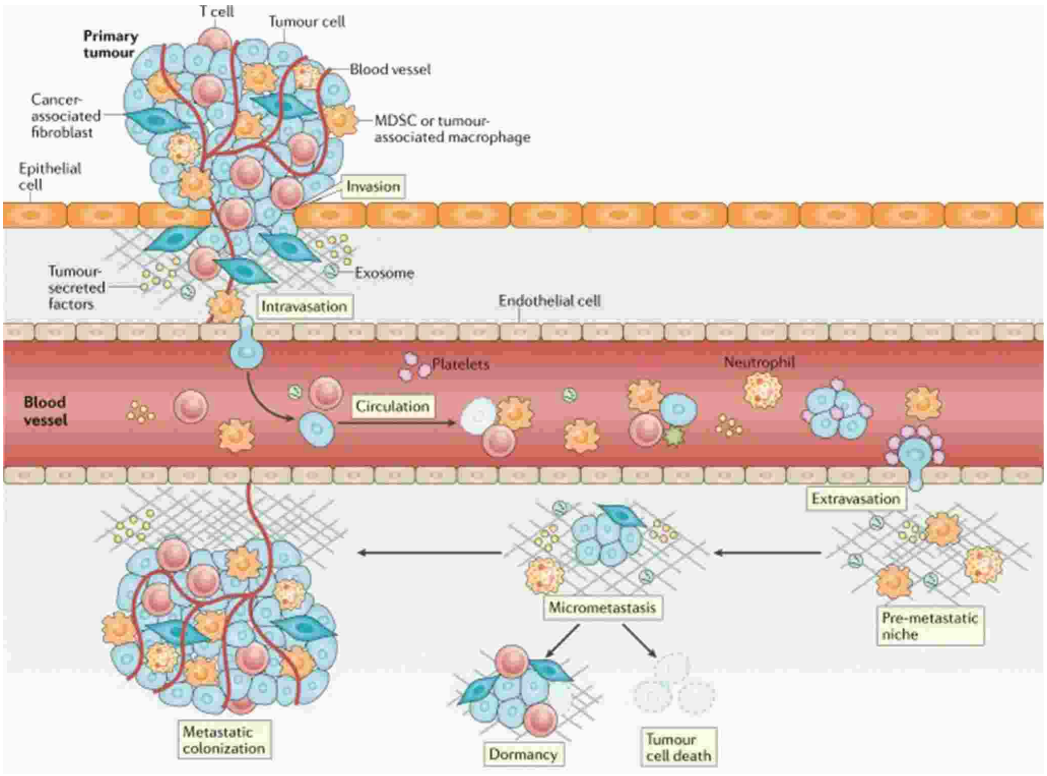

FIG. 12.21 Metastasis. Metastasis is complex with many steps. The key steps of metastasis include invasion, intravasation, circulation, extravasation, and colonization. From Anderson RL, Balasas T, Callaghan J, et al. A framework for the development of effective antimetastatic agents. *Nature Reviews. Clinical Oncology*, 2019;16:185–204. https://doi.org/10.1038/s41571-018-0134-8.

An illustration shows the different steps in metastasis. The steps in the illustration are as follow. 1. Invasion. The primary tumor is a cluster of T cells, tumor cells, cancer-associated fibroblasts, blood vessels, and M D S C or tumor-associated macrophage. The primary tumor is partially embedded through a layer of epithelial cells, releasing tumor-secreted factors and exosomes. 2.

Intravasation. Tumor cells pass through the layer of endothelial cells along the blood vessel. 3. Circulation. Tumor cells flow with platelets and neutrophils in the blood vessel. 4. Extraversion. The tumor cell, covered with platelets, pass through the blood vessel and into the system, where it undergoes pre-metastatic niche and micrometastasis, leading to dormancy or tumor cell death. 5. Metastatic colonization. The tumor cell proliferates and colonizes.

The Main Trigger: Chromosomal Instability

Dissemination of cancer cells leads the initial steps of the invasion-metastasis cascade.[67] Chromosomal instability becomes the "trigger" causing constant and continuous errors in chromosome segregation during mitosis (Fig. 12.22). Abnormalities in chromosome segregation cause the rupture of micronuclei and the secretion of genomic DNA into the surrounding cytosol. This cytosolic DNA then activates sensing pathways such as cyclic GMP-AMP synthase-stimulator of interferon (IFN genes) and downstream nuclear factor κ-light chain-enhancer of activated B (NF-κB) signaling.[68]

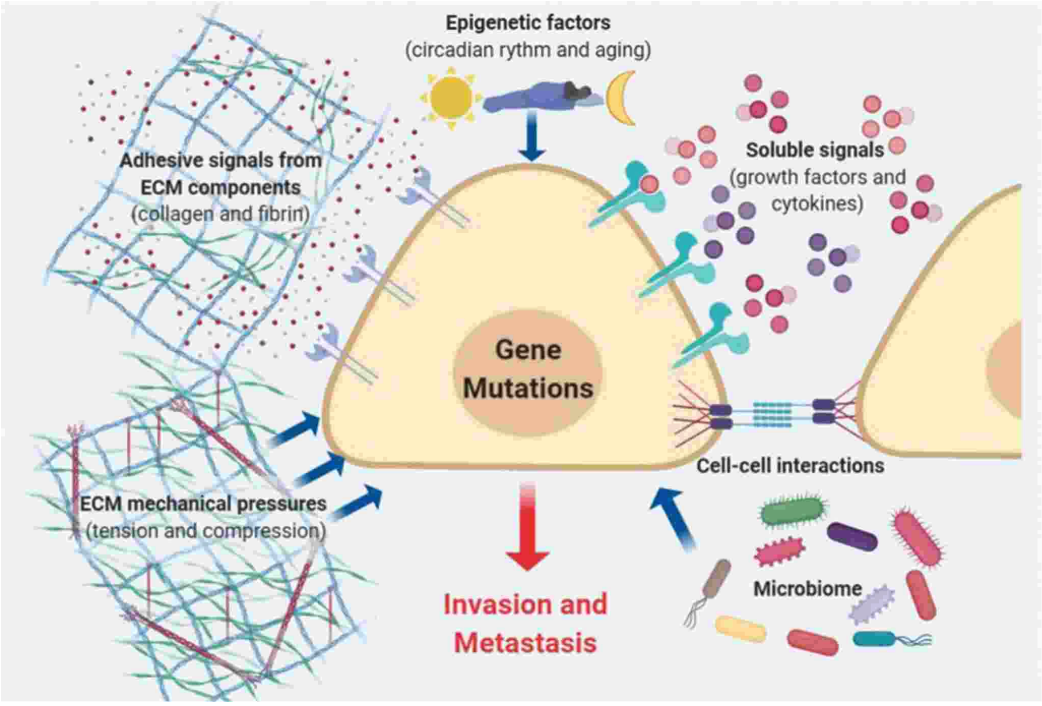

FIG. 12.22 Determinants of Metastases. Invasion and metastasis is triggered by epigenetic factors induced by environmental stimuli, such as aging, circadian disruptions, and many others; adhesive signals from the extracellular matrix *(ECM)* constituents, such as collagen and fibrin; ECM mechanical pressures, including tension and compression; cell-interactions; soluble signals, such as growth factors and cytokines; and the intratumoral microbiota Data from Fares J, Fares MY, Khachfe HH, et al. Molecular principles of metastasis: a hallmark of cancer revisited. *Signal Transduction Target Therapy*, 2020;5:28.

An illustration shows the determinants of metastases. Invasion and metastasis are a result of gene mutation triggered by the following factors. • Epigenetic factors (circadian rhythm and aging. • Soluble signals (growth factors and cytokines). •

Adhesive signals from E C M components (collagen and fibrin). • Cell-cell interactions. • E C M mechanical pressures (tension and compression). • Microbiome.

Investigators suggest that the nature of the primary seeding cancer cell determines the various and different metastatic properties aligned with growth and response to therapy.[69]

Both in vivo and in vitro studies show that metastatic cancer cells migrate individually.[70] In humans, however, it is believed that seeding requires the joint action of a cluster of tumor cells moving together,[71] which now highlights **epithelial-mesenchymal transition (EMT)**.

Epithelial-Mesenchymal Transition (EMT)

EMT is the developmental (transdifferentiation) process whereby transformed epithelial cells lose their cell polarity and cell-cell adhesion, and gain the ability to invade, resist stress, and disseminate. Usually, epithelial cells are immobile and tightly bound to each other by tight junctions, gap junctions, and adherens junctions and to the neighboring EMC.[72] EMT is a reversible biochemical process that permits a specific epithelial cell to attain a mesenchymal phenotype, such as a stem cell, which is critical for cancer progression and metastasis (Fig. 12.23).Thus, EMT involves profound morphological and phenotypic changes to a cell. From the study of using a mouse model of breast cancer, the determinant of metastasis is the availability of asparagine synthetase, a metabolic enzyme.[73] Decreasing the level of asparagine through L-asparaginase treatment through dietary restriction decreased metastatic spread. Thus, asparagine availability promoted EMT. It is now known that the EMT program is a spectrum of *transitional stages* between the epithelial and mesenchymal phenotypes and not full-epithelial and full-mesenchymal phenotypes.[74] The transition is

assisted by growth factors and signaling pathways. A spontaneous EMT in primary tumor cells shifts between different intermediate states with different invasive, metastatic, and differentiation characteristics.[75] Importantly, tumor cells that express a mix of epithelial and mesenchymal phenotypes are more effective in circulating, colonization at the secondary site, and the development of metastasis.[75] The various stages possess diverse cellular characteristics, chromatin landscapes, and gene expression signatures that are regulated by common and distinct transcription factors and signaling pathways. The various EMT stages are present in varied microenvironments and are in contact with diverse stromal cells.[75] For example, tumor cells with the most marked mesenchymal phenotype proliferate near endothelial cell and inflammatory cells.[75] These metastatic cells release large quantities of chemokines and proteins to attract immune cells and stimulate angiogenesis, thereby promoting the development of a unique inflammatory and very vascularized niche.[75] CAFs can also drive and direct cancer cell migration though fibronectin alignment.[76] The triggers for EMT in cancer cells include hypoxia, metabolic stressors, and matrix stiffness.[77,78] Transcription factors are programmed to repress epithelial genes and activate mesenchymal genes.[79] Epigenetic and posttranslational modulators also play a crucial role in controlling the EMT process.[74]

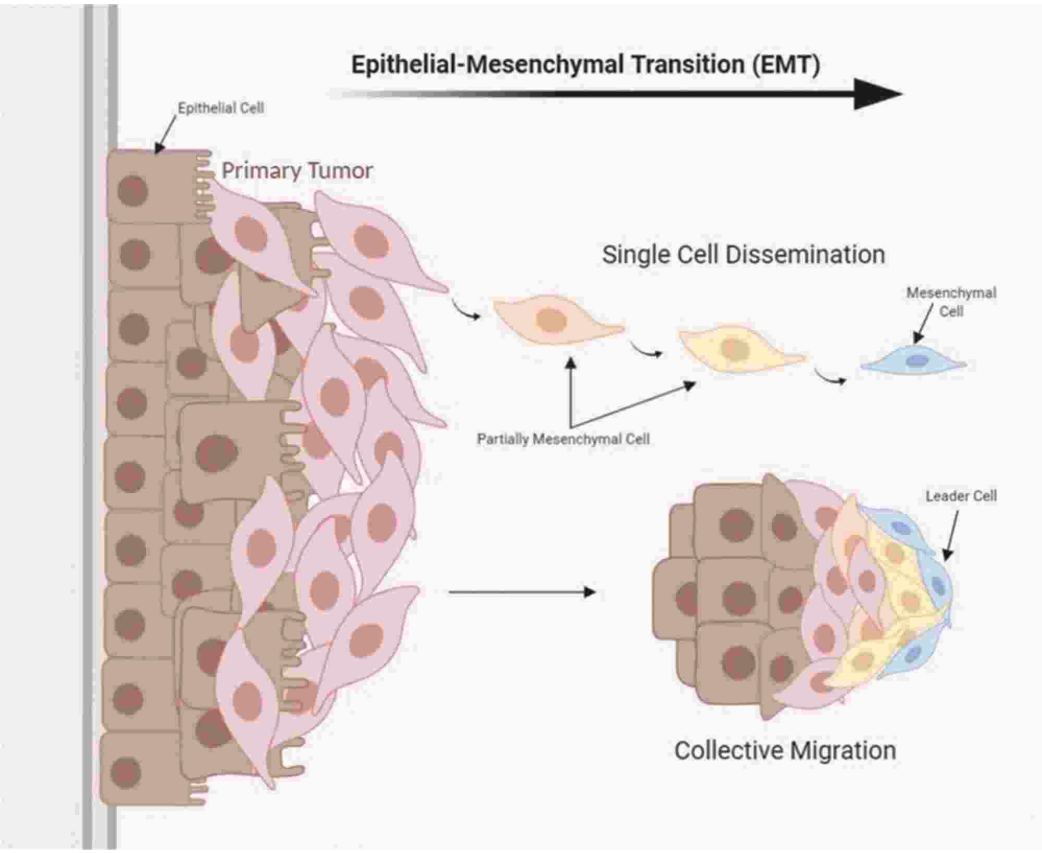

FIG. 12.23 Epithelial-Mesenchymal Transition (EMT).
EMT occurs through either single cell dissemination or collective migration. The process has several transition stages between the initial epithelial cell and the invasive mesenchymal cell.
Data from Fares J, Fares MY, Khachfe HH, et al. Molecular principles of metastasis: a hallmark of cancer revisited. *Signal Transduction Target Therapy*, 2020;5:28. doi: 10.1038/s41392-020-0134-x, 2020.

An illustration shows epithelial-mesenchymal transition (E M T). The illustration shows primary tumor cells embedded among layers of epithelial

cells. • Single cell dissemination. Partially mesenchymal cells transition to mesenchymal cells. • Collective migration. Layers of tumor cells on epithelial cells, lead by leader cells.

Despite these associations between cancer metastasis and EMT, controversy remains as to whether EMT plays a key role in cancer metastasis and resistance to chemotherapy.[79–81] For example, research in pancreatic and lung cancers reveals that EMT might not be essential for metastasis but it does contribute to chemoresistance.[80,82] Much more evidence is needed on this important issue.

Although the initiation of metastasis may involve EMT, mesenchymal-epithelial transition (MET) is necessary for metastatic progression.[64] E-selectin in the bone vasculature induces MET and WNT (signaling pathway) activation in cancer cells to drive metastatic tumor development.[83]

Metastatic Cells and Genetics

Various metastatic cells possess different genetic and epigenetic or phenotypic changes, which differentially drive tumor progression, metastasis, and drug resistance.[84] A "metastatic genetic signature" is suggested because hundreds of genes are reported associated with invasive potential.[85–87] Predominant genes somatically altered in metastatic cells include TP53, CDKN2A, PTEN, PIK3CA, and RB1.[88,89] Germline pathogenic variants were present in 12.2% of cases, and 75% were associated with DNA repair defects.[88]

Markers that predict metastatic progression have shown that advanced cancers arise from many different cell types, which significantly affects the eventual genetic and epigenetic alterations that promote metastasis.[90] These differences help explain why some cancer cells respond to treatment and others do not. It is critical to understand intertumoral heterogeneity because it can reveal the

mechanisms of metastatic progression and how the cell type of origin is related to tumor development.[64] Nonetheless, the cytotoxic immune signature and the presence of lymphatic vessels plays an essential role in cancer metastasis (see Immune Environment at the Primary Site and Metastasis).

Metabolic Metabolism of Metastatic Cells

Genetic expression is affected by oxygen homeostasis in the tumor microenvironment.[91] **Hypoxia-inducible factors (HIF)** enable cancer cells to adapt to their environment by modulating angiogenesis, EMT, invasion, metastasis, and energy metabolism.[3,64] HIF signaling drives the secretion of lysyl oxidase (LOX). LOX-like proteins, and exosomes, develop a pro-metastatic environment in the lungs and bones of individuals with breast cancer.[77,92] Hypoxic factors and other factors are associated with tumor aggressiveness and resistance to therapy.[93] Tumors with more extensive hypoxia and anoxic areas exhibit higher rates of metastasis and a poor prognosis.[64] Metabolic differences among cancer cells lead to differences in metastatic behavior, and metastatic cells depend on **mono-carboxylate transporter 1 (MCT1)** to handle oxidative stress.[64] Highly metastatic cells have increased levels of MCT1 and inhibition of MCT1 decreases their metastatic potential.[94] Changes in ATP/ADP and ATP/AMP ratios promote metastatic behavior.[95]

Priming the Premetastatic Niche

Invading cancer cells require a permissive environment before metastasis can be established. This environment is achieved through the active priming of secondary sites by the primary tumor. The host microenvironment called the **premetastatic niche** (PMN) is primed by the primary tumor even before the initiation of metastasis.[96] The development of PMN is a multistep process that involves secretory factors and extracellular vesicles that cause vascular leakage, ECM remodeling, and immunosuppression in the secondary sites, thus promoting the ability of cancer cells to successfully establish

metastasis.[96] Amazingly, high-definition microscopes have obtained images of cancer cells sharing biological material with less malignant cells, making these cells more malignant.[97] Tumor cells release vesicles that carry messenger RNA transcribed from genes that are involved in cell migration and metastasis, which are then received by cells in the PMN.[97] Once a non-cancerous cell engulfs these vesicles they start to migrate faster.[97] The transferred genes enhance the ability of cells to invade other organs.[97] Metastatic characteristics are transferred through extracellular vesicle exchange.[97]

Extracellular vesicles called exosomes transfer invasion-promoting factors from the primary tumor, such as miRNAs, to tumorigenic cancer cells.[98–100] For example, miR-10b is carried and released by exosomes driving metastatic properties in breast cancer cells.[101] Exosomes secrete EMT inducers that stimulate EMT progression in host epithelial cells, enabling them to invade and metastasize.[102–107] Additionally, exosomes can assist remodeling the ECM by communicating with fibroblasts, stromal cells, and endothelial cells to degrade components such as collagen, laminin, and fibronectin.[108] ECM altered by exosomes exhibits increased stromal cell proliferation, cancer cell migration and survival, and tumor cell resistance to apoptotic signals. These changes plus effects of growth factors and chemokines, leads to the formation of a new microenvironment for cancer cells, immune cells, and other stromal elements, known as the PMN,[109–112] where metastatic cells may arrest, extravasate, and later colonize.[113–115] Exosomes drive cancer cell organotropism or metastatic bias toward certain organs. The preference originates from exosome eagerness or avidity for specific host cells.[102] Exosome proteomic expression of bone cancer revealed different integrin patterns and specific integrins (α6β4 and α6β1) were associated with lung metastasis and αvβ5 was associated with liver metastasis.[116] Targeting integrins decreased exosome uptake and lung and liver metastasis.[116] Various membrane proteins and

lipids associated with ECM properties and adhesion influence the specific targeting of exosomes to their specific host cells.[116–120]

