
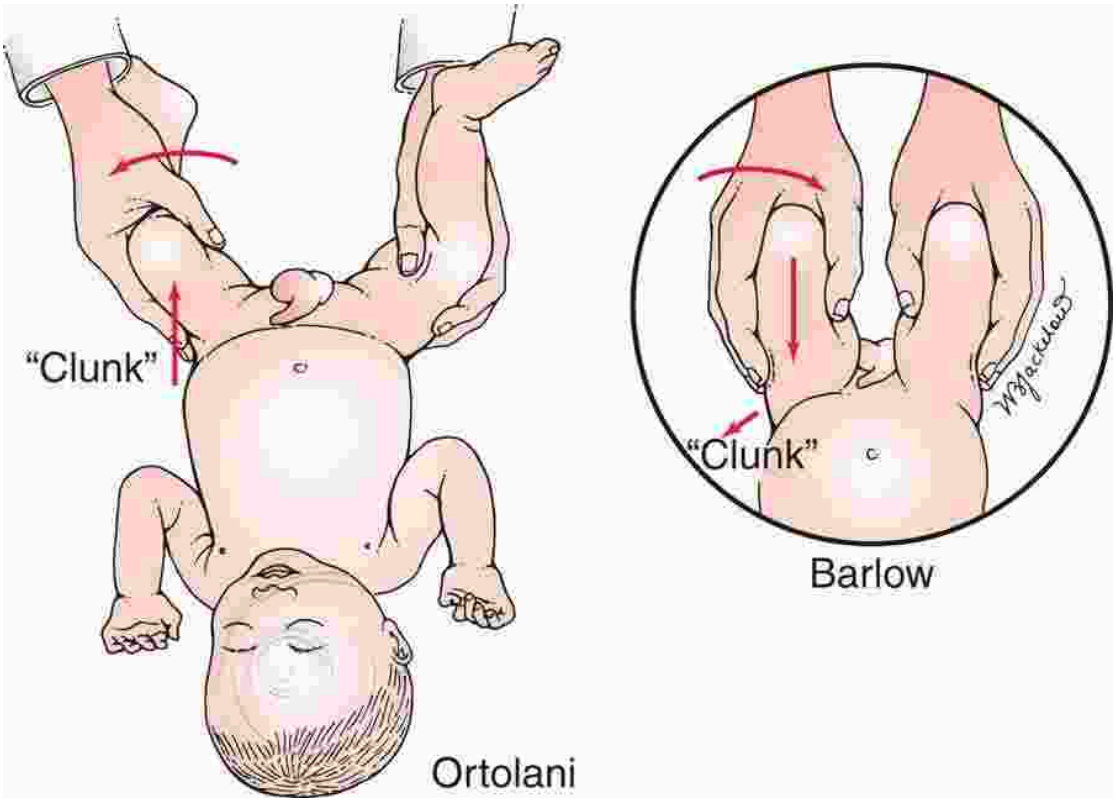

FIG. 45.5 Evaluation for Congenital Dislocation of the Hip.
(A) Barlow maneuver *(left side)*. With one hand pressing the symphysis in front and the sacral spine in back, lateral pressure is applied to the thigh with the thumb of the other hand while pressure is applied with the palm to the knee on the side being examined. The hip that has been flexed to 90 degrees is then adducted. A positive sign is a sensation of abnormal movement, indicating dislocation of the femoral head from the acetabulum. The hands are reversed for examining the other hip. This sign and the Ortolani sign may be found only in the first weeks of life. (B) Ortolani maneuver *(right side)*. Sign of jerking into correct position. After Barlow maneuver (A), the hip should be abducted to about 80 degrees while the femur is lifted anteriorly with the fingers along the thigh. A positive sign is a sensation of a jerk or snap with reduction into the joint socket. (From Dains J, Baumann L, Scheibel P. *Advanced health assessment and clinical diagnosis in primary care*, 6th ed. St. Louis: Elsevier, 2019.)

Left panel: An illustration depicts the Ortolani maneuver which shows an infant lying supine on its back and the examiners hand grasping the infants left thigh to the left and adducted with gentle downward pressure marked clunk. Right panel: An illustration depicts the Barlow maneuver which shows an infant lying supine on the back and the examiners hand grasping the infants knees while moving the left leg in medial and lateral (clunk) direction and pushing the thigh towards the abdomen.

The child also should be examined for other anomalies, such as torticollis or metatarsus adductus, which can be associated with DDH.

Evaluation and Treatment

Clinical examination is the mainstay of diagnosis and is especially important in the newborn period. The examination must be performed on a relaxed infant for accuracy. Real-time ultrasound during a hip examination is extremely valuable in the newborn period, especially in high-risk infants. The use of ultrasound allows visualization of the cartilaginous structures of the hip (the femoral head and the outer lip of the acetabulum), which are not seen on a plain roentgenogram. Radiographs are used after age 6 months when the ossific nucleus of the femoral head appears.[8]

Absolute indications for treatment include a positive Barlow sign (hip reduced but can be dislocated) (see Fig. 45.5A) or a positive Ortolani sign (hip dislocated, but reducible) (see Fig. 45.5B). Other indicators for further evaluation are limitation of abduction or apparent shortening of the femur (Galeazzi sign). Asymmetric skin folds at the groin also can be a clinical sign of hip pathology. If DDH is left untreated in the growing child, secondary changes occur. If the hip remains subluxated or dislocated, the acetabulum becomes increasingly shallow and the soft tissues shorten around the proximal femur. Subluxation leads to early osteoarthritis (OA). If the hip is dislocated, the bone acetabulum fills with soft tissue and a false acetabulum forms where the femoral head contacts the iliac crest. Adult reconstruction of a dislocated hip, even with an artificial hip, is very difficult.[5]

Treatment depends on the age of the child, severity of dysplasia, and duration of dysplasia. The earlier that treatment is begun, the better the result. In children younger than 4 months old, bracing with a Pavlik harness is successful in 90% of DDH cases (Fig. 45.6). A Barlow-positive hip is easier to treat with a Pavlik harness, and success rates approach 97%.[9] An Ortolani-positive hip must be followed closely with ultrasound and examination; the success rate with Pavlik harness is 70% in this situation.[9] If a stable reduction is not attained within 2 to 3 weeks of treatment, the Pavlik harness should be abandoned and casting or surgery pursued instead. A partially reduced hip applies pressure on the rim of the acetabulum by the femoral head and can worsen dysplasia and make treatment more difficult. In older children (6 to 12 months) or those who failed bracing with a Pavlik harness, closed reduction of the hip and spica casting (casting of the trunk of the body and one or both legs) are performed using a general anesthetic. The spica cast is worn for 3 months. Children older than 12 months require surgery on the joint, the femur, or the acetabulum, or all three.

FIG. 45.6 Pavlik Harness for Bilateral Hip Dislocation. (From Wheaton Brace Co., Carol Stream, IL.)

Deformities of the Foot

Congenital foot deformity is a broad category of deformities, with metatarsus adductus accounting for 75% of these anomalies. The terms used to describe foot abnormalities are summarized in Table 45.1. **Metatarsus adductus** is a forefoot adduction deformity associated with a normal, plantigrade hindfoot. It is believed to be secondary to intrauterine positioning. It is associated with DDH in 20% of cases; consequently, the hips of these infants must be carefully evaluated. Metatarsus adductus is usually classified by two criteria: flexibility (passively correctable vs. rigid) and degree of deformity. The degree of deformity (mild, moderate, severe) is ascertained by the heel bisection line. A mild deformity is one in which the heel bisection line passes medial to the third tow; moderate, through the third or fourth toes; and severe, lateral to the fourth toe.

Table 45.2

Osteogenesis Imperfecta Types Caused by Defects in Genes and the Collagen-Related Proteins that They Encode

	OI Type	Defective Gene	Defective Protein	Defective Mechanism	
Autosomal dominant	I	*COL1A1*	α1(I) collagen	Collagen quantity Collagen structure	85%–90% of OI case types I–IV
	II	*COL1A1* or *COL1A2*	α1(I)/α2(I) collagen		
	III	*COL1A1* or *COL1A2*	α1(I)/α2(I) collagen		
	IV	*COL1A1* or *COL1A2*	α1(I)/α2(I) collagen		
	V	*IFITM5*	BRIL	Matrix mineralization	10%–15% of OI cases
Autosomal recessive	VI	*SERPINF1*	PEDF	Collagen 3-hydroxylation	10%–15% of OI case types VI to unclassified
	VII	*CRTAP*	CRTAP		
	VIII	*LEPRE1*	P3H1		
	IX	*PPIB*	CyPB		
	X	*SERPINH1*	HSP47	Collagen chaperoning	
	XI	*FKBP10*	FKBP65	Telopeptide hydroxylation	
	XII	*BMP1*	BMP1/mTLD	Collagen processing	
	Unclassified	*SP7/OSX*	SP7/OSTERIX	Osteoblast development	
		WNT1	WNT1		
		TMEM38B	TRIC-B		
		CREB3L1	OASIS		

OI, Osteogenesis imperfecta.

Table 45.1

Terms Used to Describe Foot Abnormalities

Term	Definition
Positiona	
Abduction	Lateral deviation away from the midline of the body
Adduction	Lateral deviation toward the midline of the body
Eversion	Twisting of the foot outward along its long axis
Inversion	Twisting of the foot inward on its long axis
Dorsiflexion	Bending of the foot upward and backward
Plantar flexion	Bending of the foot downward and forward
Abnormalitya	
Talipes equinovarus	Congenital abnormality of the foot (clubfoot)
Pes	Acquired deformity of the foot
Varus	Inversion and adduction of the heel and forefoot
Valgus	Eversion and abduction of the heel and forefoot
Equinus	Plantar flexion of the foot in which the heel is lower than the toes
Calcaneus	Dorsiflexion of the foot in which the heel is lower than the toes
Planus	Flattening of the medial longitudinal arch of the foot (flatfoot)
Cavus	Elevation of the medial longitudinal arch of the foot (high arch)
Equinovarus	Coexistent equinus and varus deformities
Calcaneovarus	Coexistent calcaneus and varus deformities
Equinovalgus	Coexistent equinus and valgus deformities
Calcaneovalgus	Coexistent calcaneus and valgus deformities

[a]The positions listed can all be achieved by voluntary movement of the normal foot; an abnormality exists if the foot is fixed in one or more of the positions while at rest.

Clubfoot, technically **talipes equinovarus**, describes a range of congenital foot deformities in which the foot turns inward and downward. It can affect one or both feet, where the heel is positioned varus (inwardly deviated) and equinus (plantar flexed) (Fig. 45.7). The clubfoot deformity can be positional (correctable passively), idiopathic, or teratologic (as a result of another syndrome, such as spina bifida).

FIG. 45.7 Bilateral Clubfoot.
(A) Infant with bilateral congenital talipes equinovarus. (B) Ponseti casting. (A, Courtesy Dr. A.E. Chudley, Section of Genetics and Metabolism, Department of Pediatrics and Child Health, Children's Hospital and University of Manitoba, Winnipeg, Manitoba, Canada. In Moore KL, et

al., eds. *The developing human*, 10th edition. Philadelphia: Saunders; 2016. B, From Scher DM. The Ponseti method or clubfoot correction. *Operative Techniques in Orthopaedics*, 2005;15(4):345–349.)

A. Close shot of an infants both feet rotated inwards B. Close shot of an infant's bilateral lower extremities applied with knee casts made of semirigid synthetic soft cast according to the Ponseti method.

Positional equinovarus is a deformity in which an infant's foot is in equinovarus position but does have flexibility without deep creases at the posterior ankle or midfoot. The Achilles tendon is still flexible. The foot can be passively brought to a plantigrade position and is amenable to stretching and casting. In general, conservative therapy corrects this foot without the need for surgical intervention or lengthy bracing.

Idiopathic congenital equinovarus (Fig. 45.8) is the most common pediatric deformity and occurs once in every 1000 live births. Etiology is unknown. Smoking is the major environmental factor, especially in combination with multiple gene alterations.[10] In one human fetal study, all clubfeet were associated with identifiable anterior horn cell changes in L5 and S1. Muscle biopsies of both the anterior tibialis long flexors and the peroneus brevis muscles in clubfoot reveal that at least 50% of cases show a decreased number of muscle fibers and/or abnormal fiber histology. The soleus often has an increase in type 1 fibers, whereas the peroneus brevis has a fiber type disproportion. The more abnormal the histopathology, the more severe the deformity, and the greater the change of recurrent deformity after treatment. The genetic component is unclear and studies are ongoing.

FIG. 45.8 Idiopathic Clubfoot.
Idiopathic clubfoot displaying forefoot adduction (toward midline of body) and supination (upturning) and hindfoot equinus (pointed downward). Note skin creases along arch and back of heal.

Teratologic equinovarus is caused by either neuromuscular, syndromic, or osteochondrodysplasia etiology. Examples of such include spina bifida and diastrophic dwarfism. The teratologic clubfoot, unlike the idiopathic type, more often fails to be corrected with Ponseti casting and may require operative intervention (see Fig. 45.7B). The surgery is often more extensive, and revision surgery is also more common (Box 45.1).

Box 45.1

Ponseti Casting and Achilles Tenotomy

Ponseti casting implements toe-to-groin casts changed weekly for 6 weeks. Casting begins as early as possible after birth and culminates in a percutaneous tendo Achilles lengthening in the clinic, followed by a final cast worn for 3 weeks. In recalcitrant cases, a full surgical posteromedial release (PMR) still may be required. The need for PMR in idiopathic clubfoot has significantly decreased when this casting technique is used. Long-term results, presumably because of less scarring and more long-term flexibility, are better with Ponseti casting than with the PMR method. The hindfoot equinus portion of the deformity often requires lengthening of the Achilles tendon, which can be performed in a clinic with the use of a local anesthetic. Achilles tenotomy (complete transection of the tendon) can be safely performed with local anesthetic until 8 or 9 months after birth. After this age, a formal lengthening and repair procedure using a general anesthetic is required. Bracing is required until age 3.

Pes planus (flatfoot) deformity is a typical parental concern. However, a flexible flatfoot is often as functional as one with a "normal" arch. The majority of babies are born with flat feet. The arch becomes more apparent with age. Significant ankle valgus, vertical talus, tarsal coalition, and skewfoot must be accurately differentiated from flexible pes planus.

Flexible pes planus appears to have a genetic predilection, with occasional association of generalized ligamentous laxity. The flexibility of the hindfoot is evaluated by having the child stand on his or her toes facing away from the examiner. In flexible pes planus, the hindfoot swings into a varus position as the planter fascia tightens in toe raise. In rigid pes planus, the hindfoot stays in valgus, and the child has more difficulty going up onto tiptoe.

There is a small subset of children with painful, flexible flat feet. For these children, careful attention to the possibility of Achilles contracture or tarsal coalition (congenital union of the hindfoot bones) must be made. In rigid flat feet, a computed tomography (CT) scan often will reveal a coalition, a bony or cartilaginous connection between the bones—if painful, this can be resected in surgery (see Box 45.1).

Abnormal Density or Modeling of the Skeleton

Osteogenesis Imperfecta

Pathophysiology

Osteogenesis imperfecta (OI), or **brittle bone disease**, is an inherited bone dysplasia related to collagen, the main component of bone and blood vessels. The major errors in OI lie in the synthesis of collagen, a triple helix with two matching α chains and one β chain. Collagen is present in bone, cartilage, eye tissue, skin, and the vascular system. The severity of the OI phenotype and the related anomalies of the eye, dentition, or vascular system are all dependent on the severity of the genetic anomaly and the part of the triple helix that is affected.[11] Classification systems are based on the mode of inheritance, identifying the defective gene, protein, or mechanism (Table 45.2).[12]

Clinical Manifestations

The classic clinical manifestations of OI are osteopenia (decreased bone mass) and an increased rate of fractures. Other possible manifestations include bony deformation (bowing), triangular facies, vascular weakness (aortic aneurysm), blue sclerae, fatigue, pain, hearing loss, and poor dentition. In the most severe form of this disorder, the child is usually stillborn or dies soon after birth, although some survive into childhood. OI in its more severe forms is evident at birth because fractures and deformity have occurred in utero. The less severe forms may not become evident until the child begins to walk. Some children with this milder form then experience numerous fractures that can be mistaken for nonaccidental trauma (NAT; e.g., child abuse) until the diagnosis is made.

Evaluation and Treatment

Evaluation of OI is primarily based on the clinical manifestations. Serum alkaline phosphatase level is elevated in all forms of the disease. OI can be diagnosed prenatally by ultrasound or chorionic villi sampling. Analysis of cultured skin fibroblast collagen by electrophoresis shows a decreased quantity of collagen in 95% of individuals.

The goal of treatment of OI is to reduce the number of fractures and to prevent long bone deformities. Medications and surgical interventions are available. Biophosphonate therapy is the mainstay of pharmacologic fracture prevention, with marked improvements of bone density. Chronic bone pain and fatigue also are thought to be lessened with routine bisphosphonate therapy. Telescoping rods, which grow with the child, are improving in efficacy and have been shown to reduce the reoperative rate by 30%.[13] Genetic counseling for affected families should aim at primary prevention.

Rickets

Rickets is a disorder in which growing bone fails to become mineralized (ossified) prior to closure of the growth plates, resulting in "soft" bones and skeletal deformity (Fig. 45.9). Rickets results from either insufficient vitamin D, insensitivity to vitamin D, wasting of vitamin D by the kidney, or inability to absorb vitamin D and calcium in the gut. Calcipenic rickets is usually caused by insufficient dietary intake of vitamin D and/or calcium. It is the most common cause of rickets worldwide. Phosphopenic rickets is nearly always caused by wasting of vitamin D by the kidney.

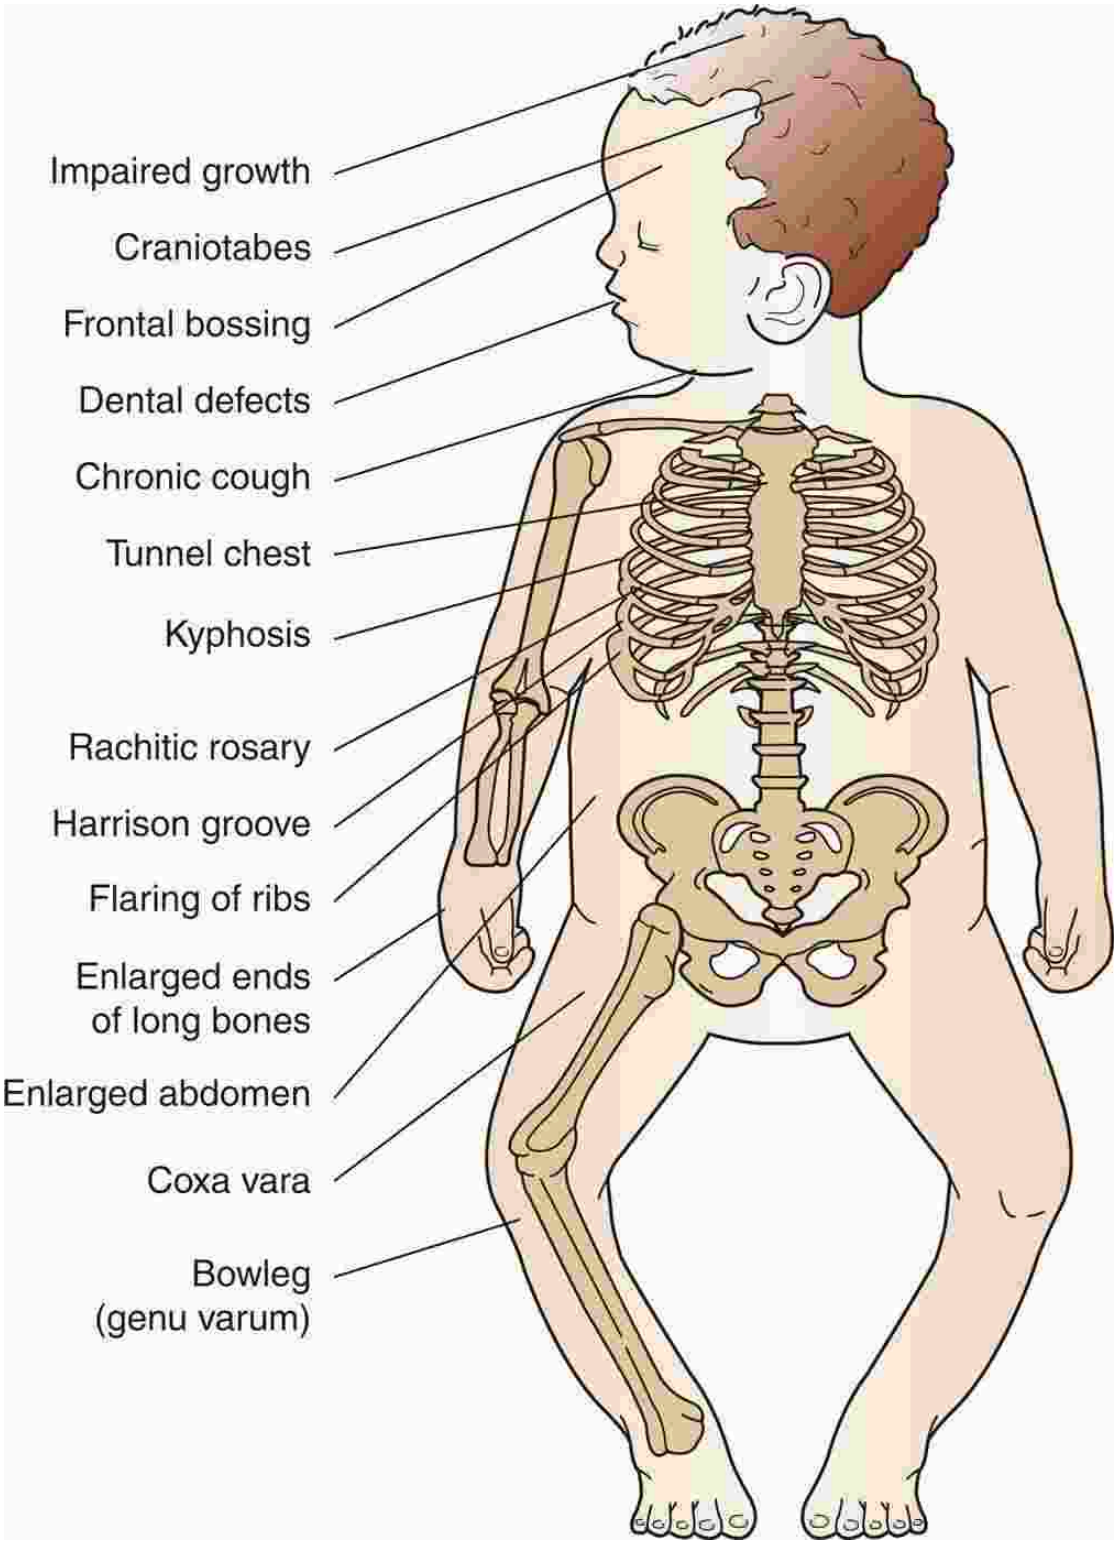

FIG. 45.9 Rickets.

An illustration of the anatomy of a child with symptoms of rickets is labeled. The labels from top to bottom are as follows. Impaired growth, craniotabes,

frontal bossing, dental defects, chronic cough, tunnel chest, kyphosis, rachitic rosary, Harrison groove, flaring of ribs, enlarged ends of long bones, enlarged abdomen, coxa Vara, and bowleg or genu varum.

Severe metabolic rickets in the immature skeleton leads to short stature and bowing of the limbs with broad, irregular growth plates. The rows of cells in the growth plate that are intended to ossify fail to do so as they reach the metaphysis, because calcification is impeded. Children with rickets are often listless and irritable. They have hypotonia and muscle weakness and may be unable to walk without support. In both forms, skeletal findings are similar, which include abnormal parietal flattening and frontal bossing of the skull, (the calvaria become soft, and the sutures may widen), costochondral junction enlargement, widening of the wrist, and lateral bowing of the femur and the tibia.Growth is restricted, and fractures are common. Serum alkaline phosphatase is elevated in both types of rickets. Like osteogenesis imperfecta, surgical treatment of bony deformity can be required. However, medical management of calcium, phosphorous, and vitamin D levels must be optimized before surgical intervention. In addition to medical management, children may benefit from guided growth techniques to correct persistent deformity.

Scoliosis

Scoliosis is a rotational curvature of the spine most obvious in the anteroposterior plane (Fig. 45.10). It can be classified as nonstructural or structural. **Nonstructural scoliosis** results from a cause other than the spine itself, such as posture, leg length discrepancy, or pain. **Structural scoliosis** is curvature of the spine associated with vertebral rotation. Nonstructural scoliosis can become structural if the underlying cause is not found and treated. Scoliosis can also be idiopathic. **Idiopathic scoliosis** is classified as infantile, juvenile, or adolescent, depending on the child's age at the time of onset. In infantile scoliosis, spinal curvature develops during the first 3 years of life; in juvenile scoliosis, curvature develops between the skeletal age of 4 years and the onset of adolescence; and in adolescent scoliosis, it develops after the skeletal age of 10.

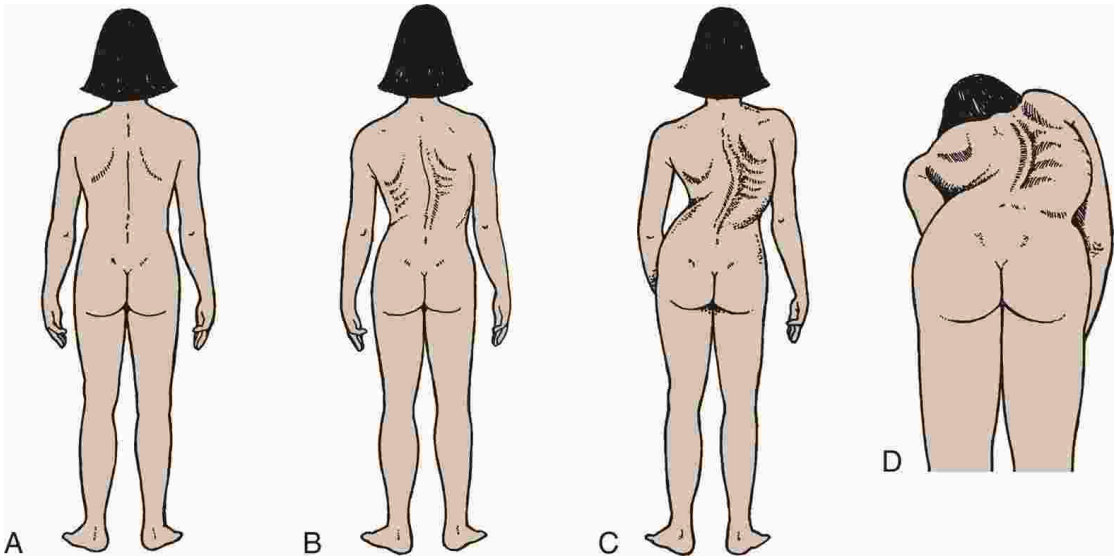

FIG. 45.10 Scoliosis in Children.
Normal spinal alignment and abnormal spinal curvatures associated with scoliosis. (A) Normal. (B) Mild. (C) Severe. (D) Rotation and curvature of scoliosis.

Four illustrations of the posterior view of a female depict the stages of scoliosis. Illustration A depicts the normal spinal alignment. Illustration B depicts the mild spinal curvature which shows the convex side of the curve bends to the left. Illustration C depicts the severe spinal curvature which shows the rounded side of the curve bends to the left. Illustration D depicts the rotation and curvature of scoliosis which shows the vertebrae and spinous processes in the area of the major curve rotate toward the concavity of the curve.

Adolescent idiopathic scoliosis is the most common form of scoliosis and affects 1% to 3% of US adolescents between 10 and 18 years of age.[14] The etiology is not completely understood; however, it is defined by a lateral curvature of the spine (Cobb angle) of at least 10 degrees (mild) in the absence of underlying congenital or neuromuscular abnormalities.[14,15] Genetic factors are thought to be a contributing factor in idiopathic scoliosis, but inheritance patterns are variable.[14]

Pathophysiology. The earliest pathologic changes occur in the soft tissue. The muscles, ligaments, and other soft tissues become shortened on the concave side of the curve. Vertebral deformity occurs as asymmetric forces are applied to the epiphyseal center of the ossification by shortened and tight soft tissues on the concave side of the curve. True curves involve not only bending but also twisting of the torso, leading to the "rib hump" seen when the child bends forward. The curves increase most rapidly during periods of rapid skeletal growth. If the curve is less than 40 degrees at skeletal maturity, the risk of progression is quite small. In curves greater than 50 degrees, the spine is biomechanically unstable, and the curve usually progresses even after the cessation of growth. Curves in the thoracic spine greater than 80 degrees result in decreased pulmonary function, whereas the most common complication of large curves in the lumbar spine is back pain. Many new treatment options are available for individuals with idiopathic scoliosis (see Emerging Science Box: Idiopathic Scoliosis).Clinical Manifestations.The clinical manifestations of nonstructural scoliosis are mild spinal curvature with prominence of one hip or rounded shoulders. The curvature disappears with forward flexion of the spine, lying down, or traction of the head. The clinical manifestations of structural scoliosis include asymmetry of hip height, asymmetry of shoulder height, shoulder and scapular (shoulder blade) prominence, and rib prominence. Evaluation and Treatment.Spinal curvature is usually visible or palpable, and muscles on

one side of the lower back (the convex side) may be prominent or bulging. Most cases of idiopathic scoliosis are noticed during school screening programs. In girls the deformity may be noticed because clothing does not "hang" properly on the body. Diagnosis is made by roentgenographic examinations. Treatment for nonstructural scoliosis is correction of the underlying disorder. Brace treatment is indicated for children with curves of 25 to 40 degrees who have at least 2 years of growth remaining. A rigid, low-profile thoracolumbar brace is used in most cases. Low-profile braces are worn for 18 to 23 hours per day until skeletal maturity. Bracing will only prevent progression of the curve; it will not correct the curvature.Bracing is not effective in large curves or in skeletally mature individuals; the most effective time for bracing is in growing prepubescents with a small curve. Surgical treatment using spinal fusion with instrumentation is recommended for curves greater than 40 to 50 degrees. If surgery is indicated, it is better performed during the adolescent years while there is greater flexibility of the curves and less risk of complications.

Bone and Joint Infection

Osteomyelitis

Osteomyelitis is an infection of the bone. Acute osteomyelitis can affect infants and children of any age, but it occurs most often in children younger than age 5 years.[16,17] The bacterial etiology varies by age, but the most prevalent pathogen in pediatrics is *Staphylococcus aureus* (Box 45.2).[16,17,19]

Box 45.2

Causative Microorganisms of Osteomyelitis According to Age

Newborns (0–2 months)
- *Staphylococcus aureus* (both methicillin-sensitive [MSSA] and methicillin-resistant [MRSA])*Escherichia coli*
- Group B *Streptococcus*
- Gram-negative enteric bacilli

Infants/Toddlers (2 months to 4 year)
- *S. aureus* (MSSA and MRSA)

Group A β-hemolytic *Streptococcus*
- *Kingella kingae* (most common pathogen in Europe and Middle East)[18]
- *Haemophilus influenzae* (decreasingly less common secondary to immunization)

Child (5–10 years)
- *S. aureus* (MSSA and MRSA)

Staphylococcus epidermidis
- *Salmonella*

Pseudomonas aeruginosa

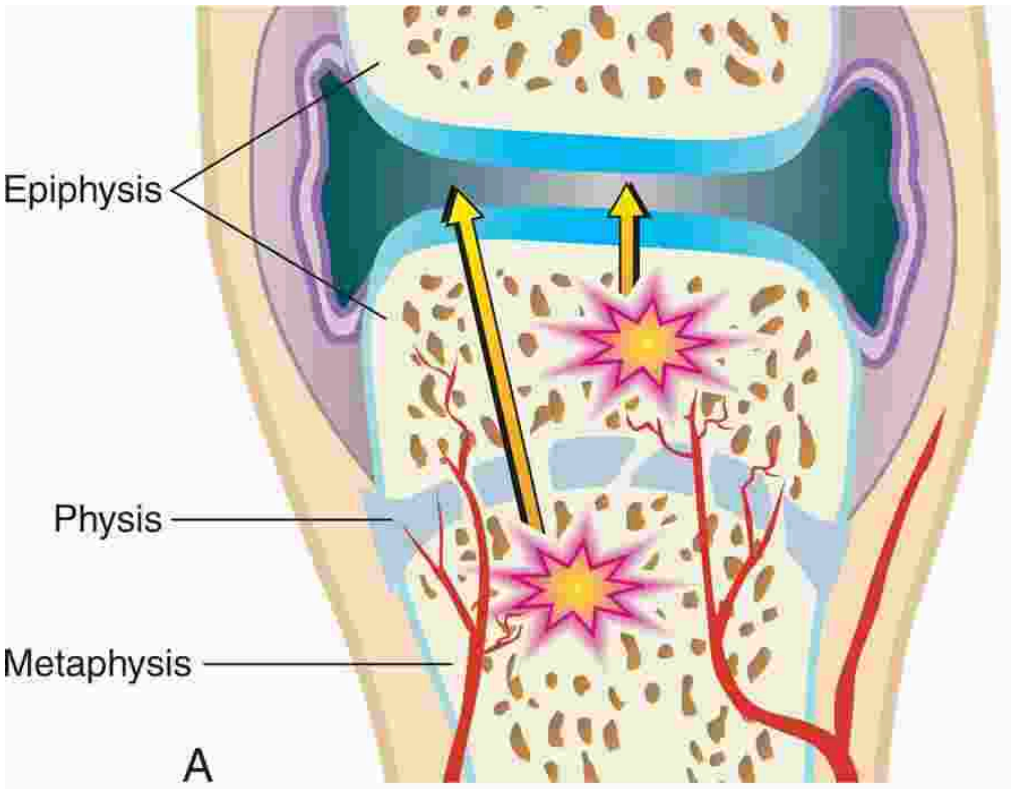
Adolescents (10–19 years)
- *S. aureus* (MSSA and MRSA)
- *Pseudomonas*
- *Mycobacterium tuberculosis*
- *Neisseria gonorrhoeae*

Pathophysiology.Bacterial dissemination can be hematogenous (infection entering the bone through the bloodstream), contiguous (infection originating from soft tissues that spreads to the bone), or via direct inoculation (open fractures, puncture wounds, prostheses).[20] Bacteria may lodge at the end of the venous loops beneath the epiphyseal plate, and infection develops because there are no phagocytic cells present to remove the bacteria.[20]

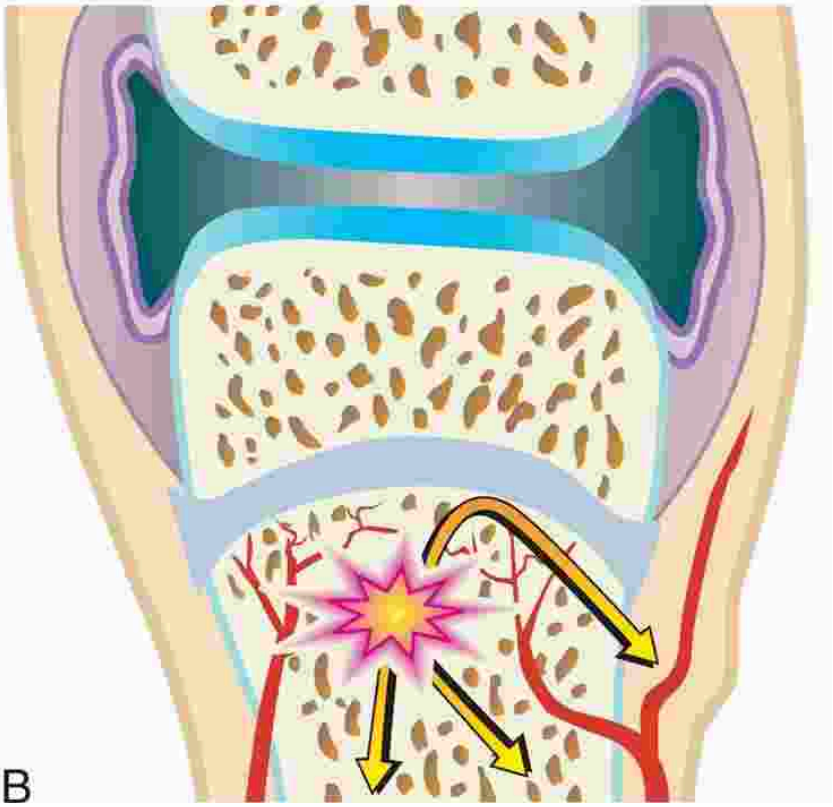
Osteomyelitis most frequently affects the metaphyseal region of long bones (27% in the femur, 22% the tibia, 5% fibula, 12% humerus, 4% radius, and 3% the ulna) because the rich metaphyseal blood supply, with vascular loops and turbulent flow, facilitates bacterial colonization.[20]

Factors that predispose an individual to the development of osteomyelitis include sickle cell disease, prematurity, respiratory distress syndrome, trauma, sepsis, bacteremia, chronic catheterization or indwelling vascular lines, and immunodeficiency.[19,20]

Acute hematogenous osteomyelitis is the most common type of bone infection in children. The infection is initiated by bacteria that has exponential growth leading to bone resorption. A purulent exudate forms, creating a subperiosteal abscess in the metaphysis of a long bone where blood flow is sluggish and bacteria can collect.[20] With increasing pressure, the infection will rupture out of the periosteum and spread along the diaphysis of the bone. In infants younger than 1 year old, infection may go through the physis (growth plate) and into the epiphysis (Fig. 45.11). Because the periosteum is separated from an adequate blood supply, sections of the bone die; these pieces of dead bone are called **sequestra**. A new shell of bone can develop under the elevated periosteum and can become an **involucrum**. All three of these changes are apparent on radiograph. In children older than 2 years, the epiphyseal plate prevents the spread of a metaphyseal abscess into the epiphysis and the cortex of the metaphysis is thicker. These anatomic differences increase the likelihood that the metaphyseal abscess will extend into the diaphysis, and the blood supply of the bone will be disrupted. The periosteum is also more difficult to perforate in older children; this may lead to a larger subperiosteal abscess that could endanger the periosteal blood supply as well. This process results in extensive sequestrum formation and chronic osteomyelitis.[20]



Epiphysis
Physis
Metaphysis
A



B

FIG. 45.11 Pathogenesis of Acute Osteomyelitis Differs with Age.
(A) In infants younger than 1 year the epiphysis is nourished by arteries penetrating through the physis, allowing development of the condition within the epiphysis. (B) In children up to 15 years of age, the infection is restricted to below the physis because of interruption of the vessels.

Clinical Manifestations

Initially, osteomyelitis presents as pain, worse with ambulation, local tenderness, swelling, erythema, and warmth.[21] Children often will have fever, decreased appetite, fatigue, elevated white blood cell (WBC) count (36%), but, if both the C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are elevated, the sensitivity for infection is 98%.[21] Blood culture is positive in 40% or less of cases, whereas bone, joint, or soft tissue cultures have a higher yield, in the range of 70%.[21]

Evaluation and Treatment

Conventional radiographs are the first step in imaging evaluation; however, radiographic bone changes are not usually apparent until 10 days after the onset of symptoms. MRI has become the recommended modality for evaluation of a child with suspected osteomyelitis.[21] Bone scans can be quite helpful with diagnosis, and in children younger than 1 year are absolutely required to define whether multiple sites are involved.

Death is rare, but serious sequelae may occur. The course of the disease and prognosis depend on the age of the child, the rapidity with which the diagnosis is established, the initiation of early treatment, and maintenance of treatment for an adequate time (typically at least 4 weeks). The most serious complications are growth arrest, osseous necrosis, and recurrence. Recurrence with presently available antibiotic regimens is approximately 1 to 2%.[22]

Septic Arthritis

Septic arthritis (SA) is a bacterial or granulomatous infection of the joint space. This is always a surgical emergency. The bacteria and the lysosomes created by WBCs fighting the bacteria can quickly destroy the articular cartilage of the joint and affect the blood supply to the epiphyseal bone nearby. Both of these complications have poor outcomes and can lead to a lifetime of disability.

SA can occur primarily or secondary to osteomyelitis that spreads from the metaphysis of the bone into the joint space (Fig. 45.12). The metaphyses of the pediatric hip, shoulder, proximal radius, and distal lateral tibia are all located within the joint capsule, and therefore osteomyelitis in these regions must be carefully monitored for secondary SA. The most common sites for SA are knees, hips, ankles, and elbows.

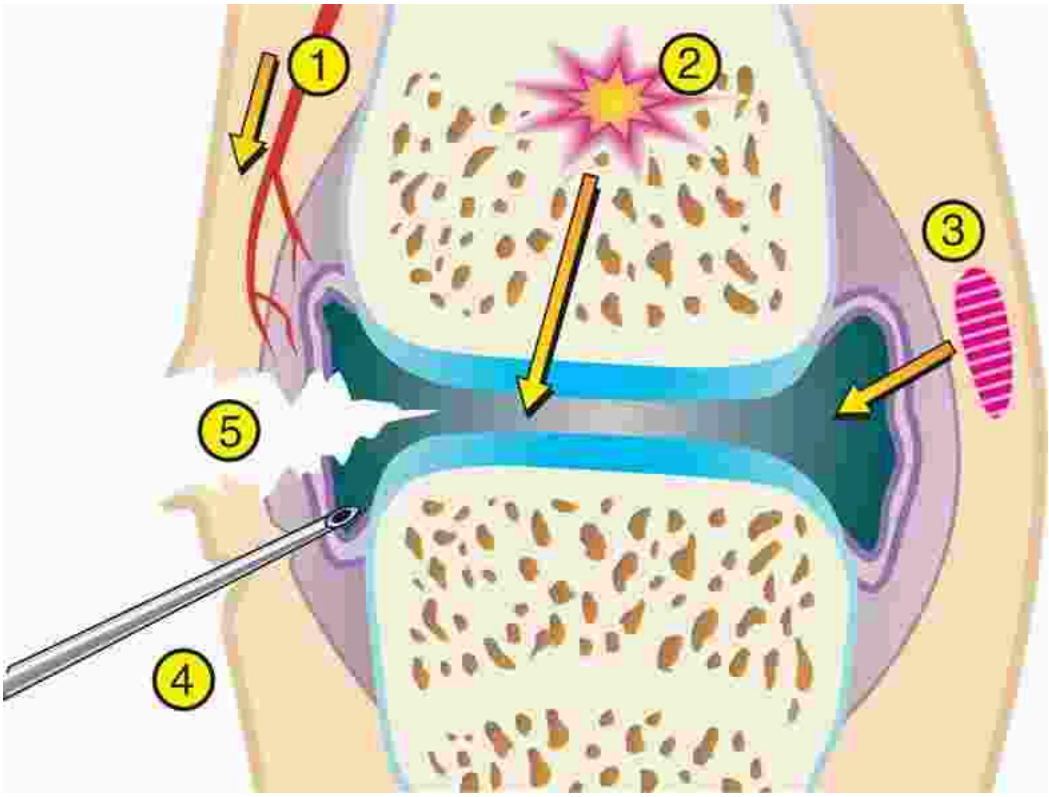


FIG. 45.12 Routes of Infection to the Joint.
(1) Hematogenous route. *(2)* Dissemination from osteomyelitis. *(3)* Spread from an adjacent soft tissue infection. *(4)* Diagnostic or therapeutic measures. *(5)* Penetrating damage by puncture or cutting.

Children with SA present with severe joint pain, "pseudoparalysis," or marked guarding to motion of the joint; inability to bear weight; and malaise, often with anorexia. Children appear quite ill with this diagnosis. Nonpyogenic arthritis, such as juvenile idiopathic arthritis (JIA), can be difficult to distinguish clinically from SA because both can lead to malaise and elevated ESR. The Kocher criteria are often used to distinguish septic joints from joint pain of another cause. If three of the four criteria are met, there is a reported 93% probability of SA. If four of the four criteria are met, then there is a reported 99% probability of SA. However, joint aspiration is still required. The criteria include[23]:

1. WBC >12,000 cells/μL
2. Inability to bear weight on the joint
3. Fever >101.3°F (38.5°C)
4. ESR >40 mm/h

A 2017 retrospective chart review found that the Kocher criteria plus ultrasound were not sufficient to make a diagnosis of SA of the hip joint, and consideration should be given to add MRI to the work-up.[24] Synovial fluid aspiration and evaluation are definitive criteria for diagnosis, which should include WBC count, Gram stain, culture, and susceptibility testing.

Rheumatologic Disorders

Juvenile Arthritis

Juvenile arthritides are a group of inflammatory disorders that affect children. **Juvenile idiopathic arthritis (JIA)** is the most common type of arthritis in children younger than the age of 16 and is the

childhood form of rheumatoid arthritis (also see Chapter 44).

The International League of Associations for Rheumatology (ILAR) developed criteria for classification of juvenile arthritis[25]:

- Systemic arthritis
- Polyarthritis (rheumatoid factor [RF] positive; RF negative)
- Oligoarthritis (persistent or extended)
- Enthesitis-related arthritis
- Psoriatic arthritis
- Undifferentiated arthritis

However, JIA remains a diagnosis of exclusion (see Emerging Science Box: Serum Interleukin-18 and Systemic Juvenile Idiopathic Arthritis).

The disease must manifest before 16 years of age, the symptoms must persist for at least 6 weeks, and there can be no other explainable etiology for the symptoms.[25]

JIA has three distinct modes of onset: **oligoarthritis** (fewer than five joints), **polyarthritis** (more than five joints), and **Still disease** (severe systemic onset). JIA differs from adult rheumatoid arthritis in several ways:

Large joints are most commonly affected.
Chronic uveitis (inflammation of the anterior chamber of the eye) is common, especially if serum antinuclear antibodies (ANA) is positive. Slit lamp examination by a trained ophthalmologist is required every 6 months to avoid vision loss.
Serum tests may be negative for RF; RF-positive children have a worse prognosis.
Subluxation and ankylosis may occur in the cervical spine if disease progresses.
Rheumatoid arthritis that continues through adolescence can have severe effects on growth and adult morbidity.

Systemic juvenile idiopathic arthritis (sJIA) involves one or more joints and fever with at least one of the following additional symptoms: erythematous rash, hepatomegaly, splenomegaly, lymph node enlargement, or serositis. Systemic onset, or "seropositivity," of the disease is more likely consistent with lifelong arthritis. Therefore treatment is supportive, not curative. Nonsteroidal antiinflammatory drugs (NSAIDs) are a mainstay of treatment, and methotrexate is also being used with success. The goals are to minimize inflammation and deformity. Polyarthritis refers to the subgroup of JIA individuals with five or more joints affected. Inclusion in this subgroup is independent of the RF test results; however, the category can be further subdivided into RF positive and RF negative. Many children with oligoarthritis who are "seronegative" (blood tests negative for RF or ANA) will resolve their symptoms over time.Enthesitis is common in children with JIA and refers to the inflamed and painful areas that connect a tendon or ligament to the bone. The enthesis is the area surrounding a joint where tendons or ligaments insert (Fig. 45.13).Psoriatic arthritis is a form of JIA that is characterized by clinical diagnosis of psoriasis and arthritis plus at least two of the following criteria: dactylitis, alterations in the fingernails that typically accompany psoriasis (e.g., pitting or painless detachment from the nail bed), or a first degree relative with psoriasis. Children with symptoms that do not fall into any of the aforementioned categories or suffer from symptoms that overlap categories are diagnosed with undifferentiated arthritis. Categorization of juvenile arthritis continues to evolve and change as the categories of disease are better understood.

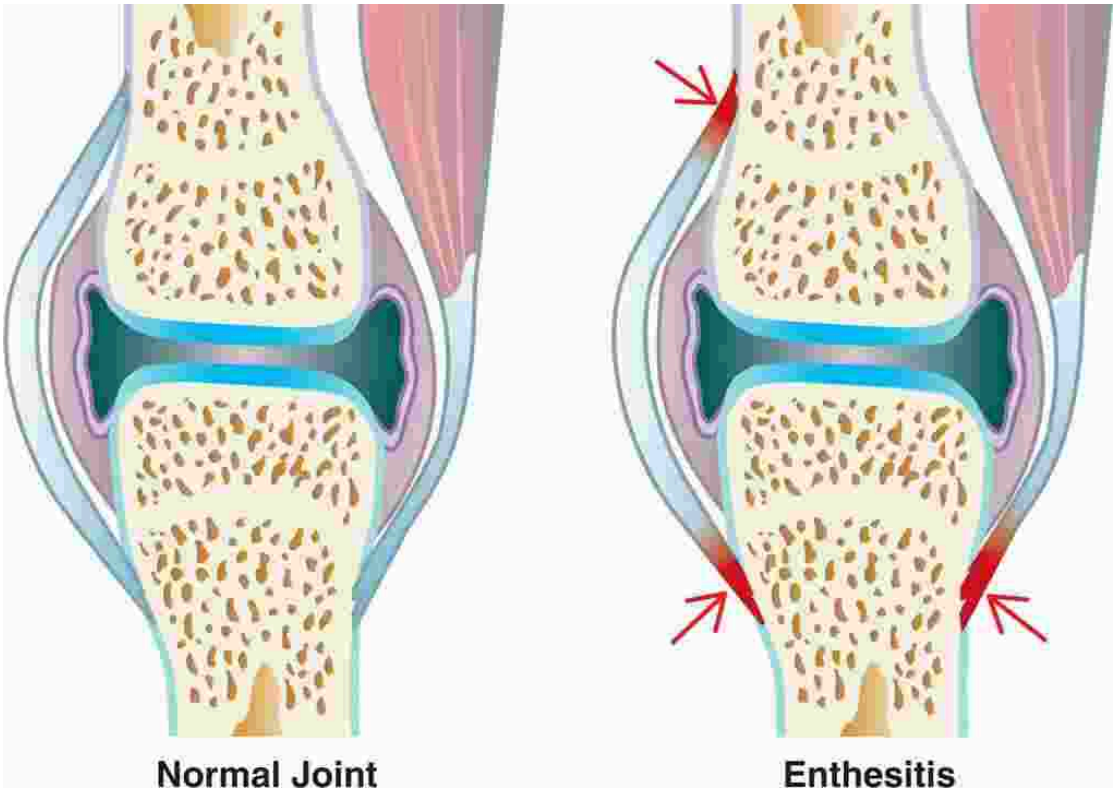

FIG. 45.13 Enthesitis.

Avascular Disease Of The Bone

Osteochondroses

The **osteochondroses** are a series of avascular diseases caused by insufficient blood supply to growing bones. These childhood diseases involve areas of significant tensile or compressive stress (e.g., tibial tubercle, Achilles insertion, hip epiphysis). The pathophysiology is partial loss of blood supply, death of bone (osseous necrosis), progressive bony weakness, and then microfracture. The cause of the decreased blood supply is controversial; trauma, a change in clotting sensitivity, vascular injury, genetic predisposition, or a combination of these factors is presently considered most likely. In addition, during the years of rapid bone growth, blood supply to the growing ends of bones (epiphyses) may become insufficient, resulting in necrotic bone, usually near joints. Because bone is normally undergoing a continuous rebuilding process, the necrotic areas can self-repair over a period of weeks or months.

Use of antiinflammatory medications, modification of activities, immobilization, and rest are recommended during active stages of the disease. Reparative correction by revascularization is the rule, although years may be required for full healing, and deformity from compression during the period of osseous necrosis can persist.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes (LCP) disease is a common osteochondrosis of the capital femoral epiphysis of the femoral head, usually occurring in children between the ages of 3 and 12 years, with a peak incidence at 6 years.[26] This self-limited disease, which runs its natural course in 2 to 5 years, is presumably created by recurrent interruption of the blood supply to the femoral head. The disorder is bilateral in 10% to 20% of children.[27] Male children are affected four to five times more often than female children, which is thought to be caused by males having a more poorly developed blood supply to the femoral head than

do females of the same age.[27] The role of genetics is unclear, but LCP is more common in northern European and Japanese children and rare in Black children; family history is positive in 20% of cases. Obesity and lower socioeconomic status have been associated with LCP.[28,29]

Pathophysiology

In the initial stage of LCP, the soft tissues of the hip (synovial membrane and joint capsule) are swollen, edematous, and hyperemic, often with fluid present in the joint (Fig. 45.14). The joint space widens, and the joint capsule bulges. This first stage lasts approximately 2 weeks. Next, the anterior 50% or more of the epiphysis of the femoral head dies because of a lack of blood supply, and the metaphyseal bone at the junction of the femoral neck and capital epiphyseal plate is softened because of increased blood supply and decalcification.[30] In the fragmentation stage, the body reabsorbs the infarcted bone.[30] Granulation tissue (procallus) and blood vessels then invade the dead bone. This stage lasts several months to 1 year. Then the regenerative healing stage, which ordinarily lasts 2 to 4 years, replaces the dead bone in the femoral head by procallus, and new bone is established (see Fig. 45.14).[30] In the final stage, remodeling takes place, and the newly formed bone is organized into a live spongy bone.[30]

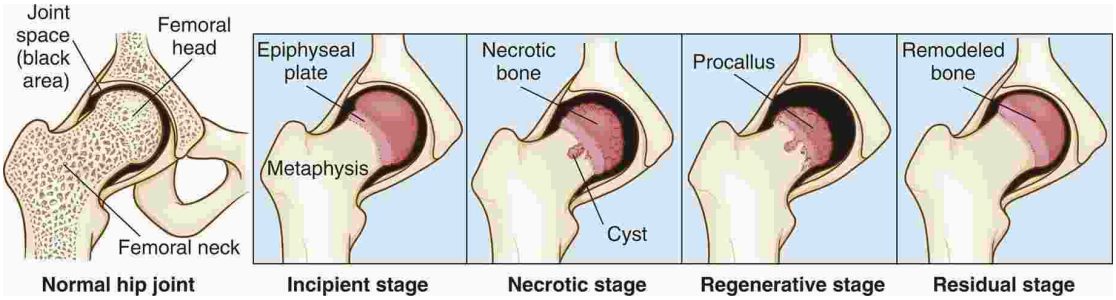

FIG. 45.14 Stages of Legg-Calvé-Perthes Disease, a Form of Osteochondrosis.

A series of five illustrations of the hip joint depicts the stages involved in the Legg-Calve-Perthes Disease. The first illustration depicts a normal hip joint with labels indicating joint space or black area, femoral head, and femoral neck. The second illustration depicts the incipient stage showing the hip joint with labels indicating an epiphyseal plate in metaphysis. The third illustration depicts the necrotic stage showing the hip joint with labels indicating necrotic bone and cyst. The fourth illustration depicts the regenerative stage showing the hip joint with the label indicating Proclus. The fifth illustration depicts the residual stage showing the hip joint with a label indicating remodeled bone.

Clinical Manifestations

Injury or trauma precedes the onset of LCP in approximately 30% to 50% of children with the disease. For several months the child complains of a limp and pain that can be referred to the knee, inner thigh, and the groin, following the path of the obturator nerve. The pain is usually aggravated by activity but is not always relieved with rest.

The typical physical findings include spasm on rotation of the hip, limitation of internal rotation and abduction of the hip, leg length discrepancy, and hip flexion–adduction deformity. If the child is walking, an early abnormal gait termed an ***antalgic*** *(painful) abductor lurch*, or a "Trendelenburg gait" (gluteus medius gait pattern), is apparent. If the hip pain or limp has been present for a prolonged period, muscles of the hip and thigh atrophy.

Evaluation and Treatment

Diagnosis is based on level of suspicion and confirmed by radiographic examination. However, early radiographic evidence may be normal in appearance. MRI may prove more helpful in the diagnosis because it will reveal bone marrow changes. Bone scans have the ability to reveal decreased profusion to the affected area.[31]

The goals of treatment are to preserve normal congruity of the femoral head and acetabulum and maintain spasm-free and pain-free range of motion in the hip joint. Currently, most children can be managed with antiinflammatory medications and activity modification during periods of synovitis. Serial radiographs are obtained to monitor the progress of the disease and to ensure that the femoral head remains congruent in the acetabulum. Surgery may be necessary if the femoral head becomes subluxated or incongruent with the acetabulum (Fig. 45.15). Children older than age 6 years (by bone age) have a worse prognosis attributable to poor remodeling potential. Older children require surgery more often to avoid poor congruence of the hip. Poor congruence predisposes to early OA, with nearly 50% requiring hip replacement surgery by age 40.[32]

FIG. 45.15 Pelvis of a 7-Year-Old Male With Legg-Calvé-Perthes Disease.
(A) The femoral head *(arrow)* is flat and extruded from the edge of the joint. This hip is at risk for early arthritis if left to revascularize and heal in this position. (B) Surgical replacement of the femoral head. As the Perthes heals, the ball has assumed a round shape that matches the socket well.

A. Radiograph of pelvis represents the Legg-calve-Perthes disease with an arrow mark indicating a flat edge of the pelvic joint. B. Radiograph of pelvis represents the surgically repaired femoral head.

Osgood-Schlatter Disease

Osgood-Schlatter disease (OSD) consists of osteochondrosis of the tibia tubercle and associated patellar (kneecap) tendonitis. OSD occurs most often in children undergoing rapid growth and those who participate in sports, placing stress on the developing tubercle through patellar tendon force.[33] The disease is more prevalent in males than in females.

Pathophysiology

The severity varies from mild tendonitis to a complete separation of the anterior tibial apophysis, a part of the tibial tubercle. The mildest form of OSD causes ischemic (avascular) necrosis in the region of the bony tibial tubercle, with hypertrophic cartilage formation during the stages of repair. In more severe cases, the abnormality involves a true apophyseal separation of the tibial tubercle with avascular necrosis.[33]

Clinical Manifestations

The child complains of pain and swelling in the region around the distal patellar tendon and tibial tubercle, just below the knee, which becomes prominent and is tender to direct pressure. The pain is most severe after physical activity that involves vigorous quadriceps contraction (jumping or running) or direct local trauma to the tibial tubercle area, and is relieved with rest (Fig. 45.16A–C).[33]

(B) An osseous body *(arrowhead)* of equivalent size was partially fused to the hypertrophied tibial tuberosity of the left knee. (C) Clinical manifestations include pain and swelling in the region around the patellar tendon and tibial tubercle, just below the knee, which becomes prominent and is tender to direct pressure. (A and B, From Choi W, Jung K. Intra-articular large ossicle associated to Osgood-Schlatter disease. *Cureus*, 2018;10(7):e3008. doi:10.7759/ *cureus*.3008.)

A. Radiograph of knee represents the osseous lesion indicated by an arrow mark. B. Radiograph of knee represents the osseous body indicated by an arrowhead. C. An illustration depicts the longitudinal section of the knee with labels indicating patellar tendon and inflammation.

Evaluation and Treatment

Radiologic evidence may indicate superficial ossicle in the patellar tendon, soft tissue swelling anterior to the tibial tuberosity, and thickening of ligamentum patellae.[33] Ultrasound, MRI, and CT are other imaging modalities used for the diagnosis of OSD. Ultrasound may show the thickened patellar tendon better than plain radiography. It can also demonstrate pretibial swelling, fragmentation of the ossification center, and excessive fluid collection in the infrapatellar bursa.[33] The goal of treatment for OSD is to decrease the stress at the tubercle. Most cases will spontaneously resolve as the skeleton matures. Treatment is typically aimed at symptom relief and includes a period of 4 to 8 weeks of restriction from strenuous physical activity, administration of antiinflammatory medications, and stretching of the quadriceps muscle. Bracing with a tubercle band can be very helpful. If the pain is not relieved, a cast or knee immobilizer is required, a situation that is particularly difficult if the condition is bilateral, which occurs in only 10% to 20% of cases. Gradual resumption of activity is permitted after 8 weeks, but return to unrestricted athletic participation requires an additional 8 weeks to allow for revascularization, healing, and ossification of the tibial tubercle. With skeletal maturity and closure of the apophysis, OSD resolves. Arthroscopic surgery is sometimes needed for unresolved lesions.[33]

The condition may recur for 12 to 18 months before complete resolution at skeletal maturity. This correlates with the closure of the apophysis.[33]

Sever Disease

Sever disease, or Calcaneal apophysitis, is the primary cause of heel pain in children between 8 and 15 years of age.[34] This injury mainly occurs during puberty with an open growth plate in the immature calcaneus.[34] The calcaneal apophysis experiences more metabolic activity during rapid periods of growth. Similar to OSD, this condition is more common in athletic children. Repetitive motion, frequent running and jumping, and abnormal heel strike cause microinjuries that induce repetitive pain with activity, wearing unsupported footwear (e.g., sandals), or athletic footwear with cleats. Radiographic evidence is not required to make the diagnosis but may be useful to differentiate from different disease processes. MRI may be useful in severe cases.[35]

Neuromuscular Disorders

The **neuromuscular disorders** are a group of inherited disorders that cause progressive muscle fiber loss leading to weakness, mostly of the voluntary muscles. Common forms of neuromuscular disorders are described in Table 45.3. They cause significant disability in children, resulting in lifelong neurologic, orthopedic, and pulmonary complications. Neuromuscular disorders have different inheritance patterns and different biochemical alterations that cause each specific type, and different disorders can cause

disease in different stages of life. Although the classification of neuromuscular disorders has historically been based on age of onset, rate of progression, distribution of muscular involvement, findings from muscle biopsy, and patterns of inheritance, genetic testing is increasingly being used for diagnosis and classification. Distribution of muscle weakness in common types of muscular dystrophy is depicted in Fig. 45.17.

Table 45.3

Major Neuromuscular Disorders in Children

Disease	Mode of Inheritance	Age at Clinical Onset	Usual Distribution	Rate of Progression	Intell Disab
Duchenne muscular dystrophy (DMD)	X-linked recessive	About 3 years	Hips and shoulders, quadriceps femoris, gastrocnemius (pseudohypertrophy)	Rapid	Frequ
Spinal muscular atrophy (SMA)	Autosomal recessive	Variable depending on subtype (infant to childhood)	Proximal greater than distal, especially involving hip and shoulder girdles	Rapid	Abser
Facioscapulohumeral dystrophy	Autosomal dominant	In first or second decade	Shoulder girdle, neck, face, pelvic girdle (late)	Moderate	Occas
Limb girdle (LG) dystrophy	Poorly defined or recessive	Variable	Pelvic and shoulder girdles	Variable	Varial
Myotonic dystrophy (MyD)	Autosomal dominant	Variable—birth to fifth decade	Distal extensor muscle, eyelids, face, neck, hands, pharynx	Slow, related to age at clinical onset, faster with younger individuals	Frequ

FIG. 45.17 Distribution of Muscle Weakness in Common Types of Muscular Dystrophy. (A) Duchenne muscular dystrophy. (B) Emery-Dreifuss muscular dystrophy. (C) Limb girdle. (D) Facioscapulohumeral. (E) Distal. (F) Oculopharyngeal. (From Emery-Dreifuss AE: *Lancet* 359[9307]:687–695, 2002.)

Six illustrations, A through F, depict the distribution of predominant muscle weakness in different dystrophy types. Illustration A depicts the distribution of muscle weakness in Duchenne-type and Becker-type involving shoulder, upper arm muscles, muscles of the hips and thighs, and legs. Illustration B depicts the distribution of muscle weakness in the Emery-Dreyfuss type involving shoulder, upper arm, and legs. Illustration C shows the distribution of muscle weakness in the limb-girdle type involving the shoulders, upper arm, and thigh. Illustration D depicts the distribution of muscle weakness in the facioscapulohumeral type involving shoulder, upper arm, and leg. Illustration E depicts the distribution of muscle weakness in the distal type involving the elbow and leg. Illustration F depicts the distribution of muscle weakness in the Oculopharyngeal type involving shoulder and thighs.

Cerebral Palsy

Cerebral palsy (CP) is a general term that refers to nonprogressive disorders of movement and posture resulting from injury or malformation of the developing central nervous system. Although the rate of childhood CP is decreasing, it is the most common motor disability of childhood.[36,37] The resulting disability may be mild, manifesting as a stiff (spastic) gait, or severe, in which the child is in a wheelchair and needs lifelong help eating, ambulating, and communicating. Comorbid conditions, such as intellectual disability, seizures, scoliosis, and hearing or vision loss, are common, especially in children with more severe forms. The overall incidence is approximately 1 in 345 children (3 per 1000 8-year-old children) in the United States and ranges from 1 to nearly 4 per 1000 live births around the world.[37] Nearly 50% of children identified with CP have co-occurring epilepsy, and 7.5% have autism spectrum disorder.[37] Children born preterm or at a low birthweight have a higher prevalence of CP. The number of children born with CP has drastically reduced in some parts of the world by as much as 30%, likely due to a combination of comprehensive obstetric and neonatal intensive care interventions.[36]

Evaluation and Treatment

The diagnosis of CP is often made after failure to meet gross motor milestones at predicted ages. In some infants, diagnosis is made at birth or in the first months of life because the child has an underlying diagnosis, such as a major brain malformation, that is known to be associated with CP. Other children are diagnosed after a routine developmental screening reveals delays in motor and movement. By the time a child is 30 months of age, most movement delays can be found.[37] Classic patterns of motor involvement include hemiplegia, involving only one side of the body; diplegia, involving only the lower extremities; and quadriplegia, involving all four extremities. In addition to the developmental evaluation, additional tests, including brain imaging with x-ray, CT, or MRI, can be done to look for a cause of CP.[37] An electroencephalogram (EEG), genetic testing, metabolic testing or a combination of these may also be done.[37] CP is generally diagnosed during the first or second year after birth. However, with milder symptoms, it can be difficult to make a diagnosis until the child is a few years older.

Treatment of CP is multifaceted and focused on maximizing functional abilities. Early intervention can help the child to learn new skills and provide needed support and training to the family. Services may include counseling; home visits; occupational, physical, or speech therapy; hearing loss services; health, nutrition, social work, and assistance with service coordination; assistive technology devices and services; and transportation.[37] Children with CP should receive speech/language therapy with trials of augmentative communication devices so that underlying cognitive abilities, which may not be apparent because of motor problems, are given a chance to manifest. Physical and occupational treatments, use of orthotics, spasticity reduction (by selected dorsal rhizotomy, or with pharmacotherapies), botulinum-A (Botox) toxin injections, and surgery are commonly used approaches. In many centers, a multispecialty approach is used so that a family may, within one clinic visit, see neurology, pediatrics, orthotics, orthopedic surgery, and rehabilitation clinicians. Children with CP should be carefully followed and given all possible opportunities to flourish. Although CP is a static disorder, progressive deformity because of increased muscle tone can occur. Monitoring these children as they grow with a multispecialty approach is essential to their optimal outcome.

It is imperative within clinical practice to establish clearly defined goals for the child and family and elect interventions that address the child's specific goal based on the intervention's effect.[36]

Duchenne Muscular Dystrophy

Pathophysiology

Duchenne muscular dystrophy (DMD) is the most common of the muscular dystrophies, affecting approximately 1 in 3500 male births because of the X-linked recessive inheritance.[38] More modest mutations with residual dystrophin expression result in **Becker muscular dystrophy (BMD)**. The onset of symptoms is typically seen later in BMD than seen in DMD; however, there are more cardiac manifestations seen in BMD.[38] Both DMD and BMD are caused by mutations in the gene that encodes **dystrophin**, a large membrane-stabilizing protein.[39] Dystrophin mediates anchorage of the actin cytoskeleton of skeletal muscle fibers to the basement membrane through a membrane-glycoprotein complex. Dystropin is present in normal muscle cells but absent in DMD. The lack of dystrophin causes poorly anchored fibers, which are torn apart under the repeated stress of contraction. Free calcium then enters the muscle cells, causing cell death and fiber necrosis. Disruption of the cell membrane allows the escape of creatine kinase (CK), increasing serum levels up to 10 to 100 times upper limits of normal. Marked elevations of CK levels are early identified in children suspected to have DMD and are an important diagnostic component. As muscle degenerates, there is increased endomysial connective tissue and fat; loss of striations; and concomitant hyaline, granular, and fatty degeneration of fibers. Disorganization of tendinous insertions is associated with fat accumulation in these areas (see Fig. 45.17). Although fibers regenerate in the younger child, regeneration is not able to keep up with muscle cell death, resulting in progressive weakness (Fig. 45.18A).[40]

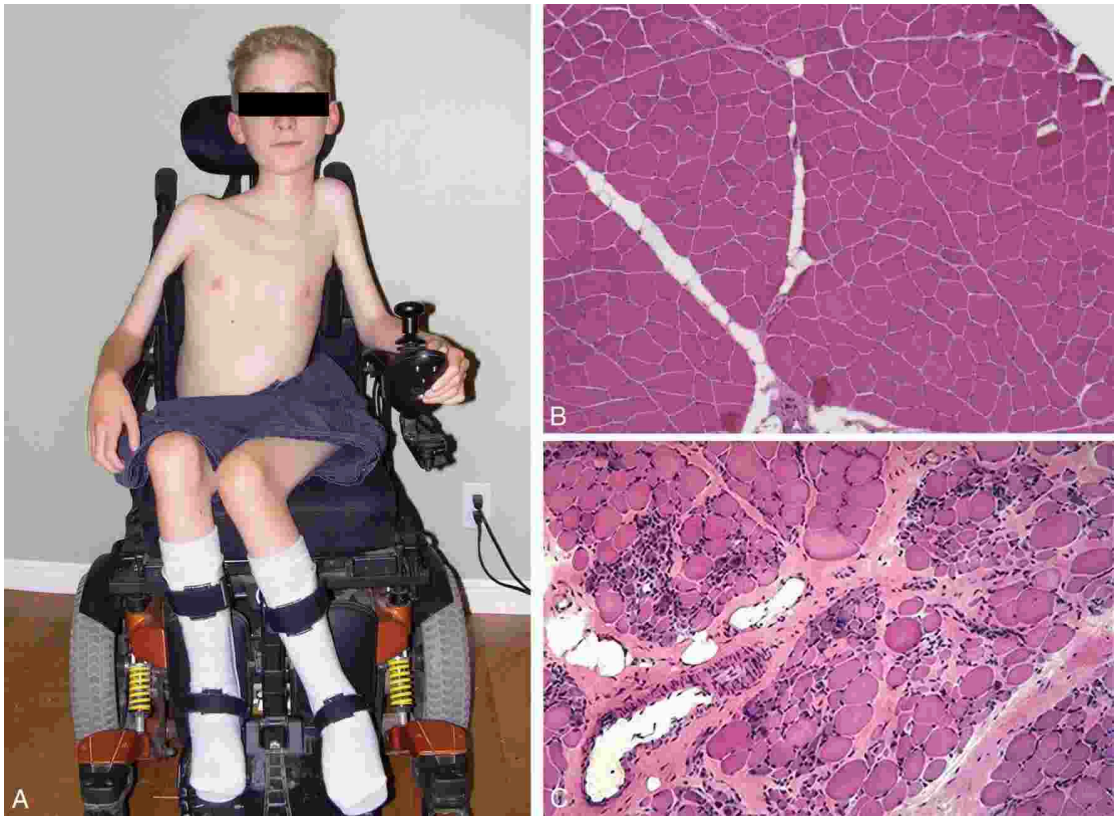

FIG. 45.18 Duchenne Muscular Dystrophy.

Microscopic view of a transverse section of stained gastrocnemius muscle representing the histology of normal tissue and muscle which shows mosaic aspect of fiber size variation. C. Microscopic image of transverse section of stained gastrocnemius muscle shows an extensive replacement of muscle fibers by fat cells.

Clinical Manifestations

DMD is usually identified in children at approximately 3 to 4 years of age, when the parents first notice gait abnormalities, difficulty getting up from the ground, and frequent falls.[41] Parents also may notice enlargement of the calf muscles, which is caused by normal muscle fiber replacement with fat and connective tissue (see Fig. 45.18B and C). Muscular weakness begins in the pelvic girdle, causing a "waddling" gait. The method of rising from the floor by "climbing up the legs" (Gower sign) is characteristic and is caused by weakness of the lumbar and gluteal muscles.[39] The foot assumes an equinovarus position, and the child tends to walk on the toes because of weakness of the anterior tibial and peroneal muscles. Within 3 to 5 years, muscles of the shoulder girdle become involved.

Progressive weakness results in loss of ambulation between 12 and 15 years of age. Subsequent progression includes slowly progressive respiratory insufficiency; cardiomyopathy; and orthopedic complications, including scoliosis. Cognitive dysfunction is a common and often overlooked aspect of DMD. Full-scale IQ is 85, which is significantly lower than the average IQ of 100, although studies suggest this decrease may be caused by specific learning disabilities rather than a true decreased intelligence. As the condition progresses, constipation and incontinence of urine and stool may develop, possibly because of smooth muscle involvement. Although the life expectancy of males with DMD continues to increase, death usually occurs from respiratory tract infection and a compromised respiratory system, with the majority living into their middle twenties. Some individuals who have chosen ventilatory support live a decade or more longer. With increased survival, cardiac complications are becoming an important contributor to mortality.

Evaluation and Treatment

Diagnosis is suggested by a high blood CK level, which can be 10 to 100 times the normal level even during infancy and before the onset of weakness. However, a high CK level does not confirm the diagnosis because many other alterations also can increase CK. Diagnosis is confirmed by genetic testing for mutations in the dystrophin gene, which is informative in 95% of cases. Muscle biopsy may be necessary in complicated cases where gene expression is not apparent on large deletion/duplication genetic testing.

Children with DMD require a multidisciplinary approach to care, including attention to heart and breathing problems, weight loss/gain, constipation, rehabilitative/developmental problems, psychosocial needs, neurologic issues, and orthopedic problems (Fig. 45.19). Maintaining function in unaffected muscle groups for as long as possible is the primary goal of treatment. Although activity fosters maintenance of muscle function, strenuous exercise may hasten the breakdown of muscle fibers. Range of motion exercises, bracing, and surgical release of contracture deformities are used to maintain normal function as long as possible. To prolong respiratory function or walking ability, or both, surgery for scoliosis is suggested when curves reach greater than 20 degrees.

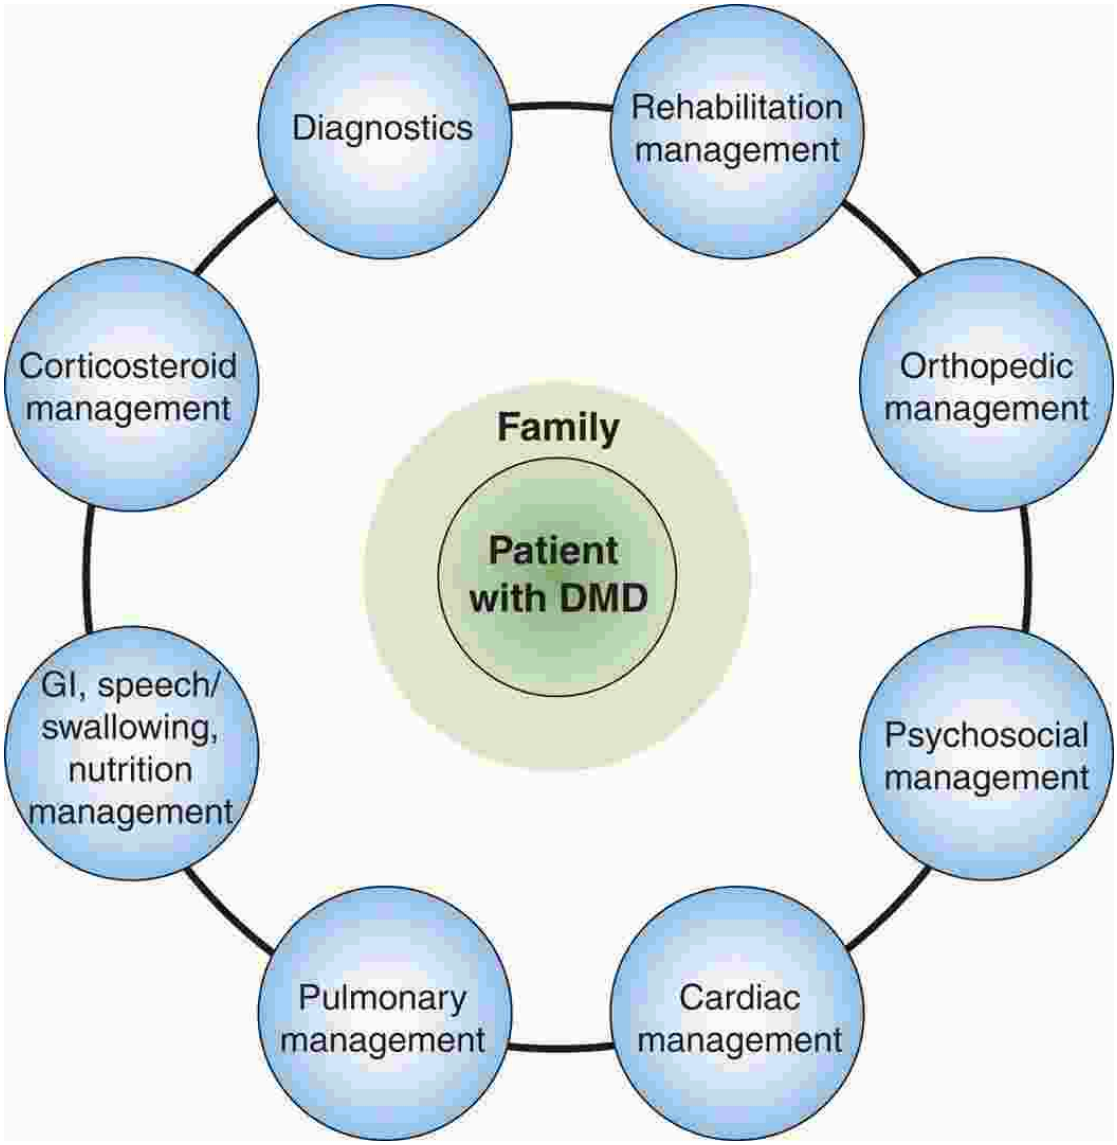

FIG. 45.19 Multisystem Approach for Evaluation and Treat-ment of Duchenne Muscular Dystrophy.
DMD, Duchenne muscular dystrophy; *GI*, gastrointestinal. (Adapted from Bushby K. Diagnosis and management of Duchenne muscular dystrophy part 1: diagnosis and pharmacological and psychosocial management. 2009; Bushby K. Diagnosis and management of Duchenne muscular dystrophy part 2: implementation of multidisciplinary care. 2009. Available at www.thelancet.com/neurology. Published online November 30, 2009.)

An illustration depicts the multidisciplinary approach for Duchenne muscular dystrophy which includes diagnostics; rehabilitation management; orthopedic management; psychosocial management; cardiac management; pulmonary management; G I, speech or swallowing nutrition management, and corticosteroid management.