Exosome-mediated metastasis is not just dependent upon tumor-released exosomes. For example, astrocyte-derived exosomes mediate the intercellular transfer of miRNAs that target the PTEN tumor suppressor gene to metastatic cancer cells, advancing invasion and brain metastasis.[121] This leads to increased secretion of CCL2, which recruits myeloid cells, increasing the outgrowth of brain metastatic cells and reducing the effect of apoptotic signaling.[121] Inhibition of astrocytic exosome release prevents PTEN loss and inhibits brain metastasis.[121]

Epigenetic Factors in Metastasis

Chromatin and associated epigenetic mechanisms stabilize gene expression, cellular states, and appropriate responses to developmental or environmental cues.[122] Genetic, environmental, and metabolic conditions influence chromatin to become permissive or "plastic" states. Chromatin alterations can induce cells to gain oncogenic characteristics. Researchers are studying the specific effects of epigenetic *plasticity* when *permissive* chromatin induces oncogenic expression to promote metastatic development.[122] Approximately 50% of human cancers have mutations in chromatin proteins.[123,124] Malignant cells exhibit epigenetic changes such as genome-wide alterations in DNA methylation, chromatin structures, and regulatory element activities. Also, many tumors exhibit altered developmental programs indicative of differentiation block or epigenetic reprogramming.[125–127] The overriding premise is that specific genetic, environmental, and metabolic stimuli disrupt the homeostatic balance of chromatin, causing it to become either aberrantly restrictive or aberrantly permissive. Thus, chromatin is switchable. Such stimuli may act in a pre-malignant cell to promote tumor initiation and in a malignant cell to accelerate tumor evolution and adaptation.[122] This model is critical to understand as it can explain *diverse* oncogenic stimuli whose effects are mediated through

chromatin aberrations. The pervasiveness of such stimuli suggests that epigenetic defects contribute to *diverse* aspects of cancer biology and may, in fact, satisfy every hallmark of cancer.[2,3]

One example of how epigenetics may influence metastasis is with cutaneous melanoma. Older individuals with melanoma exhibit different patterns of metastasis than younger cohorts. Older individuals with melanoma tend to develop fewer metastases in proximal sentinel lymph nodes but have more distal metastases and worse survival than that of the younger cohorts.[128] Aging is a process (often stated as stimuli) affected by chromatin and epigenetic processes, such as DNA methylation. Aging also is characterized by alterations in immunity and the motility of immune cells leading to changes in the immune microenvironment. Age-related physical changes in the ECM inhibit or promote tumor cell motility, invasion, and metastasis.[64] From in vitro studies, increased lymphatic permeability of endothelial membranes was shown to be the reason as lymph nodes of older cohorts exhibited less ECM complexity in comparison with those of younger cohorts with metastatic melanoma.[128,129] Further study revealed that hyaluronan and proteoglycan link protein 1 (*HAPLN1*) is responsible for controlling endothelial permeability.[128,129] These data suggest age-related changes in tumor phenotype (epigenetics) drive lymphatic metastasis. Importantly, the biological effects of aging on patterns of metastases have not been explored sufficiently and has significant clinical implications. For example, regional lymphatic metastases are treated frequently with surgery, whereas distant metastases are often incurable.[128]

Microbiome and Cancer Metastasis

Bacteria have been detected in tumors constituting the *tumor microbiome*.[64] Microbes have been reported to confer vulnerability to specific cancers; however, no links have been established to patient outcome or survival.[130] Bacteria selectively translocate to tumors rich in vascular vessels and chemotactic pressures. Anaerobic and

facultative bacteria survive well in hypoxic tumor microenvironments.[131,132]

Tumoral bacteria are metabolically active and can change the chemical structure of chemotherapeutic agents affecting the response to treatment.[133,134] For example, gammaproteobacteria in pancreatic tumors confer resistance to gemcitabine, a common drug used in GI cancers.[133–136] Fap2 protein of Fusobacterium prevents the activation of NK cells, protecting the tumor cells of adenocarcinoma cell lines.[137] Some bacteria stimulate antitumoral immunity; others cause immunosuppression, contributing to the response of immunotherapy.[131,138,278–282]

Circadian Cycle and Dietary Effects on Tumorigenesis

Importantly, the circadian clock controls a wide spectrum of processes in cellular physiology through metabolic and gene expression pathways. It has been associated with cancer initiation and progression.[64] Epidemiological studies of night-shift workers, meal timing, and exposure to light have linked circadian patterns to tumorigenesis,[139–145] revealing that an active epigenetic mechanism may be responsible for genome alterations.[64]

Alterations in transcription complexes and cellular metabolism drive cancer progression by affecting cancer cell interactions with the microenvironment.[146] The MYC oncogene plays a role in cyclical metabolism in osteosarcoma cells resulting in increased consumption of glucose and glutamine.[147] Several circadian regulating genes have been linked to MYC expression.[64]

Diet has also been shown to impact cancer metastasis. Some of these dietary effects may be related to changes in the microbiome. Other effects are more direct. For example, as stated previously, asparagine is an important promotor of metastasis, and researchers have found that removing asparagine from the diet of mice reduced breast cancer metastases.[73] CD36+ metastasis-initiating cells rely on palmitic acid, a dietary lipid, to promote metastasis and blocking CD36+ inhibits metastatic ability.[148] These and other emerging data

suggest that diet affects the metastatic potential of metastasis-initiating cells.[149]

Invasive Cancer Cells: Remodeling the Extracellular Matrix

The **extracellular matrix** (ECM) is a scaffold, the interstitial matrix forms porous three-dimensional networks around cells that interconnect cells in the stroma and can connect to the basement membrane (see Chapter 1). Tissues are dynamically shaped by bidirectional communication between resident cells and the ECM through cell-matrix interactions and ECM remodeling.[150] The interstitial matrix assures the structural integrity of tissues and organs and modulates cellular processes such as cell differentiation and migration.[150] The interstitial matrix is composed of collagens, fibronectin, and elastin. Amount and composition of the interstitial matrix vary between tissue types, between microenvironments within the same tissue and can be remodeled in response to stress or trauma such as wound repair or tissue regeneration.[151] In cancer, remodeling of the interstitial ECM causes a broad range of biophysical and biochemical changes affecting cell signaling, ECM stiffness, cell migration, and tumor progression.[152] Contrastingly, the basement membrane is more stable, sheetlike, dense, and lines the basal surface of, for example, epithelial and endothelial cells, surrounds muscle cells and adipocytes, and separates tissues into different, well-organized compartments.[150] Binding of cells to the basement membrane is critical for establishing cell polarity (see Fig. 1.12D) and crucial for several developmental processes and maintenance of tissue homeostasis.[153]

Remodeling of the basement membrane is required for cancer cells to invade stromal tissue and become a malignant tumor.[154] Changes in the ECM are a result of different remodeling mechanisms that can be divided into four major processes: (1) ECM deposition, which refers to changing the abundance and composition of ECM components, which affect biochemical and mechanical ECM properties; (2) chemical modification at the post-translational level, which alters biochemical and structural properties of the ECM; (3)

proteolytic degradation from ECM-degrading enzymes called *matrikines* are released to remodel the ECM, re-establish an appropriate functional meshwork, and maintain tissue homeostasis; and (4) force-mediated physical remodeling, which affects ECM organization by aligning ECM fibers and opening up passages for cell migration.[150] It comes as no surprise that ECM remodeling becomes dysregulated in pathologic conditions such as inflammatory diseases, tissue fibrosis, and cancer.[155]Cancer cells and tumor-associated stromal cells modify all four ECM remodeling mechanisms, hijacking the normal matrix into a cancer-supporting matrix or niche that actively contributes to the pathology of the tumor (Fig. 12.24).

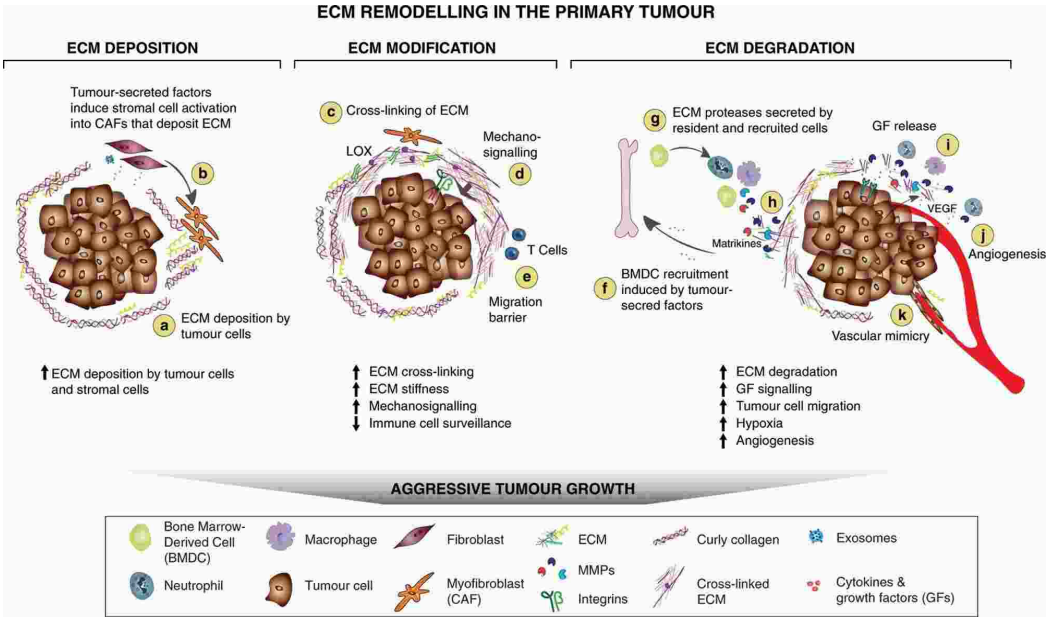

FIG. 12.24 Extracellular Matrix Remodeling in the Primary Tumor.

(**a and b**) Tumor-derived factors activate stromal cells which differentiate into cancer-associated fibroblasts *(CAFs)*, which leads to the secretion and deposition of large amounts of extracellular matrix *(ECM)* constituents along with the cancer cells. **(c)** ECM-modifying enzymes such as lysyl oxidase *(LOX)* expressed by tumor cells and CAFs cross-link and align collagen fibers, which increases matrix stiffness around the tumor and **(d)** the formation of a physical barrier to evade immune surveillance by T-cells. **(e)** Increased matrix stiffness promotes the interaction between ECM constituents and cell-surface receptors on tumor cells that triggers mechanosignaling mediated by integrins. **(f)** In order to sustain a tumorigenic microenvironment, tumor cells and resident immune cells secrete cytokines, chemokines, and growth factors (GFs), which differentiate and recruit bone marrow-derived cells (BMDCs). **(g)** The BMDCs, CAFs and tumor cells secrete ECM-degrading proteases, including

MMPs, which are cell surface-bound (e.g., MT1-MMP) or secreted (e.g., MMP-9). **(h)** Proteolytic ECM degradation generates bioactive matrikines and **(i)** releases matrix-bound GFs. These factors induce pro-tumorigenic ECM signaling that promotes tumor proliferation, migration, invasion, and angiogenesis. **(j)** Altogether the changes to the ECM create a hypoxic environment. Neutrophils secrete potent MMP-9 that degrades ECM and releases matrix-bound VEGF that forms a concentration gradient for new angiogenic sprouting. **(k)** Stimulated by dense ECM, the tumor cells can gain endothelial-like functions and mimic the vasculature that connects to blood vessels. Data from Winkler J, Abisoye-Ogunniyan A, Metcalf KJ, et al. Concepts of extracellular matrix remodelling in tumour progression and metastasis. *Nature Communications*, 2020;11:5120. https://doi.org/10.1038/s41467-020-18794-x.

An illustration shows E C M remodeling in the primary tumor. There are three stages in the remodeling. • E C M deposition. Tumor-secreted factors induce stromal cell activation into C A Fs that deposit E C M. The illustration shows a cluster of tumor cells surrounded by curly collagen, fibroblasts, myofibroblasts, E C M, exosomes, and cytokines. a. E C M deposition by tumor cells. b. Fibroblasts differentiate to myofibroblasts. There is increased E C M deposition by tumor cells and stromal cells. • E C M modification. The illustration shows a cluster of tumor cells surrounded by curly collaged, E C M,

cross-linked E C M, T cells, L O X, myofibroblasts, integrins, and T cells. c. Cross-linking of E C M. d. Mechano-signaling. e. Migration barrier. There is increased E C M cross-linking, increased E C M stiffness, increased mechanosignaling, and decreased immune cell surveillance. • E C M degeneration. The illustration shows a bone and a cluster of tumor cells surrounded by bone marrow-derived cell (B M D C), macrophages, neutrophils, E C M, M M Ps, curly collagen, cross-linked E C M, and cytokines. f. B M D C recruitment induced by tumor-secreted factors. g. E C M proteases secreted by resident and recruited cells. i. G F release. j. Angiogenesis. k. Vascular mimicry. There is increased E C M degradation, increased G F signaling, increased tumor cell migration, increased hypoxia, and increased angiogenesis.

Tumor cells themselves show altered expression of ECM components, such as collagens I and III and ECM-modifying enzymes such as LOX and LOX-like proteins (see Fig. 12.24A). In healthy tissue and tumors, the key producers of ECM in the interstitial matrix are fibroblasts, specifically when activated and transformed to myofibroblasts. Chondrocytes and osteoblasts are also important depending on the context and tissue.[156] Myofibroblasts have a combined phenotypic characteristic of fibroblasts and smooth muscle cells; they secrete ECM and exert contractile functions allowing mechanical alterations of the geography of the ECM.[150] Activation of myofibroblasts is triggered by inflammation resulting in the secretion of TGF-β.[157]

Sustained inflammatory stimuli and subsequent TGF-β secretion by immune cells, such as macrophages and tumor cells can produce deregulated, hyperproliferative and overactive myofibroblasts that are the major offender in pathologic conditions such as fibrosis and cancer.[158] Tumor-derived activation factors induce the differentiation of stromal cells towards CAFs, which function as myofibroblasts and remodel the ECM to support tumor growth.[45,158–160]

An important step in invasion is the disassembly of the ECM and its constituents through enzymes such as MMPs.[161] MMPs have a significant role in cell proliferation, immune response, angiogenesis, and survival.[154,158,162] They are associated with poor prognosis.[163,164] Remodeling of the ECM by cancer cells drives cancer growth.[64] ECM is complex, and numerous specific cells and matrikines engage in invasion and metastasis.

Autophagy and Cancer Cell Invasion

Autophagy is a self-degradative or catabolic process that targets cellular contents to the lysosomal compartment for degradation (see Chapter 2).[165] Autophagy is initiated by the advancement of several cancers to metastasis. In vivo studies reveal that autophagy participates in modulating tumor cell motility and invasion, cancer stem viability and differentiation, resistance to **anoikis** (apoptosis in cells upon loss of attachment to the ECM), EMT, metastatic cell dormancy, and escape from immune surveillance at the primary site (Fig. 12.25).[165] Many attributes of these autophagy-dependent changes during acquisition of invasiveness possibly contribute to the ability of disseminating cells to intravasate, survive, and migrate in the circulation before extravasating at secondary sites. Autophagy, at the secondary site, is required to maintain tumor cells in a dormant state, probably through its ability to promote quiescence and a stem cell phenotype linked to tumor cell survival and drug resistance.[165] From laboratory studies, inhibition of autophagy significantly reduced tumor cell invasion.[64,166]

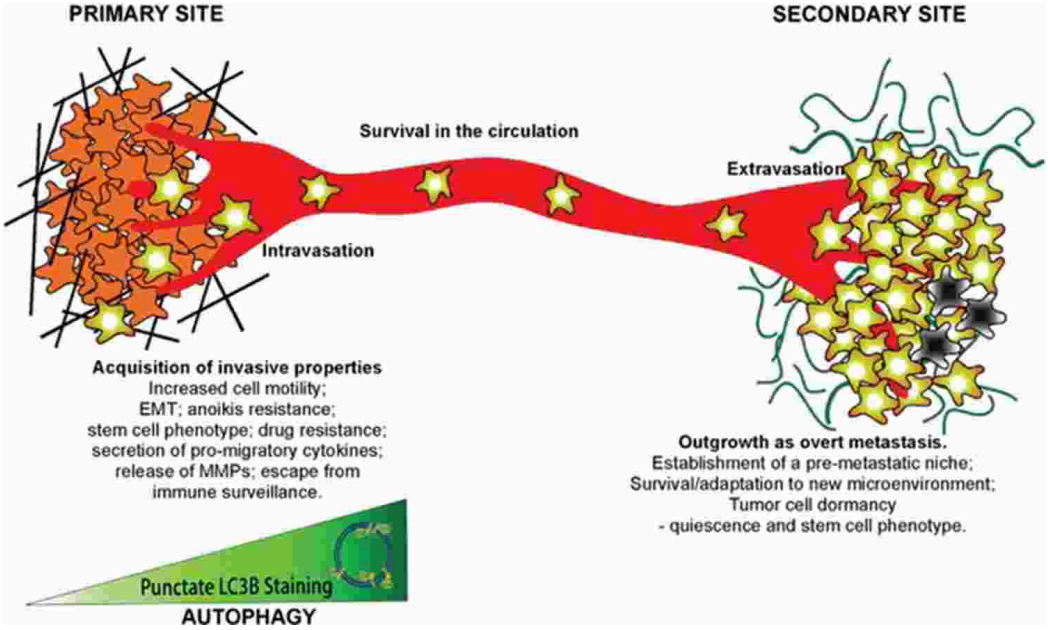

FIG. 12.25 Autophagy in the Metastatic Cascade.
Autophagy increases as tumor cells progress to invasion, which is linked to increased cell motility, epithelial-mesenchymal transition *(EMT)*, a stem cell phenotype, secretion of pro-migratory factors, release of matrix metalloproteinases *(MMPs)*, drug resistance, and escape from immune surveillance at the primary site in some tumors. Many of these autophagy-linked properties during acquisition of invasiveness possibly contribute to the ability of disseminating tumor cells to intravasate, survive and migrate in the circulation before extravasating at secondary site. At the secondary site, autophagy is required to maintain tumor cells in a dormant state, which is linked to tumor cell survival, and drug resistance. Data from Mowers EE, Sharfin MN, MacLeod KF. Autophagy in cancer metastasis. *Oncogene*, 2017;36:1619–1630.

An illustration shows autophagy in the metastatic cascade. The illustration shows a primary site

(intravasation). Acquisition of invasive properties include the following. • Increased cell motility. • E M T. • Anoikis resistance. • Stem cell phenotype. • Drug resistance. • Secretion of pro-migratory cytokines. • Release of M M Ps. • Escape from immune surveillance. An illustrated right-angled triangle for autophagy reads, punctate L C 3 B staining. Some tumor cells survive the circulation from the primary site to the secondary site (extravasation). Outgrowth as overt metastasis include the following. • Establishment of pre-metastatic niche. • Survival or adaptation to new microenvironment. • Tumor cell dormancy. • Quiescence and stem cell phenotype.

Neurons and Metastasis

How nerves emerge in the tumor microenvironment and just what their function is have always been mysteries. Recently, investigators found neural progenitors from the central nervous system that express doublecortin infiltrate in prostate tumors and metastases.[167] These progenitors initiate neurogenesis (neurons produced from neural stem cells).[168] Importantly, nerve fibers in the tumor microenvironment regulate cancer initiation and dissemination, mandating much further research on targeting doublecortin-expressing neurons for treatment.

Immune Environment at the Primary Site and Metastasis

The immune environment surrounding the tumor plays a significant role in dictating the metastatic potential of the disseminating cells.[64] An investigation of about 800 people with colorectal cancer

compared people with whose tumors were metastatic with those whose tumors were not.[169] Both groups had analogous mutation patterns in cancer genes; but tumors that had fewer cytotoxic T cells had metastasized.[169] The invasive ends of the spread tumor cells had reduced densities of lymphatic vessels that transport immune cells.[169] These changes contribute to metastasis and suggest immunotherapies that augment T-cell responses can stop metastasis in people with early-stage cancer.[170] Silencing the IFN regulatory factor (Irf)-7 pathway contributes to metastatic cells escape from immune surveillance.[171] Restoration of Irf7 in tumor cells or administration of IFN decreased bone metastases and enhanced longer survival time.[171] Irf7-driven suppression of metastasis depends on IFN signaling to host immune cells.[170,171] More research on suppression of metastases is key for increasing survival.

Surgical Intervention and Metastatic Dissemination

Sometimes disseminated cancer cells survive and can invade even after the removal of the primary tumor.[64] For example, individuals with pancreatic ductal adenocarcinoma often develop liver metastases following surgical excision of the primary tumor.[64,172] Metastasis may arise from dormant disseminated cancer cells that avoid elimination by the immune system and are present at the time of surgery.[172] Studies of mouse models and tissue samples from individuals with pancreatic ductal adenocarcinoma showed dormant disseminated cancer cells do not express a cell surface molecule or phenotype that triggers T-cell-mediated attacks.[172] This phenotype is associated with their inability to relieve endoplasmic reticulum stress (refers to various stressors) (Fig. 12.26 and Chapter 2).[172] Once the stress is resolved, disseminated cells start multiplying and invading tissue to form metastases.[172]

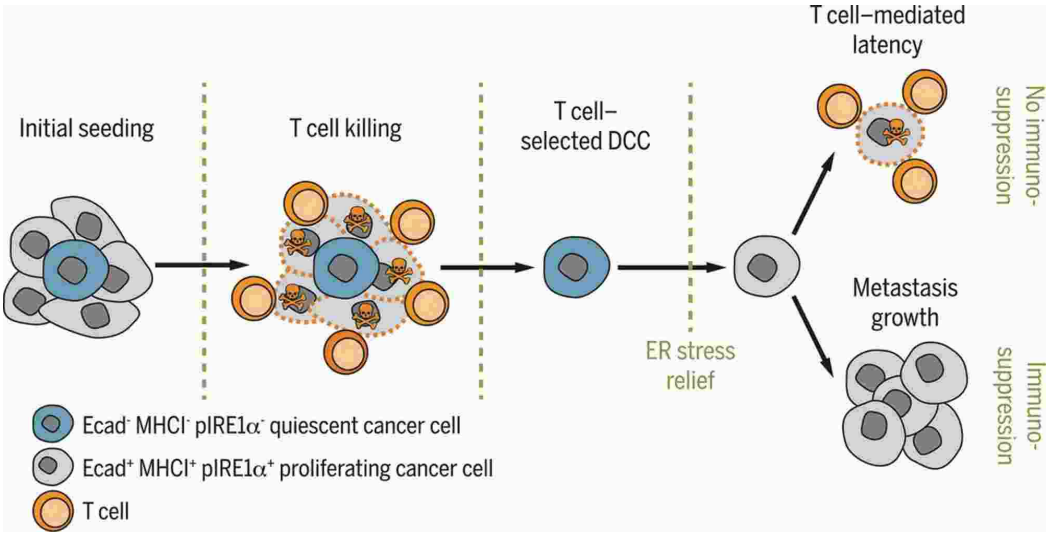

FIG. 12.26 Unresolved Endoplasmic Reticulum *(ER)* Stress Allows Disseminated Cancer Cells to Escape the T cell Response. Quiescent cancer cells that have unresolved ER stress lack expression of MHCI. With this phenotype they avoid killing by T cells and become latent disseminated cancer cells *(DCCs)*. Resolution of ER stress allows DCCs to regain proliferative abilities and then grow as metastases, only if the T cell response is disrupted, because they regain MHCI. *Ecad*, E-cadherin; *MHCI*, major histocompatibility complex class I. Data from Pommier A, Anaparthy N, Memos N, et al. Unresolved endoplasmic reticulum stress engenders immune-resistant, latent pancreatic cancer metastases. *Science*, 2018;360:6394, eaa04908.

An illustration shows how E R stress relief results in immunosuppression or the lack of it. There are four stages in the illustrations. 1. Initial seeding. The illustration shows an E c a d negative M H C I negative p I R E 1 alpha negative quiescent cancer cell surrounded by E c a d positive M H C I positive p I R

E 1 alpha positive proliferating cancer cells. 2. T cell killing. The illustration shows an E c a d negative M H C I negative p I R E 1 alpha negative quiescent cancer cell surrounded by T cells that have destroyed the E c a d positive M H C I positive p I R E 1 alpha positive proliferating cancer cells. 3. T cell-selected D C C. An illustration shows an E c a d negative M H C I negative p I R E 1 alpha negative quiescent cancer cell. 4. T cell-mediated latency. When there is no immunosuppression, T cells destroy the cancer cell. When there is immunosuppression, the cancer cell undergoes metastasis growth.

Another mechanism for promoting metastatic dissemination is anesthetics during surgery.[64] Murine models of breast cancer, sevoflurane led to significantly increased lung metastasis compared with that of propofol.[173] Sevoflurane increased IL-6, which led to the signal transducer and activation of transcription (STAT)-3 and subsequent infiltration of myeloid cells into the lung.[173]

Intravasation

Intravasation, or the movement of cancer cells through the lumen of the vasculature, is mediated both actively and passively, depending on the tumor type, microenvironment, and vasculature.[174–176] An in vitro model shows that the endothelium poses a barrier to tumor cell intravasation and is regulated by factors in the tumor microenvironment.[177] In vitro models using live-cell fluorescence reveal a mitosis-mediated mechanism where tumor cells located along the vessel periphery disrupt the vessel endothelium from cell division and detach into the circulation.[178] Tissue itself imposes

mechanical pressures on invading tumor cells during intravasation.[179] Disruptive is nuclear squeezing on integrity of the nucleus, which causes genomic rearrangement increasing the metastatic potential.[179]

Almost every step of cancer progression involves **integrins** or critical cellular adhesion receptors.[180] Altered integrin expression is common in tumors, and they have roles in supporting oncogenic signals, such as oncogenic GFR signaling.[180] Importantly, integrins regulate the colonization process by easing anchorage-independent survival of circulating tumor cells (CTCs). Metastatic cells use **E-cadherin** in metastatic sites to detach, disseminate, and seed, thereby promoting metastatic cell survival and block apoptosis.[181] Inhibiting E-cadherin in metastatic cancer cells may be an essential treatment strategy that needs much more research.[181]

Circulation

CTCs need help to survive the vasculature. Survival of tumor cells in the circulation is challenging. Interactions between CTCs and the microenvironmental components of circulation determine survival and the ability of CTCs to extravasate in distant places.[182–184]

Circulating tumor cells interaction with immune cells

Most CTCs circulate as single cells and others as clusters (Fig. 12.27). Circulating clusters appear to be "hardier" and more likely to form metastases.[185] Clusters not only involve invading cancer cells but contain stromal cells and immune components from the original microenvironment that contribute to the heterogeneity of the cluster and augment its survival.[185–189] Neutrophils increase the chances of CTCs survival because they suppress leukocyte activation. Additionally, the interaction of CTCs with platelets leads to the formation of a "shield" coating the cancer cells that prevents CTC detection by immune cells and provides the structure to withstand the physical stresses of circulation.[190–192] The dissemination of CTCs is supported by very close association with activated platelets and

macrophages.[193] Data show that CTCs form aggregates that sustain adhesion to the endothelium and contribute to metastasis.[190] A CTC-immune cell association was found in 70 women with advanced breast cancer.[194] The leukocytes that showed the greatest interaction were neutrophils, suggesting that neutrophil clustering with CTCs increases their metastatic potential.[194] Women with advanced breast cancer who had CTC-neutrophil clusters experienced faster metastatic advancement.[194] Mice studies showed CTCs from both CTC-neutrophil clusters and others that had not been part of clusters were injected into blood vessels had an increased number of metastases. From this remarkable study, the eradication of neutrophils from mice with breast tumors, the number of CTC-neutrophil clusters was significantly decreased (KLM add to Breast Cancer section).[200] Furthermore, these mice had delayed metastases in the lungs when compared with those mice with breast tumors that did not have their neutrophils removed.[194] Thus, the complex interaction between cancer cells and leukocytes promotes metastasis because metastatic cells possess sugar on their cell surface that binds to galectin-3.[195]**Galectin-3** increases the ability of cells to colonize by interacting with mobilized leukocytes.[195]

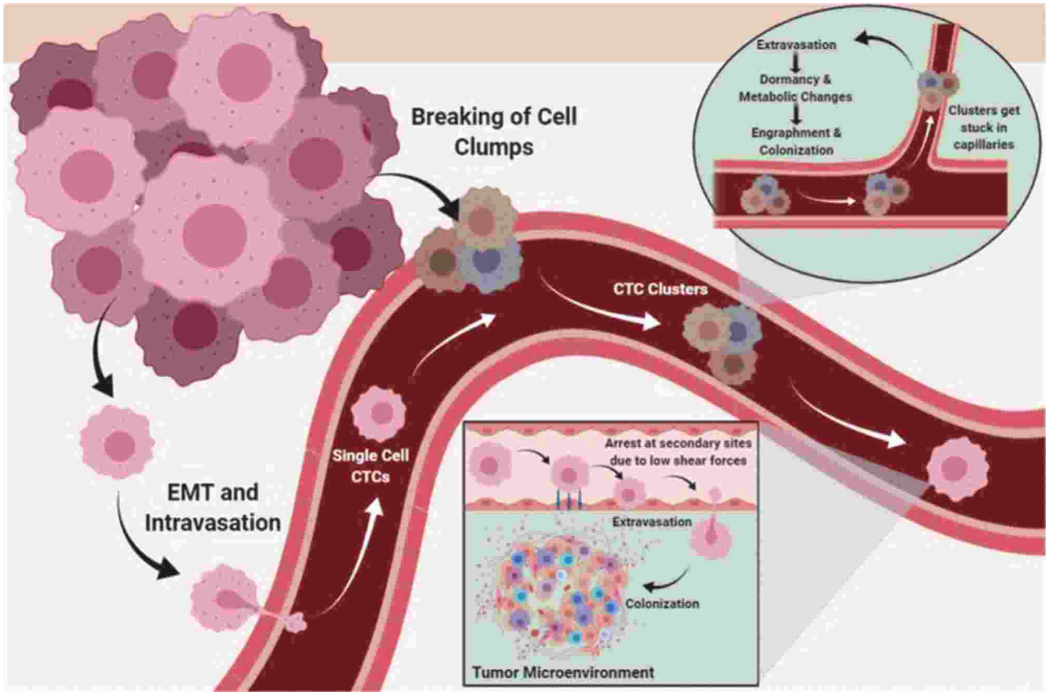

FIG. 12.27 How Cancer Cells Circulate.
Cancer cells circulate as single cells or in clusters. After arrest at secondary sites or getting stuck in tiny capillaries, circulating cancer cells *(CTCs)* extravasate and colonize their new home or niche. Some cells become dormant as an adaptive mechanism to the new stressful environment. Data From Fares J, Fares MY, Khachfe HH, et al. Molecular principles of metastasis: a hallmark of cancer revisited. *Signal Transduction Target Therapy*, 2020;5:28.

An illustration shows how cancer cells circulate. The illustration shows a cluster of cancer cells and demonstrates two mechanisms of circulation. • E M T and intravasation. Single cells enter the blood vessel. An accompanying illustration shows tumor microenvironment. Single cells are arrested at secondary sites due to low shear forces, leading to extravasation and subsequently to colonization. •

Breaking of cell clumps. C T C clusters enter the blood vessel. An accompanying illustration shows a cluster of cells stuck in a capillary, leading to extravasation, dormancy and metabolic changes, and engraphment and colonization.

Despite these findings, questions remain. Challenging these data are studies suggesting that an increase in megakaryocytes provide some measure of protection against metastasis.[196] Other data suggest that neutrophils may inhibit metastasis.[67,197] Further study about the interactions of CTCs with immune cells is ongoing.

Fighting against vascular forces and mechanical pressure

CTCs can sense and respond to tissue mechanics and initiate brief or lasting tissue alterations, including compression and deformation, ECM stiffening, protein unfolding, proteolytic remodeling, and clogging or obstructing transitions.[198] Distant metastases are dependent on CTCs flow through the vasculature, locating, and depositing at distant sites.[199] Easy passage of CTCs through the bloodstream is interrupted when their adhesive properties become greater than the shear forces imposed by the blood flow.[199] Thus, regions with low hemodynamic flow are the regions where most CTCs stabilize and engage with endothelial cells. It is here in these regions that single CTCs might form intravascular clusters. CTCs that are fixed in the microvasculature are fragmented by the flow of blood allowing immune-derived molecules to promote extravasation and develop metastases from the surviving CTCs. This hypothesis was tested in 100 individuals with brain metastases, and the results showed that these metastases formed in those regions with low cerebral blood flow.[199] Thus, shear forces are important in hematogenous metastasis and determinations of the CTCs final resting site.[64]

Release of chemokines and cytokines assist circulating tumor cells

Chemokines and complement components direct tumor cells through the vasculature.[200,201] Obese mice induce granulocyte macrophage colony-stimulating factor and cytokines such as IL-5, lead to lung neutrophilia and assist in breast cancer metastasis.[202] Crowded cancer cells boost the production of IL-6 and IL-8, two immune molecules that stimulate biochemical pathways and assist tumor migration.[203] Importantly, in mouse models, blocking of IL-6 and IL-8 receptors decreased metastasis at lymph nodes, lungs, and liver compared with the control group.[203] Further data revealed that metastatic tumors induce the release of IL-1β, which induces gamma delta (γδ) T cells to release IL-17. IL-17 suppresses the cytotoxic CD+8 T lymphocytes and therefore promotes metastasis. Also, the loss of *TP53* in cancer cells causes the secretion of WNT ligands that produce IL-1β causing metastatic neutrophilic inflammation (see previous discussion on *TP53*).[204]

Routes of tumor cell circulation

Most now accept that CTCs use or even exploit and survive in the bloodstream during metastasis.[199,205] CTCs also cause distant metastases through the lymphatic circulation.[206–208] The *sequential progression model* is the basis for excision of tumor-draining lymph nodes during surgery.[206] Metastatic tumor cells travel from a primary site to a distant site directly through the bloodstream or through a lymph node close to the primary tumor site.[209] Not completely clear are the biological mechanisms by which tumor cells survive and grow within lymph nodes. In vitro studies show cancer cells shift to fatty acid oxidation to survive the lymph node microenvironment.[209] The yas-associated protein (YAP) transcription factor facilitated the shift to fatty acid oxidation and importantly, inhibition of fatty acid oxidation or YAP blocked lymph node metastasis in mice.[209] Overall, the metabolic achievements need much more research.

Diagnosing cancer from the circulation

Laboratory enrichment of CTCs improved their classification and tumor identification.[210] CTC characterization identifies the molecular aspects of metastatic tumors. An emerging approach is the analysis of cell-free DNA (cfDNA).[211] cfDNA identifies the heterogeneity of CTCs in individuals with high counts of CTCs, and this helps with clinical management. Also, cfDNA profiling tracks the subclonal traits of cancer metastasis.[212] As such, liquid biopsy of CTCs and/or cfDNA in the bloodstream may have the potential to augment current understanding of cancer metastasis (see Emerging Science Box: Liquid Biopsy).[210]

Targeting circulating tumor cells

Advancements in the field of CTC detection assays offers hope for future successful applications.[64] In fact, a paradigm shift is occurring in the field. For example, a photoacoustic method for direct use in individuals with melanoma has been developed, enabling the detection of very low numbers of CTCs in vivo and their destruction with laser pulses.[213] This amazing advancement reflects the therapeutic potential of such patient-centered approaches. In addition, with DNA methylation profiles more clearly identifying tumor phenotypes among CTC clusters than from single cells, it can add another key target to the destruction of CTCs. These phenotypic differences were found in clusters instead of single cells from patients and in vitro studies with breast cancer.[214] Importantly, tumor cell clustering shapes DNA methylation to enable metastasis seeding.[214]

Emerging Science BoxLiquid Biopsy Enters the Clinic

Studies of disseminated tumor cells in bone marrow and circulating tumor cells in peripheral blood have provided major insights into cancer biology and metastasis. Advances in the detection and characterization of circulating tumor DNA (ctDNA) have enabled the introduction of liquid biopsy assays into clinical

practice.The FDA has approved single gene assays, and more recently, multigene assays to detect genetic alterations in plasma cell-free (cfDNA). These approvals are for personswith advanced-stage cancer. The next goal is likely to be the systemic treatment of persons with "ctDNA relapse," a term introduced for ctDNA detection prior to imaging-detected relapse after intention to cure for early-stage disease. In the future, after more rigorous research, applications are for screening and diagnosis.

Data from Ignatiadis M, Sledge GW, Jeffrey SS. Liquid Biopsy enters the clinic-implementation issues and future challenges. *Nature Reviews. Clinical Oncology*, 2021;18:297–312.