Genetic counseling is recommended for all families who have children with DMD. Approximately one-third of the time, the mutation in a body with DMD is sporadic; that is, the boy is the first person in

the family to develop the mutation causing DMD. Because of the X-linked inheritance, male siblings of an affected child have a 50% chance of being affected and female siblings have a 50% chance of being carriers. Prenatal diagnosis is possible, and female carriers can be identified, especially if there is a known genetic defect in another family member. Treatment with oral corticosteroids has become the standard of care and has dramatically improved outcomes.[39] Children are able to walk an additional 2 to 5 years, and life expectancy has increased.[39] Complications, such as compromised pulmonary function and kyphoscoliosis ("humped" upper spine combined with scoliosis), are delayed. A gene editing tool (clustered regularly interspaced short palindromic repeats [CRISPR]) is being investigated in animals (dogs and mice) to halt disease progression as a model for humans.[42]

Families of children with DMD should receive genetic counseling for recurrence risk and prenatal screening. Various strategies to develop gene modification or gene replacement are currently in development for children with DMD.[43]

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a common, autosomal recessive disorder characterized by degeneration of motor neurons in the spinal cord leading to progressive muscle atrophy. Children have progressive weakness and loss of motor skills. Clues to diagnosis include tongue fasciculation (involuntary muscle twitching), a bell-shaped chest in the most severely affected infants, and tremor and quadriceps atrophy in older children. Genetically, SMA is caused by a mutation in the *SMN1* gene. Approximately 1 in 40 individuals carries the common mutation in the *SMN1* gene, making it one of the most common recessive disorders.[44]

The severity of SMA is variable, ranging from children who are never able to independently sit to children who can walk short distances. SMA is classified as types 0 through 4 and is categorized according to the onset of disease. Genetic testing is required for diagnosis and was added to the Recommended Uniform Screening Panel (RUSP) in the United States in 2018.[45]

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy (FSHD) is a complex genetic disorder, inherited in an autosomal dominant fashion.[46]Pathophysiology. FSHD is caused by genetic changes involving the long arm of chromosome 4. It is the third most common form of muscular dystrophy in children and is further classified into two subtypes, based on the route in which decreased methylation and a failure of epigenetic repression takes place. Approximately 95% of FSHD cases are type 1, and the other 5% are FSHD type 2.[47] Progression is usually slow and life span is normal or near normal.[46] Age at onset varies from early childhood to adulthood.Clinical Manifestations. As the name implies, clinical manifestations begin with asymmetric weakness and atrophy of facial and scapulohumeral (shoulder girdle) muscles. The disease progresses slowly, and life span is normal or near normal. Individuals with FSHD often have weak eye closure, are not able to whistle or inflate a balloon, appear expressionless, and have scapular winging (an abnormal protrusion of the shoulder blade).[48] The most common initial physical exam finding seen in FSHD is difficulty in the abduction of the arms over the glenohumeral joint with asymmetric muscle involvement.[48] Muscle involvement gradually progresses to the distal legs and then up to the trunk.[48] FSHD generally does not involve contractures surrounding muscle groups, which differs from other dystrophies. FSHD also may be associated with mild hearing loss, retinal abnormalities, and mild cardiac problems.

Evaluation and Treatment. Diagnosis is by genetic testing, although muscle biopsies, electromyography (EMG) studies, MRI, and laboratory tests may be performed as part of the diagnostic evaluation.[49] FSHD is genetically confirmed by the presence of eight or fewer D4Z4 repeats at the 4q35 gene locus of one or more alleles. The major complications seen in FSHD are chronic pain and impaired daily functioning, which negatively impacts psychological functioning.[50] Treatment is primarily focused on supportive therapy. Administration of NSAIDs, heat treatments, physical therapy, aerobic exercise, strength training, and massage may decrease pain and inflammation.[46] Bracing may be performed for

function (e.g., dorsiflexion of the feet with ankle-foot orthotics to prevent tripping or to provide support and comfort).[51]

Myotonic Muscular Dystrophy

Myotonic muscular dystrophy (MMD) is an autosomal dominant multisystem disease that occurs because of mutations in either of two genes resulting in type 1 (DM1) (dystrophia myotonica protein kinase *[DMPK]* gene on chromosome 19) and type 2 (DM2) (*ZNF9* gene on chromosome 3) MMD. DM1 may demonstrate a genetic mechanism called *anticipation*, in which children born to a mother with MMD usually have a more severe form of the disease. The childhood (infantile) subset of DM1 typically presents around age 10.

Clinical Manifestations. MMD affects the brain, skeletal and smooth muscles, eyes, heart, and endocrine system, manifesting as distal muscle weakness, learning problems, behavioral problems, intellectual disability, or a combination.[52] In addition, children can have dysphagia, constipation, cardiac dysrhythmias that, if untreated, may be life threatening, diabetes, and cataracts. Males with MMD also may manifest testicular atrophy and early male pattern baldness. A hallmark of the disease is myotonia—difficulty relaxing muscles. For example, they may have difficulty relaxing their handgrip after a handshake or opening their eyes after closing them tightly.

Children with mild disease do not develop symptoms until adolescence or older and may display mild muscle weakness (usually more pronounced in the distal muscles), cataracts, and myotonia but have normal life spans. Children with a more classic form of the disease also have onset of symptoms in the teenage years but have progressive muscle weakness, cataracts, and cardiac conduction abnormalities; they may have a shortened life span and require a wheelchair for mobility. The congenital form, the most severe, may be present at birth or become obvious over the first few years of life.[53]

Evaluation and Treatment. Diagnosis is typically made clinically and confirmed by genetic testing for the two genes known to cause MMD. In each case, an abnormal segment of deoxyribonucleic acid (DNA) causes abnormal functioning of muscle and other cells. Type 1 is more common and can present in infancy (the congenital form). Infants with MMD may have life-threatening breathing[53] and swallowing problems and developmental delay or intellectual disability, although MMD is not observed until childhood or even adolescence. Other testing, including serum CK, hepatobiliary function tests, electrodiagnostic testing, and muscle biopsy, may be added as part of the diagnostic evaluation.[54–56]

There is no curative treatment for DM; therefore the goal is to maximize individual independence with supportive management. Steroids are not useful for the treatment of DM; however, maintaining muscle function is important, including range of motion exercises, bracing, and surgical release of contractures when necessary. Children need to be followed closely by neurologists and primary care providers with treatment for the various aspects of the disease, such as dysphagia, heart dysrhythmias, and constipation, as well as other problems.[57]

Musculoskeletal Tumors In Children

Bone Tumors

Bone tumors are uncommon but, when cancerous, can contribute significantly to the morbidity and mortality of teenagers and young adults. Of the malignant bone tumors, osteosarcoma and Ewing sarcoma are the most common. Benign bone tumors are much more common than malignant bone tumors. However, true incidence and prevalence data are difficult to discern because most benign tumors are asymptomatic and are usually discovered accidentally during the work-up for a different issue. The most common forms of benign bone tumors are osteochondroma, nonossifying fibroma, simple bone cyst (SBC), aneurysmal bone cyst (ABC), osteoid osteoma, and fibrous dysplasia (FD) (Fig. 45.20).

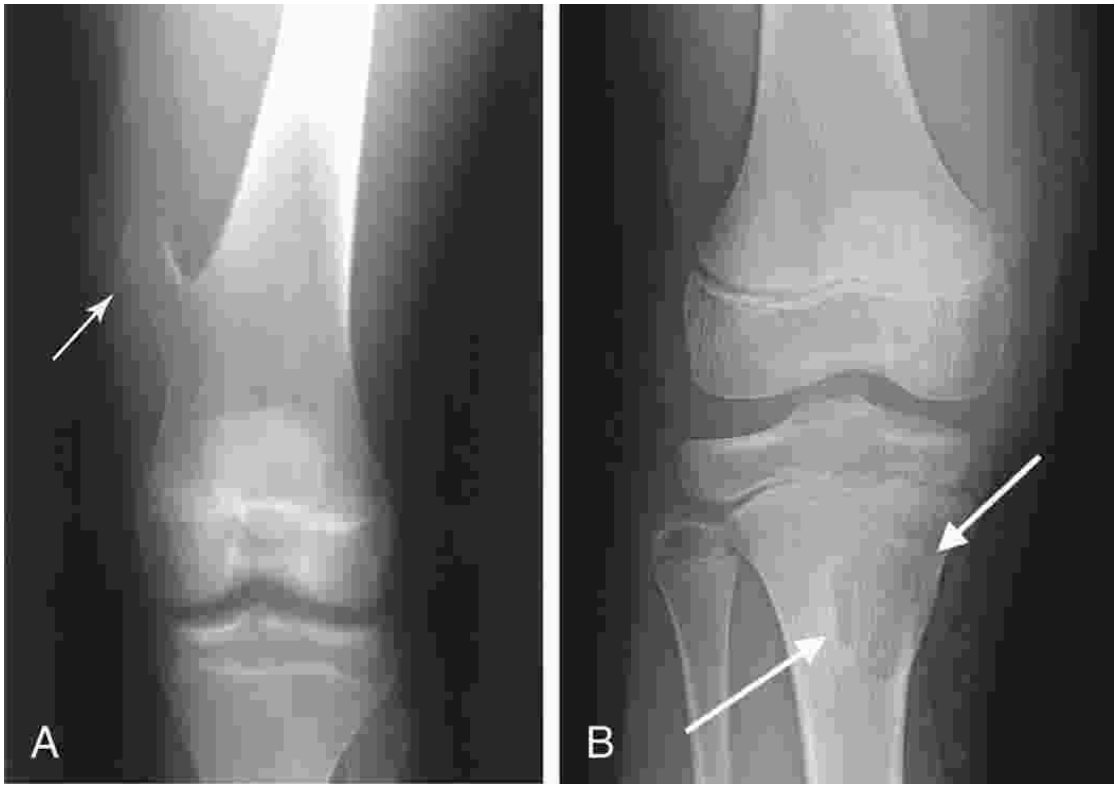

FIG. 45.20 Benign Bone Tumors.
(A) Osteochondroma *(white arrow)* arising from the distal femur. (B) Nonossifying fibroma *(white arrows)* mostly lytic.

Benign Bone Tumors

Osteochondroma

Osteochondroma (or exostosis) is a cartilaginous bony spur on the external surface of a bone. They can occur as a solitary lesion or as an inherited syndrome of **hereditary multiple exostoses (HME)**.[58] HME is an autosomal dominant condition with two or more exostoses occurring throughout the skeleton.

The long proposed hypothesis is that a fragment of the growth plate herniates through the periosteum, continues to grow, and results in either a sessile or pedunculated lesion, commonly in the region of the metaphysis.[59] This separation of the growth plate fragment can occur either spontaneously (primary osteochondroma), or secondarily from surgery, radiation, or fractures (secondary osteosarcoma).[59] However, recently researchers have identified genetic mutations in the gene encoding exostosin 1, suggesting that solitary osteochondromas represent true benign neoplasms.[60] HME is associated with a loss-of-function type of mutation in the tumor suppressor genes exostosin 1 and exostosin 2, which results in heparan sulfate proteoglycan (HSPG) deficiency and subsequent development of multiple osteochondromas.[60]

Osteochondromas are generally asymptomatic lesions that are incidental findings on a radiograph for noncontributory symptoms. When lesions are symptomatic, they can appear as bony protuberances because of genetic anomalies near active growth plates of the proximal humerus, distal femur, or proximal tibia. The most common presentation is a palpable mass that is painful when traumatized. Symptomatic lesions may also be secondary to fracture, malignant transformation, compression of adjacent neurovascular structures, bursal formation and/or bursitis, or palpable mass. The lesions can disturb growth plates and lead to growth disturbances. Individuals with HME are generally more severely affected, present at a younger age, and have multiple osseous deformities such as bowing of

the extremities, short limbs, short stature, leg length discrepancy, coxa valgus, or genu valgus (knock knees).[58,61] Upper extremity lesions can lead to a pronounced deformity in the forearm with a very short ulnar bone. These lesions grow until skeletal maturity; growth or pain after skeletal maturity is a sign of possible malignant transformation, especially in the pelvis or scapular region. Transformation to chondrosarcoma is very rare, occurring in less than 1% of children. Osteochondromas involving the long bones (most common location) generally have a pathognomonic appearance and require no further imaging evaluation. However, radiography and MRI are useful for individuals who are symptomatic or demonstrate the need for further evaluation.[62]

Solitary osteochondroma lesions that are asymptomatic without suspicious imaging features require only follow-up. Treatment for symptomatic lesions or lesions with suspicious imaging features requires surgical resection.[63,64]

Nonossifying fibroma

Nonossifying fibromas are sharply demarcated, cortically based lesions of fibrocytes that have replaced normal bone. The lesion can occur in any bone, at any age; however, they occur ordinarily in the metaphysis of long bones, most commonly in the lower extremities on the distal femur, distal tibia, and proximal tibia.[65] These fibromas are found in approximately 30% of the population.[65] In approximately 80% of nonossifying fibroma tumors, there is cell mutation, causing activation of the RAS-MAPK (mitogen-activated protein kinase) pathway.[66]

Most fibrous cortical defects resolve spontaneously as they are obliterated by reparative ossification. In some cases, the nonossifying fibroma persists and proliferates, affecting the structural integrity of the bone.[65]

Because nonossifying fibromas are typically asymptomatic, they are incidentally noted on radiographs obtained for other symptomatology.[65] In the 1950s, when fluoride was added to drinking water, random skeletal surveys were done on hundreds of children and nonossifying fibromas were discovered in 20% to 30% of children and distributed in nearly every bone of the body. Treatment is spared until the lesion occupies more than 50% of the diameter of the width of the bone or extends 3 to 4 cm into the cortex. Quantitative CT scans help to define a large lesion clearly and are used for preoperative planning.[67]

Simple bone cyst

Simple bone cysts (SBCs) are solitary fluid-filled lesions of the central region of the metaphyseal area in children. The most common sites for a simple cyst are the proximal humerus and proximal femur.[68] With growth, these lesions may appear within the diaphysis. Affected children are typically asymptomatic until pathologic fracture or incidental discovery occurs. Lesions often heal after a fracture, but large lesions may require further intervention. Nonoperative management is the choice for mild symptoms. Surgical interventions are rarely required and are typically reserved for very large lesions that affect weight bearing.[69]

Aneurysmal bone cyst

Aneurysmal bone cysts (ABCs) are typically solitary, eccentric, blood-filled osteolytic lesions that occur in adolescence. The etiology remains controversial; many consider an ABC lesion as secondary to another process, such as giant cell tumor, or the result of a vascular malformation within the bone.[70] The lesions can be found on any bone but most often are located on the spine, femur, and tibia.[70] ABCs are locally destructive and grow aggressively. The area can be painful and edematous, causing a limp or neurologic symptom. Surgical intervention is necessary to stop their expansion and inhibit reoccurrence.[71]

Osteoid osteoma

Osteoid osteoma is a bone-forming tumor that presents as a painful lesion of the diaphysis or metadiaphysis of long bones. Involvement of the posterior elements of the spine, with resultant

"splinting" scoliosis, can occur. Night pain is common, as is relief from symptoms with NSAIDs, because these tumors release prostaglandins. Advanced treatment options may be necessary for lesions causing intolerable pain, limp, or scoliosis. Radiofrequency -guided laser ablation, surgical resection, cryotherapy, and MRI-guided high-intensity focused ultrasound are options.[72]

Fibrous dysplasia

Fibrous dysplasia (FD) is a disease that causes thinning of the bone or lesion formation. Portions of the bone are replaced by fibrous tissue. FD can occur in one bone (monostotic) or in multiple bones (polyostotic). Although any bone can be affected, the long bones, ribs, and skull are the most common. A radiographic "ground-glass" appearance is present primarily in the metaphyseal or metadiaphyseal areas. Deformity can be marked and necessitate operative intervention.[73]

Malignant Bone Tumors

Malignant bone tumors are uncommon tumors in childhood, accounting for fewer than 5% of childhood malignancies and occurring mostly during adolescence. The two most common malignant bone tumors are osteosarcoma and Ewing sarcoma.

Osteosarcoma

Osteosarcoma, although very rare overall, is the most common malignant bone tumor found during childhood. Osteosarcoma originates in bone-producing mesenchymal cells and accounts for 60% of all malignant bone tumors. There is a bimodal age distribution overall, but in children, presentation usually occurs in adolescence between the ages of 13 and 16. Molecular analysis has demonstrated deletion of genetic material on the long arm of chromosome 13, leading to the identification of a tumor-suppressor gene as part of the mechanism for tumor development. The oncogene *src* also has been associated with osteosarcoma.

Pathophysiology

Osteosarcoma arises sporadically, with few cases associated with known inherited defects in cell cycle regulation, but approximately 70% of tumor specimens demonstrate a chromosomal abnormality.[74] Alterations to TP53 and RB1 tumor suppressor genes play a role in osteosarcoma.[75] Osteosarcoma occurs mainly in the metaphyses regions of long bones near sites of active physeal growth.[76] The tumor most commonly occurs at the distal femur, proximal tibia, or proximal humerus. As a tumor of mesenchymal cells, osteosarcoma makes osteoid tissue.

Osteosarcoma is a bulky tumor that extends beyond the bone into a soft tissue mass. It may encircle the bone and destroy the trabeculae of the diseased area. Osteosarcoma disseminates through the bloodstream, usually to the lung.[76] As many as 20% of children diagnosed with osteosarcoma exhibit lung metastases at diagnosis.[75] Other sites of metastatic spread include other bones and visceral organs.

Clinical Manifestations

The most common presenting complaint is pain at the site of the tumor.[77] Night pain, awakening a child from sleep, is a particularly foreboding sign. There may be swelling, warmth, and redness caused by the vascularity of the tumor.[77] Symptoms also may include cough, dyspnea, and chest pain if lung metastasis is present. If a lower extremity is involved, a child may limp or suffer a pathologic fracture.[77] Although osteosarcoma is not the result of trauma, trauma may call attention to a preexisting tumor.

Evaluation and Treatment

Diagnostic imaging (x-ray, MRI, CT, bone scan, and positron emission tomography [PET] scan) may suggest osteosarcoma, but a biopsy is confirmational.[77] Although needle biopsy is often sufficient to establish the diagnosis, tissue biopsy confirms it. The World Health Organization's (WHO's) histologic classification of bone tumors divides osteosarcoma into central, intramedullary, and surface tumors, with a number of subtypes under each group. The tumor is graded according to degree of malignancy; the higher the grade, the worse the prognosis.

Treatment is determined by the extent of the disease. Localized disease can be treated with chemotherapy with or without surgical intervention. Individuals with metastatic disease or relapse have poor prognoses. However, chemotherapy, surgery, and enrollment in clinical trial testing are options.[78]

Ewing sarcoma

Ewing sarcoma is a malignant round cell tumor of bone and soft tissue and is the second most common and most lethal malignant bone tumor that occurs during childhood.[79] The most common period of diagnosis is between 5 and 15 years of age. Ewing sarcoma is slightly more common in males than females and is linked with periods of rapid bone growth.

Pathophysiology

The pathognomonic molecular hallmark of Ewing sarcoma is a translocation between the EWS (*EWSR1* or *FUS*) gene and ETS-transcription (E26 transformation-specific or E-twenty-six) gene family (FLI*1*, *ERG*, *ETV1*, *ETV4*, or *FEV*).[80]

Ewing sarcoma is most commonly located in the diaphysis of long bones or in flat bones. The most common sites include the femur, pelvis, and humerus; however, it may occur in almost any bone or soft tissue (Fig. 45.21). Arising from bone marrow, Ewing sarcoma can penetrate the cortex of the bone to form a soft tissue mass (see Fig. 45.21A and B). Metastasis occurs early and is usually apparent at diagnosis or within 1 year. The most common sites are the lung, other bones, lymph nodes, bone marrow, liver, spleen, and central nervous system, although metastasis to any organ is possible.

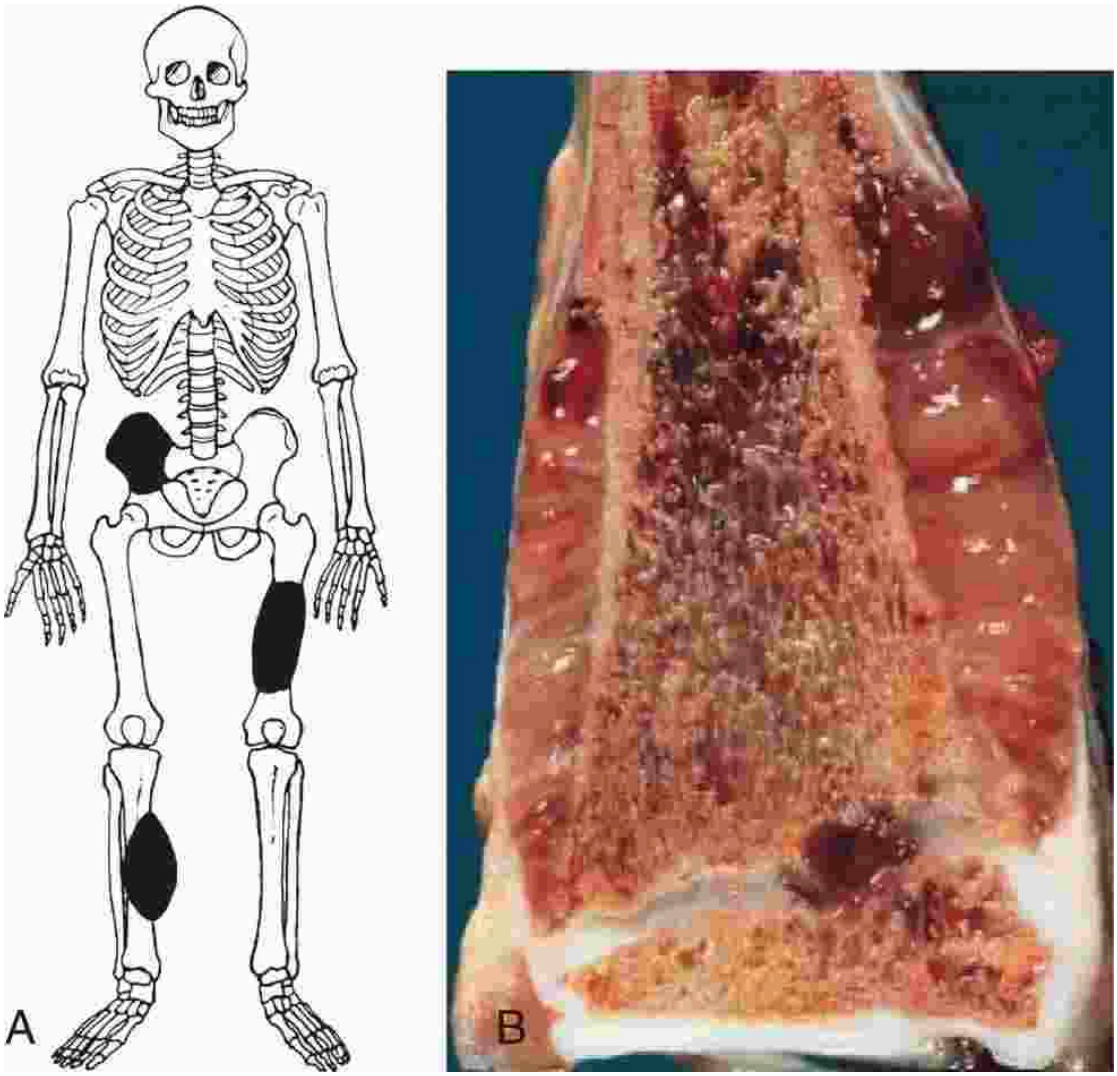

FIG. 45.21 Ewing Sarcoma
(A) Most common anatomic sites. (B) Close-up view of Ewing sarcoma of the distal end of the tibia. Tumor extends into the soft tissue. (A, From Damjanov I, Linder J, eds. *Anderson's pathophysiology*, 10th edition. St. Louis: Mosby; 1996. B, Fletcher CDM. Diagnostic *histopathy of tumors*, 5th edition. Philadelphia: Elsevier.)

A. An illustration depicts the human skeleton with the shaded portions of the left pelvic, left lower extremity, and right upper extremity. B. A close shot of the distal end of the tibia with Ewing sarcoma measuring 15 centimeters.

Clinical Manifestations

As with osteosarcoma, the most common complaint is pain, stiffness, and edema that increases in severity. A soft tissue mass is often present. Additional symptoms may include fever, malaise, and anorexia. Typically, the symptoms have been present for months preceding the presentation for treatment. However, a pathologic fracture is present upon diagnosis in 10% to 15% of cases.[81]

Evaluation and Treatment

Initial evaluation typically begins with a radiographic study. A poorly defined permeative, destructive lesion is typically seen and often times associated with a soft tissue mass. A distinctive "moth-eaten" appearance is common along with "Codman triangle" of the elevated periosteum, or multilayered "onion-skin" periosteal reaction. Diagnostic imaging of primary sites includes MRI and/or CT, with contrast is of prime importance.[82] Classification can be determined using the TNM by the American Joint Committee on Cancer (AJCC), which is based on tumor size, lymph node metastasis, distant metastasis, and tumor grade (cellular differentiation, mitotic rate, and extent of necrosis). However, the most commonly used staging system for Ewing sarcoma is classification of the tumor by grade (low grade is stage I, high grade is stage II, and distant metastasis is stage III) and compartmental status (located in the bone cortex versus extended beyond the bone cortex), which was developed by the Musculoskeletal Tumor Society (MSTS).

Biopsy is used to conclusively establish the diagnosis, which can be done with a CT-guided core-needle biopsy. The identification of t(11;22) chromosomal translocation within the tumor cells confirms the diagnosis.[83] Bone marrow aspiration with smear and bone marrow biopsy may also be considered. A serum lactate dehydrogenase (LDH) should be done because it carries prognostic significance.

The standard of treatment for Ewing sarcoma is multidrug chemotherapy and local therapy, which includes surgery and radiotherapy. Chemotherapy is continued for 12 to 18 months after resection. The major predictor of prognosis appears to be the location of the primary tumor and the presence of metastases at diagnosis.[84] Supportive care must include monitoring and treating the increased risks and adverse health outcomes associated with the current treatment for Ewing sarcoma, including severe neutropenia, recurrent fever, opportunistic infections, and mucositis.

Muscle Tumors

Most soft tissue tumors in children are benign. Only two malignant soft tissue tumors occur with any frequency: rhabdomyosarcoma (RMS) in the younger child and synovial cell sarcoma in the teenager. Both of these occur rarely. Soft tissue tumors originate from the primitive mesenchymal cells that normally give rise to muscle, tendons, blood vessels, lymphatic structures, fibrous and connective tissue, bursa, and fascia. Table 45.4 identifies the classification of soft tissue tumors according to origin. All malignant soft tissue tumors are characterized as highly aggressive tumors that invade surrounding structures and metastasize early.

Table 45.4

Classification of Tumors by Origin

Tissue	Tumor
Muscle	
Striated	Rhabdomyosarcoma
Smooth	Leiomyosarcoma
Adipose	Liposarcoma
Fibrous	Fibrosarcoma
Synovial mesothelium	Synovial sarcoma
Lymphatic structures	Lymphangiosarcoma
Blood vessels	Hemangiopericytoma
Nerve sheath	Neurogenic sarcoma

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma of childhood and accounts for approximately 50% of all soft tissue tumors.[85] RMS arises from embryonal rhabdomyoblasts that

normally differentiate into mature striated muscle. RMS can develop anywhere striated muscle is located. Primary locations include the head and neck, trunk, extremities, and the genitourinary tract. Recent studies demonstrate an association between *TP53* (a tumor-suppressor gene) mutations and sporadic RMS.[86] Four major subtypes of RMS have been identified: embryonal (most common), botryoid, sclerosing and spindle cell, and alveolar.[87] Clinical manifestations of RMS are outlined in Table 45.5.

Table 45.5

Clinical Manifestations of Rhabdosarcoma

Location	Manifestation
Head and Neck	
Orbit	Ptosis Exophthalmos Proptosis
Paranasal sinuses	Nasal obstruction Epistaxis Swelling Chronic sinusitis
Nasopharynx	Hypernasal speech Nasal discharge Visible polypoid mass
Oropharyngeal	Dysphagia Painful mastication
Middle ear	Chronic serous otitis media Discharge from affected ear Facial nerve palsy Conduction hearing loss Visible polypoid mass
Extremities	
All locations	Deep-seated, fixed palpable mass
Retroperitoneal	
All locations	Usually asymptomatic May have vague abdominal pain

Location	Manifestation
	Bowel or genitourinary obstruction (late) Possible palpable mass
Genitourinary	
Vaginal	Abnormal vaginal bleeding Protruding polypoid mass
Prostate	Urinary tract obstruction
Bladder	Urinary retention Straining to void Hematuria
Paratesticular	Mass in scrotum that may be painful

Nonaccidental Trauma

In the past year, at least 1 in 7 children have experienced child abuse and/or neglect, and this is likely an underestimate.[88] In 2019, 1840 children died of abuse and neglect in the United States.[88] Maltreatment may be physical, sexual, emotional, or neglect.[88] Skeletal trauma is present in a significant number of abused children (Fig. 45.22).[89–91] Accurate and appropriate referrals to child protection agencies not only are legally mandated but also are essential for the well-being of the child.

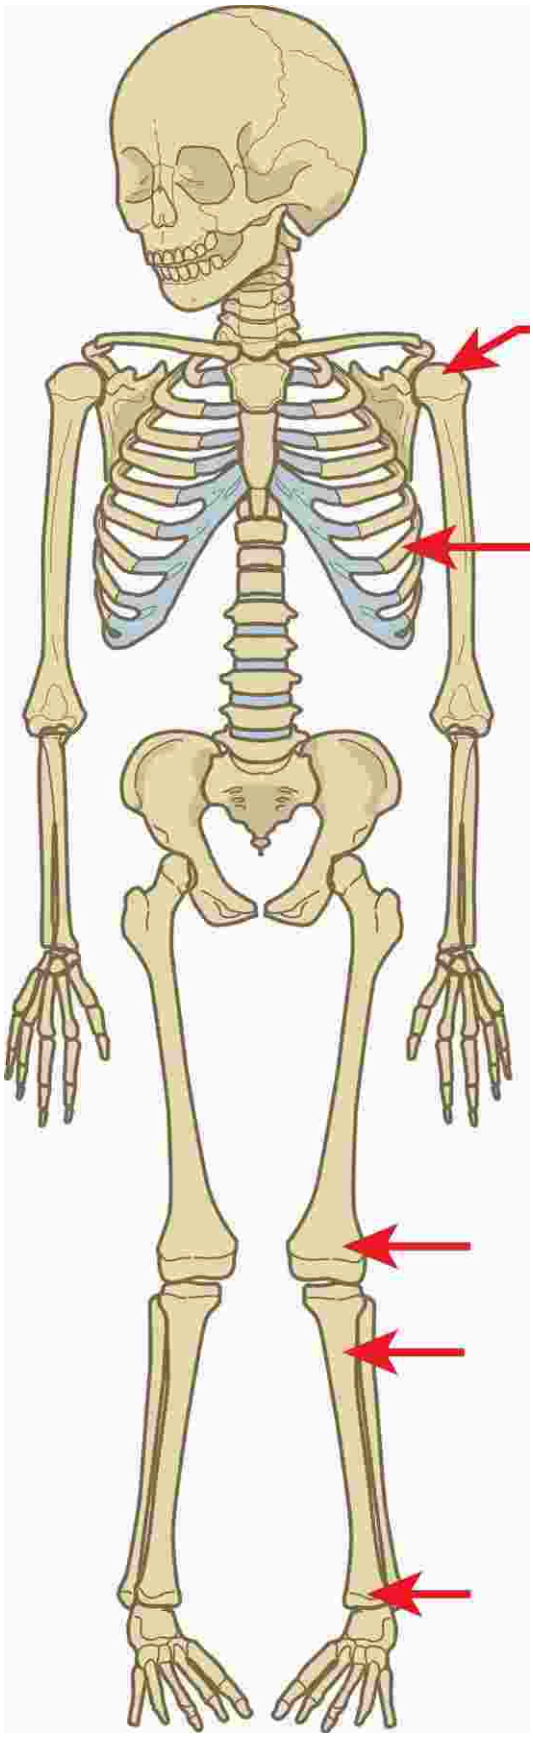

FIG. 45.22 Rib and Metaphyseal Fractures.
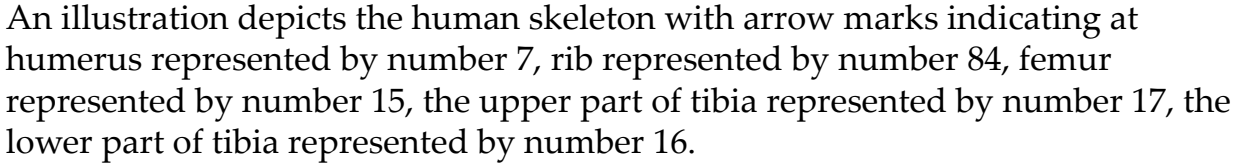
Rib fractures are very common and highly specific for abuse. There is an extremely high incidence of rib and metaphyseal fractures in children who die as a result of abuse. The red arrows indicate common sites of fracture related to abuse. (Data from Radiology Assistant Radiology Assistant Educational Site, Radiological Society of the Netherlands. Available from www.radiologyassistant.nl/.)



Fractures in Nonaccidental Trauma

Children who are not yet ambulatory and present with a long bone fracture have more than a 75% chance of that fracture being caused by nonaccidental trauma (NAT).[92] An unexplained humeral fracture in children younger than 15 months of age should be considered suspicious for abuse.[93] Multiple fractures in any location without overt trauma are also strongly associated with abusive injury. Rib fractures are the most common abnormality in abused children.[93] **"Corner" metaphyseal fractures** are nearly always from abuse and are considered a highly specific marker for abuse in infants (Fig. 45.23).[94] Fractures highly suggestive of physical abuse include rib fractures, classic metaphyseal lesions, those unsuspected or inconsistent with the history or age of the child, multiple fractures involving more than one skeletal area, and fractures of differing ages.[93] Fractures at multiple stages of healing also suggest abuse; however, OI or other causes of systemic osteomalacia must be ruled out. The most common presentation is a transverse tibia fracture. After walking age, only 2% of long bone fractures are the result of NAT.[95]

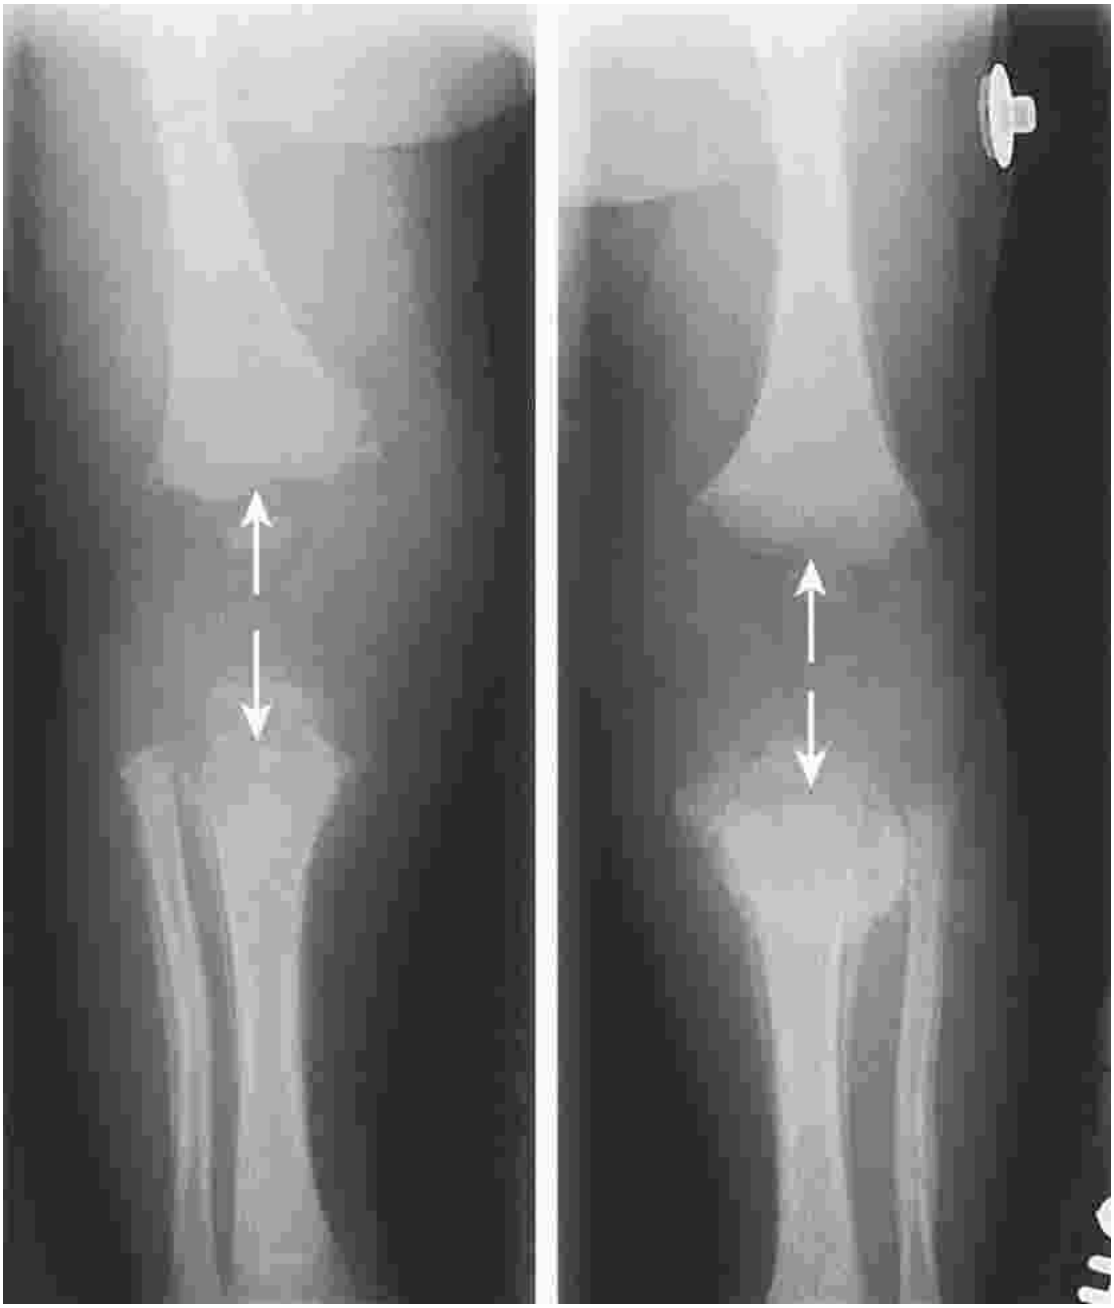


FIG. 45.23 Corner Fracture.
Bilateral knee radiograph showing healing corner fractures of bilateral proximal tibias and distal femurs. Note the varying amount of callus formation signifying fractures at different stages of healing.

Evaluation and Treatment

If abuse is suspected, NAT necessitates early consultation with child protective services. The healthcare provider is legally responsible to report suspected NAT. A thorough history must be obtained for all identified injuries. The child should undergo skeletal survey (especially if younger than 2 years of age) and have a complete physical examination to evaluate for pattern bruising, burns, or multiple soft tissue injuries. The American College of Radiology (ACR) Appropriateness Criteria should be followed to rate

the appropriateness of imaging and treatment procedures for specific clinical scenarios.[93] Ophthalmologic examination and brain CT should be used to evaluate for retinal or brain hemorrhage caused by shaking.

The treating healthcare provider must have a nonjudgmental attitude. The child and family involved in NAT are emotionally delicate and require not only physical but also emotional care. Social workers need to be involved early to ensure that the child receives appropriate medical care. Fortunately, fractures tend to heal quickly for those in this age group. However, neurologic injury and social disease are much more difficult to cure.

Summary Review

Musculoskeletal Development in Children

1. Skeletal growth and development consist of two phases: (a) delivery of bone cell precursors to sites of bone formation and (b) the aggregation of these cells at primary centers of ossification where they mature to secrete osteoid.
2. Ossification takes place in two centers in long bones: (a) the primary center, or the diaphysis (the long, central portion of the bone); and (b) the secondary center, or the epiphysis (the end portions of the bone).
3. Peak bone mass is achieved by the middle to late 20 s.
4. By 1 year of age, 50% of the total growth of the spine has occurred, and most children have achieved 50% of their adult height by 2 years of age.
5. The appendicular skeleton (extremities) grows faster during childhood than does the axial skeleton.
6. Muscle fibers reach their maximal size in females at 10 years of age and at 14 years of age in males.

Musculoskeletal Alterations in Children

1. The most common congenital defect of the upper extremities is syndactyly (webbing of the fingers or toes).
2. Polydactyly, or supernumerary digits, is another common congenital limb anomaly of the fingers or toes.
3. Developmental dysplasia of the hip (DDH) is an abnormality in the development of the femoral head, acetabulum, or both. DDH can be idiopathic or teratologic. It is a serious and disabling condition in children if not diagnosed and treated early, with best outcomes when treated before walking age.
4. Clubfoot (equinovarus) is a common deformity in which the foot is twisted out of its normal shape or position. Clubfoot can be positional, idiopathic, or teratologic. Positional is correctable passively; however, idiopathic and teratologic may require casting, bracing, or surgery.
5. Osteogenesis imperfecta (brittle bone disease) is a genetic disorder of collagen that affects primarily bones and results in fractures of many bones.
6. Rickets is a condition caused by deficiencies in vitamin D, calcium, and usually phosphorus that is characterized by the failure of bones to become mineralized (ossified) and results in skeletal deformity.
7. Scoliosis is a lateral curvature of the spinal column that can be caused by congenital malformations of the spine, neuromuscular disease, trauma, extraspinal contractures, bone infections, metabolic bone disorders, joint disease, and tumors. Nonstructural scoliosis results from a cause other than the spine itself, such as posture, leg length discrepancy, or splinting from pain. Structural scoliosis is a curvature of the spine associated with vertebral rotation.

Bone and Joint Infection

1. Osteomyelitis is a local or generalized bacterial infection of bone and bone marrow. Bacteria are usually introduced by direct extension from a nearby infection, through the bloodstream, or by trauma. Infection starts in the metaphysis, then ruptures out to spread into the diaphysis.
2. Septic arthritis is a bacterial or granulomatous infection of the joint space and is a surgical emergency. It can occur on its own, or secondary to osteomyelitis in very young children in which the metaphysis is still located within the joint capsule of certain joints.

Juvenile Idiopathic Arthritis

1. Juvenile idiopathic arthritis is an inflammatory joint disorder characterized by pain and swelling. Large joints are most commonly affected.

Avascular diseases

1. Avascular diseases of the bone are collectively referred to as *osteochondroses* and are caused by an insufficient blood supply to growing bones.
2. Legg-Calvé-Perthes disease is one of the most common osteochondroses. This disorder is characterized by epiphyseal necrosis or degeneration of the head of the femur followed by regeneration or recalcification.
3. Osgood-Schlatter disease is characterized by inflammation or partial separation of the tibial tubercle caused by chronic irritation, usually as a result of overuse of the quadriceps muscles. The condition is seen primarily in muscular, athletic adolescent males.
4. Calcaneal apophysitis or Sever disease is the primary cause of heal pain in children between 8 and 15 years of age.

Neuromuscular Disorders

1. The muscular dystrophies are a group of genetically transmitted diseases characterized by progressive atrophy of symmetrical groups of skeletal muscles without evidence of involvement or degeneration of neural tissue. There is an insidious loss of strength in all forms of the disorder with increasing disability and deformity.
2. Cerebral palsy is a general term that refers to nonprogressive disorders of movement and posture resulting from injury or malformation of the developing central nervous system. Cerebral palsy is the most common motor disability of childhood.
3. Duchenne muscular dystrophy is characterized by the absence of the membrane-stabilizing protein dystropin in muscle cells. Weakness leads to abnormal gait, frequent falls, and eventual loss of ambulation. Respiratory, cardiac, and neurologic problems are also present, requiring a multidisciplinary approach to care.
4. Spinal muscular atrophy is characterized by degeneration of motor neurons in the spinal cord leading to progressive muscle atrophy. Children have progressive muscle weakness and lack of motor skills.
5. Facioscapulohumeral muscular dystrophy involves asymmetric muscle weakness, starting in the face and then progressing to the shoulders and legs.
6. Myotonic muscular dystrophy classically presents with myotonia, or a difficulty relaxing muscles. It also can affect the brain, eyes, heart, and endocrine system.

Musculoskeletal Tumors

1. Musculoskeletal tumors may be benign (osteochondroma and nonossifying fibroma) or malignant (osteosarcoma and Ewing sarcoma).
2. Osteochondroma appears as a solitary bony protuberance near active growth plates of the proximal humerus, distal femur, or proximal tibia. Hereditary multiple exostoses is

characterized by multiple bony protuberances throughout the skeleton.

3. Nonossifying fibromas are lesions in which fibrocytes have replaced normal bone. Treatment may be required if the lesions grow so large that they compromise the strength of the bone.
4. Osteosarcoma, the most common malignant childhood bone tumor, originates in bone-producing mesenchymal cells and is most often located near active growth plates, such as the distal femur, proximal tibia, or proximal humerus. It is a bulky tumor that creates osteoid tissue. Pain, especially night pain, is the most common presenting symptom. It commonly causes lung metastases. The primary treatments for osteosarcoma are surgery and chemotherapy.
5. Ewing sarcoma originates from cells within the bone marrow space and is most often located in the midshaft of long bones or in flat bones. The most common sites include the femur, pelvis, and humerus, and the most common presenting symptom is pain that increases in severity. Ewing sarcoma metastasizes to nearly every organ. The primary treatment for Ewing sarcoma is a combination of chemotherapy, radiation, and surgery.

Nonaccidental Trauma

1. Nonaccidental trauma (NAT) must be considered with any long bone injury in a preambulatory child.
2. Evidence of soft tissue injury, corner fractures, and fractures at different stages of healing is extremely helpful in making a diagnosis of NAT. The healthcare provider is legally responsible to report suspected NAT.
3. The presence of soft tissue injury, corner fractures, and multiple fractures at different stages of healing is extremely helpful for making a diagnosis of NAT. When NAT is suspected, a child must be evaluated radiographically for other fractures, head trauma, and retinal hemorrhage.
4. All social strata are at risk for NAT.

When NAT is suspected, a child must be evaluated radiographically for other fractures, burns, multiple soft tissue injuries, and retinal hemorrhage.

Emerging Science BoxIdiopathic Scoliosis

Idiopathic scoliosis is the most common spinal disorder in the pediatric population. There are many treatment options for scoliosis, including core strengthening exercises, bracing, and surgery. The goals of treatment are to restore symmetry and optimize the individual's quality of life. Often, the severity of the scoliosis is measured objectively with the Cobb angle measurement. A Cobb angle in the range of 10–20 degrees is considered mild, 20–40 degrees is moderate, and greater than 40 degrees denotes severe scoliosis. The goals of treatment can be achieved by correcting the deformity and preventing progression of the curvature.

Exercise, such as the Schroth exercise, has proven beneficial especially for individuals with a Cobb angle of 10–30 degrees. People who practiced the exercise for more than 1 month had the best outcomes. This includes positive influence on the structural deformity and core muscle strength improvement. Interestingly, people who underwent Schroth exercise treatment perceived improved status even if the Cobb angle did not improve more than 5 degrees, which is considered the conventionally accepted threshold. This perceived improvement without significant Cobb angle improvement is leading researchers to investigate alternatives to the Cobb angle that might be more relevant.

New surgical techniques for scoliosis include robotic-assisted pedicle screw placement, vertebral body stapling, vertebral body tethering, magnetically controlled growing rods, and sublaminar polyester bands.

Emerging Science BoxSerum Interleukin-18 and Systemic Juvenile Idiopathic Arthritis

Interleukins (ILs) are a group of cytokines that regulate cell growth, differentiation, and motility, but are especially important in immunity and inflammation. IL-18 is a specific inflammatory cytokine. Serum IL levels may prove useful as a marker to distinguish the diagnosis of systemic juvenile idiopathic arthritis (sJIA) from other febrile diseases. A study by Xia et al. (2017) measured serum concentrations of S1000A8, S100A9, IL-6, and IL-8 from a group of individuals with various febrile conditions as well as a control group without disease. The level of IL-8 was significantly higher in the sJIA group. Another study, by Mizuta et al. (2020) suggests that levels can be used for diagnosis but also to predict the disease course and assessing remission. In people with polycyclic disease, serum IL-18 levels were elevated during flares and normalized during the inactive phase. Macrophage activation syndrome (MAS) is a severe compilation of sJIA and is characterized by a proliferation of T lymphocytes and macrophages. Yasin et al. (2020) concluded that IL-18 levels are elevated in sJIA individuals but even higher in those with active disease and a history of MAS. Furthermore, an increase in IL-18 may indicate an increase in disease action or the development of MAS.

Data from Bracaglia C, et al. Macrophage activation syndrome different mechanisms leading to a one clinical syndrome. *Pediatric Rheumatology Online Journal*, 2017;15(1):5. doi:10.1186/ s12969-016-0130-4; Mizuta M, et al. - Alopecia 1534
- Hirsutism 1535

Disorders of the Nail 1535
- Paronychia 1535
- Onychomycosis 1535

The skin is the largest organ of the body, accounting for about 20% of the body's weight. Combined with the accessory structures of hair, nails, and glands, it forms the integumentary system. The skin's

primary function is environmental protection by serving as a barrier against microorganisms, ultraviolet (UV) radiation, loss of body fluids, and the stress of mechanical forces. The skin regulates body temperature within a very narrow range and is involved in immune surveillance and the activation of vitamin D. Touch and pressure receptors provide important protective functions and pleasurable sensations. The microbiome of the skin protects against pathologic bacteria.

Structure and Function of the Skin

Layers of the Skin

The skin is formed of three major layers: (1) a superficial, or outer, layer of epidermis; (2) a deeper layer of dermis (the true skin); and (3) the subcutaneous layer (hypodermis), the lowest lying layer of connective tissue that contains macrophages, fibroblasts, fat cells, nerves, fine muscles, blood vessels, lymphatics, and hair follicle roots (Fig. 46.1). Each skin layer contains cells that represent progressive stages of skin cell differentiation and function. These are summarized in Table 46.1.

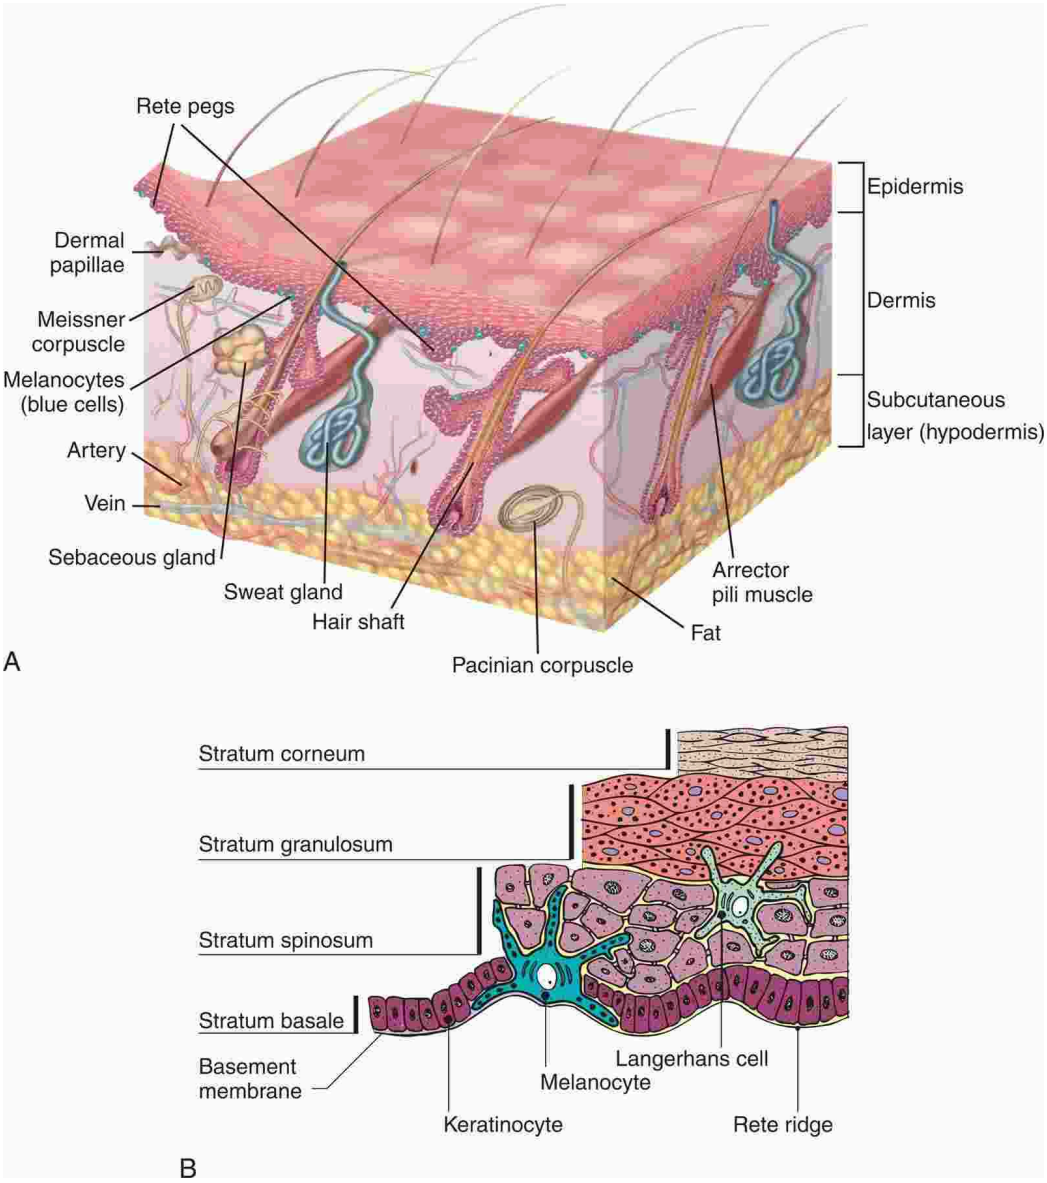

FIG. 46.1 Structure of the Skin.
(A) Cross section showing major skin structures.
(B) Layers of the epidermis. A, From Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Saunders; 2021. B, From Gawkrodger D, Ardern-Jones M. *Dermatology*, 5th edition. Philadelphia: Churchill Livingstone; 2012.

Two illustrations, A and B, depict the anatomy of the skin. Illustration A depicts the cross-section of skin

with three layers labeled epidermis, dermis, and subcutaneous, and its part labeled as follows. The epidermis includes Rete pegs. The dermis consists of dermal papillae, Meissner corpuscle, melanocytes or blue cells, sebaceous gland, sweat gland, hair shaft, Pacinian corpuscle, and arrector pili muscle. The subcutaneous layer or hypodermis consists of artery, vein, and fat. Illustration B depicts the cross-section of the epidermis layer with its parts labeled as follows. Stratum corneum, stratum granulosum, stratum spinsouom, stratum Basale, basement membrane, keratinocyte, melanocyte, Langerhans cell, and Rete ridge.

Table 46.1

Layers of the Skin

Structure	Cell Types	Characteristics
Epidermis	Keratinocytes	Most important layer of skin; normally very thin (0.12 mm) but can thicken and form corns or calluses with constant pressure or friction; includes rete pegs that extend into papillary layer of dermis
	Langerhans (dendritic) cells	Antigen presenting cells and immune functions
Stratum corneum	Keratinocytes	Tough superficial layer covering the body
Stratum lucidum	Keratinocytes	Clear layers of cells containing eleidin, which becomes keratin as cells move up to corneum layer
Stratum granulosum	Keratinocytes	Keratohyalin gives granular appearance to this layer
	Melanocytes	
Stratum spinosum	New keratinocytes	Polygonal shaped with spinous processes projecting between adjacent keratinocytes

Structure	Cell Types	Characteristics
Stratum basale (germinativum)	Keratinocytes	Basal layer where keratinocytes divide and move upward to replace cells shed from surface
	Melanocytes	Melanocytes synthesize pigment melanin
	Merkel cells	Mechanoreceptors for light touch
Dermis	Macrophages	Irregular connective tissue layer with rich blood, lymphatic, and nerve supply; contains sensory receptors and sweat glands (apocrine, eccrine, sebaceous), macrophages (phagocytic and important for wound healing), and mast cells (release histamine and have immune functions) (see Chapter 7)
Papillary layer (thin)	Mast cells	
Reticular layer (thick)	Histiocytes	Wandering macrophages that collect pigments and inflammatory debris
Subcutaneous Layer		Subcutaneous tissue or superficial fascia of

Structure	Cell Types	Characteristics
(Hypodermis)		varying thickness that connects overlying dermis to underlying muscle; contains macrophages, fibroblasts, fat cells, nerves, blood vessels, lymphatics, and hair follicle roots

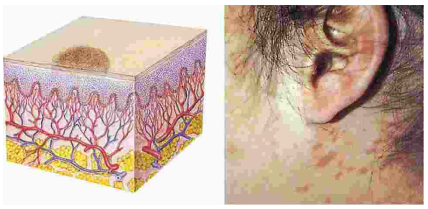
Epidermis

The **epidermis** is a defensive barrier that continually renews itself. The thickness of the epidermis varies from 0.05 mm on the eyelids to 1.5 mm on the palms of the hands and soles of the feet, and averages about 0.12 mm. The epidermis is made up of several distinct layers (see Fig. 46.1B) that ensure continual renewal of the skin. The epidermis is formed primarily of keratinocytes embedded in a lipid matrix. These cells are named for the substances they produce. **Keratinocytes** produce **keratin**, a protein that provides protection from mechanical stress and is the main constituent of skin, hair, and nail cells. Keratinocytes are formed in the **basal layer** (**stratum basale**) move upward and differentiate, forming the **spinous layer** (**stratum spinosum**). In the **granular layer** (**stratum granulosum**) surface keratin formation begins. This layer is specifically important because it discharges Odland bodies (lamellar granules) that contribute to stratum corneum cell cohesion and form a barrier to water loss. In the **stratum corneum**, cells become flattened, stacked, and cornified as they ascend to the skin surface, where the cells are continuously shed. The **stratum lucidum** lies between the stratum corneum and the stratum granulosum but is only seen in the thicker skin on the palms of the hands and the soles of the feet. Cornification, or keratinization, prevents dehydration of deeper skin layers and loss of body water. The average turnover of the epidermis is about 30 days.

The epidermis has three additional types of cells that facilitate its function: melanocytes, Langerhans cells, and Merkel cells. The **melanocytes** are usually located near the base of the epidermis (see Fig. 46.1B). They synthesize and secrete the pigment melanin with exposure to UV light in response to melanocyte-stimulating hormone (MSH). Melanin in the epidermis provides a shield against UV radiation and determines skin color. **Vitiligo** is thought to be an autoimmune-related loss of melanocytes resulting in the depigmentation of patches of skin (see "patch" in Table 46.3). **Langerhans cells** migrate to the epidermis from the bone marrow. Langerhans cells (a type of dendritic cell) and dermal dendritic cells initiate an immune response by presenting processed antigen to T cells, thus providing a defense against environmental antigens. **Merkel cells** are touch receptors and function as slowly adapting mechanoreceptors when stimulated by deformation of the epidermis. They are most numerous around hair follicles.

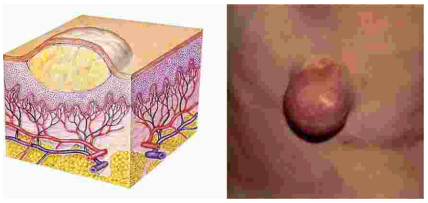
Table 46.3

Primary Skin Lesions

Macule	Plaque
A flat, circumscribed area that is a change in the color of the skin; less than 1 cm in diameter	Elevated, firm, and rough lesion with flat top surface greater than 1 cm in diameter
Examples: Freckles, flat moles (nevi), petechiae, measles, scarlet fever	Examples: Psoriasis, seborrheic and actinic keratoses
	


Macules[a]	Plaque[d]
Papule	Wheal
An elevated, firm, circumscribed area less than 1 cm in diameter	Elevated, irregularly shaped area of cutaneous edema; solid, transient; variable diameter
Examples: Wart (verruca), elevated moles, lichen planus, fibroma, insect bite	Examples: Insect bites, urticaria, allergic reaction

Lichen Planus[b]	Wheal[e]
Patch	Nodule
A flat, nonpalpable, irregular-shaped macule more than 1 cm in diameter	Elevated, firm, circumscribed lesion; deeper in dermis than a papule; 1-2 cm in diameter
Examples: Vitiligo, port-wine stains, mongolian spots, café au lait spots	Examples: Erythema nodosum, lipomas
	Vitiligo[c]	Lipoma[f]
Tumor	Pustule
Elevated, solid lesion; may be clearly demarcated; deeper in dermis; more than 2 cm in diameter	Elevated, superficial lesion; similar to a vesicle but filled with purulent fluid
Examples: Neoplasms, benign tumor, lipoma,	Examples: Impetigo, acne

neurofibroma, hemangioma	
	


Neurofibroma[f]	Acne[c]
Vesicle	Cyst
Elevated, circumscribed, superficial; does not extend into dermis; filled with serous fluid; less than 1 cm in diameter	Elevated, circumscribed, encapsulated lesion; in dermis or subcutaneous layer; filled with liquid or semisolid material
Examples: Varicella (chickenpox), herpes zoster (shingles), herpes simplex	Examples: Sebaceous cyst, cystic acne
Vesicles[g]	Sebaceous Cyst[c]
Vesicle more than 1 cm in diameter	Telangiectasia

Examples: Blister, pemphigus vulgaris	Fine (0.5-1 mm), irregular red lines produced by capillary dilation; can be associated with acne rosacea (face), venous hypertension (spider veins in legs), systemic sclerosis, or developmental abnormalities (port wine birthmarks)
	Example: Telangiectasia in rosacea
Bulla[h]	Telangiectasia[e]

Dermis

The **dermis** is 1 to 4 mm thick and is composed of three types of connective tissue: (1) collagen, (2) elastin, and (3) reticulin. The haphazard arrangement of connective tissue allows the skin to be mobile and to stretch and contract with body movement. Hair follicles, sebaceous glands, sweat glands, blood vessels, lymphatic vessels, and nerves are contained in the dermis. The conelike projections of the papillary dermis interface with the epidermis. The papillae provide texture to the surface of the skin by forming *rete pegs*.

The cells of the dermis include fibroblasts, mast cells, and macrophages. **Fibroblasts** secrete the connective tissue matrix and collagen. **Mast cells** release histamine and play a role in hypersensitivity reactions in the skin. **Macrophages** are phagocytic and participate in immune responses.

Subcutaneous Layer

The third layer of the skin is **subcutaneous tissue** (**hypodermis**) and consists of adipose tissue. The lobules are separated by fibrous walls (septa) of collagen and large blood vessels. Dermal collagen is continuous with the collagen found in the subcutaneous tissue.

Dermal Appendages

The **dermal appendages** include the nails, hair, sebaceous glands, and the eccrine and apocrine sweat glands. The fingernails and toenails are protective keratinized plates. They are composed of (1) the proximal nail fold, (2) the eponychium (cuticle), (3) the matrix from which the nail grows and its nail root, (4) the hyponychium (nail bed), (5) the nail plate, and (6) the paronychium (lateral nail fold) (Fig. 46.2). Nail growth continues throughout life at 1 mm or less per day.

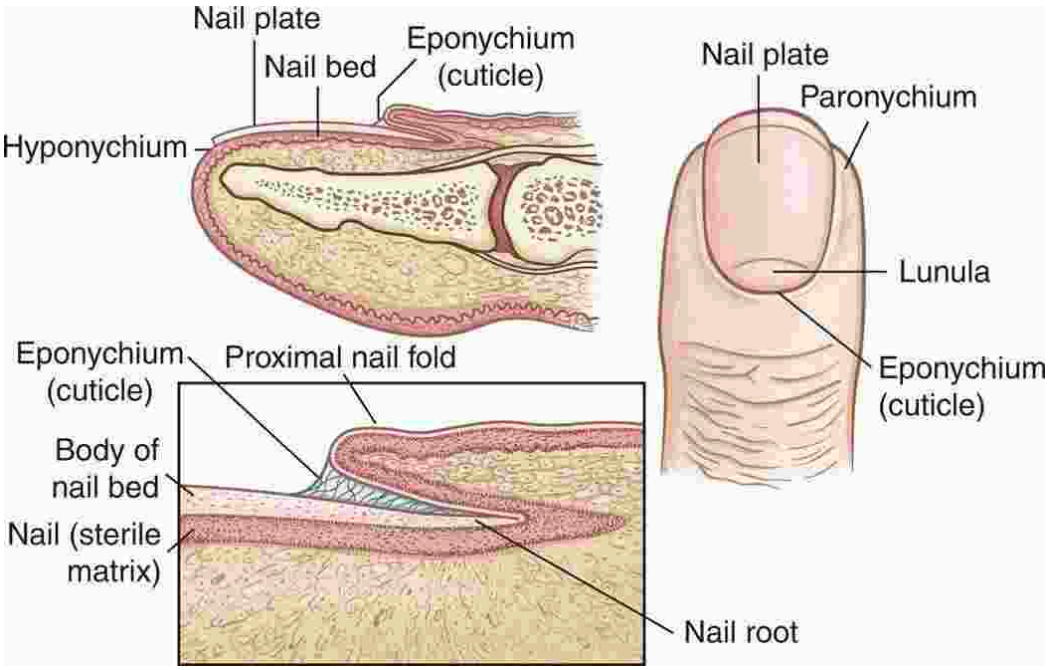

FIG. 46.2 Structures of the Nail. (Redrawn from Thompson JM, et al. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002.)

Three illustrations depict the anatomy of the nail. The illustration on the left top depicts the cross-section of the nail with its part labeled clockwise from the left. Hyponychium, nail plate, nail bed, eponychium or cuticle. The illustration on the right depicts the dorsal view of the nail with its part labeled clockwise from the left. Nail plate, paronychium, lunula, eponychium or cuticle. The illustration on the left bottom depicts the enlarged view of hyponychium with its components labeled clockwise from the left. Nail or sterile matrix, the

body of nail bed, eponychium or cuticle, proximal nail fold, and nail root.

Hair color, density, grain, and pattern of distribution vary among people and depend on age, sex, and race. **Hair follicles** arise from the matrix (or bulb) located deep in the dermis. They extend from the dermis at an angle and have an erector pili muscle attached near the mid-dermis that straightens the follicle when contracted, causing the hair to stand up. Hair growth begins in the bulb, with cellular differentiation occurring as the hair progresses up the follicle. Hair is fully hardened, or cornified, by the time it emerges at the skin surface. Hair color is determined by melanin-secreting follicular melanocytes. Hair growth is cyclic, with periods of growth and rest that vary over different body surfaces. Changes in hair color and distribution also occur. Graying is caused by loss of melanocytes from hair bulbs. A byproduct of hair growth is the production of hydrogen peroxide, which is normally degraded by catalase. With aging, there is a decrease in catalase and accumulation of hydrogen peroxide and oxidative stress with damage to and loss of melanocytes.[1]

Hair follicles and sebaceous glands are integrated units (see Fig 46.1A). The **sebaceous glands** open onto the surface of the skin through a canal. They are found in greatest numbers on the face, chest, and back, with modified glands on the eyelids, lips, nipples, glans penis, and prepuce. Sebaceous glands secrete sebum, composed primarily of lipids, which oils the skin and hair and prevents drying. Androgens stimulate the growth of sebaceous glands, and their enlargement is an early sign of puberty.

The **eccrine sweat glands** are distributed over the body, with the greatest numbers in the palms of the hands, soles of the feet, and forehead. They are important in thermoregulation and cooling of the body through evaporation. The **apocrine sweat glands** are fewer in number but produce significantly more sweat than the eccrine glands. They are located near the bulb of hair follicles in the axillae,

scalp, face, abdomen, and genital area. Their ducts open into the hair follicle. The interaction of sweat with commensal (normal) flora bacteria contributes to the odor of perspiration.

Blood Supply and Innervation

The blood supply to the skin is limited to the **papillary capillaries**, or plexus, of the dermis. These capillary loops are supplied by a deeper cutaneous arterial plexus. Branches from the deep plexus also supply hair follicles and sweat glands. A subpapillary network of veins drains the capillary loops. Arteriovenous anastomoses in the dermis facilitate the regulation of body temperature. Heat loss is regulated by (1) variations in skin blood flow through the opening and closing of arteriovenous anastomoses and (2) the evaporative heat loss of sweat. The sympathetic nervous system regulates both vasoconstriction and vasodilation of hair-bearing skin through α-adrenergic receptors in the skin. Non–hair-bearing skin (glabrous skin) of the palms, soles, and lips has the most arterio-venous anastomoses and is innervated solely by sympathetic vasoconstrictors with passive vasodilation.[2] The lymphatic vessels of the skin arise in the papillary dermis and drain into larger subcutaneous trunks, removing cells, proteins, and immunologic mediators.

Tests of Skin Function

Initial diagnostic evaluations of skin disorders are completed by gathering historical information, performing a physical examination, and observing the distribution and characteristics of the presenting lesions. Additional diagnostic studies are summarized in Table 46.2.

Table 46.2

Summary of Skin Diagnostic Procedures

Test	Purpose
Dermoscopy	Magnified illumination of the skin using a liquid medium and transparent plate to examine skin lesions
Reflectance confocal microscopy	High resolution assessment of cellular details and microstructures of the skin for evaluation of skin cancer
Skin biopsy	Histologic examination of tissue to determine differential diagnosis of cellular structure (i.e., benign growths vs. carcinoma, chronic infections, blistering diseases, and vasculitis)
Microscopic immunofluorescence	Identification of antibodies, immunoglobulins, and complement components for diseases such as pemphigus, vasculitis, and discoid lupus erythematosus using fluorescent light on slide-mounted biopsy specimens
Gram stain	Differentiation of gram-positive from gram-negative bacteria according to stain absorption
Culture	Identification of chronic bacterial and fungal infections by incubating skin specimens in culture media

Test	Purpose
Wood lamp examination	Examination of skin or hair to identify fungus that fluoresces bright yellow-green under ultraviolet light
Patch and scratch tests	Application of suspected allergens to skin by patch or scratch for evaluation of immune system responses to known allergens and evaluation of cell-mediated immune function (*Candida albicans*, skin fungus, chemicals, aeroallergens, and foods)
Skin scrapings	Application of potassium hydroxide and low heat to skin scrapings on a glass slide to identify dermatophytes and *C. albicans*
Side lighting	Indirect lighting of the skin using light to the side of the lesions to evaluate patterns of depression and elevation of skin lesions
Diascopy	Use of glass or clear plastic pressed on the skin to differentiate erythema caused by dilated capillaries (blanching) from extravasation of blood (no blanching)
Tzanck smear	A microscopic examination of cellular material from skin lesions to help diagnose vesicular diseases, including herpes simplex virus and varicella-zoster virus

Clinical Manifestations of Skin Dysfunction

Lesions

Lesions of the skin are readily observable and easily assessed for distribution and structure. Identification of the morphologic structure of the skin, including differentiation between primary and secondary lesions, and assessment of the appearance of the skin in combination with obtaining a health history, are essential to identify underlying pathophysiology. Tables 46.3 and 46.4 describe and illustrate primary and secondary lesions of the skin. Special skin lesions are described in Table 46.5. Clinical manifestations of vascular skin lesions are described in Table 46.6.

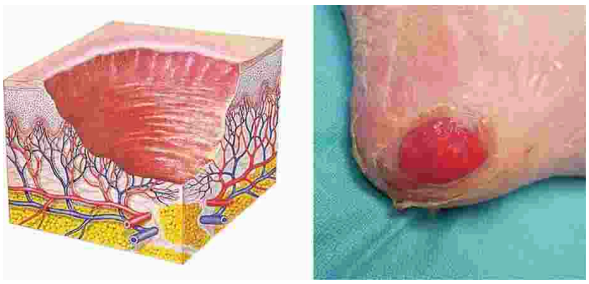
Table 46.4

Secondary Skin Lesions

Scale	Scar
Heaped-up, keratinized cells; flaky skin; irregular shape; thick or thin; dry or oily; variation in size	Thin to thick fibrous tissue that replaces normal skin after injury or laceration to the dermis
Examples: Flaking of skin with seborrheic dermatitis after scarlet fever, or flaking of skin after a drug reaction; dry skin	Examples: Healed wound or surgical incision
	Fine Scaling[a]	Hypertrophic Scar[d]

Lichenification	Excoriation
Rough, thickened epidermis secondary to persistent rubbing, itching, or skin irritation; often involves flexor surface of extremity	Loss of epidermis; linear, hollowed-out, crusted area
Example: Chronic dermatitis	Examples: Abrasion or scratch, scabies
	Atopic Dermatitis of Arm[b]	Scabies[c]
Keloid	Fissure
Irregularly shaped, elevated, progressively enlarging scar; grows beyond boundaries of wound; caused by excessive collagen formation during healing	Linear crack or break from the epidermis to the dermis; may be moist or dry
Examples: Keloid formation after surgery	Examples: Athlete's foot, cracks at the corner of mouth, anal fissure, dermatitis

	Keloid[c]	Fissures From Infected Dermatitis[c]
Erosion	Atrophy
Loss of part of the epidermis; depressed, moist, glistening; follows rupture of a vesicle or bulla or chemical injury	Thinning of skin surface and loss of skin markings; skin appears translucent and paperlike
Example: Chemical injury	Examples: Aged skin, striae
	Erosion on Leg[e]	Aged Skin[g]
Ulcer	
Loss of epidermis and dermis; concave; varies in size	
Examples: Pressure ulcer, stasis ulcers	

Pressure Ulcer on Heel[f]

Table 46.5

Special Skin Lesions

Type	Clinical Manifestations
Comedone	A plug of sebaceous and keratin material lodged in the opening of a hair follicle; an open comedone has a dilated orifice (blackhead), and a closed comedone has a narrow opening (whitehead)
Burrow	A narrow, raised, irregular channel caused by a parasite

Table 46.6

Vascular Skin Lesions

Type	Clinical Manifestation
Hemangioma	Bright red, superficial collection of blood vessels
Petechiae	Circumscribed area of blood less than 0.5 cm in diameter
Purpura	Circumscribed area of blood greater than 0.5 cm in diameter
Telangiectasia	Dilated, superficial blood vessels

Pressure injury

Pressure injury is defined by the National Pressure Injury Advisory Panel (NPIAP) as localized damage to the skin and underlying soft tissue usually over a bony prominence or a medical device. The injured skin and soft tissue can remain intact or present as an ulceration. The injury is a direct result of pressure, shear, or a combination of both.[3,4] Pressure that consistently interrupts normal blood flow to and from the skin or underlying tissues is the most common cause. Pressure injuries have substantial financial implications to healthcare organizations and are a major part of quality-of-care indicators. The risks for pressure injury are summarized in Box 46.1.

Box 46.1

Pressure Injury Risk Factors

Prolonged Pressure/Immobilization

Lying in bed or sitting in chair or wheelchair without changing position or relieving pressure over an extended period

- Lying for hours on hard x-ray and operating tables
- Neurologic disorders (coma, spinal cord injuries, peripheral neuropathy, cognitive impairment, or cerebrovascular disease)
- Fractures or contractures
- Debilitation: elderly persons in hospitals and nursing homes
- Pain
- Sedation
  Shearing forces
- Turning by dragging on coarse bed sheets

Disease/Tissue Factors

Thin or fragile skin
Impaired perfusion; ischemia
Fecal or urinary incontinence; prolonged exposure to moisture
Malnutrition, dehydration
Chronic diseases accompanied by anemia, edema, renal failure, malnutrition, peripheral vascular disease, or sepsis
Previous history of pressure ulcers

Additional Risk Factors for the Critically Ill

Norepinephrine infusion
Acute Physiology and Chronic Health Evaluation (APACHE II) score
Anemia
Age greater than 40 years
Multiple organ system disease or comorbid complications
Length of hospital stay
Use of ventilators or extracorporeal membranous oxygenation support

Data from Cowan L, Broderick V, Alderden JG. Pressure injuryprevention considerations for older adults. *Critical Care Nursing Clinics of North America*, 2020;32(4):601–609; Alderden JG, Shibily F, Cowan L. Best practice in pressure injury prevention among critical care patients. *Critical Care Nursing Clinics of North America*, 2020;32(4):489–500.

Pressure injuries usually develop over bony prominences, such as the sacrum, heels, ischia, and greater trochanters. Continuous pressure on tissue between the bony prominence and a resistant outside surface distorts capillaries and occludes the blood flow and oxygen supply. Pressure injury also can occur in soft tissues from medical devices—for example, from nasal cannulas or endotracheal tubes. If the pressure is relieved within a few hours, a brief period of reactive hyperemia (redness related to vasodilation) occurs and there may be no lasting tissue damage. If the pressure continues unrelieved, the endothelial cells lining the capillaries become disrupted with platelet aggregation, forming microthrombi that block blood flow and cause anoxic necrosis of surrounding tissues. Shearing and friction are mechanical forces moving parallel to the skin (dragging) and can extend to the bony skeleton, causing detachment and injury of tissues. Individuals with darkly pigmented skin are at greater risk for developing pressure injuries because early signs of skin damage may not be clearly visible.[5] Pressure injuries are staged or graded, and there are several scales available. One classification scheme is available from the National Pressure Advisory Panel at https://npuap.org/page/PressureInjuryStages. The stages are illustrated in Fig. 46.3 and summarized in Box 46.2.

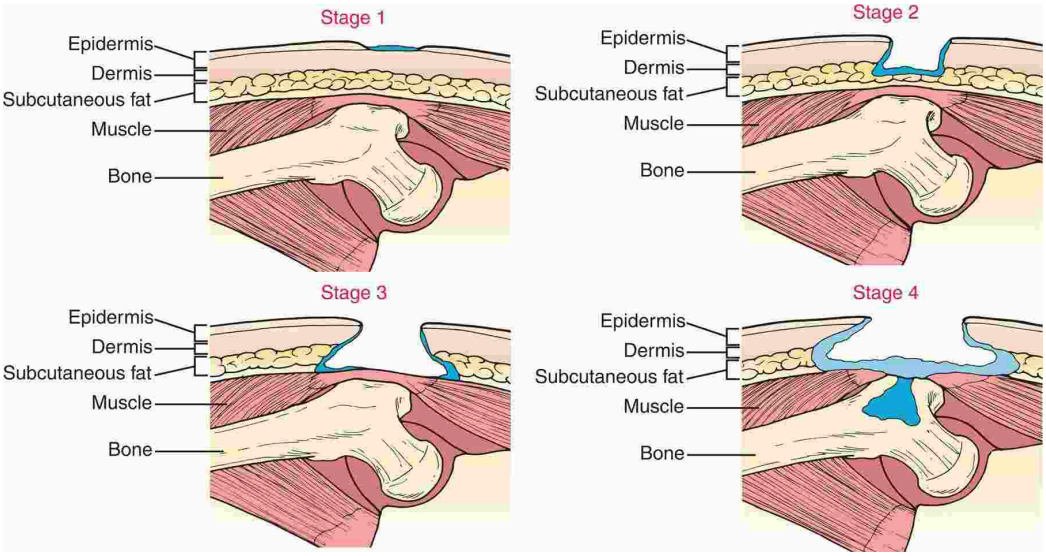

FIG. 46.3 Stages of Pressure Injury.