Extravasation

Critical in the metastatic process is the ability of CTCs to adhere and extravasate through endothelial cells and colonize the premetastatic niche (PMN).[215] When CTCs arrest in capillaries, they either extravasate by transendothelial migration or grow in the vessel itself before extravasation and colonization of the PMN.[216–219]

How Do Circulating Tumor Cells Extravasate?

In small capillaries CTCs become trapped leading to either rupture or extravasation. Organs with highly permeable sinusoidal vessels exhibit a high rate of metastasis, such as liver and bone.[64] Other organs require genetic and molecular changes to be able to extravasate among tight barriers and basement membranes. Extravasation is a complex process. It involves ligand-receptor interactions, chemokines, and circulating non-tumor cells.[175,220,221] Integrins are once again very important; they help to determine the location for extravasation and colonization.[180] Many have reported that extravasation occurs in a similar fashion to leukocyte transendothelial migration.[175,222,223] Recently, it was shown that cancer cells induce programmed necrosis of endothelial cells, driving metastatic cells to extravasate. Specific treatments, such as the

receptor-interacting serine/threonine-protein kinase, and others reduced endothelial necrosis and metastatic extravasation.[224]

Circulating Tumor Cells Target Specific Sites

It appears that most cancers metastasize to specific target organs, a process called **metastatic organotropism**. Breast cancer research has supported this process, and researchers have defined the genetic basis for cancer colonization in distant sites.[225] Importantly, the host microenvironment and the ensuing adaptive process that invading cancer cells undergo play a role in extravasation and colonization at specific sites.[226] For example, breast cancer metastasizes most frequently to the bone, often after long latency, suggesting that metastatic seeds are resistant to therapy and can regrow. Metastasis to bone is a common characteristic of many cancers including breast, prostate, lung, thyroid and kidney.[227] Metastatic organotropism is illustrated in Fig. 12.28.

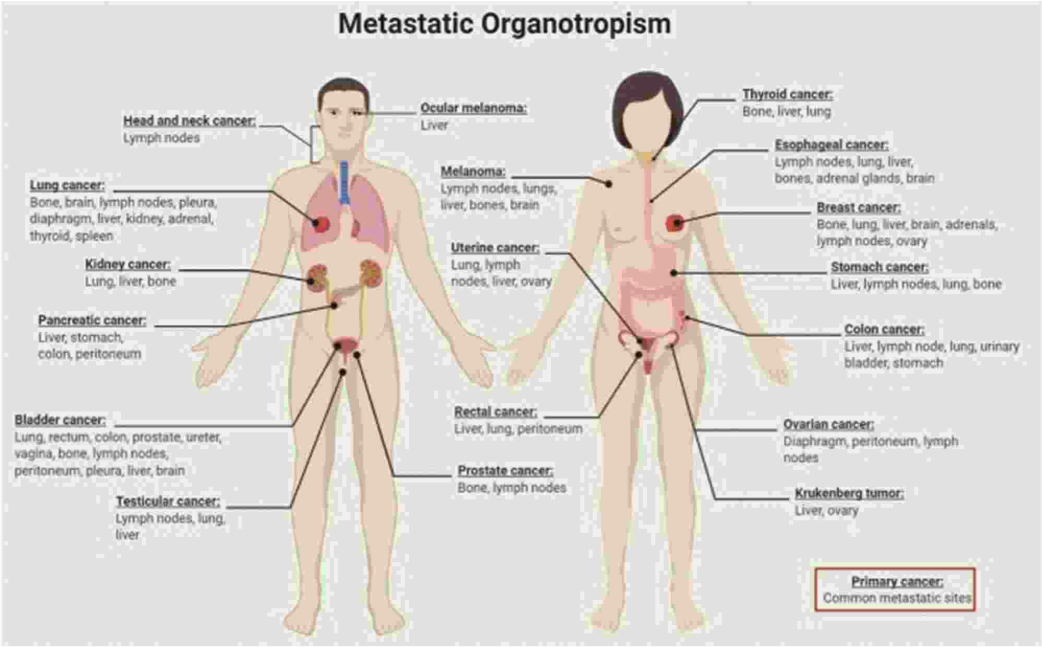

FIG. 12.28 Metastatic Organotropism.
Clinical data suggest most cancers metastasize to specific organs, a process known as metastatic organotropism. Data from Fares J, Fares MY, Khachfe HH., et al. Molecular principles of metastasis: A hallmark of cancer revisited. *Signal Transduction Target Therapy*, 2020;5:28.

An illustration of the anterior views of the male and female anatomy illustrates metastatic organotropism, identifying common metastatic sites for each primary cancer. The following cancers are identified in the male anatomy. • Ocular melanoma: liver. • Head and neck cancer: lymph nodes. • Lung cancer: bone, brain, lymph nodes, pleura, diaphragm, liver, kidney, adrenal, thyroid, and spleen. • Kidney cancer: lung, liver, and bone. • Pancreatic cancer: liver, stomach, colon, and peritoneum. • Bladder cancer: lung, rectum, colon, prostate, ureter, vagina, bone, lymph

nodes, peritoneum, pleura, liver, and brain. • Testicular cancer: lymph nodes, lung, and liver. • Prostate cancer: bone and lymph nodes. The following cancers are identified in the female anatomy. • Thyroid cancer: bone, liver, and lung. • Esophageal cancer: lymph nodes, lung, liver, bones, adrenal glands, and brain. • Breast cancer: bone, lung, liver, brain, adrenals, lymph nodes, and ovary. • Stomach cancer: liver, lymph nodes, lung, and bone. • Colon cancer: liver, lymph node, lung, urinary bladder, and stomach. • Ovarian cancer: diaphragm, peritoneum, and lymph nodes. • Krukenberg tumor: liver and ovary. • Uterine cancer: liver, lung, and peritoneum. • Rectal cancer: liver, lung, and peritoneum.

A mechanism between the bone osteogenic niche and cancer cells is the influx of calcium, which promotes the progression of bone metastasis.[228] Women with postpartum breast cancer are at increased risk for liver metastasis.[229] The identification of the "weaning-induced liver involution," with its established metastatic microenvironment, accounts in part for the poorer prognosis of women with postpartum breast cancer.[229]

Colonization

To establish metastatic tumors at distant sites, extravasated CTCs must locate, exploit, and modify the structural and metabolic features of secondary sites. Circulating cells face harsh conditions after extravasation at the distant site.[230]

Colonizing Cells and Stromal Challenges

Formation of the PMN, where the tumor cells colonize and grow depends on signaling from various tumor secreted derived factors and bone marrow-derived factors.[72,92,231,232] Importantly, exosomes play a major role (discussed earlier).[232] Like breast cancer, these results apply to pancreatic cancer, whereby exosomes initiated PMN formation in the liver.[115] Optimal colonization depends on cancer-cell host interactions. For example, hepatocytes control myeloid cell accumulation and fibrosis within the liver and increase the susceptibility of the liver to metastatic colonization.[64] From murine models, hepatocytes induce IL-6-mediated STAT3 signaling and increase secretion of serum amyloid A1 and A2 (SAA). Inhibition of IL-6-STAT3-SAA signaling prevents the formation of a PMN and inhibits liver metastasis.[233] These important findings need more research.

Formation of a vascular network is critical for optimal colonization. Vascular mimicry is a process where tumors create their own channels for fluid transport that drives the ability of some breast cancer cells to contribute to distant metastases through the expression of *SERPINE2* and *SLPI*.[234] These two genes are increased in women with breast cancer lung metastases, suggesting their role in metastatic progression.[234]

Colonizing cancer cells use signaling from neuronal pathways for growth and adjustment to new sites. For example, proximity of breast cancer cells to neuronal synapses enables cancer cells to hijack *N*-methyl-D-aspartate receptor signaling to promote brain metastasis.[235] Metastatic cancer cells use cancer-cell astrocyte gap junctions to transfer cGAMP to astrocytes activating IFN genes and producing inflammatory cytokines which supports tumor growth and chemoresistance.[236]

Sleeping or Dormant Cancer Cells

Cancer dormancy is a rest phase in cancer progression that occurs during the primary tumor formation phase or after invasion into

secondary sites.[237] Metastatic dormancy occurs because of the delayed adjustment of disseminating cells to their secondary niches or sites affecting single invading cells or cancer clusters after circulation.[238] These dormant cancer cells (DCCs) are rarely detectable with current diagnostic approaches.[239]

The details of dormancy are emerging, but dormancy is not completely understood. DCCs are present long after the primary tumor has been removed and are thought to be responsible for late relapses.[238] Dormancy involves quiescence and angiogenic dormancy, whereby a balance is attained between dividing and dying cancer cells. Immune-mediated dormancy is when the tumor mass is preserved by immune cell cytotoxicity.[71,240]

Regulation of tumor cell dormancy is dependent on communication or reciprocal crosstalk between the environment and transcriptional programs (Fig. 12.29).[241] Much evidence supports the notion that extracellular signal-regulated kinase (ERK) activation has a determinant role in whether cancer cells will proliferate or enter the phase of dormancy.[239] Proliferating cancer cells exhibit essential ERK activation, which permits cell cycle phase transition and cell division.[242,243] During ERK-induced proliferation, a high level of p38 mitogen-activated protein kinase (p38) activity functions as an inhibitory regulator of ERK and prevents cell proliferation by inducing cell cycle arrest or triggering senescence and apoptosis.[239] In vivo studies visualized ERK and p38 MAPK activities providing direct evidence of p38/ERK activity as an indicator of DCCs in various cancers, including breast, prostate, melanoma, and fibrosarcoma.[239,244] Importantly, many pharmacological and genetic interventions that change the balance of p38/ERK activity in favor of ERK broke in vivo dormancy and induced cancer growth.[239] Overall, the genetic and signaling pathways that regulate cancer cell dormancy and future reactivation involve intracellular signaling, extracellular signaling, and induction signals derived from the bone marrow niche.[64]

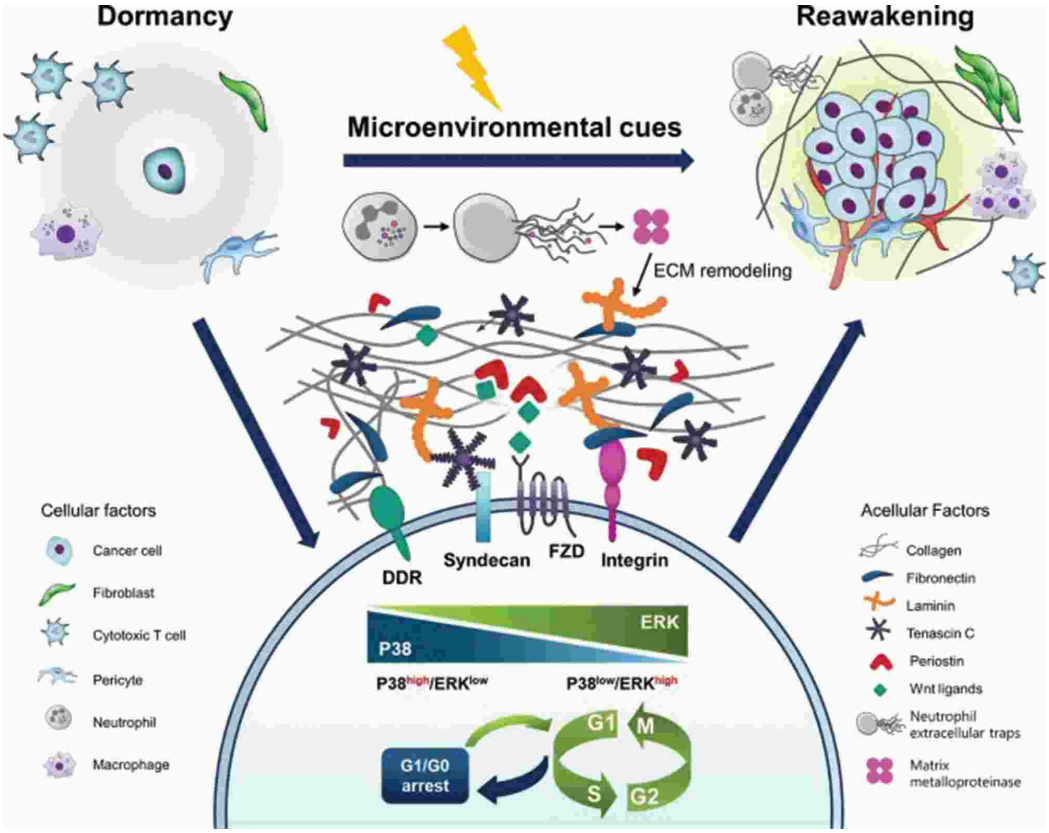

FIG. 12.29 Cancer Cells Become Dormant to Escape Immune Attack.

After cancer cells reach a new location, these dormant cancer cells *(DCCs)* receive signals from the surrounding tissue and gain the ability to re-enter the cell cycle. Chronic inflammation can reactive DCCs, triggering tumor development. Critical signaling pathways involved in DCC reactivation are being investigated which, may help to fight this leading cause of death from cancer. *DDR*, Discoidin domain receptor; *ECM*, extracellular matrix; *FZD*, frizzled. Data from Park SY, Nam JS. The force awakens: Metastatic dormant cancer cells. *Experimental and Molecular Medicine*, 2020;52:569–581.

An illustration shows how cancer cells become dormant to escape immune attack. Dormancy. The cellular factors in this state are a cancer cell, a macrophage, cytotoxic T cells, a fibroblast, and a pericyte, all of which are independent. Under microenvironmental cues, the cells reawaken. The illustration shows a cluster of cancer cells surrounded by collagen, neutrophil extracellular traps, fibroblasts, pericytes, neutrophils, macrophages, and cytotoxic T cell. A neutrophil generates extracellular traps that release matrix metalloproteinase, which differentiate to laminin. Other acellular factors that reawaken dormant cancer cells include tenascin C, periostin, and w n t ligands that bind to D D R, syndecan, F Z D, and integrin.

As discussed earlier, chronic inflammation is involved in cancer development (see Table 12.3), yet not all individuals who have experienced chronic inflammatory diseases eventually develop cancer.[239] In situ carcinoma lesions can be found without chronic inflammation. This observation has caused debate about the cause-effect relationship between chronic inflammation and cancer.[239] One explanation about this conflicting evidence is that reawakening DCCs could be a critical factor for cancer development from chronic inflammation.[239] For example, chronic inflammation supports angiogenesis, which disrupts cancer dormancy by supplying sufficient oxygen and nutrients and advances cancer growth.[245] Also, there is a robust correlation between inflammation and recurrence of cancer, including recurrence of endometrial,[246] oral,[247] and breast cancer.[248,249] In vitro studies show that escape of cancer from

dormancy can be induced by the inflammatory cytokine interferon-gamma (IFN-γ).[238] Further support of this hypothesis has been shown with the correlation between the high levels of serum inflammatory cytokines and cancer recurrence.[238] From a cohort of 734 individuals with breast cancer, high levels of circulating acute phase proteins (APPs) were positively correlated with distant recurrence.[250] C-reactive protein (CRP) and IL-6, other markers of inflammation, have shown their potential as posttreatment prognostic factors for predicting the risk of cancer recurrence and death.[239] Altogether, these data support the hypothesis that inflammation can be the DCC reawakening factor and can function as a cancer-promoting factor.[239] Chronic inflammation can induce epigenetic alterations and DNA mutations in tumor suppressor genes, thus promoting carcinogenesis.[239]

A growing body of evidence indicates the potential of CD4 and CD8 T cells in maintaining cancer dormancy.[251,252] Studies are indicating that DCCs can escape anticancer immunity and survive for an extended time.[239] Neutrophils are gaining attention because of their DCC-reawakening activity.[239] Exposure to tobacco smoke or the nasal instillation of polysaccharide induced chronic lung inflammation and converted DCCs to aggressively growing cancer cells and metastasis. From this process, neutrophils governed the DCC reawakening through the formation of neutrophil extracellular traps (NETs), which are scaffolds of chromatin released into the extracellular space.[253] Treatment with antibodies against NET-remodeled laminin prevented the DCCs from awakening and reduced metastasis.[239] In summary, the existence of DCCs has led to the emergence of therapy resistance because critically, the cells may resume growth, increasing the risk of unleashing lethal metastatic outbreaks even after a long latency period of months to years.[239]

Plasticity of Cancer Cells and Tumor Progression

Plasticity is the ability of cancer cells to dynamically switch between a differentiated state with limited tumorigenic potential and an

undifferentiated or cancer stem-like state, required for long-term tumor growth.[64] Unfortunately, cancer cell plasticity facilitates the development of therapy resistance and malignant progression.[64] The hope is that cancer cell plasticity may be treatable. Researchers have forced the trans differentiation of EMT-derived breast cancer cells into adipocytes by using MEK inhibitors and rosiglitazone, an antidiabetic drug, and inhibited the metastatic cascade.[254]

Cell plasticity directly contributes to tumor heterogeneity and is critical for malignant tumor progression and therapy challenges. For example, breast cancer reveals a mutational spectrum or tumor heterogeneity and tumor cell plasticity. Glucocorticoids have been used to treat individuals with cancer complication. The progression of breast cancer is initiated by increasing stress hormone and glucocorticoid levels, which activates secondary site glucocorticoid receptors, increases cancer colonization, and decreases survival rates.[255] The activation of the glucocorticoid receptor increases heterogeneity and metastasis, which suggests caution when treating with glucocorticoid therapy.[255]

Recent data reveal questions about treating with cytotoxic chemotherapy for invasive breast cancer. Despite the exhibited effectiveness of cytotoxic chemotherapy in treating invasive breast cancer, studies have shown that the treatment has prometastatic effects.[64,256] From mice studies, paclitaxel and doxorubicin trigger the production of tumor-derived extracellular vesicles in models of chemoresistant breast cancer.[256] The vesicles facilitate colonization of tumors in metastatic sites in the lungs.[64,256]

Treatment Strategies to Target Metastasis

Metastasis suppressors inhibit cancer growth and proliferation at the metastatic site but do not affect the primary tumor.[257] Specifically, they target oncogenic pathways and proteins involved in invasion and subsequent metastatic colonization.[64] In the last decade, a significant number of metastasis suppressors have been identified, most notably miRNAs.[257–261]

Numerous investigators are studying and exploring strategies that target pathways in the metastatic cascade.[64] The seeding of cancer cells can be targeted by inhibiting intratumoral interactions, intercellular interactions through ECM adhesion molecules, EMT, the release of proteases and intravasation.[64] Mounting evidence of the majority of approved cancer drugs, including TKIs, systemic cytotoxic therapies (chemotherapy) and antibody-drug conjugates (ADCs), reveals they do not have a durable impact with metastatic disease often because of therapeutic resistance.[262,263]

Metastatic cancers may be approached through a biomarker-driven strategy that validates single-agent or combination of agents depending fully on the molecular makeup of individual tumors.[263] Concurrent depletion of immune-suppressive factors and tumor-intrinsic targeting will be a central paradigm to improve survival (also see the section on Immunotherapy).[263] Combinational therapies with specific mechanisms of action will be critical to preventing metastasis-associated resistance and promoting durable responses.[263]

A priority is the importance of lifestyle and diagnostic factors in reducing cancer mortality.[263] Obesity is becoming a critical etiologic driver of cancer and initiation of metastasis[202] (also see Chapter 23). Worldwide, other preventable risk factors are a major cause of cancer (also see Chapter 13). For those cancers with a slow onset of metastasis, improved diagnostic, and early detection efforts will clearly improve survival.[263] Finally, prevention, early diagnosis and treatment methods must be comprehensively optimized to reduce cancer mortality.[263]

Clinical Manifestations of Cancer

The clinical manifestations of cancer are numerous and depend on the localization and type of tumor, and some are apparent before actual diagnosis of a malignancy. Generally, the variety and intensity of symptoms will increase as the malignancy progresses.