Four illustrations of a cross-section of skin with labels depict the four stages of pressure injury. The labels from top to bottom are as follows. Epidermis, dermis, subcutaneous fat, muscle, and bone. The illustration on the left top depicts the stage one injury, which shows an inflamed skin but not broken. The illustration on the right top depicts the stage two injury, which shows the skin is broken to the dermis. The illustration on the left bottom depicts the stage three injury, which shows the injury extends to the subcutaneous fat layer. The illustration on the right bottom depicts the stage four injury, which shows the injury extends to the bone.

Box 46.2

Pressure Injury Stages

Stage 1: Non-blanchable erythema of intact skin usually over a bony prominence; darkly pigmented skin may appear differently; color changes do not include purple or maroon discoloration.
Stage 2: Partial-thickness skin loss with exposed dermis (erosion or intact or ruptured blistering) involving epidermis or dermis presenting as a shallow open ulcer with a red-pink, viable wound bed, without slough. Deeper tissues are not visible.
Stage 3: Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend to, but not through, underlying fascia. Adipose tissue visible in the ulcer, granulation tissue and rolled wound edges (epibole) are often present.
Stage 4: Full-thickness skin and tissue loss with exposure of muscle, bone, or supporting structures (tendons or joint capsules); can include undermining and tunneling.

Unstageable Pressure Injury: Obscured full-thickness skin and tissue loss; the extent of the damage cannot be determined due to being obscured by devitalized tissue

Deep Tissue Pressure Injury (DTPI): persistent, non-blanchable deep red, maroon, or purple discoloration; skin is intact; pain and/or temperature changes can precede the color changes; may be difficult to discern in darkly pigmented skin

Medical Device Related Pressure Injury: a direct result from the use of a medical device such as an indwelling urinary catheter; the injury mimics the pattern or shape of the device; the injury should be stages via the aforementioned staging system, but with correctly identified etiology

Mucosal Membrane Pressure Injury: injury to mucous membranes from a medical device in the anatomical location of the injury; these injuries cannot be staged

Data from: Pressure ulcers get new terminology and staging definitions. *Nursing*, 2017;47(3):68–69. Stages available at: https://cdn.ymaws.com/npiap.com/resource/resmgr/online_store/npiap_pressure_injury_stages.pdf.

Superficial damage results in a layer of dead tissue that forms as an abrasion, blister, erosion, or non-blanchable red/darkened skin or as a reddish blue discoloration when there is deeper tissue damage. Superficial lesions are more common on the sacrum as a result of shearing or friction forces (forces parallel to the skin). Deep lesions develop closer to the bone because of tissue distortion and vascular occlusion from pressure perpendicular to the tissue (over the heels, trochanter, and ischia). Bacteria colonize the dead tissue, and infection is usually localized and self-limiting. Proteolytic enzymes from bacteria and macrophages dissolve necrotic tissues and cause a foul-smelling discharge that resembles, but is not, pus. The necrotic tissue initiates an inflammatory response with potential pain, fever, and leukocytosis. If the lesion is large, toxicity and pain lead to a host of possible complications, including loss of appetite, debility, local/systemic infections, and renal injury.

The primary goals for those at risk for pressure injury are prevention and early detection. Preventive techniques include frequent assessment of the skin, repositioning and turning of the individual, promotion of movement, implementation of pressure reduction (type of positioning and use of specialty beds), pressure removal (positioning interval), use of pressure distribution devices (positioning aids), and elimination of excessive moisture and drainage (use of moisture wicking products). Adequate nutrition, oxygenation, and fluid balance must be maintained.[6] A number of new bioengineering techniques have been developed for assessment and monitoring of tissue pressure and tissue pressure alterations.[7]

Superficial lesions should be covered with flat, moisture-retaining but not wet dressings (e.g., hydrogel dressings) that cannot wrinkle and cause increased pressure or friction. Successful healing requires continued adequate relief of pressure, debridement of necrotic

tissue, opening of deep pockets for drainage, and repair of damaged tissue by construction of skin flaps for large, deep ulcers. Infection requires treatment with antibiotics, and pain should be controlled.[8] Many advances have been made in the treatment of deep wounds associated with pressure injury.[9] Skin tissue engineering techniques are advancing the treatment of skin deficits (see Emerging Science Box: Skin Engineering).

Emerging Science Box

Skin Engineering

Replacing skin deficits can be traced back in literature as far back as the 16th century. Partial or split-thickness as well as full-thickness skin graft techniques continue to be commonplace in healthcare today. Synthetic products (skin substitutes) include biologic, synthetic, or biosynthetic options and work as skin equivalents specifically in the management of acute and chronic wound care. Although extremely useful and successful, synthetic products have yet to produce skin appendage substitutes such the microvascular networks, sweat glands, and hair follicles, which are critical for regulating body temperature and mediating the sensation of touch and pain.

Over the past decade, stem cell research has afforded scientists the ability to grow human skin, complete with hair follicles and sebaceous glands in a mouse model. The skin grows in tiny and odd shaped clusters called organoids from human pluripotent stem cells. Organoids are in vitro biological complexes with 3D structures that contain one or more cell types and partially recapitulate the structure and function of their in vitro counterparts. In approximately 4–5 months of incubation, an organoid of stratified epidermis, dermis, pigmented hair follicles complete with sebaceous glands, sensory neurons, and Schwann cells emerge. The resulting organoid has been equated to the facial skin of human fetuses in the second trimester of development.

Progress has also been made in the use of 3-D bioprinting for the development of pre-vascularized skin substitutes that permit rapid perfusion and enhance the deposition of collagen and increased dermal thickness. The use of nanoparticles has allowed the integration of angiogenic and growth factors and antibiotics to support the microenvironment. This research may prove to be the future of disease modeling and use of skin substitutes for treatment of burns, ulcers and reconstructive surgery.

Keloids and hypertrophic scars

Keloids and hypertrophic scars both result from abnormal wound healing related to excessive inflammation and tissue remodeling. A genetic susceptibility is likely. **Keloids** are rounded, firm elevated scars with irregular claw-like margins that extend beyond the original site of injury (see Table 46.4C and Fig. 46.4). They are most common in darkly pigmented skin types and generally appear weeks to months after a stable scar has formed. Keloids have excessive and disorganized deposition of fibroblast-derived extracellular matrix proteins, particularly types I and III collagen with persistent inflammation and fibrosis. Macrophages have a role in release of proinflammatory cytokines and growth factors that promote keloid formation.[10] The fibroblasts have high metabolic and mitotic rates. Keloids first appear as pink or red, firm, well-defined rubbery plaques that persist for several months after trauma. Later, uncontrolled overgrowth causes extension beyond the site of the original wound, and the tumor becomes smoother, irregularly shaped, hyperpigmented, and harder. Keloids can cause pain and

pruritus. Numerous options are available for prevention and treatment.[11]

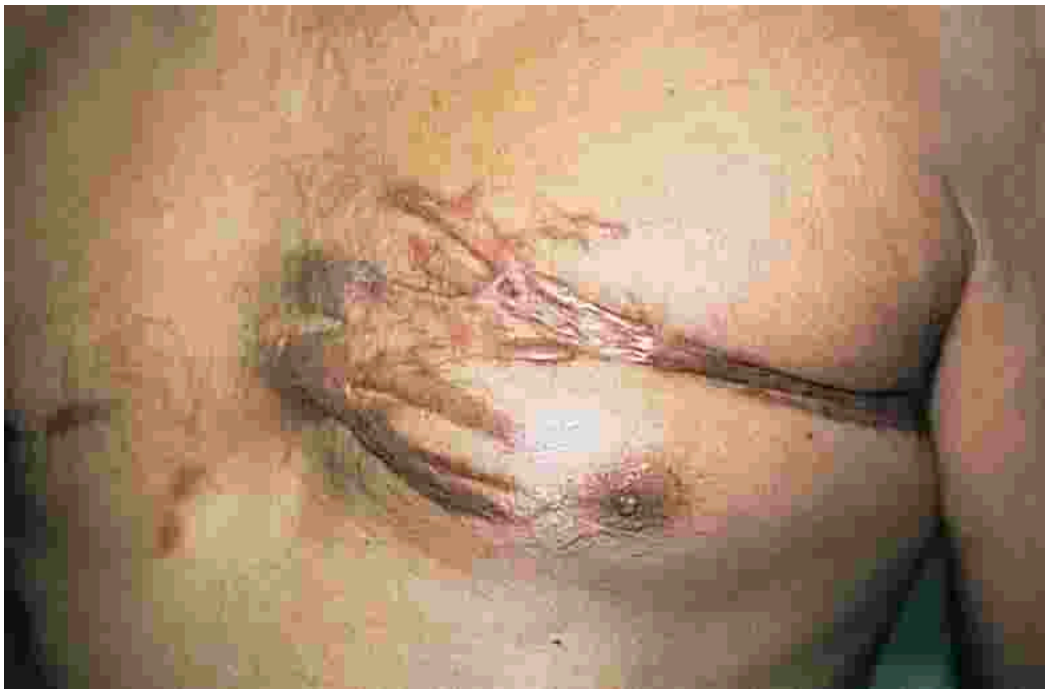

FIG. 46.4 Keloid. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Hypertrophic scars are elevated erythematous fibrous lesions that do not extend beyond the border of injury and primarily contain type III collagen (see Table 46.4D and Fig. 46.4). Hypertrophic scars appear within 3 to 4 months after injury and usually regress within 1 year. Excessive or poorly aligned tension on a wound, introduction of foreign material into the skin, infection, and certain types of trauma (e.g., burns) are all provocative factors. Those parts of the body at risk include shoulders, back, chin, ears, and lower legs. Like keloids, hypertrophic scars are caused by abnormal wound healing with inflammation, increased macrophage activity, excessive fibroblast activity and collagen formation, and loss of control of normal tissue repair and regeneration.[12]

Pruritus

Pruritus, or itching, is a symptom associated with local events in the skin such as dry skin (xerosis), eczema, psoriasis, or insect infestations, or it can be a manifestation of systemic disease (e.g., chronic renal failure, cholestatic liver disease, thyroid disorders, iron deficiency, neuropathies, or malignancy) or the use of medications such as opiate drugs. It may be acute (mosquito bite) or chronic (neuropathic itch), localized or generalized, and migratory (moves from one location to another). Multiple stimuli can produce itching, and there is interaction between itch and pain sensations. There are many itch mediators, including histamine, serotonin, prostaglandins, bradykinins, neuropeptides, acetylcholine opioids; and itch modulators, including interleukin-2 and -31 (IL-2 and IL-31), substance P, proteinases, and nerve growth factor.[13] Small unmyelinated type C nerve fibers and thinly myelinated Aδ fibers in the epidermis transmit itch sensations, and specific spinal pathways carry itch sensations to the brain.

Central nervous system mechanisms also can modulate itching, which is less perceptible when the mind is distracted by other stimuli. How the central nervous system influences the itch sensation is unclear, but it may be related to dampened central inhibition of itch pathway neurons. *Neuropathic itch* (itch without pruritogenic stimuli) is related to pathology along an afferent pathway. *Psychogenic itch* is associated with psychologic disorders (e.g., depression and obsessive compulsive disorder). Chronic itching is an unpleasant sensation that may or may not be relieved by scratching—often done so intensely that trauma to the skin occurs, resulting in infection, skin thickening (lichenification), and scarring. Both central and peripheral sensitization occurs.[14] Management of pruritus is challenging and depends on the cause; the primary condition must be treated. Both topical and systemic therapies are used.

Disorders of the Skin

Disruptions of the skin integrity may be precipitated by trauma, abnormal cellular function, infection, immune responses,

inflammation, and systemic diseases. Many skin disorders are benign and self-limiting, whereas others are severe and life-threatening. Many rashes and skin lesions have been described in association with COVID-19 viral infections (see Emerging Science Box: COVID-19 and Cutaneous Manifestations).

Emerging Science Box

COVID-19 and Cutaneous Manifestations

The novel coronavirus of 2019 (COVID-19) causes severe acute respiratory system disease in humans. Cutaneous manifestations in individuals with COVID-19 have been identified with variance across age groups, different populations, and morphology of presentation. The incidence and timing of presentation is difficult to discern. The American Academy of Dermatology and the International League of Dermatology Societies collaborated to form The American Academy of Dermatology's COVID-19 Registry. This registry was created for healthcare providers to report cases so that data can be complied, examined, and used to further understand COVID-19 related dermatoses.

In individuals with confirmed COVID-19 positive tests, the most common dermatoses in the literature include macular or maculopapular lesions (morbilliform), pernio (chillblain)-like rash, urticarial, vesicular lesions, and retiform purpura (vascular lesions). Pernio is a disorder separate from COVID-19 that presents with red to violet or blue macules, papules or nodules that typically present on the digits (known as Covid toes or fingers) and is more common in younger individuals and milder disease. It is related to vasospasm and a probable type 1 interferon reaction to viral infection. Macular or maculopapular (morbilliform) lesions, the most common type, are red with flat or raised borders. These occur early and are more commonly found on the trunk and with more severe disease. Urticaria is common and may be related to activation of mast cells with viral infection. Vesicular lesions may be associated with herpes virus co-infection.

Retiform purpura is a vaso-occlusive response associated with severe disease and the elderly. An erythema-multiforme-like pattern and Stevens-Johnson syndrome were most frequently linked to hydroxychloroquine treatment. There have been reports of infants born to COVID-19 positive mothers with diffuse maculopapular rash.

Data from Conforti C, et al. Cutaneous manifestations in confirmed COVID-19 patients: A systematic review. *Biology (Basel)*, 2020;9(12):449; Freeman EE, et al. The spectrum of COVID-19-associated dermatologic manifestations: an international registry of 716 patients from 31 countries. *Journal of the American Academy of Dermatology*, S0190-9622(20)32126-5, 2020. Advance online publication. https://doi-org.pnw.idm.oclc.org/10.1016/j.jaad.2020.06.1016; Tan SW, et al. Skin manifestations of COVID-19: A worldwide review. *JAAD International*, 2021;2:119–133; Sharma S, et al. Cutaneous manifestations and dermatological sequelae of Covid-19 infection compared to those from other viruses. *Australasian Journal of Dermatology*, 2021;62(2):141–150. doi:10.1111/ajd.13561. Epub ahead of print. PMID: 33595840.

Inflammatory Disorders

The most common inflammatory disorders of the skin are eczema and dermatitis. **Eczema** and **dermatitis** are general terms that describe a particular type of inflammatory response in the skin and are often used interchangeably. Eczematous disorders are generally characterized by pruritus, lesions with indistinct borders, and epidermal changes. These lesions can appear as erythemic papules or scales; they can present in an acute, subacute, or chronic phase. Edema, serous discharge, and crusting occur with continued irritation and scratching. In chronic eczema, the skin becomes lichenified, leathery, and hyperpigmented from recurrent irritation and scratching. Eczematous inflammations need to be differentiated from other epidermal rashes and dermatoses, particularly psoriasis.

Allergic Contact Dermatitis

Allergic contact dermatitis (ACD) is a common form of T-cell–mediated or delayed hypersensitivity (see Chapter 9 for different

types of allergic responses). The response is a consequence of alterations in skin barrier function with reaction to the exogenous agent; release of cytokines, chemokines, and cytotoxins from keratinocytes; Langerhans cells; and natural killer cells and neuronal responses, such as pruritis. Genetic susceptibility involves several genes, including loss of function mutations in the gene encoding the epidermal protein filaggrin, which binds keratin filaments and provides a skin barrier.[15]

Various allergens (e.g., microorganisms, chemicals, foreign proteins, latex, drugs, metals) can form a sensitizing antigen. Contact with the oil of the poison ivy plant, urushiol, is a common example (Fig. 46.5).When the allergen contacts the skin, it is bound to a carrier protein, forming the sensitizing antigen. The Langerhans cells process the antigen and present it to T cells. T cells then become sensitized to the antigen, inducing the release of inflammatory cytokines and chemokines, leading to leukocyte infiltration and antigen-specific inflammation resulting in the symptoms of dermatitis.[16] Latex allergy can be either a type IV delayed hypersensitivity reaction to chemicals used in latex rubber processing or a type I immediate hypersensitivity reaction with immunoglobulin E (IgE) antibodies formed in response to latex rubber protein.[17]

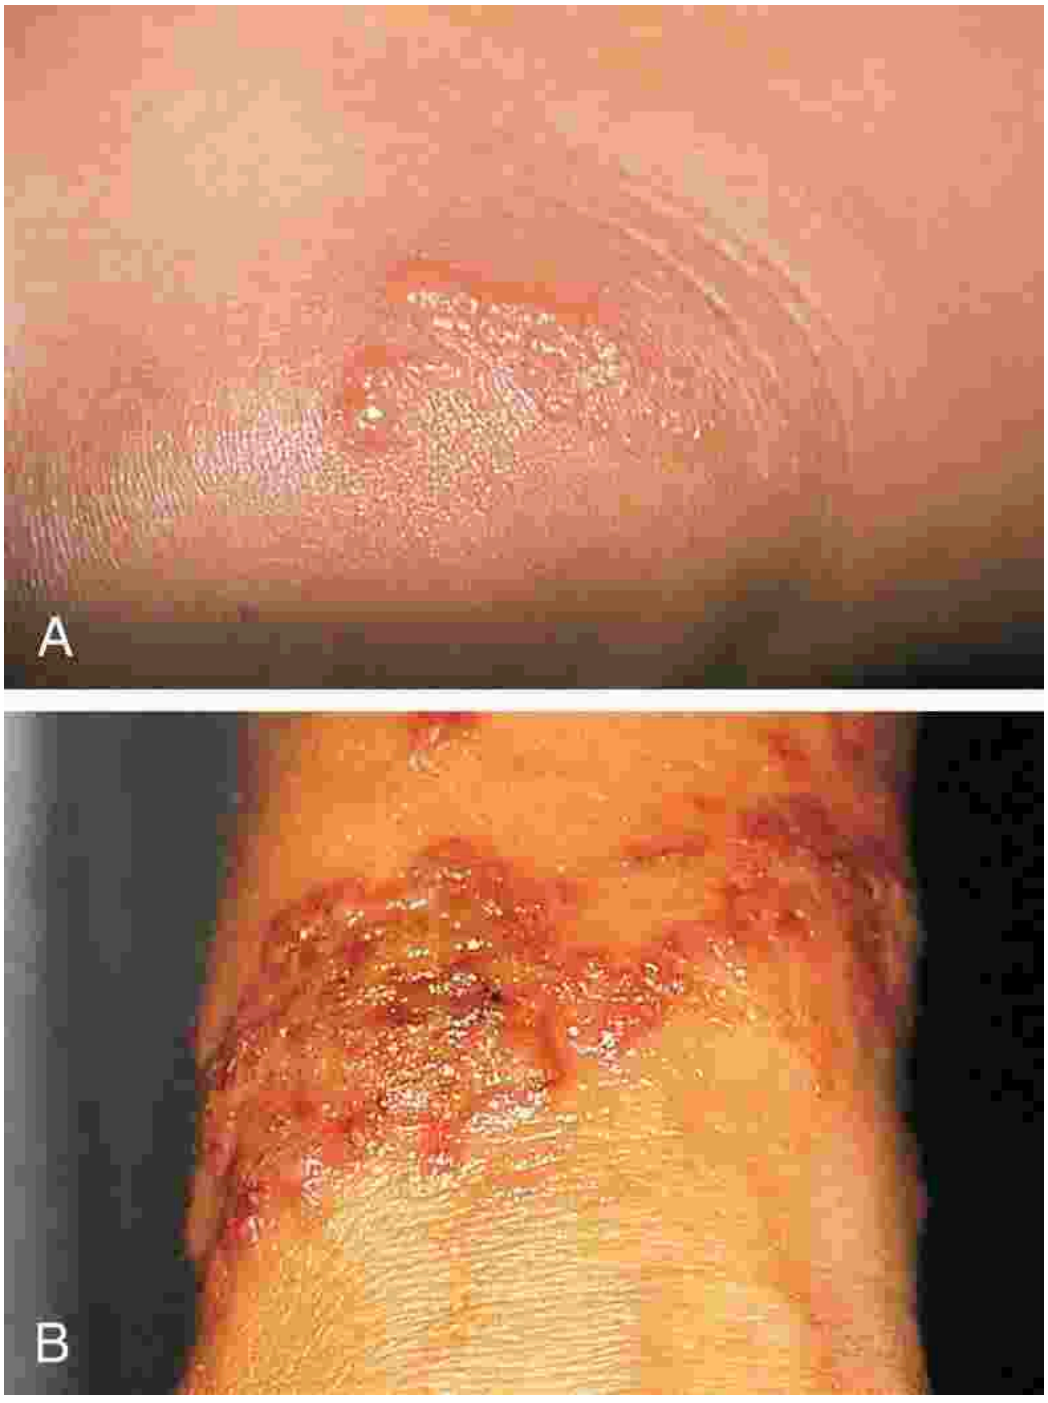

FIG. 46.5 Poison Ivy.
(A) Poison ivy on knee. **(B)** Poison ivy dermatitis.
(Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

The manifestations of allergic contact dermatitis include erythema and edema with pruritic (itching) vesicular lesions, typically seen in the areas of allergen contact. The pattern of distribution provides clues to the source of the antigen (e.g., hands exposed to chemical solutions or boundaries from rings, necklaces, or bracelets). The antigen must be removed for the inflammatory response to resolve and tissue repair to begin. Treatment may require topical or systemic steroids.

Irritant Contact Dermatitis

Irritant contact dermatitis (ICD) is a localized, nonspecific inflammatory dermatitis caused by the direct cytotoxic action of the offending physical or chemical agent. Unlike ACD, ICD is not mediated by the immune system. The severity of the inflammation is related to the concentration of the irritant, length of exposure, disruption of the skin barrier and age. Irritation can occur from almost anything, especially if the epidermal barrier is compromised in any way. Common irritants include water (from frequent hand washing), detergents, solvents, acids, alkalis, fiberglass, dust, metal salts, insecticides, herbicides, dyes, fragrances, and preservatives. Irritant contact dermatitis is the most common type of occupational dermatitis, particularly in hairdressers, bakers, cooks, mechanics, industry workers, healthcare workers, and housekeepers. The hands are the primary site of involvement. The skin lesions are similar in appearance to ACD but range from mild pruritic xerosis and erythema to more severe formation of eczematous skin changes, vesicle and bullae formation, or even tissue necrosis. Patch testing can help to differentiate irritant from allergic contact dermatitis. Removing the source of irritation and using topical agents provide effective treatment.[18]

Atopic Dermatitis

Atopic dermatitis (atopic eczema) is common in individuals with a history or family history of atopy eczema, asthma, and/or allergic rhinitis) and is associated with IgE antibodies. It is more common in

infancy and childhood, but some individuals are affected throughout life. Specific details of this disorder are presented in Chapter 47.

Stasis Dermatitis

Stasis dermatitis (or stasis eczema) usually occurs on the lower extremities as a result of venous hypertension, incompetent venous valves, calf muscle pump failure, or any combination of these. It is associated with edema, varicosities, phlebitis, and vascular trauma (Fig. 46.6). The lesions must be different from those caused by arterial occlusive disease, diabetic neuropathy, malignancy, pyoderma gangrenosum, and other inflammatory ulcers. Pooling of venous blood traps neutrophils that may release oxidants and proteolytic enzymes. Increased venous pressure widens interendothelial pores and, coupled with the deposition of red blood cells, fibrin, and other macromolecules, makes them unavailable for repair while promoting inflammation.[19]

FIG. 46.6 Stasis Ulcer. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Erythema and pruritus develop initially, followed by scaling, telangiectasia, and hyperpigmentation, specifically called hemosiderin staining. As the disease progresses, vascular permeability increases, causing the chronic release of fibrin, cytokines, leukocytes, and inflammatory mediators which can lead to tropic skin changes, lipodermatosclerosis, and ulcerations, particularly above the medial or lateral malleolus. Ulcerations are typically difficult to treat, and re-ulceration frequently occurs. Preventive treatment includes elevating the legs as often as possible,

not wearing tight clothes around the legs, and not standing for long periods. Defined infections are treated with antibiotics. Chronic lesions with ulceration are treated with moist dressings, external compression/dressings, and vein ablation surgery. New treatments include biologics, such as bilayer living skin construct, fibroblast derivatives, and extracellular matrices. Non-biologic products such as poly-*N*-acetyl glucosamine have been beneficial in clinical trials.[20]

Seborrheic Dermatitis

Seborrheic dermatitis is a common, chronic, relapsing, inflammation of the skin occurring in areas rich in sebaceous gland activity such as the scalp, eyebrows, eyelids, ear canals, nasolabial folds, axillae, chest, or back (Fig. 46.7). The cause is unknown, but proposed etiologies include genetic predisposition, *Malassezia* fungal infection, immunosuppression, and epidermal hyperproliferation. The lesions develop from infancy to old age with periods of remission and exacerbation. The most commonly recognized and most mild form of seborrheic dermatitis is scalp dandruff. In more severe disease, lesions appear as pruritic erythematous plaques with greasy white or yellow scales.

FIG. 46.7 Seborrheic Dermatitis. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Topical therapy includes antifungal shampoos, calcineurin inhibitors (immunomodulating agents that reduce inflammation), and low-dose steroids for acute flares. Non-pharmacologic topical preparations may be used to control facial symptoms. Corticosteroids should not be used for maintenance therapy.[21]

Papulosquamous Disorders

Psoriasis, pityriasis rosea, lichen planus, acne vulgaris, hidradenitis suppurativa, acne rosacea, and lupus erythematosus are characterized by papules, scales, plaques, and erythema. Collectively they are described as **papulosquamous disorders**.

Psoriasis

Psoriasis is a chronic, relapsing, proliferative, immune mediated inflammatory disorder that involves the skin, scalp, and nails, often accompanied by systemic comorbidities. The prevalence of psoriasis

is between 0.5% and 11% in adults and is more prevalent in high-income countries and regions with older populations.[22] Genetic risk factors are predominant, and several alleles have been identified. Environmental factors, such as skin trauma or infection and smoking, can promote exacerbations. The onset is generally established by 40 years of age, but it can occur in children. The onset of psoriasis later in life is less familial and more secondary to comorbidities, such as obesity, smoking, hypertension, and diabetes.

The inflammatory cascade of psoriasis involves complex interactions between macrophages, fibroblasts, dendritic cells, natural killer cells, T-helper cells, and regulatory T cells. These immune cells lead to the secretion of numerous inflammatory mediators, such as tumor necrosis factor-α (TNF-α), and other cytokines, including IL-12, IL-17, and IL-23, that promote keratinocyte proliferation, angiogenesis, and infiltration of other immune cells into the lesions of psoriasis. IL-23–mediated activation of the T-helper cell 17 pathway is thought to be a predominant mechanism of disease. These inflammatory markers are the target for several therapeutic drugs known as biologic agents.[23]

Both the dermis and the epidermis are thickened because of cellular hyperproliferation, altered keratinocyte differentiation, and expanded dermal vasculature. Epidermal shedding time escalates to 3 to 4 days from the norm of 14 to 20 days. Cell maturation and keratinization are bypassed, and the epidermis thickens and plaques form. The loosely cohesive keratin gives the lesion a silvery appearance. Capillary dilation and increased vascularization occur from release of angiogenic factors, such as vascular endothelial growth factor (VEGF), and accommodate the increased cell metabolism and causes erythema. The disease can be mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions. Psoriasis is marked by remissions and exacerbations.

The clinical features depend on the types of psoriasis. The variants include plaque (psoriasis vulgaris), inverse, guttate, pustular, and erythrodermic. **Plaque psoriasis** is the most common. The typical

plaque psoriatic lesion is a well-demarcated, thick, silvery, scaly, erythematous plaque surrounded by normal skin that can appear anywhere on the body (Fig. 46.8). Small, erythematous papules enlarge and coalesce into larger inflammatory lesions on the face, scalp, elbows, knees, and sites of trauma (Koebner phenomenon). Pruritus is common with moderate to severe psoriasis or during exacerbation.

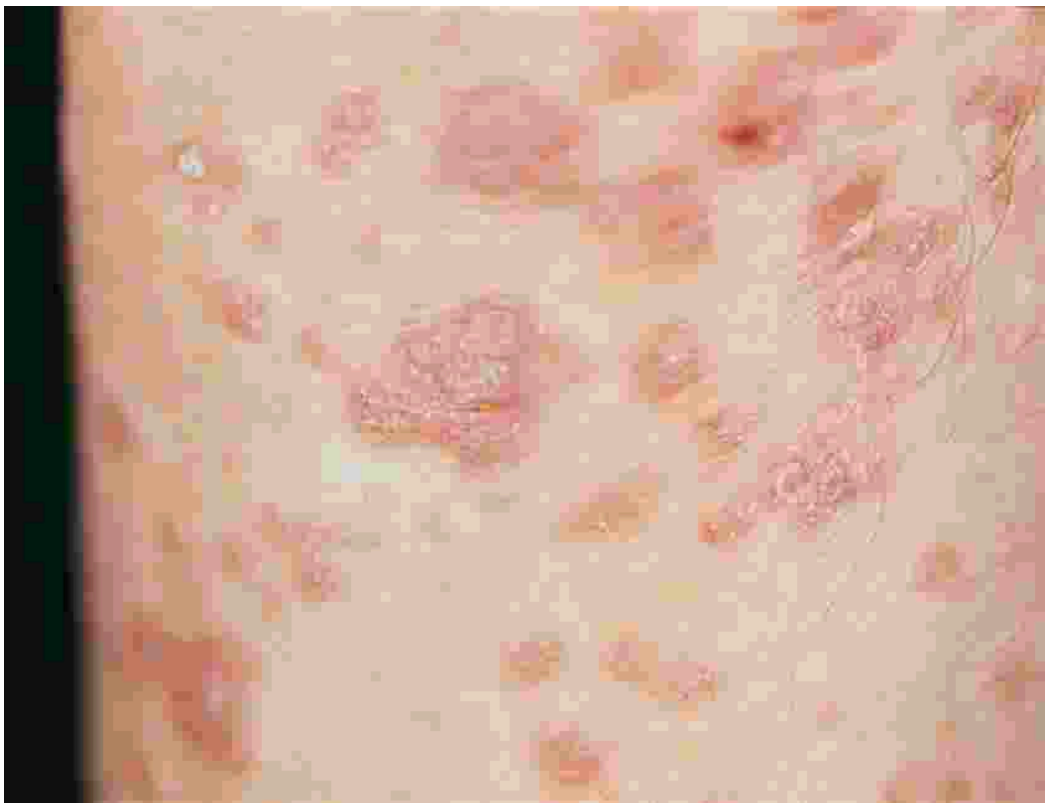

FIG. 46.8 Plaque Psoriasis.
Typical oval plaque with well-defined borders and silvery scale. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Other types of psoriasis are less common. **Inverse psoriasis** is rare and involves lesions that develop in skin folds (e.g., the axilla or groin). Often misdiagnosed as fungal infections, they are large, smooth, dry, and deep red. In **guttate psoriasis**, small papules

appear suddenly on the trunk and extremities a few weeks after a streptococcal respiratory tract infection (Fig. 46.9). Guttate psoriasis may resolve spontaneously in weeks or months. **Pustular psoriasis** appears as blisters of noninfectious pus (collections of neutrophils) that develop over areas of plaque psoriasis. **Erythrodermic (exfoliative) psoriasis** is characterized by widespread red, scaling lesions that cover a large body surface area (BSA) and is often accompanied by pruritus or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.

FIG. 46.9 Guttate Psoriasis After Streptococcal Infection.
Numerous uniformly small lesions may abruptly occur after streptococcal pharyngitis. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Psoriatic arthritis (PA) is associated with the proinflammatory cytokines that cause psoriatic skin lesions. Approximately 70% of individuals presenting with PA have a history of psoriasis. There are

several phenotypes, including asymmetric arthritis of the major joints, enthesitis (inflammation of ligaments and tendons), dactylitis (involvement of finger and toes), and nail disease. **Psoriatic nail disease** can occur in all psoriasis subtypes with pitting, onycholysis, subungual hyperkeratosis, and nail plate dystrophy.

Psoriasis also is a risk factor for a number of comorbidities, including uveitis; inflammatory bowel disease; metabolic syndrome, including hypertension, insulin resistance, dyslipidemia, and abdominal obesity; depression and anxiety; chronic obstructive pulmonary disease; and increased risk for atherosclerosis, cardiovascular disease, and stroke that is independent of traditional risk factors for these diseases.[24] The underlying mechanisms are thought to be related to increased levels of systemic proinflammatory mediators and chemokines, which are central to the chronic inflammation, oxidative stress, and angiogenesis of psoriasis.

Treatment is individualized and related to maintaining skin moisture, reducing epidermal cell turnover and pruritus, promoting immunomodulation, preventing and managing comorbidities, and assuring support systems to maintain quality of life. Mild psoriasis is treated with topical corticosteroids, vitamin D analogues, emollients, keratolytic agents (e.g., salicylic acid), and ultraviolet light therapy. Systemic therapy is indicated for moderate to severe disease or with the presence of psoriatic arthritis and includes methotrexate, acitretin, cyclosporine (short term) and biologics that target TNF-α, IL-17, and IL-23.[25,26]

Pityriasis Rosea

Pityriasis rosea is an acute and self-limiting inflammatory disorder that occurs more often in young adults. The cause is thought to be a herpes-like virus (e.g., human herpesvirus 6 [HHV6-roseola] and HHV7).[27] Pityriasis rosea begins as a single lesion **(herald patch)** (Fig. 46.10) that is circular, demarcated, and salmon-pink, approximately 3 to 10 cm in diameter, and usually located on the trunk. Early lesions are maculopapular, followed by lesions that

develop within 14 to 21 days and extend over the trunk and upper part of the extremities, although rarely on the face. The small, erythematous, rose-colored papules expand into characteristic oval lesions that are bilateral, symmetrically distributed, and have raised, scaly borders. The pattern of distribution on the back follows the skin lines around the trunk and resembles a drooping pine tree. The scales are slough from the margin of the lesions, forming a collarette pattern. Pruritis is the most common symptom. Occasionally headache, fatigue, or sore throat precedes the development of the lesions. One study has found an increased risk for miscarriage or premature delivery associated with pityriasis rosea infection.[28]

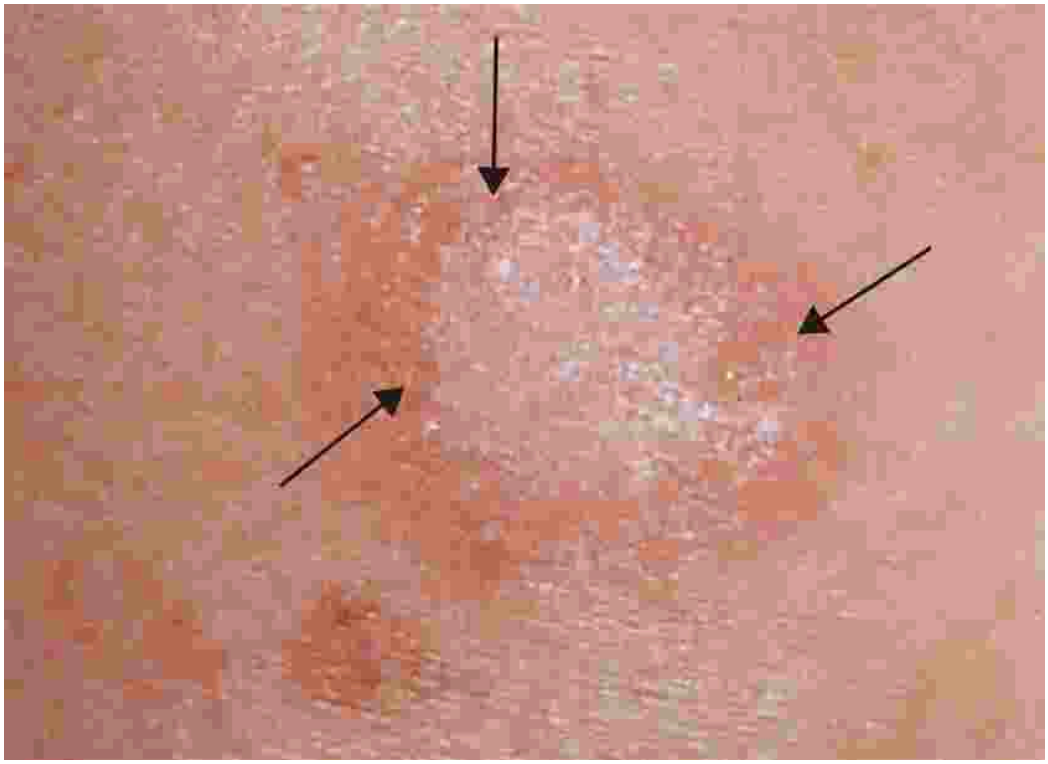

FIG. 46.10 Pityriasis Rosea Herald Patch. A collarette pattern has formed around the margins *(arrows)*. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

The diagnosis of pityriasis rosea follows the clinical appearance of the lesion. Secondary syphilis, psoriasis, drug eruption, nummular eczema, and seborrheic dermatitis are among the differential diagnosis considerations. The disorder is usually self-limiting and resolves in a few months with symptomatic treatment for pruritus or cosmetic concerns. Ultraviolet light (with some risk for hyperpigmentation) or systemic corticosteroids have been used to control pruritus. Acyclovir and erythromycin also may be used for treatment.[27]

Lichen Planus

Lichen planus (LP) is a benign autoimmune inflammatory disorder of the skin, nail, and mucous membranes with multiple clinical variations. The age of onset is usually between 30 and 70 years. The cause is unknown, but T cells, adhesion molecules, inflammatory cytokines, perforin, and antigen-presenting cells are involved. LP also is linked to numerous drugs and to the hepatitis C virus. The disorder begins with non-scaling, purple-colored, flat-topped, polygonal pruritic papules 2 to 4 mm in size, usually located symmetrically on the wrists, ankles, lower legs, and genitalia (Fig. 46.11). New lesions are pale pink and evolve into a dark violet color. Persistent lesions may be thickened and red, forming hypertrophic lichen planus.[0] Nail lichen planus manifests as thinning and splitting of nails. Part, or all, of the nail may be shed.

FIG. 46.11 Hypertrophic Lichen Planus on Arms.
(Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Oral lesions (oral lichen planus) appear as lacy white rings that must be differentiated from leukoplakia or oral candidiasis. Lesions may be precancerous in about 2% of cases.[29] Fine lines, known as *Wickham striae*, can be seen throughout the oral lesions on magnification. Oral lesions do not commonly ulcerate, but if present, they are painful and require treatment.

Pruritus is the most distressing symptom. The lesions are self-limiting and may last for months or years, with an average duration of 6 to 18 months. Post-inflammatory hyperpigmentation is a common consequence of the lesion. Approximately 20% of individuals have a recurrence. The diagnosis is made by the clinical appearance and the histopathology of the lesion. Treatment is individualized and includes topical, intralesional, or systemic corticosteroids, topical retinoids, immunomodulators (or both), and topical light therapy.[30]

Acne Vulgaris

Acne vulgaris is an inflammatory disorder of the pilosebaceous follicle (the sebaceous gland contiguous with a hair follicle) that usually occurs during adolescence. Details of this disorder are presented in Chapter 47.

Hydradenitis Suppurativa (Inverse Acne)

Hydradenitis suppurativa (inverse acne) is a chronic, inflammatory, recurring scarring disease of the pilosebaceous follicular ducts involving areas of skin where there are folds and hair follicles (Fig. 46.12). The incidence is unknown but is estimated at 1% to 4% of the population and is more common in females. The pathogenesis of the disease is complex and includes a combination of genetic, hormonal, immune, and environmental factors. Aggravating factors include smoking (the most significant factor, as nicotine activates keratinocytes, fibroblasts, and immunocytes), tight clothing, heat, perspiration, shaving of prone areas, obesity, and stress.[31] An aberrant response to commensal follicular bacteria results in inflammatory cytokine production with follicular hyperkeratosis and occlusion of the pilosebaceous unit causing peri folliculitis, abscess formation, sinus tracts, and scarring. The sweat glands are not primarily involved.

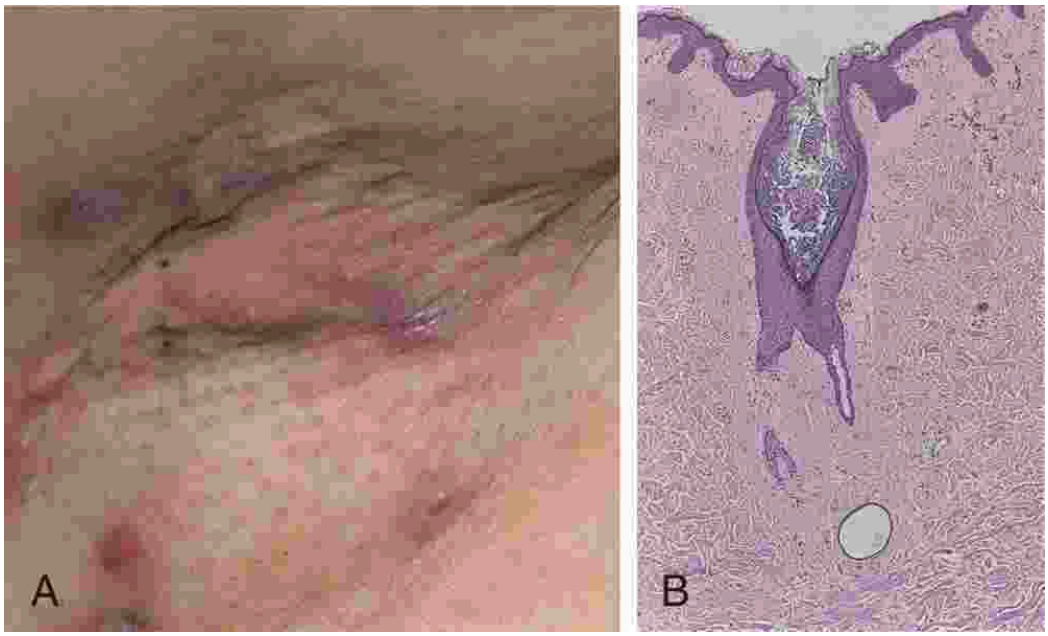

FIG. 46.12 Hydradenitis Suppurative.
(A) Characteristic painful pustules and draining sinus tract. (B) Histology shows follicular plugging and connection to a dilated apocrine duct. (A, Courtesy Kalman Watsky, MD; from Bolognia JL Jorizzo JL, Schaffer JV, eds. *Dermatology*, 3rd edition. Philadelphia: Saunders; 2012. B, From Bolognia JL, Jorizzo JL, Rapinin RP, eds. *Dermatology*, 2nd edition. Philadelphia: Saunders; 2008.)

The lesions present as deep, firm painful subcutaneous nodules that tract and rupture horizontally under the skin. They are different from furuncles because furuncles extend vertically and discharge onto the skin. Sites of involvement include apocrine gland–rich areas (e.g., the axillae, groin, perianal region, and perineum). Other areas include the neck, adjacent scalp, back, buttocks, scrotum or labia, and inframammary or mammary region in women. Lesions may be minimal or severe, with multiple draining fistulas. Complete, spontaneous resolution is rare. The disease can recur for years with negative effects on quality of life. Treatment includes smoking cessation, anti-inflammatories, antibiotics, immunotherapy, combination therapy, and incision and drainage of nodules.[32]

Acne Rosacea

Acne rosacea is a chronic inflammation of the skin that develops in middle-aged adults and occurs more commonly in women and those with fair skin. There are four subtypes of lesions, and they may occur singly or in combination: erythematotelangiectatic, papulopustular, phymatous (nodular), and ocular (eyelids and ocular surface). The exact cause is unknown, but genetic factors, immune dysregulation, and neurovascular dysregulation are involved. There is a familial tendency, and several genes have been identified. Factors that trigger immune responses, such as neurovascular dysregulation and infection, include chronic sun exposure and damage, heat, drinking alcohol or hot beverages, hormonal fluctuations, and stress. *Demodex folliculorum* (mites) and microorganisms residing on their surface are associated with the pathogenesis of rosacea.[33] The most common lesions are erythema, papules, pustules, and telangiectasia. They occur in the middle third of the face, including the forehead, nose, cheeks, and chin (Fig. 46.13). Neurovascular dysregulation is associated with chronic, inappropriate vasodilation, resulting in flushing, a burning sensation, and sun sensitivity. Sebaceous hypertrophy, fibrosis, and telangiectasia may be severe enough to produce an irreversible bulbous appearance of the nose, known as rhinophyma. Disorders of the eye often accompany rosacea or can occur independently of other manifestations, particularly conjunctivitis and keratitis, which can result in visual impairment.[34]

FIG. 46.13 Granulomatous Rosacea.
Pustules and erythema occur on the forehead,

cheeks, and nose. (From Dinulos GH. *Habif's clinical dermatology*, 7th edition. Philadelphia: Saunders.)

Treatment includes photoprotection (sunscreen, wide-brimmed hat), along with avoidance of other triggers. Both topical and systemic therapies may be effective. Laser therapy can be effective for removing telangiectasias. Surgical excision of excessive tissue may be required for rhinophyma.[35]

Lupus Erythematosus

Lupus erythematosus is a systemic inflammatory, autoimmune disease with cutaneous manifestations (see Chapter 9). Cutaneous lupus erythematosus (CLE) is limited to the skin but can progress to systemic lupus erythematosus (SLE).

Cutaneous lupus erythematosus

Cutaneous lupus erythematosus (CLE) usually occurs in genetically susceptible adults, particularly women in their late thirties or early forties, but people of any age can be affected. Three subtypes of CLE have been described with specific manifestations of the disease: acute, subacute, and chronic. The lesions may be single or multiple and vary in size (Fig. 46.14). Often the lesions are located on light-exposed areas of the skin, and photosensitivity is common. The face is the most common site of lesion involvement, with a butterfly pattern of distribution found over the nose and cheeks. The characteristic clinical manifestations of the different categories of CLE are summarized in Table 46.7.

FIG. 46.14 Subacute Cutaneous Lupus (Discoid Lupus Erythematosus). (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Table 46.7

Categories and Manifestations of Cutaneous Lupus Erythematous

Category of Dle	Clinical Manifestations
Acute	
Localized	Butterfly pattern of erythema over bridge of nose and malar areas of face (malar rash); may have fine surface scales and underlying edema; scalp areas may develop alopecia; lasts for hours to days
Generalized	Diffuse or papular erythema of face, upper trunk, or extremities; develops quickly and lasts hours to days
Subacute	Erythematous macules and papules that evolve into *papulosquamous* or *annular* plaques developing on sun-exposed areas of the upper body (V area of neck, upper chest, back, shoulders, extensor surface of arms and hands); can be associated with reaction to drugs; may be accompanied by mild systemic disease
Chronic	Classic discoid lupus erythematosus is the most common form; lesions are red to purple macules or papules with a superficial brownish scale involving head, scalp and neck; scale can penetrate hair follicle leaving a carpet-tack appearance when removed; may have residual scarring, dermal atrophy hypopigmentation, alopecia, and telangiectasia; Raynaud phenomenon occurs in some individuals

Data from Data from Hejazi EZ, Werth VP. Cutaneous lupus erythematosus: An update on pathogenesis, diagnosis and treatment. *American Journal of Clinical Dermatology*, 2016;17(2):135–146; Lenormand C, Lipsker D. Lupus erythematosus: Significance of dermatologic findings. *Annales de Dermatologie et de Venereologie*, 2021;148(1):6–15.

The cause is unknown but is related to genetic and environmental factors and an altered immune response to an unknown antigen or to UV B wavelengths. There is development of self-reactive T and B cells, a decreased number of regulatory T cells, infiltration of neutrophils, and increased levels of proinflammatory cytokines. Autoantibodies and immune complexes infiltrate the dermal-epidermal junction and cause tissue damage and inflammation.[36] Exacerbation of manifestations can occur with UV exposure, certain drugs (e.g., hydrochlorothiazide and proton pump inhibitors) and smoking. Skin biopsy with immunofluorescent observation reveals lumpy deposits of immunoglobulins, including IgM, IgG, and C3. The revised Cutaneous Lupus Erythematous Disease Area and Severity Index (CLASI) can be used to assess disease severity.[37] Individuals with CLE must use sunscreen and sun protection because direct sun exposure initiates or exacerbates lesions (see Fig. 46.14).

The early lesion is asymmetric, a 1 to 2 cm raised red plaque with a brownish scale. The scale penetrates the hair follicle and leaves a visible follicle opening (carpet-tack appearance) when removed. The lesions persist for months and then resolve spontaneously or atrophy, causing a depressed scar. Healed lesions may have residual telangiectasia and hypopigmented scarring. Treatment options include sun protection and use of topical steroids, calcineurin inhibitors, antimalarial drugs (e.g., hydroxychloroquine sulfate), and targeted immunotherapy. These medications must be used with caution to prevent serious side effects.[38]

Vesiculobullous Diseases

Vesiculobullous skin diseases share a common characteristic of vesicle, or blister, formation. Two such diseases are pemphigus and erythema multiforme.

Pemphigus

Pemphigus (meaning to blister or bubble) is a group of rare, life-threatening autoimmune diseases of the intradermal skin and oral mucous membranes with formation of autoantibodies against desmoglein, an adhesion molecule (Fig. 46.15). **Bullous pemphoid** is the formation of autoantibodies against hemidesmosome adhesion molecules that attach keratinocytes to the basement membrane causing subepidermal blistering. The cause of antibody formation is unknown. Pemphigus can occur in all age groups but is more prevalent in persons between 40 and 50 years of age. There is a genetic predisposition, as well as environmental (viral infections, drug-induced, dietary intake, or physical effects, such as radiation or surgery) and endogenous (emotional or hormonal stressors) influences. There are four main groups of pemphigus:

- **Pemphigus vulgaris** is the most common form and is caused by circulating immunoglobulin G (IgG) autoantibodies and C3 complement bind to the desmoglein-3 adhesion molecules, resulting in the destruction of cell-to-cell adhesion (acantholysis) at the desmosomal cell junction in the suprabasal layer of the epidermis with fluid accumulation and the resulting symptom of blister formation. With rupture, the lesion can evolve into painful erosions in the skin or mucosal surface and leads to increased risk of water loss, electrolyte imbalance, and infections.[39] Oral lesions precede the onset of skin blistering, which is more prominent on the face, scalp, and axilla.
- **Pemphigus foliaceus** is a milder form of the disease and involves demsmoglen-1 with acantholysis at the subcorneal level with blistering, erosions, scaling, crusting, and

erythema, usually of the face and chest. Oral mucous membranes are not involved.

- **Paraneoplastic pemphigus** is the most severe form of pemphigus and is associated with lymphoproliferative neoplasms. Internal organs, including lungs, thyroid, kidney, smooth muscle, and the gastrointestinal tract, are also involved, leading to the term paraneoplastic autoimmune multiorgan syndrome. In contrast to pemphigus vulgaris, the lesions develop from inflammatory papules or macules rather than normal skin.
- **IgA pemphigus** is the most benign form of pemphigus characterized by tissue-bound and circulation of IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis. Acantholysis is not as severe as that in pemphigus vulgaris, but there is still vesicle or pustule formation with erythematous plaques with crusts.

FIG. 46.15 Pemphigus.
Generalized eruption with blisters arising from an edematous erythematous annular base. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

The diagnosis of pemphigus is made from the clinical, histologic findings of autoantibodies at the site of blister formation and positive direct immunofluorescence microscopy. The clinical course of the disease may range from rapidly fatal to relatively benign. The primary treatment for pemphigus is systemic corticosteroids in combination with adjuvant immunosuppressants.[40]

Erythema Multiforme

Erythema multiforme (EM) is an uncommon syndrome characterized by inflammation of the skin and/or mucous membranes. EM is often associated with a T-cell-mediated type IV hypersensitivity reaction to a microorganism, particularly viral infections (e.g., herpes simplex virus, Epstein-Barr virus,

histoplasmosis, and *Mycoplasma pneumoniae*) or related to drug reactions. Erythema multiforme major has moderate to severe mucosal involvement and some systemic symptoms, such as fever, weakness, and arthralgia. Erythema multiforme minor is characterized by inflammation of the skin without (or with very minor) mucosal disease and without associated systemic symptoms. Both EM minor and major have characteristic "bull's-eye" or "target" lesions develop on the skin surface with a central dusky region surrounded by concentric rings or alternating edema, and inflammation commonly over the extensor surfaces of the limbs. The lesions usually occur suddenly in groups over a period of 2 to 3 weeks. Urticarial plaques, 1 to 2 cm in diameter, can develop without the target lesion (Fig. 46.16). EM major includes mucous membrane lesions and erythematous plaques which can be quite painful. Single or multiple vesicles or bullae may arise on a part of the plaque, accompanied by pruritus and burning. EM is usually self-limiting, and the lesions heal within a few weeks.[41]

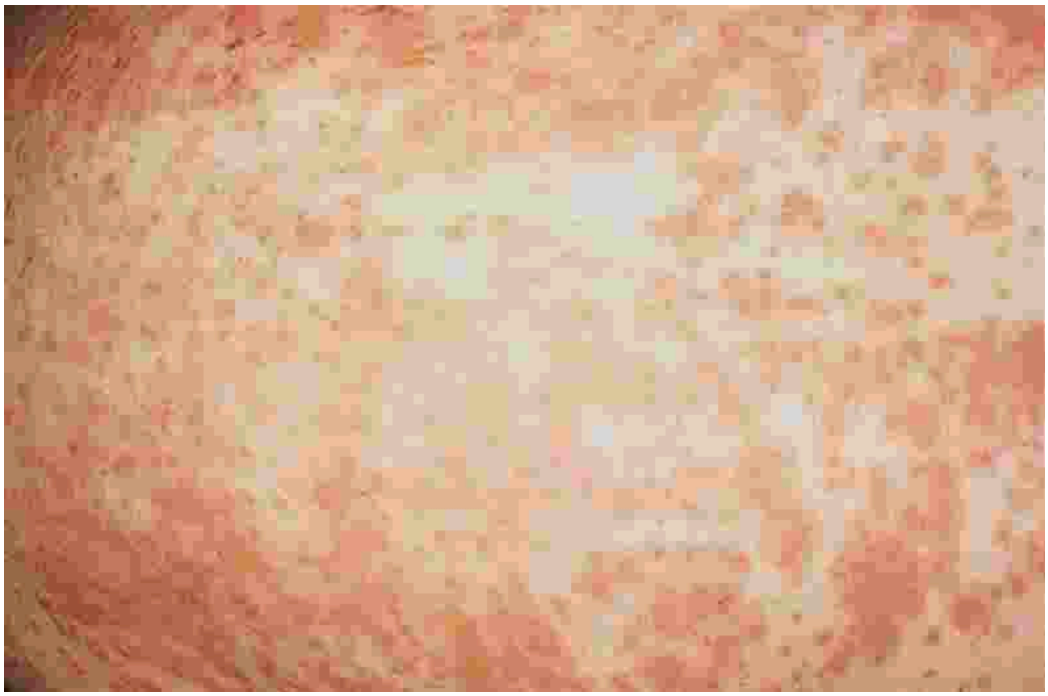

FIG. 46.16 Erythema Multiforme Caused by Doxepin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Stevens-Johnson syndrome (SJS) and **toxic epidermal necrolysis (TEN)** are the same disease with a continuum of symptoms based on clinical presentation and severity. Both conditions are rare, distinct from EM, and are type IV hypersensitivity reactions to drugs. They are associated with severe mucocutaneous drug reactions with extensive keratinocyte cell death, extensive bullous epidermal detachment, mucositis, and organ involvement. SJS is less severe and involves <10% of the BSA. TEN involves >30% of the BSA. SJS/TEN overlap describes individuals with between 10% and 30% of BSA. The mechanism of cell injury is not completely understood, but involves cytotoxic T lymphocytes (CTLs), human leukocyte antigen (HLA), and the major histocompatibility complex (MHC).[42]

Prodromal symptoms of SJS/TEN include fever, headache, malaise, sore throat, and cough, which develop in approximately one third of cases. Vesicles and bullae form and the skin begins to

slough as the disease progresses. Secondary erosions and crusts then develop. Mucosal involvement may be extensive and involve the mouth, air passages, esophagus, urethra, and conjunctiva. Blindness can result from corneal ulcerations. Difficulty eating, breathing, and urinating may develop, with severe manifestations. Severe cases of the disease can be fatal as the complications of extensive skin detachment can include acute kidney injury, bacteremia, multiorgan system failure, sepsis, and death.

Establishing a medication history is vital to the diagnosis of SJS/TENS. Skin biopsy findings are supportive, but not independently diagnostic. Any ongoing drug therapy should be withdrawn and reevaluated, and underlying infections should be treated. Treatment is individualized according to severity and, in severe cases, requires the care of a burn unit. Mortality can be as high as 25%. Ophthalmic, kidney, and lung involvement require special care. In mild cases, resolution occurs in 8 to 10 days, usually without scarring. Mucosal lesions may take 6 weeks to heal.[43]

Infections

Cutaneous infections are common forms of skin disease. They generally remain localized, although serious complications can develop with systemic involvement that can be life-threatening. The types of skin infection include bacterial, viral, and fungal. The microbiome (normal flora) of the skin consists of aerobes, yeast, and anaerobes and often provides protection against pathogens that cause skin infections, including *Staphylococcus* and *Streptococcus*.[44]

Bacterial Infections

Most acute bacterial skin and skin-structure infections are caused by local invasion of pathogens. Coagulase-positive *Staphylococcus aureus* and, less often, beta-hemolytic streptococci are the common causative microorganisms. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is also a cause of serious skin infection, particularly skin abscesses (Box 46.3).

Box 46.3

Community-Acquired Methicillin-Resistant *Staphylococcus aureus*

Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is a serious skin and soft tissue infection that includes abscesses, cellulitis, and necrotizing fasciitis and can serve as a source for bloodstream infections. Infections are documented among healthy individuals who have no known risk factors, that is, no recent hospitalization, surgical procedures, or prolonged antibiotic treatment. Outbreaks have been documented among athletic teams, among prisoners, in daycare centers, and homeless shelters. CA-MRSA strains are epidemiologically and clonally different from hospital or nursing home acquired MRSA, although CA-MRSA onset in hospitals is emerging. The most common tests involve genotyping for the staphylococcal chromosomal cassette mec (SCCmec) type IV that encodes resistance to methicillin and Panton-Valentine leukocidin and other genes that encode virulence toxins. The USA300-0114 strain has been epidemic in the United States and is difficult to treat with the development of biofilm formation. It is spreading internationally and has caused life-threatening pneumonia, osteomyelitis, and septic arthritis. Virulence factors include toxins (hemolysins and leukocidins), immune-evasive surface factors (e.g., capsule and protein A) and enzymes that promote tissue invasion (e.g., hyaluronidase). CA-MRSAs are more sensitive to antibiotic treatment and there is a wider choice of antibiotic treatment options for CA-MRSA compared with hospital-acquired MRSA. CA-MRSA is usually susceptible to a variety of oral non–beta-lactam antibiotics, including trimethoprim-sulfamethoxazole, clindamycin, tetracyclines, and linezolid. Parenteral therapy with vancomycin or daptomycin can also be considered. Ceftaroline has been effective for both skin and systemic infections. Dalbavancin, oritavancin, and tedizolid are options for drug resistant strains. Mupirocin may be used to clear MRSA from nasal secretions if

cultures show contamination in the nose. New drugs are under investigation. Preventive measures include practicing good hand hygiene, applying antiseptics, covering cuts and abrasions, using antibacterial soaps for showers after contact sports, avoiding sharing towels and razors, and frequently washing towels. Development of a vaccine is a priority for prevention.

Data from Chalmers SJ, Wylam ME. Methicillin-resistant *Staphylococcus aureus* infection and treatment options. *Methods in Molecular Biology*, 2020;2069:229–251.

Folliculitis

Folliculitis is an inflammation of the hair follicle and is typically infectious, caused by bacteria, viruses, parasites, or fungi; *S. aureus* is a common culprit. Noninfectious causes include trauma or plugging of the follicle. The infection develops from proliferation of the microorganism around the opening and inside the follicle. Inflammation is caused by the release of chemotactic factors and enzymes from the bacteria. The lesions appear as papules or pustules with a surrounding area of erythema. Lesions are most prominent on the scalp and extremities but can occur on any hair-bearing area. Prolonged skin moisture, occlusive clothing, topical agents, skin trauma (e.g., shaving facial hair), and poor hygiene are associated contributing factors to the development of folliculitis. Cleaning with soap and water and topical antibiotics are effective treatments.

Furuncle, or "boil" is an inflammatory nodule involving a hair follicle. It may develop from a preceding folliculitis that spreads through the follicular wall into the surrounding dermis. The invading microorganism is usually *S. aureus*, including CA-MSRA. Any skin area with hair can be affected. The initial lesion is a well-circumscribed firm, red, painful nodule 1 to 5 cm in diameter (Fig. 46.17). Within a few days, the erythematous nodules change to a large, fluctuant, and tender cystic nodule that may be accompanied by cellulitis. No systemic symptoms are present, and the lesion may drain large amounts of pus and necrotic tissue.

FIG. 46.17 Furuncle of the Forearm. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

A **carbuncle** is a coalescence of several furuncles and usually occur on the back of the neck, the upper back, and the lateral thighs. The lesion begins in the subcutaneous tissue and lower dermis as a firm mass that evolves into an erythematous, painful, swollen abscess that drains through many openings. Chills, fever, and malaise can occur during the early stages of lesion development.

Furuncles and carbuncles are treated with warm compresses to provide comfort and promote localization and spontaneous drainage. Abscess formation, recurrent infections, extensive lesions, or lesions associated with cellulitis or systemic symptoms require incision and drainage and are treated with topical or systemic antibiotics.[45]

Cellulitis

Cellulitis is an infection of the dermis and subcutaneous tissue usually caused by group A *Streptococcus, Streptococcus* pyogenes, or *Staphylococcus aureus* (including methicillin-resistant strains). Cellulitis can occur as an extension of a skin wound, as an ulcer, or

from a furuncle or carbuncle. Risk factors include diabetes mellitus, edema, peripheral vascular disease, tinea pedis, insect bites, and immune suppression from disease or medications. The infected area is erythematous, warm, edematous, painful, and without a distinct border. It can extend to the lymphatic system and the blood causing systemic infection.

Cellulitis must be differentiated from necrotizing fasciitis. **Necrotizing fasciitis** is a rare, rapidly spreading infection. It is commonly caused by *Streptococcus pyogenes*, which resists phagocytosis and releases toxins. Infection starts in the fascia, muscles, and subcutaneous fat, with subsequent necrosis of the overlying skin and can progress to sepsis and death without early diagnosis and treatment. Treatment requires antibiotics and often surgical debridement to prevent toxic shock syndrome.[46]

Erysipelas

Erysipelas is an acute, nonpurulent, superficial infection of the upper dermis and superficial lymphatics most often caused by beta-hemolytic streptococci. The face, ears, and lower leg are common sites of involvement. Similar to cellulitis, erysipelas is nearly always unilateral. Systemic manifestations such as chills, fever, and malaise often precede the onset of lesions by hours to days. The initial lesions appear as firm, red spots that enlarge and coalesce to form a clearly circumscribed, advancing, bright red, hot lesion with a raised border. There is a clear demarcation between involved and uninvolved skin, which differs from the presentation of cellulitis. Vesicles may appear over the lesion and at the border. Pruritus, burning, and tenderness are present. Cold compresses provide symptomatic relief, and systemic antibiotics are required to arrest the infection.[44]

Impetigo

Impetigo is a superficial infection of the skin that is caused by coagulase-positive *Staphylococcus* or beta-hemolytic streptococci. The

disease occurs in adults but is more common in children (see Chapter 47).

Lyme disease

Lyme disease is a multisystem inflammatory disease caused by the spirochete *Borreliella burgdorferi*. It is transmitted by the bite of the *Ixodes* tick, and it is the most frequently reported vector-borne illness. The highest incidence of Lyme disease is among children. The microorganism is difficult to culture; escapes immune defenses through antigenic variation; blocks complement-mediated killing; impedes release of antimicrobial peptides, leukocyte chemotaxis, and antimicrobial killing; and hides in tissue. It spreads to other tissues by entering capillary beds.

Symptoms of the disease occur in three stages, although about half of infected individuals are symptom free. Early localized infection occurs soon after the bite (within 3 to 32 days), presenting with the erythema migrans (bull's-eye rash). This commonly appears at the site of tick attachment. Erythema migrans is a T-cell–mediated response. Within days to weeks after the onset of the illness, there is *disseminated infection*, with secondary erythema migrans, usually with myalgias, arthralgias, and more rarely, meningitis, neuritis, or carditis. Late Lyme disease syndrome, or *chronic Lyme disease*, may develop months to years after the initial infection and antibiotic therapy. Symptoms include arthritis, typically involving one or a few large joints; encephalopathy, polyneuropathy, and heart failure are less prominent but can also occur. *Post-treatment Lyme disease syndrome* is the persistence of pain, fatigue, insomnia, depression, and/or difficulty thinking that lasts for 6 months or more with the absence of an identifiable infection.

The diagnosis of Lyme disease is based on the clinical presentation and history of the tick bite, if known. Serologic tests are used to confirm the diagnosis, although there is a delayed antibody response and the test may be negative during the first 3 weeks after infection. Antibiotics (e.g., doxycycline [not used in children younger than 8 years or in pregnant or breast-feeding women], amoxicillin, or

cefuroxime) are used for treatment.[47] Reinfection can occur. There is currently no vaccine for Lyme disease.[48]

Viral Infections

Herpes simplex virus

Skin infections with **herpes simplex virus (HSV)** are commonly caused by two types of HSV: HSV-1 and HSV-2. Either type can occur in different parts of the body, including oral and genital locations. Encephalitis is a rare manifestation. Their differences are distinguished by laboratory tests. HSV-1, transmitted by contact with infected oral secretions, is generally associated with oral infections (cold sore or fever blister) or infection of the cornea (herpes keratitis) or mouth (gingivostomatitis), but it can also cause genital herpes. With initial (primary) infection, the virus infects epithelial cells, embeds in sensory nerve endings, and moves by retrograde axonal transport to the dorsal root ganglion, where the virus develops lifelong latency by inhibiting apoptosis of target cells. The incubation period ranges from 2 to 14 days. During the secondary phase, the lesions occur at the same site from reactivation of the virus. The virus travels down the peripheral nerve to the site of the original infection, where it is shed. Exposure to ultraviolet light, skin irritation, fever, fatigue, or stress may cause reactivation.

The lesions for HSV-1 appear as clusters of inflamed and painful vesicles on an erythematous base (e.g., within the mouth, over the tongue, on the lips, around the nose) (Fig. 46.18). Increased sensitivity, paresthesias, pruritus, and mild burning may occur before the onset of the lesions. The vesicles rupture, forming a crust. Lesions may last 2 to 6 weeks but usually resolve within 2 weeks. HSV-1 disease can be severe, especially in the immunocompromised host. Encephalitis, meningitis, respiratory tract infections, and esophagitis are rare.[49]

FIG. 46.18 Herpes Simplex.
Typical presentation with tense vesicles appearing on the lips and extending onto the skin. (From *Habif TP. Clinical dermatology: A color guide to diagnosis and therapy*, 4th edition. St. Louis: Mosby; 2004.)

Genital infections are more commonly caused by HSV-2. The virus is spread by skin-to-skin mucous membrane contact during viral shedding. Risk of infection is high in immunosuppressed persons or in persons who have sexual contact with infected individuals and among individuals who are asymptomatic. Vertical transmission

from mother to neonate is associated with significant neonatal neurologic morbidity and mortality.[50] The initial infection is asymptomatic. With recurrent exposure, the lesions begin as small vesicles that progress to ulceration within 3 to 4 days with pain, itching, and weeping. Treatment is symptomatic and includes topical or oral antiviral agents, topical lidocaine, and nerve blocks. Long-term suppression of HSV-1 and HSV-2 may be attempted with daily antiviral dosing. Progress is being made with prophylactic vaccines to prevent HSV infection.[51]

Varicella-zoster virus

Varicella (chickenpox) and **herpes zoster** (shingles) (see Chapter 47), also known as human herpesvirus 3, are caused by the same herpesvirus and spread via airborne droplets or via direct contact with the actively viral shedding lesions. Varicella-zoster virus (VZV) is highly infectious and enters the body via the respiratory tract, followed by rapid spread from the pharyngeal lymphoid tissue to circulating T lymphocytes, then enters the skin 10 to 21 days later. The virus remains latent in trigeminal and dorsal (sensory) root ganglia, followed years later by reactivation of the virus to cause herpes zoster (HZ). HZ has initial symptoms of pain and paresthesia localized to the affected dermatome (the cutaneous area innervated by a single spinal nerve; see Chapter 15), followed by vesicular eruptions, then crusting (Fig. 46.19). The thoracic or lumbar dermatome are the most common sites affected, but HZ can appear on any dermatome. If the ophthalmic branch of the trigeminal nerve is affected, it should be considered a medical emergency as it is sight-threatening. The rash does not typically cross the body's midline, although two or even three dermatomes adjacent may be affected. Local symptoms are alleviated with compresses, calamine lotion, baking soda, topical lidocaine, or nerve blocks.[52] Approximately 15% to 20% of individuals experience postherpetic neuralgia (PHN), particularly those older than age 60. There is no cure for herpes zoster. The varicella vaccine is safe and effective in

children and adults to prevent chicken pox. The herpes zoster vaccine is given to adults 60 years and older to prevent shingles.[52]

Diffuse involvement of a dermatome. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Warts

Warts (verrucae) are benign lesions of the skin caused by the many different types of human papillomavirus (HPV) that infect the stratified epithelium of skin and mucous membranes. The lesions can occur anywhere. Lesions can be flat, round, or fusiform and are typically elevated with a rough, grayish surface. Warts are transmitted by direct contact. Specific viruses are associated with specific kinds and locations of lesions. HPV 1 commonly affects the pressure points on the plantar surface of the feet producing plantar warts. Common warts (verruca vulgaris) occur most often in

children and are usually on the fingers (Fig. 46.20). Spontaneous remission occurs more readily in children (within about 2 years) than adults (several years or longer). Both topical and systemic retinoids have been used for treatment.[53]

FIG. 46.20 Verruca Vulgaris (Near Toes). (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Condylomata acuminata (venereal warts) are caused by HPV types 6 and 11. These warts are sexually transmitted and highly contagious. The cauliflower-like lesions occur in moist areas, along the glans of the penis, vulva, and anus (see Chapter 27). Oncogenic types of HPV (e.g., 16 and 18) are a primary cause of cervical and other types of cancer and are preventable by prophylactic vaccination.[54]

Fungal infections

The fungi causing superficial skin infections are called dermatophytes, and they thrive on keratin (stratum corneum, hair, nails). Fungal disorders are known as *mycoses;* when caused by dermatophytes, the mycoses are termed *tinea* (dermatophytosis or ringworm).

Tinea infections

Tinea infections are transmitted via direct contact with the causative organism, either through person to person contact or via non-living object (fomite), such as walking barefoot on a locker room floor. They are classified according to their location on the body. Fig. 46.21 shows the location and extension of tinea pedis. The most common sites are summarized in Table 46.8. Tinea is diagnosed by culture, microscopic examination of skin scrapings prepared with potassium hydroxide (KOH) wet mount, or observation of the skin with an ultraviolet light (Wood lamp) and dermoscopy. The spores fluoresce blue-green when exposed to ultraviolet light. Cultures establish the diagnosis for a particular type of fungus. Fungi have characteristic spores and filaments, known as ***hyphae***, that are more prominent when prepared in potassium hydroxide.[55] Treatment is related to the type of fungi and includes both topical and systemic antifungal medication.

FIG. 46.21 Tinea Pedis.
Inflammation has extended from the web area onto the dorsum of the foot. (Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Table 46.8

Common Sites of Tinea Infections

Site	Clinical Manifestations
Tinea capitis (scalp)	Scaly, pruritic scalp with bald areas; hair breaks easily
Tinea corporis (skin areas, excluding scalp, face, hands, feet, groin; also known as "ringworm")	Circular, clearly circumscribed, mildly erythematous scaly patches with slightly elevated ringlike border; some forms are dry and macular, and other forms are moist and vesicular with satellite pustules
Tinea cruris (groin, also known as "jock itch")	Small, erythematous, and scaling vesicular patches with well-defined borders that spread over inner and upper surfaces of thighs; occurs with heat and high humidity
Tinea pedis (foot; also known as "athlete's foot")	Occurs between toes and may spread to soles of feet, nails, and skin or toes; slight scaling; macerated, painful skin, occasionally with fissures and vesiculation
Tinea manuum (palmar surface of the hand)	Dry, scaly, erythematous, annular lesions, or moist, vesicular lesions that begin with clusters of intensely pruritic, clear vesicles; often associated with fungal infection of feet

Site	Clinical Manifestations
Tinea unguium or onychomycosis (nails)	Superficial or deep inflammation of nail that develops yellow-brown accumulations of brittle keratin over all or portions of nail

Candidiasis

Candidiasis is caused by the yeastlike fungus *Candida albicans* and normally can be found on mucous membranes, on the skin, in the gastrointestinal tract, and in the vagina. *C. albicans* can change from a commensal (normal) microorganism to a pathogen, particularly in the critically ill and those who are immunosuppressed.

Factors that predispose to *C. albicans* infection include (1) local environment of moisture, warmth, maceration, or occlusion; (2) systemic administration of antibiotics; (3) pregnancy; (4) diabetes mellitus; (5) Cushing disease; (6) debilitated states; (7) infants younger than 6 months of age (as a result of decreased immune reactivity); (8) immunosuppression; and (9) certain neoplastic diseases of the blood and monocyte/macrophage system.

The commensal bacteria on the skin, mainly cocci, inhibit proliferation of *C. albincans*. Cell-mediated immunity plays a major role in the defense against infections. *C. albincans* can activate the complement system by the alternative pathway resulting in abscess. Candidiasis affects only the outer layers of mucous membranes and skin, and occurs in the mouth, vagina, uncircumcised penis, nail folds, interdigital areas, and large skin folds (inframammary area, intertriginous area, perianal region, and abdominal creases). Table 46.9 lists the points of differentiation of various sites of candidiasis habitation. *C. albincans* is highly adaptable in the human host environment, thus promoting its infection and colonization.[56] Invasive candidiasis can affect the blood, heart, brain, eyes, bones, and other parts of the body and is a serious infection associated with high morbidity and mortality.[57]

Table 46.9

Sites of Candidiasis

Site	Risk Factors	Clinical Manifestations
Vagina (vulvovaginitis, most common)	Heat, moisture, occlusive clothing Systemic glucocorticoid therapy Systemic antibiotic therapy Increased estrogen levels (contraception, pregnancy) Diabetes mellitus Immunocompromise (disease or therapy) Sexual intercourse with infected male	Vaginal *itching*; white, watery, or creamy *discharge* Red, swollen vaginal and labial membranes with erosions Lesions may spread to anus and groin
Penis (balanitis)	Uncircumcised Sexual intercourse with infected	Pinpoint, red, tender papules and pustules on glans and shaft of penis

Site	Risk Factors	Clinical Manifestations
	partner	
Mouth (oropharyngeal)	Diabetes mellitus Immunocompromise (disease or therapy) Inhaled steroid therapy Bottle fed infants Older adults who wear dentures	Red, swollen, painful tongue and oral mucous membranes Localized erosions and plaques appear with chronic infection
Skinfolds (intertrigo)	Heat and moisture Diabetes mellitus Immunocompromise (disease or therapy) Obesity Bedridden	Pruritic and erythematous plaques with satellite papules and pustules Abdominal, inguinal, and breast skin fold.

Vascular Disorders

Vascular abnormalities are commonly associated with skin diseases; they may be congenital or may involve vascular responses to local or

systemic vasoactive substances. Blood vessels may increase in number, dilate, constrict, or become obliterated by disease processes.

Cutaneous Vasculitis

Vasculitis (angiitis) is an inflammation of the blood vessel wall that can result in bleeding aneurysm formation, or occlusion with ischemia or infection of surrounding tissue. The extensive vascular bed in the skin results in vasculitic syndromes that may be localized and self-limiting or generalized with multiorgan involvement. The initiating site may be the blood, the vessel wall, or the adjacent tissue. Small vessels are usually affected.