Paraneoplastic Syndromes

Paraneoplastic syndromes are rare disorders with complex clinical manifestations that are triggered by a cancer but are not caused by direct local effects of the tumor mass. In paraneoplastic syndromes, malignant cells do not cause symptoms related to metastasis, but they generate autoantibodies, cytokines, hormones, or peptides that affect may organ systems.[264] Most cases of paraneoplastic syndrome exhibit immunologic mechanisms; however, there are also non-immunologic mechanisms of paraneoplastic syndrome.[264] A number of cancers trigger an antibody response that attacks the nervous system, causing a variety of neurologic disorders that can precede other symptoms of cancer by months. An example of a non-immunologic mechanism is carcinoid tumors that release substances, including serotonin, into the bloodstream causing flushing, diarrhea, wheezing, and rapid heartbeat.

Although infrequent, paraneoplastic syndromes are significant because they may be the earliest symptom of an unknown cancer and, in affected individuals, can be serious, often irreversible, and sometimes life-threatening. Table 12.4 presents the classifications of paraneoplastic syndromes. Other clinical manifestations of cancer are summarized in Box 12.3. Factors predisposing individuals with cancer to infection are contained in Table 12.5.

Table 12.4

Paraneoplastic Syndromes

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
Endocrinopathies		
Cushing syndrome	Small cell carcinoma of lung Pancreatic carcinoma Neural tumors	ACTH or ACTH-like substance
Syndrome of inappropriate antidiuretic hormone (SIADH) secretion	Small cell carcinoma of lung Intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung Breast carcinoma Renal carcinoma Adult T-cell leukemia/lymphoma	Parathyroid hormone-related protein (PTHRP), TGF-α, TNF, IL-1
Hypoglycemia	Ovarian carcinoma	Insulin or insulin-like substance

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
	Fibrosarcoma Other mesenchymal sarcomas	
Polycythemia	Renal carcinoma Cerebellar hemangioma Hepatocellular carcinoma	Erythropoietin
Osteomalacia	Phosphaturic mesenchymal tumor	FGF-23
Nerve and Muscle Syndromes		
Myasthenia	Bronchogenic carcinoma Thymic neoplasms	Immunologic
Disorders of the central and peripheral nervous systems	Breast carcinoma	
Dermatologic Disorders		

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
Acanthosis nigricans	Gastric carcinoma Lung carcinoma Uterine carcinoma	Immunologic; secretion of epidermal growth factor
Dermatomyositis	Bronchogenic carcinoma Breast carcinoma	Immunologic
Osseous, Articular, and Soft Tissue Changes		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma Thymic neoplasms	Unknown
Vascular and Hematologic Changes		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma Bronchogenic carcinoma Other cancers	Tumor products (mucins that activate clotting)
Disseminated intravascular coagulation	Acute promyelocytic leukemia	Tumor products that activate clotting

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
	Prostatic carcinoma	
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Red cell aplasia	Thymic neoplasms	Unknown
Others		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
Endocrinopathies		
Cushing syndrome	Small cell carcinoma of lung Pancreatic carcinoma Neural tumors	ACTH or ACTH-like substance
Syndrome of inappropriate antidiuretic hormone (SIADH) secretion	Small cell carcinoma of lung Intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung Breast carcinoma Renal carcinoma Adult T-cell leukemia/lymphoma	Parathyroid hormone-related protein (PTHRP), TGF-α, TNF, IL-1
Hypoglycemia	Ovarian carcinoma Fibrosarcoma Other mesenchymal sarcomas	Insulin or insulin-like substance
Polycythemia	Renal carcinoma Cerebellar hemangioma Hepatocellular carcinoma	Erythropoietin
Osteomalacia	Phosphaturic mesenchymal tumor	FGF-23
Nerve and Muscle Syndromes		
Myasthenia	Bronchogenic carcinoma Thymic neoplasms	Immunologic
Disorders of the central and peripheral nervous systems	Breast carcinoma	
Dermatologic Disorders		
Acanthosis nigricans	Gastric carcinoma Lung carcinoma Uterine carcinoma	Immunologic; secretion of epidermal growth factor
Dermatomyositis	Bronchogenic carcinoma Breast carcinoma	Immunologic
Osseous, Articular, and Soft Tissue Changes		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma Thymic neoplasms	Unknown
Vascular and Hematologic Changes		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma Bronchogenic carcinoma Other cancers	Tumor products (mucins that activate clotting)
Disseminated intravascular coagulation	Acute promyelocytic leukemia Prostatic carcinoma	Tumor products that activate clotting
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Red cell aplasia	Thymic neoplasms	Unknown
Others		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

ACTH, Adrenocorticotropic hormone; *FGF-23*, fibroblast growth factor-23; *IL*, interleukin; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor.

Box 12.3

Common Side Effects of Cancer and Cancer Therapy

Anemia: Commonly associated with malignancy, with 20% of persons diagnosed with cancer having hemoglobin concentrations less than 9 g/dL (normal value = 15 g/dL). Mechanisms of anemia include chronic bleeding (resulting in iron deficiency), severe malnutrition, cytotoxic chemotherapy, and malignancy in blood-forming organs. Chronic bleeding and iron deficiency can accompany colorectal or genitourinary malignancy. Iron also is malabsorbed in individuals with gastric, pancreatic, or upper intestinal cancer.

Bone Density Loss: Osteoporosis, or less severe osteopenia, may occur secondary to hormone treatment, such as used for breast cancer and prostate cancer, or in individuals treated with steroids.

Cachexia: A syndrome that includes many symptoms including anorexia, early satiety (filling), weight loss, anemia, asthenia (marked weakness), taste alterations, and altered protein, lipid, and carbohydrate metabolism. It is the most severe form of malnutrition associated with cancer and results in wasting, emaciation, and decreased quality of life. Cytokines and metabolites from the tumor may contribute to cachexia.

Cardiac and Pulmonary Damage: Chemotherapy and localized radiation can damage the heart and lungs, resulting in increased risk for heart failure and decreased pulmonary function.

Fatigue: Severe fatigue is the most frequently reported and persistent symptom of cancer and cancer treatment, particularly chemotherapy. Suggested causes include sleep disturbances, chronic inflammation, anemia, depression, level of activity, nutritional status, and other environmental and physical factors.

Gastrointestinal (GI) Tract: Rapidly proliferating cells of the GI tract are particularly sensitive to radiation and chemotherapy, leading to oral ulcers (stomatitis), malabsorption, and diarrhea, as well as increased risk for infection from the individual's own microbiome.

Hair Loss (Alopecia) and Skin: Some chemotherapy generally affects hair follicles, whereas radiation is more localized. It is usually temporary, although hair may regrow with a different texture initially. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection. Radiation therapy may cause skin erythema (redness) and contribute to breakdown.

Infection: The most significant cause of complications and death in people with malignant disease is infection. Immune suppression, lymphopenia, and granulocytopenia may result from the underlying cancer or secondary to treatment increasing the risk of serious microbial (bacterial and fungal) infections. (Factors that predispose individuals with cancer to infection are summarized in Table 12.5.) The prevalence of hospital-acquired (nosocomial) infections increases because of indwelling medical devices, inadequate wound care, and the introduction of microorganisms from visitors and other individuals.

Infertility: Male or female infertility may be secondary to the cancer, surgical treatment, or treatment with chemotherapy

or radiation. Many infertility clinics will freeze sperm, eggs, or embryos before initiation of therapy.

Leukopenia and Thrombocytopenia: Causes can include many chemotherapeutic drugs and radiation therapy because they are toxic to the bone marrow, often causing granulocytopenia and thrombocytopenia. Thrombocytopenia is a major cause of hemorrhage in people with cancer and is often treated with platelet transfusions.

Lymphedema: Accumulation of fluid in the tissues results from damage to the lymphatic system from lymphoid cancer or metastatic disease, surgery, or radiation treatment.

Pain: Pain may occur during the early stages of malignant disease but intensifies with disease progression. Direct pressure, obstruction, invasion of a sensitive structure, stretching of visceral surfaces, tissue destruction, infection, and inflammation all can cause pain. Chronic pain may result from nerve damage secondary to surgery, chemotherapy, or radiation.

Table 12.5

Factors Predisposing Individuals with Cancer to Infection

Factor	Basis
Age	Many common malignancies occur mostly in older age. Immunologic functions decline with age. General debility reduces immunocompetence. Immobility predisposes to infection. Far-advanced cancer often results in immobility and general debility that worsen with age. Elderly persons are predisposed to nutritional inadequacies. Malnutrition impairs immunocompetence.
Tumor	Nutritional derangements can result. Sites and circumstances favorable to growth of microorganisms (obstruction, serous or blood effusion, ulceration) can be created. Far-advanced disease predisposes individuals to debility and immobility. Humoral or cellular immune defects may result. Metastasis to bone marrow may cause leukopenia or other defects in immunity.
Leukemias	Inadequate granulocyte production can occur (e.g., neutropenia, impaired phagocytosis). Thrombocytopenia (bleeding) can occur. Late effect: chronic lung disease from *Pneumocystis carinii* pneumonia can develop during therapy.
Lymphomas and other mononuclear	Humoral and cellular immune defects (anergy, altered immunoglobulin production) result.

Factor	Basis
phagocyte malignancies	Late effect: splenectomy in children can cause increased susceptibility to infection.
Surgical treatment	Invasive procedure interrupts first lines of defense. Radical nature of surgery (removal of large blocks of tissue in lengthy procedures) causes hemorrhage, decreased tissue perfusion, creation of dead spaces, and tissue necrosis. Procedure may be "dirty" surgery (bowel, infected, or contaminated areas). Persons for surgery are often older and at poor risk. Long preoperative hospitalization often precedes surgery. They may have received previous adrenocorticosteroid therapy, and they may have infections at sites remote from the operative area. Nutritional derangements (especially important in head and neck surgery) may result. Lymph node dissection may predispose an individual to local infection and impair containment to area. Gynecologic surgery may result in fistulae. Lung surgery may cause bronchopleural fistulae. Debility and immobility may result.

Molecular Mechanisms of Cachexia

Cachexia is a complex metabolic syndrome associated with basic illness and is characterized by the loss of muscle with or without loss of fat mass (Fig. 12.30).[265] Cachexia is observed in many medical conditions, including cancer, AIDS, chronic obstructive pulmonary disease, multiple sclerosis, chronic heart failure, tuberculosis, familial

amyloid polyneuropathy, mercury poisoning, and hormonal deficiency.[265] Cancer cachexia is characterized by systemic inflammation, negative protein and energy balance, and loss of lean body mass with or without wasting of adipose tissue.[266] Clinically, cachexia affects 50% to 80% of people with cancer, is represented by substantial weight loss, and may account for up to 20% of cancer deaths.[267] The most obvious symptom of cancer cachexia is the loss of skeletal muscle mass and cardiac muscle wasting, while other visceral organs may maintain muscle mass. Although management of advanced cancers usually does not reverse cachexia, treatment of earlier cancers can reverse the cachexia syndrome.[265] Because individuals receiving total parenteral nutrition still lose weight, increased resting energy expenditure may be the cause of the wasting syndrome.

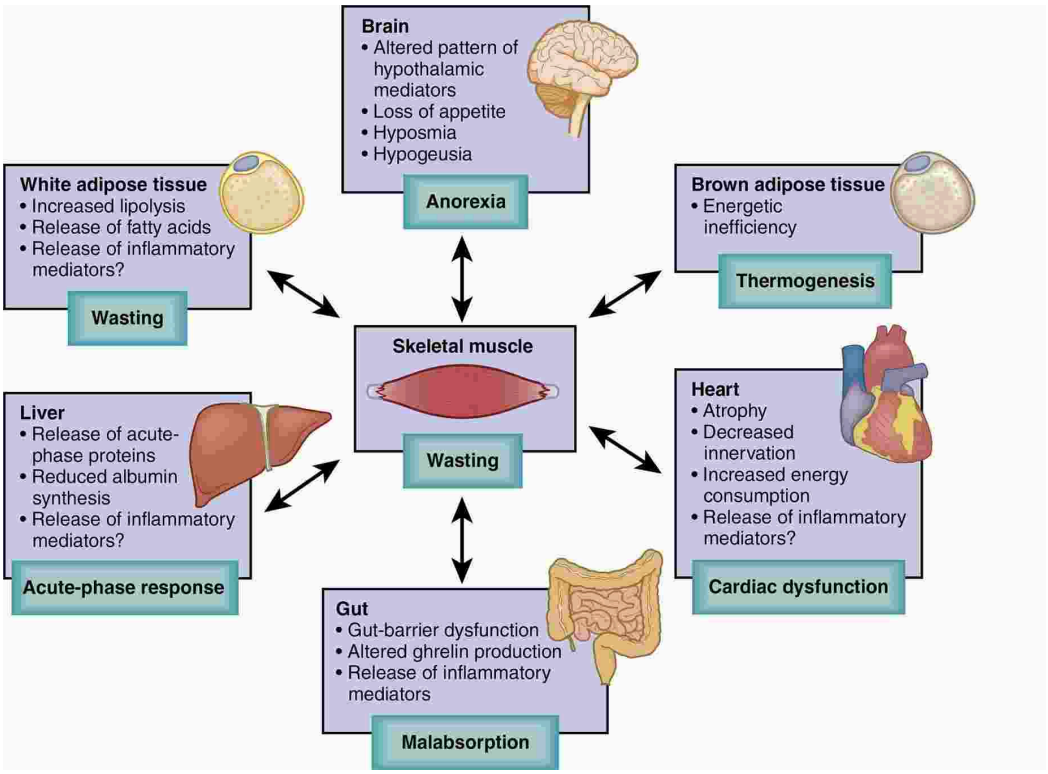

FIG. 12.30 Cachexia: A Multiorgan Syndrome. Loss of skeletal muscle and adipose tissue are major contributors to cachexia. But many other organs have a role in the cachexia syndrome, and the wasting that takes place in muscle may be dependent on alterations in these other organs or tissues. Changes in hypothalamic function and activation of brown adipose tissue, as well as alterations in liver and heart function, also are involved in the syndrome. Recent studies support a role for gut microbiota in cancer cachexia and the possibility of a gut–microbiota–skeletal muscle relationship. Recent data suggest that the conversion of white adipose tissue to brown adipose tissue is triggered by both humoral inflammatory mediators, such as interleukin-6, and tumor-derived compounds, such as parathyroid hormone–related protein. From Bindels LB, Delzenne NM. Muscle wasting: The gut microbiota as a new

therapeutic target? *International Journal of Biochemistry and Cell Biology*, 2013;45:2186–2190; Bindels LB, Beck R, Schakman O, et al. Restoring specific lactobacilli levels decreases inflammation and muscle atrophy markers in an acute leukemia mouse model. *PLoS One*, 2012;7(6):e37971.

An illustration shows the conditions for cachexia. Wasting of skeletal muscle leads to cachexia. Other organs and their roles contributing to cachexia are as follows. • Anorexia; Brain. Altered pattern of hypothalamic mediators, loss of appetite, hyposmia, and hypogeusia. • Thermogenesis; Brown adipose tissue. Energetic inefficiency. • Cardiac dysfunction; Heart. Atrophy, decreased innervation, increased energy consumption, and release of inflammatory mediators. • Malabsorption; Gut. Gut-barrier dysfunction, altered ghrelin production, and release of inflammatory mediators. • Acute-phase response; Liver. Release of acute-phase proteins, reduced albumin synthesis, and release of inflammatory mediators. • Wasting; White adipose tissue. Increased lipolysis, release of fatty acids, and release of inflammatory mediators.

Multiple mechanisms are involved in the development and progression of cachexia, including anorexia, decreased secretion of anabolic hormones, inflammation, decreased physical activity, and altered metabolic responses with abnormalities in protein, lipid, and carbohydrate metabolism (see Fig.12.30).[265] Investigators are

studying the role of both mitochondria and sarcoplasmic reticulum (SR) in muscle function and the relationship to cachexia. Muscle weakness and fatigue are related to loss of myofibrillar proteins in muscle cells (Fig. 12.31). Contributing further to muscle wasting are an increase in apoptosis and an impaired capacity for regeneration. Many signaling pathways are involved in protein turnover, leading to the wasting process, and are activated by inflammatory mediators including cytokines, myostatin, and tumor-derived factors. In addition to muscle wasting, miRNAs may be involved in stimulating the breakdown of adipose tissue. In cancer cachexia, skeletal muscle loss includes significant loss of **white adipose tissue (WAT)**. The WAT loss is thought to be caused by (1) increased lipolysis, (2) decreased activity of lipoprotein lipase (LPL), and (3) decreased new or de novo lipogenesis in adipose tissue. Data show that WAT cells undergo a "browning" process during cancer cachexia where they change to beige cells called *BAT-like cells*. Browning is associated with increased thermogenesis. Tumor-derived compounds, such as IL-6 (which also may be released by immune cells) and parathyroid hormone–related protein (PTHRP), may be the drivers of thermogenesis.