Cutaneous small vessel vasculitis (CSVV) develops from the deposit of immune complexes in small blood vessels as a toxic response to drugs (penicillin, cephalosporins, phenytoin, allopurinol, sulfonamides), allergens, streptococcal or viral infection (such as hepatitis B or C), or as a component of systemic vasculitic syndromes. The deposits activate complement, which is chemotactic for polymorphonuclear leukocytes (neutrophils), and proinflammatory cytokines. This results in palpable purpura and/or petechiae lesions. The lower extremities and feet are the chief sites affected. The lesion may initially present with burning, pruritis, and pain. The pattern of skin involvement may progress from purpura to hemorrhagic bullae with necrosis and ulcerations from occlusion of the vessel (Fig. 46.22). Lesions appear in clusters and persist for 1 to 4 weeks. The disease may be self-limiting and occur as a single episode. Biopsy and direct immunofluorescence confirm the diagnosis. Treatment includes avoiding triggering drugs and anti-inflammatory agents.[58]

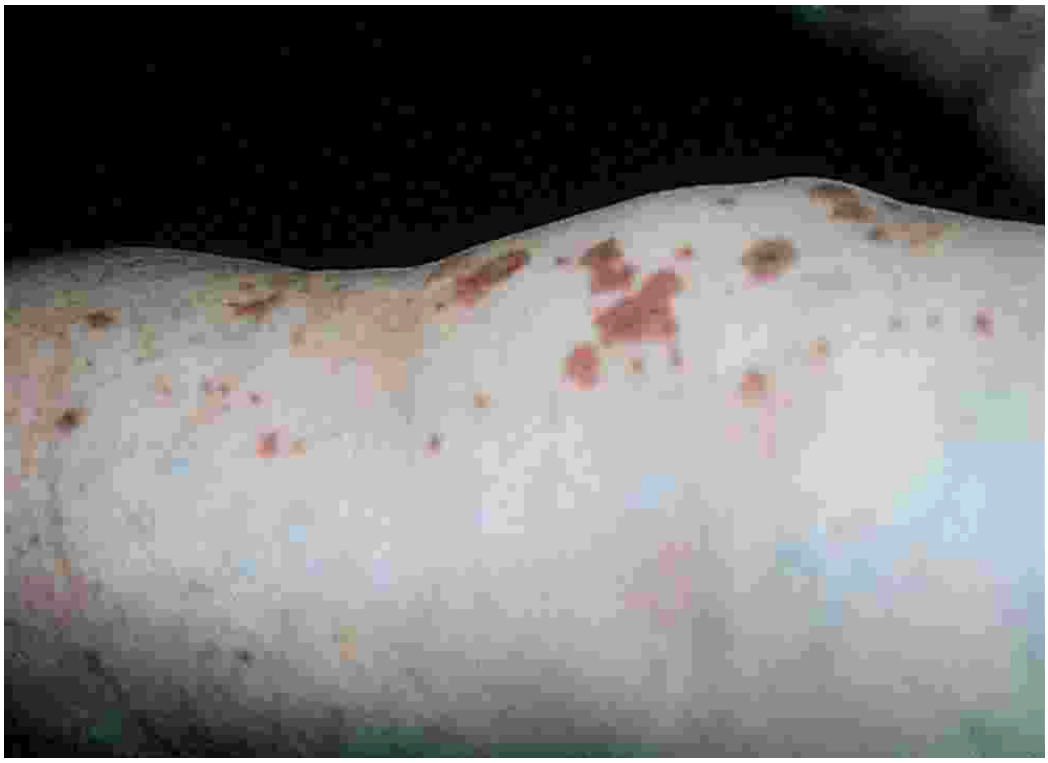

FIG. 46.22 Vasculitis of the Leg. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Urticaria

Urticaria (hives) is a circumscribed area of raised erythema and edema of the dermis. **Urticarial lesions** are most commonly associated with type I hypersensitivity reactions to drugs (penicillin, aspirin), certain foods (strawberries, shellfish, food dyes), environmental exposure (pollen, animal dander, insect bites), systemic diseases (intestinal parasites, lupus erythematosus), or physical agents (heat or cold) (see Chapter 9). The lesions are mediated by IgE-stimulated histamine release from sensitized mast cells, basophils, or both, which causes the endothelial cells of skin blood vessels to contract increasing permeability. The leakage of fluid from the vessel appears as wheals, welts, or hives, and there may be few or many that are distributed over the entire body (Fig. 46.23). IgG antibody directed against the IgE receptor and other

inflammatory and vasodilatory substances, such as serotonin, leukotrienes, prostaglandins, and kinins also may be mediators of urticaria. Most lesions resolve spontaneously within 24 hours, but new lesions may appear. Antihistamines are commonly used for treatment and all possible causes of the reaction should be removed.

FIG. 46.23 Urticaria. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Chronic urticaria (recurrent wheals for more than 6 weeks) is either idiopathic or autoimmune in origin, rarely because of allergy, and involves inappropriate activation of mast cells. Angioedema (welts or swelling deeper within the skin or mucous membranes of the face and oropharynx) is associated with both groups and more commonly affects the eyes and mouth, which can result in life-threatening respiratory compromise. Treatment includes antihistamines, steroids, and immunosuppressive agents with varying results.[59]

Scleroderma

Scleroderma is a connective tissue disease associated with immune dysregulation, vascular alterations, and progressive fibrosis. There are two categories of scleroderma. Localized scleroderma or morphea is usually more benign and self-limiting and is confined to the skin and /or underlying tissues. Systemic sclerosis is characterized by cutaneous sclerosis with organ involvement. Both disease types can vary in severity and rate of progression.[60]

Localized scleroderma (morphea) means sclerosis of the skin and underlying tissue. The disease is rare, more common in females, and the cause is unknown. Genetic predisposition, autoimmunity, and an immune reaction to a toxic substance are possible igniting mechanisms of the disease. T helper cells (Th1 and Th17) and their cytokines are associated with fibroblast proliferation and fibrosis. Several autoantibodies also have been identified, including antinuclear antibody (ANA), antihistone antibody (AHA), anti-endothelial cell antibodies and single-stranded DNA antibodies (ss-DNA ab). There are subtypes of localized scleroderma, but all involve thickening of the skin.[61] Localized scleroderma is differentiated from the systemic form of the disease by the absence of the following: sclerodactyly, Raynaud phenomenon, abnormalities of the nail bed capillaries, or internal organ involvement.

Systemic scleroderma (SSc) involves the connective tissues of the skin and internal organs, including the lungs, kidneys, gastrointestinal tract, and blood vessels.[60] Fibrosis occurs in the papillary and reticular dermis and in the subcutaneous tissue and deep fascia. There are massive deposits of type I collagen with progressive fibrosis accompanied by inflammatory reactions. Vascular changes in the capillary network with a decrease in the number of capillary loops, dilation of the remaining capillaries, formation of perivascular infiltrates, and development of occlusion and ischemia are an early manifestation.

The cutaneous lesions are most often on the face, hands, neck, and upper chest, although the entire skin can be involved. The skin is hard, hypopigmented, taut, shiny, and tightly connected to the

underlying tissue. The tightness of the facial skin projects an immobile, masklike appearance, and the mouth may not open completely. The nose may assume a beaklike appearance. The hands are shiny and sometimes red and edematous (Fig. 46.24). The fingers become tapered and flexed, often with contractures, depressed scars, and loss of fingertips from atrophy. Progressive fibrosis of internal organs occurs, and death is caused by subsequent respiratory failure, cardiac dysrhythmias and heart failure, renal failure, or esophageal or intestinal obstruction or perforation. The clinical features of systemic scleroderma are summarized in Box 46.4.

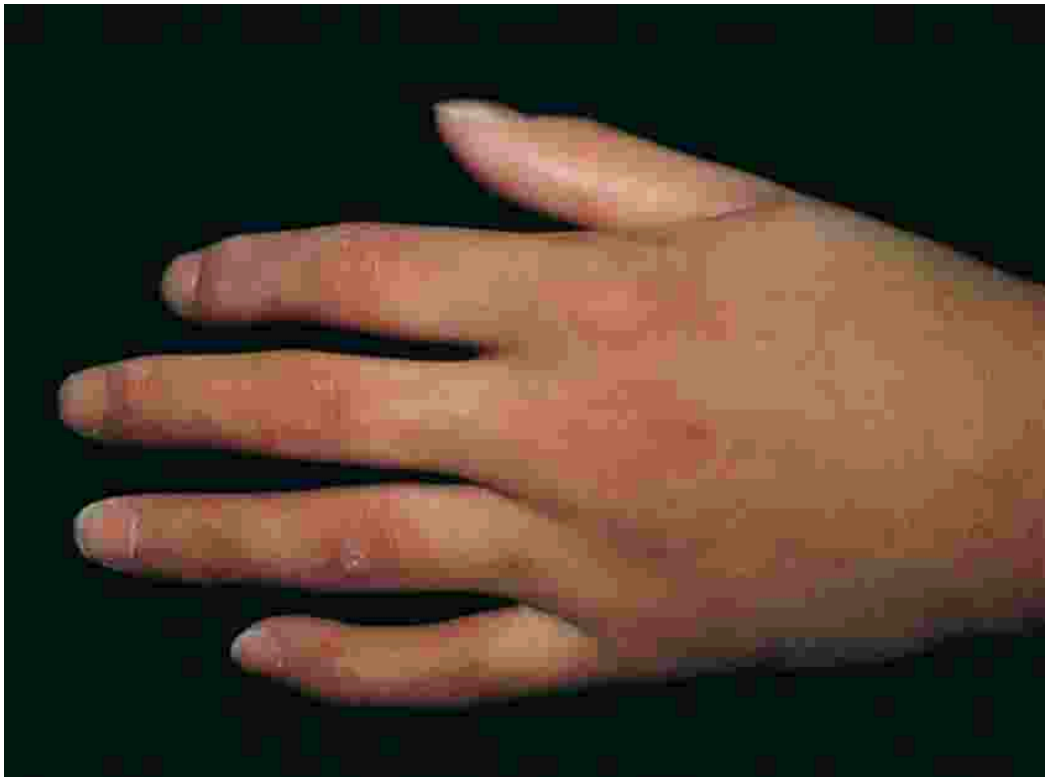

FIG. 46.24 Scleroderma.
Note inflammation and shiny skin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Box 46.4

Clinical Features of Systemic Scleroderma

Raynaud phenomenon—episodes of arteriolar vasoconstriction or spasm in response to cold or stress, often a sentinel sign of disease.
Non pitting edema of both hands
Skin thickening of the fingers of both hands
Sclerodactyly—tightening of skin over the fingers and toes leading to tapering of the digits with scarring and tissue atrophy
Abnormal nail fold capillaries
Facial skin thickening
Telangiectasias—dilation of capillaries causing small weblike (0.5 cm) red marks on skin surface
Pulmonary arterial hypertension and/or interstitial lung disease
Esophageal changes—swallowing difficulty related to acid reflux and increased esophageal fibrosis
Pericardial or myocardial disease
Arthralgias and myalgias
Kidney disease

Data from D'Silva KM, Bolster B. Systemic sclerosis: acomprehensive approach to diagnosis and management. *Physician Assistant Clinics*, 2021;6(1):159–175.

Suitable clothing and a warm environment are essential for protecting the hands. Trauma and smoking should be avoided. Treatment is individualized and based on the severity and progression of the disease and includes anti-inflammatory, immunosuppressive, antifibrotic, and stem cell therapy.[62]

Benign Tumors

Most benign tumors of the skin are associated with aging. Benign tumors include seborrheic keratosis, keratoacanthoma, actinic keratosis, and moles.

Seborrheic Keratosis

Seborrheic keratosis is a benign proliferation of cutaneous basal cells that produces flat or slightly elevated lesions that may be smooth or warty in appearance. The pathogenesis is unknown. These benign tumors are usually seen in people over the age of 50 but can also appear in young adults. The lesions can occur singularly or in multiples on the chest, back, and face. The color varies from tan to waxy yellow, flesh colored, or dark brown to black. Lesion size varies from a few millimeters to several centimeters, and they are often oval and greasy-appearing, with a hyperkeratotic scaly "stuck on" appearance (Fig. 46.25). Cryotherapy with liquid nitrogen, shave excisions, and laser therapy are effective treatments. 40% hydrogen peroxide may be an alternative for facial lesions.[63]

FIG. 46.25 Seborrheic Keratosis. Typical lesion is broad and flat with a comparatively smooth surface. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Keratoacanthoma

A **keratoacanthoma** is a benign, self-limiting tumor of squamous cell differentiation arising rapidly from hair follicles. It usually occurs on sun-damaged skin of elderly and fair skinned individuals who smoke. The incidence is highest among males by nearly three times. The most commonly affected sites are the face, back of the hands, forearms, neck, and legs (Fig. 46.26). The lesion develops in stages (proliferative, mature, and involution) over a period of 1 to 2 months with a histologic pattern resembling that of squamous cell carcinoma (SCC). However, there is debate as to the relationship between KA and SCC about whether they are two distinct pathologies, or if KA is a clinical precursor to SCC and metastasis.[64]

FIG. 46.26 Keratoacanthoma.
Classic presentation of a fully developed tumor. Round, smooth, dome-shaped mass with a central keratin-filled crater. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Although the lesions will resolve spontaneously, they can be removed by curettage or excision to improve the cosmetic appearance and reduce the risk of evolution to SCC. Topical and intralesional therapies are available. A biopsy is performed to rule out SCC.[65]

Actinic Keratosis

Actinic keratosis (AK), or solar keratosis, is a lesion composed of aberrant proliferations of epidermal keratinocytes caused by prolonged exposure to ultraviolet radiation. The prevalence is highest in individuals with unprotected, light-colored skin, immunosuppression, older age, and genetic predisposition. It is rare in those with dark-colored skin. The lesions may be single or multiple and appear as pink, red, or brownish patches, papules, or plaques (Fig. 46.27). Surrounding areas may have telangiectasias.

AKs may evolve to SCC.[66] Dermoscopy and biopsy aid in the evaluation and differentiation between AK and SCC. The lesions should continue to be evaluated for progression to or development of SCC. Treatment options include cryoablation, photodynamic therapy, laser surgery, and topical therapies. Continuous sun protection is important.[67]

FIG. 46.27 Actinic Keratosis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Nevi (Moles)

Nevi (moles) are benign pigmented or nonpigmented lesions (Fig. 46.28). Melanocytic nevi, formed from melanocytes, may be congenital or acquired and small (less than 1 cm) or large (greater than 20 cm). During the early stages of nevi development, the cells accumulate at the junction of the dermis and epidermis (junctional nevi) and are macular lesions. Over time, the cells move deeper into the dermis and the nevi become nodular and symmetric without

irregular borders (compound nevi). Nevi may appear on any part of the skin, may vary in size, may occur singly or in groups, and may undergo transition to malignant melanoma. Nevi irritated by clothing or trauma or large lesions may be excised. Multiple and changing moles require regular evaluation.[68]

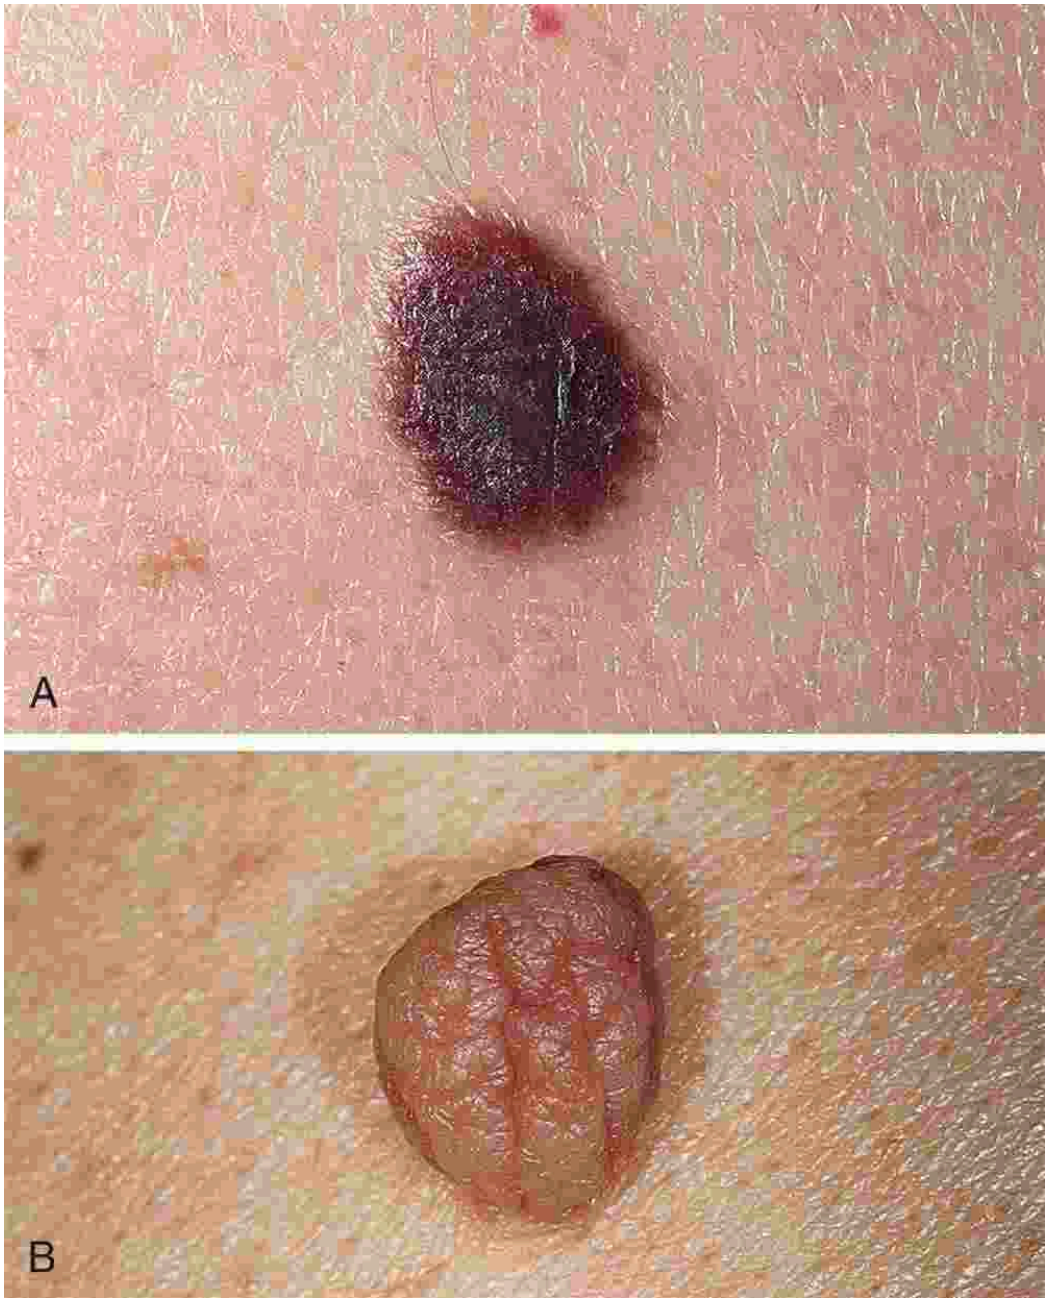

FIG. 46.28 Nevi.
(A) Junction nevus: slightly raised, dark, and uniform. **(B)** Dermal nevus: pedunculated with a soft, flabby, wrinkled surface. (From Habif TP. *Clinical dermatology: A color guide to diagnosis and therapy*, 5th edition. Philadelphia: Mosby; 2010.)

Skin Cancer

Cutaneous basal cell carcinoma (BCC) and SCC are collectively known as nonmelanoma skin cancers, which are the most prevalent forms of cancer. Malignant melanoma is the most serious type of skin cancer and the most common cause of death from skin cancer.[69] Important trends related to skin cancer are described in Box 46.5.

Box 46.5

Important Trends for Skin Cancer

Nonmelanoma skin cancer was reported at more than 5.4 million cases among 3.3 million people in the United States in 2012, the most recent year new statistics available.
Greater in women younger than age 40 years; greater in men after age 40 years; 40 times more prevalent in whites than in blacks; increases steadily with age; increasing among young individuals with chronic exposure to artificial UV radiation
Majority of cases are highly curable basal or squamous cell cancers, and the most serious is malignant melanoma with an estimated 106,110 new cases and 101,280 cases of in situ melanoma in 2021; it represents 1% of all skin cancer cases but causes about 79% of all skin cancer deaths.

Mortality

Total estimated deaths in 2016 were 10,130 from melanoma and approximately 3520 from other nonepithelial types of skin cancer.

Risk Factors

Excessive exposure to ultraviolet radiation from the sun

Exposure to artificial UV radiation, particularly in ages less than 25 years
Fair complexion, blue eyes, blonde hair
Occupational exposure to coal tar, pitch, creosote, arsenic compounds, and radium
Exposure to human papillomavirus and human immunodeficiency virus
Immunosuppression
Family history of skin cancer
Skin cancer is negligible in blacks because of heavy skin pigmentation

Warning Signals

Any change on the skin, especially a change in the size or color of a mole or other darkly pigmented growth or spot

Prevention and Early Detection

Avoidance of artificial UV radiation and sun when ultraviolet light is strongest (e.g., 10 a.m. to 3 p.m.); use of protective clothing and sunscreen preparations, especially those containing ingredients such as *para*-aminobenzoic acid (PABA); prevention for all types of skin cancer should begin in childhood
Routine visual screening for skin cancer may be a benefit for those at highest risk.

Survival

For basal cell and squamous cell cancers, cure is highly likely with early detection and treatment; malignant melanoma metastasizes quickly, accounting for a lower 5-year survival rate

Data from American Cancer Society. *Cancer Facts and Figures 2021*. Atlanta: The Society; 2021; Carr S, Smith C, Wernberg J. Epidemiology and risk factors of melanoma. *Surgical Clinics of North America*, 2020;100(1):1–12.

Chronic exposure to UV radiation causes most skin cancers. Lesions are most common on the face, neck, hands, and other areas subject to intense, repetitive sunlight exposure. Protection from the sun and avoidance of tanning beds, particularly during childhood, significantly reduce the risk of skin cancer in later years. Genetic mutations in oncogenes and tumor-suppressor genes (see Chapter 12) are associated with skin cancers. This leads to loss of keratinocyte repair functions and apoptosis resistance of DNA-damaged cells.[70] Dark-skinned persons and those who avoid sunlight are significantly less likely to develop these malignant tumors. In dark-skinned persons, basal cells contain more of the pigment melanin, a protective factor against sun exposure.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) of the skin is the most common cancer in the world. BCC is thought to be caused by UV radiation exposure and is also associated with arsenic in food or water, radiation therapy, and long-term immunosuppressive therapy. BCC is a surface epithelial tumor originating from undifferentiated basal or stem cells. It arises from mutation in the TP53 tumor-suppressor gene, leading to loss of keratinocyte repair functions and apoptosis resistance of DNA-damaged cells. BCC is primarily associated with the Sonic Hedgehog signaling axis with disinhibition of the PTCH1 gene and overexpression of the signaling pathway.[71]

BCCs have numerous subtypes, including superficial, nodular, morpheaform (sclerosing), and combinations of these. Thus, they can have very different clinical presentations (Fig. 46.29). The lesion often begins as a nodule (greater than 5 mm) that is pearly or ivory in appearance and slightly elevated above the skin surface with small blood vessels on the surface (telangiectasias). The tumors grow upward and laterally or downward to the dermal-epidermal

junction. They usually have depressed centers and rolled borders. As the lesion grow, it often ulcerates, develops crusting, and becomes firm to the touch. If left untreated, basal cell lesions invade surrounding tissues and, over months or years, can destroy a nose, eyelid, or ear. Metastasis is rare because these tumors do not invade blood or lymph vessels.

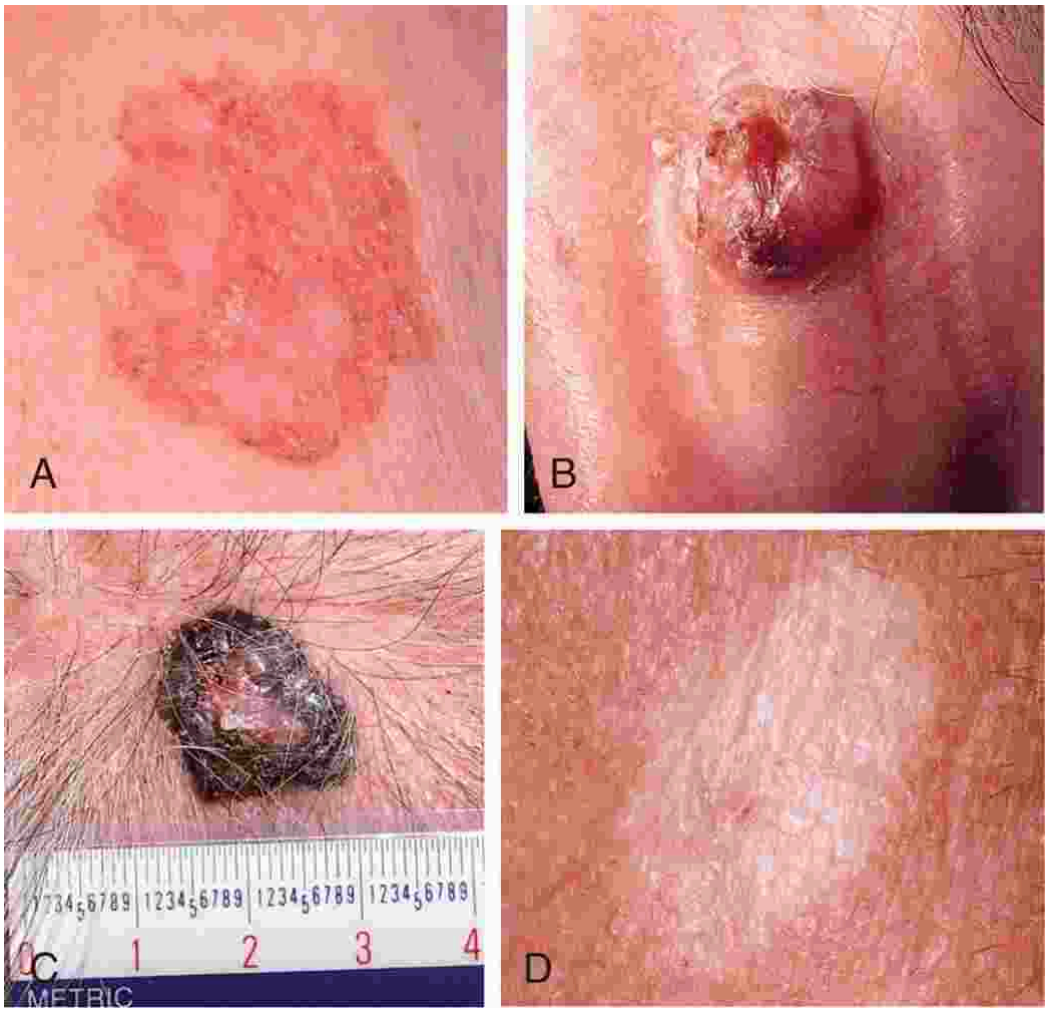

FIG. 46.29 Types of Basal Cell Carcinoma.
(A) Superficial. **(B)** Nodular. **(C)** Pigmented. **(D)** Morpheaform-recurrent tumor. (A and D from Bolognia JL, et al. *Dermatology*, 3rd edition. Philadelphia: Saunders; 2012. B and C from James WD, et al. *Andrews' diseases of the skin: Clinical dermatology*, 11th edition. Philadelphia: Saunders; 2009.)

A. Close shot of patchy red lesion with an irregular border. B. Close shot of raised, crusted, reddish to the purple nodule. C. Close shot of reddish to the dark brown lesion with irregular border measuring 2

centimeters. D. Close shot of white discolored patchy lesion.

Treatment includes complete surgical excision (micrographic surgery with histologic analysis), radiotherapy, curettage, cryotherapy, photodynamic therapy, and topical applications of imiquimod or 5-fluorouracil. If left untreated, basal cell lesions invade surrounding tissues and, over months or years, destroy tissue (i.e., nose, eyelid, or ear). These are known as locally advanced basal cell carcinomas (laBCC). Metastatic spread is rare because these tumors do not invade blood or lymph vessels. In laBCC or inoperable tumors, the Smoothened receptor in the Sonic Hedgehog pathway can be inhibited using targeted drugs.[72]

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) of the skin is a malignant tumor of the epidermis and is the second most common human cancer. Two types are characterized: in situ and invasive. Chronic UV radiation exposure causes SCC via mutation of the TP53 gene and other oncogenic signaling; however, it is unclear as to how UV light produces the alterations in DNA, DNA repair, and resistance to apoptosis.[71] Other risk factors include genetic predilection, chronic arsenic exposure, exposure to x-rays and gamma rays, immunosuppression, and light-colored skin. Areas typically affected include sun-exposed skin of the head, neck, and hands.

Keratoacanthoma is a benign dome shaped epidermal tumor that originates from the pilosebaceous unit of the skin. It may spontaneously resolve or transform into SCC.[73]

In situ SCC is usually confined to the epidermis (intraepidermal) but may extend into the dermis. Bowen disease is a dysplasia of the epidermis or carcinoma in situ found on unexposed areas of the body, such as the glans penis (erythroplasia of Queyrat). The lesions are flat and red with scaly patches. These lesions may enlarge to more than 1 cm in diameter, rarely invading surrounding tissue,

very rarely metastasize, and are associated with HPV. Other cellular components of the skin (e.g., sweat glands, hair follicles) can give rise to SCC, but these cancers are relatively uncommon. Invasive SCC can arise from premalignant lesions of the skin. Premalignant lesions include AK, leukoplakia (whitish discolored areas), scars, radiation-induced keratosis, tar and oil keratosis, and chronic ulcers. It rarely arises from normal-appearing skin (de novo). Invasive SCC grows more rapidly than BCC; it penetrates the basement membrane between epidermis and dermis and can spread to regional lymph nodes with metastasis. The tumors are firm and increase in elevation and diameter. The surface may be granular and bleed easily (Fig. 46.30).

FIG. 46.30 Squamous Cell Carcinoma.
The sun-exposed ear is a common site for squamous cell carcinoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

SCC is the most common cause of *lip cancer* and is more prevalent in older white men. The lower lip is the most common site. Long-

term environmental exposure results in dryness, chapping, hyperkeratosis, and predisposition to malignancy. Immunosuppression, pipe smoking, and chronic alcoholism increase the risk for lip cancer. The most common lesion is termed *exophytic* and usually develops in the outer part of the lip along the vermilion border. The lip becomes thickened and evolves to an ulcerated center with a raised border (Fig. 46.31). These lesions have an irregular surface, follow cracks in the lip, and tend to extend toward the inner surface and progress slowly. Early diagnosis and surgical resection are usually curative.[74]

FIG. 46.31 Lip Cancer.
Biopsy confirmed squamous cell carcinoma. Lip vermilion shows diffuse actinic keratosis. (From Bagheri SC, Khan HA, Cuzalina A. *Current therapy in oral and maxillofacial surgery*. Philadelphia: Saunders; 2012.)

For small, low-risk, superficial SCC, treatment includes cryotherapy, 5-FU, and photodynamic therapy. For advanced SCC, complete microsurgical excision with histologic analysis and radiotherapy with consideration of immunotherapy and adjuvant chemotherapy is recommended.[75]

Cutaneous Melanoma

Cutaneous melanoma is a malignant tumor of the skin originating from the transformation of melanocytes. Melanocytes are cells that arise from neural crest tissue and synthesize the pigment melanin.

They are located in the basal layer of the skin and arise in mucosal tissue and the uveal tract. Melanoma is the most serious skin cancer, and its incidence increases with age. Risk factors include a personal or family history, or both; UV radiation exposure (including sun bed use before age 30 years); immunosuppression; fair hair; light skin with repeated sunburns; freckles; younger females and older males; geographic location; past pesticide exposure; and three or more clinically atypical (dysplastic) nevi.[76] Multiple melanocytic nevi are associated with nonchronic sun-damage melanomas and BRAF mutations and occur more commonly on the trunk and extremities. Discovering melanoma at an early stage increases 5-year survival.

Cutaneous melanomas arise as a result of malignant degeneration of melanocytes located either along the basal layer of the epidermis or in a benign melanocytic nevus. There are four major subtypes of melanoma associated with cumulative solar damage and based on their histologic growth patterns: superficial spreading melanoma (SSM), primary nodular melanoma (PNM), lentigo malignant melanoma (LMM), and acral lentiginous melanoma (ALM) (Fig. 46.32). SSM is the most common subtype of melanoma and is most likely to be associated with a preexisting nevus. Their growth is radial (or lateral) and evolves over time to vertical (invasive) growth. Typically, these lesions are asymmetrical with a variable pigment of color (red, tan, black, brown, grey, and white). PNM are vertically growing lesions that are aggressive. Rare and difficult to diagnose subtypes include desmoplastic melanoma, which resembles a scar, and amelanotic (nonpigmented) melanoma tumor with pigment loss as the tumor progresses.[77]

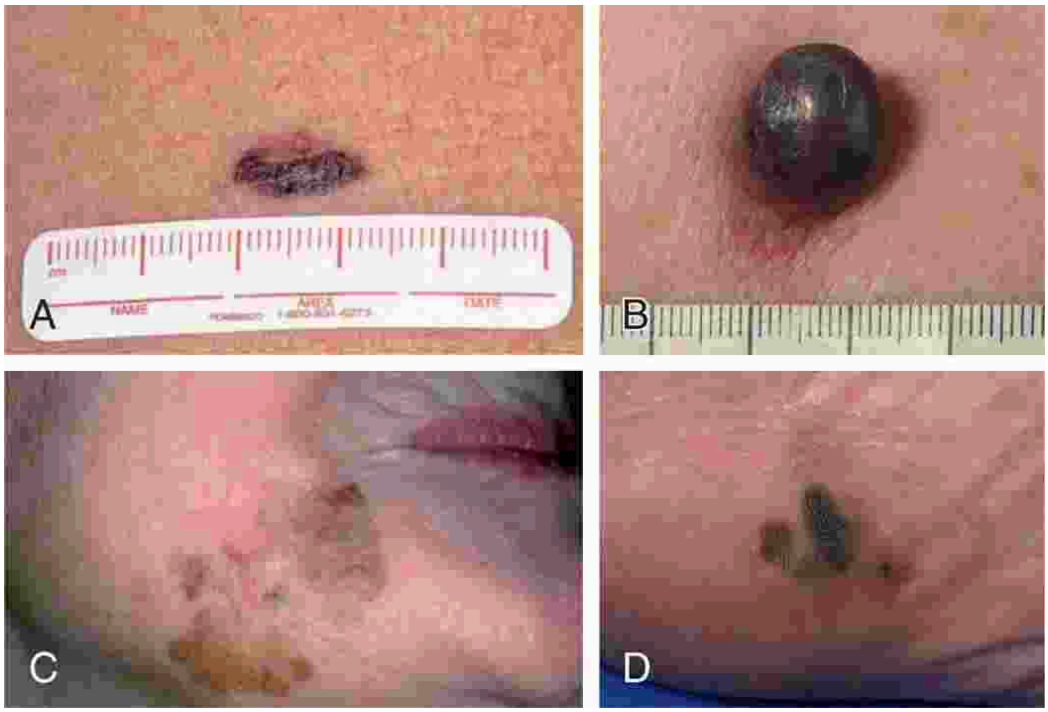

FIG. 46.32 Types of Melanoma.
(A) Superficial spreading melanoma. **(B)** Nodular melanoma. **(C)** Lentigo malignant melanoma. **(D)** Acral lentiginous melanoma on plantar surface of foot. (From Bolognia JL, et al. *Dermatology essentials*. Philadelphia: Saunders; 2014.)

A. A close shot of a black lesion measuring 1 centimeter on the skin surface. B. Close shot of dark brown raised nodule. C. Close shot of patch of black discolored skin lesion. D. Close shot of black patch on the plantar surface of the foot.

LMM is frequently found in the elderly and often confused with age spots (lentigines). Most commonly arising from sun-damaged areas of the skin, LMM present as a macule that gradually evolves into a palpable lesion. These lesions transform slowly and can be present for 10 to 50 years before the vertical growth phase begins.

ALM are rare and occur on non–hair-bearing surfaces such as the palms of the hands and the soles of the feet, as well as in mucous membranes. ALM are more commonly seen in African American and Asian persons.[77] The clinical characteristics of subtypes of melanomas are summarized in Table 46.10.

Table 46.10

Clinical Characteristics and Subtypes of Cutaneous Melanoma

Characteristic	Description
Lentigo Malignant Melanoma	
Frequency	5%–15% of cutaneous melanomas
Age at diagnosis	50–80 years old, mean age 65 years
Primary location	Head, neck, dorsum of hands (sun-exposed areas)
Pigmentation according to thickness	
<1.5 mm (levels I and II)	Tan and brown
>1.5 mm (level III)	Tan, brown, and blue-black
>1.5 mm (levels IV and V)	Nodule formation
Superficial Spreading Melanomas	
Frequency	50%–75% of cutaneous melanomas
Age at diagnosis	20–60 years old
Primary location	Legs of females; upper back of both genders
Pigmentation according to thickness	
	Tan and brown

Characteristic	Description
<1.5 mm (levels I and II)	
>1.5 mm (level III)	Tan, brown, and blue-black
>1.5 mm (levels IV and V)	Nodule formation
Acral-Lentiginous Melanoma	
Frequency	5% –8% in whites; 30%–75% in blacks, Hispanics, Asians
Age at diagnosis	20–60 years old, male more common
Primary location	Palms, soles of feet, mucous membranes
Pigmentation at any thickness	Blue-black irregular macules, papules, or nodules
Primary Nodular Melanoma (usually invasive at diagnosis)	
Frequency	15%–35% of cutaneous melanomas
Age at diagnosis	20–60 years old, mean age 53 years
Primary location	Trunk, head, or neck
Pigmentation according to thickness	
>1.5 mm (level III)	Small nodule (any hue)
>1.5 mm (levels IV and V)	Large nodule (any hue)

Data from Johnston RB. *Weedon's skin pathology essentials*, 2nd edition. Elsevier; 2017; Longo C, Pellacani G. Melanomas. *Dermatologic Clinics*, 2016;34(4):411–419.

The pathogenesis of malignant melanoma is complex. There is an accumulation of genetic mutations that activate oncogenes, inactivate tumor suppressor genes, and impair DNA repair genes. Most familial melanomas are associated with cyclin-dependent kinase 4 gene (CDK4) and cyclin-dependent kinase inhibitor 2 A gene (p16/CDKN2A) located on chromosome 9p21, both of which function to suppress cellular growth. The CDKN2A gene encodes two potent tumor-suppressor proteins that are cell-cycle inhibitors. Both CDNKN2A and CDK4 are highly penetrant susceptibility genes and result in melanomas. A number of proto-oncogenes have been identified, including BRAF point mutations (the most common), NRAS, and genes involved in the regulation of mitogen-activated protein kinase (MAPK) and other signaling pathways. Melanomas have a high mutation rate stimulated by ultraviolet radiation (UVR), making gene sequencing difficult.[78]

The relationship between nevi and melanoma makes it important for the clinician to understand the various forms of nevi (see Fig. 46.32). Most nevi never become suspicious, but suspicious pigmented nevi need to be evaluated and removed. Indications for biopsy include any color change, size change, irregular notched margin, itching, bleeding or oozing, nodularity, scab formation, ulceration or an unusual pattern of presentation, or a de novo nevi. The ABCDE rule is used as a guide: **A**symmetry, **B**order irregularity, **C**olor variation, **D**iameter larger than 6 mm, and **E**levation or **E**volving, which includes raised appearance or rapid enlargement.[79] Staging of melanoma is determined by vertical lesion thickness (depth of **t**umor), lymph **n**ode involvement, presence of ulceration, and presence of **m**etastasis (TNM staging). Criteria established by the American Joint Committee on Cancer is used to guide treatment and is summarized in Box 46.6.

Box 46.6

Tumor, Node, Metastasis Staging Criteria for Melanoma

Stage 0: carcinoma in situ (TisN0M0)
Stage I A/B: includes lesions up to 2 mm with no nodal or distant metastases (T1aN0M0, T1bN0M0, T2aN0M0).
Stage II A/B/C: includes larger lesions, greater than 2 mm without positive nodes or distant metastases (T2bN0M0, T3aN0M0, T3bN0M0, T4aN0M0, T4bN0M0).
Stage III: includes lesions of any size with positive lymph nodes (TxN1M0, TxN2M0, TxN3M0).
Stage IV: includes lesions of any size with distant metastases (TxNxM1).

Data from Keung EZ, Gershenwald JE. The eighth edition American Joint Committee on Cancer (AJCC) melanoma staging system: Implications for melanoma treatment and care. *Expert Review of Anticancer Therapy*, 2018;18(8):775–784.

Prognostic factors include the thickness of the lesion, mitotic index, immunohistochemical assessment, ulceration, and metastasis (e.g., number of lymph nodes or viscera involved). Efforts are in progress to refine the morphologic classifications by adding subgroups that include molecular markers for proto-oncogene mutations and specific signaling pathways.[80]

Early detection of cutaneous melanomas can have a major effect on achieving a surgical cure and decreasing morality from metastatic disease. Local excision biopsy is completed for suspicious lesions. Melanoma with no evidence of metastatic disease involves wide surgical excision of the primary lesion site. A lymph node biopsy of the peripherally draining lymph node (sentinel node) is warranted for lesions greater than 1 mm deep and, if positive, regional

lymphadenectomy is performed. Lesions on the extremities have the best surgical prognosis. Radiation therapy, chemotherapy, and immunotherapy are used to treat metastatic disease and have demonstrated long-term improvement in disease outcome. Promising new immunotherapies are used for advanced disease, including checkpoint inhibitors, programmed cell death protein 1 (PD-1) receptor antibody, anti-CTLA4 antibody, and targeted therapy, including *BRAF* and/or mitogen-activated protein kinase kinase (MEK) inhibition, *C-kit* gene inhibitors of tyrosine kinases, and platelet derived growth factor. Vaccines, cell therapy, and biomarkers to assess treatment effectiveness are under continuing investigation. Prevention of melanoma includes avoidance of UVR exposure through use of protective clothing and sunscreens, as well as avoidance of artificial UVR exposure.[81]

Merkel Cell Carcinoma

Merkel cell (a skin mechanoreceptor) carcinoma is a very rare aggressive cutaneous carcinoma usually localized to the head and neck. Risk factors include ultraviolet radiation, Merkel cell polyomavirus infection, immunosuppression, male, and age older than 50 years. The lesions appear as nodules or skin-colored or purple dome-shaped papules or plaques, usually on sun-exposed areas of the skin. Treatment includes wide excision and adjuvant radiotherapy. Targeted therapies, including checkpoint inhibitors, are improving outcomes. Mortality is high for metastatic lesions.[82]

Kaposi Sarcoma

Kaposi sarcoma (KS) is a vascular malignancy associated with immunodeficiency states. Human herpesvirus type 8 (HHV8 also known as Kaposi sarcoma herpes virus [KSHV]) is the etiological agent and is found in all lesions of KS. HHV8 is also associated with primary effusion lymphoma and multicentric Castleman's disease. Four forms of KS have been described: classic (more benign and more common in men), epidemic (rapidly progressive and associated with AIDS), endemic (associated with HPV and occurring

in equatorial Africa), and iatrogenic (associated with immunosuppressant treatment, including organ transplant). Genetic and environmental cofactors determine disease progression. The virus can remain latent and avoid immune surveillance or have lytic reactivation and spread to new hosts.[83]

Saliva is thought to be the primary route of transmission, however KSHV has also been detected in breast milk, semen, and blood. The endothelial cell is the progenitor of KS with inflammation, angiogenesis, and cellular proliferation. Infection with KSHV is lifelong because the virus can establish latency in endothelial cells and B cells. The viral genome is replicated with the host genome during normal cell division.[84] The lesions emerge as red, purple, or brown macules and develop into plaques and nodules. They tend to be multifocal rather than spreading by metastasis. The lesions initially appear over the lower extremities in the classic form (Fig. 46.33). The rapidly progressive form associated with AIDS tends to spread symmetrically over the upper body, particularly the face and oral mucosa. The lesions are often pruritic and painful. Most individuals with epidemic KS have involvement of lymph nodes, particularly in the gastrointestinal tract and lungs. Organ involvement is much less common in the classic form than in the epidemic form. The rapidly progressive form has a poor prognosis and shorter survival rates than the classic form. (See Chapter 10 for a further discussion of AIDS.)

The purple lesion commonly seen on the skin.
(Courtesy Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT.)

Diagnosis is by medical history, physical examination, and skin biopsy, with a high index of suspicion for those with immunodeficiency. Local lesions can be removed or treated topically. Multiple disseminated lesions may be treated with a combination of α-interferon, radiotherapy, and cytotoxic drugs. Antiangiogenic agents are being tested. Individuals receiving highly active antiretroviral therapy (HAART) have a markedly reduced incidence of KS.[85]

Primary Cutaneous Lymphomas

Primary cutaneous lymphomas are cutaneous T-cell and B-cell neoplasms present in the skin without evidence of extracutaneous disease at the time of diagnosis (see Chapter 29) for classification and general pathophysiology of lymphomas). Cutaneous lymphomas develop from clonal expansion of B cells, T-helper cells, and rarely,

T-suppressor cells. Cutaneous lymphomas are more common in men and generally present after age 50; 75% of cases are T-cell lymphomas and 25% are B-cell lymphomas.[86] Mycosis fungoides is the most prominent subtype of cutaneous T cell lymphoma (CTCL). **Mycosis fungoides** can present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors (Fig. 46.34) Lesions are pruritic and cause considerable distress and debilitation. There may be patches of alopecia. The lesions progress over a period of months or years. Involvement of other organs can occur in advanced stages of the disease. Sézary syndrome (a leukemic variant) and primary cutaneous CD30-positive lymphoproliferative disorders are most aggressive. Cutaneous B-cell Lymphomas (CBCL) are less common than CTCL and include primary cutaneous marginal zone lymphoma, primary cutaneous follicle center lymphoma, primary cutaneous diffuse large B-cell lymphoma (leg type), and Epstein-Barr virus (EBV)—positive mucocutaneous ulcer.[87]

FIG. 46.34 Mycosis Fungoides.
(A) Hypopigmented patches of mycosis fungoides. **(B)** Plaques of mycosis fungoides. **(C)** Tumors of mycosis fungoides combined with patches. (Courtesy of Ellen Korn, M.D. In James WD, Berger TG, Elston DM. *Andrews' diseases of the skin: Clinical dermatology*, 11th edition. Philadelphia: Saunders; 2011.)

A. A close shot of skin shows lightly pigmented patches scattered at distance. B. Close shot of posterior view of pelvis shows large dark pink overgrowths with irregular borders. C. A close shot

of skin shows large white and pink irregular overgrowths.

The differential diagnosis of the different types of cutaneous lymphomas is based on clinical manifestations, histologic, immunologic, and cytogenetic features, and response to appropriate treatment. Treatment is based on the clinical presentation and staging of the disease and includes topical therapy, immunotherapy, chemotherapy, radiation therapy, and phototherapy.[88]

Cold Injury

Exposure to extreme cold includes a spectrum of injuries[89]:

- *Frostnip*—mild and completely reversible cold injury characterized by skin pallor and numbness, no permanent tissue damage (Fig. 46.35)
- *Chilblains*—more serious than frostnip; violaceous skin color with plaques or nodules, pain, and pruritus, but no ice crystal formation; repetitive exposure to damp cold (above freezing point); chronic vasculitis can develop; permanent damage is uncommon
- *Frostbite*—tissues freeze and form ice crystals at temperatures below −2°C (28°F); progresses from distal to proximal and potentially reversible
- *Flash freeze*—rapid cooling with intracellular ice crystals associated with contact with cold metals or volatile liquids

FIG. 46.35 Frostnip on an ear. (Courtesy Ian Davis. From Auerbach, PS. *Wilderness medicine*, 6th edition. Philadelphia: Elsevier; 2012.)

The most common areas affected are fingers, toes, ears, nose, and cheeks. Skin damage can range from mild to severe. Initially, the body responds with alternating cycles of vasoconstriction and vasodilation—the hunting reflex. The mechanism of injury is complex but is related to direct cold injury to cells, indirect injury, cell death from extracellular and intracellular ice crystal formation, impaired circulation with anoxia because of thrombosis in the exposed area, and re-perfusion injury. Mild frostbite causes pallor and pain, followed by redness and discomfort during rewarming, with no tissue damage. Frostbite occurs when tissues freeze slowly with ice crystal formation. Frozen skin becomes white or yellowish and has a waxy texture. There is numbness and no sensation of pain. Frostbite injury is related to direct cold injury to cells, indirect injury from ice crystal formation, and endothelial cell damage. During rewarming, there is indirect injury related to progressive

microvascular thrombosis followed by reperfusion injury with the release of inflammatory mediators (including thromboxanes, prostaglandins, bradykinins, and histamines) with impaired circulation and anoxia to the exposed area. Cyanosis and mottling develop, followed by redness, edema, and burning pain on rewarming in more severe cases. Edema can cause capillary compression and vascular stasis. Within 24 to 48 hours, vesicles and bullae appear that resolve into crusts that eventually slough, leaving thin, newly formed skin. Frostbite may be classified by depth of injury: first degree, second degree, third degree, and forth degree.[90]

- *First degree:* superficial, characterized by a numb central white area surrounded by erythema and edema; includes partial skin freezing without bullae
- *Second degree:* full-thickness skin freezing with bullae and surrounding erythema and edema; develops within 24 hours of exposure; there is no tissue loss
- *Third degree:* full-thickness and subcutaneous freezing with tissue necrosis; hemorrhagic vesicle formation; black eschar develops in one to several weeks
- *Fourth-degree:* extends past the subcutaneous level of the skin to muscle and bone; complete tissue necrosis with clear line of demarcated tissue loss

A prediction tool has been developed for frostbite of the hands and feet. It is based on the appearance of the lesions after the affected area has been treated in warm water.[91]

Grade 1: no cyanosis; no amputation or sequelae likely
Grade 2: distal cyanosis; soft tissue amputation as well as nail sequelae likely
Grade 3: distal and intermediate cyanosis; bone amputation of the digit and functional sequelae likely
Grade 4: cyanosis over the proximal areas of the hands or feet (carpal or tarsal bones); bone amputation of the limb and

functional sequalae likely

Frostbite can develop in minutes. Risk factors for frostbite includes any activity that would increase heat loss or decrease the body's ability to produce heat. Examples of heat loss through convection include exposure to wind. Conductive heat loss can develop via contact with metal or water. Concomitant medical conditions that increase risk include peripheral arterial disease, diabetes, mental illness, alcohol abuse, dehydration, and malnutrition. Environmental conditions that increase risk include wind and higher altitudes.[91]

Imaging is important for determining the precise severity, depth, and level of tissue injury, the proper demarcation of dead tissue and for monitoring response to treatment. Immediate treatment of frostbite is removal of wet clothing and covering affected areas with other body surfaces and warm clothing. The area should not be rubbed or massaged. Rewarming for severe frostbite should occur with immersion in a warm water bath (40°C to 42°C [104°F to 107.6°F]) until frozen tissue is thawed. Pain is severe and should be treated with potent analgesics. Antibiotics may be given. Vasodilators, thrombolytics, hyperbaric oxygen, and sympathectomy may improve healing responses. Debridement or amputation of necrotic tissue occurs when there is a clear line of demarcation.

Disorders of the Hair

Alopecia

Alopecia means partial or complete loss of hair from an area of the body where it normally grows. Hair loss occurs when there is disruption in the growth phase of the hair follicle. Hair loss can be associated with systemic disorders such as hypothyroidism and iron deficiency, chemotherapy for cancer, malnutrition, compulsive hair pulling (trichotillomania), traction on hair from braiding and ponytails, use of hair treatment chemicals, hormonal alterations, peripheral arterial disease, medications, and immune reactions.

Androgenic Alopecia

Androgenic alopecia, or localized hair loss, occurs in about 80% of men by 80 years of age. It is not a disease but rather a variation in the androgen receptor (AR) gene and a predisposed response to androgens that clusters in families. Within the distribution of hair over the scalp, androgen-sensitive hair follicles are on top and androgen-insensitive follicles are on the sides and back. In genetically predisposed men, the androgen-sensitive follicles are transformed into vellus follicles. The normal hair is shed and replaced by vellus hair which is fine, light, and short. Male-pattern baldness begins with frontotemporal recession and progresses to loss of hair over the top of the scalp.[92] Minoxidil may be used to stimulate hair growth. It relaxes smooth muscle around hair follicles and hair follicle perfusion increases, extending the anagen phase of hair growth and delaying conversion from terminal to vellus hair. Finasteride (a 5α-reductase inhibitor) may reduce the effect of androgens on hair follicles. Options are available for non-medical treatment including low level laser therapy and microneedling.[93]

Female-Pattern Alopecia

Female pattern alopecia, formerly known as androgenetic alopecia, is the slow progressive thinning and loss of terminal hair over the central part of the scalp. Prevalence increases with advancing age. Contrary to male-pattern baldness, there is usually no loss of hair along the frontal hairline but the hairs are shorter and thinner (follicular miniaturization). The mechanism of hair loss is unknown but related to genetic and hormonal changes. The role of androgens is not clearly known. Treatment includes topical minoxidil and light therapy.[94]

Alopecia Areata

Alopecia areata is an autoimmune T-cell–mediated or natural killer cell mediated chronic inflammatory disease with loss of immune privilege in hair follicles. Exposure to self-antigens promotes infiltration of inflammatory cells, release of interferon gamma and other cytokines, and inflammation and apoptosis that disrupts the

normal hair cycle, resulting in inhibition of hair growth.[95,96] There is a rapid onset of hair loss in multiple areas of the scalp, usually in round patches. The eyebrows, eyelashes, beard, and other areas of body hair can be involved. The cause is not completely understood, but stressful events, genetic susceptibility, and metabolic disorders (e.g., Addison disease, thyroid disease, and lupus erythematosus) are associated with alopecia areata.

The affected areas have round or oval hair loss that may coalesce. The skin is smooth or may have short shafts of poorly developed hair that breaks at the surface ("exclamation point" hairs) with white shafts. Regrowth occurs within 1 year, but hair loss may recur at the same site. Permanent regrowth of hair usually occurs but is unpredictable. Some individuals will progress to total loss of scalp hair (alopecia totalis) or loss of all body hair (alopecia universalis). The diagnosis is made by observation of the pattern of hair loss. Biopsy may show a lymphocytic infiltrate around the follicle. There are several treatments for alopecia areata, including corticosteroids and topical immunotherapy, but long-term effectiveness is difficult to achieve.[97]

Hirsutism

Hirsutism occurs in women and is the abnormal growth and distribution of terminal hair on the face, body, and pubic area in a male pattern. There is also frontotemporal hair recession. These areas of hair growth are androgen sensitive. Variations of hair growth in women are great, and a male pattern may be normal. The development of hirsutism is usually a result of an underlying endocrine disorder such as polycystic ovarian syndrome (PCOS), adrenal hyperplasia, or adrenal tumors. These disorders require specific treatment. If no hormonal pathologic conditions exist, treatment may include cosmetic removal of hair, suppression of excessive androgen production, or blockage of peripheral androgen receptors.[98]

Disorders of the Nail

Paronychia

Paronychia is an acute or chronic inflammation of the lateral and/or proximal nail fold. One or more fingers or toes may be involved. Individuals whose hands are frequently exposed to moisture are at greatest risk, along with habits such as nail biting, nail picking, thumb sucking, and excessive manicuring. Acute paronychia is manifested by the rapid onset of painful inflammation of the cuticle, usually after minor trauma. An abscess may develop requiring incision and drainage for relief of pain. The skin around the nail becomes more edematous and painful with progressive infection. Pus may be expressed from the proximal nail fold, and an abscess may develop. The nail plate is usually not affected, although it can become discolored with ridges. Typically, organisms present in the skin's normal flora such as *S. aureus* and *S. pyogenes* will be the culprit. Occasionally *Proteus vulgaris* and *Candida* will be present.

Chronic paronychia develops slowly and has been present for more than six weeks. There is tenderness and swelling around the proximal or lateral nail folds that tends to affect more than one nail. It is typically caused by repeated exposure to irritants or allergens that entices infiltrating organisms, such as those encountered by health care workers, food handlers, and farmers. Prevalence of chronic paronychia is also associated with other inflammatory skin disorders.[99]

Treatment includes prevention by keeping the hands dry. Oral antifungals are not effective because they do not penetrate the affected tissues. Therapy includes warm soaks, oral antibiotics and topical application of anti-inflammatory agents and antifungals, steroids, or calcineurin inhibitors.

Onychomycosis

Onychomycosis is a chronic infection of the toenails or fingernails caused by fungi, dermatophyte, yeasts, or nondermatophyte molds or mixed infections. Dermatophyte infection is the most common,

typically caused by Trichophyton mentagrophytes and Trichophyton rubrum. Candida species are the most common yeasts. Transmission requires direct contact with the offending agent. Many times, infection from the toenails will transfer to the fingernails through nail picking or biting. Presentation varies, but discoloration, hyperkeratosis, splitting, and nail plate destruction are common. The most common pattern is a nail plate that turns yellow or white and becomes elevated with the accumulation of hyperkeratotic debris within the plate. Fungal infections of the nail are differentiated from psoriasis, lichen planus, and trauma by culture, microscopy and polymerase chain reaction. There is absence of pitting on the nail surface, which is characteristic of psoriasis. Treatment is difficult because topical or systemic antifungal agents do not penetrate the nail plate readily. Systemic antifungal drugs are effective and topical drugs are available; when used in combination the potential for success improves. Rarely, surgical excision of the nail may be required. Education is essential to preventing recurrence.[100]

Geriatric Considerations

Aging and Changes in Skin Integrity

- Skin becomes thinner, dryer, and more wrinkled with loss of pigmentation. These changes are accelerated by exposure to ultraviolet light exposure, air pollution, tobacco smoke, poor nutrition, and gravity.
- DNA repair of damaged skin decreases.
- Keratinocyte atrophy and cells contain less moisture and change shape.
- A loss of epidermal rete pegs occurs, which weakens the connection to the dermis and gives skin a smooth, shiny, and wrinkled appearance with an increased likelihood of tearing from shearing forces.

- The dermis thins, producing translucent, paper-thin quality that is more susceptible to tearing.
- Dermal fibroblasts age and release proinflammatory mediators and disrupt collagen synthesis with loss of extracellular matrix. The dermis becomes more permeable and less able to clear noxious substances, so they accumulate, cause irritation, and delay wound healing. There is a loss of elastin, contributing to wrinkling.
- There is a loss of flexibility of collagen fibers, so skin cannot stretch and regain shape as readily.
- The barrier function of the stratum corneum is diminished, increasing the risk for injury and infection.
- A significantly decreased number of Langerhans cells reduces the skin's immune response.
- The dermoepidermal border flattens, shortening and reducing the number of capillary loops.

Other Skin Changes With Aging

- Wound healing declines as a result of decreased estrogen in both men and women, decreased blood flow, and a slower rate of basal cell and fibroblast turnover.
- There are fewer melanocytes; pigmentation becomes irregular, giving decreased protection from ultraviolet radiation and leading to graying of hair.
- Atrophy of eccrine, apocrine, and sebaceous glands causes dry skin.
- Pressure and touch receptors and free nerve endings decrease in number, causing reduced sensory perception.
- With compromised temperature regulation, loss of cutaneous vasomotion, and decreased eccrine sweat production, there is an increased risk of heat stroke and hypothermia.
- Loss of hair stem cells results in thinner finer hair.
- The nail plate thins, and nails are more brittle.

Summary Review

Structure and Function of the Skin

1. Skin is the largest organ of the body and equals 20% of body weight. Its major functions are to provide a protective barrier and to regulate body temperature.
2. The skin has three layers—the epidermis (outermost layer), dermis, and hypodermis (subcutaneous layer).
3. The epidermis is a continually renewing defensive layer that contains distinct layers with melanocytes, keratinocytes, Langerhans cells, and Merkel cells.
4. The dermis is composed of connective tissue elements, hair follicles, sweat glands, sebaceous glands, blood vessels, nerves, and lymphatic vessels.
5. The subcutaneous layer (hypodermis) contains connective tissue, fat cells, fibroblasts, and macrophages.

6. The dermal appendages include the nails, hair, sebaceous glands, and eccrine and apocrine sweat glands.
7. The papillary capillaries provide the major blood supply to the skin, arising from deeper arterial plexuses.
8. Heat loss and heat conservation are regulated by arteriovenous anastomoses that lead to the papillary capillaries in the dermis and evaporative loss of sweat.
9. Clinical manifestations of skin dysfunction include lesions, keloids and hypertrophic scars, and pruritus.
10. Pressure injury is localized damage to the skin that results from unrelieved pressure and shearing forces that occlude capillary blood flow, with resulting ischemia and necrosis. Areas at greatest risk are pressure points over bony prominences, such as the greater trochanters, sacrum, ischia, and heels.
11. Keloids are sharply elevated scars that extend beyond the border of traumatized skin. Hypertrophic scars are elevated fibrous lesions that do not extend beyond the border of injury. Both are caused by excess fibroblast activity and abnormal wound healing.
12. Pruritus, or itching, is associated with many skin disorders. It can be acute or chronic, localized or generalized, and migratory.

Disorders of the Skin

1. The most common inflammatory disorders of the skin are eczema and dermatitis. Eczema is characterized by pruritus, lesions with indistinct borders, and epidermal changes. There are multiple types of dermatitis.
2. Allergic contact dermatitis is a form of delayed hypersensitivity that develops with sensitization to allergens, such as metal, chemicals, or plant oils.
3. Irritant contact dermatitis develops from prolonged exposure to chemicals, such as acids or soaps, with disruption of the

skin barrier.

4. Atopic or allergic dermatitis is associated with a family history of asthma or allergic rhinitis and is associated with elevated IgE levels. It is more common in infancy and childhood.
5. Stasis dermatitis, or stasis eczema, occurs on the lower extremities as a result of venous hypertension, chronic venous stasis, venous value reflux, calf muscle pump dysfunction, and edema. The disease can progress into ulcerations that are difficult to treat and lipodermatosclerosis.
6. Seborrheic dermatitis ranges from the fine white scale of dandruff to greasy, scaly, white or yellowish, inflammatory plaques. This typically occurs in areas rich in seborrheic glands such as the scalp, eyebrows, eyelids, ear canals, chest, axillae, and back. The cause is unknown but a genetic predisposition, *Malassezia* fungal infection, immunosuppression, and epidermal hyperproliferation have been implicated.
7. Papulosquamous disorders are characterized by papules, scales, plaques, and erythema and include psoriasis, pityriasis rosea, lichen planus, acne vulgaris, hidradenitis suppurative, acne rosacea, and lupus erythematosus.
8. Psoriasis is a chronic inflammatory skin disease associated with a complex inflammatory cascade involving multiple immune cells resulting in cellular proliferation of both the epidermis and the dermis; it is characterized by scaly, erythematous, pruritic plaques.
9. Pityriasis rosea is a self-limiting inflammatory disease characterized by oval lesions with scales around the edges; it is located along skin lines of the trunk and may be caused by a herpes-like virus.
10. Lichen planus is an autoimmune, papular, violet-colored inflammatory lesion of unknown origin manifested by severe pruritus.
11. Acne vulgaris is an inflammation of the pilosebaceous follicle.

12. Hidradenitis suppurativa (inverse acne) is an inflammatory disease involving the deep sections of apocrine glands. The lesions present in apocrine-gland rich areas as deep, firm painful subcutaneous nodules, often with sinus tracts, and rupture horizontally under the skin.
13. Acne rosacea develops on the middle third of the face with hypertrophy and inflammation of the sebaceous glands and is associated with altered innate immune responses.
14. Cutaneous lupus erythematosus manifests with inflammatory lesions, usually occurring in sun-exposed areas with a butterfly distribution over the nose and cheeks. The cause is unknown but is related to genetic and environmental factors and an altered immune response.
15. Pemphigus is a group of rare, blistering, life-threatening autoimmune diseases of the skin and oral mucous membranes. There are four main subtypes: pemphigus vulgaris (most common), pemphigus foliaceus, paraneoplastic pemphigus, and IgA pemphigus.
16. Erythema multiforme is an uncommon syndrome characterized by inflammation of the skin and/or mucous membranes. EM is an immune-mediated condition caused by an immunologic reaction to a drug or microorganisms. Lesions appear target-like, with alternating rings of edema and inflammation.
17. Stevens-Johnson syndrome (severe mucocutaneous bullous form involving up to 10% of the body surface area) and toxic epidermal necrolysis (severe mucocutaneous bullous form involving 30% or more of the body surface area) are the same disease with a continuum of symptoms. Both are type IV hypersensitivity reactions to drugs and are medical emergencies.
18. Cutaneous infections generally remain localized and can be bacterial, viral, and fungal in origin.
19. Folliculitis is a bacterial infection involving the hair follicles.
20. A furuncle is an infection of the hair follicle that extends to the surrounding tissue.

21. A carbuncle is a coalescence of furuncles.
22. Cellulitis is a diffuse infection of the dermis and subcutaneous tissue usually caused by *S. pyogenes* or CA-MRSA.
23. Erysipelas is a superficial infection of the dermis typically caused by beta-hemolytic streptococci.
24. Impetigo is a superficial infection of the skin caused by coagulase positive *S. aureus* or alpha-hemolytic streptococci. It occurs more commonly in children.
25. Lyme disease is an immune response caused by the spirochete *Borrelia burgdorferi*. It is transmitted by tick bites and often presents with migrating erythematous bull's eye lesions that can progress to chronic myalgias, arthralgias, and neurologic manifestations.
26. HSV-1 causes cold sores but can infect the cornea, mouth, and labia. HSV-2 commonly causes genital lesions and is usually spread by sexual contact.
27. Herpes zoster (shingles) and varicella (chickenpox) are both caused by the same varicella-zoster virus, with herpes zoster manifesting years after the initial infection from latent harboring of the virus.
28. Warts are benign, rough, elevated lesions caused by human papillomavirus. Condylomata acuminata, or venereal warts, are spread by sexual contact.
29. Tinea infections (fungal infections) can occur anywhere on the body and are classified by location (i.e., tinea pedis, tinea corporis, tinea capitis).
30. Candidiasis is a yeastlike fungal infection caused by *C. albicans* occurring on the skin, mucous membranes, in the gastrointestinal tract, and the vagina.
31. Cutaneous vasculitis is an inflammation of skin blood vessels related to immune complex deposition, with purpura, ischemia, and necrosis resulting from vessel necrosis.
32. Urticarial lesions are commonly associated with type I hypersensitivity responses and appear as wheals, welts, or hives.

33. Localized scleroderma is an autoimmune-mediated fibrosis that primarily affects the skin.
34. Systemic scleroderma is an autoimmune-mediated sclerosis of the skin that may also affect systemic organs and cause renal failure, bowel obstruction, or cardiac dysrhythmias.
35. Seborrheic keratosis is a benign proliferation of basal cells that produces elevated, smooth, or warty lesions of varying size. It is most common among the elderly population.
36. Keratoacanthoma arises from hair follicles on sun-exposed areas. Three stages of development over a period of 1 to 2 months characterize the lesion. Lesions resolve spontaneously or can be removed.
37. Actinic keratosis is a rough, poorly defined papule that develops in sun-exposed individuals with fair skin. The lesion may become malignant in the form of a squamous cell carcinoma.
38. Nevi (moles) arise from melanocytes and may be pigmented or nonpigmented. They occur singly or in groups and may undergo transition to malignant melanoma.
39. Skin cancer is usually caused by chronic exposure to ultraviolet radiation and is the most common cancer in the world.
40. Basal cell carcinoma is the most common skin cancer and occurs most often on ultraviolet-exposed areas with different subtypes and morphologic presentations.
41. Squamous cell carcinoma is a tumor of the epidermis with uncontrolled growth of keratinocytes associated with sun exposure and can be localized (in situ) or invasive.
42. Cutaneous melanoma is a malignant tumor that arises from melanocytes. If it is not excised early, metastasis occurs through the lymph nodes.
43. Kaposi sarcoma is an endothelial cell vascular malignancy associated with immunodeficiency states and herpesvirus 8.
44. Primary cutaneous lymphomas are clonal expansions of T-cell and B-cell lymphocytes. Mycosis fungoides is the most common T-cell lymphoma.

45. Cold injury usually occurs on the face and digits, with direct injury to cells and impaired circulation.

Disorders of the Hair

1. Androgenic alopecia is an inherited form of baldness with hair loss in the central scalp and recession of the frontotemporal hairline that occurs in men.
2. Female-pattern alopecia is a thinning of the central hair of the scalp in women and is associated with endocrine disorders.
3. Alopecia areata is patchy loss of hair associated with an autoimmune process and triggered by stress or metabolic diseases; it is usually reversible.
4. Hirsutism is a male pattern of terminal hair growth in women that may be normal or the result of excessive secretion of androgenic hormones.

Disorders of the Nail

1. Paronychia is an inflammation of the lateral or proximal nail fold that can be acute or chronic. It is usually caused by staphylococci, streptococci, or fungi.
2. Onychomycosis is a fungal, yeast, or dermophyte infection of the nail plate.

Aging and Changes in Skin Integrity

1. Skin becomes thinner, drier, and more wrinkled.
2. Wound healing decreases.
3. Fewer melanocytes mean pigmentation becomes irregular, providing less protection from ultraviolet light.

- Pediculosis (Lice Infestation), 1551

Vascular Anomalies, 1551
- Infantile Hemangiomas, 1551

Other Skin Disorders, 1553
- Psoriasis, 1553
- Newborn Rashes, 1553

Children frequently develop alterations of the skin, which range in severity. Cutaneous manifestations may provide information for other systemic concerns and provide clinical clues to assist with diagnostic dilemmas. Some skin diseases resolve spontaneously and require no treatment. Diagnosis is commonly made from the history, appearance, and distribution of the lesion or lesions. Common skin diseases of childhood are presented here.

Acne Vulgaris

Acne vulgaris is the most common skin disease and occurs primarily between the ages of 12 and 25 years. Acne tends to occur in families, and genetic susceptibility may determine the severity of the disease.

Acne develops at distinctive pilosebaceous units, known as *sebaceous follicles*. Located primarily on the face and upper parts of the chest and back, these follicles have many large sebaceous glands, a small vellus hair (very short, nonpigmented, and very thin hair), and a dilated follicular canal that is visible as a pore on the skin surface. Acne lesions may be noninflammatory or inflammatory (cystic) (Fig. 47.1). In **noninflammatory acne**, the comedones are open (blackheads) and closed (whiteheads), with the accumulated material causing distention of the follicle and thinning of follicular canal walls. **Inflammatory (including cystic) acne** develops in closed comedones when the follicular wall ruptures, expelling sebum into the surrounding dermis and initiating inflammation (see Fig. 47.1). Pustules form when the inflammation is close to the surface; papules and cystic nodules can develop when the inflammation is deeper, causing mild to severe scarring. Both types of lesions may exist in the same individual.

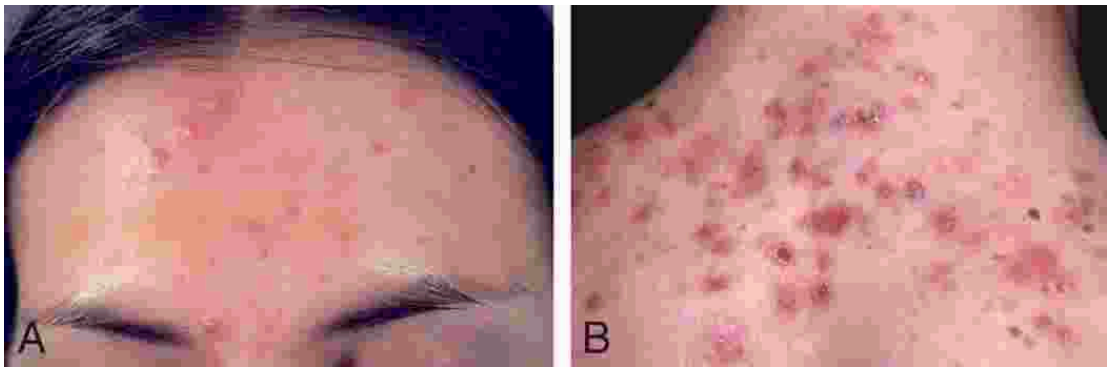

FIG. 47.1 Acne.
(A) Inflammatory papules and pustules. (B) Severe nodular cystic acne. (From Nelson WE, Behrman RE, Kliegman RM, et al., eds. *Nelson textbook of pediatrics*, 21st edition. Philadelphia: Elsevier; 2020.)

The causal mechanism is not completely understood. The pathophysiology includes (1) hyperkeratinization of the follicular epithelium; (2) altered sebum production, including hyperseborrhea and dysseborrhea; (3) follicular proliferation of anaerobic *Cutibacterium acnes* (*C. acnes*, previously known as *Propionibacterium acnes*); and (4) inflammation and rupture of a follicle due to accumulated debris and bacteria. *C. acnes* strains shift from being symbiotic to a pathogenic strain of bacteria and shift from being noninflammatory to inflammatory. The main hormones responsible for the development of acne vulgaris include androgens, insulin, and insulin-like growth factor-1; additional hormones have also been identified.[1] Androgens (dehydroepiandrosterone sulfate and testosterone) that are synthesized in increasing amounts during puberty increase the size and productivity of the sebaceous glands, promoting comedome formation. Rupture of comedomes causes release of inflammatory mediators and proliferation of inflammatory *C. acnes* strains in susceptible individuals. Scarring results from chronic inflammation and lesions below the reticular dermis.[2]

The treatment of acne should be individualized, according to severity. Combinations of topical products that contain retinoids, benzoyl peroxide, and antimicrobial agents, remain preferred. Retinoids are anticomedogenic and comedolytic, have anti-inflammatory effects, and target multiple pathogenic microorganisms associated with acne. Benzoyl peroxide is antimicrobial, with some keratolytic effects. Recognition that acne is an inflammatory condition, not an infectious one, has led to a call for reduction in oral antibiotic use to avoid antibiotic resistance and to promote future effectiveness of the drugs. Use of oral antibiotics with a narrower spectrum of activity is another strategy.[3] Use of systemic therapies, including oral contraceptives, corticosteroids, and isotretinoin (requires pregnancy prevention and monthly monitoring), may be limited by side effects. Acne surgery, including comedone extraction, intralesional steroids, and cryosurgery, is useful in selected individuals. Special consideration must be given to treatment for those with darker skin because they have greater risk for hyperpigmentation and keloidal scarring. Severe scarring may be treated with dermabrasion, lasers, and resurfacing techniques. Laser and light modalities, although not sufficiently studied for first-line use, show promise for the future. The relationship between nutrition and acne, allowing the identification of a certain number of potential triggers, such as dairy products, hyperglycemic load, and the excessive intake of whey proteins is still unclear.[3] Psychologic support is important because acne negatively affects quality of life, self-esteem, and mood in adolescents and is associated with an increased risk of anxiety, depression, and suicidal ideation. Guidelines are available for the treatment of acne.[4]

Acne conglobata is a rare yet highly inflammatory form of acne, with communicating cysts and abscesses beneath the skin that can cause scarring and disfigurement. The bacterium involved in acne vulgaris–Propionibacterium acnes–may also play a role in acne conglobate by changing the bacteria's reactivity as an antigen. Hypersensitivity to the bacterium antigens results in an immunological response that leads to a chronic inflammatory state. Androgens and anabolic steroids, as well as exposure to thyroid medications and halogenated aromatic hydrocarbons, may result in the formation of acne conglobate. Attempts to hide the disease with clothing may lead to excessive warmth and humidity in the area of the acne, and these conditions can worsen the disease.[5] This type of acne requires the use of systemic and combination therapies to prevent drug resistance, and severe scarring may require treatment.

Dermatitis

Atopic Dermatitis

Atopic dermatitis (AD), also known as atopic eczema, is the most common cause of eczema in children. Onset is usually from 2 to 6 months of age, and most cases develop within the first 5 years of life; however, AD can affect individuals of any age.

The cause of this chronic relapsing form of pruritic eczema involves an interplay of genetic predisposition. Atopic comorbidities of asthma, allergic rhinitis, and food allergies are well recognized in persons with AD. The skin barrier function is altered and associated with filaggrin gene mutations and filaggrin deficiency (proteins that bind keratin in the epidermis); reduced ceramide (a stratum corneum lipid) levels; decreased antimicrobial peptides; altered innate immunity; and altered immune responses to allergens, irritants, and microbes. There is an altered skin microbiome with formation of biofilm by *Staphylococcus aureus*, that may act as super-antigens, causing exacerbations of eczema. Although AD is predominantly associated with type 2 immune responses, activation of T-cell cytokine pathways have been reported,[6] resulting in new therapeutic targets using novel biologic therapy.[7]

AD has a constellation of clinical features, including severe pruritus and a characteristic eczematoid appearance with redness, edema, and scaling. The skin becomes increasingly dry, itchy, sensitive, and easily irritated because the barrier function of the skin is impaired. Itching is the hallmark of AD; rubbing and scratching to relieve the itch are responsible for many of the clinical skin changes of AD. In young children, a rash appears primarily on the face, scalp, trunk, and extensor surfaces of the arms and legs (Fig. 47.2A). In older children and adults, the rash tends to be found on the neck, antecubital and popliteal fossae, and hands and feet. Individuals with AD also tend to develop viral, bacterial, and fungal skin infections in the eczematous areas. Another common manifestation is secondary creases in the skin below the lower eyelids, known as Dennie-Morgan fold (see Fig. 47.2B); it may be related to skin edema and chronic spasm of Mullër eyelid muscles, resulting from hypoxia linked to poor blood circulation. This sign may be accompanied with dark eye circles, caused by accumulation of blood and other fluids in the infraorbital groove and an associated allergic rhinitis.[8] There are no specific laboratory features of AD that can be used for diagnostic and treatment purposes. Most affected individuals show increased serum levels of immunoglobulin E (IgE), eosinophils (eosinophilia), and positive skin test results to a variety of common food and inhalant allergens.

A

FIG. 47.2 Atopic Dermatitis.
(A) Characteristic lesions with crusting from irritation and scratching over knees and around ankles. (B) Dennie-Morgan fold (*white arrows*) with dark eye circles. (A, Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT. B, From Blanc S, Bourrier T, Albertini M, et al. Dennie–Morgan fold plus dark circles: Suspect atopy at first sight. *Journal of Pediatrics*. 2015;166[6]:1541.)

Management of individuals with AD includes accurate diagnosis, comprehensive evaluation of triggers, response to treatment, management of confounding factors (sleep disruption), and education provided to individuals and caregivers. Successful AD management strategies are published in national and international treatment guidelines. Treatment is implemented in a stepwise approach, tailored to the individuals.[7,9] Avoidance of triggers and promotion of skin hydration, including soaking baths and consistent use of an emollient moisturizer, are the cornerstone to good therapy.[10] Topical anti-inflammatory agents, such as corticosteroids, calcineurin inhibitors, and phosphodiesterase type 4 inhibitors, are first-line treatment options during active flare-ups of eczema at all levels of severity. Sedating antihistamines, as well as topical and oral antibiotics and bleach baths, may be added as indicated. Therapy is increased for moderate to severe AD, which may include systemic immunomodulator therapy, biologic agents, and wet wrap therapy.[7,9–11]

Contact Dermatitis

Contact dermatitis is an umbrella term that describes an eczematous eruption, resulting from either delayed hypersensitive reaction to an allergen (allergic contact dermatitis) or direct irritation to the skin from an irritating substance (irritant contact dermatitis).[12] This results in nonspecific intracellular edema and inflammation. Key management requires the identification and elimination of future exposure to the specific allergen or irritant.

Allergic Contact Dermatitis

Allergic contact dermatitis is caused by delayed hypersensitivity reaction to contact with the allergen, which is a T-cell mediated, type IV delayed immune response. Common allergens in children are nickel exposure from metals in jewelry and snaps, as well as topical products and plants.

Clinical manifestations of allergic contact dermatitis are often localized, pruritic, and rash with discrete border and shape. Skin lesions are usually in the distribution of the contacting allergen and may appear as erythematous papular lesions, blisters, vesicles, or just erythematous linear rash. Lesions appear a day or two after exposure to allergen and may last for weeks, without further exposure. Patch testing is the gold standard for diagnosis. Treatment includes topical therapies[12] and avoidance of allergens.