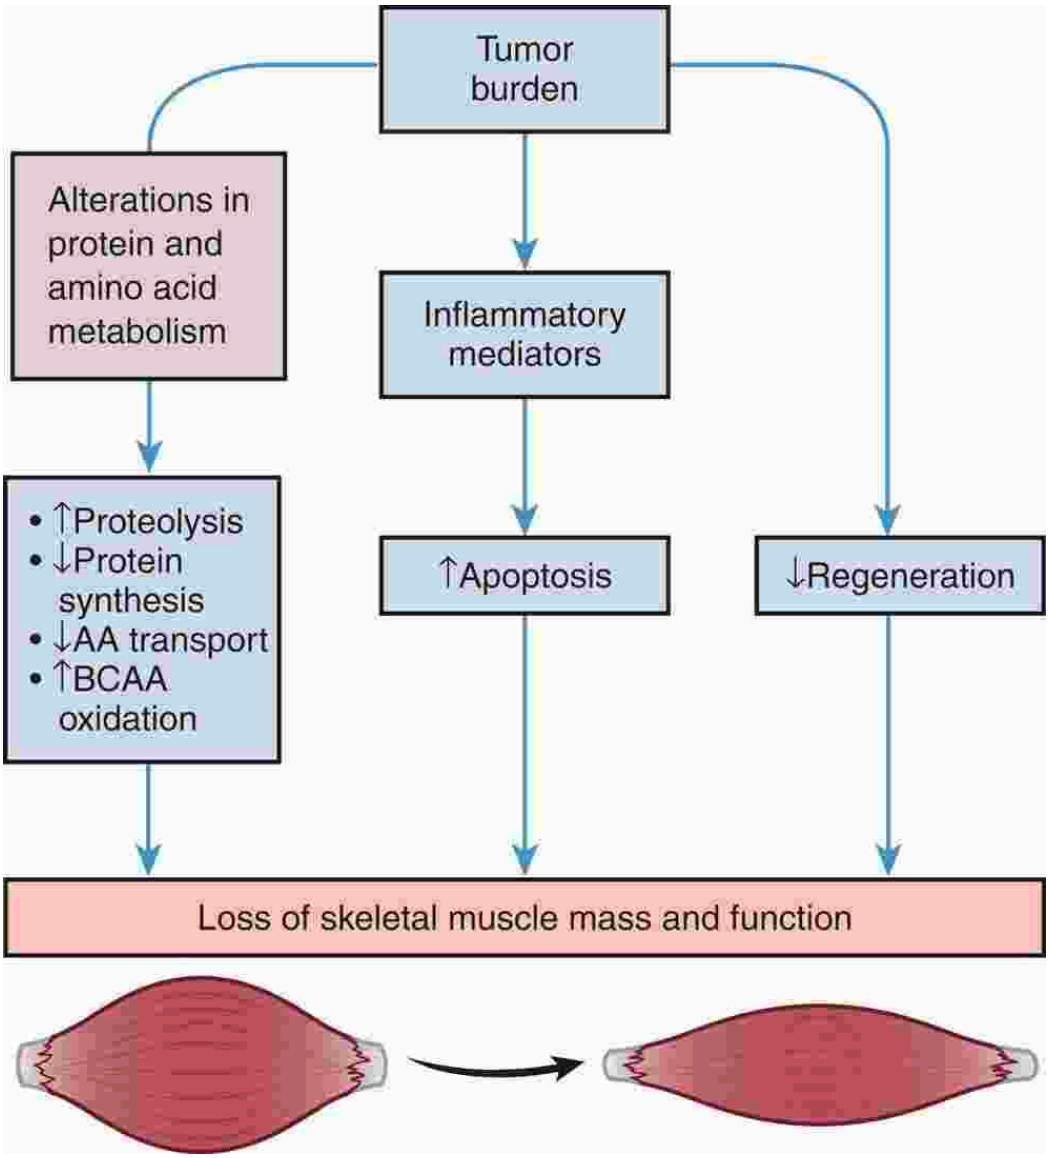

FIG. 12.31 Wasting of Skeletal Muscle. Inflammation plays a significant role in muscle wasting and is linked to alterations in protein and amino acid metabolism, activation of muscle cell apoptosis, and decreased regeneration. *AA*, amino acids; *BCAA*, branched-chain amino acids.

Adapted from Argilés JM, Busquets S, Stemmler B, et al. Cancer cachexia: Understanding the molecular basis. *Nature Reviews. Cancer*, 2014;14(11):754–762.

A flowchart shows the wasting of skeletal muscle. Tumor burden leads to the following. • Alterations in protein and amino acid metabolism. This leads to increased proteolysis, decreased protein synthesis, decreased A A transport, and increased B C A A oxidation, resulting loss of skeletal muscle mass and function. • Inflammatory mediators. This leads to increased apoptosis, resulting in loss of skeletal muscle mass and function. • Decreased regeneration, resulting in loss of skeletal muscle mass and function.

An unusual and frustrating component of cancer care is the person's early satiety, or a sense of being full after only a few mouthfuls of food. Brain mediators are involved in the regulation of food intake and include appetite, satiation, taste, and smell of food. Therefore, the brain is an important organ in anorexia and consequently altered energy balance. Both the **orexigenic** (appetite-stimulating) and **anorexigenic** (appetite-suppressing) **brain pathways** are profoundly altered. (Cytokines are discussed in detail in Chapters 6 and 7.)

Diagnosis and Staging of Cancer

Histologic Staging

Cancer can be discovered in many ways: after screening tests, from routine exams, and after investigation of symptoms. The symptoms a cancer produces are as diverse as the types of cancer. The location of the cancer can determine symptoms by physical pressure, obstruction, and loss of normal function, or a cancer can cause problems far away from its source by pressing on nerves or secreting bioactive compounds. Whatever the initial complaint, once the diagnosis is suspected and a tumor has been identified, the tumor

tissue must be obtained to establish a definitive diagnosis and correctly classify the disease. Various methods of obtaining tissue are described in Table 12.6. and Emerging Science Box describes the liquid biopsy. Once tissue is obtained, it is examined microscopically by the pathologist for the histologic hallmarks of cancer detailed in the beginning of this chapter. The classification of the cancer can be further facilitated by a variety of clinically available tests, including immunohistochemical stains, flow cytometry, electron microscopy, chromosome analysis, and genetic studies.

Table 12.6

Obtaining Tissue—The Biopsy

Procedure	Purpose	Example
Excisional biopsy	Complete removal, usually with a margin of normal tissue	Full resection (e.g., mastectomy, partial colectomy)
Incisional biopsy	Removal of a portion of a lesion	Lymph node biopsy, muscle mass biopsy
Core needle biopsy	Often performed with direct vision, or guided with ultrasound or computed tomography (CT)	Needle biopsy of prostate or liver mass
Fine-needle aspiration	Obtains dissociated cells for cytologic study but does not preserve tissue structure	Thyroid, breast mass
Exfoliative cytology	Cells shed from the surface, for example, from cervix, sputum (lung), or urine	Brushings from lung or colon endoscopy

If the diagnosis of cancer is established, it is critical to determine if the cancer has spread, known as the *stage of the cancer*. **Cancer staging** initially involves determining the size of the tumor, the degree to which it has invaded locally, and the extent to which it has spread (metastasized). Specific molecular tests are increasingly being used in staging. Diverse schemes are used for staging different tumors. In general, a four-stage system is used, with CIS regarded as a special case. Cancer confined to the organ of origin is stage 1; cancer that is

invasive locally is stage 2; cancer that has spread to regional structures, such as lymph nodes, is stage 3; and cancer that has spread to distant sites (e.g., a liver cancer that has spread to a lung or a prostate cancer that has spread to bone) is stage 4. One common scheme for standardizing staging is the World Health Organization's TNM system: *T* indicates tumor spread, *N* indicates node involvement, and *M* indicates the presence of distant metastasis (see Fig. 12.28). The prognosis generally worsens with increasing tumor size, lymph node involvement, and metastasis. Staging also may alter the choice of therapy; more aggressive therapy is delivered to more invasive disease.

Tumor Markers

During surveillance or diagnosis of cancer, as well as following therapy, specific biochemical markers of tumors have proven to be helpful. These **tumor markers** are substances produced by both benign and malignant cells that are either present in or on tumor cells or found in blood, spinal fluid, or urine. Some tumor markers have been known for many decades. Tumor markers include hormones, enzymes, genes, antigens, and antibodies (Table 12.7). For example, the tumor-associated antigen carcinoembryonic antigen (CEA) is released from colon cancer. If the tumor marker itself has biologic activity, then it can cause symptoms, such as those described in Table 12.7. For example, the adrenal medulla normally secretes the catecholamine epinephrine (adrenaline). Benign tumors of the adrenal medulla (pheochromocytoma) can produce catecholamines (e.g., adrenaline) in vast excess, leading to rapid pulse rate, high blood pressure, diaphoresis (i.e., sweating), and tremors. Detection of elevated blood or urine levels of catecholamines helps confirm the diagnosis, and treatment of the disease relieves the symptoms. Tumor markers can be used in three ways: (1) to screen and identify individuals at high risk for cancer; (2) to help diagnose the specific type of tumor in individuals with clinical manifestations relating to their tumor, as in adrenal tumors or enlarged liver or prostate; and (3) to follow the clinical course of a tumor.

Table 12.7

Examples of Tumor Markers in Body Fluids

Marker Name	Nature	Type of Tumor
Adrenocorticotropic hormone (ACTH)	Peptide hormone	Pituitary adenomas
Alpha fetoprotein (AFP)	70-kDa protein	Hepatic, germ cell
Beta-2-microglobulin (β2 M)	11-kDa protein	Multiple myeloma, CLL
Beta-human chorionic gonadotropin (β-hCG)	Glycopeptide hormone β-chain	Germ cell, choriocarcinoma
CA15-3/CA27-29	Large MW glycoproteins	Breast
CA-125	Large MW glycoprotein	Ovary
CA19-9	201-kDa glycoprotein	Pancreas, gallbladder, bile duct, gastric
Calcitonin	3.4-kDa polypeptide hormone	Thyroid
Carcinoembryonic antigen (CEA)	200-kDa glycoprotein	GI, pancreas, lung, breast, etc.
Catecholamines	Epinephrine and precursors	Pheochromocytoma (adrenal medulla)
CD20	33–36-kDa glycosylated	Non-Hodgkin lymphoma

Marker Name	Nature	Type of Tumor
	phosphoprotein	
Chromogranin A (CgA)	48-kDa protein	Neuroendocrine
Homovanillic acid/vanillylmandelic acid (HVA/VMA)	Catecholamine metabolites	Neuroblastoma
Prostate-specific antigen (PSA)	33-kDa glycoprotein	Prostate
Urinary Bence-Jones protein	Ig light chain	Multiple myeloma

CLL, Chronic lymphocytic leukemia; *GI*, gastrointestinal; *Ig*, immunoglobulin; *kDa*, kilodalton(s); *MW*, molecular weight.

To date, no tumor marker has proven satisfactory to screen populations of healthy individuals for cancer. Testing large populations will always detect a few normal individuals with test results at the high end of the normal distribution (the "false positives"), which can lead to expensive and invasive additional tests and unnecessary concern. Similarly, some individuals with disease will have test results in the normal range ("false negatives"). More importantly, some nonmalignant conditions can produce tumor markers. The presence of an elevated tumor marker, therefore, may suggest a specific diagnosis, but it is not used alone as a definitive diagnostic test. For instance, prostate tumors secrete *prostate specific antigen (PSA)* into the blood. But enthusiasm has waned for routine testing for PSA levels, and now the US Preventive Services Task Force (USPSTF) recommends that clinicians inform men ages 55 to 69 years about the potential benefits and harms of PSA screening for prostate cancer.[268] Screening offers a small potential benefit of reducing the chance of dying of prostate cancer. Many men, however, will experience harm from screening, including false-positive results that require additional testing and possible biopsy, overdiagnosis and overtreatment, and treatment complications such as incontinence and erectile dysfunction. Clinicians should not screen men who do not

express a preference for screening.[268] Falling levels of PSA after radiation or surgical therapy may indicate successful treatment for prostate cancer, and a later rise may indicate a recurrence. Identification of ideal sensitive and specific tumor markers that are elevated early during common cancers remains a high priority because the early detection of cancer often improves the treatment outcome.

Classification of Tumors: Immunohistochemical and Genetic Analysis

Because knowledge about the cellular and molecular alterations in individual cancers can influence the choices of therapy, it becomes increasingly important for clinicians to accurately classify each cancer. The classification, and hence the treatment decisions, of cancers was originally based on gross and light microscopic appearance and is now commonly accompanied by immunohistochemical analysis of protein expression. Increasingly, this is supplemented by a more extensive genetic analysis of the tumors. The range of genetic analysis is expanding rapidly. In a research setting and increasingly in clinical settings, global gene expression and mutation analysis can be measured using polymerase chain reaction (PCR), microarray, or advanced DNA sequencing technology. These analyses can be used to classify tumors more precisely and may predict the most effective therapy. This detailed analysis of each tumor is a form of **personalized medicine** that offers therapy based on a very detailed knowledge of the characteristics of each individual's specific cancer. This enhanced molecular characterization subdivides cancers into therapeutically and prognostically relevant smaller groups. As an example, breast cancers can now be subclassified into over four types (luminal A, luminal B, basal-like, and others) based on their expression of specific markers, such as estrogen receptor, *HER2/Neu*, and other specific genes and proteins. Each subtype has a different response to therapy and a different prognosis.

Treatment of Cancer

Until late in the last century the mainstays of cancer therapy have been surgery, chemotherapy, and radiation therapy. These approaches have been highly successful for certain types of cancer but have many limitations. Evidence has long been emerging that the immune system, in particular T cells, is capable of waging war on cancer tissue—**Immunotherapy**.[269,270] Immunotherapy has now established itself as a pillar of cancer care from the metastatic stage to the adjuvant and neoadjuvant settings in many cancer types.[270] From almost miraculous results to current pitfalls and limitations of checkpoint immunotherapy, novel research in the fields of personalized cancer vaccines, autoimmunity, the microbiome, the tumor microenvironment and metabolomics is aiming to solve those challenges.[270] Current immunotherapeutic approaches are being developed and tested to address the complexity of cancer pathogenesis, immune destruction, and precise cancer targeting (see further discussion under Immunotherapy).[269]

Cancer therapy is in a process of rapid evolution. Armed with a clearer understanding that cancer is in fact multiple diseases that share general hallmarks/enablers, and that the specific mechanisms underlying each hallmark may vary considerably among cancers (e.g., the large variety of oncogenes that may be used to differentiate cancers), modern cancer therapy is reaching a stage where complete genetic analysis of an individual cancer may determine the appropriate combination of therapies. Thus, effective therapy may include a combination of reagents targeting several hallmarks and under constant modification to target the evolving cancer cells.

Classic Approaches

Surgery

Surgery plays many roles in the care of individuals with cancer. The multiple approaches to obtaining tissue for diagnosis have been discussed. Surgery is often the definitive treatment of cancers that do not spread beyond the limits of surgical excision. It also is indicated

for the relief of symptoms, for instance, those caused by tumor mass obstruction. In selected high-risk diseases, surgery plays a role in the prevention of cancer. For example, individuals with familial adenomatous polyposis because of germline mutations of the *APC* gene have close to a 100% lifetime risk of colon cancer, so a prophylactic colectomy is indicated. Similarly, women with *BRCA1/2* mutations have a markedly increased risk of breast and ovarian cancer, and often choose prophylactic mastectomy or bilateral salpingo-oophorectomy (removal of ovaries and fallopian tubes), or both.

Key principles apply specifically to cancer surgery, including obtaining adequate surgical margins during a resection to prevent local recurrences, placing needle tracks and biopsy incision scars (that may be contaminated with cancer cells) carefully so they can be removed in subsequent incisions, avoiding the spread of cancer cells during surgical procedures through careful technique, and paying attention to obtaining adequate tissue specimens during biopsies so that the pathologist can be confident of the diagnosis. Additionally, the surgeon provides critical staging information by inspection, sampling, and removal of local and regional lymph nodes during procedures.

Radiation Therapy

Radiation therapy is used to kill cancer cells while minimizing damage to normal structures. Ionizing radiation damages cells by imparting enough energy to cause molecular damage, especially to DNA. The damage may be lethal, in which the cell is killed by radiation; potentially lethal, in which the cell is so severely affected by radiation that modifications in its environment will cause it to die; or sublethal, in which the cell can subsequently repair itself. Cellular compartments with rapidly renewing cells are, in general, more radiosensitive. Effective cell killing by radiation also requires good local delivery of oxygen, something not always present in large cancers. Radiation produces slow changes in most cancers and irreversible changes in normal tissues as well. Because of these irreversible changes, each tissue has a maximum lifetime dose of

radiation it can tolerate. Radiation is well suited to treat localized disease in areas that are hard to reach surgically, for example, in the brain and pelvis. Several radiation delivery methods are available, with external beam being the most common. Radiation sources, such as small ^{125}I-labeled capsules (also called *seeds*), can also be temporarily placed into body cavities, a delivery method termed **brachytherapy**. Brachytherapy is useful in the treatment of cervical, prostate, and head and neck cancers.

Chemotherapy

The era of modern chemotherapy began with the observation in World War II that mustard gas exposure caused suppression of the bone marrow. Related compounds, such as nitrogen mustard and cyclophosphamide, were then tested and produced clinical responses in hematologic malignancies, including lymphomas. Also in the late 1940s, based on the remarkable clinical observation that the vitamin folic acid could *increase* leukemia growth, antifolate drugs were developed (leading ultimately to methotrexate) that produced remissions in previously untreatable leukemia.

All chemotherapeutic agents take advantage of specific vulnerabilities in target cancer cells. Antimetabolites, such as methotrexate and L-asparaginase, block normal growth pathways in all cells, but leukemia and other cancer cells are exquisitely sensitive to folic acid and asparagine deprivation, whereas nonmalignant cells are far less sensitive. Similarly, some cancer cells are highly sensitive to DNA-damaging agents, such as cyclophosphamide and anthracyclines, because of the oncogenic mutations that accelerate the cell cycle and DNA synthesis. Cellular checkpoints prevent normal cells treated with microtubule-directed drugs, such as vincristine and the taxanes, from undergoing mitosis, whereas cancer cells treated with these agents lack normal checkpoints, continue through mitosis, and undergo mitotic catastrophe (see Chapter 1).

Single chemotherapeutic agents often shrink cancers, but these drugs given alone rarely provide a cure. Increasing evidence of the majority of approved cancer drugs, including TKIs, systemic cytotoxic therapies (chemotherapy) and ADCs, reveals they do not

have a durable impact with metastatic disease often because of therapeutic resistance.[262,263] Hence chemotherapy drugs are usually given in combinations designed to attack a cancer from many different weaknesses at the same time and to limit the dose and, therefore, the toxicity of any single agent.

Chemotherapy can be used for several distinct purposes. **Induction chemotherapy** seeks to cause shrinkage or disappearance of tumors. In Hodgkin lymphoma, for example, chemotherapy alone can be used in some cases to cure the disease. In other settings, chemotherapy may shrink the tumor and improve symptoms without ultimately providing a cure. **Adjuvant chemotherapy** is given after surgical excision of a cancer with the goal of eliminating micrometastases. **Neoadjuvant chemotherapy** is given before localized (surgical or radiation) treatment of a cancer. As with induction chemotherapy, the effectiveness, or lack thereof, of neoadjuvant therapy can be measured (for example, with follow-up scans). Neoadjuvant therapy can shrink a cancer so that surgery may spare more normal tissue. For example, in the bone cancer osteogenic sarcoma, neoadjuvant therapy often converts a large tumor mass into a much smaller mass, allowing the surgeon to perform a limb-sparing excision rather than an amputation.

A major complication of chemotherapy is death of rapidly dividing cells that are not cancerous, such as those of the bone marrow. Hematopoietic growth factors also have been used to counter the effects of chemotherapy on bone marrow cells.

Immunotherapy

Cancer immunotherapy has been transformational in the care of persons with cancer, providing significant improvements for both survival and quality of life.[270] The field of cancer immunotherapy has a long history, and since the 1950s, the quest has been characterized by promises and frustrations. Yet, in the twentieth century, cancer immunotherapy made significant advances with the advent of new technology and even a Nobel Prize in Physiology or Medicine to Drs. Allison and Honjo.[269,270] The expression of unique antigens on cancer

cells that can be targeted by T cells has driven the quest for effective therapies to initiate an immune response, boost a currently inadequate immune response, or convert a tumor-protective immune response to a destructive one.[271] The recent discovery of T cell immune checkpoints, such as **cytotoxic T lymphocyte antigen 4 (CTLA-4)** and **programmed cell death 1 (PD-1)**, moved the field of immuno-oncology into its current era. The challenge is harnessing immune signals that maintain a fine balance between immune surveillance against foreign pathogens or abnormal cells and autoimmunity. Blocking T cell surface receptors results in increased autoimmunity that induces an immune response against tumors but can also enhance the chance of powerful autoimmune reactions.[270]

Immune Checkpoint Inhibitors

Various immune system components protect the host against primary tumor development, enhance tumor escape from immune mechanisms, or both. The process of orchestrating tumor immunogenicity or reducing antitumor immune responses is tightly regulated by **immune checkpoints**. These checkpoints are immune-cell surface receptors regulating either the activation or the inhibition of immune responses.[270] On the one hand, activation of the immune system is the desired outcome, but on the other hand, it is responsible for autoimmunity.[270] CTLA4 blocking antibodies (*α*-CTLA4), especially when bound to an Fc receptor (FcR) on an antigen-presenting cell (APC), can promote antibody-dependent cellular cytotoxicity (ADCC) (see Chapter 8). PD1 engages with its specific ligand (PDL1 or PDL2) to decrease activation. Blocking of the PD1 axis through the administration of an anti-PD1 (or anti-PDL1 or anti-PDL2) antibody prevents this inhibitory interaction and releases antitumoral T lymphocyte activity by increasing T cell activation and proliferation. The process is further supported by promoting formation of memory cells. The result is the release of cytolytic mediators, such as perforin and granzyme, causing increased tumor killing.[269]

Immune checkpoint inhibitor (ICI) therapies are now indicated in numerous cancer types.[269] Clinical trials are assessing the potential of other inhibitory or agonistic checkpoints to affect clinical outcomes.[270] The checkpoints are not equal in their outcomes; for example, the agonistic OX40 antibody has modest clinical activity, but the CD28 antibody resulted in a severe immune reaction called **cytokine syndrome** even at very subtherapeutic doses (see Chapter 10).[270] Critical is finding the right combination of ICIs hence, requiring ongoing clinical trials. Recently, a meta-analysis reported a fatality rate of up to 1 person in every 77 treated using an ICI combination.[272] Immunotherapies are limited by their **immune-related adverse events (irAEs)**. For specific irAEs, such as immune-related myocarditis, the mortality rate is as high as 50% in treated individuals.[273] Numerous predictors of irAEs have been proposed and will need prospective research validation. Promising results of single-agent PD-1 inhibitor varies from almost non-existent in pancreatic cancer and microsatellite-stable colonic adenocarcinoma, to an average of 15% to 30% in most other tumor types, but an impressive 50% to 80% in melanoma, Hodgkin lymphoma, squamous-cell carcinoma of the skin, and Merkle cell carcinoma.[270] Dedicated scientists and clinicians are mobilized to achieve a higher response rate without increasing autoimmunity.

One logical approach has been to combine an ICI with another therapy that can sensitize the host's immune system to the tumor in advance.[270] Recent studies have shown that using a person's own cancer cells to develop a vaccine (personalized neoantigen-base tumor specific vaccines) holds great promise.[270]

Vaccines

Tumor cell vaccines were one of the first attempts at immunotherapy for cancer and have been extremely effective in protecting individuals against infective agents. Two categories of vaccines are prophylactic and therapeutic. Prophylactic vaccines against hepatitis B and HPV

have been important in reducing the incidence of hepatocellular carcinoma and cervical cancer, respectively.[269,274]

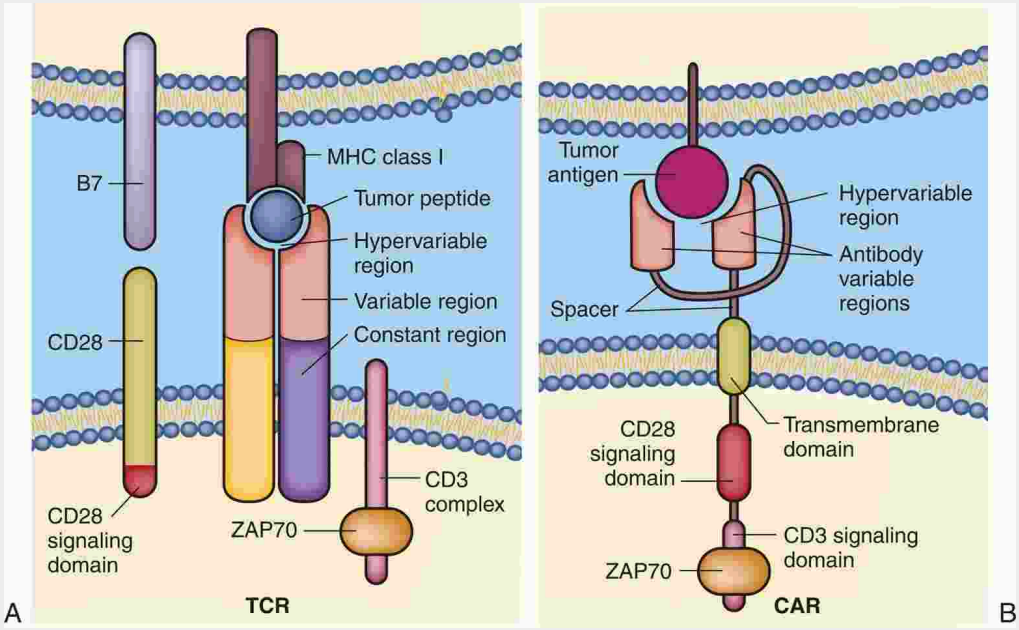
Therapeutic vaccines aim to harness the immune system to rid disease-causing cells that are cancerous.[274] The research required is rigorous, and requires data points longitudinally, numerous tumor vaccines are in phase II and phase III trials but have yet to receive FDA approval.[269] Hematologic malignancies have a common antigen that is uniformly expressed on the surface of all malignant cells, making it possible to target therapies with **chimeric antigen receptor T cells** (**CAR T cell**) (Box 12.4). CAR T cells are engineered with *chimeric* (artificially derived from two different genes) antigen receptors. Solid tumors, however, either lack such an antigen or undergo mutations when exposed to therapeutic interventions like monoclonal antibodies.[270] Bioinformatics is guiding precision immuno-oncology to identify personal neoantigens for targeting.[270] Efficacy for the optimal vaccine relies on the selection of a target antigen for delivering a personalized vaccine. Using a person's own cancer cells to develop a vaccine and then to combine this approach with another immunotherapy, like ICI, is evolving.

Box 12.4

Engineering T Cells for Better Anticancer Killing and Chimeric Antigen Receptor T Cells

The specificity and function of T-cytotoxic cells (Tc cells) is controlled by three signals: (1) the T-cell receptor (TCR) that binds antigen and is associated with a complex of transmembrane signaling molecules (CD3); (2) the transmembrane co-receptor CD8 that binds to class I major histocompatibility complex (MHC) that is presenting antigen, resulting in proximity of CD3 with the intracellular portion of CD8 leading to activation of a signaling molecule; and (3) transmembrane accessory molecules, such as CD28, that bind to ligands on the target cell surface and provide an

additional activation signal (see Fig. A). Cancers have developed multiple mechanisms for escaping the cytotoxic effects of Tc cells, among which are suppression of antigen presentation, reduction of CD3 expression, and inhibition of the CD28 signal by expression of soluble CTLA-4, which competes for binding to the CD28 ligand. Thus recognition of cancer-associated antigens by the Tc cell may be completely suppressed.



A variety of approaches have been designed to bypass suppression of the TCR. Initial attempts included cloning Tc cells expressing high-affinity TCRs for tumor antigen. However, suppression of antigen presentation by the tumor prevented recognition by these Tc cells. This has led to a unique approach of engineering T cells with chimeric antigen receptors (CAR T cells). Early success with these novel cells has led to further sophisticated approaches to constructing more complex CARs.

The process involves collection of circulating white blood cells from the blood of an individual with cancer using leukapheresis. The lymphocytes are enriched, induced to proliferate, and transfected by a virus containing the genetically engineered CAR.

The CAR T cells are cloned in bulk, verified for expression of the CAR, and cryopreserved. When used, the cells are thawed and infused into the individual with cancer.

The CAR receptors are V_H and V_L regions cloned from monoclonal antibodies and inserted in tandem into the *CAR* gene. Because tumors suppress MHC presented antigen, the CAR receptors are designed against other surface molecules that do not require presentation. The *CAR* gene also contains information for hydrophobic transmembrane regions, followed by genetic information for costimulatory signals. Initially the costimulatory signals included the cytoplasmic portions of CD28 and CD3, but more recently developed CARs include multiple costimulatory signaling peptides. Thus binding of the receptor to a cancer-related molecule activates linked intracellular signaling peptides, such as CD3, CD28, and others, contained sequentially in the *CAR* gene. (Fig. B)

Targets for CAR T cells have included CD19, CD20, and CD22 on hematologic cancers and HER2, EGFR, and others on solid tumors. The most notable success has been treatment of CD19-positive B-cell malignancies. CD19 is expressed on cancer cells at a very high level related to normal B cells. Infusion of CAR T cells has led to remissions of greater than 80% of people with ALL and about 50% of those with CLL. Success against solid tumors has been less spectacular.

The next generation of CAR T cells is in development. These include the addition of more costimulatory signals, simultaneous expression of two CAR molecules on the T cell (both targeted to the same cancer-related molecule, but one CAR providing a strong TCR-like signal and the second providing a costimulatory signal), CARs directed to apoptosis-inducing molecules or cytokine receptors, and the use of engineered allogeneic T cells. The use of allogeneic T cells would accelerate treatment by circumventing the current 2- to 3-week process of preparing CAR T cells from the individual's own cells.

ALL, Acute lymphocytic leukemia; *CLL*, chronic lymphocytic leukemia.

The host microbiome plays a significant role in the efficacy of vaccine immune responses, promotion of carcinogenesis, efficacy and toxicity of anticancer treatments, such as ICIs.[270] The tumor microenvironment has a critical role in the modulation of anticancer immune responses. From research findings the term "immune contexture" has been proposed and validated with tumors classified by their tumor microenvironment and include four categories (hot, excluded, immunosuppressed, and cold). There is ongoing work to convert "cold" tumors with a strong expression of mesenchymal and collagen barriers that impede migration of tumor-infiltrating lymphocytes to the tumor bed.[270] Thus, research is progressing on the transformation of "cold" tumors into fertile "hot" tumors that are much more responsive to ICIs. Hot tumors are characterized by the accumulation of proinflammatory cytokines and T cell infiltration.[275]

Targeted Disruption of Cancer

As discussed previously, cancers appear to share a variety of hallmarks that contribute to the malignant phenotype. Recent molecular and genetic analyses of groups of cancer can classify an individual's cancer by the spectrum of mutations underlying the cancer phenotype.

Tumor growth and progression are dependent on a variety of mutations leading to expression of oncogenes, inactivation of tumor-suppressor molecules, and interactions with inflammatory cells in the tumor microenvironment. These interactions foster angiogenesis, resistance to apoptosis and immune-mediated cancer cell death, altered tumor cell metabolism, and metastasis. An efficacious

therapeutic approach, therefore, may be a combination of drugs highly targeted to cancer hallmarks.[276]

The NCI describes the many different targeted therapies approved for use in cancer treatment.[277] Cancer-targeting agents include those that inactivate oncogenes, block angiogenesis, and affect cancer cell metabolism. Monoclonal antibodies are available that induce apoptosis in tumor-infiltrating cells such as TAM, Treg cells, and tumor endothelium. Additionally, specific antagonists may neutralize the effects of cytokines, chemokines, and other tumor-enhancing mediators produced in the tumor microenvironment. These are usually in the form of monoclonal antibodies, which are available against tumor necrosis factor-α (TNF-α), VEGF, HER-2, and other ligands and their receptors. Such highly specific targeting would minimize secondary toxic effects. Information on the prevention of cancer by altering and eliminating high-risk lifestyle behaviors is contained in Chapter 13.

Summary Review

Cancer Terminology and Characteristics

1. Cancer is a leading cause of suffering and death in the developed world. Intensive research is defining this collection of related complex diseases. It is a disease in which abnormal cells divide uncontrollably, invade, and metastasize to other tissues. A tumor is a new growth, or neoplasm.
2. Cancer is more than 100 diseases, each caused by a specific and often unique age-related accumulation of genetic and epigenetic alterations. Environment, behavior, and heredity modify the risk of developing cancer and the response to treatment.
3. Benign tumors are usually encapsulated and well differentiated with well-organized stroma and do not spread to distant locations. They are named for the tissues from which they arise. Benign tumors are noncancerous.

4. Malignant tumors are cancerous. Compared with benign tumors, malignant tumors have more rapid growth rates, specific microscopic alterations (anaplasia, or loss of differentiation, and pleomorphism, or variability in size and shape), absence of normal tissue organization, and no capsule. They invade blood vessels and lymphatics and have distant metastases. The stroma is disorganized with loss of normal tissue structure.
5. Cancers are named for the cell type from which they originate. Carcinomas arise from epithelial tissue, lymphomas are cancers of lymphatic tissue, and leukemias are cancers of blood-forming cells.
6. Carcinoma in situ (CIS) refers to noninvasive epithelial tumors of glandular or squamous cell origin. These early–stage cancers are localized to the epithelium and have not penetrated the local basement membrane.

The Biology of Cancer Cells

1. Cancer is a complex disease, and the microenvironment of a tumor is a heterogenous mixture of cells, both cancerous and benign.
2. Tumor initiation is dependent on mutational and epigenetic changes and characteristics of the microenvironment. Tumor progression is governed further by more genetic mutations, epigenetic alterations, and changing microenvironment.
3. Genetic changes include small and large DNA mutations that alter genes, chromosomes, and non–coding RNAs, as well as epigenetic changes because of altered chemical modifications of DNA and histones.
4. Driver mutations “drive” the progression of cancer. Passenger mutations are random events that do not contribute to the malignant phenotype. After a critical number of driver mutations, the cell becomes cancerous.

5. Mutations activate growth-promotion pathways, block antigrowth signals, prevent apoptosis, stimulate telomerase and new blood vessel growth, and allow tissue invasion and distant metastasis.
6. Each cancer cell may develop its own set of mutations resulting in a genomically heterogeneous mixture of cancer cells with subsets that have accumulated more and more mutations. Intratumoral genetic heterogeneity or diversity arises from ongoing proliferation and mutation and can lead to therapy resistance.
7. The processes that occur during the development of cancer are analogous to wound healing. The proliferation of cancer cells and enlargement of the tumor elicit synthesis of proinflammatory mediators by the cancer cells and adjacent nonmalignant cells.
8. Like wound healing, mediators recruit inflammatory/immune cells and cells normally associated with tissue repair. These cells form the stroma (tumor microenvironment) that surrounds and infiltrates the tumor.
9. Hallmarks of cancer that are primarily genomic alterations include sustained proliferative signaling, evading growth suppression, genomic instability, and replicative immortality.
10. Other hallmarks secondary to genomic change include induction of angiogenesis and reprogramming energy metabolism. A third group, tumor resistance to destruction by the host's protective mechanisms, include resistance to apoptotic cell death, tumor-promoting inflammation, avoiding immune destruction, and the last hallmark activating invasion and metastasis.
11. Many of the hallmarks of cancer are consequences of cancer-stromal interactions.
12. Normal cells only enter proliferative phases in response to growth factors. Cancerous cells characteristically express mutated or overexpressed proto-oncogenes, referred to as oncogenes, which are independent of normal regulatory mechanisms and signal uncontrolled sustained proliferation.

Genetic translocation alters the MYC proto-oncogene and hyperproduction of MYC protein drives proliferation and blocks differentiation.

13. Some oncogenes, such as *RAS*, result from point mutations. Other oncogenes can result from genetic translocations. Genetic translocation alters the MYC proto-oncogene and hyperproduction of MYC protein drives proliferation and blocks differentiation.
14. Translocation can cause excess and inappropriate production of a proliferation factor, such as with Burkitt lymphoma. Translocations can also lead to production of novel proteins with growth-promoting properties, as is seen with the Philadelphia chromosome in chronic myeloid leukemias (CMLs).
15. Tumor-suppressor genes normally regulate cell cycle, but they must be inactivated in cancer cells by mutations to each allele, one from each parent.
16. The most mutated gene in a wide variety of human cancers is the p53 tumor-suppressor gene *(TP53)*. The protein, p53 acts as a tumor suppressor, thus it regulates cell division by restricting cells from growing and dividing too fast or in an uncontrolled way the "guardian of the genome." The *p53* is in the nucleus and attaches directly to DNA. If DNA is damaged by such agents or stressors as toxic chemicals, radiation or ultraviolet radiation and others the protein plays a critical role in whether DNA is repaired, or the damaged cells undergo apoptosis. If the DNA can be repaired, p53 activates other genes or caretaker genes, for repair. If the DNA cannot be repaired, p53 prevents the cell from dividing and signals it to undergo apoptosis.
17. The p53 controls initiation of senescence (cease dividing), which has been shown to exhibit both a tumor suppressor and an oncogenic effect.
18. Cellular senescence can promote cancer development by altering the cellular environment through a senescence-associated secretory phenotype (SASP).