Irritant Contact Dermatitis

Irritant contact dermatitis may occur at any age and be due to anything that is irritating to the individual. Irritants include topical use of almost anything used on the skin, including cleansers, moisturizers, antiseptics, shampoos, and others. It is common in young infants due to skin sensitivity and exposure to primary irritants. Irritant contact dermatitis due to irritation in the diaper area is frequently referred to as diaper dermatitis.[13] It is one common form of irritant contact dermatitis and initiated by a combination of factors including prolonged exposure to and irritation by urine wetness and feces, as well as maceration by wet diapers, airtight plastic diaper covers, or use of diaper wipes. Disposable diaper designs have decreased the incidence of diaper dermatitis in infants. Diapers with a mesh-like, aperture top sheet may represent a better way to mitigate known causes of diaper dermatitis through their superior ability to absorb fecal matter.[14] Often, diaper dermatitis is secondarily infected with *Candida albicans*. The resulting inflammation affects the lower aspect of the abdomen, genitalia, buttocks, and upper portion of the thigh.

The lesions vary from mild erythema to erythematous papular lesions and can affect overall infant health.[12] Candidal (monilial) diaper dermatitis is usually very erythematous, with sharp margination and pustulovesicular satellite lesions (Fig. 47.3).

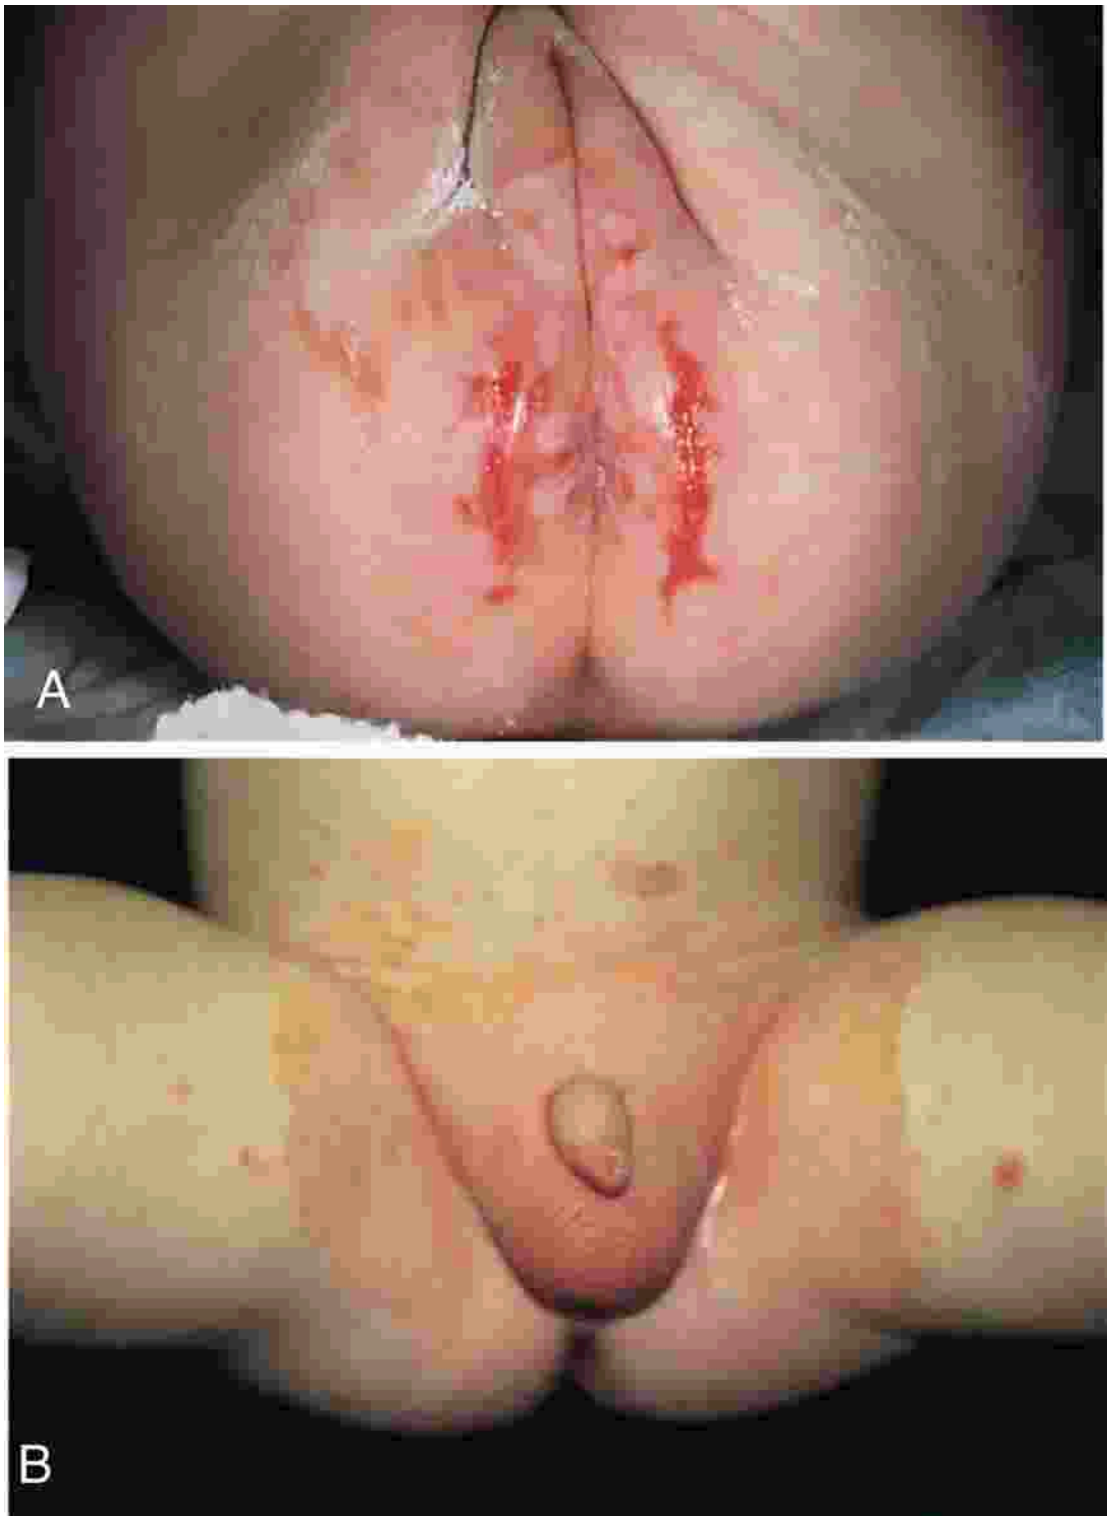

FIG. 47.3 Irritant Contact Dermatitis (ICD) in Diaper Area.
(A) ICD in diaper area with erosions. (B) ICD in diaper area with *Candida albicans* secondary infection. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

A. Close shot of severe red sore in the buttock area of an infant. B. Close shot of reddish patch of the lesion in the genital area spreading of till the lower abdomen and both inner thighs of the infant.

Treatment involves frequent diaper changes to keep the affected area clean and dry or regular exposure of the perineal area to air and to use of superabsorbent diapers.[14] Topical protection of the skin can be obtained by using a product containing petrolatum or zinc oxide, or both. Cleaning should be limited to gentle washing with water, using a soft washcloth or cotton balls, without using diaper wipes, and using fragrance-free products. Additionally, for allergic dermatitis, low-potency topical corticosteroids to the groin or diaper area are indicated. Topical antifungal medication is used to treat *C. albicans* when present.

Infections of the Skin

Infectious diseases caused by bacteria, viruses, and fungi constitute the major forms of skin disease. Breaks in the skin integrity, particularly those that inoculate pathogens into the dermis and epidermis, may cause or exacerbate infections. Most infections tend to occur superficially; however, systemic signs and symptoms develop occasionally and can be life-threatening in immunosuppressed children.

Bacterial Infections

Impetigo

Impetigo is the most common bacterial skin infection in children 2 to 5 years of age and is highly contagious. *S. aureus* and, less commonly, *Streptococcus pyogenes* cause impetigo.[15] The mode of transmission is by both direct and indirect contact. The disease is more common in mid- to late summer, with a higher incidence in hot, humid climates. Impetigo is particularly infectious among people living in crowded conditions with poor sanitary facilities or in settings such as day-care facilities. It affects children in good health, but conditions such as anemia and malnutrition are predisposing factors.

Bacterial invasion occurs through minor breaks in the cutaneous surface or as a secondary infection of a preexisting dermatosis or infestation. The staphylococci produce bacterial toxins *(exfoliative toxins [ETs])* that cause a disruption in the skin barrier with blister formation. There are two types of impetigo: nonbullous or vesicular and, more rarely, bullous (caused only by *S. aureus*), in which blisters enlarge or coalesce to form bullae. Both forms of impetigo begin as vesicles that rupture to form a honey-colored crust (Fig. 47.4). The lesions are often located on the face, around the nose and mouth, but the hands and other exposed areas are also involved.

FIG. 47.4 Impetigo. Multiple crusted and oozing lesions of impetigo. (From Kliegman RM, Nelson WE, eds. *Nelson textbook of pediatrics*, 19th edition. Philadelphia: Saunders; 2011.)

Impetigo is clinically characterized by crusted erosions or ulcers that may arise as a primary infection or as a secondary infection of other pre-existing dermatosis or infestation. Resistance patterns in a wide range of pathogens against oral or topical antibiotics and antiseptics, used for the treatment of dermatological conditions such as impetigo, have been reported. When making treatment decisions for impetigo, methicillin-resistant *Staphylococcus aureus* (MRSA) and other antimicrobial resistance has to be considered. Many treatment options exist, including bleach baths and topical antibiotics, such as mupirocin, fusidic acid, retapamulin, and ozenoxacin.[15] For extensive or complicated impetigo, systemic antibiotics may be warranted, but β-lactam antibiotics should be avoided if MRSA is suspected. Prompt treatment avoids complications, such as glomerulonephritis, necrotizing fasciitis, and septic shock syndrome. Lesions usually resolve in 2 to 3 weeks, without scarring. Using good handwashing techniques and isolating the infected child's washcloth, towels, drinking glass, and linen are important for prevention.

Staphylococcal Scalded-Skin Syndrome

Staphylococcal scalded-skin syndrome (SSSS), also known as **Ritter disease**, is considered a pediatric emergency. It is the most serious staphylococcal infection that affects the skin and often may occur in infants and younger children under age 5.[16,17] SSSS is caused by virulent group II strains of staphylococci that produce an exfoliative toxin. The toxin attacks desmoglein and keratinocyte adhesion molecules and causes a separation of the skin just below the granular layer of the epidermis with blister formation. The toxin is usually produced at body sites other than the skin and arrives at the epidermis through the circulatory system. Staphylococci typically are not found in the skin lesions themselves. Adults have circulating antistaphylococcal antibodies and

are better able to metabolize and excrete the toxin. Neonates are at the highest risk because of their lack of immunity, with no prior exposure to the toxin.

The clinical symptoms begin with fever, malaise, rhinorrhea, and irritability, followed by generalized erythema with exquisite tenderness of the skin. The severity may vary from a few lesions to systemic exfoliation. There may be an associated impetigo, but the infection often begins in the throat or chest. The erythema spreads from the face and trunk to cover the entire body, except for the palms, soles, and mucous membranes. The diagnosis is mainly clinical, based on the findings of tender erythroderma, bullae, and desquamation with a scalded appearance, especially in friction zones, periorificial scabs/crusting, positive Nikolsky sign, and absence of mucosal involvement. Within 48 hours, blisters and bullae may form, giving the child the appearance of being scalded. The pain is severe (Fig. 47.5). Fluid loss from ruptured blisters and water evaporation from denuded areas may cause dehydration. Perioral and nasolabial crusting, as well as fissures develop. In severe cases, the skin of the entire body may slough. When secondary infection can be prevented, healing of the involved skin occurs in 10 to 14 days, usually without scarring.[17]

FIG. 47.5 Staphylococcal Scalded-Skin Syndrome (SSSS). The skin lesions, showing desquamation and wrinkling of the skin margins, appeared 1 day after drainage of a staphylococcal abscess. (From Kliegman RM, et al. *Nelson textbook of pediatrics*, 19th edition. St. Louis: Saunders; 2011.)

Although generally a clinical diagnosis, culture and histologic or exfoliative cytologic studies should be initiated prior to treatment. Prompt empiric treatment with intravenous anti-

staphylococcal antibiotic, such as nafcillin, oxacillin, or flucloxacillin, is essential until cultures are available to guide therapy. Ophthalmology is consulted for eye involvement to prevent scarring. When SSSS infection is confirmed, treatment with intravenous antibiotics begins, as well as fluid and electrolyte management. The skin should be treated in the same manner as a severe burn, with meticulous aseptic technique. Special care is required when the lips and eyelids are involved. Infection control practices are important for prevention.[17]

Fungal Infections

Dermatophyte infections

Dermatophyte infections of keratin-containing skin and skin structures result in tinea capitis (scalp), tinea corporis (body), tinea pedis (foot), and tinea unguium (nails). These fungal infections are some of the most common worldwide. The three dermatophyte genera include *Trichophyton*, *Microsporum*, and *Epidermophyton*. Most of the dermatophyte species are parasitic and can cause disease in either humans or animals, often being adapted to a single or narrow range of host species.[18]

Tinea Capitis

Tinea capitis, a fungal infection of the scalp (scalp ringworm), is the most common fungal infection of childhood. It rarely affects infants and is seen in children between 2 and 10 years of age. The primary microorganism responsible for this disease in North America is *Trichophyton tonsurans*, and less commonly *Microsporum* is involved.[18,19] There is direct human transmission of *T. tonsurans* in crowded areas, the most prevalent environment of the fungus, and from contact with animals like infected cats and dogs.[20] The lesions are often circular and manifested by the presence of scales and broken hairs 1 to 3 mm above the scalp, leaving a partial area of alopecia from 1 to 5 cm in diameter (Fig. 47.6). A slight erythema and scaling, with raised borders, can be observed.

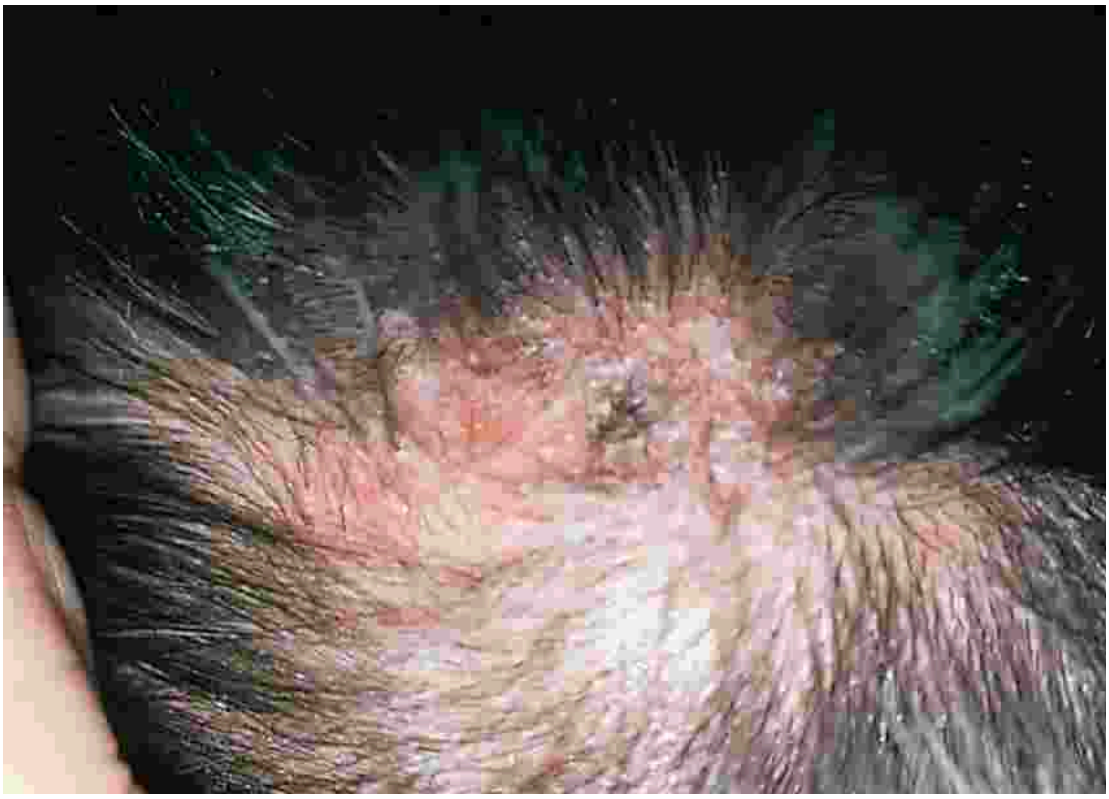

FIG. 47.6 Tinea Capitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

Diagnosis is best confirmed by dermoscopy, potassium hydroxide (KOH) examination of the scale from a scraping, and fungal culture. The most efficient method of sample collection[20] is the hairbrush collection method or by carefully removing broken hair stubs with forceps. Tinea capitis always requires systemic treatment because topical antifungal agents do not penetrate the hair follicle. Several oral antifungal agents are available for treatment.[18,19]

Tinea Corporis

Tinea corporis (ringworm) is a common superficial dermatophyte infection in children. The organisms most commonly responsible for this disease are *Microsporum canis* and *Trichophyton mentagrophytes*. As in tinea capitis, contact with infected kittens and puppies is a common source of the disorder. Tinea corporis preferentially affects the nonhairy parts of the face, trunk, and limbs. Lesions are often erythematous (round or oval scaling patches that spread peripherally with clearing in the center), creating the ring appearance, which is why this disease is commonly referred to as *ringworm*. The lesions are distributed asymmetrically, and multiple lesions, when present, overlap. Transmission occurs by direct contact with an infected lesion and through indirect contact with personal items used by the infected person. At times, a Majocchi granuloma develops as organisms (typically *T. rubrum*) penetrate along hair follicles to the level of the dermis, producing follicular-based pustules or nodules.[18] KOH examination of the scale from the border of the lesions or fungal culture confirms the diagnosis. Current diagnosis is critical as guessing and the inappropriate treatment of fungal disease with topical corticosteroids worsens this condition. Cutaneous lesions generally respond well to topical therapy; however, for hair or nail involvement, oral treatment is usually warranted.

Candida

Candida comprises the genus that causes the most frequent fungal infections in humans. A wide range of yeasts that reproduce via budding, often by forming long chains called pseudohyphae, are contained in this genus. There are at least 15 distinct species of Candida, the most common of which is *Candida albicans*, which comprises about 50% of Candida infections and is found normally colonized on the skin, mouth, intestinal tract, and vagina.[18]

Oral candidiasis, also known as oral thrush, is the term used to describe the presence of *C. albicans* in the mucous membranes of the mouths. It is commonly encountered in the newborn period where infants can acquire this infection in utero or postnatally, via passage through the vaginal canal.[18] It occurs in immunocompromised individuals of all ages. *C. albicans* penetrates the epidermal barrier more easily than other microorganisms because of its keratolytic proteases, other enzymes, and evasion of neutrophil killing. Oral thrush is characterized by the formation of white plaques or spots in the mouth that lead to shallow ulcers, caused by keratolytic proteases from the microorganism. The tongue may have a dense, white covering. The underlying mucous membrane is red and tender and may bleed when the plaques are removed. The prevalence of oral candidiasis is much higher in bottle-fed versus breast-fed infants.[18] The disease is often accompanied by fever and gastrointestinal irritation. The infection commonly spreads to the groin, buttocks, and other parts of the body. Treatment may be difficult and includes oral antifungal washes, such as nystatin oral suspension. Simultaneous treatment of a *Candida* nipple infection or vaginitis in the mother is helpful in reducing the *C. albicans* surface colonization of the infant. Feeding bottles and nipples should be sterilized to prevent reinfection.

Viral Infections

Molluscum Contagiosum

Molluscum contagiosum is a benign self-limiting skin disease, caused by infection with a pox virus. The virus is spread from person-to-person direct contact, auto inoculation, or through contaminated fomites.[21,22] It occurs worldwide, primarily in children and more often in warm climates.[23] Molluscum contagiosum virus (MCV) is the sole member of the *Molluscipoxvirus* genus and the causative agent of molluscum contagiosum. The lesions of molluscum are discrete, slightly umbilicated, dome-shaped papules 1 to 5 mm in diameter that appear anywhere on the skin or conjunctiva (Fig. 47.7). There is generally no inflammation surrounding molluscum lesions, unless they are traumatized, or secondary infection occurs. Scarring may occur with healing. Generally mollusca are diagnosed clinically and do not require biopsy or other diagnostic procedures. Most lesions are self-limiting and clear in 6 to 9 months; however, some may persist for 3 to 4 years.[23]

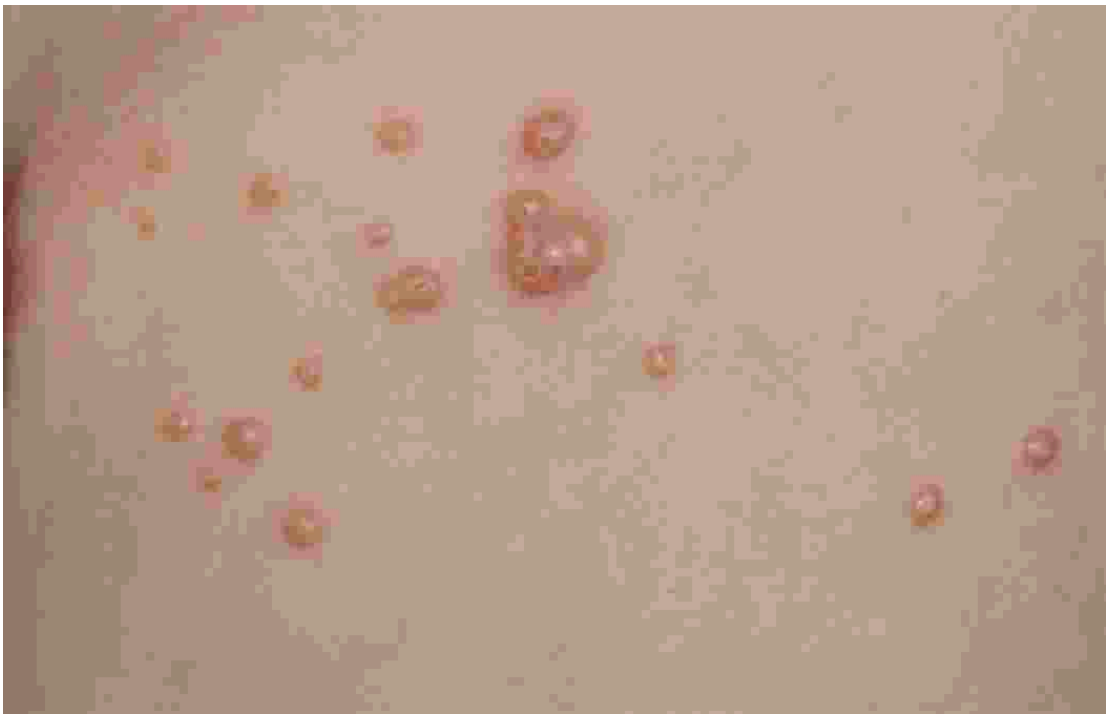

FIG. 47.7 Molluscum Contagiosum. Waxy pink globules with umbilicated centers. (From Habif TP. *Clinical dermatology: A color guide to diagnosis and therapy*, 4th edition. St. Louis: Mosby; 2004.)

Treatment is not necessary and usually initiated to alleviate discomfort and itch, to prevent secondary infection, to prevent trauma to lesions and bleeding, to limit the spread of the lesions, and for the social stigma or cosmetic reasons related to the infection. Although many options for treatment have been tried,[22] to date, the evidence does not support any treatment (destruction, oral, or topical) as superior to placebo.[23]

Verruca Vulgaris

Warts (verruca vulgaris) are benign lesions caused by human papillomavirus (HPV), with 189 subtypes identified. Clinical manifestations/locations have been correlated to specific subtypes. Although they may occur in any part of the body, they favor areas of epithelial disruption and mucosa. They may be spread by direct and indirect contact. Malignant transformation may occur in in immunocompromised individuals, genital warts, high-risk subtypes, or those subtypes implicated in epidermodysplasia verruciformis. This is a clinical diagnosis and does not require biopsy, unless concern for malignancy exists. Generally, warts resolve spontaneously over several years. Treatment is dependent on individual preference, type of wart, location, size, and number. Elective treatments may require multiple sessions. Treatment may be poorly tolerated or result in scarring. Generally, first-line treatment is application of salicylic acid, which is available without prescription.[24,25] Intralesion immunotherapy is an emerging alternative therapy.[26]

Rubella (German or 3-Day Measles)

Rubella is a common communicable disease of children and young adults, caused by an enveloped, positive-stranded RNA virus and classified as a Rubivirus in the Togaviridae family. Rubella is transmitted primarily through direct or droplet contact from nasopharyngeal secretions. Humans are the only natural hosts. In temperate climates, infections usually occur

during late winter and early spring.[27] This disease is mild in most children. The incubation period ranges from 12 to 23 days. Prodromal symptoms include enlarged cervical and postauricular lymph nodes, low-grade fever, headache, sore throat, rhinorrhea, and cough. A faint-pink to red confluent maculopapular rash develops on the face, with spread to the trunk and extremities 1 to 4 days after the onset of initial symptoms (Fig. 47.8). The rash is thought to be the result of virus dissemination to the skin. The rash subsides after 2 to 3 days, usually without complication. People infected with rubella are most contagious when the rash is erupting, but they can be contagious from 7 days before and 7 days after the rash appears (Table 47.1).[27] There is no specific antiviral treatment for rubella, and most therapy is supportive. Antibiotic therapy is initiated if secondary bacterial infections develop. Recovery is usually spontaneous, although lymph nodes may remain enlarged for weeks.

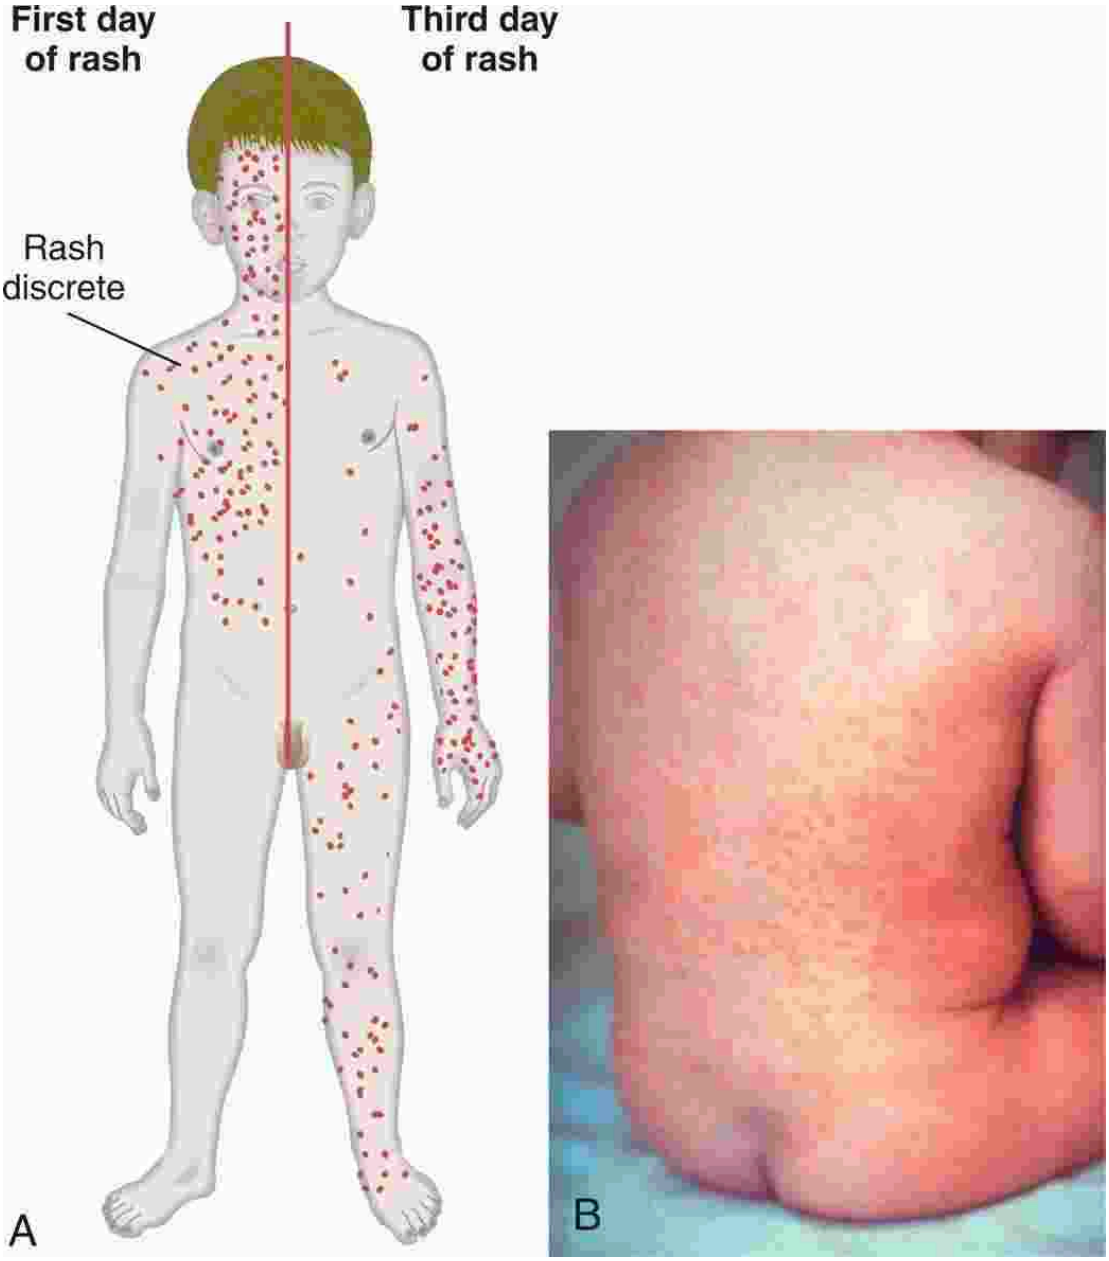

FIG. 47.8 Rubella (3-Day Measles).
(A) Typical distribution of full-blown maculopapular rash with tendency to coalesce. (B) Rash of rubella. (From Centers for Disease Control and Prevention: Image Bank, Figure #712. https://www.cdc.gov/rubella/about/photos.html. Accessed April 12, 2022.)

A. An illustration of a small body depicts the rash discrete relatively on the trunk and face on the left side of the body on the first day and rash discretely over the hands and legs on the third day of the rash. B. A close shot of an infantâ€™s back with a reddish rash spread over the entire surface of the back.

Table 47.1

Differential Presentation of Viral Diseases Producing Rashes

Viral Disease	Incubation	Prodromal Symptoms	Duration/Characteristics	Clinical Symptoms
Rubella (German measles; rubivirus)	14–21 days	1–2 days Mild fever Malaise Respiratory symptoms	1–3 days Pink-red maculopapular rash Face and trunk	Enlarged and tender occipital and periauricular lymph nodes
Rubeola (measles; paramyxovirus)	7–12 days	2–5 days Fever Cough Respiratory symptoms	3–5 days Purple-red to brown maculopapular papules Face, trunk, extremities	Koplik spots[a] 1–3 days before rash Rash develops when fever subsides
Roseola (exanthema subitum; human herpesvirus 6 and 7)	5–15 days	2–5 days High fever	1–3 days Pink-red macular papules Neck and trunk	
Varicella (chickenpox; varicella- zoster virus)	11–20 days	1–2 days Low-grade fever Cough May be asymptomatic	Red papules, vesicles, pustules in clusters	Eruption of new lesions for 4–5 days Occasional ulcerative lesion in mouth
Hand, foot, and mouth disease (coxsackie A virus and enterovirus A71)	4–6 days	Fever, sore throat, anorexia	3–7 days Gray thick-walled vesicles 3–6 mm in diameter with a red or noninflamed base,	None or fever, diarrhea, sore throat

Viral Disease	Incubation	Prodromal Symptoms	Duration/Characteristics	Clinical Symptoms
			commonly on palms, soles and sides of feet, and mouth mucosa	

Viral Disease	Incubation	Prodromal Symptoms	Duration/Characteristics	Clinical Symptoms
Rubella (German measles; rubivirus)	14–21 days	1–2 days Mild fever Malaise Respiratory symptoms	1–3 days Pink-red maculopapular rash Face and trunk	Enlarged and tender occipital and periauricular lymph nodes
Rubeola (measles; paramyxovirus)	7–12 days	2–5 days Fever Cough Respiratory symptoms	3–5 days Purple-red to brown maculopapular papules Face, trunk, extremities	Koplik spots[a] 1–3 days before rash Rash develops when fever subsides
Roseola (exanthema subitum; human herpesvirus 6 and 7)	5–15 days	2–5 days High fever	1–3 days Pink-red macular papules Neck and trunk	
Varicella (chickenpox; varicella- zoster virus)	11–20 days	1–2 days Low-grade fever Cough May be asymptomatic	Red papules, vesicles, pustules in clusters	Eruption of new lesions for 4–5 days Occasional ulcerative lesion in mouth
Hand, foot, and mouth disease (coxsackie A virus and enterovirus A71)	4–6 days	Fever, sore throat, anorexia	3–7 days Gray thick-walled vesicles 3–6 mm in diameter with a red or noninflamed base, commonly on palms, soles and sides of feet, and mouth mucosa	None or fever, diarrhea, sore throat

[a]Koplic spots: clusters of white lesions on the lower buccal mucosa.

Vaccination for rubella is usually given in combination with mumps and measles (rubeola) (MMR). The Centers for Disease Control and Prevention vaccine recommendations are available at https://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html. The measles, mumps, and rubella (MMR) vaccine has an outstanding safety record and is highly efficacious.[28] High coverage with MMR has led to the elimination of endemic measles, rubella, and congenital rubella syndrome in the United States. The biggest challenges to global measles and rubella control and elimination are insufficient vaccination coverage globally and increasing hesitancy.[28] The MMR vaccine has rarely been associated with adverse neurologic events. A common misconception is that inoculation with MMR can cause autism; however, studies conclude that MMR immunization does not cause autism.[28] Lack of vaccination, however, leads to loss of herd immunity and significant morbidity and mortality with pneumonia, croup, and encephalitis being causes of death worldwide. Women of childbearing age are immunized if their rubella hemagglutination-inhibition titer is low. Pregnancy should be avoided for 3 months after vaccination because the attenuated virus in the vaccine may remain viable for this period.

Pregnancy in women who have rubella early in the first trimester has been associated with congenital defects.

Rubeola

Rubeola is a highly contagious, acute viral disease of childhood. Transmitted by direct contact with droplets from infected persons, rubeola is caused by an RNA-containing paramyxovirus with an incubation period of 7 to 12 days, during which there are no symptoms.[29] The virus enters the respiratory tract, attaches to alveolar macrophages, amplifies in local lymphatic tissue, and progresses to systemic disease. Prodromal symptoms include high fever (up to 40.5°C [104.9°F]), malaise, enlarged lymph nodes, rhinorrhea, conjunctivitis, and barking cough. Characteristic pinpoint white spots, surrounded by an erythematous ring, develop over the buccal mucosa and are known as *Koplik spots*. These spots appear 2 to 3 days after viral symptoms begin and precede the body rash by 1 to 2 days. Within 3 to 4 days, an erythematous maculopapular rash develops over the head and spreads distally over the trunk, extremities, hands, and feet. Early lesions blanch with pressure, followed by a brownish hue that does not blanch as the rash fades. The rash then subsides within 3 to 5 days.[29]

Complications associated with measles may be caused by the primary infection or by a secondary bacterial infection. Measles encephalitis occurs rarely, and most children recover completely; only a small minority of children develop permanent brain damage or die. Bacterial complications include otitis media and pneumonia, usually caused by group A hemolytic *Streptococcus*, *Haemophilus influenzae*, or *S. aureus* infection.

Measles is prevented by vaccination, as discussed in rubella section above. There is no specific viral treatment for measles, and supportive and care therapy is the same as that recommended for rubella.

Roseola Infantum (Exanthema Subitum, Sixth Disease)

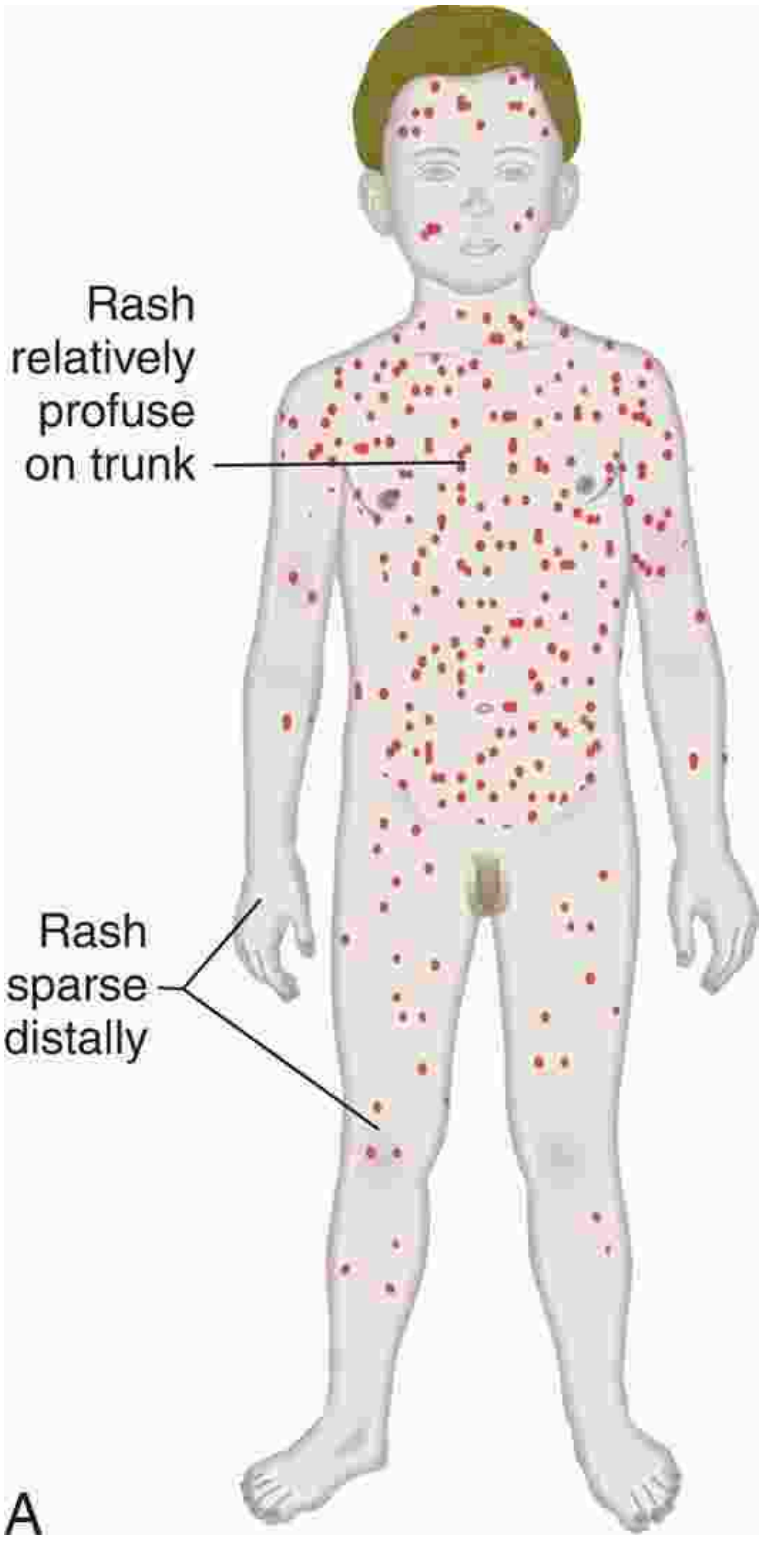
Roseola Infantum is a common viral illness of childhood, also known as exanthema subitum and sixth disease. It is caused by a primary infection with human herpesvirus 6 (HHV-6) and caused less frequently by human herpesvirus 7 (HHV-7). The disease presents in children ages 6 to 12 months, with 90% of cases occurring in children younger than 2 years. Caused by the B variant of HHV-6, individuals with the virus classically present with an acute onset of a high-grade fever up to 40°C (104°F) for 3 to 5 days.[30] As the fever diminishes, a nonpruritic, pink papular rash appears, primarily over the trunk and neck and lasts about 24 hours. Children usually feel well, eat normally, and have few other symptoms, after fever subsides. It is a self-limited illness that is treated symptomatically.

Chickenpox

Chickenpox (varicella) is a highly contagious viral illness caused by the varicella-zoster virus and is spread by close person-to-person contact and by airborne droplets. Introduction of an infected person into a household results in a 90% possibility of susceptible persons developing the disease within the incubation period, usually 14 days. Vesicular lesions occur in the epidermis as infection occurs within keratinocytes. An inflammatory infiltrate is often present. Vesicles eventually rupture, followed by crust formation or the development of transient ulcers on mucous membranes. Children are contagious for at least 1 day before development of the lesions. Transmission of the virus may occur until approximately 5 to 6 days after the onset of the first skin lesions in healthy children. In immunocompromised children, the virus is recoverable for a longer period, but infected children must be considered contagious for at least 7 to 10 days.

Normally, children who develop chickenpox have no prodromal symptoms. The first sign of illness may be pruritus or the appearance of vesicles, usually on the trunk, scalp, or face. The rash later spreads to the extremities. Characteristically, lesions can be seen in various stages of

maturation with macules, papules, and vesicles present in a particular area at the same time (Fig. 47.9). The vesicular lesions are superficial and rupture easily. New lesions will erupt for 4 to 5 days, until there are approximately 100 to 300 in different stages of development. The vesicles become crusted, and over time only the crust remains, although there may be an occasional vesicle on the palm later in the disease. Although uncommon, ulcerative lesions are sometimes seen in the mouth and, less commonly, on the conjunctiva and pharynx. Fever usually lasts 2 to 3 days, with body temperature ranging from 38.5°C to 40°C (101.3° to 104°F).



Rash relatively profuse on trunk
Rash sparse distally

FIG. 47.9 Chickenpox.
(A) Pattern of generalized, polymorphous eruption. (B) Chickenpox lesions.
(From Centers for Disease Control and Prevention: Image Bank, Figure #6121. https://phil.cdc.gov/details.aspx?pid=6121. Accessed April 12, 2022.)

A. An illustration of a small boy depicts the rash as relatively profuse on the trunk and rash sparse distally on extremities. B. Close shot of a patientâ€™s back with a number of pus-filled reddish bumps.

Complications are rare in children but more common in adults. They can include transient hematuria (from rupture of vesicles in the bladder), epistaxis, laryngeal edema, and varicella pneumonia. One case of chickenpox produces almost complete immunity against a second attack. Rarely, the fetus may be malformed (congenital varicella syndrome) if chickenpox develops in the first half of pregnancy. Infants whose mothers have chickenpox at any stage of pregnancy have a higher risk of developing herpes zoster during the first few years of life.[31] Varicella-zoster immunoglobulin should be administered to neonates whenever the onset of maternal disease is between 5 days before delivery and 2 days after delivery.

Uncomplicated chickenpox requires no specific therapy. Baths, wet dressings, and oral antihistamines occasionally help relieve pruritus and prevent secondary infection from developing as a result of scratching. Oral antibiotics should be given if secondary bacterial infection is present. Zoster immune globulin may be administered to immunodeficient individuals if given within 72 hours after exposure to chickenpox. Oral acyclovir may be valuable in immunosuppressed or other select groups of children. The varicella vaccine and subsequent booster protects against varicella.[32]**Herpes zoster** is a vesicular eruption from a recurrence of the latent varicella virus, along the distribution of a dorsal root ganglion (see Chapter 46).

Hand, Foot, and Mouth Disease

Hand, foot, and mouth disease (HFMD) is a contagious viral disease primarily of children under 5 years of age. It is commonly caused by coxsackie virus and enterovirus A71. The infection manifests as fever; vesicular ulcerous lesions in the mouth; and vesicular rashes on the hands, feet, and buttocks. Atypical presentations may mimic other infections and be misleading but generally have not been associated with worse outcomes. A small number of children may experience severe complications, such as meningitis, encephalitis, acute flaccid paralysis, and neurorespiratory syndrome. The disease is self-limiting with supportive care. Research is in progress to develop a preventive vaccine.[33,34]

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum (fifth disease) is caused by infection with B19 parvovirus. The infection is characterized by a mild fever, headache, sore throat, pruritus, and arthralgia, followed by a blotchy, macular, lacy rash on the cheeks (slapped-cheek), which spreads to the trunk and limbs and may last for up to 6 weeks. Symptoms are usually self-limiting. Diagnosis is related to symptoms and can include immunologic assays or a polymerase chain reaction test to identify the virus. Treatment is symptomatic and includes nonsteroidal anti-inflammatory drugs for arthralgias and antihistamines for pruritus. Infection in women less than 20 weeks pregnant can lead to miscarriage and requires special care. The virus causes severe fetal anemia, and pregnancy loss is due to suppression of erythroid progenitor cells.[35] A new viral rash was seen with the emergence of the coronavirus. It has been called COVID toes and may be the only sign of the coronavirus infection. The rash presents as erythematous or purplish in color and usually develops on the toes (see the box Emerging Science Box: Coronavirus Rash).

Insect Bites and Parasites

Insect bites and infestations are common causes of skin disorders in children and adults. Skin damage occurs by various mechanisms, including trauma of bites and stings, allergic reactions, transmission of disease, injection of substances that cause local or systemic reactions, and inflammatory reactions resulting from embedded and retained insect mouth parts and scratching of the skin. Anaphylactic reactions are treated with epinephrine (adrenaline), and children with a history of anaphylactic reaction should be provided with epinephrine autoinjectors (i.e., an EpiPen). Skin testing and subcutaneous immunotherapy can be considered for subsequent stings and bites. Papular urticaria is a chronic inflammatory skin eruption, caused by exposure to arthropod bites usually associated with flea bites or mosquitos and is usually seen in younger children primarily in tropical environments. Generally the lesions are papular, but wheals vesicles, blisters, and scabs have been reported.[36]

Scabies

Scabies is a parasitic infestation of the skin caused by the mite, *Sarcoptes scabiei* (Fig. 47.10A). The pregnant mite burrows into the epidermis of its human host and lays eggs, which hatch in 48 to 72 hours and create new burrows. They reach adulthood in 1 to 14 days. They then mate, and the cycle is repeated. It is transmitted by close personal contact. Scabies is often epidemic in areas of overcrowded housing, with poor sanitation, and in children. Immunocompromised individuals are at greater risk. Scabies can facilitate *S. pyogenes* and *S. aureus* skin coinfections, with systemic complications. The scabies mite has adapted mechanisms to overcome host defenses.

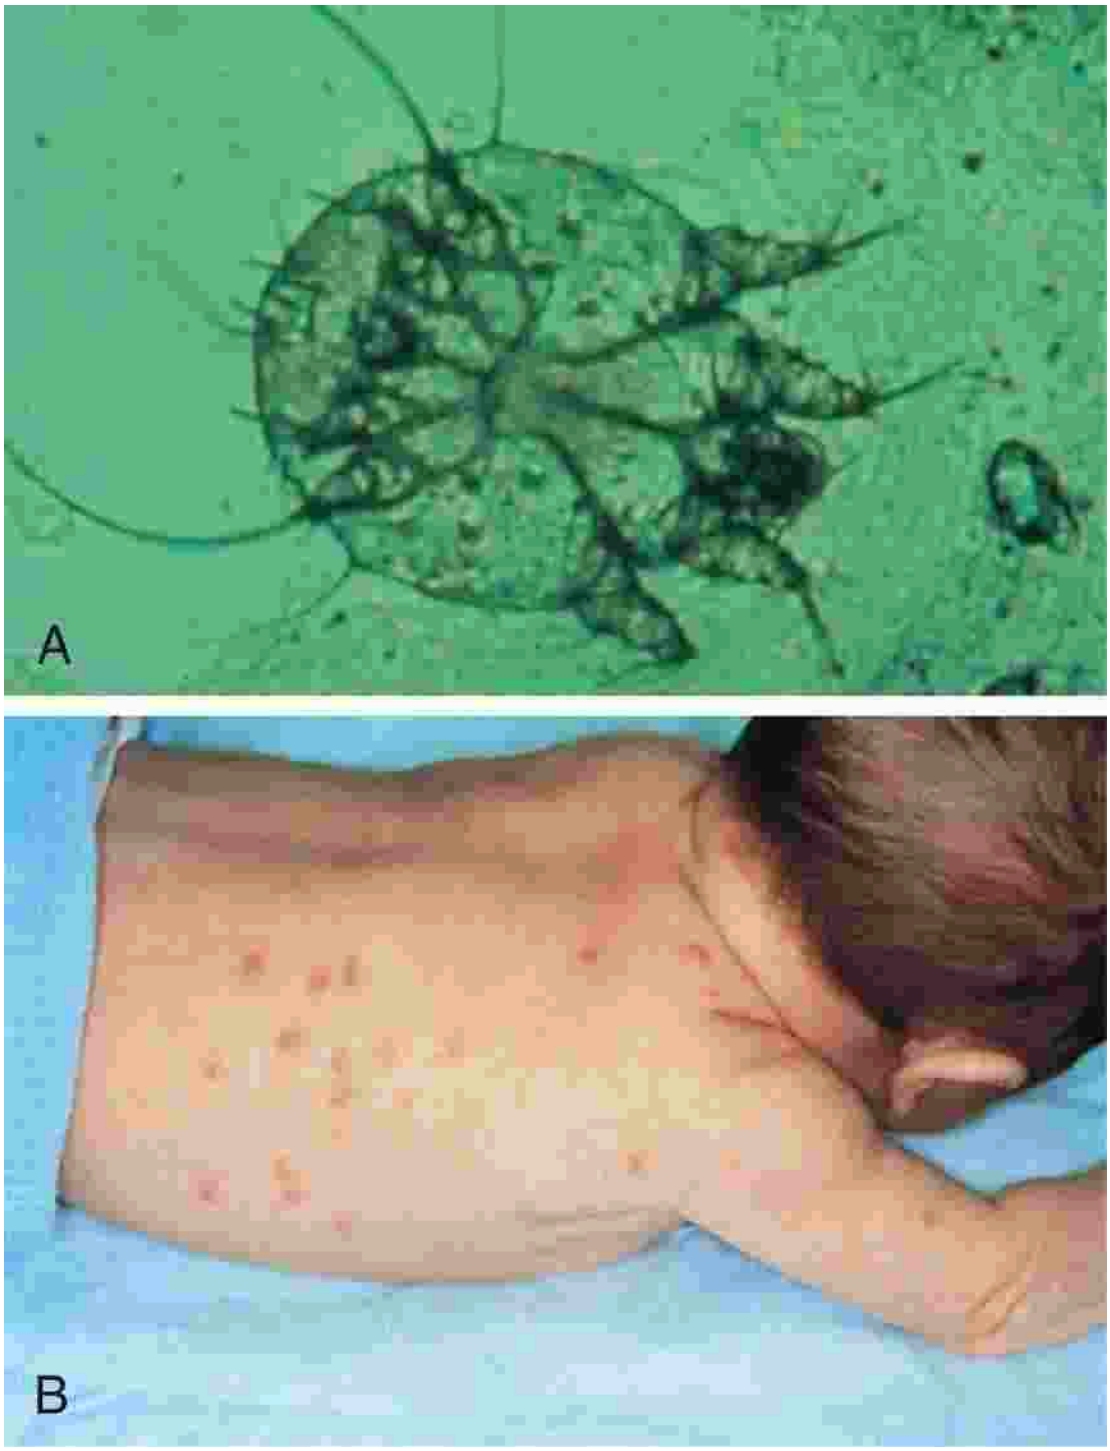

FIG. 47.10 Scabies.
(A) Scabies mite, as seen clinically when removed from its burrow. (B) Characteristic scabies bites. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

Symptoms appear 3 to 5 weeks after infestation. The primary lesions are burrows, papules, and vesicular lesions, with intense pruritus that worsens at night. Pruritus is thought to be related to

immune and inflammatory responses. In older children and adults, the lesions occur in the webs of fingers; in the axillae; in the creases of the arms and wrists; along the belt line; and around the nipples, genitalia, and lower buttocks. Infants and young children have a different pattern of distribution, with involvement of the palms, soles, head, neck, and face (see Fig. 47.10B). Secondary infections and crusting develop as a result of scratching and eczematous changes.

Diagnosis of scabies is made by observation of the tunnels and burrows and by microscopic examination of scrapings of the skin to identify the mite, its eggs, or its feces. Treatment involves the application of a scabicide, which is curative. All clothing and linens should be washed and dried in hot cycles, dry-cleaned, or kept in a sealed bag for 48 to 72 hours.[37,38]

Fleas and Bedbugs

Fleas and bedbugs are blood-sucking arthropod parasites, which bite human hosts and cause a variety of skin lesions. Bites from these insects produce pruritic, erythematous-edematous papules in a linear array or in a classic pattern of three bites, often coined the breakfast, lunch, and dinner sign (Fig. 47.11). Bed-bug bites appear as a small dot and are often unnoticed. Previous sensitization to their saliva can cause the intense erythematous papular and pruritic reactions (Fig. 47.12). Secondary infections may occur because of the scratching associated with the bites. Prevention is focused on environmental control of the offending insects, both indoor and outdoor. Reactions to bites are treated with symptomatic measures to control itching and prevent infection.[39]

Pediculosis (Lice Infestation)

The three known types of human lice are (1) the head louse *(Pediculus human capitis)*, (2) the body louse *(Pediculus humanas corporis)*, and (3) the crab or pubic louse *(Phthirus pubis)*. They are parasites and survive by sucking blood from the host. Their mouth is shaped for piercing and sucking and are attached to the skin of the host while the louse is feeding. When piercing the skin, the louse secretes toxic saliva, and the mechanical trauma and toxin produce a pruritic dermatitis.[40]

Pediculosis human capitus are ectoparasites. They reproduce by attaching to the hair shaft close to the scalp and laying eggs (nits). The nits hatch in 7 to 10 days.[41,42] This is commonly spread by head-to-head contact. As a result, children are more often infected. Initially, the person may be asymptomatic; however, over time may be more pruritic. Diagnosis is usually made by presence of live lice or adherent nits on the scalp. Treatment should be reserved for confirmed cases of active lice. Lindane is no longer recommended for treatment in the United States due to safety and efficacy concerns, with recommendations for safer alternatives that are both available with and without prescription. Manual removal of nits is advisable but not mandated for treatment.[41,42] OTC products are first-line recommendations, and prescription treatments are also available.[43] All close contacts should be treated at the same time to prevent spread of the infestation.[44] The Center for Disease Control has a helpful fact sheet for families, which addresses housekeeping recommendations to prevent the spread of lice to close contacts.[45]

Body lice and pubic lice are ectoparasites, require blood meals about five times per day, and have been implicated in transmission of disease. They differ from head lice as they do not reside

on the host's body but infest clothes, primarily seams, and migrate to the host for meals. Because of their migration and infestation in clothing, infections are more problematic in impoverished and densely populated areas. Transmission may occur directly or via fomites. Lesions are pruritic and present as erythematous macules, papules, or papular urticaria with a central punctum. Iron deficiency anemia has been reported with this infestation due to their feeding cycle. Environmental control of the contaminated articles is mandated. Secondary infections are treated with antibiotics. Resistance has been reported with current available therapies, necessitating further research to control this infestation in populations.[46]

Vascular Anomalies

Vascular anomalies are a group of common and rare disorders of blood-vessel growth. These lesions may be further classified by their presentation and associated deformities. The International Society for the Study of Vascular Anomalies (ISSVA) revised their classification of vascular disorders in 2018. Lesions classified as benign vascular tumors included infantile hemangioma, congenital hemangioma, tufted angioma, spindle-cell and epithelioid hemangioma, and pyogenic granuloma. Additional classifications include locally aggressive or borderline vascular tumors and malignant vascular tumors. The committee also classified capillary malformations, lymphatic malformations, venous malformations, and combined malformations. The classifications have been expanded to include the known causal genes for these malformations, which has further defined these disorders.[47]

Infantile Hemangiomas

Infantile hemangiomas have glucose transporter protein-1 (GLUT1)-positive endothelial cells. It is proposed that in utero episodes of hypoxia may lead to upregulation of GLUT-1 and angiogenic cytokines, contributing to hemangioma formation. They consist of proliferating endothelial-like cells with disorganized angiogenesis, overexpression of growth factors, and a variable rate of growth. Many of these lesions resolve over time and require no treatment, however, lesions that are disfiguring or life threatening may require systemic therapy.[48] Lesions are usually classified as superficial (little or no subcutaneous involvement) (Fig. 47.13), deep (located in deeper tissues and may appear blue on surface skin) (Fig. 47.14), or combined (both components evident). Additionally, they are categorized as localized (well defined focal lesions), segmental (usually plaque like, >5 cm in diameter and in a anatomic region), indeterminate, or multifocal (multiple lesions). Life-threatening lesions usually occur in the beard distribution, with concern for airway obstruction or greater than five discrete lesions and with concern for liver involvement, cardiac failure, and hypothyroidism. Functional impairment if the lesion is periocular may result in vision alterations, or if it occurs on lip or oral cavity may result in feeding impairment. Additionally, these lesions may be disfiguring if large or located on the face, scalp, or breast. Infantile hemangiomas, if segmental on the face or scalp, may be associated with systemic anomalies known as PHACE syndrome ([P]osterior fossa and other structural brain malformations; large [H]emangiomas of the face, neck, and/or scalp; anatomical anomalies of the cerebral or cervical [A]rteries; [C]ardiac anomalies/[C]oarctation of the aorta; and [E]ye abnormalities) or in the pelvic area associated with LUMBAR syndrome ([L]ower body hemangioma, [U]rogenital abnormalities / ulceration, [M]yelopathy, [B]ony deformities, [A]norectal malformations / arterial anomalies, and [R]ectal anomalies), requiring further imaging and multidisciplinary care.[49] Infantile hemangiomas grow rapidly in the first 3 months of life, and most of the growth has been completed by 5 months of age.[48,49] Clinical practice guidelines recommend propranolol as the systemic drug of choice for larger and more problematic lesions with topical treatment, using timolol for smaller, superficial lesions.

Propranolol inhibits tumor growth and angiogenesis and promotes vasoconstriction. Surgery and laser treatment are usually considered for residual skin changes post-involution and are not usually first-line therapy.[49,50]

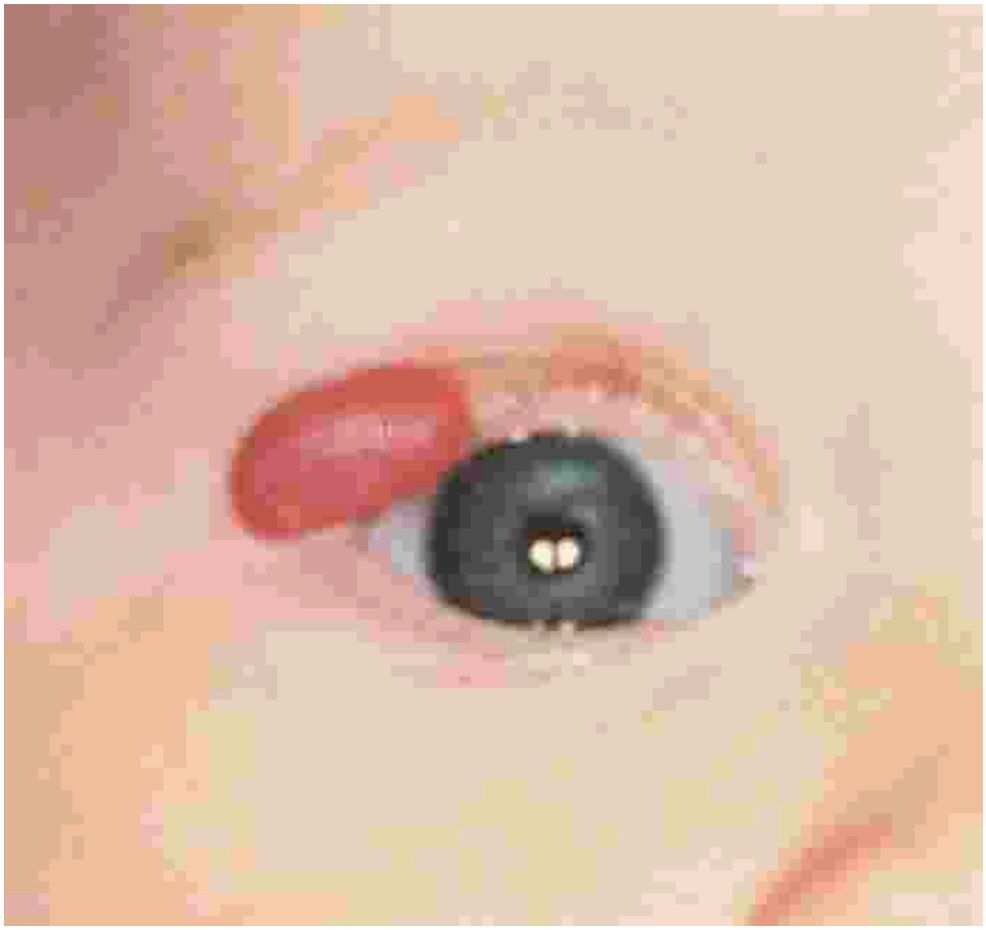

FIG. 47.13 Superficial (Capillary) Hemangioma. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

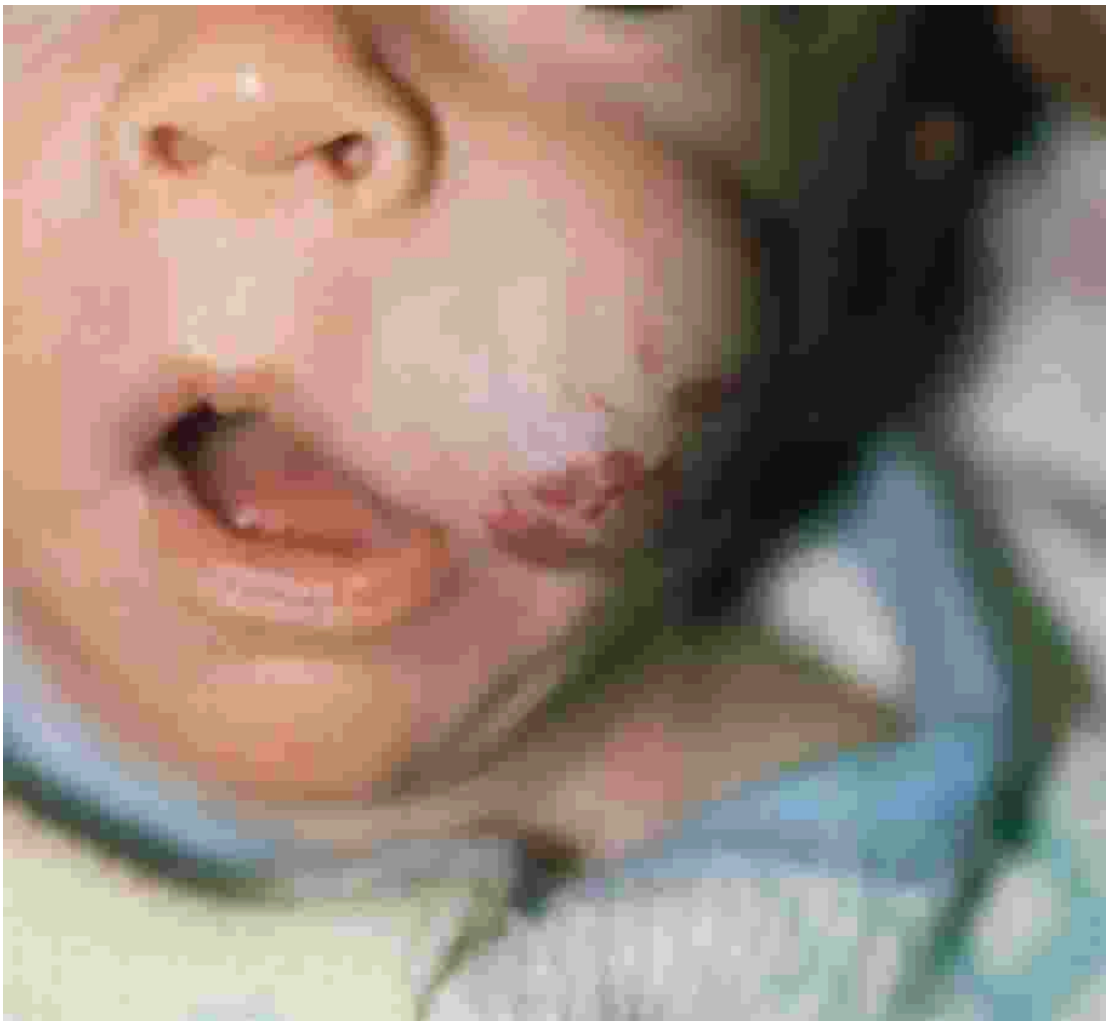

FIG. 47.14 Deep Hemangioma. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

Cutaneous vascular malformations are rare anomalies of blood vessels present at birth but may not be apparent for several years. They grow proportionately with the child.[51] Vascular malformations may demonstrate rapid growth, particularly during the hormonal changes of puberty or pregnancy and in association with trauma. These lesions are classified as low flow or high flow. *Low-flow malformations* involve capillaries, veins, and lymphatics. *High-flow malformations* involve arteries. In addition to locations within the skin, they may involve the gastrointestinal tract (blue rubber bleb nevus syndrome), bone, the eye, and vascular malformation of the brain (Maffucci syndrome, Sturge-Weber syndrome). *Overgrowth syndromes* can occur with either high- or low-flow malformations, with overgrowth of the underlying structures (i.e., legs, arms, facial bones). The most common capillary malformations are port-wine stain (nevus flammeus) and salmon patches (nevus simplex).

Port-wine (nevus flammeus) stains are congenital vascular malformations of the dermal capillaries that involve both genetic and molecular alterations in capillary endothelial cells.[52] The lesions are flat and their color ranges from pink to dark reddish purple, and they do not fade with age. Involvement of the face and other body surfaces is common, and the lesions may be large and may become darker and thicker over time (Fig. 47.15). During adolescence and later adult years, the port-wine stain may become papular and cavernous. The pulsed-dye laser is the

treatment of choice to successfully lighten the color and flatten the more nodular and cavernous lesions. **Sturge-Weber syndrome** is a port-wine stain distributed along the ophthalmic branch of the trigeminal nerve and is associated with the leptomeninges of the brain and choroid, glaucoma, seizures, stroke, and intellectual disability. These capillary malformations are associated with a mutation in the *GNAQ* gene (guanine nucleotide-binding protein G, q polypeptide).[53]

FIG. 47.15 Port-Wine Hemangioma.
Port-Wine hemangioma in a child caused by malformation of dermal capillaries. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

Salmon patches (nevus simplex) are macular pink or lilac lesions present at birth and located on the occipital scalp, forehead, upper eyelids, or nasolabial fold. They are a more superficial variant of nevus flammeus and one of the most common congenital malformations in the skin. The pink color results from distended dermal capillaries and 95% of patches fade by 1 and 3 years

of age. Those located at the occipital scalp may persist for a lifetime but generally do not present a cosmetic problem.

Other Skin Disorders

Psoriasis

Psoriasis is a chronic, relapsing autoimmune-mediated inflammatory disease affecting the skin and nails. Onset of disease can occur in children, but the differences in pathogenesis between children and adults is not clearly determined. T-cell-mediated interleukin 17 cytokines are involved in keratinocyte proliferation and inflammatory responses. In adults, the disease is also associated with joint disease and multiple comorbidities (see Chapter 46).[54,55] Morphology and distribution may vary with the age at presentation. Infants and toddlers may present with refractory diaper dermatitis.[56]

Older children may present with plaque or guttate lesions, with less common phenotypes to include pustular, erythrodermic, inverse and drug-induced psoriasis. Identified triggers include trauma to the skin, infection (primarily streptococcus), emotional stress, and medications. Overweight and obesity have emerged as risk factors in the development of psoriasis.[57] Diagnosis is usually made clinically. Unique to psoriatic lesions is the presence of the Auspiz sign, which is the presence of punctuate bleeding when the scale is scraped off the lesions. Additionally, the lesions are often present in areas of trauma (Koebner phenomena). Guidelines are available for the care of psoriasis in children, and studies are in progress for targeted treatment unique to children.[58,59] Psoriasis has a detrimental impact on quality of life, and control of exacerbation triggers and psychosocial support is recommended as part of an ongoing treatment plan.[53]

Newborn Rashes

Miliaria

Miliaria presents as a self-limited eruption, occurring in infants due to the occlusion of the sweat ducts, causing an outflow obstruction and entrapment of the sweat within the skin. The types are distinguished depending on the anatomic level of the obstruction, with the more superficial obstruction presenting as noninflammatory pinpoint vesicles usually found in intertriginous folds known as **miliaria crystallina** and the deeper obstruction presenting as erythematous papules or papulovesicles on the trunk, arms, or intertriginous folds. Removal of the occlusion resolves in resolution of symptoms. Generally, this can be due to tight-fitting garments or swaddling, overbundling, fever, or warm climates. Loose-fitting clothes, cool baths, and cool environments will improve this condition (Fig. 47.16).[60]

FIG. 47.16 Miliaria Rubra.
Note discrete erythematous papules or papulovesicles. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT.)

Erythema Toxicum Neonatorum

Erythema toxicum neonatorum (toxic erythema of the newborn) is a benign, erythematous accumulation of macules, papules, or pustules that appears at birth or 3 to 4 days after birth. The lesions first appear as a blotchy, macular erythematous rash. The macules vary from 1 mm to 1 cm in diameter. When papules or pustules develop, they are light yellow or white and 1 to 3 mm in diameter. There may be a few or several hundred lesions, and any body surface can be affected, with the exception of the palms and soles, where there are no pilosebaceous follicles. The cause of the lesion is unknown but may be related to an innate immune response to the first commensal microflora, with release of inflammatory mediators. It is self-limiting and resolves spontaneously within a few weeks after birth. No treatment is required.[61]

Summary Review

Acne Vulgaris

1. Acne vulgaris is a common disorder related to obstruction of pilosebaceous follicles and proliferation of *Cutibacterium acnes*, with follicular occlusion and inflammation primarily of the face, neck, and upper trunk. It is characterized by both noninflammatory and inflammatory lesions. Treatment is dependent on severity.

Dermatitis

1. AD is an alteration in the skin barrier. It occurs as red, scaly lesions on the face, cheeks, and flexor surfaces of the extremities in infants and young children. AD is associated with inflammatory cytokines. Successful AD management strategies are implemented in a stepwise approach tailored to the individuals and are severity-based. Contact dermatitis is an eczematous eruption resulting from either delayed hypersensitive reaction to an allergen (allergic contact dermatitis) or direct irritation to the skin from an irritating substance (irritant contact dermatitis). Diaper dermatitis is a type of irritant contact dermatitis that develops from prolonged exposure to urine and feces and may become secondarily infected with *Candida albicans*.

Infections of the Skin

1. Impetigo is a contagious bacterial disease occurring in two forms: bullous and vesicular. The toxins from the bacteria produce a weeping lesion with a honey-colored crust.
2. SSSS (Ritter disease) is a staphylococcal skin infection that produces an exfoliative toxin with painful blisters and bullae formation over large areas of the skin, requiring emergency care and systemic antibiotic treatment.
3. Tinea capitis (scalp ringworm) and tinea corporis (ringworm) are fungal infections of the scalp and body caused by dermatophytes.
4. Thrush is a fungal infection of the mouth caused by *Candida albicans*.
5. Molluscum contagiosum is a poxvirus infection of the skin that produces pale papular lesions filled with viral and cellular debris.
6. Rubella (German or 3-day measles) is a communicable viral disease characterized by fever, sore throat, enlarged cervical and postauricular lymph nodes, and a generalized maculopapular rash that lasts 1 to 4 days.
7. Rubeola (red measles) is a viral contagious disease with symptoms of high fever, enlarged lymph nodes, conjunctivitis, and a red rash that begins on the head, spreads to the trunk and extremities, and lasts 3 to 5 days. Both bacterial and viral complications may accompany rubeola.
8. Roseola (exanthema subitum) is a benign disease of infants with a sudden onset of fever that lasts 3 to 5 days, followed by a rash that lasts 24 hours.
9. Chickenpox (varicella) is a highly contagious disease caused by the varicella-zoster virus. Vesicular lesions occur on the skin and mucous membranes. Individuals are contagious from 1 day before the development of the rash until about 5 to 6 days after the rash develops.
10. Hand, foot, and mouth disease (HFMD) is a contagious viral disease commonly caused by coxsackievirus and enterovirus that manifests with fever, vesicular ulcerous lesions in the mouth, and vesicular rashes on the hands, feet, and buttocks.
11. Erythema infectiosum (fifth disease) is an infection caused by B19 parvovirus that usually causes mild symptoms of fever, headache, pruritus, and arthralgias followed by a rash on the cheeks spreading to the trunk and limbs.

Insect Bites and Parasites

1. Scabies is a pruritic lesion caused by the itch mite, which burrows into the skin and forms papules and vesicles. The mite is very contagious and is transmitted by direct contact.
2. Flea and bedbugs are blood-sucking parasites and their bites can produce pruritic, erythematous-edematous papules.

3. Pediculosis (lice infestation) is caused by blood-sucking parasites that secrete toxic saliva and damage the skin to produce pruritic dermatitis. Lice are spread by direct contact and are recognized by the ova or nits that attach to the shafts of body hairs.

Infantile Hemangiomas

1. Infantile hemangiomas are benign tumors that form from the rapid growth of vascular endothelial cells and result in formation of extra blood vessels that can be superficial or deep or a combination of both. Location and distribution affect treatment considerations and concern for PHACES or LUMBAR syndromes.

Other Skin Disorders and Newborn rashes

1. Psoriasis is a chronic relapsing autoimmune mediated inflammatory disease affecting the skin and nails which has also been associated with joint disease and multiple comorbidities.
2. Miliaria is characterized by a vesicular eruption that results from obstruction of the sweat duct opening in infants. In miliaria crystallina, ductal rupture occurs within the stratum corneum and appears as 1- to 2-mm clear vesicles without erythema. In miliaria rubra (prickly heat), the ductal rupture occurs in the lower epidermis, attracts inflammatory cells, and appears as 2- to 4-mm discrete erythematous papules or papulovesicles
3. Erythema toxicum neonatorum is a benign accumulation of macules, papules, and pustules that spontaneously resolves within a few weeks after birth.

Emerging Science BOX

Coronavirus Rash

The COVID-19 pandemic has differing presenting symptoms in children as compared to adults.

The pediatric population has increased cutaneous manifestations as the initial, and sometimes only, symptom of the virus. Cutaneous manifestations that have been observed in adults and children include urticaria, maculopapular rash, or vesicular rash; however, chilblains, erythema multiforme, urticaria, and Kawasaki disease-like inflammatory multisystemic syndrome are more frequently observed in children and teenagers. The lesions most common were the chilblains, often times referred to "COVID toes." Microscopic features of COVID-19 chilblains include three main components: a background area, globules, and reticular network. The background area is variously described as red, purple, brown, or grey with globules that are usually red to purple in color, and finally, a grey–brown reticular network located peripherally within the background area. While there is not a specific pathogenesis currently related to the skin manifestations observed in the pediatric population, there are similarities to rashes caused by other viral infections. A temporospatial association exists between COVID-19 and a severe multisystemic condition named pediatric inflammatory multisystem syndrome. Inflammatory markers (e.g., CRP, erythrocyte sedimentation rate, neutrophil count, and ferritin) were elevated in pediatric cases, along with pancytopenia.

- Types of Shock, Clinical Manifestations, and Treatment 1560

Multiple Organ Dysfunction Syndrome 1569

Thermal Injury and Burns 1575
- Epidemiology and Etiology 1575
- Burn Wound Depth 1575

Shock is a life-threatening condition that occurs when the circulatory system fails to perfuse tissues, cells, and organs adequately, resulting in widespread impairment of cellular metabolism and tissue function. **Tissue perfusion** is defined as the adequacy of blood flow through the small vessels to maintain tissue function.[1] Inadequate tissue perfusion occurs when there is decreased delivery of blood, oxygen, and nutrients to cells and tissues and increased oxygen consumption, such as from a decrease in cardiac output, a reduction in blood volume or hemoglobin level, or a significant reduction in blood pressure. Multiple etiologies exist for shock, but shock from any cause will progress to organ failure and death unless physiologic mechanisms reverse the process or clinical intervention succeeds in stopping the progression. Untreated, shock overwhelms the body's compensatory mechanisms and results in organ dysfunction that may progress to multisystem organ failure.

Multiple organ dysfunction syndrome (MODS) is progressive and involves the failure of two or more organ systems after a severe illness or injury. The disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyperdynamic state that persists as organ dysfunction develops. For many years the syndrome was referred to as *multiple organ failure* or *multiple systems organ failure*. Gradually it was recognized that the term *organ dysfunction* more accurately describes the syndrome as a process of physiologic deterioration.

Major burns result in extensive immediate tissue injury and thus are a form of trauma with wide-reaching effects on all organ systems. The cause of injury may be thermal contact, flame, chemical agents, or electrical agents; each cause requires a different approach in diagnosis and treatment. Closely associated with thermal burns is smoke inhalation injury, which accounts for about 25% of all burn unit admissions. As a multiorgan problem, thermal injuries can have an overwhelming effect on survival of the burned individual. Regardless of the cause of burns, the result is a final common pathway of physiologic response dependent on the extent of burn surface involvement and the depth of tissue destruction.

Shock

Shock can be classified by type, principal pathophysiologic process, or clinical manifestations. Classification by type is perhaps the most useful because it suggests the cause and

pathophysiologic process of the underlying disorder, which must be treated to prevent the irreversible cellular alterations and impairment of cellular metabolism. **Shock** is classified as 1) distributive [septic (caused by infection), anaphylactic (caused by hypersensitivity), and neurogenic or vasogenic (caused by alterations in vascular smooth muscle tone)]; 2) cardiogenic (caused by heart failure); 3) hypovolemic [hemorrhagic (caused by insufficient intravascular fluid volume)]; or 4) obstructive. These four types of shock are not exclusive, and many individuals have multifactorial shock.