19. The retinoblastoma gene1 *(RB1)*, a tumor suppressor gene is mutated in childhood retinoblastoma and in some lung, breast, bladder, bone cancers, leukemias, and melanoma.
20. Genomic instability refers to an increased tendency of mutations in the genome during the life cycle of cells. Genomic instability in inherited and acquired mutations in caretaker genes increase the level of genomic instability and risk for developing cancer. Genomic instability may result from increased epigenetic silencing or modulation of gene function.
21. Changes in gene regulation can affect entire networks of signaling, not just single genes. Gene expression networks can be regulated by changes in microRNAs (miRNAs or miRs) and other non–coding RNAs (ncRNAs).
22. Oncomirs or oncogenic miRNAs promote multiple cancer pathways.
23. In addition to specific gene mutations and abnormal epigenetic silencing, chromosome instability (CIN) also appears to be increased in malignant cells, resulting in a high rate of chromosome loss, as well as loss of heterozygosity and chromosome amplification.
24. Cancer cells are immortal. When they reach a critical age, most cancer cells re-activate telomerase to restore and maintain their telomeres, thereby allowing cancer cells to divide repeatedly. Cancer cells move closer to immortality by upregulating telomerase and downregulating tumor suppressor genes.
25. Telomerase also affects DNA replication, cellular apoptosis, tumorigenesis, and resistance to therapy.
26. Cancer stem cells (CSCs) are a subpopulation of tumor cells that have replication immortality. They arise from tissue resident stem cells or develop from transformed differentiated cells. Transformation from differentiated cells into CSCs occurs through the activation of oncogenes, inactivation of tumor suppressor genes, and re-expression of telomerase.

27. CSCs can change their appearance and function in response to the tumor microenvironment such that they drive cancer progression, serving as the cellular seeds for tumor growth, metastases, and disease recurrence.
28. Access to the vascular system is essential for tumor growth. Cancerous tumors maintain secretion of angiogenic factors and prevent the release of angiogenic inhibitors, which stimulates new blood vessel growth (called neovascularization or angiogenesis).
29. The vessels formed within tumors originate from endothelial sprouting from existing capillaries and irregular branching, rather than regular branching seen in healthy tissue. The vessels are also more porous and prone to hemorrhage and allow passage of tumor cells into the vascular system.
30. Another form of angiogenesis in tumors is called vasculogenic mimicry. Tumor cells form tubular structures like blood vessels that contain erythrocytes. These tubular tissues can attach to blood vessels to form a vascular network.
31. Cancer cells can reprogram energy metabolism. The successful cancer cell divides rapidly, with the consequent requirement for the building blocks of new cells, such as ATP. Many cancer genes encourage aerobic glycolysis instead of oxidative phosphorylation, which allows for a more efficient production of molecular building blocks needed for rapid growth.
32. Oncogenes can drive metabolic reprogramming, enabling cancer cells to (1) maintain deregulated proliferation, (2) withstand challenges associated with oxygen and nutrient limitations, (3) maintain a dedifferentiated state with associated alterations in gene expression, and (4) corrupt the surrounding microenvironment to assist tumor growth and dissemination.
33. In cancer, defects in the intrinsic or extrinsic cell death pathways, or both, provide resistance to apoptotic cell death.
34. The inflammatory response contributes to the onset of cancer, and cancer is a cause of chronic systemic and local

inflammation. Tumors can manipulate the inflammatory process in their local tumor microenvironment to benefit tumor progression and spread.

35. Cancer also causes systemic perturbations in both innate and adaptive immune processes that reduce the body's ability to fight the cancer.
36. Some conditions of chronic inflammation increase the risk of developing cancer. A prime example is the association between gastric cancer and infection with *Helicobacter pylori*.
37. One of the key cells that promotes tumor survival is the tumor-associated macrophage (TAM). Most tumors have large numbers of TAMs, whose presence may correlate with a worse prognosis.
38. Cancer-associated fibroblasts (CAFs) contribute greatly to cancer progression, local spread, and metastasis. Studies have documented how the number of CAFs, or their function is linked to outcomes. The heterogeneity of CAFs, their functions and possible changeability, pose a challenge for the field,
39. Several viruses are associated with cancer and include human papillomavirus (HPV), Epstein-Barr virus (EBV; also known as HHV4), Kaposi sarcoma herpesvirus (KSHV; also known as HHV8), hepatitis B and C viruses (HBV, HCV), and Merkel cell polyomavirus. Cancer of the cervix and hepatocellular carcinoma account for approximately 80% of virus-linked cancer cases.
40. Although some cancer cells do express tumor-specific antigens that can be recognized by the immune system, most cancer cells do not, and those that do, most often present antigens that are undetectable by the immune system. Cancer cells have developed multiple mechanisms to evade the immune system. As cancer cells proliferate, clonal development of immune-resistant variants arises.
41. Immune cells have surface molecules whose purpose is to activate (co-stimulatory factors) or suppress (co-inhibitory factors) immune responses to antigens. Co-inhibitory

molecules are often called immune *checkpoints*. Cancer cells may suppress T cells by binding to immune checkpoints, causing the lymphocyte to turn off its attack. Checkpoint inhibitors are a group of immunotherapy drugs that block this interaction, thus reactivating the immune cell to attack the tumor.

42. The role of the immune system in protecting against cancer has been clearly documented against oncogenic viruses. Antibodies induced by vaccines against oncogenic viruses, such as human papillomavirus (HPV) and hepatitis B virus (HBV), protect against initial infection and development of cervical and liver tumors, respectively.

Activating Invasion and Metastasis

1. New paradigms in the study of metastasis have identified molecular underpinnings of the dissemination process.
2. Improved understanding of how the invading tumor cell interacts with other proteins and cells has elucidated new biological principles by which metastatic cells regulate their mobility and plasticity.
3. Communications with the tumor microenvironment allows invading cancer cells to conquer stromal challenges, settle, and colonize. Characteristics are driven by genetics and epigenetic changes within the tumor cell itself and its microenvironment.
4. Hanahan and Weinberg identify that “activating invasion and metastasis” is a hallmark of cancer. Understanding these mechanisms of the metastatic process is critical to develop successful treatment interventions.
5. Dissemination of cancer cells leads the initial steps of the invasion-metastasis cascade. Chromosomal instability becomes the “trigger” causing constant and continuous errors in chromosome segregation during mitosis.

6. Investigators suggest that the nature of the primary seeding cancer cell determines the various and different metastatic properties aligned with growth and response to therapy.
7. Seeding may require the joint action of a cluster of tumor cells moving together.
8. EMT is the developmental (transdifferentiation) process whereby transformed epithelial cells lose their cell polarity and cell-cell adhesion, and gain the ability to invade, resist stress, and disseminate. The triggers for EMT in cancer cells include hypoxia, metabolic stressors, and matrix stiffness.
9. Research in pancreatic and lung cancers reveals that EMT might not be essential for metastasis, but it does contribute to chemoresistance.
10. Although the initiation of metastasis may involve EMT, mesenchymal-epithelial transition (MET) is necessary for metastatic progression.
11. Various metastatic cells possess different genetic and epigenetic or phenotypic changes, which differentially drive tumor progression, metastasis, and drug resistance.
12. Genetic expression is affected by oxygen homeostasis in the tumor microenvironment.
13. Hypoxia-inducible factors (HIFs) enable cancer cells to adapt to their environment by modulating angiogenesis, EMT, invasion, metastasis, and energy metabolism.
14. Metastatic characteristics are transferred through extracellular vesicle exchange. Extracellular vesicles called exosomes transfer invasion-promoting factors from the primary tumor, such as miRNAs, to tumorigenic cancer cells. Exosomes secrete EMT inducers that stimulate EMT progression in host epithelial cells, enabling them to invade and metastasize.
15. ECM altered by exosomes exhibits increased stromal cell proliferation, cancer cell migration and survival, and tumor cell resistance to apoptotic signals. These changes plus effects of growth factors and chemokines, lead to the formation of a new microenvironment for cancer cells, immune cells, and other stromal elements, known as the PMN.

16. Age-related physical changes in the ECM inhibit or promote tumor cell motility, invasion, and metastasis.
17. The circadian clock controls a wide spectrum of processes in cellular physiology through metabolic and gene expression pathways. It has been associated with cancer initiation and progression.
18. Diet has been shown to impact cancer metastasis. Some of these dietary effects may be related to changes in the microbiome. Other effects are more direct. For example, asparagine is an important promotor of metastasis, and researchers have found that removing asparagine from the diet of mice reduced breast cancer metastases.
19. In cancer, remodeling of the interstitial ECM causes a broad range of biophysical and biochemical changes affecting cell signaling, ECM stiffness, cell migration, and tumor progression.
20. Binding of cells to the basement membrane is critical for establishing cell polarity, and crucial for several developmental processes and maintenance of tissue homeostasis. Remodeling of the basement membrane is required for cancer cells to invade stromal tissue and become a malignant tumor.
21. Tumor-derived activation factors induce the differentiation of stromal cells towards CAFs, which function as myofibroblasts and remodel the ECM to support tumor growth. ECM is complex, and numerous specific cells and matrikines engage in invasion and metastasis.
22. The immune environment surrounding the tumor plays a significant role in dictating the metastatic potential of the disseminating cells.
23. Intravasation, or the movement of cancer cells through the lumen of the vasculature, is mediated both actively and passively depending on the tumor type, microenvironment, and vasculature.
24. Importantly, integrins regulate the colonization process by easing anchorage-independent survival of circulating tumor

cells (CTCs). Metastatic cells use E-cadherin in metastatic sites to detach, disseminate, and seed, thereby promoting metastatic cell survival and block apoptosis.

25. Interactions between CTCs and the microenvironmental components of circulation determine survival and the ability of CTCs to extravasate in distant places. The dissemination of CTCs is supported by very close association with activated platelets and macrophages. The leukocytes that showed the greatest interaction were neutrophils, their role in metastasis is not yet clear. The complex interaction between cancer cells and leukocytes promotes metastasis because metastatic cells possess sugar on their cell surface that binds to galectin-3. Galectin-3 increases the ability of cells to colonize by interacting with mobilized leukocytes.
26. In mouse models, blocking of IL-6 and IL-8 receptors decreased metastasis at lymph nodes, lungs, and liver.
27. CTCs use, exploit, and survive in the bloodstream during metastasis and cause distant metastases also through the lymphatic circulation. CTC characterization identifies the molecular aspects of metastatic tumors.
28. Cell-free DNA (cfDNA) identifies the heterogeneity of CTCs in those with high counts of CTCs. Liquid biopsy of CTCs and /or cfDNA in the bloodstream may have the potential to increase understanding of metastasis. A photoacoustic method for direct use in persons with melanoma enables the detection of very low numbers of CTCs in vivo and their destruction with laser pulses. Additionally, DNA methylation profiles more clearly identify tumor phenotypes among CTC clusters than from single cells.
29. Critical in the metastatic process is the ability of CTCs to adhere and extravasate through endothelial cells and colonize the premetastatic niche (PMN).
30. Extravasation is a complex process. It involves ligand-receptor interactions, chemokines, and circulating non-tumor cells. Integrins are once again very important. They help to determine the location for extravasation and colonization.

Cancer cells induce programmed necrosis of endothelial cells, driving metastatic cells to extravasate.

31. Most cancers metastasize to specific target organs, a process called metastatic organotropism. The host microenvironment and the ensuing adaptive process that invading cancer cells undergo play a role in extravasation and colonization at specific sites.
32. Formation of the PMN, where the tumor cells colonize and grow, depends on signaling from various tumor secreted derived factors and bone marrow-derived factors. Exosomes play a significant role. Formation of a vascular network is critical for optimal colonization.
33. Vascular mimicry where tumors create their own channels for fluid transport drives the ability of some breast cancer cells to contribute to distant metastases through the expression of *SERPINE2* and *SLPI*.
34. Colonizing cancer cells use signaling from neuronal pathways for growth and adjustment to new sites.
35. Cancer dormancy is a rest phase in cancer progression that occurs during the primary tumor formation phase or after invasion into secondary sites. Metastatic dormancy occurs because of the delayed adjustment of disseminating cells to their secondary niches or sites affecting single invading cells or cancer clusters after circulation. These dormant cancer cells (DCCs) are rarely detectable with current diagnostic approaches. Much evidence supports the notion that extracellular signal-regulated kinase (ERK) activation has a determinant role in whether cancer cells will proliferate or enter the phase of dormancy. Reawakening DCCs could be a critical factor for cancer development from chronic inflammation. Chronic inflammation can induce epigenetic alterations and DNA mutations in tumor suppressor genes, thus promoting carcinogenesis. Existence of DCCs has led to the emergence of therapy resistance because the cells may resume growth, increasing the risk of unleashing lethal

metastatic outbreaks even after a long latency period of months to years.

36. In the last decade a significant number of metastasis suppressors have been identified, most notably miRNAs. Metastatic cancers may be approached through a biomarker-driven strategy that validates single-agent or combination of agents depending fully on the molecular makeup of individual tumors.
37. A priority is the importance of lifestyle and diagnostic factors in reducing cancer mortality. Obesity is becoming a critical etiologic driver of cancer and initiation of metastasis. Worldwide, other preventable risk factors are a significant cause of cancer.

Clinical Manifestations of Cancer

1. Paraneoplastic syndromes are rare disorders with complex clinical manifestations that are triggered by a cancer but are not caused by direct local effects of the tumor mass. Malignant cells do not cause symptoms related to metastasis, but they generate autoantibodies, cytokines, hormones, or peptides that affect may organ systems.
2. Common side effects of cancer and cancer therapy include anemia, bone density loss, cachexia, cardiac and pulmonary damage, fatigue, gastrointestinal issues, hair loss and skin conditions, infection, infertility, leukopenia and thrombocytopenia, lymphedema, and pain.
3. Anemia associated with cancer usually occurs because of malnutrition, chronic bleeding and resultant iron deficiency, chemotherapy, radiation, and malignancies in the blood-forming organs.
4. Cachexia is a complex metabolic syndrome associated with basic illness and is characterized by the loss of muscle with or without loss of fat mass. Cancer cachexia is characterized by systemic inflammation, negative protein and energy balance,

and loss of lean body mass with or without wasting of adipose tissue. Multiple mechanisms are involved in the development and progression of cachexia including anorexia, decreased secretion of anabolic hormones, inflammation, decreased physical activity, and altered metabolic responses with abnormalities in protein, lipid, and carbohydrate metabolism. Profoundly altered are both appetite-stimulating and appetite-suppressing brain pathways.

5. Fatigue is the most frequently reported symptom of cancer and cancer treatment.
6. The gastrointestinal tract relies on rapidly growing cells to provide an absorptive surface for nutrients. Both chemotherapy and radiation therapy may cause decreased cell turnover, thereby leading to oral ulcers (stomatitis), malabsorption, and diarrhea.
7. Alopecia (hair loss) results from chemotherapy effects on hair follicles. Alopecia is usually temporary, although hair may initially regrow with a different texture. Not all chemotherapeutic agents cause alopecia. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection.
8. Infection is a significant cause of complications and death. Immune suppression, lymphopenia, and granulocytopenia may result from the underlying cancer or secondary to treatment increasing the risk of serious microbial infections.
9. Leukopenia and thrombocytopenia are usually a result of chemotherapy (which is toxic to bone marrow) or radiation (which kills circulating leukocytes). Thrombocytopenia is a major cause of hemorrhage in people with cancer.
10. Pain is generally associated with the late stages of cancer. It can be caused by pressure, obstruction, invasion of a structure sensitive to pain, stretching, tissue destruction, and inflammation.

Diagnosis and Staging of Cancer

1. Tumor tissue is obtained to establish a definitive diagnosis and correctly classify the disease. Once tissue is obtained, it is examined microscopically by the pathologist for the histologic hallmarks of cancer. Cancer classification is established by a variety of tests including immunohistochemical stains, flow cytometry, electron microscopy, chromosome analysis, and genetic studies.
2. Tumor staging involves the size of the tumor, the degree to which it has locally invaded, and the extent to which it has spread. One common scheme for staging is the T (tumor spread), N (node involvement), and M (metastasis) system.
3. Tumor markers are substances (i.e., hormones, enzymes, genes, antigens, antibodies) found in cancer cells and in blood, spinal fluid, or urine. They are used to screen and identify individuals at high risk for cancer, to help diagnose specific types of tumors, and to follow the clinical course of cancer. To date, no tumor marker has proven satisfactory to screen populations of healthy individuals for cancer.
4. Cancer is treated routinely with surgery, radiation therapy, chemotherapy, and combinations of these modalities. Immunotherapy has now established itself as a pillar of cancer care from the metastatic stage to the adjuvant and neoadjuvant settings in many cancer types. Cancer therapy is rapidly evolving, and genetic analysis may help determine appropriate therapies.
5. Surgical therapy is used for nonmetastatic disease (in which cure is possible by removing the tumor) and as a palliative measure to alleviate symptoms.
6. Ionizing radiation causes cell damage; therefore, the goal of radiation therapy is to damage the tumor without causing excessive toxicity or damage to no diseased structures.
7. The theoretic basis of chemotherapy is the vulnerability of tumor cells in various stages of the cell cycle. Modern

chemotherapy uses combinations of drugs with different targets and different toxicities.

8. Increasing evidence of most approved cancer drugs, including tyrosine kinase inhibitors (TKIs), systemic cytotoxic therapies (chemotherapy) and antibody-drug conjugates (ADCs), reveals they do not have a durable impact with metastatic disease often because of therapeutic resistance.
9. Induction chemotherapy seeks to cause shrinkage or disappearance of tumors. Adjuvant chemotherapy is given after surgical excision of a cancer with the goal of eliminating micrometastases. Neoadjuvant chemotherapy is given before localized (surgical or radiation) treatment of a cancer to shrink a cancer so that surgery may spare more normal tissue.
10. The recent discovery of T cell immune checkpoints, such as cytotoxic T lymphocyte antigen 4 (CTLA-4) and programmed cell death 1 (PD-1), moved the field of immuno-oncology into its current era. The challenge is harnessing immune signals that maintain a fine balance between immune surveillance against foreign pathogens or abnormal cells and autoimmunity. Immunotherapy attempts to modify the immune system from a cancer-protective state to a destructive condition. Dedicated scientists and clinicians are mobilized to achieve a higher response rate without increasing autoimmunity.