Cellular Alterations and Impairment of Cellular Metabolism

The body consists of many organs, tissues, and cells that may function or malfunction at different stages of metabolic impairment. The common pathway in all types of shock is impairment of cellular metabolism, attributable to decreased delivery of oxygen and nutrients, frequently coupled with an increased demand and consumption of oxygen and nutrients and a decreased removal of cellular waste products.[2] In septic shock, for example, a deficiency in cellular metabolism and the buildup of lactic acid may precede the decreased tissue perfusion. Fig. 48.1 illustrates the pathophysiology of shock at the cellular level.

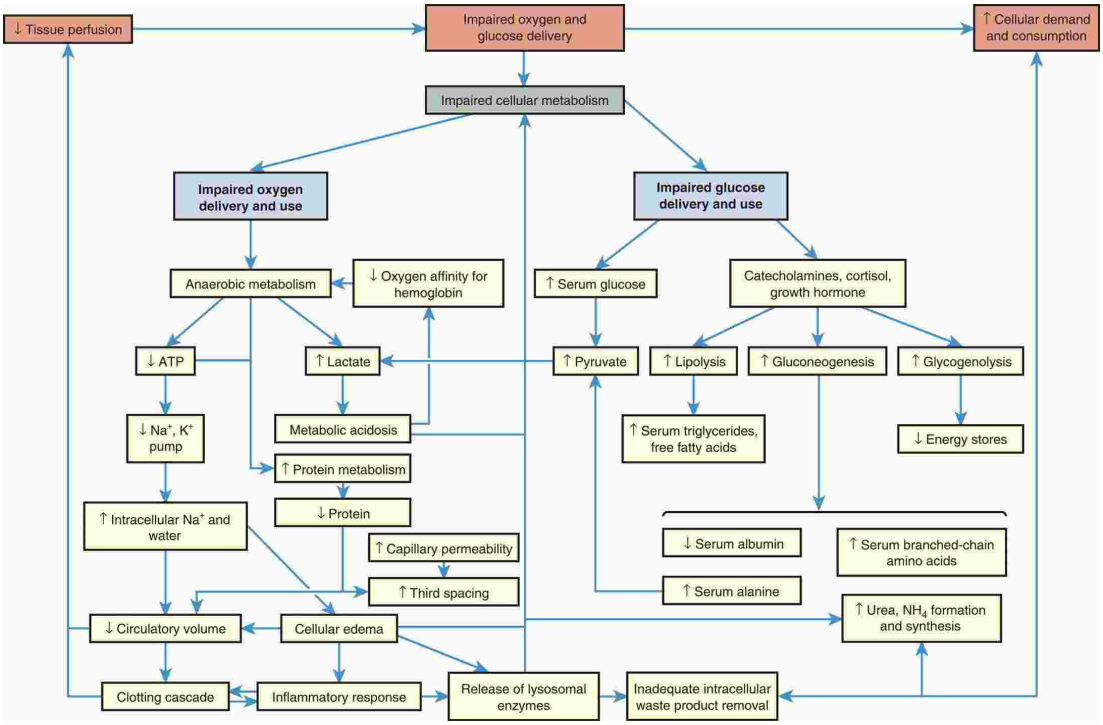

FIG. 48.1 Impairment of Cellular Metabolism by Shock.
ATP, Adenosine triphosphate.

A flow diagram illustrates the pathophysiology of shock at the cellular level. The diagram begins as follows. â€¢ Impaired oxygen and glucose delivery due to decreased tissue perfusion and increased cellular demand and consumption leads to impaired cellular metabolism. The impaired cellular metabolism is divided into impaired oxygen delivery and use and impaired glucose delivery and use. â€¢ Impaired oxygen delivery and use leads to anaerobic metabolism caused by decreased oxygen affinity for hemoglobin. â€¢ Anaerobic mechanism leads to decrease in A T P; increase in lactate; increase in protein metabolism. â€¢ Decrease A T P leads to decrease sodium and potassium pump which increases intracellular sodium and water leading to decrease circulatory volume causing clotting cascade. â€¢ Clotting cascade leads to inflammatory response. â€¢ Inflammatory response leads to release of lysomal enzymes. â€¢ Increase lactate leads to metabolic acidosis which further leads to decrease oxygen affinity for hemoglobin. â€¢ Decrease in protein and increase in circulatory volume leads to third spacing due to capillary permeability. â€¢ Impaired glucose delivery and use leads to increase in serum glucose; Catecholamines, cortisol, growth hormone. â€¢ Increase in serum glucose leads to increase in pyruvate.

Catecholamines, cortisol, growth hormone leads to increase in lipase, gluconeogenesis, glycogenolysis. â€¢ Increase in lipolysis leads to increase in serum triglycerides, free fatty acid. â€¢ Increase in gluconeogenesis leads to decrease in serum albumin; increase in serum alanine; increase in serum branched-chain amino acids; increase in urea, ammonia, formation and synthesis. â€¢ Increase in glycogenesis leads to decrease energy stores. â€¢ Increase in cellular demand and consumption leads to inadequate intracellular waste product removal.

Impairment of Oxygen Delivery, Increased Oxygen Consumption, and Volume Changes

Normal tissue perfusion allows for the delivery of more oxygen to the capillary beds and cells than is consumed at the cellular level. In all types of shock, the cells do not receive adequate amounts of oxygen because of decreased delivery or increased cellular consumption, or both, and therefore are unable to use oxygen normally (see Fig. 48.1). In cardiogenic shock, cardiac output, either stroke volume or heart rate, is too low to deliver adequate oxygen to the cell. In hypovolemic shock, oxygen delivery is impaired by inadequate numbers of red blood cells or hemoglobin (which carries oxygen) and insufficient blood volume. In neurogenic, anaphylactic, and septic shock, systemic vascular resistance (SVR) becomes very low because of vasodilation, resulting in inadequate perfusion pressure in the capillaries. Thus the pressure needed to drive oxygen and nutrients across cell membranes is inadequate. In septic shock, hypoxia is worsened both by increased inflammatory responses (such as fever), which raise the cell's oxygen demands and consumption rate, and by direct toxic and inflammatory chemical disruption of cellular metabolism, which impairs the cell's ability to use oxygen. In particular, each molecule of hemoglobin is normally capable of carrying four molecules of oxygen, but it delivers only one molecule of oxygen at the capillary bed for delivery to the cells; however, as tissue perfusion decreases and oxygen needs increase, two molecules of oxygen will be extracted to meet needs. When this compensatory mechanism is exhausted, cellular demand becomes abnormally greater than delivery. Without oxygen, the result of poor delivery and increased consumption, the cells shift from aerobic to anaerobic metabolism, resulting in lactic acid production at the cellular level.

Both positive compensatory mechanisms, such as lysosomal enzyme and cytokine release, and negative compensatory mechanisms, such as anaerobic metabolism and decreased intravascular volume in any shock state, further impair oxygen delivery and use. Concurrently in the inflammatory state of sepsis, diffusion across capillary membranes is slowed because blood flow in the capillary beds becomes sluggish as a result of decreased fluid volume and increased blood viscosity. Sluggish capillary flow decreases tissue perfusion, which may result in microvascular clot formation, and activation of the clotting cascade may begin (see Chapter 28). Microemboli formation and platelet aggregation account for common complications of shock caused by blocked tissue perfusion to end organs, such as the kidneys (causing acute tubular necrosis) or the lungs (causing acute respiratory distress syndrome [ARDS]). Disseminated intravascular coagulation (DIC) may be activated by the inflammatory response along with clotting cascade abnormalities.[3]

Anaerobic metabolism results in disruption of electrolyte and lysosomal enzymatic processes, thus changing the normal ionic and osmotic levels in cells governed by the

physical law of diffusion. Diffusion of nutrients and wastes into and out of the cell takes longer, and cellular metabolism is further distorted. Anaerobic metabolism is a less efficient method of extracting energy from carbon bonds, and the cell begins to use adenosine triphosphate (ATP) faster than it can be replaced. Without ATP the cell loses its ability to maintain an electrochemical gradient across its selectively permeable membrane. Specifically, the cell cannot operate the sodium-potassium pump. Sodium and chloride accumulate inside the cell and potassium exits the cell. Cells of the nervous system and myocardium are profoundly and immediately affected. The resting potentials of these cells are reduced, and the action potentials decrease in amplitude (see Chapter 1). Myocardial depressant factor is released, which decreases the contractility of the heart. A variety of clinical manifestations of impaired central nervous system and myocardial function results. As sodium moves into the cell, water follows. Throughout the body, the water drawn from the interstitium into the cells is "replaced" by water that is in turn drawn out of the vascular space, often called "third spacing" of fluid. This results in further decreases in circulatory volume. Within the cells, water causes cellular edema that disrupts cellular membranes, releasing lysosomal enzymes that injure the cells internally and then leak into the interstitium.

In addition to decreasing ATP stores, anaerobic metabolism affects the pH of the cell, and metabolic acidosis develops, which is indirectly measured by increasing lactate levels in the blood. A compensatory mechanism is initiated that enables cardiac and skeletal muscles to use pyruvate, of which lactic acid is the byproduct, as a fuel source, but only for a limited time. The decreasing pH of the cell that is functioning under anaerobic conditions has serious consequences. Enzymes necessary for cellular function dissociate under acidic conditions. Enzyme dissociation stops cell function, repair, and division. As lactic acid is released systemically, blood pH drops, reducing the oxygen-carrying capacity of the blood, and the heart's ability to pump. Therefore less oxygen is delivered to the cells and further hypoxia results in metabolic acidosis, which triggers more lysosomal enzyme release caused by disruption of lysosomal membrane integrity. Lysosomal enzymes released during shock injure the cell that released them and injure adjacent cells. By damaging the mechanisms of surrounding cells, lysosomal enzymes extend areas of impaired metabolism and cellular injury.

Intravascular fluid loss into the intracellular and interstitial spaces, described as "third spacing" earlier, is amplified when serum albumin and other plasma proteins are consumed for fuel, which results in decreased intravascular osmotic pressure, shift of fluid to the interstitial or extracellular spaces, and decreased circulatory volume, which can cause a relative hypovolemic state. Decreased intravascular volume causes decreased cardiac output in septic, neurogenic, and anaphylactic shock states, but it is the decreased mechanical ability to eject volume from the heart pump that reduces cardiac output in cardiogenic shock. In individuals with anaphylactic, neurogenic, or septic shock and an already dilated vasculature, hypotension worsens as a result of decreased circulatory volume.

Impairment of Glucose Delivery and Use

Impaired glucose use can be caused by either impaired glucose delivery or impaired glucose uptake by the cells (see Fig. 48.1). The reasons for inadequate glucose delivery are the same as those enumerated for inadequate oxygen delivery. In addition, in septic and anaphylactic shock, glucose metabolism and consumption may be increased or disrupted because of fever or bacteria, and glucose uptake can be prevented by the presence of vasoactive toxins, endotoxins, histamine, and kinins.

Some of the compensatory mechanisms activated by shock contribute to decreased glucose uptake and use by the cells. High serum levels of cortisol, growth hormone, and catecholamines account for hyperglycemia and insulin resistance, tachycardia, increased SVR, and increased cardiac contractility. Cells shift to glycogenolysis, gluconeogenesis, and lipolysis to generate fuel for survival (see Chapter 1). Except in the liver, kidneys, and muscles, the body's cells have extremely limited stores of glycogen. In fact, total body stores can fuel the metabolism for only about 10 hours. The depletion of fat and glycogen stores is not itself a cause of organ failure, but the energy costs of glycogenolysis and lipolysis are considerable and contribute to the cellular failure.

Impairment of Protein Metabolism and Depletion of Protein Stores

The depletion of protein is, however, a cause of organ failure. When gluconeogenesis causes proteins to be used for fuel, these proteins are no longer available to maintain cellular structure, function, repair, and replication. The breakdown of protein occurs in starvation states, hyperdynamic metabolic states, and septic shock. Under anaerobic metabolism, protein breakdown liberates alanine, which is converted to pyruvate. Pyruvic acid is changed into lactic acid, leading to an increased affinity for oxygen to bind to hemoglobin with resultant hypoxia and metabolic acidosis.

As proteins are metabolized anaerobically, ammonia and urea are produced. Ammonia is toxic to living cells. Uremia develops, and uric acid further disrupts cellular metabolism. Proteins are broken down preferentially. Serum albumin and other plasma proteins are consumed for fuel first. Serum protein consumption decreases capillary osmotic pressure and contributes to the development of interstitial edema, creating another negative compensatory outcome that decreases circulatory volume. In septic shock, plasma protein breakdown includes breakdown of immunoglobulins, thereby impairing immune system function when it is most needed.

Muscle wasting caused by protein breakdown weakens skeletal and cardiac muscle. Skeletal muscle wasting impairs the muscles that facilitate breathing. Muscle wasting therefore alters the actions of both heart and lungs. The delivery of oxygen and glucose to the cells is directly reduced, as is the removal of metabolic waste products, such as the formation of carbon dioxide and lactic acid, causing metabolic acidosis with resultant inability of muscles, organs, and tissues to function mechanically and electrically.

The metabolic wastes that accumulate in the cell and interstitial spaces are toxic to the cells and further disrupt cellular function and membrane integrity.

Types of Shock, Clinical Manifestations, and Treatment

Each type of shock (distributive, cardiogenic, hypovolemic, and obstructive) involves numerous clinical manifestations, signs, and symptoms that also may characterize other conditions, making diagnosis difficult. If there are overlapping shock states that occur simultaneously, it can be difficult to determine the etiology of shock based only on clinical manifestations, therefore an individual's history, risks, and situation are correlated with the specificity of the shock state suspected or anticipated.

The initial management for shock is to discover, diagnose, and correct or remove the underlying cause. Although this seems a simple tenet, it is one that is not always executed. Thus, treatment for cardiogenic shock begins with diagnosis and treatment of heart failure or at least enhancement of cardiac output. In hypovolemic shock, hemorrhage and other causes of fluid loss must be stopped and replaced. In neurogenic shock, as a result of spinal cord

trauma, stabilization of the spine and surrounding tissue is an initial approach, followed by treatment to counteract the vasodilatory effect and decreased blood pressure related to the parasympathetic control below the level of spinal cord injury. For anaphylactic shock, antigens must be identified, removed, or neutralized. Management for septic shock begins with identification and eradication of the infective agent, with blood cultures followed by administration of antimicrobials and fluids.

Simultaneous to correcting the underlying cause or condition, treatment is directed at targeting improvement of microcirculatory tissue perfusion.[3] Optimizing oxygenation is an absolute necessity in all shock states. The goal has a dual purpose to both optimize oxygen delivery and reduce oxygen consumption. Intravenous fluid or blood products are administered to expand intravascular volume and thereby improve tissue perfusion by increasing blood pressure, hemoglobin level, and cardiac output, except in cases of cardiogenic shock, which requires diuresis to reduce preload, so that the pump is not overloaded, or augmentation therapies to increase cardiac output. Effective glucose level control in various shock states has been shown to improve outcomes. Hyperglycemia, caused by insulin resistance in the liver and muscle, is a common finding in the critically ill. This is most likely an adaptive response providing glucose for the brain, cell nourishment and production, and wound healing; it also causes the increase in circulating corticosteroids produced in the stress response. The extent of appropriate glucose level control has been evaluated in recent years, leading to more aggressive treatment with continuous, titrating insulin infusions to maintain blood glucose levels closer to normal, thus promoting normal cellular function and healing.[4]

Once cellular and organ dysfunction and physiologic derangement are established, risk of morbidity and mortality increases in all shock states. Prevention and early treatment offer the best prognosis.

Distributive Shock

Distributive shock (vasodilatory shock) is characterized by severe peripheral vasodilation and has several etiologies, including sepsis, systemic inflammatory response syndrome (SIRS), neurogenic or vasogenic, anaphylaxis, drug and toxin induced, and endocrine.

Septic shock

Septic shock is the endpoint of a physiologic state of hypoperfusion with profound underlying circulatory, cellular, and metabolic abnormalities.[5] Septic shock is a subset of sepsis, a life-threatening organ dysfunction caused by a dysregulated host response to infection.[5] Sepsis often begins with an infection entering the bloodstream, causing bacteremia, leading to progressive dysfunction. Septic shock is associated with an intense proinflammatory and immunosuppressive response with multiorgan dysfunction.[6] Sepsis, the most common cause of distributive shock, is associated with high morbidity and mortality and accounts for one of the largest causes of death and healthcare expenditures worldwide.[7]

Pathophysiology

Septic shock is commonly caused by gram-positive bacteria (e.g., Pneumococcus, Enterococcus), gram-negative bacteria (e.g., Pseudomonas, Klebsiella, Enterobacter), viruses (e.g., Coronavirus), and fungi (e.g., Candida). Antibiotic resistant organisms (e.g., methicillin-resistant staphylococcus) are linked to healthcare-associated infections and are a major factor determining clinical unresponsiveness to treatment and rapid evolution to sepsis and septic

shock.[8] The largest contributors to sepsis cases and sepsis-related mortality across all ages are diarrheal diseases and lower respiratory infections.[9] The most commonly identified sources of infections in the intensive care setting associated with sepsis are respiratory tract, abdomen, urinary, wound/skin, catheter, and bloodstream.[10]

Advances in antibiotic therapy and broad-spectrum use of antibiotics in the treatment of sepsis have led to a significant increase in antibiotic-resistant infections, many of which may be hospital-acquired, but are frequently not reported to institutions such as the Centers for Disease Control and Prevention (CDC). Even when properly treated with available therapies, morbidity and mortality are extremely high. Prognosis is significantly affected by the source and virulence of the infectious microorganism, which has prompted the expansion of efforts by the CDC and its partners to describe the epidemiology of sepsis, prevent infections that lead to sepsis, and educate clinicians and individuals about reducing the risk for sepsis.[11] Sepsis outcomes depend on the person's health before infection and the degree of organ dysfunction after infection.[12]

The nidus of infection in sepsis may be readily discernible or extremely difficult to locate (Fig. 48.2). Bacteria, viruses, and fungi enter the bloodstream to produce bacteremia in one of two ways: (1) directly from the site of infection or (2) indirectly from toxic substances released by the bacteria directly into the bloodstream. These toxic substances, which act as triggering molecules, include endotoxins released by gram-negative microorganisms, lipoteichoic acids and peptidoglycan released by gram-positive microorganisms, and superantigens.[6] The triggering molecules activate the immune system and cause the host to initiate both a proinflammatory and anti-inflammatory response (see the box Emerging Science Box: Pro-Inflammatory and Anti-Inflammatory Responses in Sepsis) (see Chapter 7). Inflammatory mediators are released and include polymorphonuclear leukocytes, macrophages, monocytes, and platelets. Box 48.1 lists the proinflammatory and anti-inflammatory mediators released.[3,15,16] Presumably the end result is a mixed antagonistic response syndrome as proinflammatory and anti-inflammatory mediators respond, intensify, and lead the host into MODS.

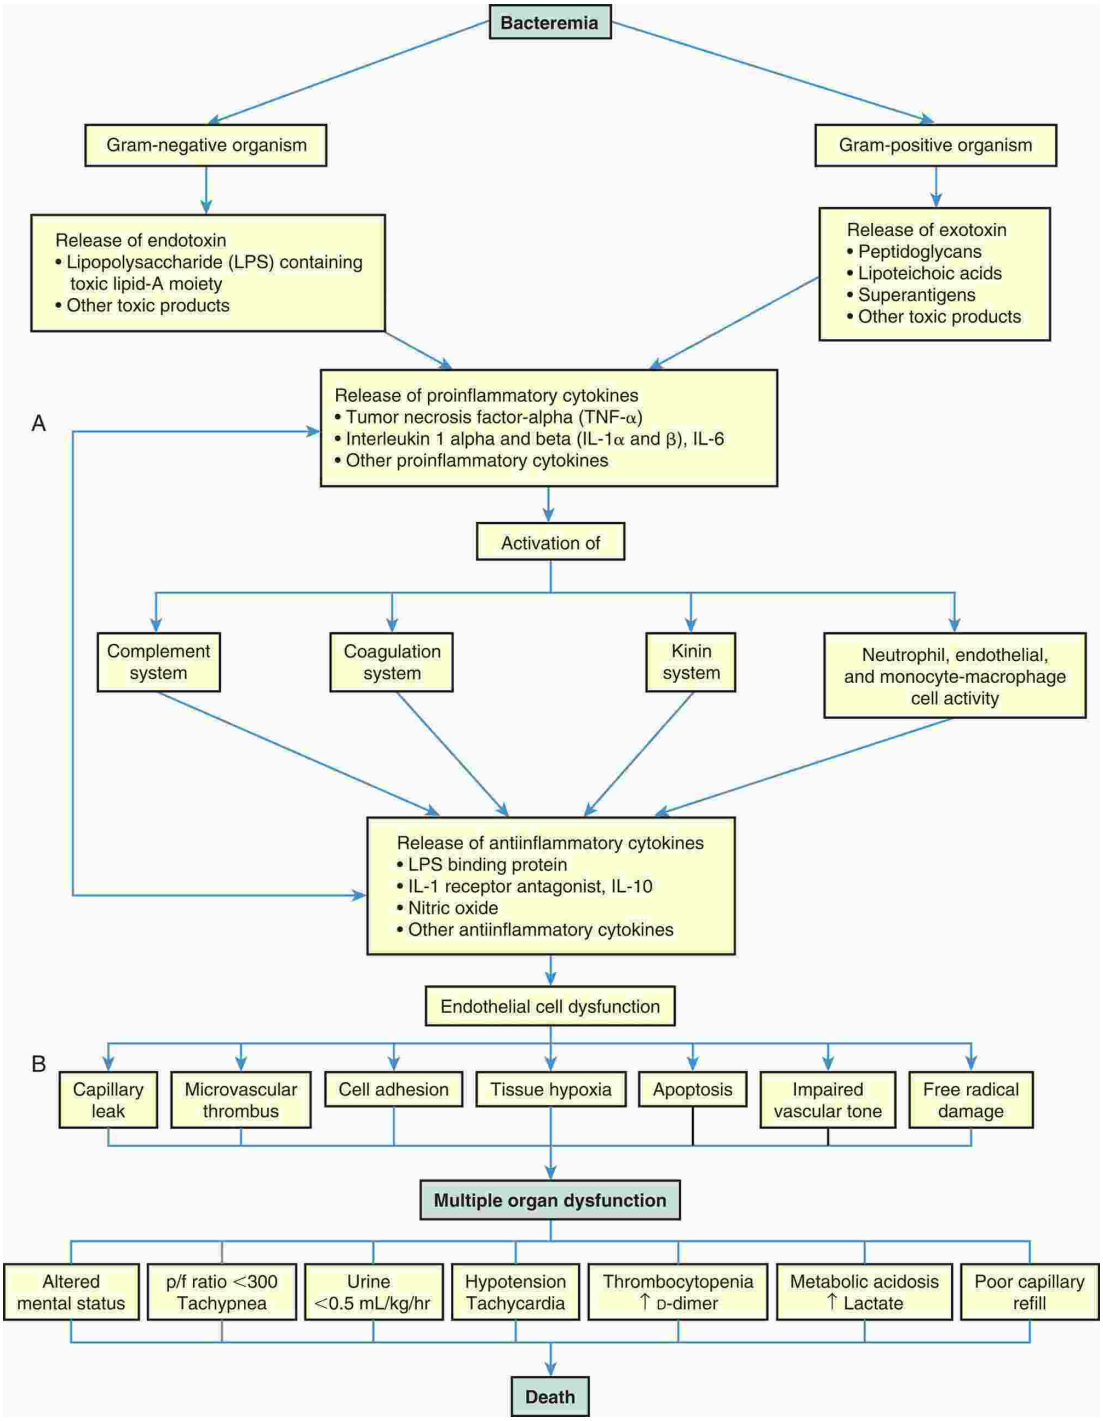

FIG. 48.2 Summary of Sepsis Pathology.

p/f (Pao_2/Fio_2), Oxygenation ratio. (A, From Lazaron V, Barke RA. Gram-negative bacterial sepsis and the sepsis syndrome. *Urologic Clinics of North America*, 1999;26[4]:687. B, Copyright 2003, Eli Lilly and Company. All rights reserved. Reprinted with permission from Eli Lilly and Company.)

A flow diagram illustrates the summary of sepsis pathology. The diagram begins as follows. â€¢ Bacteremia is classified into a gram-negative organism and a gram-positive organism. â€¢ Gram-negative organism leads to the release of endotoxin and release of exotoxin. â€¢ Release of endotoxin includes lipopolysaccharide containing toxic lipid A moiety and other toxic products. â€¢ The release of exotoxin includes peptidoglycans, lipoteichoic acids, superantigens, and other toxic products. Both releases of exotoxin. â€¢ Endotoxin lead to the release of proinflammatory cytokines, which provides for tumor necrosis factor-alpha; interleukin 1 alpha and beta; other proinflammatory cytokines. â€¢ The release of proinflammatory cytokines leads to activation of complement system, coagulation system, kinin system, neutrophil, endothelial, and monocyte-macrophage cell activity, which leads to the release of anti-inflammatory cytokines leading to endothelial cell dysfunction. â€¢ The release of anti-inflammatory cytokines includes L P S binding protein, I L-1 receptor antagonist, I L -10, nitric oxide, and other anti-inflammatory cytokines. â€¢ The endothelial cell dysfunction leads to capillary leak, microvascular thrombus, cell adhesion, tissue hypoxia, apoptosis, impaired vascular tone, and free radical damage. â€¢ The endothelial cell dysfunction leads to multiple organ dysfunction, including altered mental status, pf ratio greater than 300 tachypnea, urine greater than 0.5 milliliters per kilogram per hour, hypotension, tachycardia, thrombocytopenia with increased D-dimer, metabolic acidosis with increased lactate, poor capillary refill. â€¢ Multiple organ dysfunction leads to death.

Box 48.1

Pro-Inflammatory and Anti-Inflammatory Mediators Released During Immune Response to Sepsis

The pro-inflammatory mediators released include cytokines (interleukins [IL-1, IL-2, IL-6, IL-8, and IL-15], tumor necrosis factor-alpha [TNF-α], and granulocyte cell–stimulating factor)[13,14]; complement and complement cascade activation factors; kinins; arachidonic acid metabolites (prostaglandins, prostacyclin, leukotrienes, and thromboxane); soluble adhesion molecules; platelet-activating factor; endorphins; vasoactive neuropeptides; histamine; serotonin; monocyte chemoattractant proteins 1 and 2; proteolytic enzymes (e.g., elastase and lysosomal enzymes); protein kinase; tyrosine kinase; CD14; toxic oxygen metabolites (e.g., superoxide, hydroxyl radical, hydrogen peroxide, peroxynitrite);

neopterin; and clotting cascade activation factors. Proinflammatory cytokines can cause fever, hypotension, leukocytosis, induction of other proinflammatory cytokines, and the simultaneous activation of coagulation and fibrinolysis. Anti-inflammatory mediators released include lipopolysaccharide-binding protein; IL-1 receptor antagonist; soluble CD14; type 2 IL-1 receptor; leukotriene B_4 receptor antagonist; IL-4, IL-10, and IL-13; soluble tumor necrosis factor receptor; transforming growth factor-β (TGF-β); epinephrine; and nitric oxide.[3,15,16]

Clinical manifestations

Clinical manifestations common in septic shock are fever, tachycardia, tachypnea, and elevations in immune responses, such as leukocytosis. Elevated circulating blood glucose level, cyanosis, mottling, decreased urine output, and hypotension with altered mental status may be present in any shock state. Subjective complaints often are nonspecific and general, such as chief complaints of weakness, malaise, or shortness of breath. Clinical criteria for septic shock includes (1) hypotension, (2) requiring vasopressors to maintain a mean arterial pressure >65 mmHg, and (3) a serum lactate of >2 mmol/L despite adequate volume resuscitation.[5] Other manifestations of septic shock are persistent low arterial pressure, low tissue perfusion, low SVR from vasodilation, and an alteration in oxygen extraction by all cells (see Comments column in Table 48.1). Two main mechanisms contribute to lactic acid accumulation in sepsis: tissue hypoxia and epinephrine-induced stimulation of aerobic glycolysis.[17] Low-flow states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate ATP-sensitive and calcium-regulated potassium channels (K_{ATP} and K_{Ca}, respectively) in vascular smooth muscle (see Chapter 32), and lead to depletion of ADH (vasopressin) (Fig. 48.3). Tachypnea is a compensatory mechanism to increase oxygen. Tachycardia, in the initial stages of sepsis, supports cardiac output to remain normal or become elevated, although myocardial contractility is reduced. Sustained tachycardia is deleterious to improving cardiac output, especially when underlying comorbid states of heart disease exist. Temperature instability, ranging from hyperthermia to hypothermia, may indicate deterioration of the immune response, or may partially be caused by latent vasoconstriction or a vasopressor drug effect. Effects on other organ systems may result in deranged renal function, gastrointestinal mucosa changes, and ischemia that lead to translocation of bacteria from the gut, jaundice related to liver dysfunction, and clotting abnormalities that cause microemboli formation. Although deterioration of mental status and tachypnea are attributable to the low tissue perfusion described, complications such as stroke and ARDS often contribute to the distribution of these microemboli lodging in the microcirculation of the end organs, such as the brain, splanchnic organs, and pulmonary vascular system.

Table 48.1

Definitions of Septic Shock Components

Term	Basic Definition	Comments
Infection	A pathologic process that results from an invasion of a normal part of the body by pathogenic or potentially pathogenic microorganisms	Suspicion of infection necessitates immediate identification of possible pathogens, bacteria, fungi, or viruses with blood culture(s). Without benefit of microbiologic confirmation, clinical judgment should be used to identify signs, symptoms, and risk stratification of potential infection to promote early identification. SIRS criteria may still be used to screen for infection (see *What's New?* Sepsis and Septic Shock).
Bacteremia	Presence of viable bacteria in the blood	Insufficient to make a diagnosis of sepsis, especially in the absence of organ dysfunction.
Organ dysfunction	Abnormality or impairment of normal organ function, with or without direct insult or damage to the organ	Indirect insult of organ perfusion is caused by the septic cascade and hypoperfusion. Organ dysfunction can be represented by an increase in the Sequential Organ Failure Assessment (SOFA) score by 2 points or more when evaluating 6 organ systems. Evidence of 2 of 3 quickSOFA (qSOFA) criteria: respiratory rate of 22/min or greater; altered mentation, Glasgow Coma Scale <15 (new/worsening from baseline); or systolic blood pressure of 100 mmHg or less is considered positive for organ dysfunction. The quickSOFA (qSOFA) is not as predictive as the full SOFA score in the intensive care setting; however, it is superior to SOFA when applied to individuals outside the intensive care unit.
Sepsis	Life-threatening organ dysfunction caused by a dysregulated host response to infection	Common organ systems showing dysfunction are the respiratory, hematologic, cardiac, renal, hepatic, and central nervous systems.

Term	Basic Definition	Comments
		Additional clinical signs, symptoms, biomarkers, and variables that may be used to identify inflammation, inadequate tissue perfusion, and organ dysfunction: 1. General variables a. Fever >38°C (100.4°F) or hypothermia <36°C (96.8°F) b. Tachycardia, heart rate >90 beats/min c. Tachypnea d. Progressive deterioration of mental status e. Altered mental status f. Significant edema or positive fluid balance (>20 mL/kg over 24 h) g. Hyperglycemia (blood glucose >140 mg/dL) in the absence of diabetes 2. Inflammatory variables a. Leukocytosis or leukopenia (WBC > 12,000/mm^3, < 4000/mm^3, or > 10% bands) b. CRP > 2 SD above the normal value c. PCT > 2 SD above the normal value 3. Hemodynamic variables a. Arterial hypotension (SBP <90 mmHg; MAP <70 mmHg, or an SBP decrease >40 mmHg) b. $Sv^{-}O_2$ > 70% c. Cardiac index >3.5 L/min 4. Organ dysfunction variables a. Arterial hypoxemia (PaO_2/FiO_2 < 300 mmHg)

Term	Basic Definition	Comments
		b. Acute oliguria (urine output <0.5 mL/kg/h or 45 mL for at least 2 h) c. Creatinine increase >0.5 mg/dL d. Coagulation abnormalities (INR > 1.5 or PTT > 60 s) e. Ileus f. Thrombocytopenia (platelet count <100,000/m^3) g. Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L) 5. Tissue perfusion variables a. Hyperlactatemia (>1 mmol/L) b. Decreased capillary refill or mottling
Septic shock	A subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone	Clinically identified by a vasopressor requirement to maintain a mean arterial pressure of 65 mmHg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia.

Term	Basic Definition	Comments
Infection	A pathologic process that results from an invasion of a normal part of the body by pathogenic or potentially pathogenic microorganisms	Suspicion of infection necessitates immediate identification of possible pathogens, bacteria, fungi, or viruses with blood culture(s). Term	Basic Definition	Comments
Septic shock	A subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone	Clinically identified by a vasopressor requirement to maintain a mean arterial pressure of 65 mmHg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia.

CRP, Plasma C-reactive protein; *INR*, international normalized ratio; *MAP*, mean arterial pressure; Pao_2/Fio_2, partial pressure of oxygen in arterial blood/fraction of inspired oxygen; *PCT*, plasma procalcitonin; *PTT*, partial thromboplastin time; *SBP*, systolic blood pressure; *SD*, standard deviation; *SIRS*, systemic inflammatory response syndrome; $S\bar{v}O_2$, saturation of hemoglobin with oxygen; *Temp*, core temperature; *WBC*, white blood cell(s).

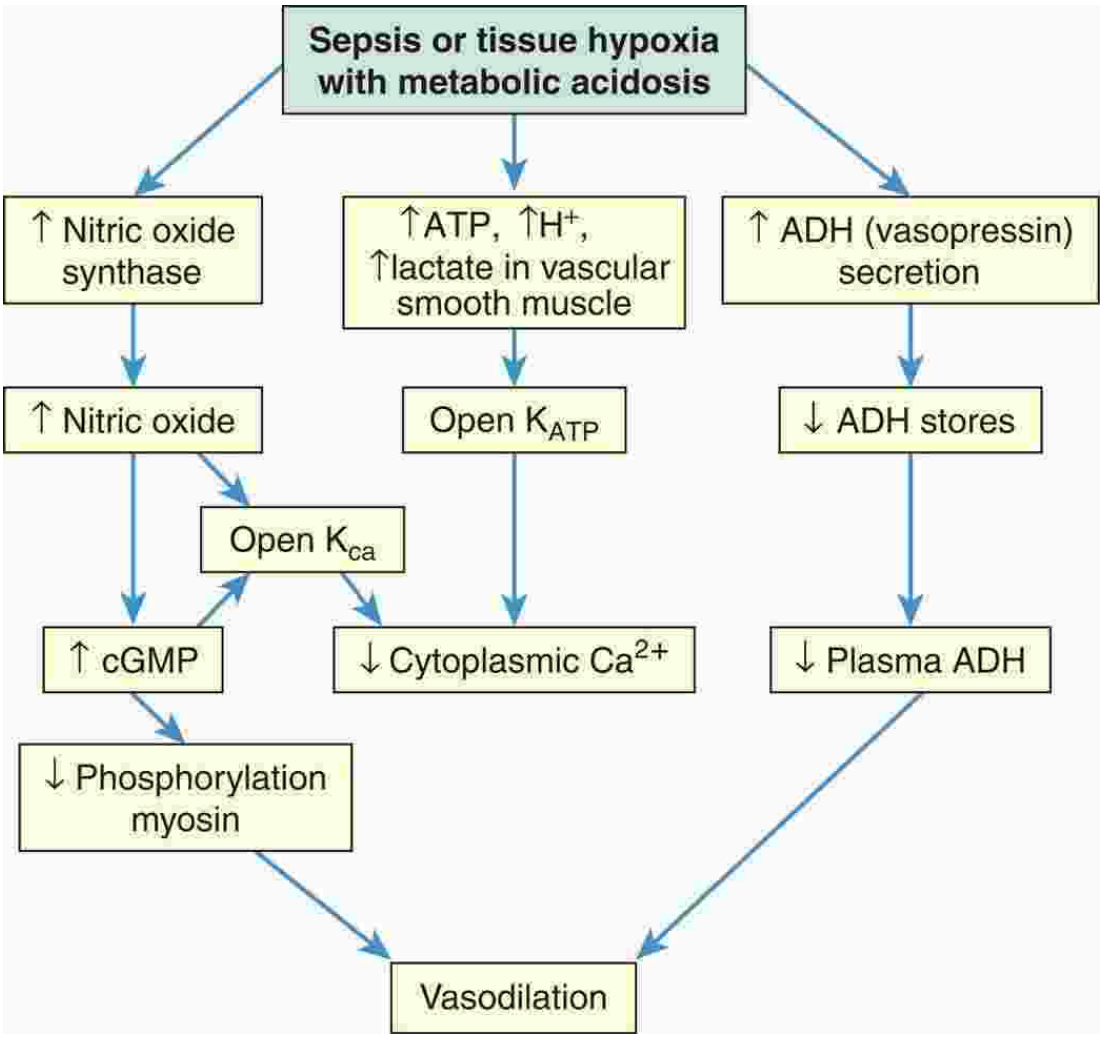

FIG. 48.3 Mechanisms of Vasodilation in Shock.
Vasodilatory shock is caused by the inappropriate activation of vasodilatory mechanisms and the failure of constrictor mechanisms. Unregulated nitric oxide, by regulating guanylate cyclase and generating cyclic guanosine monophosphate *(cGMP)*, causes dephosphorylation of myosin and, thus, vasodilation. Nitric oxide synthesis and metabolic acidosis activate the potassium channels (K_{ATP} and K_{ca}) in the plasma membrane of vascular smooth muscle. The resulting hyperpolarization (see Chapter 3) of the membrane presents the calcium that mediates norepinephrine-induced and angiotensin II–induced vasoconstriction from entering the cell. Therefore hypotension and vasodilation stubbornly persist despite high plasma levels of these hormones. In contrast, and unexpectedly, the plasma level of antidiuretic hormone *(ADH)* (vasopressin) is low despite the presence of hypotension. The early, massive release of ADH may result in future depletion.

A flow diagram illustrates the mechanism of vasodilation in shock. The diagram begins as follows. â€¢ Sepsis or tissue hypoxia with metabolic

acidosis leads to an increase in nitric oxide synthase; increase in A T P, hydrogen ion; lactate in vascular smooth muscle; increase A D H or vasopressin secretion. â€¢ Increase in nitric oxide synthase leads to increase in nitric oxide. â€¢ Increase nitric oxide leads to increase in C G MP and open K subscript ca. â€¢ open K subscript ca leads to decrease in cytoplasmic calcium. â€¢ Increase in C G M P leads to decrease in phosphorylation myosis which leads to vasodilation. â€¢ Increase in A T P, Hydrogen, lactate in vascular smooth muscle leads to open K subscript A T P. â€¢ open K subscript A T P leads to decrease in cytoplasmic calcium. â€¢ Increase A D H leads to decrease in A D H stores. â€¢ Increase in A D H stores leads to plasma A D H which further leads to vasodilation.

Evaluation and treatment

The 2021 international guidelines for management of sepsis and septic shock recommend hospitals and health care systems use a performance improvement program that includes screening for sepsis in acutely ill and high-risk individuals.[19] The quickSOFA (qSOFA) is no longer recommended as a single screening tool, but can be utilized to identify the presence of three variables to predict death and prolonged ICU stay in patients with known or suspected sepsis, which include altered mentation with a Glasgow Coma Score of < 15, respiratory rate ≥22 breaths/min, and systolic blood pressure ≤100 mm Hg.[5] Other screening tools include systemic inflammatory response syndrome (SIRS), Sequential Organ Failure Assessment (SOFA) criteria, National Early Warning Score (NEWS), or Modified Early Warning Score (MEWS). Standard operating procedures for sepsis are now considered "usual care" which includes components of the sepsis bundle, early identification, lactate, cultures, antibiotics, and fluids.[19]Laboratory testing includes serum lactate (a biomarker of tissue hypoxia and dysfunction), blood cultures to determine bacteremia, urinalysis with culture if UTI suspected, complete blood count, comprehensive metabolic panel, procalcitonin (elevated level indicates a nonspecific proinflammatory response seen in bacterial infection), and C-reactive protein (CRP).[18] CRP is an acute phase reactant protein produced by the liver, mainly in response to interleukin-6 produced by inflammation of any type. CRP is most sensitive to acute phase reactants; consequently, its level rises rapidly during inflammation. Similar to procalcitonin, CRP is nonspecific to types of inflammation, but may be used to trend severity of infection and response to treatment, especially in occult and resistant infections, such as osteomyelitis. Diagnostic imaging studies include chest x-ray to rule out pneumonia, abdominal computed tomography (CT) to rule out intraabdominal process, and echocardiogram to rule out infectious endocarditis.

Treatment management needs to begin immediately. Fluid resuscitation should be initiated within the first 3 hours using IV crystalloids at a minimal rate of 30 ml/kg.[19] Fluid volume increases cardiac output (CO) and MAP; however, excess volume can cause pulmonary edema, acute kidney injury, and increase mortality, but this should not preclude adequate volume resuscitation. Therefore, it is important to monitor fluid volume status.[18] Fluid

administration beyond the initial resuscitation is given as repeated small boluses and should be guided by careful assessment of intravascular volume status and organ perfusion through the use of dynamic measures including CO measurement combined with passive leg raising, fluid challenges against stroke volume (SV), systolic pressure or pulse pressure, and increases of SV in response to changes in intrathoracic pressure.[19] Albumin is suggested if large volumes of crystalloid have been infused.

The Surviving Sepsis Guidelines recommend the initiation of broad-spectrum antibiotics within 1 hour of presentation, after obtaining a full screen for infectious agents through blood, urine, and sputum cultures.[19] The initiation of empiric antibiotics should be directed toward gram-positive and gram-negative bacteria with consideration given to an individual's comorbidities, presentation, and risk of methicillin resistant Staphylococcus aureus (MRSA). Individuals with an increased risk for multidrug resistant (MDR) organisms, two antimicrobials with gram-negative coverage are recommended.[19] Antimicrobial therapy should be narrowed once cultures identify causative pathogen(s) and susceptibilities or discontinued if a non-infectious syndrome is demonstrated.[19,20] Monitoring serial procalcitonin levels, a precursor hormone to calcitonin, may be used to guide cessation of antibiotic therapy along with clinical evaluation.[19,20] Procalcitonin levels are not recommended as an indicator to start antibiotics; however, if levels are monitored sequentially at the start of empirical antibiotics and then drop, discontinuation or de-escalation may be clinically indicated.[19,20] The precise role of procalcitonin remains to be defined. Seeking to decrease use of antibiotics in the critically ill, and thereby prevent resistance to antibiotics, is an important strategy in treating infection. Adequate source control also is important and includes removal of any potentially infected intravascular access device after establishing another access site and following initial resuscitation.

Pharmacologic hemodynamic support and adjunctive therapy to maintain tissue perfusion include vasoactive agents. Norepinephrine is the initial vasopressor of choice.[18,19] Dopamine or epinephrine can be used as alternatives if norepinephrine is not available; however, these are less preferred because of potential tachycardia, dysrhythmias, or reduction in splanchnic blood flow. Dobutamine, an inotropic agent, should be used if myocardial dysfunction is present or hypoperfusion remains after adequate intravascular volume and arterial blood pressure are achieved. When an inadequate MAP is obtained using norepinephrine, then vasopressin is added as a second agent in lieu of increasing the norepinephrine. If the MAP levels remain inadequate despite these two agents, then epinephrine is added as a third vasopressor.[19]Sepsis induced hypoxic respiratory failure may require ventilation support. The use of high flow nasal oxygen over noninvasive ventilation is recommended.[19] Intravenous corticosteroids are suggested in septic shock to help replace intrinsic loss of cortisol, but only when hemodynamic stability is not obtained with adequate fluid resuscitation and vasopressor therapy.[19] Other supportive therapies in the treatment of septic shock include blood product administration to maintain hemoglobin levels above 7 g/dL, maintenance of targeted tidal volume (6 mL/kg) when mechanically ventilated with plateau pressure less than 30 cm H2O, utilization of sedation and analgesic protocols when needed, and avoidance of neuromuscular blockers if possible. The initiation of insulin therapy should begin with a glucose level of > 180 mg/dL with a glucose target range of 140-180 mg/dL.[19] If renal dialysis is required, intermittent hemodialysis and continuous venovenous hemofiltration are considered equivalent. Bicarbonate therapy is contraindicated for the purpose of treating hypoperfusion lactic acidemia unless the pH is <7.2 and acute kidney injury is present. Use of

low-molecular-weight heparin over low-dose unfractionated heparin is recommended for deep vein thrombosis prophylaxis, or mechanical compression if other agents are contraindicated. Stress ulcer prophylaxis with H2-receptor antagonists or proton pump inhibitors should be initiated if there is a risk of gastrointestinal bleeding.[19,23] Digestive tract decontamination and selective oropharyngeal decontamination are recommended in the prevention of ventilator-acquired pneumonia.[24,25] It is important to provide open communication with the patient and family regarding the disease process, discussing advance directives, peer support programs, post-critical illness follow-up programs, and post-hospital rehabilitation programs.[19,21]

Anaphylactic shock

Anaphylactic shock is the outcome of a widespread hypersensitivity to an allergen that triggers a reaction known as *anaphylaxis*. An allergen (usually a protein) is an antigen to which an individual mounts an immune response; this response is an example of hypersensitivity. (see Chapters 8 and 9, for discussions of immunity, inflammation, and hypersensitivity.) Immunologic causes are related to the inflammatory and vasodilatory effects triggered by a pathologic allergic reaction to an antigen. An interaction occurs between an allergen and the allergen-specific immunoglobulin E (IgE)/high-affinity receptor (FcεRI) complex expressed on effector cells, predominantly mast cells and basophils.[27] *Anaphylactoid* type reactions, which are non-immunologic and are not IgE mediated in origin, can be related to drugs (e.g., opioids), ethanol, cold, heat, sunlight, and exercise.[27] Physiologic alterations related to the inflammatory and immune response, similar to neurogenic shock, are massive; vasodilation, peripheral pooling, and relative hypovolemia lead to decreased tissue perfusion and impaired cellular metabolism (Fig. 48.4). Anaphylactic shock is often severe and has immediate symptoms, including an itchy rash, throat swelling, and low blood pressure, related to the massive vasodilation and systemic inflammation that may progress to death in minutes if emergency treatment is not rendered.

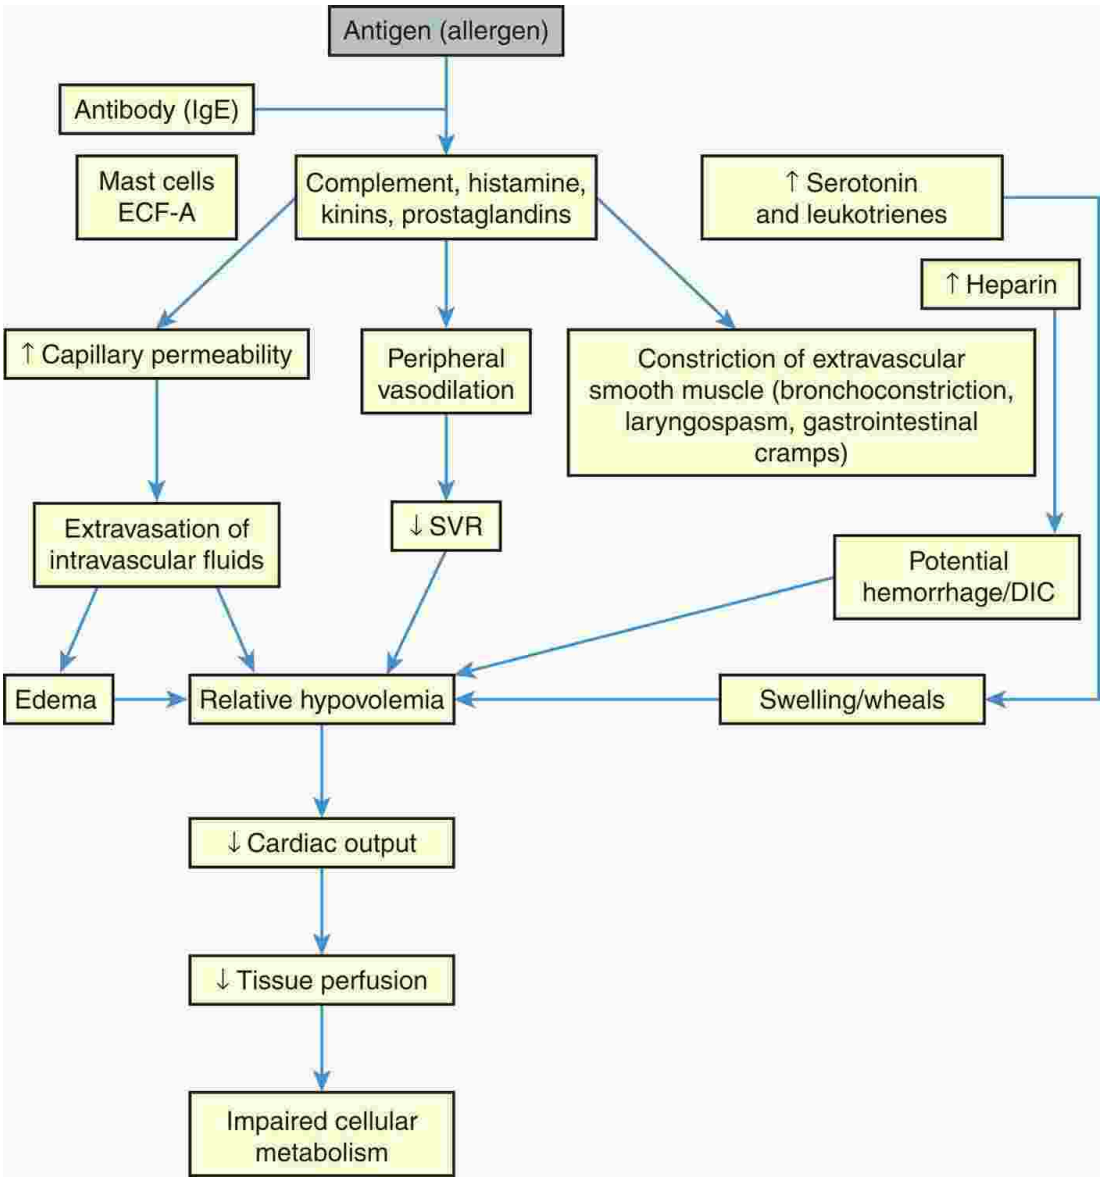

FIG. 48.4 Anaphylactic Shock.
DIC, Disseminated intravascular coagulation; *ECF-A*, eosinophil chemotactic factor of anaphylaxis; *IgE*, immunoglobulin E; *SVR*, systemic vascular resistance.

A flow diagram illustrates the mechanism of anaphylactic shock. The diagram begins as follows. â€¢ Antigen or allergen leads to complement histamine, kinins, prostaglandins by antibody I g E and mast cells E C F-A. â€¢ Complement histamine, kinins, prostaglandins leads to increase capillary permeability, peripheral vasodilation, constriction of extravascular smooth muscle (bronchoconstriction, laryngospasm, gastrointestinal cramps. â€¢ Increased capillary permeability leads to

extravasation of intravascular fluids, which causes edema. â€¢ Peripheral vasodilation causes a decrease in S V R, increase in heparin, serotonin, and leukotrienes which leads to potential hemorrhage or D I C and swelling wheals. â€¢ Edema, swelling wheals, decrease in S V R, and potential hemorrhage or D I C causes relative hypovolemia, which leads to a decrease in cardiac output, tissue perfusion, and impaired cellular metabolism.

Some allergens known to cause hypersensitivity reactions include foods (e.g., hen's eggs, cow's milk, wheat, shellfish, and peanuts), venom (e.g., bee stings, red ant bites, and snakebites), seminal fluid, latex, pollens, medications (nonsteroidal anti-inflammatory drugs [NSAIDs], dextrans), and contrast dye. Once in the body, the allergen or antigen causes immune inflammatory responses that range from mild to life-threatening or fatal.[27] Vascular effects of this response include vasodilation and increased vascular permeability, resulting in peripheral pooling and tissue edema. Extravascular effects include constriction of extravascular smooth muscle, such as the smooth muscle found in the walls of airways (e.g., the larynx and bronchioles; see Chapter 34), which may cause the extreme bronchoconstriction commonly associated with asthma and other severe allergic reactions.

Symptoms often affect multiple organ systems, including gastrointestinal (e.g., nausea, abdominal pain, vomiting, diarrhea), cutaneous (e.g., erythema, pruritus, urticaria, or angioedema), respiratory (e.g., shortness of breath, cough, rhinorrhea, tightening of throat, difficulty swallowing, wheezing), cardiovascular (e.g., diaphoresis, pallor, hypotension), or hematologic (e.g., fever, hemolysis). Other ominous clinical manifestations of anaphylactic shock may be anxiety, confusion, or impaired mentation. A precipitous decrease in blood pressure may account for altered mental status and may result in oliguria. Treatment begins with removal of the antigen (if possible) and assessment of airway, breathing, circulation, mental status, and skin. Epinephrine is administered to decrease mast cell and basophil degranulation, cause vasoconstriction, and reverse airway constriction.[27] Provide high flow oxygen to individuals with respiratory distress and those requiring further doses of epinephrine. Volume expanders or crystalloids (e.g., Lactated Ringer solution) are given intravenously to reverse the relative hypovolemia and cardiovascular instability. Antihistamines and corticosteroids are given to stop the inflammatory reaction.

The World Allergy Organization (WAO) updated guidelines in 2020 for assessment and management of anaphylaxis.[27] The guidelines include recommendations for validation of the clinical criteria for diagnosis, severity grading, diagnostic evaluation, use of epinephrine, and education. The emphasis on management of severe cases is shifting toward identification of triggers, determination of genetic predispositions, prevention of recurrence, development of tests to distinguish clinical risk from asymptomatic sensitization, and immune modulation to prevent anaphylaxis.

Neurogenic shock

Neurogenic shock, also called **vasogenic shock**, refers to a widespread and massive vasodilation that results from an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle (see Chapter 32). Occasionally, parasympathetic overstimulation or sympathetic understimulation persists, causing vasodilation and low

blood pressure for an extended period. Extreme, persistent vasodilation leads to neurogenic shock (Fig. 48.5). Neurogenic shock creates a "relative hypovolemia." Blood volume has not changed, but the amount of space containing the blood has increased, causing the SVR to decrease drastically as a result of vasodilation.[28] Thus, pressure in the vessels is inadequate to drive oxygen and nutrients across capillary membranes and delivery to the cells is impaired, leading to impaired cellular metabolism.

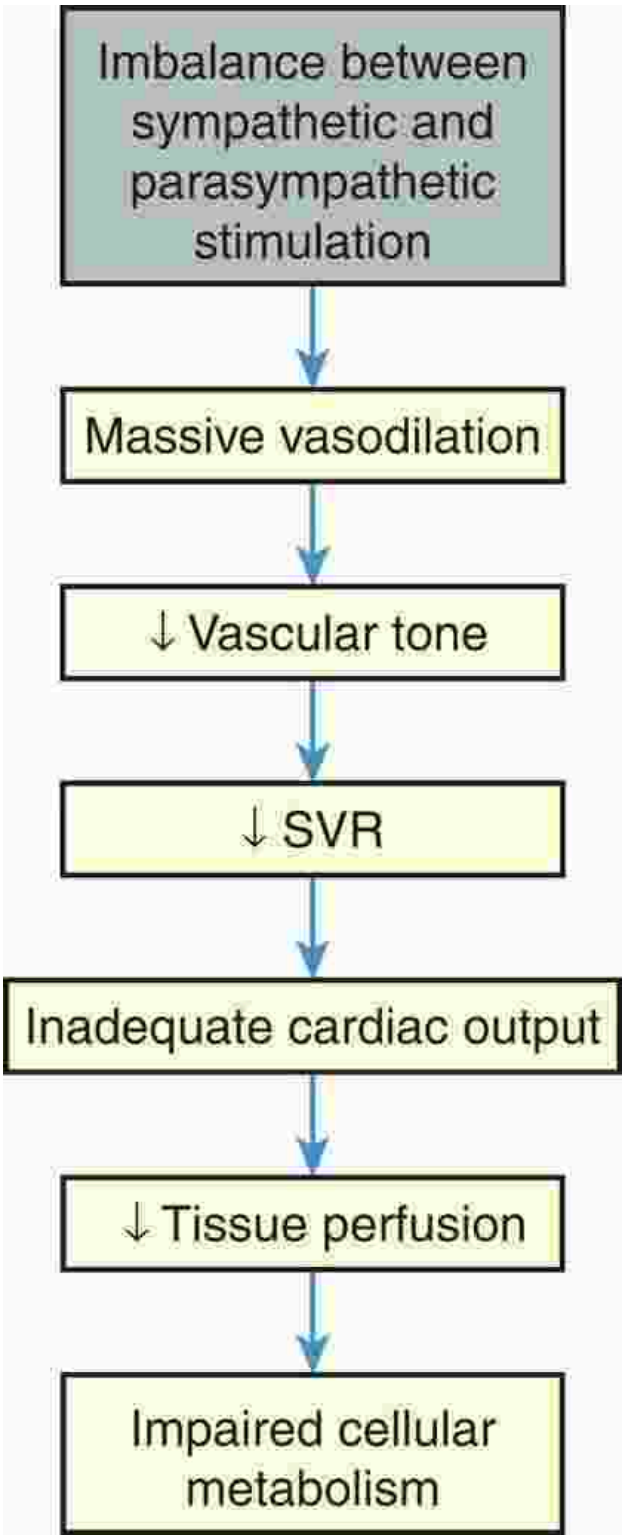

FIG. 48.5 Neurogenic Shock.
SVR, Systemic vascular resistance.

A flow diagram illustrates the mechanism of neurogenic shock. The diagram begins as follows. â€¢ The imbalance between sympathetic and parasympathetic stimulation leads to massive vasodilation, which leads to a decrease in vascular tone, S V R. â€¢ The decrease in S V R leads to inadequate cardiac output, which decreases tissue perfusion, causing impaired cellular metabolism.

Neurogenic shock can be caused by any factor that stimulates parasympathetic activity or inhibits sympathetic activity of vascular smooth muscle. Parasympathetic stimulation automatically inhibits sympathetic activity and vice versa (see Chapter 32). Normally, sympathetic stimulation maintains muscle tone. If sympathetic stimulation is interrupted or inhibited, vasodilation occurs. Therefore, trauma to the spinal cord or medulla, conditions that interrupt the supply of oxygen to the medulla, or conditions that deprive the medulla of glucose (e.g., insulin reactions) can cause neurogenic shock by interrupting sympathetic activity.[29] Depressive drugs, anesthetic agents, and severe emotional stress and pain are other causes of neurogenic shock.

The clinical hallmark of neurogenic shock is a very low SVR, along with other indicators of excessive parasympathetic activity. Bradycardia is the most obvious manifestation, especially in the early stages. Bradycardia may cease when compensatory mechanisms, particularly an increase in sympathetic system activity, have been initiated. The ejection fraction remains high, indicating a healthy myocardium, whereas central venous pressure decreases as the veins dilate. Neurogenic shock causes fainting if blood pressure decreases to the point at which cerebral metabolism is not sufficient to support consciousness. Most episodes of fainting are *not* shock; however, rarely do such episodes progress to shock. By allowing the blood pressure to equalize from head to toe as the individual becomes prone, fainting can actually prevent shock.

Cardiogenic Shock

Cardiogenic shock results from the inability of the heart to pump adequate blood to tissues and end organs.[30]**Cardiogenic shock** is a state of inadequate systemic tissue perfusion caused by a depression in contractility, despite adequate left ventricular filling pressure and intravascular volume. It is caused by extensive myocardial damage and appears to be aggravated by a systemic inflammatory response. The result is hypotension with metabolic acidosis and often has a fatal outcome; however, medical treatment, revascularization after acute myocardial infarction (MI), and hypothermia in the treatment of post–cardiac arrest states have been shown to improve outcomes.[31] Overall, hospital mortality because of cardiogenic shock has decreased from approximately 90% in the 1970s to a recent estimate of 40% to 50%.[31] Pathologic conditions that reduce contractility, cause pump failure, impair diastolic filling, or cause obstruction can lead to cardiogenic shock. Decreased contractility and pump failure can result from (1) acute myocardial infarction (AMI), cardiomyopathy, sepsis, myocarditis, pericarditis, aneurysm, dysrhythmias, contusion, metabolic abnormalities, and papillary muscle rupture; (2) impaired diastolic filling related to dysrhythmias; and (3) obstruction attributable to pulmonary embolism, cardiac tamponade, valvular disorders, tumors, and wall rupture or defects.[32] Dysrhythmias or conditions related

to post–cardiopulmonary resuscitation reduce cardiac function and output, and may be associated with any of the previous pathologies mentioned.

As cardiac output decreases, compensatory adaptive responses are activated, such as the renin-angiotensin, neurohormonal, and sympathetic nervous systems, that lead to fluid retention, systemic vasoconstriction, and tachycardia.[33] Systemic inflammation appears to play an important role in the pathogenesis and outcome of cardiogenic shock. Activation of the inflammatory response causes pathological vasodilation, releasing nitric oxide synthase and peroxynitrite, which have cardiotoxic inotropic effects. Activation of inflammatory cytokines (interleukins and tissue necrosis factor α [TNF-α]) and the complement system are additional systemic inflammatory mediators that result in vasodilation and contribute to increased mortality.[32,33] Increases in contractility, heart rate, and blood pressure are maintained in mild shock states through vasoconstriction in response to catecholamine release from the adrenals. Vasoconstriction increases vascular resistance to normalize blood pressure and improves cardiac performance by returning more blood volume and increasing perfusion to the heart; however, this increases myocardial demand and consumption of oxygen and nutrients by the heart. Increasing myocardial requirements burden the already failing heart, which can no longer pump an adequate volume of blood with sufficient force to perfuse the tissues. Thus increased coronary, tissue, and cellular ischemia further deteriorates myocardial function and shock.

Morbidity and mortality caused by cardiogenic shock is reduced by use of percutaneous intravascular interventions to open coronary arteries; temporary mechanical circulatory support (e.g., intraaortic balloon pump [IABP]; transvalvular pump giving only left-sided support [Impella]; or extracorporeal membrane oxygenation [ECMO]), cardiosupportive drug regimens, and mild hypothermia, which has been shown to increase contractility while decreasing oxygen demand and metabolism, also have shown improved outcomes.[33,34] Following MI, reperfusion and revascularization can be achieved with treatment modalities that include fibrinolytic therapies (medications that disintegrate the coronary thrombus) and percutaneous interventions (balloon angioplasty, stent placement, and thrombectomies). Surgery (coronary artery bypass, ventriculoplasty, ventricular assistive device [VAD], or heart transplant) is also utilized to open the coronary vessels during an acute myocardial infarction or to replace irreparable heart muscle. Cardiovascular supportive drugs and fluid regimens are initiated to maintain adequate blood pressure and essential fluid and electrolyte balance, as well as to optimize coronary perfusion to the myocardium. Mechanical assist devices, specifically intraaortic balloon pumps and percutaneous or VADs, are used to support cardiac output temporarily until the individual improves or until transplantation is possible.[35]

Implantable VADs, pacemakers, or internal defibrillator devices are sometimes used as permanent treatment for those who survive cardiogenic shock. Continuous hemodynamic monitoring should be employed to evaluate vascular volume and pressures, optimize fluid levels, and monitor drug administration with the goal of improving cardiac output and tissue perfusion.[33]

The clinical manifestations of cardiogenic shock are caused by inadequate perfusion to the heart and end organs (Fig. 48.6). Subjective complaints of chest pain, dyspnea, and faintness, along with feelings of impending doom, are often present. Classic observable signs and symptoms of tachycardia, tachypnea, hypotension, jugular venous distention, dysrhythmia, and low measured cardiac output are hallmarks. Cyanosis; skin mottling; rapid, faint, or irregular pulses; low urine output; and occasional peripheral edema are additional signs and symptoms of end-organ hypoperfusion. Myocardial dysfunction from fluid overload may

result in extra heart sounds, pulmonary edema, hypoxemia, and elevated end-organ laboratory values. The amount of brain natriuretic peptide, produced when the heart stretches in relation to increased volume with decreased cardiac output, is increased to help the diuresis of fluid volume excess.[36] Pulmonary edema increases as volume accumulates and expands from the heart into the lungs as evidenced by audible crackles and wheezes, as well as abnormal vascular congestion on chest radiography. Metabolic abnormalities involving electrolyte imbalances, metabolic acidosis, and elevated levels of inflammatory markers may result from or concur with the cardiac cascade of shock.

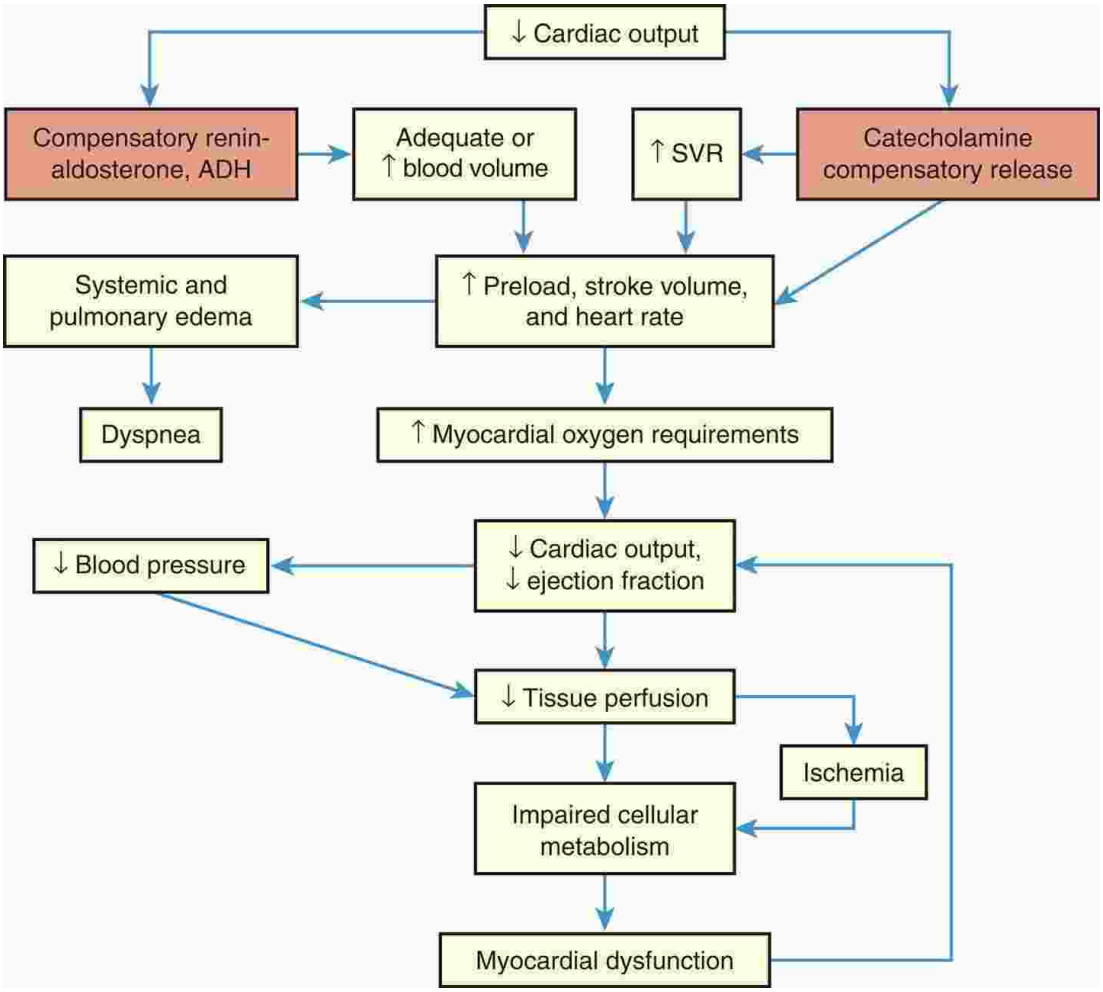

FIG. 48.6 Cardiogenic Shock.
Shock becomes life-threatening when compensatory mechanisms *(orange boxes)* cause increased myocardial oxygen requirements. *ADH*, Antidiuretic hormone; *SVR*, systemic vascular resistance.

A flow diagram illustrates the mechanism of cardiogenic shock. The diagram begins as follows. â€¢ Decrease in cardiac output due to catecholamine compensatory release and compensatory renin-aldosterone, A D H. â€¢ compensatory release and compensatory renin-aldosterone, A D H leads to increase in adequate blood volume. â€¢ catecholamine compensatory leads to increase in S V R. â€¢ Increase in blood volume and S V R leads to increase preload, stroke volume, and heart rate causing systemic and pulmonary edema. â€¢ The systemic and pulmonary edema leads to dyspnea. â€¢ The increase in preload, stroke volume, and heart rate leads to increased myocardial oxygen requirement. â€¢ Increased myocardial oxygen requirement leads to

myocardial dysfunction due to a decrease in cardiac output, ejection fraction, tissue perfusion, and impaired cellular metabolism. â€¢ The impaired cellular metabolism is caused due to ischemia by a decrease in blood pressure and tissue perfusion.

Hypovolemic Shock

Hypovolemic shock is caused by reduced intravascular volume (preload) from loss of whole blood (hemorrhage), plasma (burns), or interstitial fluid (diaphoresis, diabetes mellitus, diabetes insipidus, emesis, or diuresis) in large amounts, which reduces cardiac output. Hypovolemic shock is categorized as hemorrhagic, the loss of whole blood or plasma, and nonhemorrhagic, caused by the loss of interstitial fluid other than blood. Nonhemorrhagic losses can cause an indirect "relative" hypovolemia by promoting diffusion of plasma from the intravascular to the extravascular space. Hypovolemic shock begins to develop when intravascular volume has decreased by about 15%. Hemorrhagic shock can be related to blunt or penetrating trauma (fractures) and upper or lower gastrointestinal (GI) bleeding. Nonhemorrhagic shock can be caused from GI losses (diarrhea or vomiting), skin losses (burns, Stevens-Johnson syndrome), renal losses (diuresis, hypoaldosteronism), or third spacing (crush injury, cirrhosis).

Hypovolemia is offset initially by compensatory mechanisms (Fig. 48.7). Heart rate and vasoconstriction increase as a result of catecholamine release by the adrenals. This boosts cardiac output and tissue perfusion pressures. Compelled by a decrease in capillary hydrostatic pressures, interstitial fluid moves into the vascular compartment. The liver and spleen add to blood volume by disgorging stored red blood cells and plasma. In the kidneys, renin (through several intermediaries) stimulates aldosterone release and the retention of sodium (and hence water), whereas antidiuretic hormone (ADH, or vasopressin) from the posterior pituitary gland increases water retention. Data on the compensation of ADH, however, show that as shock worsens, ADH in plasma decreases. Eventually, hypovolemic shock results in extreme vasoconstriction and increased SVR and afterload in order to improve blood pressure and perfusion to core organs.

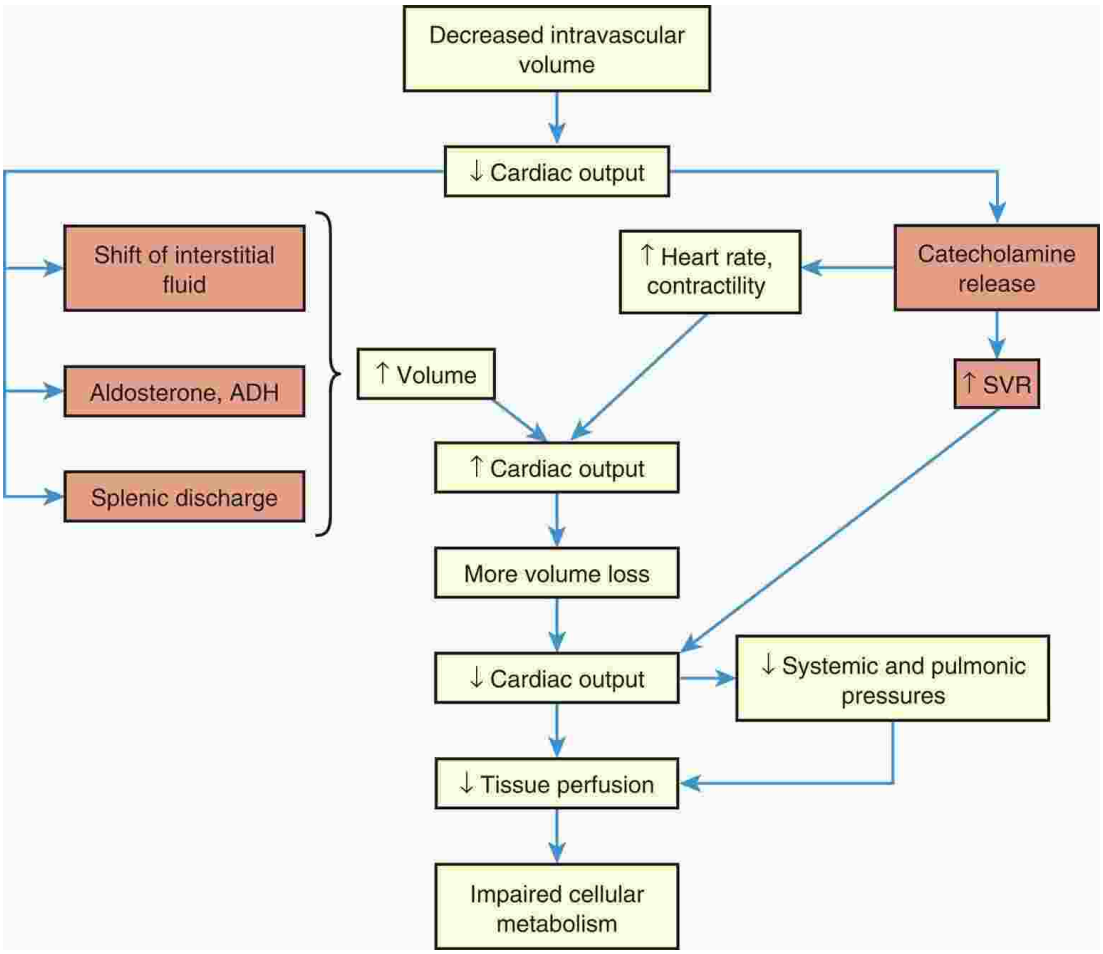

FIG. 48.7 Hypovolemic Shock.
This type of shock becomes life-threatening when compensatory mechanisms *(orange boxes)* are overwhelmed by continued loss of intravascular volume. *ADH*, Antidiuretic hormone; *SVR*, systemic vascular resistance.

A flow diagram illustrates the mechanism of hypovolemic shock. The diagram begins as follows. â€¢ Decreased intravascular volume leads to decrease cardiac output, causing a shift of interstitial fluid, aldosterone, A D H, splenic discharge, and catecholamine release due to an increase in heart rate contractility and S V R. â€¢ The increase in volume due to the shift of interstitial volume and increase in heart rate contractility leads to increase in cardiac output causing more volume loss and decrease in cardiac output and tissue perfusion due to decrease in systemic and pulmonic pressures which further leads to impaired cellular metabolism.

These compensatory mechanisms are, however, finite. If the initial fluid or blood loss is great or if loss continues, compensation fails, resulting in decreased tissue perfusion. Nutrient delivery to the cells is impaired, and cellular metabolism fails. Mortality from traumatic hemorrhagic shock ranges from 10% to 31%. Prompt control of hemorrhage, if present, is the treatment of choice. Fluid replacement is essential, but the type of fluid to be used and the rate of replacement are controversial.[37,38]

The clinical manifestations of hypovolemic shock include high SVR, pallor and cool extremities, increased thirst, oliguria, low systemic and pulmonary preloads, and rapid heart rate.

Obstructive Shock

Obstructive shock is a form of shock that is commonly combined with cardiogenic shock (see section on cardiogenic shock). Obstructive shock is associated with a mechanical obstruction to and/or from the heart generally within the great vessels, which causes an inadequate cardiac output. Common causes include pulmonary embolism, cardiac tamponade, and tension pneumothorax.[39,40] The clinical manifestations are specific to the related cause, but also may be accompanied by disturbances of consciousness, centralization, oliguria, hypotension, and tachycardia.[39] See chapter 35 for further information on these causes. Obstructive shock is a potentially life-threatening condition due to hemodynamic instability. This requires an expeditious and purposeful diagnosis and a rapid and directed treatment plan.[39]

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS) is the progressive dysfunction of two or more organ systems resulting from an uncontrolled inflammatory response to a severe illness or injury. The organ dysfunction can progress to organ failure and death. In 2016, an international consensus conference developed an updated set of definitions for sepsis and related disorders (see Table 48.1). MODS is the end stage of a variety of injuries that terminate in a severe, systemic inflammatory and cell stress response, including apoptosis.[41]

MODS was first recognized as a distinct clinical syndrome in the early 1970s when advances in resuscitation and support technologies allowed many individuals to survive life-threatening illness or trauma only to die of complications of their disease. Today MODS remains a leading cause of mortality in surgical intensive care units (ICUs). Mortality for individuals with MODS increases progressively from 54% with two failing organ systems to 100% with five failing organ systems. Moreover, mortality has not improved much over the past 15 to 20 years in the medical community, but restrictive transfusion protocols in the surgical populations have demonstrated modest reduction in mortality.[42–45]

Although sepsis and septic shock are the most common causes, MODS can be initiated by any severe injury or disease process that activates a massive systemic inflammatory response by the host. Documented clinical infection is not necessary for its development. Other common triggers are severe trauma, major surgery, burns, circulatory shock, acute pancreatitis, acute renal failure, ARDS, blood transfusion, heat stroke, liver failure, mesenteric ischemia, propofol infusion syndrome, persistent inflammatory foci, DIC, and tissue necrosis (Box 48.2). MODS is the major cause of death following septic shock, trauma, burn injuries, and ARDS. People at greatest risk for developing MODS are older adults and persons with significant tissue injury or preexisting disease.[5] The SOFA system (see Table 48.1), a clinically

useful sepsis staging system, stratifies individuals with disease by baseline risk of adverse outcomes and potential to respond to therapy.[5]

Box 48.2

Other Common Triggers of Multiple Organ Dysfunction Syndrome

Severe trauma
Major surgery
Burns
Circulatory shock
Acute pancreatitis
Acute renal failure
Acute respiratory distress syndrome
Blood transfusion
Heat stroke
Liver failure
Mesenteric ischemia
Propofol infusion syndrome
Persistent inflammatory foci
Necrotic tissue
Disseminated intravascular coagulation (DIC)

P

athophysiology

In **primary MODS**, the organ injury is directly associated with a specific insult, most often ischemia or impaired perfusion from an episode of shock or trauma, thermal injury, soft tissue necrosis, or invasive infection.[46] This decreased perfusion is local (in the injured organs themselves) and generalized. The generalized hypoperfusion in primary MODS usually cannot be detected clinically. As a result of the insult, a stress response is initiated and stress hormones, catecholamines in particular, are released. The inflammatory and stress responses are not as evident because they are in secondary MODS. In primary MODS during the inflammatory response, presumably neutrophils and macrophages are "primed" by cytokines.[46] Any second insult, such as additional tissue injury, infection, or organ ischemia, may then activate the primed cells to produce an exaggerated response of secondary MODS (Fig. 48.8).[46,47]

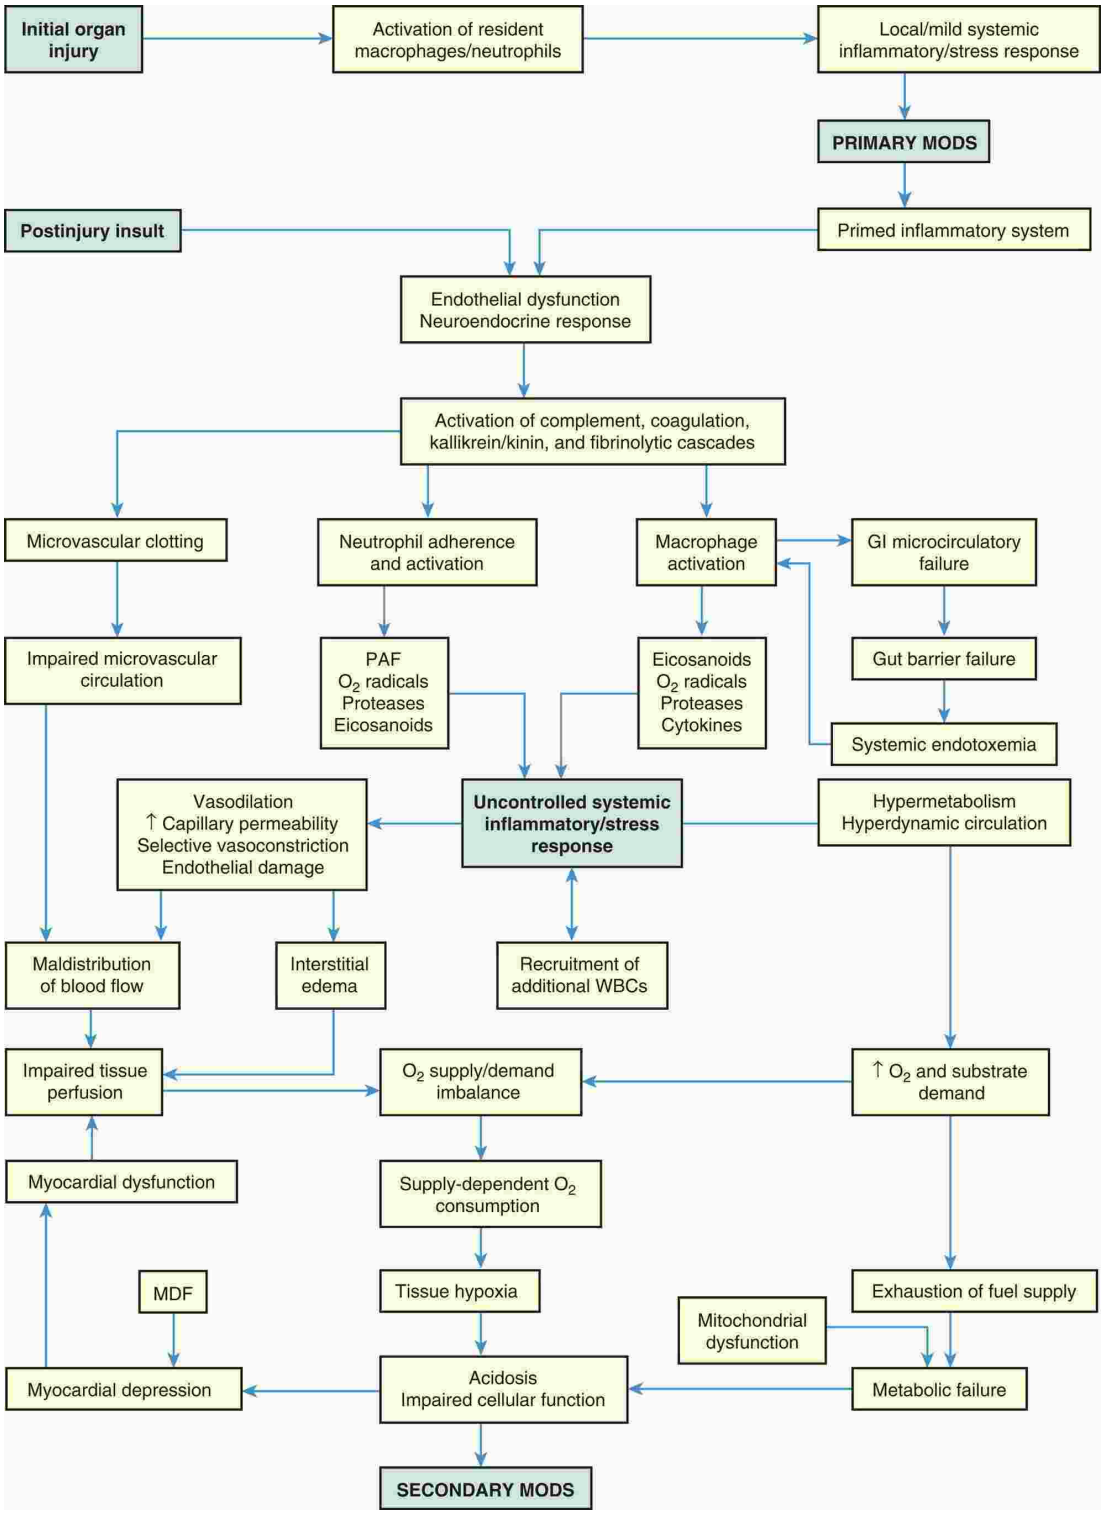

FIG. 48.8 Pathogenesis of Multiple Organ Dysfunction Syndrome.
GI, Gastrointestinal; *MDF*, myocardial depressant factor; *MODS*, multiple organ dysfunction syndrome; *PAF*, platelet-activating factor; *WBCs*, white blood cells.

A flow diagram illustrates the pathogenesis of multiple organ dysfunction syndrome. The diagram begins as follows. â€¢ Initial organ injury leads to activation of resident macrophages or neutrophils and local or mild systemic inflammatory or stress. â€¢ Activation of resident macrophages or neutrophils and local or mild systemic inflammatory or stress leads to primary M O D S causing primed inflammation. â€¢ Postinjury insult and primed inflammation lead to endothelial dysfunction. â€¢ The neuroendocrine response leads to activation of complement, coagulation, kallikrein or kinin, and fibrinolytic cascades, which includes microvascular clotting, neutrophil adherence, and activation, macrophage activation. â€¢ The microvascular clotting leads to impaired microvascular circulation. â€¢ Neutrophil adherence and activation lead to P A F O 23 radicals proteases Eicosanoids. â€¢ Macrophage activation leads to G I microcirculatory failure leading to gut barrier failure and systemic endotoxemia due to macrophage activation, which causes an uncontrolled systemic inflammatory stress response. â€¢ The uncontrolled systemic inflammatory stress response leads to secondary M O D S by vasodilation, increased capillary permeability, selective vasoconstriction, endothelial damage, maldistribution of blood flow, interstitial edema, impaired tissue perfusion, myocardial dysfunction, myocardial depression, recruitment of additional WB Cs, O 2 supply and demand imbalance, supply-dependent O 2 consumption, tissue hypoxia, acidosis impaired cellular function, hypermetabolism, hyperdynamic circulation, increased O 2 and substrate demand, mitochondrial dysfunction, exhaustion of fuel supply, metabolic failure leading to acidosis impaired cellular function leading to secondary M O D S.

The progressive organ dysfunction of **secondary MODS** is the result of an excessive inflammatory reaction, after a latent period following the initial injury, in organs distant from the site of the original injury. It is postulated that the resulting organ trauma is caused by the host response to a second insult rather than being a direct result of the primary injury. The second insult is often mild but produces an immense disproportionate response because of the previous priming of leukocytes. The interaction of injured organs then leads to a self-perpetuating inflammation.

Secondary MODS is initiated by the delayed postinjury insult as primed macrophages release a barrage of mediators, particularly the cytokines TNF and IL-1. These mediators damage the endothelium throughout the body. If a gram-negative bacterial infection is present, endotoxin released from the bacteria also causes severe damage to endothelial cells. Normal endothelial cells have little interaction with leukocytes, but when stimulated by TNF,

IL-1, IL-6, or endotoxin, they change to a proinflammatory state and express adhesion molecules that mediate adhesion of neutrophils. The adhered neutrophils then migrate through the endothelium, aggregate in the area of damaged tissue, and amplify the inflammation. The activated endothelial cells increase production and release of nitric oxide (endothelium), a potent vasodilator, which is considered an important factor in blood flow changes and loss of vascular tone noted in systemic inflammation.[48] The injured endothelium also becomes much more permeable, allowing fluid and protein to leak into the interstitial spaces. An important function of normal endothelium is anticoagulation. When damaged, the endothelium loses much of its ability to prevent blood clotting, allowing microvascular thrombi to develop.

The postinjury insult also activates the neuroendocrine system, resulting in a second, more extensive stress response. The normal function of the stress response is to maintain basal and stress-related homeostasis[49]; however, homeostasis cannot be maintained in MODS. In fact, the endocrine response becomes excessive and injurious. There is an early increase in the levels of circulating catecholamines that contributes to many of the clinical manifestations of MODS, such as tachycardia, hypermetabolism, and increased oxygen consumption. Cortisol, glucagon, insulin, human growth hormone, ADH (which may become depleted), and endorphin levels also are increased. Many of these hormones contribute to the extreme catabolic state of MODS, and endorphins, which are vasodilators, decrease SVR. The sympathetic nervous system, to compensate for complications resulting from the injury (e.g., fluid loss, hypotension), also is stimulated. The stimulation persists throughout the period of critical illness.[49] The stress response can be amplified by a number of factors, including pain, anxiety, psychosis, and hyperthermia. (The stress response is discussed in detail in Chapter 11.)

Because of endothelial cell dysfunction and the release of mediators, four major plasma cascades are activated: complement, kallikrein-kinin, coagulation, and fibrinolytic.[50,51] Complement components, particularly the anaphylatoxins C3a and C5a, cause vasodilation by stimulating release of histamine from mast cells. They also have strong chemotactic properties. C5a, especially, causes adhesion and the activation and degranulation of neutrophils. Complement is thought to be a powerful trigger for the exaggerated inflammatory response. Activation of the kinin system results in the production of bradykinin, a very potent vasodilator known to decrease SVR. Coagulation mechanisms also are activated and, because tissue injury and endothelial dysfunction are extensive, microvascular thrombosis occurs throughout the body, resulting in impaired microvascular circulation and organ ischemia. Concurrently, fibrinolytic mechanisms are activated. The tendency toward clotting, however, is greater, resulting in a net procoagulant state that can lead to the development of DIC. The overall effect of the activation of the plasma cascades is a hyperinflammatory and hypercoagulant state that contributes to vasodilation, vasopermeability, cardiovascular instability, endothelial dysfunction, and clotting abnormalities.[46,51,52]

Once cytokines and other mediators have been released and the plasma enzyme cascades have been activated, a massive systemic inflammatory response develops. It involves several types of inflammatory cells, particularly neutrophils, macrophages, and mast cells. These cells, having been primed by their response to the initial organ injury, now pour large amounts of chemical mediators into tissues and into the systemic circulation. Neutrophils have tremendous inflammatory potential. The accumulation of activated neutrophils in organs is thought to play a key role in the pathogenesis of MODS.[53] When neutrophils adhere

to the endothelium, they undergo a "respiratory burst" (oxidative burst) and release oxygen free radicals. The respiratory burst occurs as the activated neutrophil experiences a sudden increase in oxidative metabolism, producing large quantities of highly toxic oxygen free radicals. These reactive oxygen species (ROS) cause oxidative stress. The primary ROS produced are superoxide, hydrogen peroxide (H_2O_2), hydroxyl radical (OH^-), and singlet oxygen (O). Oxygen free radicals are extremely damaging to vascular endothelium and tissue cells, attacking deoxyribonucleic acid (DNA), cross-linking membrane structures, and inducing membrane peroxidation reactions that disorganize cell membranes and lead to tissue necrosis (also see Chapter 2).[3]

Other important mediators released by neutrophils are proteases, particularly collagenase and elastase. Proteases directly damage endothelium and neighboring cells, resulting in increased capillary permeability and organ damage. When activated, neutrophils also release platelet-activating factor (PAF), a mediator that damages endothelium, stimulates clot formation, and activates increasing numbers of phagocytes. Finally, neutrophils release arachidonic acid metabolites (eicosanoids) as a result of lipid peroxidation of their cell membranes. Of the arachidonic acid metabolites (prostaglandins, thromboxanes, leukotrienes), two are particularly important in the pathogenesis of organ hypoperfusion: prostacyclin (PGI_2) and thromboxane A_2 (TXA_2). TXA_2 is a powerful vasoconstrictor, and PGI_2 is a potent vasodilator. When released in varying amounts in different organ beds, they are largely responsible for the maldistribution of blood flow characteristic of MODS. In total, neutrophils produce at least 50 to 60 toxins.[54,55] Collectively, products released by neutrophils cause endothelial dysfunction, systemic vasodilation, selective vasoconstriction (vasoconstriction of certain organ beds or parts of organ beds), increased vascular permeability, and microvascular coagulation.

Macrophages, present in most tissues, are activated by endotoxin, complement, and monocyte chemotactic substances.[56] Macrophages share a key role in the development of the unregulated inflammation of secondary MODS with the neutrophils. Like neutrophils, they produce oxygen free radicals, proteases, cytokines, nitric oxide, and arachidonic acid metabolites. It has been reported that excessive or prolonged stimulation of macrophages leads to the overproduction of cytokines and nitric oxide that initiate the cycle of harmful effects in MODS.[3,56] TNF and IL-1, which share many of the same functions and act synergistically, are the major cytokines that mediate inflammation.[56,57] TNF has potent metabolic effects, including fever, anorexia, hyperglycemia, hypermetabolism, and weight loss. It activates neutrophils, damages endothelial cells, and potentiates hypotension and shock. IL-1 also has metabolic effects, inducing fever, hypermetabolism, and muscle wasting. Normally, TNF activates cytokines, the coagulation system, fibrinolysis, and neutrophils. With the exception of neutrophil activation, IL-1 causes similar activation in individuals with cancer.[54] In the pathogenesis of MODS, the cytokines are linked to all cellular, hemodynamic, and metabolic alterations.

The gastrointestinal mucosa is particularly vulnerable to inflammatory mediators released by macrophages and neutrophils. Under normal circumstances the gut mucosa serves as a barrier to prevent bacteria in the gastrointestinal tract from entering the systemic circulation. Damage to the mucosa results in microcirculatory failure of the gut and consequent loss of the gut barrier function. The loss of intestinal barrier function leads to the systemic spread of bacteria or endotoxin, or both, from the gut (systemic endotoxemia). This phenomenon is called *translocation of bacteria*. The idea that the gut acts as a reservoir of bacteria and endotoxin that can initiate or perpetuate the development of MODS is known as the **gut**

hypothesis. The gut hypothesis provides a possible explanation for the fact that an infectious focus is not always found in individuals with MODS. Although this hypothesis has been substantiated by animal studies and has much support, the evidence from human studies is inconclusive.[58] The numerous inflammatory processes operating in MODS cause maldistribution of blood flow and hypermetabolism. **Maldistribution of blood flow** refers to the uneven distribution of flow to various organs and between the large vessels and capillary beds of the body. It is caused by generalized vasodilation, increased capillary permeability, selective vasoconstriction, endothelial dysfunction, and impaired microvascular circulation. It is a major factor in the pathophysiology of MODS.[51] The alterations in blood flow—which can occur at the cellular, organ, or regional level—lead to impaired tissue perfusion and a decreased supply of oxygen to the cells. The organs most severely affected by hypoperfusion are the lungs, splanchnic bed, liver, and kidneys. Despite supernormal systemic blood flow, oxygen delivery to the tissues decreases. Several factors contribute to the problem. First, blood is shunted past selected regional capillary beds. Shunting, caused by loss of autoregulation in some organs, may be an early indicator of progression of sepsis into MODS.[59] This occurs because inflammatory mediators, particularly TXA_2, override the normal vascular control mechanisms to cause selective vasoconstriction and because injured endothelial cells are unable to respond to normal vasodilator mediators. Second, interstitial edema, resulting from microvascular permeability, contributes to decreased oxygen delivery to cells by increasing the distance oxygen must travel to reach the cells. Third, capillary obstruction occurs because of the formation of microvascular thrombi and the aggregation of leukocytes.[3,56]

Hypermetabolism, with accompanying alterations in carbohydrate, fat, and lipid metabolism, is initially a compensatory measure to meet the body's increased demands for energy. Eventually, however, hypermetabolism becomes detrimental, placing enormous demands on the heart. Hypermetabolism is the result of (1) the neuroendocrine response to stress with the release of catecholamines and cortisol, and (2) the action of TNF and IL-1. With increased metabolism the calorie requirements are markedly increased,[60] and the cardiac output increases to 1.5 to 2 times normal.[61,62] The alterations in metabolism affect all aspects of substrate use. Most important is the catabolism of protein, primarily of skeletal muscle and visceral organs. The extreme catabolism of protein can rapidly deplete lean body mass. Hyperglycemia occurs as gluconeogenesis by the liver increases and glucose use by the cells decreases. Fatty acids are mobilized from adipose tissue. The net result of the hypermetabolism is depletion of oxygen and fuel supplies.

Myocardial depression also accompanies MODS. The cause remains unclear, but possible explanations are the effects of myocardial depressant factor (MDF), TNF, and IL-1 on cardiac contractility; alterations in α-adrenergic receptors in the heart; and hypoxia of the myocardium.[63]

The decreased oxygen delivery to the cells (resulting from the maldistribution of blood flow) and the increased oxygen needs of the cells (resulting from hypermetabolism) combine to create an imbalance in oxygen supply and demand. This imbalance is critical in the pathogenesis of MODS because it results in a pathologic condition known as **supply-dependent oxygen consumption**. Ordinarily the amount of oxygen consumed by the cells depends only on the needs of the cells because there is an adequate reserve of oxygen that can be delivered if required. In MODS, however, the reserve has been exhausted and the amount of oxygen consumed becomes dependent on the amount the circulation is able to deliver. Because the amount is inadequate in MODS, the tissues become hypoxic. Compounding the

hypoxic damage to cells is a phenomenon called *reperfusion injury* (see Chapter 2). Much of the organ damage in MODS occurs with the reestablishment of blood flow after a period of ischemia. During the ischemic episode, energy stores and ATP are depleted, and the enzyme *xanthine dehydrogenase* is converted to *xanthine oxidase*. With reperfusion of the ischemic tissue, oxygen free radicals are formed from oxygen by the action of xanthine oxidase, and they attack the already damaged tissues. Consequently, although reperfusion is necessary to restore oxygen supply to ischemic organs, it can increase the extent of injury. Therefore because of supply-dependent oxygen consumption and reperfusion injury, already compromised tissues become increasingly hypoxic. The result is cellular acidosis, impaired cellular function, and ultimately multiple organ failure.

Clinical manifestations

In MODS, the organs that show clinical manifestations of failure are not always the organs involved as part of the initial injury, and there is usually a lag time between the initial insult and the development of systemic organ failure. The development of primary MODS is difficult to monitor, but there is a well-established general pattern in the clinical development of secondary MODS.[46] Following the inciting event and aggressive resuscitation of an individual for approximately 24 hours, the individual develops low-grade fever, tachycardia, tachypnea, dyspnea, altered mental status, and a general hyperdynamic and hypermetabolic state (Box 48.3). Following this, the lungs begin to fail, and ARDS may appear within 24 to 72 hours (see discussion of ARDS in Chapter 35). Between days 7 and 10, the hypermetabolic and hyperdynamic state intensifies; bacteremia with enteric organisms is common; and signs of hepatic, intestinal, and renal failure develop. During days 14 to 21, renal failure and liver failure become more severe. Hematologic failure and myocardial failure are usually later manifestations. Encephalopathy, characterized by mental status changes ranging from confusion to deep coma, may occur at any time. This sequence can evolve rapidly, with death occurring between 14 and 21 days later, or it can evolve over weeks. Individuals can recover from either the slowly or the rapidly evolving course.

Box 48.3

Clinical Manifestations of Organ Dysfunction

Pulmonary

- Acute respiratory distress syndrome (ARDS) pattern of respiratory failure (dyspnea, patchy infiltrates, refractory hypoxemia, respiratory acidosis, abnormal O_2 indices)
- Pulmonary hypertension

Gastrointestinal

- Abdominal distention and ascites
- Intolerance to enteral feedings
- Paralytic ileus
- Upper and lower gastrointestinal bleeding (guaiac-positive stools)
- Diarrhea

- Ischemic colitis
- Mucosal ulceration
- Decreased bowel sounds
- Bacterial overgrowth in stool

Liver

- Increased serum bilirubin level (hyperbilirubinemia)
- Increased liver enzyme levels (serum aspartate transaminase [SAST], serum alanine aminotransferase [SALT], lactic dehydrogenase [LDH], alkaline phosphatase)
- Increased serum ammonia level
- Decreased serum transferrin level
- Jaundice
- Hepatomegaly

Gallbladder

- Right upper quadrant tenderness or pain
- Abdominal distention
- Unexplained fever
- Decreased bowel sounds

Metabolic/Nutritional

- Decreased lean body mass
- Muscle wasting
- Severe weight loss
- Negative nitrogen balance
- Hyperglycemia
- Hypertriglyceridemia
- Increased serum lactate levels
- Decreased serum albumin, serum transferrin, prealbumin, retinol-binding protein

Renal

- Increased serum creatinine level and blood urea nitrogen
- Oliguria, anuria, or polyuria consistent with prerenal azotemia or acute tubular necrosis
- Urinary indices consistent with prerenal azotemia or acute tubular necrosis

Cardiovascular

Hyperdynamic

- Decreased pulmonary capillary wedge pressure

- Decreased systemic vascular resistance
- Decreased right atrial pressure
- Decreased left ventricular stroke work index
- Increased oxygen consumption
- Increased cardiac output, cardiac index, heart rate

Hypodynamic

- Increased systemic vascular resistance
- Increased right atrial pressure
- Increased left ventricular stroke work index
- Decreased oxygen delivery and consumption
- Decreased cardiac output and cardiac index

Central Nervous System

- Lethargy
- Altered level of consciousness
- Fever
- Hepatic encephalopathy

Coagulation and Hematologic

- Thrombocytopenia
- Disseminated intravascular coagulation

Immune

- Infection
- Decreased lymphocyte count
- Anergy

Data from Thelan LA, et al. *Critical care nursing: Diagnosis and management*, 6th edition. St. Louis: Mosby; 2010.

The clinical manifestations of failure of individual organs in MODS are caused by inflammatory mediator damage, tissue hypoxia, and hypermetabolism. Respiratory failure progresses early to ARDS and is characterized by tachypnea, pulmonary edema with crackles and diminished breath sounds, use of accessory muscles, and hypoxemia. Liver failure, although early in its development, is not clinically detectable until the later stages of MODS, when jaundice, abdominal distention, liver tenderness, muscle wasting, and hepatic encephalopathy appear. All aspects of metabolism, substance detoxification, and immune response are impaired. Albumin and clotting factor synthesis decreases, protein wastes accumulate, and liver tissue macrophages (Kupffer cells) no longer function effectively.

The gastrointestinal system is very sensitive to ischemic and inflammatory injury. Clinical manifestations of bowel involvement are hemorrhage, ileus, stress ulcers, malabsorption, diarrhea or constipation, vomiting, anorexia, abdominal pain, and pancreatitis. Intolerance to

enteral feeding may develop. Adding to damage caused by injury to the bowel is bacterial translocation into the bloodstream resulting from the loss of the gut barrier function. The overwhelmed liver is unable to clear the bacteria from the systemic circulation. Thus regardless of whether infection or some other injury was the precipitating cause of MODS, once intestinal bacteria enter the systemic circulation, it is likely that sepsis will be a problem. Renal failure develops at about the same time and is marked by progressive oliguria, azotemia, and edema. If renal shutdown is severe, anuria, hyperkalemia, and metabolic acidosis occur.

The first manifestations of cardiac failure are similar to those of septic shock: tachycardia, bounding pulse, increased cardiac output, fall in SVR, hypotension, warm skin, and supraventricular dysrhythmias. In the terminal stages, profound hypotension and ventricular dysrhythmias may develop. Changes in central nervous system function may be noted. Ischemia and inflammation are responsible for the changes, which include apprehension, confusion, disorientation, restlessness, agitation, headache, decreased cognitive ability and memory, and decreased level of consciousness. When ischemia is severe, seizures and coma can occur.

Evaluation and treatment

Because there is no specific therapy for MODS, early detection or prevention is extremely important so that supportive measures are initiated instantly.[64] Frequent assessment of the clinical status of individuals at known risk is essential. Unfortunately, there is no way to determine with certainty when an organ is failing. Indicators of organ dysfunction are presented in Table 48.1.

Several systems for scoring severity of illness also have been developed. Commonly used systems are the **Acute Physiology and Chronic Health Evaluation II and III (APACHE II and APACHE III)**, the logistic organ dysfunction score (LODS), the SOFA, the MODS score, and the predisposition, infection (or insult), response, and organ dysfunction (PIRO) staging system.[65]

Once organ failure develops, monitoring of laboratory values and hemodynamic parameters is necessary to assess the degree of clinical impairment.

The therapeutic management of MODS consists of prevention and support. Prevention of the syndrome is essential! First, if possible, the initial source of inflammation must be eliminated or controlled. Next, a second insult must be avoided. It is paramount to remove any potential site of infection by debriding necrotic tissue, draining abscesses, reducing the number of invasive procedures performed, and removing hematomas. Nosocomial infections from contaminated lines and catheters are of concern and must be prevented. Nosocomial infection rates of 15% to 25% have been reported in critically ill individuals.[66] Early reduction of long-bone fractures and surgical repair of injured tissues also are important preventive measures.

The goals of therapy are to control infection, provide adequate tissue oxygenation, restore intravascular volume, and support the function of individual organs.[24,67–69]

After the initial injury has been aggressively treated and sources of infection have been removed, antibiotics usually are administered. The choice of agents is based on the individual's disease process, but the regimen is usually a combination of antibiotics that covers both gram-negative and gram-positive organisms.

Because oxygen is not stored in the tissues, it must be continuously delivered. Maintaining an arterial oxygen saturation of 88% to 92% is recommended; current literature supports

using a restrictive transfusion strategy (transfuse only if hemoglobin is <7 g/day or <8.0 if the individual has ischemic or current acute coronary syndrome).[42,70,71]

Mixed venous oxygen saturation greater than or equal to 70% is recommended. For oxygen delivery blood transfusions may be necessary to ensure an adequate hemoglobin level. To deliver oxygen to the organs in the face of profound systemic vasodilation, fluid volume must be restored. Therefore, aggressive fluid therapy is initiated early. Usually large volumes of isotonic crystalloid solutions are administered, although colloids (often albumin) also may be added to maintain adequate preload and circulation volume.[42,70,71]

Finally, support for individual organ systems must be provided. Respiratory failure is treated with mechanical ventilation with low tidal volumes, high oxygen concentrations, and positive end-expiratory pressures (PEEPs).[72]

To provide adequate nutrition and metabolic support, the failing gastrointestinal system is supported with enteral feedings. It is now well recognized that enteral feedings help preserve gut microbial barrier function, and thus are preferred to parenteral feedings.[73] However, if the individual is unable to tolerate the amount of enteral feeding required to meet the enormous metabolic demands, hyperalimentation may be added. Ideally the feeding formula is carefully calculated to meet the individual's nutritional requirements. Glucose level control (140 to 180 mg/dL) is recommended.[73] Once renal failure is established, dialysis or continuous hemofiltration may be required to maintain fluid and electrolyte balance. To support the failing cardiovascular system, inotropic drugs, such as low-dose dopamine and dobutamine, or vasopressors, such as norepinephrine, may be required to maximize cardiac contractility and maintain cardiac output. Although steroids have antiinflammatory effects, their use is controversial because studies showing benefit and injury are both published; however they have been shown to be effective in adults with septic shock. Obtaining an adrenocorticotropic hormone (ACTH) level is not recommended. Deep vein thrombosis prophylaxis also is important.[23]

Scientific knowledge gained about MODS and inflammatory mediators has led to many investigational therapies. Novel molecular approaches targeting a variety of interdependent mediators of MODS are being investigated.

Thermal Injury and Burns

Major **thermal injury** is a source of massive tissue injury and destruction that has wide-reaching effects on virtually all organ systems. **Burn** is a generic term used to describe cutaneous injury caused by thermal contact (friction, cold, heat), radiation, chemicals, or electrical causes.[74] In addition to cutaneous injury, burns are often associated with smoke inhalation injury or other traumatic injuries that aggravate the local and systemic problems of burns. Pulmonary injury, both primary and secondary, is common in this population and often requires ventilator support. The clinical significance of a thermal injury is dependent on the depth of the burn, the percentage of body surface area involved, the injuries caused internally from inhalation, and the timeliness of treatment. This model of multisystem injury provides an opportunity to examine the interaction of shock, inflammation, and immunocompromise in a clinical setting.

Epidemiology and Etiology

Burns are the fourth most common trauma worldwide.[75] Over 450,000 individuals seek care every year in the United States for burn injuries with approximately 10% requiring

hospitalization.[75] Individuals between 20 and 59 years of age have the highest prevalence of burns accounting for 55% with young children accounting for 24%.[75] Deaths consequent to burn injuries decreased more than 50%, from 9000 in 1971[76] to 3275 annually.[75] This clinical progress is the result of several factors, such as ongoing research in burn physiology and burn care,[77] a nationally increased focus on fire safety and burn prevention, the establishment of regional burn centers, the use of smoke detectors, regulation of consumer product safety, and occupational safety mandates. A decrease in hospitalization is a result of a shift to outpatient care and improved prehospital and emergency treatment, as well as an improvement in burn assessment and delivery of care.[78] This may reduce medical transport and treatment costs. Worldwide expansion of telemedicine has occurred at an increasing rate over the past decade. These advances in care are changing measures of healthcare value from burn survival to functional outcomes in burn survivors. In fact, worldwide, digital health communications are becoming common in burn centers due to improved convenience, accuracy, efficiency, productivity, and clinical decision-making.[79]

The causes of burn injury may be **thermal** or **nonthermal**, such as chemical, electrical, or radioactive. Thermal burns may result from thermal contact, flame, or scald. Adherent materials (e.g., asphalt, tar, or plastic) may likewise produce a serious contact burn. Chemical injuries are a result of contact with substances that are directly toxic to the skin or the lining of the respiratory or alimentary tract. Such chemicals are often acidic, alkali, or organic agents, termed **vesicants**, which cause blistering of the epithelial surfaces. Electrical burns may be the result of the conduction of electrical current through the body with heating of tissue or flash over the body surface associated with an electrical discharge. Quality of life can be mildly to severely affected by a burn but can improve with proper and expeditious intervention.

Burn Wound Depth

The classification of **burn wound depth** is usually based on the physical appearance and the symptoms associated with the affected skin (see Chapter 46 on the structure and function of the integumentary system). The definitive diagnosis is determined by the histologic depth of tissue necrosis. Such historic evaluation, unfortunately, necessitates a skin biopsy. Because of the invasive nature of biopsy, clinical depth assessment is used and the ultimate fate of the wound determines final diagnosis. Advances in Laser Doppler Imaging (LDI) have been validated for determining burn wound depth.[79] LDI is a non-invasive mechanical extension of the clinical physical exam to assess burn injuries and guide the health care provider in the decision to perform surgical excision or grafting.[79]

First-degree burns are superficial and involve only the epidermis without penetration or injury to the underlying dermal or subcutaneous tissue (Table 48.2).[75] The skin maintains water vapor and bacterial barrier functions. Many sunburns are first-degree injuries caused by exposure of the skin to ultraviolet radiation from the sun. Initially there is local pain and erythema, and since the barrier remains intact, the area is dry (no blisters).[75] An extensive first-degree burn may cause systemic responses such as chills, headache, localized edema, and nausea or vomiting. Minimal treatment (analgesic and moisturizer) or no treatment of extensive first-degree burns is required unless the person is elderly or an infant, in which case severe nausea and vomiting may lead to inadequate fluid intake and dehydration. Therapy consists of intravenous hydration until the nausea and vomiting subside 24 to 72 hours after burn injury. Comfort measures for previously healthy children or adults with extensive first-

degree burns consist of aspirin for adults or acetaminophen for children every 4 hours in age-appropriate doses and frequent application of a water-soluble lotion.[75] First-degree burns heal in 3 to 5 days without scarring.

Table 48.2

Depth of Burn Injury

	First Degree	Second Degree		Third Degree
Characteristic		**Superficial Partial Thickness**	**Deep Partial Thickness**	**Full Thickness**
Morphology	Destruction of epidermis only	Destruction of epidermis and some dermis	Destruction of epidermis and dermis, leaving only skin appendages	Destruction of epidermis, dermis, and underlying subcutaneous tissue
Skin function	Intact	Absent	Absent	Absent
Tactile and pain sensors	Intact	Intact	Intact but diminished	Absent
Blisters	Present only after first 24 h	Present within minutes, thin walled and fluid filled	May appear as fluid-filled blisters; often is layer of flat, dehydrated "tissue paper" that lifts off in sheets	Blisters rare; usually is a layer of flat, dehydrated "tissue paper" that lifts off easily
Appearance of wound after initial debridement	Skin peels at 24–48 h, normal or slightly red underneath	Red to pale ivory, moist surface	Mottled with areas of waxy white, dry surface	White, cherry red, or black; may contain visible thrombosed veins; dry, hard leathery surface
Healing time	3–5 days	21–28 days	30 days to many months	Will not heal; may close from edges as secondary healing if wound is small
Scarring	None	May be present; low incidence influenced by genetic predisposition	Highest incidence because of slow healing rate	Skin graft; scarring minimized by early excision and grafting;

	First Degree	Second Degree		Third Degree
Characteristic		**Superficial Partial Thickness**	**Deep Partial Thickness**	**Full Thickness**
			promoting scar tissue development; also influenced by genetic predisposition	influenced by genetic predisposition

	First Degree	Second Degree		Third Degree
Characteristic		**Superficial Partial Thickness**	**Deep Partial Thickness**	**Full Thickness**
Morphology	Destruction of epidermis only	Destruction of epidermis and some dermis	Destruction of epidermis and dermis, leaving only skin appendages	Destruction of epidermis, dermis, and underlying subcutaneous tissue
Skin function	Intact	Absent	Absent	Absent
Tactile and pain sensors	Intact	Intact	Intact but diminished	Absent
Blisters	Present only after first 24 h	Present within minutes, thin walled and fluid filled	May appear as fluid-filled blisters; often is layer of flat, dehydrated "tissue paper" that lifts off in sheets	Blisters rare; usually is a layer of flat, dehydrated "tissue paper" that lifts off easily
Appearance of wound after initial debridement	Skin peels at 24–48 h, normal or slightly red underneath	Red to pale ivory, moist surface	Mottled with areas of waxy white, dry surface	White, cherry red, or black; may contain visible thrombosed veins; dry, hard leathery surface
Healing time	3–5 days	21–28 days	30 days to many months	Will not heal; may close from edges as secondary healing if wound is small
Scarring	None	May be present; low incidence influenced by genetic predisposition	Highest incidence because of slow healing rate promoting scar tissue development; also influenced by genetic predisposition	Skin graft; scarring minimized by early excision and grafting; influenced by genetic predisposition

Second-degree burns describe two categories of burn depth with markedly different characteristics. Both of these are **partial-thickness injuries**, but they evoke vastly different responses. The hallmark of **superficial partial-thickness injury** is the appearance of thin-walled, fluid-filled blisters that develop within just a few minutes after injury. Blisters form due to the breech of the epidermal barrier. As blisters break or are removed, nerve endings are exposed to air (Fig. 48.9), causing severe pain, another dominant characteristic of superficial injury. Tactile and pain sensors remain intact throughout healing, with each wound care procedure causing substantial pain. Wounds heal in 3 to 4 weeks if the individual is adequately nourished and no complications develop (Fig. 48.10). Scar formation is unusual with this injury; however any wound that requires more than the usual healing time has a higher chance of forming a hypertrophic scar.[75] The amount of scarring that develops is a genetically determined trait and is not predictable during the early course of treatment.

FIG. 48.9 Superficial Partial-Thickness Injury.
Scald injury following debridement of overlying blister and nonadherent epithelium. (Courtesy University of Utah Burn Center.)

FIG. 48.10 Axillary Burn Scar Contracture.
Note the blanching of the anterior axillary fold and small ulceration, both indicating the diminished range of motion. (Courtesy University of Utah Burn Center.)

Deep partial-thickness burns involve the entire dermis, sparing skin appendages such as hair follicles and sweat glands (see Table 48.2). The burn often looks waxy white and is surrounded by margins of superficial partial-thickness injury. The injury is often clinically indistinguishable from a full-thickness injury (Fig. 48.11), but by 7 to 10 days after burn injury, skin buds and hair will appear from hair follicles, indicating that skin appendages remain. These wounds take weeks to heal, and current therapy consists of surgical removal of the burn wound (excision) followed by application of the person's own unburned skin from another body area (autograft). Wounds that heal slowly produce more scar tissue and continue to be a potential source of infection until closed. In the presence of relative surgical contraindications, such as cardiopulmonary failure, deep partial-thickness wounds are not surgically treated but are allowed to heal naturally. The fate of partial-thickness burns can be affected by treatment, such as topical antibiotics, or by the condition of biologic membranes.[80] The ultimate healing of deep partial-thickness burns commonly results in hypertrophic scarring with poor functional and cosmetic results.

FIG. 48.11 Deep Partial-Thickness Wound.
Note pale appearance and minimal exudate. (Courtesy University of Utah Burn Center.)

Third-degree burns, or **full-thickness injuries**, involve destruction of the entire epidermis, dermis, and often the underlying subcutaneous tissue (fat) (see Table 48.2). On occasion, all underlying subcutaneous tissue is destroyed and muscle or bone may be involved. Full-thickness wounds often appear relatively innocuous when their color is white and the delineation between normal and burned skin is not accompanied by a marked color change. Elasticity of the dermis is absent, leaving the wound dry and leathery in appearance and texture (Fig. 48.12). As marked edema develops, distal circulation may be compromised in areas of circumferential burns. **Escharotomies** (cutting through burned skin) are performed to release underlying pressure. Full-thickness burns are painless because all nerve endings have been destroyed by the injury.[75]

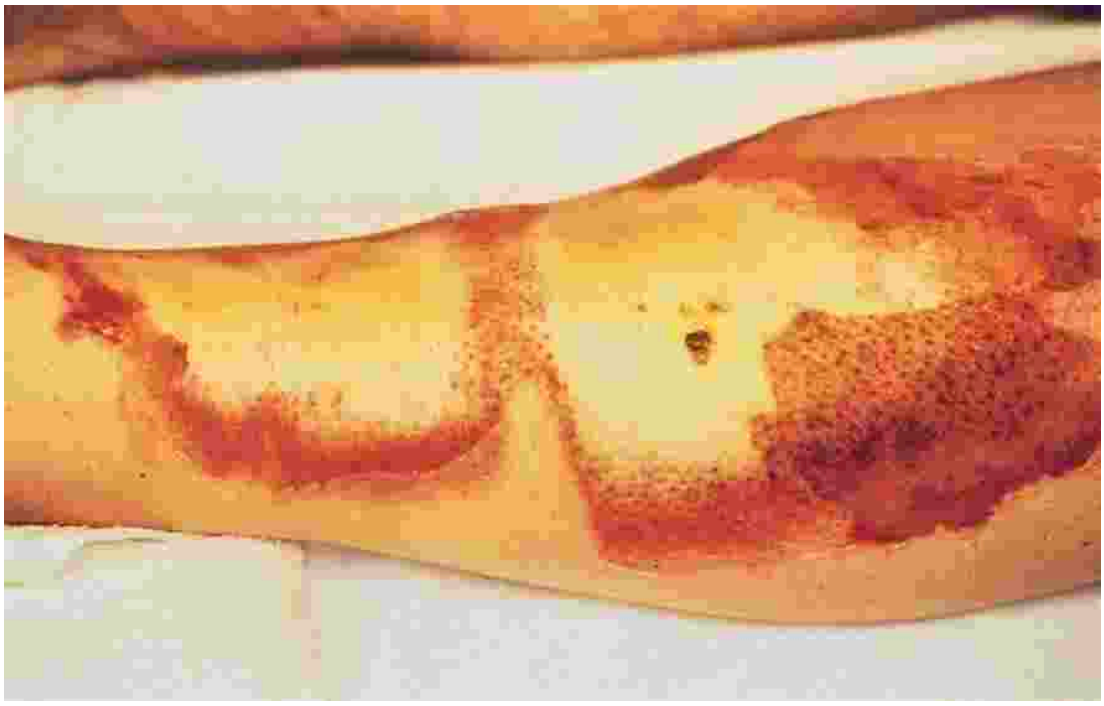

FIG. 48.12 Full-Thickness Thermal Injury.
The wound is dry and insensate. (Courtesy University of Utah Burn Center.)

Fourth-degree burns extend beyond the epidermis, dermis, subcutaneous tissue into the muscle, bone, or tendon and generally require extensive surgical repair with flaps or even amputation.[75] Burns to this extent are painless because all of the vasculature and nerves of the dermis are destroyed.

The extent of the **total body surface area (TBSA)** burn is estimated using either the "rule of nines" (Fig. 48.13) or the Lund and Browder chart (Fig. 48.14). Areas of partial-thickness and full-thickness injury are marked on the diagram (see Fig. 48.14). First-degree burns are not included in the TBSA estimate. The surface area of the palm, including palmar finger surface, averages 1% of the body surface area over a wide range of ages; thus, it can be used to estimate burn areas of irregular size and shape.[81]

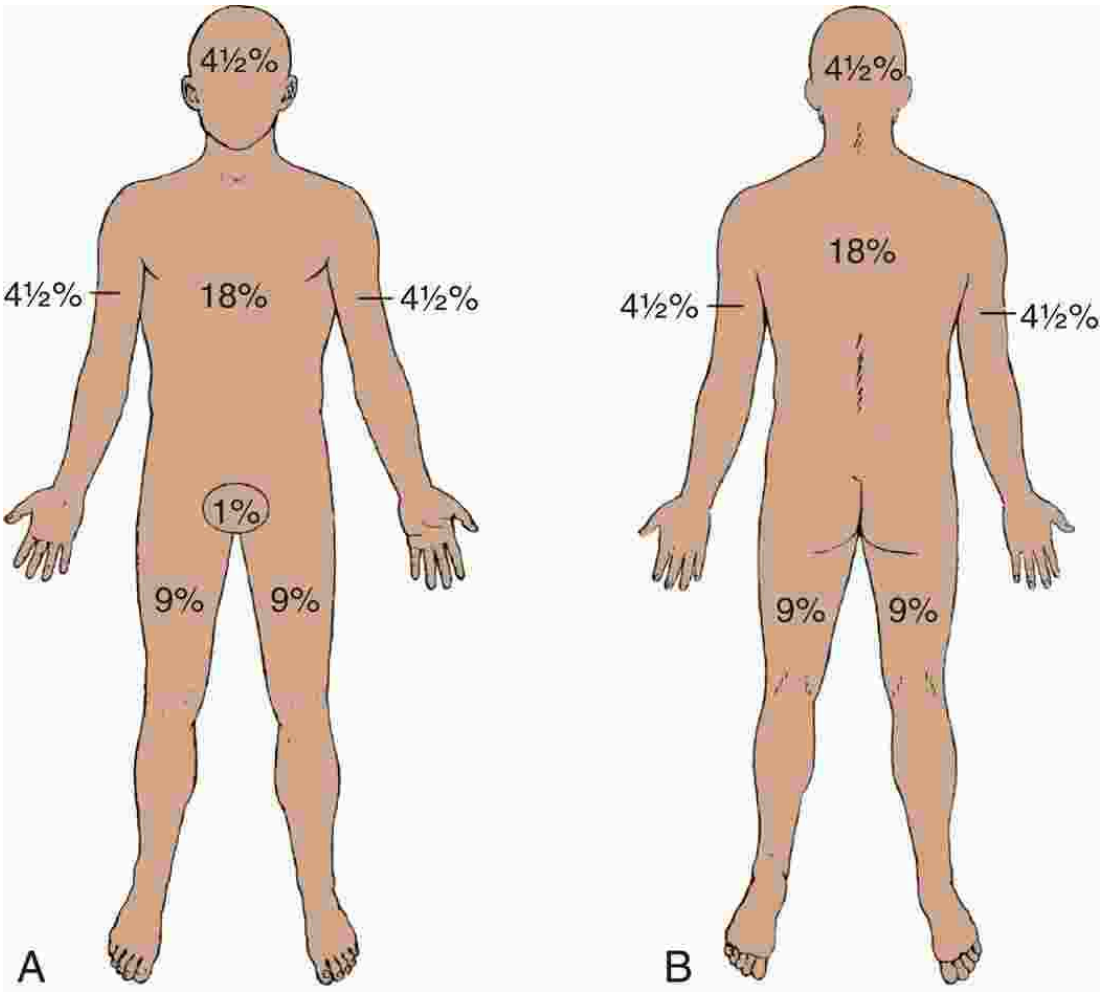

FIG. 48.13 **Rule of Nines.**
A commonly used assessment tool with estimates of the percentages (in multiples of 9) of the total body surface area burned. **(A)** Adults (anterior view). **(B)** Adults (posterior view).

Two illustrations of human, A, and B, depict the percentages of the total body surface area burned. Illustration A depicts the anterior view of an adult man with percentages as follows. Head 41 percent, chest 18 percent, each hand 4.5 percent, each leg, 9 percent, and genital part 1 percent. Illustration B depicts the posterior view of an adult man with percentages as follows. Head 41 percent, chest 18 percent, each hand 4.5 percent, each leg, 9 percent, and genital part 1 percent.

Severity of burn injury is a combination of many factors, including age, medical history, extent and depth of injury, and body area involved. The American Burn Association has defined criteria to assist healthcare professionals in identifying individuals who require care at a specialized burn center (Box 48.4). The multidisciplinary burn center is recommended for those persons who are at high risk for morbidity, mortality, or permanent functional loss.

Box 48.4

Burn Center Referral Criteria

A burn center may treat adults or children, or both. Burn injuries that should be referred to a center include the following:

1. Partial-thickness burns greater than 10% total body surface area (TBSA).
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints.
3. Third-degree burns in any age group.
4. Electrical burns, including lightning injury.
5. Chemical burns.
6. Inhalation injury.
7. Burn injury in individuals with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality.
8. Burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. If the trauma poses the greater immediate risk, the individual's condition may be stabilized initially in a trauma center before being transferred to a burn center. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burns in children; children with burns should be transferred to a burn center verified to treat children. In the absence of a regional pediatric burn center, an adult burn center may serve as a second option for the management of pediatric burns.
10. Burn injury in individuals who will require special social, emotional, or rehabilitative intervention.

Pathophysiology and clinical manifestations

Burn injury results in dramatic changes in many physiologic functions of the body within the first few hours after the event. The effect of burn depends on two factors: first, the extent of body surface involved; and second, the depth of cutaneous injury (see the box Emerging Science Box: Pathophysiology of the Burn Wound). Body surface burn extent is described by the percentage of TBSA injured. Burns exceeding 20% of TBSA in most adults are considered to be major burn injuries and are associated with massive evaporative water losses and flux of large amounts of fluid and electrolytes in the tissues, manifested as generalized edema and circulatory hypovolemia. Depth of cutaneous injury has been categorized in many ways but always depends on the severity of injury of epidermal and dermal elements of the skin and whether the alteration is a permanent or reversible injury.

With a major burn injury, a systemic pathophysiology ensues that requires therapeutic intervention to sustain life. The immediate (acute) physiologic consequences of a major burn injury center around the profound, life-threatening hypovolemic shock that occurs in conjunction with cellular and immunologic disruption within a few hours of injury (Fig. 48.15). **Burn shock** is a phenomenon consisting of both a hypovolemic cardiovascular component and a cellular component. Hypovolemia associated with burn shock results from massive fluid losses from the circulating blood volume. The losses are caused by an increase in capillary permeability that persists for approximately 24 hours after burn injury. **Fluid**

resuscitation is the administration of intravenous fluids given in an effort to restore the circulating blood volume during the period of increasing capillary permeability. Isotonic crystalloids have traditionally been used for resuscitation; however, many burn centers are now using oncotic fluids. The use of albumin or plasma is used to reduce excessive volume, which increases the risk of respiratory insufficiency, cardiac failure, and compartment syndromes.[75,82] In addition to hypovolemia, most other organ systems are affected. Cardiac contractility is diminished during the initial 24-hour resuscitation period with shunting of blood away from the liver, kidney, and gut. This is often termed the *ebb phase* of the response to trauma and can be seen with other severe injuries.[83] Normal blood volume does not result in restoration of normal cardiac output because of a phenomenon known as *myocardial depression*. The decrease in perfusion of viscera results in a decrease in their function. This may be an explanation for decreased gut barrier function seen in thermal injury.[74] Other mechanisms include hypoxia and inflammation with histologic damage of intestinal mucosa.[84]

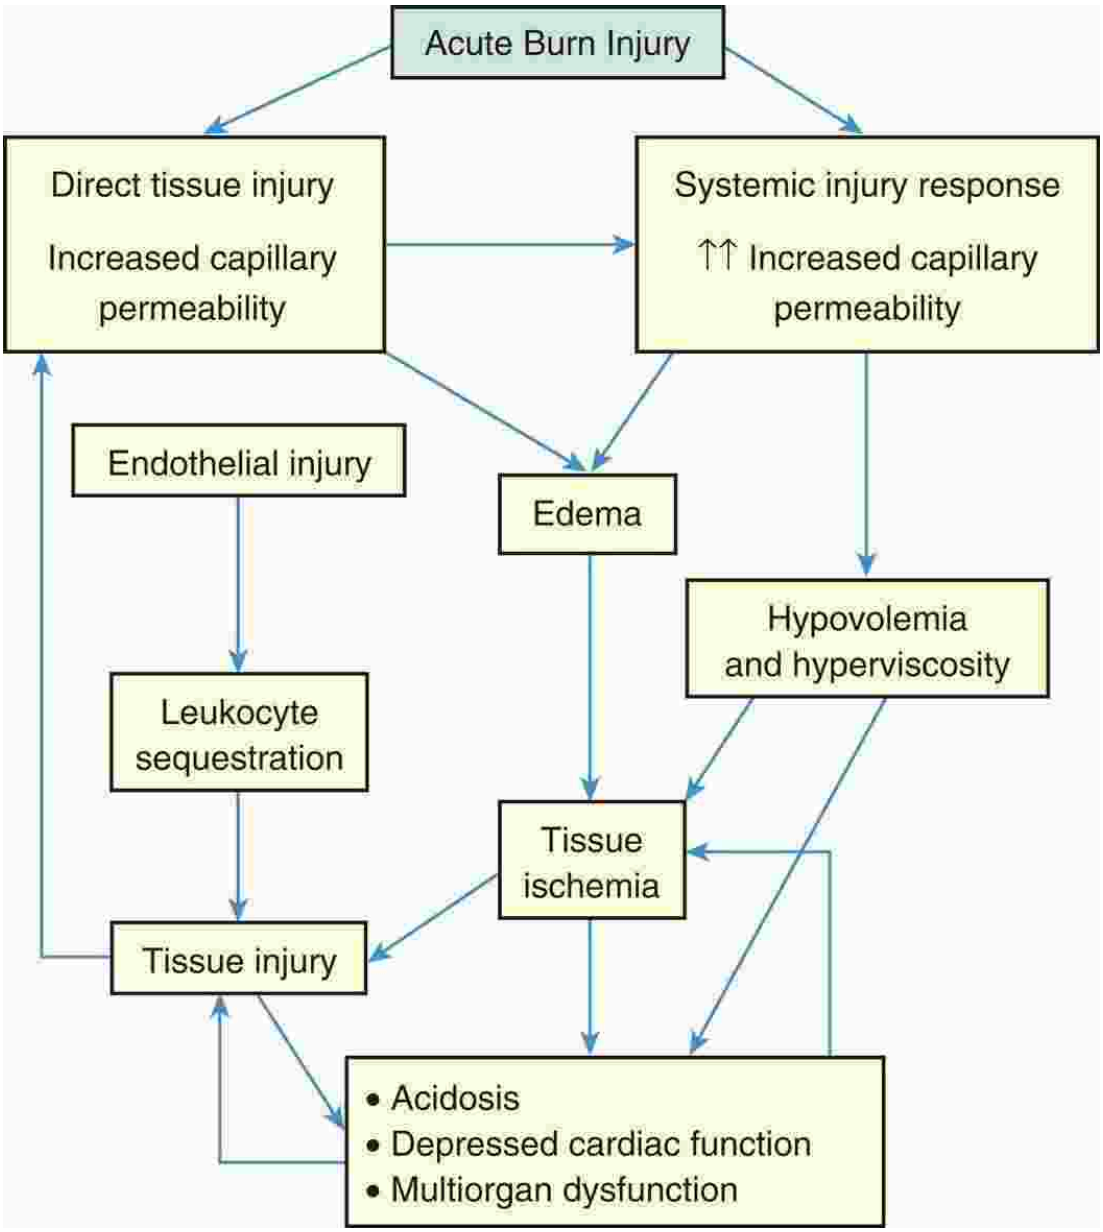

FIG. 48.15 Immediate Cellular and Immunologic Alterations of Burn Shock.

A flow diagram illustrates the mechanism for immediate cellular and immunologic alternations of burn shock. The diagram begins as follows. â€¢ Acute brain injury leads to direct tissue injury and systemic injury response. â€¢ The direct tissue injury is due to increased capillary permeability, and the systemic injury response is due to increased capillary permeability. â€¢ The direct and systemic injury responses lead to edema. â€¢ Edema leads to tissue ischemia causing acidosis, depressed cardiac function, and multiorgan dysfunction due to

hypovolemia and hyperviscosity, endothelial injury, and leukocyte sequestration, tissue injury, and ischemia.

There also is evidence that cellular metabolism is disrupted when the burn wound is created, resulting in altered cell membrane permeability and loss of normal electrolyte homeostasis. This cellular defect may be the pathophysiologic process responsible for the genesis of burn shock. There are numerous circulating factors in burn serum that may play a role in these cellular processes. Although the cardiovascular and systemic responses are intricately interwoven into the cellular response, these responses are presented here as discrete entities for purposes of description.

Cardiovascular and Systemic Response to Burn Injury

The clinical manifestations of burn shock are the result of more than simple loss of extracellular fluid at the burn wound site. Hypovolemia and numerous local mediators in the burn wound, as well as systemic signals, result in alteration of cellular function throughout the body.[83] The restoration of normal intravascular volume with either saline solutions or colloid materials (e.g., albumin, blood, or dextrans) does not reverse changes such as increases in pulmonary vascular resistance or myocardial contractility.[85–87] This is reflected in cardiac output with precipitous decreases that often result in inadequate perfusion of most tissues at the capillary level, which is the hallmark of burn shock. Fluid infusion, likewise, does not return cardiac output to preburn levels.[88,89] These findings led to the postulation of a specific MDF.[85,90,91] Other causes also have been suggested, such as reactive oxygen free radicals that attack cell membranes and other subcellular organelles as a result of first ischemia and then reperfusion of tissues during burn shock and resuscitation.[92] A third factor may be the level of nitric oxide (NO) after burn injury, which could have a direct myocardial depressant effect.[83] Burn trauma increases NO levels primarily through upregulation of inducible nitric oxide synthase (iNOS). Increased levels of NO lead to oxidative stress causing DNA breakage and activation of a protein complex that controls transcription of DNA, cytokine production, cell survival, and regulation of inflammatory responses (nuclear factor κ B [NFκB]). Inflammatory cytokines (e.g., tissue necrosis factor alpha [TNFα]) also promote iNOS activity, which leads to a persistent elevation of NO levels, contributing to cytotoxicity and cardiac dysfunction.[83] The elevation of NO causes the formation of compounds that alter mitochondrial respiration and compete with calcium for binding sites on contractile proteins (myosin and actin), which can severely depress cardiac function.[83] Regardless of the contribution of these mechanisms, fluid resuscitation eventually results in improved outcome of the massively burned person. This resuscitation involves infusion of intravenous fluid at a rate faster than the loss of circulatory vascular volume for a period of about 24 hours from the time of burn injury and may require up to 30 L in a major burn. Resuscitation from burn shock can be accomplished using any of a number of infusion protocols. The most frequently used protocol is the Parkland formula.[93,94] Lactated Ringer solution is used because it closely approximates extracellular fluid, the repository of fluid leaving the circulatory system during this phase of extensive edema formation (Table 48.3). The use of electrolyte-free fluids, such as D_5W, results in life-threatening hypovolemia and hyponatremia.

Table 48.3

Electrolyte Content of Ringer Lactate Solution and Extracellular Fluid

Electrolyte	Extracellular Fluid[a] (mEq/L)	Lactated Ringer Solution[b] (mEq/L)
Sodium	135–145	130
Potassium	3.2–4.5	4
Chloride	95–105	109
Lactate (bicarbonate)	24–28	28

[a]Normal values may vary slightly between laboratories.

[b]Plus 80–100 mL of free water per liter.

The massive edema associated with burn shock is inevitable with fluid resuscitation, and failure to administer resuscitation fluid results in irreversible hypovolemic shock and death. The edema occurs in unburned as well as burned areas (Fig. 48.16). This often leads to mechanical airway obstruction, necessitation of tracheal intubation, and increased severity of the interstitial pulmonary edema associated with inhalation injury.

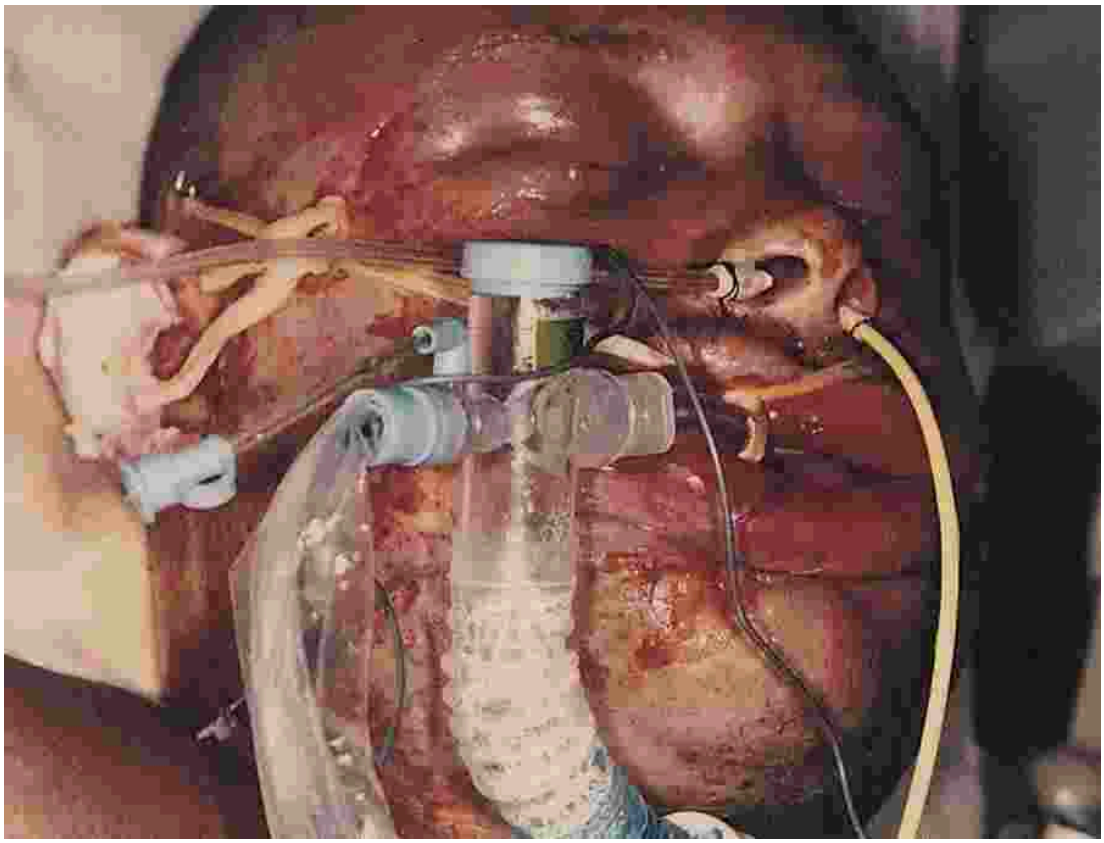

FIG. 48.16 Edema Related to Burn Injury.
Superficial facial burns can result in marked swelling, requiring prompt endotracheal intubation to maintain the airway. (Courtesy University of Utah Burn Center.)

The most reliable criterion for adequate resuscitation of burn shock is urine output. The individual is in hypovolemic shock and will, as a compensatory mechanism, decrease or stop urine output in an effort to preserve circulation volume. The adult receiving sufficient intravenous fluids will excrete urine amounting to 30 to 50 mL/h; children will produce 0.5 to 1 mL/kg/h (see Chapter 49). If the individual does not have adequate urine output, it often indicates inadequate fluid resuscitation. Fluid resuscitation remains a challenge. The massive amount of intravenous fluid required by burned individuals during the shock phase is often intimidating to the person unfamiliar with burns. It is reported in the literature that excessive fluid resuscitation in burn injury individuals can result in "fluid creep."[95] Fluid creep occurs when the fluid volume delivered exceeds the formula predictions (e.g., Parkland formula). Common concerns are that massive fluid administration will result in pulmonary edema, respiratory distress, cardiac dysfunction, conversion of superficial to deep burns, need for fasciotomies in unburned limbs, and abdominal compartment syndrome.[96] The primary goal of resuscitation in burn victims is to maintain adequate end-organ perfusion. Severe burns result in hypovolemic shock and dramatic loss of body fluid during the resuscitation period through third spacing, exudation, and evaporation.

The endpoint of burn shock is defined as the state in which the individual is able to maintain adequate urine output for 2 hours with the intravenous fluid administration rate equal to the individual's calculated maintenance rate. As burn shock ends, fluid administered

remains in the circulating volume and is reflected as an increase in urine output. The mechanism whereby capillary integrity is restored is unknown but usually occurs about 24 hours after burn injury (Fig. 48.17). After the individual has reached the endpoint of burn shock, the term used to describe the vascular status of the individual is **capillary seal**. In individuals with large burns, colloid-containing fluids may be given to help maintain oncotic pressure during the resuscitation phase and afterward to enhance the mobilization of interstitial fluid and diuresis.[97] Efforts to decrease burn edema and fluid resuscitation volumes can involve the use of hypertonic fluid resuscitation as well.[98]

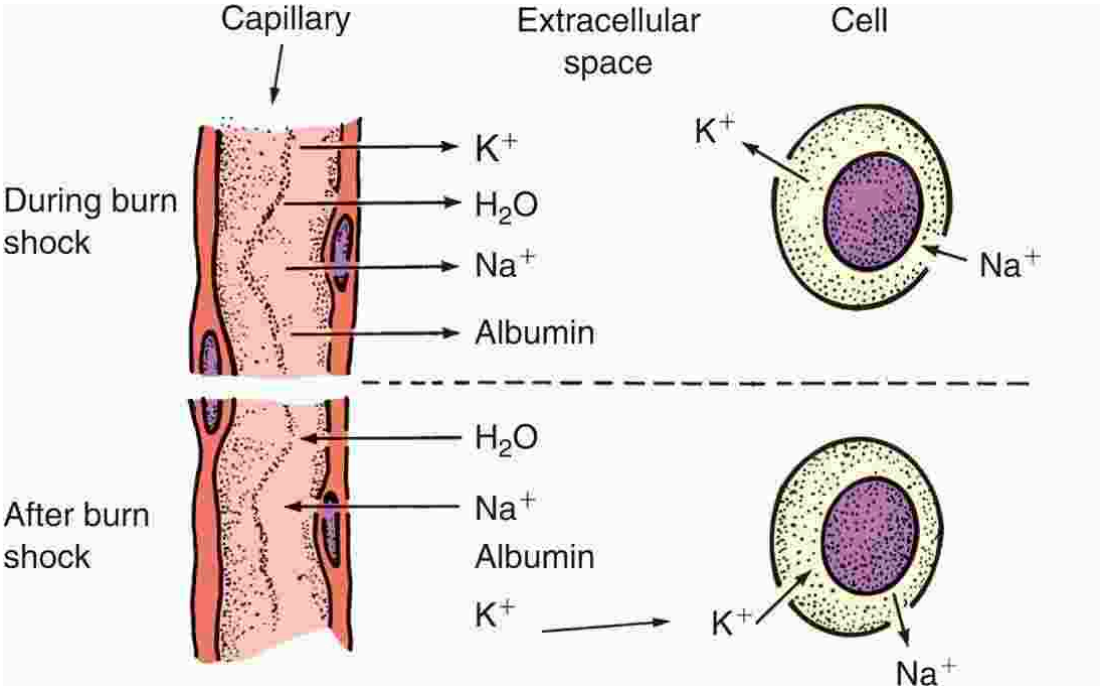

FIG. 48.17 Direction of Fluid and Electrolyte Shifts Associated With Burn Shock. (Courtesy University of Utah Burn Center.)

An illustration depicts the direction of fluids and electrolytes during burn shock and afterburn shock. During burn shock, there is an increase in potassium, water, sodium, and albumin from the capillary into the extracellular space along with movement of sodium from extracellular space to inside the cell and movement of potassium from cell to extracellular space. Afterburn shock, there is a decrease in water, sodium, and albumin from the extracellular space and into the capillary along with movement of potassium from extracellular space to inside the cell and movement of sodium from cell to extracellular space.

Cellular Response to Burn Injury

In addition to capillary endothelial permeability changes resulting in vascular fluid losses, transmembrane potential changes occur in cells not directly damaged by heat. The normal potential of −90 mV decreases to nearly −70 mV, with an increase in the levels of intracellular sodium and water. Such membrane potential changes may be caused by a circulating shock factor.[99] Apoptosis is central to the cellular responses to burn injury.[74] Other changes can be categorized as (1) a metabolic response to the burn injury or (2) an immunologic response to the burn injury.

Metabolic response

The metabolic changes after a burn injury were described in 1967 by Welt and associates as "sick cell syndrome."[100] This was considered to be a cell membrane transport defect related to an alteration in the steady-state composition characterized by high intracellular concentrations of sodium. Trunkey and colleagues[101] found a marked decrease in primate muscle extracellular water and an increase in intracellular sodium and water during hypovolemic shock. In addition, other researchers demonstrated an associated decrease in resting membrane potential, a decrease in amplitude of the action potential, and a prolongation of the repolarization and depolarization times in association with a decreased intracellular potassium concentration.[102,103] The cellular dysfunction of burn injury extends beyond the transmembrane potential disruption and the sodium-potassium pump impairment to include a loss of intracellular magnesium and phosphate[104] and elevated serum lactic acid dehydrogenase (LDH) levels.[105] Thus impairment of basic cellular function may be the underlying cause of the diminished membrane potentials. The data suggest a decrease in the efficiency of the pump. The failure of rapid intravascular volume repletion to restore membrane potential completely suggests other pathways for cellular metabolic derangement.[106]

Metabolic reactions to the stress of a major burn injury involve the response of the sympathetic nervous system and other homeostatic regulators. Catecholamines are found in elevated amounts in both the serum and urine of burned individuals. Cortisol, glucagon, and insulin levels are elevated, with a corresponding increase in gluconeogenesis, lipolysis, and proteolysis. Changes in lipid metabolism are reflected as an elevation in the level of plasma free fatty acids (FFAs) and a decrease in the levels of plasma cholesterol and phospholipids.[107] Herndon and colleagues[108] found that the use of propranolol, a nonselective β_1- and β_2-blocker, could attenuate symptoms of the hypermetabolic response, including a decrease in heart rate and lipolysis. Glucose and lactate kinetics are altered after burn injury. Although tissue hypoxia produces lactic acidosis, its persistence in the presence of adequate tissue perfusion suggests an increased rate of glycogenolysis.[109] A small study conducted by Akcay and colleagues[110] showed that growth hormone levels are diminished in major burn injuries and appear to improve survival but more clearly affect wound healing.[111]

The initial 72 to 96 hours following a burn is termed the *ebb phase*, which is a state of hypometabolism. This phase is caused by intracellular processes and characterized by a decreased metabolic rate, depleted intravascular volume, poor tissue perfusion, and low cardiac output. Following the *ebb phase*, a hypermetabolic state, the *flow phase*, is initiated and persists until wound closure (up to 36 months after initial injury).[74] A hypermetabolic response causes an increase in blood pressure, peripheral insulin resistance, as well as breakdown of glycogen, proteins, and lipids caused by stress hormones such as

catecholamines, glucocorticoids (produced by the adrenal glands), and glucagon (produced by the pancreas).[74]

The metabolic rate increases with burn size in a curvilinear relationship, with oxygen consumption rarely exceeding two times basal levels. Evaporative water loss and surface cooling are not the primary stimulus for the hypermetabolic state; rather, the hypermetabolism is related to an increase and resetting of the thermal regulatory set point. The results of these effects are increased resting energy expenditure, elevated core temperature (38.5°C [101.3°F] is typical), total body protein loss, muscle wasting, and increased stimulated synthesis of acute-phase proteins, resulting in organ catabolism associated with organ dysfunction and death.[74,75] A reflex arc mobilizes neural or hormonal afferent stimuli to the hypothalamus, producing a catecholamine response clinically manifested as hypermetabolism, hyperthermia, and hyperglycemia. Evidence also exists that the burn wound itself directly mediates the response to injury at both the local and systemic levels. Cytokines, oxygen free radicals, chemotactic substances, and eicosanoids contribute to the systemic inflammatory response and hypermetabolic state. The inflammatory response to the wound level is magnified into a generalized systemic inflammatory response that is often deleterious. Vasodilation, increased capillary permeability, and edema occur to facilitate healing of the local area. The distribution of the peripheral circulation after burn injury transports heat and glucose preferentially to the wound. The energy cost of these reparative and transport processes is reflected in the increased metabolism and hyperdynamic circulation (Fig. 48.18).[74]

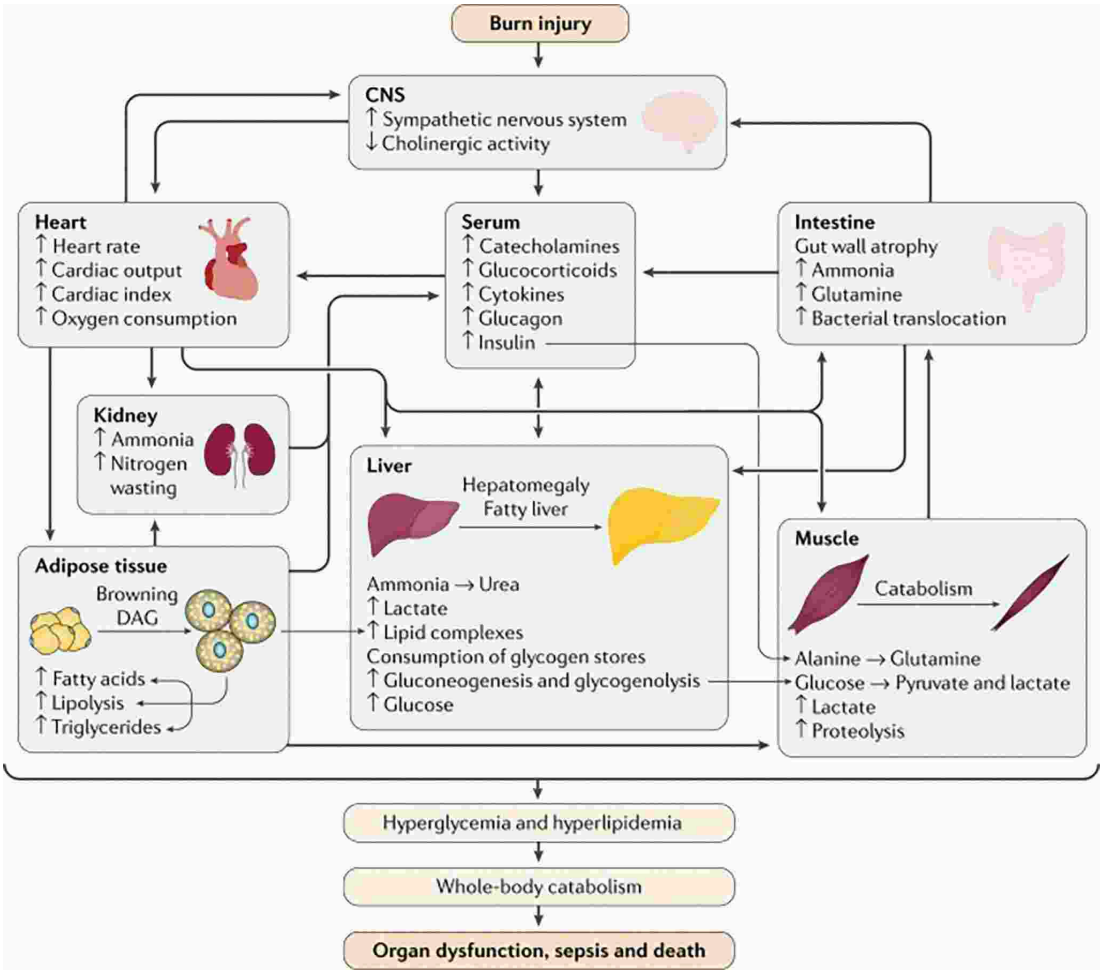

FIG. 48.18 Hypermetabolic State in Burn Injury.
Severe burn injury induces a unique and remarkably complex response that involves the release of stress hormones and pro-inflammatory mediators. The immediate response leads to a hypometabolic response that lasts for ~72 to 96 hours (ebb phase), but then rapidly turns into the flow phase that can persist for years after the initial injury. Stress mediators, such as catecholamines, glucocorticoids, and cytokines, are released into the system and cause a plethora of systemic responses. The heart goes into a hyperdynamic overdrive, increasing circulation and blood flow to increase oxygen and nutrient delivery. However, increased stress signaling causes changes in organ function and metabolic demand. Protein is degraded to deliver energy for hepatic function, the gut develops mucosal atrophy to absorb more nutrients but also enable bacterial translocation. The kidneys are hyperperfused but oxygen delivery is decreased, leading to acute kidney injury and stress signals from the kidney. The interplay between these organs accumulates, leading to metabolic and inflammatory overdrive that subsequently causes white adipose tissue to change to brown adipose tissue. Brown adipose tissue releases energy and induces substantial lipolysis with the accompanying expression of lipotoxic intermediates, such as triglycerides, free fatty acids, and diacylglycerols *(DAG)*, all of which are transferred to the liver.

The liver is unable to metabolize all of the accumulating substances and develops hepatomegaly. In turn, hyperlipidemia and hyperglycemia with insulin resistance is present, which worsens the hypermetabolic and inflammatory state. If hypermetabolism cannot be diminished or decreased, holistic catabolism ensues and, subsequently, multiple organ failure and death. *CNS*, Central nervous system. (From Jeschke MG, van Baar ME, Choudhry MA, et al. Burn injury. *Nature Reviews Disease Primers*, 2020;6[1]:11. doi:10.1038/s41572-020-0145-5)

An illustration depicts the schematic representation summarizing the hypermetabolic state in burn injury. Burn injury in C N S causes increased sympathetic nervous system, decreased cholinergic activity; heart causes increased heart rate, cardiac output, cardiac index, and oxygen consumption; serum causes increased catecholamines, glucocorticoids, cytokines, glucagon, and insulin; intestine causes gut wall atrophy, ammonia, glutamine, bacterial translocation; kidney causes increase ammonia and nitrogen wasting; adipose tissue causes browning D A G, increasing fatty acids, lipolysis, and triglycerides; liver causes ammonia to urea; increased lactate, lipid complexes, consumption of glycogen stores, gluconeogenesis and glycogenolysis, glucose; muscle causes alanine to glutamine, glucose to pyruvate and lactate; increased lactate and proteolysis leading to hyperglycemia and hyperlipidemia, whole-body catabolism, and organ dysfunction, sepsis, and death.

The extensive evaporative water loss that occurs in burn tissue is a heat-consuming process, and the energy of evaporation is provided by increased visceral heat production. The signal for the response is unknown because individuals whose wounds have been denervated continue to have a **posttraumatic hypermetabolic response**. Hypothalamic function alterations result in the elevation of human growth hormone (hGH) serum levels in the presence of hyperglycemia, a finding opposite that in normal states.[112] Further, the hypermetabolic rate is not decreased during rest, sleep, or warmth.

Evidence of hepatic response to burn injury is characterized by alterations in the clotting factors.[113] A hypercoagulable state develops as manifested by an elevated plasma fibrinogen concentration in the presence of shortened prothrombin time (PT) and activated partial thromboplastin time (PTT).[114]

In summary, extensive burn injury initiates the most marked alterations in body metabolism associated with any illness (Fig. 48.19). Much of the work explaining this response has been conducted by Wilmore,[115,116] who reported that the persistent tachycardia, hyperpnea, hyperpyrexia, and marked body wasting seen in burn injury reflect heightened metabolic activity and accelerated body catabolism. The development of decreased bone density can last long after discharge from the hospital.[117] These systemic alterations occur as a

result of the cutaneous inflammatory process and are thought to facilitate wound repair. The neural component of this alteration is in response to a sympathetic reaction that releases catecholamines in large amounts.

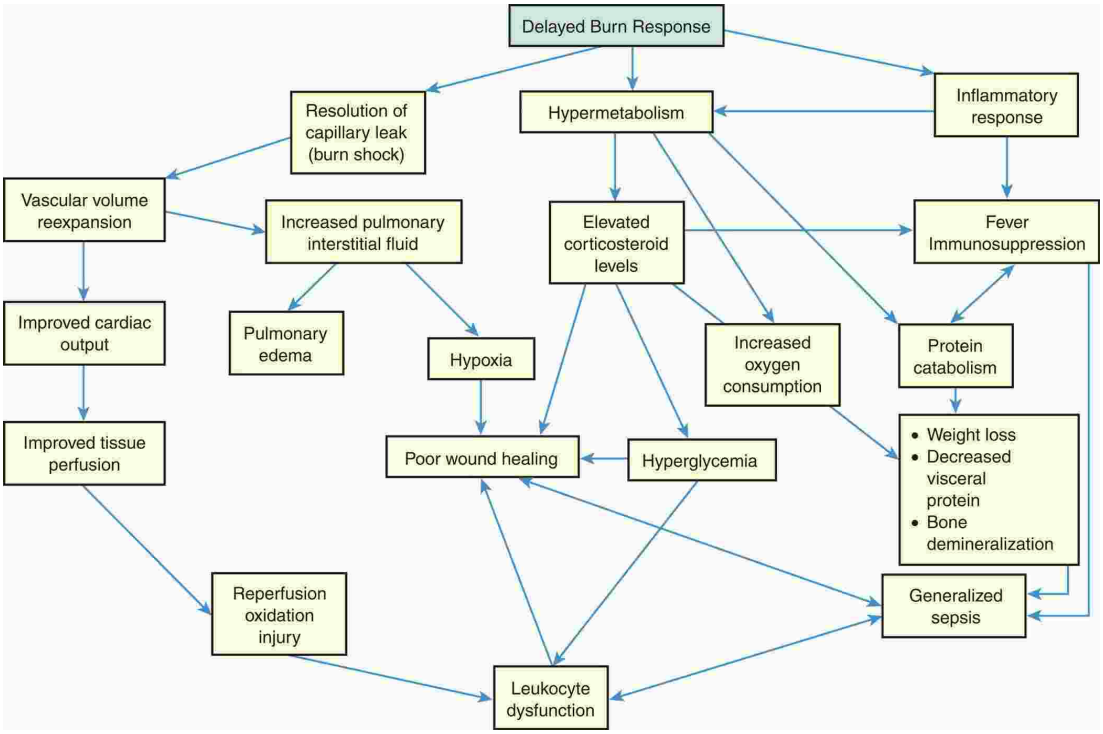

FIG. 48.19 Physiologic Alterations in Inflammatory Burn Injury Response.

A flow diagram represents the physiologic alterations in inflammatory burn injury response. The diagram begins as follows. â€¢ Delayed burn response leads to resolution of capillary leak, hypermetabolism, and inflammatory response. â€¢ Resolution of capillary leak leads to vascular volume reexpansion. â€¢ Vascular volume reexpansion leads to improved cardiac output and tissue perfusion. â€¢ Improved cardiac output leads to reperfusion oxidation injury and leukocyte dysfunction. â€¢ The vascular volume expansion leads to increased pulmonary interstitial fluid. â€¢ Increased pulmonary interstitial fluid leads to pulmonary edema and hypoxia. â€¢ Hypoxia and leukocyte dysfunction leads to poor wound healing. â€¢ Hypermetabolism leads to elevated corticosteroid levels, increased oxygen consumption, and protein catabolism. â€¢ Elevated corticosteroid levels relate to poor wound healing, hyperglycemia, fever immunosuppression, increased oxygen consumption leading to weight loss, decreased visceral protein, bone demineralization, where hyperglycemia relates to leukocyte dysfunction.

Immunologic response

The immunologic response to burn injury is immediate, prolonged, and severe. The result in individuals surviving burn shock is immunosuppression with increased susceptibility to potentially fatal systemic burn wound sepsis. Several cytokines have been identified in the immediate postburn period. Interkeukin-1 (IL-1) is detected in the serum of burned individuals. The level of IL-1 correlates inversely with burn survival; low levels may be associated with a higher mortality.[118] Fatal burn injury has often shown decreased levels of IL-2, which may result in decreased T helper 1 (Th1) lymphocytes. Th1 cells produce IL-2, interferon-gamma, and TNF, which help to initiate cellular immunity and immunoglobulin G (IgG) production. IL-4 is elevated after burn injuries and causes a shift in the T-helper cell production from Th1 to Th2 lymphocytes. Th2 cells secrete IL-4, which promotes further conversion of nonspecific Th cells to Th2 cells. Th2 cells also produce other cytokines and antibodies.[119] IL-6 levels increase quickly after burn injury and remain elevated for several weeks. The level of IL-6 correlates with the extent of burn injury.[120] IL-6, together with platelet activation factor, activates polymorphonuclear neutrophils, causing infiltration of neutrophils into burned tissue and adhesion to vascular endothelial surfaces.[121,122] IL-8 levels are elevated after burn injury with significantly greater elevations in individuals with a TBSA burn of 40% or higher. IL-8 activity may play a role in the strong and persistent activation of neutrophils noted in people with large burns.[123] Burn blister fluid contains large amounts of IL-6 and IL-8 in addition to substances such as epidermal growth factor, platelet-derived growth factor, and transforming growth factor.[124]

Macrophages, platelets, neutrophils, and vascular endothelial cells release prostaglandins and leukotrienes, which are the byproducts of arachidonic acid metabolism. These chemical mediators cause peripheral vasodilation, pulmonary vasoconstriction, increased capillary permeability, and local tissue ischemia in the burn wound.

A host of chemicals found in burn plasma in altered concentrations also may play a role in burn shock. These include vasoactive amines (histamine, serotonin), products of complement activation (C3a, C5a), prostaglandins, kinins, endotoxin, and metabolic hormones (catecholamines, glucocorticoids). A decrease in complement components C3a and C5a in the circulation after burn injury suggests a nonspecific activation of the complement system.[125] Activation of the complement system in injured tissue results in an inflammatory response caused by release of histamine and serotonin by C3a and C5a, because histamine and serotonin alter capillary permeability and participate in the mechanism of burn shock along with kinin polypeptides and other chemical mediators. Prostaglandins function in the inflammatory process by regulating the metabolism of cells of inflammation (see Chapter 7).

Burn shock can induce changes in the integrity of the intestinal wall, facilitating bacterial translocation and endotoxemia.[126] Bacterial translocation from the gut may be a mechanism of infection leading to septic shock after burn injury and other major trauma.[127] Circulating endotoxin is correlated with the development of MODS and death after major burn injury.[128]

White blood cells are also altered at this time, when their need to inhibit sepsis is vital. Natural resistance to infection in burn wounds is a function of the nonspecific immune system; that is, resistance to microorganisms that infect wounds rests almost solely on the ability of phagocytic cells (i.e., granulocytes, macrophages) to leave the bloodstream, migrate to the site of infection, and ingest and kill microorganisms.[129] Normally opsonins render bacteria susceptible to phagocytosis, but the burn injury triggers a consumptive opsoninopathy. Burn serum contains an inhibitor of C3 conversion that leads to decreased opsonization and polymorphonuclear (PMN) dysfunction.[130,131]

Individuals with altered immunocompetence before burn injury are at additional risk for complications. Opportunistic infections, such as fungal sepsis, can increase a hospital stay and ICU costs.[132] Included in this group are individuals at the extremes of age and those with cardiac disease, malnutrition, immunodeficiency disease, and a history of alcohol or drug abuse.[133,134] Additional risk factors include diabetes mellitus and pulmonary or renal dysfunction.

Evaporative Water Loss

One of the major purposes of intact skin is to serve as a barrier to evaporative water loss (EWL) from the body. With major burn injury, this ability of the skin to regulate evaporative water loss is totally disrupted. In a classic 1962 study, Moncrief and Mason[135] attempted to determine the magnitude of such a loss and determined that daily evaporative water loss was in the range of 20 times normal in the early phase of injury, with gradual decreases as wound closure is achieved. Further studies indicated that insensible water loss through burned skin is not from evaporation of water from sweat glands but rather from water vapor formed within the body and lost through the skin.[136,137]

Calculation of the amount of fluid lost by evaporative water loss includes losses from all sources. Normally the skin is the major source of insensible loss (75%) and the lungs are minor sources (25%), with a total loss of only approximately 600 to 800 mL/day. This changes dramatically with burns, because not only does skin loss increase but also lung loss increases by hypermetabolism and hyperventilation, especially in an intubated individual. Total evaporative losses exceed many liters per day in an adult with large burn wounds. Replacement of the loss is mandatory to prevent volume deficit.

Evaluation and treatment

Burn recovery can be long and difficult, with complications often the rule rather than the exception. The goal of burn management is wound closure in a manner that promotes survival. Scar formation with contractures is often a consequence of healing in deep partial-thickness and full-thickness burns (Fig. 48.20; see also Fig. 48.10). Assessment of tissue viability can be difficult in complex extremity injury; pyrophosphate nuclear scanning can assist in evaluation.[138] Early intervention may have effects on tissue survival as is evident in the zone of stasis and application of cerium nitrate.[139] The advancement in survival and outcome can be as simple as using antibiotic catheters to reduce catheter-associated bloodstream infections[140] or improving glycemic management during ICU treatment.[141] Advances in care systems have shown the value of advanced practice nurses in a collaborative role in the burn ICU and emergency departments.[142] The three essential elements of survival of major burn injury are (1) meticulous wound management, (2) adequate fluids and nutrition, and (3) early surgical excision and grafting. Current therapy for deep partial- and full-thickness burn injury includes surgical removal of the burn tissue (excision) followed by grafting of the person's unburned skin (autograft) onto the excised wound. Techniques of early wound care, such as the use of amniotic membrane,[143] may well affect the nature of burn scarring. Satisfactory wound closure with cultured epithelial autograft (Fig. 48.21) has been inconsistent and costly.[144,145] Early enthusiasm for synthetic dermal replacement has been tempered by a high rate of dermal graft loss and slow epidermal engraftment.[146,147] Such advancements in skin replacement technology include sheets of acellular dermal matrix that can be used with thin, meshed autografts or cultured epithelial autografts.[148,149]

FIG. 48.20 Hypertrophic Scarring.
Deep partial-thickness thermal injury can result in extensive hypertrophic scarring. (Courtesy University of Utah Burn Center.)

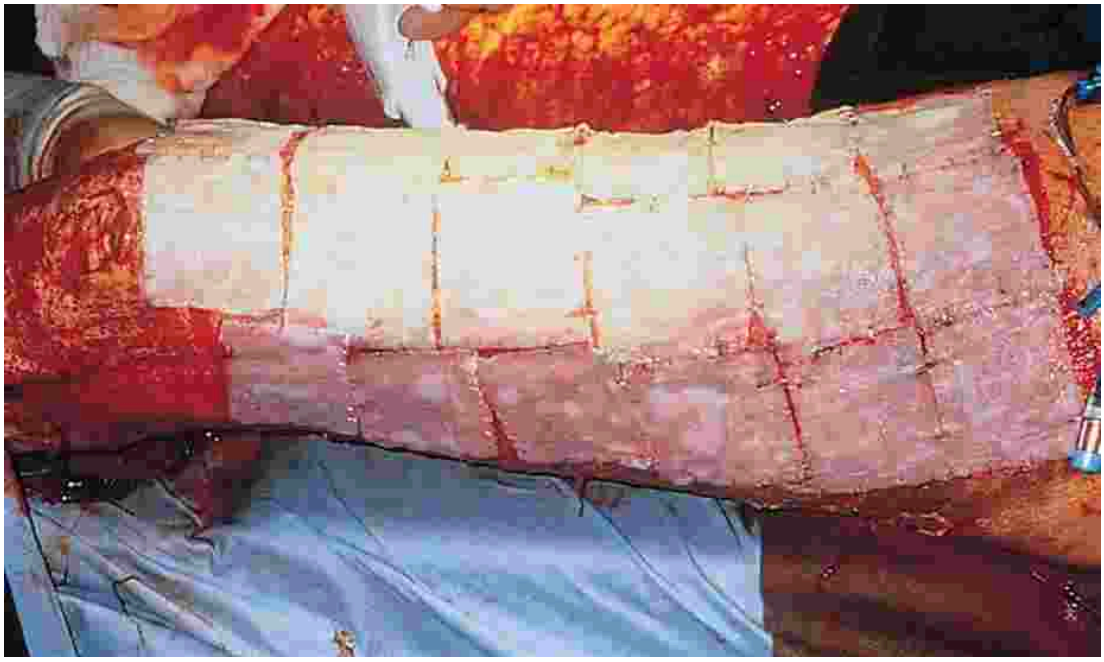

FIG. 48.21 Application of Cultured Epithelial Autografts.
The thin sheets of keratinocytes are attached to gauze backing to allow application onto the clean, excised thigh. (Courtesy University of Utah Burn Center.)

This concept also is being used on the donor site, and glycosaminoglycan hydrogels may supplement donor site wound dressings, and even topical gene therapy or stem cell applications.[150–152] Scar reduction or prevention is a challenging problem that is being addressed with pulsed-dye laser treatment.[153] Current research also is directed toward therapies to modulate hypermetabolic and inflammatory responses. Nutritional therapy is focused on early enteral feeding to reduce the potential of gut-mediated sepsis. Ongoing clinical trials using anabolic agents (e.g., recombinant human growth hormone) and pharmacologic agents that modulate inflammatory and endocrine mediators (e.g., ibuprofen, propranolol) show promise in the treatment of severe burn injuries.[154] Recent clinical data on vitamin C suggests that vitamin C might have a beneficial effect in individuals with burn injury.[155] However, there is conflicting data on renal safety.[156,157] Altered body image is a significant hurdle to those with facial burns. A framework for aiding individuals can often be useful for those reintegrating into the community.[158] Burn pain is almost always acute, and treatment strategies usually differ from strategies for chronic pain. The understanding and management of burn pain is key to recovery.[159,160] In addition to opioid-based agents, newer treatment approaches may include antianxiety agents, hypnosis, and relaxation techniques,[161] as well as virtual reality systems.[162,163]

Summary Review

Shock

1. Shock occurs when the cardiovascular system fails to perfuse tissue, cells, and organs adequately, causing a widespread impairment of cellular metabolism and tissue function. It is a downward physiologic spiral that, if not reversed, can lead to MODS.
2. The classifications of shock: (1) distributive, anaphylactic, neurogenic, or vasogenic; (2) cardiogenic; (3) hypovolemic; and (4) obstructive.
3. The final common pathway in all types of shock is impaired cellular metabolism with cells switching from aerobic to anaerobic metabolism. Energy stores drop, and cellular mechanisms relative to membrane permeability, action potentials, and lysozyme release fail.
4. Anaerobic metabolism results in activation of the inflammatory response, decrease in circulatory volume, and decrease in pH.
5. Impaired cellular metabolism results in cellular inability to use glucose because of impaired glucose delivery or impaired glucose intake, resulting in a shift of glycogenolysis, gluconeogenesis, and lipolysis for fuel generation.
6. Glycogenolysis is affected for up to 10 hours. Gluconeogenesis results in the use of proteins necessary for structure, function, repair, and replication that leads to more impaired cellular metabolism. Lipolysis is ineffective because of a lack of transport serum proteins.
7. Gluconeogenesis contributes to lactic acid, uric acid, and ammonia buildup; interstitial edema; and impairment of the immune system, as well as general muscle weakness leading to decreased respiratory function and cardiac output.
8. Distributive shock (vasodilatory shock) is characterized by severe peripheral vasodilation and has several etiologies, including sepsis, systemic inflammatory response syndrome, neurogenic or vasogenic, anaphylaxis, drug and toxin induced, and endocrine.

9. Septic shock begins with impaired cellular metabolism caused by uncontrolled septicemia. The infecting agent triggers the inflammatory and immune responses. It is part of a continuum known as *SIRS*. Mortality for septic shock is very high.
10. Anaphylactic shock is the outcome of a widespread hypersensitivity to an allergen that triggers anaphylaxis. The inflammatory response is triggered, and massive vasodilation with fluid shift into the interstitium follows. The relative hypovolemia leads to impaired cellular metabolism.
11. Neurogenic (vasogenic) shock results from massive vasodilation that occurs from an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle. It causes a relative hypovolemia (even though cardiac output may be high), and results in impaired cellular metabolism.
12. Cardiogenic shock results from persistent hypotension and tissue hypoperfusion caused by cardiac dysfunction in the presence of adequate intravascular volume and left ventricular filling pressure.
13. Hypovolemic shock is caused by loss of whole blood, plasma, or interstitial fluid in large amounts. The use of compensatory mechanisms may be vigorous, but tissue perfusion ultimately decreases and results in impaired cellular metabolism.

Multiple Organ Dysfunction Syndrome

1. MODS is the progressive dysfunction of two or more organ systems resulting from a systemic inflammatory response after a severe illness or injury. The inflammatory response can be triggered by sepsis, necrotic tissue, trauma, burns, ARDS, acute pancreatitis, major surgery, circulatory shock, DIC, acute renal failure, blood transfusion, heat stroke, liver failure, mesenteric ischemia, propofol infusion syndrome, persistent inflammatory foci, and other severe injuries.
2. Primary MODS is the immediate local or mild systemic response to the triggering event or illness. It primes the inflammatory system.
3. Secondary MODS is the uncontrollable, excessive systemic inflammatory response that develops after a latent period and results in organ dysfunction.
4. People at greatest risk for developing MODS are older adults, those with significant tissue injury or preexisting disease, and those in whom resuscitation from the initiating illness or injury has been delayed or inadequate.
5. MODS is a leading cause of mortality in surgical ICUs. Mortality for individuals with MODS increases progressively from 54% with two failing organ systems to 100% with five failing organ systems.
6. Multiple organ dysfunction involves the stress response; release of complement, coagulation, and kinin proteins; changes in the vascular endothelium; and numerous inflammatory processes mediated by substances released by activated neutrophils and macrophages. The accumulation of activated neutrophils in organs is thought to play a key role in the pathogenesis of MODS, as well as macrophages.
7. The consequences of the release of inflammatory mediators in MODS are vasodilation, increased vasopermeability, and selective vasoconstriction resulting in maldistribution of blood flow; hypermetabolism; myocardial depression; and hypoxic injury to cells. Cellular hypoxia and acidosis impair cellular metabolism, leading to organ dysfunction.
8. Clinical manifestations of the development of MODS are general during the first 24 hours: low-grade fever, tachycardia, tachypnea, dyspnea, and altered mental

status. Over the next several days, beginning with the lungs, individual organ systems show signs of failure.
9. Because there is no specific therapy for MODS, early detection is extremely important so that supportive measures can be initiated as soon as possible.
10. At present the therapeutic management of MODS consists of prevention or removal of triggering mechanisms and support of individual organs. Recent scientific knowledge about inflammatory mediators has led to many promising future therapies for MODS.

Thermal Injury and Burns

1. Burns are classified according to depth and extent of injury.
2. First-degree burns involve the superficial skin without loss of protective function.
3. Second-degree burns are superficial (blister formation) or superficial involving partial skin thickness with a waxy white appearance and no involvement of dermal appendages.
4. Third-degree burns involve full skin thickness and often underlying tissues. They are painless and can be life-threatening as a result of hypovolemic shock and metabolic and immunologic responses.
5. The TBSA burned is estimated using either the rule of nines or the Lund and Browder chart.
6. Hypovolemia associated with burn shock is caused by increased capillary permeability with massive fluid losses from blood volume.
7. Altered cell membrane permeability and loss of electrolyte homeostasis contribute to burn shock.
8. Cardiac contractility is decreased during the first 24 hours with shunting of blood away from the liver, kidney, and gut.
9. Fluid resuscitation, such as with lactated Ringer solution, involves infusion of fluid at a rate faster than the loss of circulating volume.
10. The most reliable criterion for adequate resuscitation of burn shock is urine output.
11. *Capillary seal* is the term used to indicate the end of burn shock.
12. Transmembrane potentials are altered in cells not directly damaged by heat, with impairment of the sodium-potassium pump and loss of magnesium and phosphate.
13. The stress of a major burn activates the sympathetic nervous system with release of catecholamines, cortisol, glucagon, and insulin.
14. Burn injury produces a hypermetabolic state that persists until wound closure and is related to a higher thermal regulatory set point.
15. The local inflammatory response at the burn site releases cytokines, oxygen free radicals, chemotactic factors, and eicosanoids, which lead to a systemic inflammatory response and contribute to hypermetabolism.
16. A posttraumatic hypermetabolic response is associated with increased visceral heat production.
17. Alterations in clotting factors produce a hypercoagulable state following major burns.
18. The immune response following a burn is immediate, prolonged, and severe.
19. Numerous alterations in inflammatory cytokines are evident in the immediate burn period, affecting cellular immunity, antibody production, and attraction of neutrophils and contributing to the vasodilation and increased capillary permeability associated with burn shock.

20. White blood cells are altered, and there is decreased opsonization and phagocytosis, contributing to the development of sepsis.
21. Changes in intestinal wall integrity lead to translocation of bacteria, endotoxemia, and septic shock.
22. Loss of intact skin with a major burn results in significant evaporative water loss contributing to hypovolemia.
23. Treatment of major burns involves meticulous wound management, adequate fluids and nutrition, early surgical excision and grafting, modulation of the hypermetabolic state, and pain management.

Emerging Science BOX

Pro-Inflammatory and Anti-Inflammatory Responses in Sepsis

Despite improvements in the understanding of the pathophysiology of sepsis and the implementation of improved supportive therapeutic strategies, no specific treatment for sepsis has been approved. Multiple research trials have explored therapeutics aimed at modulating the well-described hyperinflammatory phase of sepsis in which there is an overwhelming release of inflammatory cytokines resulting in fever, shock, and cardiopulmonary failure. These trials have included powerful anti-inflammatory medication such as corticosteroids and other anti-immune drugs, but to date, none have significantly impacted morbidity or mortality. In fact, evidence has emerged that mortality in sepsis more often is due to an immunosuppressed state with secondary infections that are associated with organ injury and failure. This immunosuppressed state (immune paralysis) includes decreased neutrophil and macrophage activity, loss of antigen recognition, apoptosis of lymphocytes, expansion of myeloid-derived suppressor cells (MDSCs), and adaptive immune cell dysfunction that may persist for weeks or months after the initial septic event. Any conditions that are associated with cellular metabolic dysfunction of immune cells such as hyperlipidemia, diabetes, and obesity make immune paralysis worse and are linked to higher sepsis-related morbidity and mortality. These immune changes have been termed the compensatory anti-inflammatory response syndrome (CARS) and were once thought to follow after the hyperinflammatory phase of sepsis. However, newer research suggests that immunosuppression occurs simultaneously with the hyperinflammatory response, thus leading to the term mixed antagonist response syndrome. Activation of pro-inflammatory and anti-inflammatory pathways at the same time may lead to chronic inflammatory and infectious organ injury, along with a prolonged catabolic syndrome in septic individuals. Some researchers are now exploring if measurable decreases in immune function can be used to predict sepsis outcomes, while others suggest that immune stimulant therapies, rather than anti-inflammatory medications, should be tested for the treatment sepsis.

Emerging Science BOX

Pathophysiology of the Burn Wound

Individuals with a severe burn wound require management of both the wound itself and the deleterious systemic consequences that accompany it. Recent research is providing new insights into the pathophysiologic impact of burn injury to the skin and other tissues. For example, immediately after a burn injury, the wound can be divided into three zones: coagulation, ischemia (stasis), and hyperemia. Each of these zones is characterized by cellular autophagy and apoptosis, inflammation, and thrombus formation. Numerous inflammatory cytokines and cells contribute to tissue injury, while at the same time, they trigger the release growth factors and initiate the wound healing process. The types, amounts, and locations of these inflammatory chemicals and growth factors impact the effectiveness of tissue recovery and the amount of scar that is generated. Systemic complications such as metabolic and immune dysregulation along with infection also impact the rate and effectiveness of wound healing. Efforts toward balancing the positive and negative roles of inflammation in burn wound recovery include administration of opioids, modified gels, and new types of topical anti-inflammatories. One factor of particular interest to researchers is the impact of oxidative stress on burn wound tissues and distant organ injury. Trials of antioxidant therapies and dietary changes have produced some positive results, although more research is needed. The role of genes in the host response to burn injury is also being explored. For example, there is evidence that expression of the melanocortin 1 receptor gene and the pyrin domain containing receptor 3 gene are important factors in wound healing. The role of stem cells in wound healing is also being explored. An understanding of these complex pathways may lead to improved burn wound treatment and recovery.

Chapter Outline

OUTLINE

Shock and Multiple Organ Dysfunction Syndrome 1591
Types of Shock 1592
Assessment of Shock 1592
Reperfusion and Inflammatory Injury 1606
Burns 1607
Severity of Injury 1608
Pathophysiology, Clinical Manifestations, and Treatment 1609

This chapter reviews shock, multiple organ dysfunction syndrome (MODS), and burns in children. It focuses on the assessment and care of children but also notes many of the differences between these conditions in children and adults.

Shock and Multiple Organ Dysfunction Syndrome

Shock is a condition of acute and progressive circulatory dysfunction that results in inadequate delivery of oxygen and nutrients to the tissues. Shock in children is most often categorized as hypovolemic, distributive, cardiogenic, or obstructive. Contributing factors may include severe dehydration, hemorrhage, progressive heart failure, or sepsis; in fact, all infants under 3 months of age presenting in shock should be considered septic until proven otherwise.[1] Shock may also complicate the care of the child with congenital heart disease (CHD), pulmonary hypertension (cor pulmonale), drug toxicity, electrolyte or acid-base imbalance, dysrhythmias, obstruction to blood flow (e.g., pulmonary embolus, cardiac tamponade), or multiple organ failure.

In children, shock is present when there are signs of poor systemic perfusion, regardless of the blood pressure (shock may be present with normal, high, or low blood pressure.) When the systolic blood pressure is adequate for age, but there are signs of inadequate tissue perfusion (e.g.,

tachycardia, diminished peripheral pulses, abnormal capillary refill), the child is in **compensated shock**. In this child, although the systolic blood pressure may be normal, the diastolic or mean arterial pressure is typically low.[2] When the compensatory mechanism fails, systolic hypotension, which is associated with inadequate tissue perfusion, ensues. In addition to hypotension and inadequate tissue perfusion, the child in **hypotensive** (formerly called *decompensated*) **shock** will present with clinical signs of decreased mental status, decreased urine output, diminished peripheral pulses, metabolic acidosis, and increased respirations.[1] Hypotension in pediatrics is defined by the AHA Pediatric Advanced Life Support guidelines and training materials as less than the fifth percentile for age.[3]

Shock causes tissue **ischemia** (inadequate blood flow) and **hypoxia** (inadequate oxygen delivery) that leads to acidosis and cell dysfunction. Oxygen delivery may be inadequate because arterial oxygen content or cardiac output is low or because there are increased tissue oxygen requirements or impaired cellular use of oxygen. Ischemia and tissue hypoxia are primary insults to cells. Restoration of adequate blood flow and oxygen delivery may trigger the development of *reperfusion injury*, a secondary problem characterized by an exaggerated inflammatory response that may produce cellular death and organ failure.

Multiple organ dysfunction syndrome (MODS) is the concurrent failure of at least two organs resulting from a single cause,[4] most often from a systemic inflammatory response syndrome (SIRS), associated with acute insults such as sepsis or trauma. MODS also can complicate chronic diseases, such as cancer and CHD as well as more acute insults including drowning, acute respiratory distress syndrome (ARDS), liver failure, pancreatitis, or cardiac arrest. Finally, MODS can result from treatments such as chemotherapy, surgical correction of CHD, or organ transplantation.[1,5–7] Children with chronic diseases have both an increased risk of and increased mortality from MODS.

MODS may be either primary or secondary. Primary MODS is directly attributable to an insult and typically occurs soon (3 to 7 days) after the insult. Secondary MODS typically occurs later and may be associated with more sequential development of organ dysfunction. **New or progressive MODS (NPMODS)** is a recently defined problem that can develop with severe sepsis. It is defined as a dysfunction of one or fewer organs on day 1 of sepsis recognition with subsequent development of two or more concurrent organ failures at any time during treatment.[4,7,8]

Types of Shock

Shock is categorized by type as follows[1,3]:

1. *Hypovolemic shock:* caused by inadequate intravascular volume relative to the vascular space (e.g., gastrointestinal [GI] losses, renal losses, hemorrhage, third spacing, and/or burns)
2. *Cardiogenic shock:* results from impairment of myocardial function (e.g., CHD, arrhythmia, cardiomyopathy, myocarditis, or anemia)
3. *Distributive shock* (including septic, anaphylactic, and neurogenic): results from inappropriate distribution of blood flow, increased capillary permeability, and myocardial dysfunction (e.g., septic or anaphylactic shock) or central nervous system injury (e.g., neurogenic or spinal shock)
4. *Obstructive shock:* caused by a mechanical obstruction to blood flow into and through the heart and great vessels (e.g., cardiac tamponade, pulmonary embolus, tension pneumothorax, or obstructive congenital heart lesions such as critical aortic stenosis), resulting in low cardiac output

An etiologic classification of shock is helpful because it suggests the initial therapy required. However, the etiologic classification is an oversimplification because any child with late or progressive shock is likely to demonstrate widespread cardiovascular dysfunction that may include inappropriate intravascular volume relative to the vascular space, poor myocardial function, and maldistribution of blood flow.[1] Severe shock of any kind may be followed by complications such as reperfusion injury, MODS, or NPMODS.[4] Children with septic shock demonstrate elements of hypovolemic and cardiogenic shock in addition to the complications of infection and maldistribution of blood flow. Thus, healthcare providers must assess and support all aspects of cardiovascular function and oxygen delivery during the treatment of any form of shock.[1]

Assessment of Shock

Signs of shock in children may initially be subtle; thus, detection of shock and evaluation of response to therapy typically requires careful, repeated assessments over time. Inadequate cardiac output causes signs of inadequate blood flow to some tissue beds and evidence of organ system dysfunction (Box 49.1). Critical parameters to evaluate include assessment of

consciousness, breathing, and color. This initial assessment is described in the Pediatric Advanced Life Support course.[9]

Box 49.1

Clinical Manifestations of Shock in Newborns, Infants, and Children

Signs of Shock in Infants and Children

- Change in responsiveness (initial irritability followed by lethargy)
- Tachypnea
- Mottled color, pallor (distributive shock may be associated with flushed skin)
- Tachycardia
- Cool skin, prolonged capillary refill (distributive shock may cause "flash" [instantaneous] refill)
- Diminished intensity of peripheral pulses (may also vary in intensity)
- Metabolic (lactic) acidosis (serum lactate >4 mmol/L is typically well above normal for arterial or venous blood)
- Decreased central venous oxygen saturation (more than 25%–30% below arterial oxygen saturation)
- LATE: Hypotension, bradycardia

Nonspecific Signs of Distress in Newborns

- Jitteriness or lethargy with decreased tone
- Change in oxygen requirements
- Apnea
- Bradycardia or decreased heart rate variability
- Temperature instability, hypothermia
- Glucose instability, hypoglycemia
- Feeding intolerance (e.g., increased residual volume)

Through this assessment, the provider determines if the child appears stable, in no acute distress, or in need of immediate intervention. More detailed assessment will reveal evidence of inadequate organ function resulting from inadequate organ perfusion.

The child's level of *consciousness* and *responsiveness* often provide valuable information about the severity of illness. The healthy infant should orient to faces, make eye contact, and track bright objects across a visual field. The healthy toddler is reluctant to be separated from parents or examined by strangers, and the healthy child is alert and responds to questions. By comparison, the critically ill infant or child is often extremely irritable; lethargy indicates severe deterioration in the child's level of consciousness. A decreased response to painful stimulus is abnormal and usually indicates severe cardiorespiratory or neurologic compromise.[9,10]

The infant or child normally breathes without evidence of distress or increased effort, such as retractions or nasal flaring. An extremely rapid respiratory rate (tachypnea), increased depth of respirations (hyperpnea), or evidence of increased respiratory effort (e.g., retractions, grunting) may indicate the presence of heart failure or shock. The development of apnea or inadequate respiratory rate or effort generally indicates deterioration and the need for immediate support of airway, oxygenation, and ventilation.

If perfusion is adequate and the ambient temperature is warm, the child's *color* will be consistent over the surface of the skin, and lips, nailbeds, and mucous membranes will be pink. Children who are in a cold environment, those who have undergone hypothermic surgery or a procedure in a cold room, and children in shock often demonstrate mottling (a marbled or "blotchy" appearance to the skin).[1,9]

Pallor also may be observed when perfusion is poor (Fig. 49.1). Children with sepsis occasionally demonstrate flushed, bright red (plethoric) skin.[1,9,11]

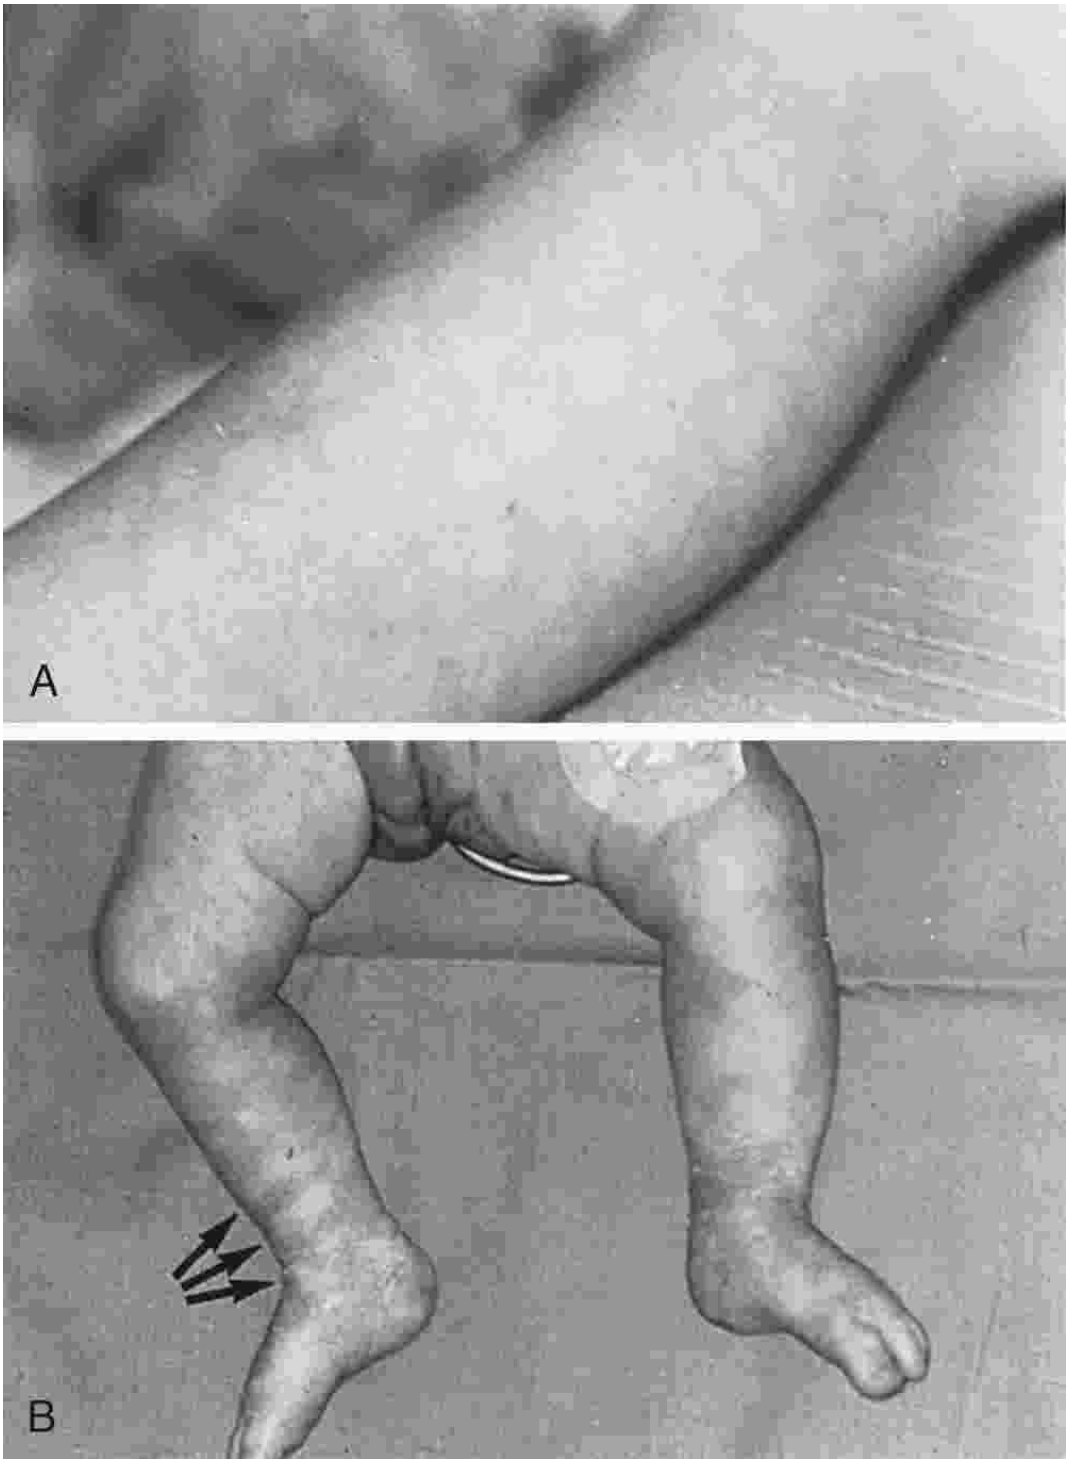

FIG. 49.1 Mottling of Skin Caused by Poor Systemic Perfusion.
(A) Mottling of skin color often indicates inadequate tissue oxygenation; this may result from hypoxemia or poor systemic perfusion. This child developed myocardial

dysfunction and signs of cardiogenic shock. **(B)** Mottled skin color is often associated with other signs of compromise of skin perfusion, including delayed capillary refill. The skin over this infant's right ankle was blanched using three fingers *(arrows)*, and the skin failed to perfuse for more than 5 seconds. This infant suffered from septic shock. (From Hazinski MF. Cardiovascular disorders. In: Hazinski MF, ed. *Nursing care of the critically ill child*, 2nd edition. St. Louis: Mosby; 1992.)

If perfusion is adequate and the ambient temperature is warm, the child's capillary refill is normally brisk (<2 seconds). Prolonged capillary refill (>2 seconds) may indicate a compromise in systemic perfusion (see Fig. 49.1B) and the development of shock.[1,9]

Septic shock may be associated with vasodilation that produces instantaneous (flash) capillary refill or may be associated with vasoconstriction and delayed capillary refill.[2]

The child's *vital signs* must be evaluated in light of the child's age and clinical condition. Normal vital signs are not always appropriate for the seriously ill or injured child (Box 49.2 and Table 49.1).[10]

Box 49.2

Estimating Blood Pressure in Children 1–10 Years of Age

Typical systolic BP for 1–10 years of age: The typical systolic blood pressure for a child 1 to 10 years of age of normal height may be estimated by adding 90 mmHg to twice the child's age in years (90 mmHg + [2 × age in years]).

Hypotensive systolic BP for 1–10 years of age: A systolic pressure less than 70 mmHg plus twice the child's age in years (<70 mmHg + [2 × age in years]) is considered hypotensive for children 1 to 10 years of age because this blood pressure corresponds to the 5th percentile systolic blood pressure for age (i.e., only 5% of normal, healthy children of average height demonstrate a systolic blood pressure lower than that number).

Hypotensive mean arterial pressure for 1–10 years of age: A mean arterial pressure less than 40 mmHg + (1.5 × age in years) is consistent with hypotension because this mean arterial pressure corresponds to the 5th percentile mean arterial pressure in children of average height.

Data from Kadec KD, McBride ME, et al. *2020 AHA pediatric advanced life support provider manual*. Dallas, TX: American Heart Association; 2020.

Table 49.1

Typical Pediatric Vital Signs

	Heart Rates		
Age	**Awake Heart Rate (per min)**	**Sleeping Heart Rate (per min)**	**Respiratory Rate[a] (Breaths/min)**
Newborn	100–205	90–160	30–60
Infant (6 mo)	100–180	90–160	30–53
Toddler	98–140	80–120	27–37
Preschooler	80–120	65–100	20–28
School-age child	75–118	58–90	18–25
Adolescent	60–100	50–90	12–20

Typical Blood Pressures				
Age	**Systolic Blood Pressure (mmHg)[b] For 1–10 Years of Age Estimated by 70 mmHg + 2 × age (Years)**	**Diastolic Blood Pressure (mmHg)[b]**	**Mean Arterial Pressure (mmHg)[c] Estimated by 40 mmHg + 2 × Patient Age (Years)**	**Systolic Hypotension (mmHg)[d]**
Birth (12 h, <1000 g)	39–59	16–36	28–42[e]	<40–50
Birth (12 h, 3-kg weight)	60–76	31–45	48–57	<50
Newborn (96 h)	67–84	35–53	45–60	<60

Infant (1–12 mo)	72–104	37–56	50–62	<70
Toddler (1–2 years)	86–106	42–63	49–62	<70+(2×age in years)
Preschool (3–5 years)	89–112	46–72	58–69	<70+(2×age in years)
School-age child (6–9 years)	97–115	57–76	66–72	<70+(2×age in years)
Preadolescent (10–12 years)	102–120	61–80	71–79	<90
Adolescent (13–15 years)	110–131	64–83	73–84	<90

Heart Rates			
Age	**Awake Heart Rate (per min)**	**Sleeping Heart Rate (per min)**	**Respiratory Rate[a] (Breaths/min)**
Newborn	100–205	90–160	30–60
Infant (6 mo)	100–180	90–160	30–53
Toddler	98–140	80–120	27–37
Preschooler	80–120	65–100	20–28
School-age child	75–118	58–90	18–25
Adolescent	60–100	50–90	12–20

Typical Blood Pressures				
Age	**Systolic Blood Pressure (mmHg)[b]** **For 1–10 Years of Age Estimated by 70 mmHg + 2 × age (Years)**	**Diastolic Blood Pressure (mmHg)[b]**	**Mean Arterial Pressure (mmHg)[c]** **Estimated by 40 mmHg + 2 × Patient Age (Years)**	**Systolic Hypotension (mmHg)[d]**
Birth (12 h, <1000 g)	39–59	16–36	28–42[e]	<40–50
Birth (12 h, 3-kg weight)	60–76	31–45	48–57	<50
Newborn (96 h)	67–84	35–53	45–60	<60
Infant (1–12 mo)	72–104	37–56	50–62	<70
Toddler (1–2 years)	86–106	42–63	49–62	<70+(2×age in years)
Preschool (3–5 years)	89–112	46–72	58–69	<70+(2×age in years)
School-age child (6–9 years)	97–115	57–76	66–72	<70+(2×age in years)
Preadolescent (10–12 years)	102–120	61–80	71–79	<90
Adolescent (13–15 years)	110–131	64–83	73–84	<90

NOTE: Always consider person's normal range and clinical condition. Heart and respiratory rates normally increase with fever or stress.

[a]Respiratory rates from Fleming S, Thompson M, Stevens R, et al. Normal ranges of heart rate and respiratory rate in children from birth to 18 years of age: A systematic review of observational studies. *Lancet*, 2011;377(9770):1011–1018.

[b]Systolic and diastolic blood pressure ranges assume 50th percentile for height for children 1 year and older, and are consistent with the Pediatric Advanced Life Support course (Chameides L, Ralston M, American Academy of Pediatrics, et al. *Pediatric advanced life support provider manual*. Dallas, TX: American Heart Association; 2011).

[c]Mean arterial pressures (Diastolic pressure+[Difference between systolic and diastolic pressures ÷ 3]) for 1 year and older, assuming 50th percentile for height.

[d]Threshold for hypotension in children 1 to 10 years old from Pediatric Advanced Life Support course (Chameides L, Ralston M, American Academy of Pediatrics, et al. *Pediatric advanced life support provider manual*. Dallas, TX: American Heart Association; 2011).

[e]Approximately equal to postconception age in weeks (may add 5 mmHg).

From Hazinski MF. Children are different. In: Hazinski MF, ed. Nursing care of the critically ill child, 3rd edition. St. Louis: Mosby; 2013.

The child's heart rate should be appropriate for age and clinical condition. The child in shock is often tachycardic. The **tachycardia** may be primary (i.e., associated with a tachydysrhythmia) or secondary to stress (i.e., sinus tachycardia). If the heart rate is extremely rapid, especially in the child with decreased myocardial function, tachycardia may be the cause rather than the symptom of shock. In general, if the ventricular rate exceeds 200 to 220 beats/min in the infant or 160 to 180 beats/min in the child, ventricular diastolic filling time and coronary artery perfusion time are significantly reduced, and stroke volume falls. Cardiac output can then fall, leading to signs of heart failure or shock. Once supraventricular or ventricular tachycardia produces signs of shock, urgent treatment is required.[12]

Bradycardia, an abnormally low heart rate, can cause a fall in cardiac output, or it can be a symptom of deterioration. In children, a fall in heart rate typically produces a commensurate fall in cardiac output.[13] The most common cause of bradycardia in young children is hypoxia.[14]

If the infant or child develops bradycardia with poor perfusion, the provider must immediately assess and support the child's airway, oxygenation, and ventilation, and be prepared to initiate chest compressions if the heart rate and systemic perfusion do not improve.[12]

Bradycardia often indicates impending cardiovascular collapse and is the most common terminal cardiac rhythm observed in children.[14] In neonates, especially preterm neonates, a *lack of heart rate variability* is a nonspecific sign of compromise, such as sepsis.[15]

The child's stroke volume may be altered by conditions affecting ventricular preload, compliance, contractility, and afterload (Table 49.2). Providers must evaluate and optimize each of these variables in the treatment of shock (see Chapter 48).

Table 49.2

Factors Affecting Cardiovascular Performance in Children

Factor	Comments
Heart rate	Major factor affecting cardiac output in children. Normally more rapid in children than in adults. Because the *stroke volume* is smaller in children than in adults, the *cardiac output* of the child is more closely related to heart rate than to stroke volume. *Tachycardia* is expected in the seriously ill or injured child, so a relatively normal heart rate may indicate deterioration. The most common cause of *bradycardia* in young children is hypoxia; bradycardia is an ominous sign if present in association with poor perfusion. Urgent treatment is required once bradycardia or supraventricular or ventricular tachycardia produces signs of shock.
Stroke volume	Averages 1.5 mL/kg; affected by conditions altering ventricular preload, compliance, contractility, and afterload.
Ventricular end-diastolic pressure (VEDP)	Optimal VEDP for children in shock is unknown. Bolus resuscitation is linked to improved survival in children with *septic* shock, provided caregivers titrate the fluid and cease bolus fluid administration if signs of hypervolemia or new or progressive signs of heart failure (rales, hepatomegaly) develop.
Ventricular compliance or distensibility	Can be affected by congenital heart defects such as atrial septal defects (ASDs) and complex congenital heart defects or surgical interventions for these defects. If compliance is low, such as in newborns and infants, relatively small quantities of volume administration may increase VEDP. Hypoplastic ventricles are often noncompliant. Hypertrophied ventricles, present in children with severe pulmonary stenosis or aortic stenosis, may become

Factor	Comments
	fibrotic and noncompliant. Increased compliance may be present in early septic shock.
Contractility	Contractility probably similar in normal newborns, infants, children, and adults. Newborn myocardium does have fewer contractile proteins and higher water content than adult myocardium, but the clinical significance of this is probably minimal.
Afterload	Newborn myocardium *can* adapt to mild, nonacute increases in afterload. Afterload may be increased in children with systemic vasoconstriction or pulmonary hypertension (constrictors include alveolar hypoxia, acidosis, hypothermia, and alveolar distention). Some uncorrected congenital heart defects may increase afterload. Coarctation of the aorta and aortic stenosis increase left ventricular afterload. Pulmonary stenosis increases right ventricular afterload. Afterload may be decreased in septic shock.
Oxygen delivery and consumption	Highest per kilogram body weight during the neonatal period and infancy. The young child requires a higher cardiac output and oxygen delivery per kilogram than the adult. Increased oxygen consumption occurs in critically ill newborns exposed to cold because they cannot shiver to generate heat. Other causes of increased oxygen consumption in children and infants include fever, sepsis, trauma, pain, and seizures.

The child's *blood pressure* must be appropriate for age and clinical condition. Shock may be present despite a systolic blood pressure within the normal range for age. When hypovolemic or cardiogenic shock is present, compensatory vasoconstriction may initially maintain the systolic blood pressure, although the mean and diastolic arterial pressures may fall. The development of systolic hypotension in the child with hypovolemic or cardiogenic shock indicates severe shock, and rapid deterioration may follow. In septic shock, by comparison, a fall in systolic or diastolic blood

pressure may develop relatively early in the clinical course. In all children, the development of systolic, diastolic, or mean arterial pressure indicates hypotensive shock, and urgent treatment is needed.[1,2]

The central venous pressure (CVP) is normally 0 to 5 mmHg. The pulmonary artery wedge pressure (PAWP, also called *pulmonary artery occlusion pressure* [*PAOP*]) is normally 5 to 8 mmHg or less, although pulmonary artery catheters are now rarely used in children. Inadequate CVP or PAWP may indicate hypovolemia, whereas high pressures typically result from heart failure or cardiogenic shock. Note that in the absence of tricuspid valve disease, tension pneumothorax, or influence from positive pressure ventilation, the CVP reflects the right ventricular end-diastolic pressure (RVEDP). The RVEDP may differ substantially from the left ventricular end-diastolic pressure.

A central venous catheter enables the evaluation of CVP and provides a route for rapid volume administration. In addition, a CVP catheter in the superior vena cava (SVC) enables the evaluation of the central venous oxygen saturation ($ScvO_2$). The $ScvO_2$ is used as a surrogate for the mixed venous oxygen saturation (which would require a sampling of blood from the pulmonary artery). If cardiac output is adequate and oxygen consumption is normal, the $ScvO_2$ will be no more than 25% to 30% below the arterial oxygen saturation. This typical arterio-venous oxygen saturation difference is still present in the child with cyanotic heart disease, provided the cardiac output and oxygen consumption are normal. A widening difference between the arterial and central venous oxygen saturation often indicates a decrease in cardiac output.

A fall in $ScvO_2$ can indicate a fall in oxygen delivery (caused by decreased arterial oxygen content or decreased cardiac output, or both), an uncompensated rise in oxygen consumption, or both. If a CVP catheter is in place in the SVC, resuscitation of a child in septic shock may target a central venous oxygen saturation (SvO_2) of 70% or greater.[16]

Shock compromises renal perfusion, so despite adequate fluid intake, urine volume decreases, typically falling to less than 2 mL/kg/h in infants, less than 1 mL/kg/h in children, and less than 0.5 mL/kg/h in adolescents. Liver enzymes may be elevated if hepatic perfusion is reduced. The development of metabolic acidosis and a rise in serum lactate to greater than 4 mg/dL indicate that blood flow to some tissues is inadequate to support aerobic metabolism.

Infants have high glucose needs and low glycogen stores that may be rapidly depleted during stress. For this reason, *hypoglycemia* (glucose

≤60 mg/dL) may be observed in seriously ill or injured infants and may be associated with cardiovascular or neurologic deterioration.[17,18]

Severe physiologic stress, such as cardiac surgery, shock, sepsis, MODS, or NPMODS can produce *critical illness hyperglycemia* (CIH), a transient glucose concentration >150 mg/dL. CIH has been documented in adults and children. It is produced by a relative insulin-resistant state associated with high levels of endogenous catecholamines and hydrocortisone secretion, with resultant gluconeogenesis and glycogenolysis. Glucose uptake by the liver is increased, while glucose uptake by peripheral tissues is decreased. Inflammatory mediators can contribute to the relative insulin resistance.[1,18,19] In children, the serum glucose is often elevated in the first 12 to 18 hours after initial insult (such as injury, shock, sepsis or MODS development, or cardiac surgery) that then falls to normal ranges. Although CIH has been associated with poor survival in critically ill children,[20,21] it is not clear if the hyperglycemia is the cause or the marker of poor outcomes.[19] An international pediatric study found that aggressive treatment of the hyperglycemia (i.e., tight glycemic control to 80 to 110 mg/dL) did not improve outcomes and did result in episodes of hypoglycemia.[22]

Hypovolemic Shock

Hypovolemic shock, the most common type of shock in children, is caused by a reduction in the intravascular volume relative to the vascular space. Intravascular volume loss (e.g., dehydration or hemorrhage) and trauma are the most common causes of hypovolemic shock in children.

Pathophysiology. Hypovolemia can develop rapidly in children. When hypovolemia is mild or moderate, such as with 5% to 10% dehydration or mild hemorrhage, compensatory adrenergic vasoconstriction redistributes blood from the skin, the mesenteric (gut), and renal circulations to maintain blood flow to the heart and brain. The blood pressure is typically adequate with mild hypovolemic shock. Hypotension is a sign of severe, decompensated hypovolemic shock and may not develop unless intravascular volume loss is rapid or severe.[1,2]

Relative hypovolemia may result from vasodilation and a redistribution of blood volume or from increased capillary permeability, which can be associated with sepsis, burns, anaphylaxis, or neurogenic shock, as well as with β_2-adrenergic drug toxicity. The translocation of extravascular fluid to a location that is neither intravascular nor intracellular, as in edema, is termed **"third spacing" of fluids**.[18]

There are compensatory responses to regain homeostasis

Significant dehydration, hypovolemia, and low cardiac output stimulate adrenergic and renal compensatory mechanisms characterized by the "fight-or-flight" response. These include tachycardia and redistribution of blood from the skin, gut, and kidney to the brain and heart. Reduced renal perfusion stimulates the renin-angiotensin-aldosterone system, resulting in renal sodium and water retention. Decreased atrial stretch stimulates the secretion of antidiuretic hormone (ADH, also known as *arginine vasopressin* [*AVP*]) and produces free water retention by the kidneys.[1] These mechanisms are similar in adults and children and may help restore or maintain intravascular volume over time. Neonatal and young infant kidneys, however, are incapable of excreting concentrated urine, so these compensatory mechanisms are relatively ineffective during the first weeks of life.[18]

Compensatory mechanisms cannot be maintained indefinitely. Systemic vasoconstriction increases left ventricular afterload and myocardial oxygen consumption and may produce tissue ischemia. Prolonged tachycardia may impair subendocardial blood flow and increase myocardial oxygen consumption; both may ultimately contribute to myocardial ischemia.[1] Extreme tachypnea increases oxygen demand and reduces effective ventilation. A severe compromise in blood flow and systemic perfusion contributes to cerebral, renal, or hepatic ischemia and possible organ failure.

Clinical Manifestations

The child with hypovolemic shock demonstrates signs of inadequate blood flow to some tissue beds and some evidence of organ system dysfunction (see Box 49.1). The infant or child may be irritable or lethargic. Respirations will be rapid and may be labored if the shock is severe or associated with myocardial failure. The skin will be mottled, although pallor also may be observed. A prolonged capillary refill time (>2 seconds) is consistent with the development of shock.[1,2,10] The child in hypovolemic shock is often tachycardic. Bradycardia in the child with shock indicates impending cardiovascular collapse and is the most common terminal cardiac rhythm observed in children.[1,12]

When hypovolemic shock is present, compensatory vasoconstriction may initially maintain the systolic blood pressure, although the mean arterial pressure may fall. The development of systolic hypotension often indicates severe shock, and rapid deterioration may follow. The CVP is typically less than 5 to 8 mmHg unless heart failure or pulmonary hypertension is present.

Hypovolemic shock compromises renal perfusion, so urine volume decreases despite adequate fluid intake. Liver enzymes may be elevated if hepatic perfusion is reduced. The development of metabolic acidosis and a rise in serum lactate indicate that blood flow to some tissues is inadequate to support aerobic metabolism.

Hypoglycemia (glucose ≤60 mg/dL) may be observed in seriously ill or injured infants, especially if intake has been compromised, and may be associated with cardiovascular or neurologic deterioration. As noted, c*ritical illness hyperglycemia, CIH* (glucose>150 mg/dL) may transiently develop in critically ill or injured children.

Clinically significant dehydration is associated with weight loss (Table 49.3). Fluid intake and output records (or reports from parents or primary caretakers) reveal a history of inadequate fluid intake or excessive fluid losses. The child with significant dehydration demonstrates dry mucous membranes, a sunken fontanel (in infants), and poor skin turgor (Table 49.4).[18]

Table 49.3

Dehydration and Hypovolemia

Type of Dehydration	Clinical Indicators
Isotonic dehydration	Fluid output exceeds intake. Loss of free water is proportional to loss of sodium, so serum sodium concentration remains normal. Fluid loss is from intravascular and extravascular compartments. Compromises peripheral perfusion when the young child has lost approximately 10% (100 mL/kg) of body weight. Compromises systemic perfusion in the adolescent with acute fluid loss equivalent to 5%–6% of body weight.
	Can produce hypotension (decompensated shock) when the young child has lost about 15% (150 mL/kg) of body weight. Can produce hypotension in the adolescent with a fluid loss equivalent to about 7%–9% of body weight because body water constitutes a smaller percentage of body weight in older children and adults than in young children.
Hypotonic/hyponatremic dehydration	Associated with a proportionately greater loss of sodium than free water; thus the serum sodium falls. Resultant acute fall in serum osmolality produces an acute extravascular fluid shift and further loss of extravascular volume. Fluid loss in hypotonic dehydration is primarily from the intravascular compartment; thus a compromise in systemic perfusion will be observed after even small quantities of fluid loss.

Type of Dehydration	Clinical Indicators
	Poor peripheral perfusion can develop in a child with a fluid loss equivalent to about 5% (50 mL/kg) of body weight. Adolescents with hyponatremic dehydration may demonstrate a compromise in peripheral perfusion with a fluid loss equivalent to approximately 3% of body weight.
	Hypotension often is observed when fluid loss is equal to approximately 10% (100 mL/kg) of body weight. Hypotension in an adolescent is observed when the fluid loss equals approximately 5%–6% of body weight.
Hypertonic/hypernatremic dehydration	Free water deficit is proportionately greater than the deficit of sodium, so serum sodium concentration rises, increasing serum osmolality and producing an intravascular shift of free water. For this reason the child with hypernatremic dehydration is likely to maintain intravascular volume and systemic perfusion until relatively large quantities of fluid are lost.
	Compromise in systemic perfusion is not likely to be observed in the *child* with hypernatremic dehydration until *severe* dehydration is present with a fluid loss equivalent to about 10% of body weight (or 5%–6% of body weight in the adolescent).
	Hypotension may not be observed until the fluid loss approximates 15% or more of body weight (7%–9% or more of body weight in the adolescent).

Type of Dehydration	Clinical Indicators
	Hypotension in the child with hypertonic/hypernatremic dehydration indicates a substantial fluid deficit. However, the deficit must be replaced carefully to correct shock and avoid rapid lowering of serum sodium concentrations.

Type of Dehydration	Clinical Indicators
Isotonic dehydration	Fluid output exceeds intake. Loss of free water is proportional to loss of sodium, so serum sodium concentration remains normal. Fluid loss is from intravascular and extravascular compartments. Compromises peripheral perfusion when the young child has lost approximately 10% (100 mL/kg) of body weight. Compromises systemic perfusion in the adolescent with acute fluid loss equivalent to 5%–6% of body weight.
	Can produce hypotension (decompensated shock) when the young child has lost about 15% (150 mL/kg) of body weight. Can produce hypotension in the adolescent with a fluid loss equivalent to about 7%–9% of body weight because body water constitutes a smaller percentage of body weight in older children and adults than in young children.
Hypotonic/hyponatremic dehydration	Associated with a proportionately greater loss of sodium than free water; thus the serum sodium falls. Resultant acute fall in serum osmolality produces an acute extravascular fluid shift and further loss of extravascular volume. Fluid loss in hypotonic dehydration is primarily from the intravascular compartment; thus a compromise in systemic perfusion will be observed after even small quantities of fluid loss.
	Poor peripheral perfusion can develop in a child with a fluid loss equivalent to about 5% (50 mL/kg) of body weight. Adolescents with hyponatremic dehydration may demonstrate a compromise in peripheral perfusion with a fluid loss equivalent to approximately 3% of body weight.
	Hypotension often is observed when fluid loss is equal to approximately 10% (100 mL/kg) of body weight. Hypotension in an adolescent is observed when the fluid loss equals approximately 5%–6% of body weight.

[a]The interpretation of the assessments must be appropriately modified for age and type of dehydration (hypotonic or hypertonic).

Modified from Perkin RM, et al. Shock, cardiac arrest and resuscitation. In: Hazinski MF, ed. *Nursing care of the critically ill child*, 3rd edition. St. Louis: Mosby; 2013.

Moderate isotonic dehydration produces signs of peripheral circulatory compromise, and severe isotonic dehydration will produce hypotension. The blood urea nitrogen (BUN) and urine specific gravity are usually elevated. The serum sodium concentration and osmolality are affected by the type and severity of dehydration present; in turn, they can affect the clinical presentation. Hypotension typically develops with greater than 10% isotonic or hypotonic dehydration in the infant or child, or greater than 6% to 7% dehydration in the adolescent.[18]

Hemorrhage is another potential cause of hypovolemic shock. To appreciate the significance of any blood lost or drawn for laboratory analysis, the total blood loss should be considered as a percentage of the child's circulating blood volume (Table 49.5).[10]

Table 49.5

Estimation of Pediatric Circulating Blood Volume

Age of Child	Blood Volume (mL/kg Body Weight)
Newborn	80–85
Infant	75–80
Child	70–75
Adolescent	65–70

From Hazinski MF. Children are different. In: Hazinski MF, ed. *Nursing care of the critically ill child*, 3rd edition. St. Louis: Mosby; 2013.

Tachycardia, peripheral vasoconstriction, and altered level of consciousness may be the only early signs of internal hemorrhage in the child with trauma (Table 49.6). Acute blood loss (hemorrhage) may not cause hypotension until an estimated 25% to 30% of intravascular volume is lost (i.e., an acute intravascular or blood loss of 16 to 24 mL/kg).[23–25] Once hypotension develops in the child with hemorrhage, cardiovascular collapse is imminent; immediate, rapid intravascular volume expansion is required, and surgical intervention may be needed.

Table 49.6

Classification of Pediatric Hemorrhagic Shock in Trauma Patients Based on Clinical Evaluation

System	Mild Hemorrhage, Compensated Shock, Simple Hypovolemia (<30%)	Moderate Hemorrhage, Decompensated Shock, Marked Hypovolemia (30%–45%)	Severe Hemorrhage, Cardiopulmonary Failure, Profound Hypovolemia (>45%)
Cardiovascular	Tachycardia Weak peripheral pulses, strong central pulses Low to normal blood pressure (systolic BP >70 mmHg+ [2×age in years]) Mild acidosis	Moderate tachycardia Thready peripheral pulses, weak central pulses Frank hypotension (systolic BP <70 mmHg+ [2×age in years]) Moderate acidosis	Severe tachycardia Absent peripheral pulses, thready central pulses Profound hypotension (systolic BP <50 mmHg) Severe acidosis
Respiratory	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Irritable, confused	Agitated or lethargic	Obtunded, comatose
Skin	Cool extremities, mottling	Cool extremities, pallor	Cool extremities, cyanosis

System	Mild Hemorrhage, Compensated Shock, Simple Hypovolemia (<30%)	Moderate Hemorrhage, Decompensated Shock, Marked Hypovolemia (30%–45%)	Severe Hemorrhage, Cardiopulmonary Failure, Profound Hypovolemia (>45%)
	Poor capillary refill (>2 s)	Delayed capillary refill (>2 s)	Prolonged (>5 s) capillary refill
Kidneys	Mild oliguria, increased specific gravity	Marked oliguria, increased blood urea nitrogen (BUN)	Anuria

System	Mild Hemorrhage, Compensated Shock, Simple Hypovolemia (<30%)	Moderate Hemorrhage, Decompensated Shock, Marked Hypovolemia (30%–45%)	Severe Hemorrhage, Cardiopulmonary Failure, Profound Hypovolemia (>45%)
Cardiovascular	Tachycardia Weak peripheral pulses, strong central pulses Low to normal blood pressure (systolic BP >70 mmHg+[2×age in years]) Mild acidosis	Moderate tachycardia Thready peripheral pulses, weak central pulses Frank hypotension (systolic BP <70 mmHg+[2×age in years]) Moderate acidosis	Severe tachycardia Absent peripheral pulses, thready central pulses Profound hypotension (systolic BP <50 mmHg) Severe acidosis
Respiratory	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Irritable, confused	Agitated or lethargic	Obtunded, comatose
Skin	Cool extremities, mottling Poor capillary refill (>2 s)	Cool extremities, pallor Delayed capillary refill (>2 s)	Cool extremities, cyanosis Prolonged (>5 s) capillary refill
Kidneys	Mild oliguria, increased specific gravity	Marked oliguria, increased blood urea nitrogen (BUN)	Anuria

From Soud T, Pieper P, Hazinski MF. Pediatric trauma. In: Hazinski MF, ed. *Nursing care of the critically ill child*, 2nd edition. St. Louis: Mosby; 1992.

Redistribution of blood volume associated with systemic vasodilation, high capillary pressure or transudative fluid losses, or capillary leak may produce a relative hypovolemia and signs of poor systemic perfusion in the absence of evidence of absolute volume loss. For example, children with end-stage hepatic failure may demonstrate a relative hypovolemia associated with ascites and hepatorenal syndrome. Maldistribution of blood flow with

distributive shock (e.g., septic shock, neurogenic shock, or severe burns) also will produce signs of relative hypovolemia because intravascular volume is inadequate relative to the vascular space.

Evaluation

and Treatment

Early detection is critical to optimize treatment for shock. Specific treatment of hypovolemic shock is volume resuscitation. Volume resuscitation is designed to restore intravascular volume relative to the vascular space and to optimize ventricular preload. The specific fluid selected and route of administration are determined by the child's clinical condition. In general, isotonic **crystalloids** (isotonic salt-containing solutions, such as normal saline or lactated Ringer solution) or **colloids** (protein-containing fluids, such as albumin or blood) are administered in boluses of 20 mL/kg given over 5 to 20 minutes. Modifications in bolus volume and rate of administration are made if hypovolemic shock is present in a child with myocardial dysfunction: smaller fluid boluses (5 to 10 mL/kg) are administered over about 10 to 20 minutes. If septic shock with hypotension is present and critical care is available, up to 2 to 3 boluses of 10 to 20 mL/kg are administered over 5 to 20 minutes.[3,16] Hypotonic fluids should not be administered.[1,17] Administration of packed red blood cells (PRBCs) (10 mL/kg) is generally reserved for the child with hemorrhagic shock (see Table 49.6). After each bolus, it is important to reassess systemic perfusion and administer additional fluids if indicated. Providers should halt bolus fluid administration immediately if the child develops signs of hypervolemia or new or worsening heart failure (e.g., new or worsening hepatomegaly, respiratory distress, or rales).

During treatment of shock caused by dehydration, providers must avoid acute or severe alterations in the serum sodium concentration.[1,18,26] Acute changes in serum sodium alter the serum osmolality and result in fluid shifts into and out of the vascular spaces. Such fluid shifts can be associated with neurologic complications including seizures, cerebral edema, and intracranial hemorrhage.[18]

Administration of blood or blood component therapy may be needed to treat hemorrhage. A "normal" hematocrit does not rule out the possibility of hemorrhage in the injured person; the hematocrit typically falls in a person who has sustained whole blood loss after the blood loss is replaced with crystalloids or colloids. When blood loss is significant, 10 mL/kg boluses of

PRBCs are administered as needed to replace blood loss and maintain hemoglobin and hematocrit.[17]

The optimal hemoglobin threshold for transfusion in critically ill children is unknown. The Pediatric Critical Care Transfusion and Anemia Expertise Initiative (TAXI) recommends critically ill children with a hemoglobin concentration of less than 5 g/dL receive PRBC transfusion; children with a hemoglobin concentration of >5 g/dL but <7 g/dL, the decision is based on clinical judgment; and children with a hemoglobin concentration of greater than 7 g/dL no PRBC transfusion be given.[27] However, higher hemoglobin and hematocrit thresholds may be necessary for unstable children with cardiac or respiratory disease, cyanotic CHD, and those with hemodynamic instability.[27]

Cardiogenic Shock

Cardiogenic shock is present when impaired myocardial function compromises cardiac output. In children, cardiac failure is most commonly due to CHD, cardiomyopathies, myocarditis, or arrhythmias.[2]

This form of shock is observed:

1. Following cardiovascular surgery or with inflammatory disease of the heart (e.g., cardiomyopathy and myocarditis)
2. With drug toxicity or severe electrolyte or acid-base imbalances
3. As a complication of any form of shock, and early in septic shock

Pathophysiology

In the early stages of cardiogenic shock, adrenergic compensatory mechanisms produce tachycardia, peripheral vasoconstriction, and constriction of the splanchnic arteries to divert blood flow from the skin, gut, and kidneys to maintain flow to the heart and brain.[1–3] These compensatory mechanisms may initially be sufficient to maintain the systolic blood pressure and effective coronary and cerebral blood flow. However, tachycardia and systemic arterial constriction increase myocardial oxygen consumption. In addition, reduction in gut and kidney blood flow may produce hepatic, mesenteric, or renal ischemia or failure. Decreased renal perfusion stimulates the renin-angiotensin-aldosterone system, as described for hypovolemic shock.[1]

A fall in the mean arterial pressure or pulse pressure reduces stimulation of the baroreceptors in the carotid sinuses and aortic arch. This reduced

baroreceptor activity removes inhibition from the vasomotor center in the medulla, resulting in increased adrenergic stimulation.[1] If myocardial dysfunction progresses, cardiac output and blood pressure ultimately fall. Myocardial ischemia then exacerbates myocardial dysfunction, and multisystem organ failure may result from persistent or severe organ ischemia.

Clinical Manifestations

The child with cardiogenic shock demonstrates signs of inadequate systemic perfusion despite evidence of adequate intravascular volume or even relative hypervolemia. This form of shock is generally associated with low cardiac output. The child's extremities are cool to touch (the extremities will cool from peripherally to proximally), with delayed capillary refill despite a warm, ambient temperature.[1] The skin may be mottled (see Fig. 49.1). If myocardial function is severely compromised, peripheral pulses may be diminished in intensity (dampened) or they may vary in intensity (pulsus alternans).

Evidence of systemic venous congestion, including high CVP, hepatomegaly, and periorbital edema, is typically present in cardiogenic shock, particularly if right ventricular failure is involved. The presence of venous congestion is considered "wet," the absence is described as "dry"; hypoperfusion is considered "cold," whereas normal perfusion is "warm."[28]

Evidence of pulmonary edema may be identified on a chest radiograph or clinical assessment (including signs of respiratory distress, reduced lung compliance during hand ventilation, or frothy pink sputum suctioned from the endotracheal tube) if left ventricular failure is present. The cardiac silhouette on the chest radiograph is usually enlarged, unless concurrent hypovolemia is present.

A low cardiac output may be documented by invasive or noninvasive devices. The $ScvO_2$ will be more than 25% to 30% below the arterial oxygen saturation. Signs of low cardiac output and cardiogenic shock can be similar to signs of cardiac tamponade. Although some classic signs, including muffled heart tones, or pulsus paradoxus, may be observed with tamponade, these signs may be difficult to appreciate if cardiac output and blood pressure are severely compromised. Therefore, if cardiogenic shock is suspected in a child after cardiovascular surgery or in any child at risk for the development of pericardial effusion, tamponade should be ruled out through an echocardiogram.

In infants following surgery for CHD, a low cardiac output syndrome score (LCOSS) can be calculated by assigning one point each for tachycardia (>20% higher than post induction heart rate in operating room), oliguria (<1 mL/kg/h), toe temperature less than 30°C (86°F), need for volume administration of >30 mL/kg/day, decreased near infrared spectrometry (NIRS) measurements (cerebral NIRS <50% and renal NIRS <75% of arterial saturation), arterial lactate >2 mmol/L, and need for vasoactive/inotropes beyond milrinone at 0.5 μg/kg/min. The score is assessed at ICU admission, 8, 12, and 24 hours postoperatively. Morbidity and resource utilization can be significantly higher among infants with peak LCOSS ≥4 and those with a cumulative LCOSS ≥7.[29]

Evaluation

and Treatment

Treatment targeting cardiogenic shock requires titration of fluid boluses as needed to optimize cardiac preload. These boluses of 5 to 10 mL/kg of isotonic crystalloid are delivered over about 10 to 20 minutes and should be stopped immediately if the child develops signs of hypervolemia or new or worsening heart failure (e.g., new or worsening hepatomegaly, respiratory distress, or rales). Vasoactive drugs are needed to improve myocardial function and inodilators; vasodilators or vasoconstrictors may be needed to support systemic perfusion. Table 49.7 summarizes drug therapy for children in shock.[1]

Table 49.7

Pediatric Vasoactive Drugs for the Treatment of Shock[a]

Dose	Effects	Cautions
Sympathomimetics		
Dobutamine: 2–20 μg/min	Selective β-adrenergic effects, increases cardiac contractility and also increases heart rate (this latter effect is variable); β_2 effects produce peripheral vasodilation; no dopaminergic or α-adrenergic effects	Extreme tachyarrhythmias have been reported, particularly in infants; hypotension may develop; may produce pulmonary vasoconstriction
Dopamine: 1–5 μg/kg per min	Dopaminergic effects predominate, including increase in glomerular filtration rate and urine volume	Can produce extreme tachyarrhythmias; can result in increase in pulmonary artery pressure; inhibits thyroid-stimulating hormone and aldosterone secretion
Dopamine: 2–10 μg/kg per min	Dopaminergic effects persist and β_1 effects are seen, especially an increase in heart rate	As Dopamine 1–5
Dopamine: 8–20 μg/kg per min	α-Adrenergic effects dominate	As Dopamine 1–5
Epinephrine: 0.05–0.15 μg/kg per min	Endogenous catecholamine, which produces α, β_1, and β_2 adrenergic effects; at	Will increase myocardial work and oxygen consumption at any dose; splanchnic

Dose	Effects	Cautions
	low doses, β_1 effects dominate	constriction will occur at even low doses
Epinephrine: 0.2–0.3 μg/kg per min	α-Adrenergic (vasoconstrictive) effects dominate	As Epinephrine 0.05–0.15
Isoproterenol: 0.05–0.1 μg/kg per min	β-Adrenergic effects; β_1 effects may result in rapid increase in heart rate; β_2 effects may produce peripheral vasodilation and also may effectively treat bronchoconstriction	Monitor for tachyarrhythmias, hypotension; will increase myocardial oxygen consumption
Norepinephrine: 0.05–1 μg/kg per min	Endogenous catecholamine with α- and β-adrenergic effects; produces potent peripheral and renal vasoconstriction; can increase blood pressure	May cause tachyarrhythmias, increased myocardial work, and increased oxygen consumption; may result in hepatic and mesenteric ischemia
Vasopressin		
Vasopressin: 0.2–2 milliunits/kg per min (0.0002–0.002 unit/kg per min)	Antidiuretic hormone analog that acts on vasopressin receptors; produces peripheral and splanchnic vasoconstriction; also used to treat GI hemorrhage for this reason	May cause hypertension, bradycardia
Phosphodiesterase Inhibitor/Inodilator		
Milrinone: loading dose,	Nonadrenergic inotropic agent that produces	

Dose	Effects	Cautions
0.05 mg/kg (50 μg/kg) over 10–60 min; infusion, 0.25–0.75 μg/kg per min	phosphodiesterase inhibition and increase in intracellular cyclic adenosine monophosphate (cAMP); intracellular calcium uptake also is delayed; these effects result in improved cardiac contractility and vasodilation	Monitor for arrhythmias (especially accelerated junctional rhythm, junctional tachycardia, and ventricular ectopy); may produce hypotension (especially if person is hypovolemic), liver and GI dysfunction, thrombocytopenia, and abdominal pain; experience in children is limited and recent Reduce dose when renal dysfunction present
Vasodilators		
Nitroglycerin: 0.25–0.5 μg/kg per min; increase as tolerated to maximum 10 μg/kg/min (adolescents, 5 μg/min; Note not per kg per min)	Arterial and venodilator	Is absorbed by polyvinyl chloride tubing; use special infusion set
Nitroprusside: 0.3–0.5 μg/kg per min; titrate up to 8 μg/kg per min (max. infusion dose:	Arterial and venodilator	Light sensitive; use special infusion set or cover tubing when infusion slow; may produce thiocyanate and cyanide toxicity, particularly for higher

Dose	Effects	Cautions
8–10 μg/kg per min)		doses or prolonged infusion

Dose	Effects	Cautions
Sympathomimetics		
Dobutamine: 2–20 μg/min	Selective β-adrenergic effects, increases cardiac contractility and also increases heart rate (this latter effect is variable); β_2 effects produce peripheral vasodilation; no dopaminergic or α-adrenergic effects	Extreme tachyarrhythmias have been reported, particularly in infants; hypotension may develop; may produce pulmonary vasoconstriction
Dopamine: 1–5 μg/kg per min	Dopaminergic effects predominate, including increase in glomerular filtration rate and urine volume	Can produce extreme tachyarrhythmias; can result in increase in pulmonary artery pressure; inhibits thyroid-stimulating hormone and aldosterone secretion
Dopamine: 2–10 μg/kg per min	Dopaminergic effects persist and β_1 effects are seen, especially an increase in heart rate	As Dopamine 1–5
Dopamine: 8–20 μg/kg per min	α-Adrenergic effects dominate	As Dopamine 1–5
Epinephrine: 0.05–0.15 μg/kg per min	Endogenous catecholamine, which produces α, β_1, and β_2 adrenergic effects; at low doses, β_1 effects dominate	Will increase myocardial work and oxygen consumption at any dose; splanchnic constriction will occur at even low doses
Epinephrine: 0.2–0.3 μg/kg per min	α-Adrenergic (vasoconstrictive) effects dominate	As Epinephrine 0.05–0.15
Isoproterenol: 0.05–0.1 μg/kg per min	β-Adrenergic effects; β_1 effects may result in rapid increase in heart rate; β_2 effects may produce peripheral vasodilation and also may effectively treat bronchoconstriction	Monitor for tachyarrhythmias, hypotension; will increase myocardial oxygen consumption
Norepinephrine: 0.05–1 μg/kg per min	Endogenous catecholamine with α- and β-adrenergic effects; produces potent peripheral and renal vasoconstriction; can increase blood pressure	May cause tachyarrhythmias, increased myocardial work, and increased oxygen consumption; may result in hepatic and mesenteric ischemia
Vasopressin		
Vasopressin: 0.2–2 milliunits/kg per min (0.0002–0.002 unit/kg per min)	Antidiuretic hormone analog that acts on vasopressin receptors; produces peripheral and splanchnic vasoconstriction; also used to treat GI hemorrhage for this reason	May cause hypertension, bradycardia
Phosphodiesterase Inhibitor/Inodilator		
Milrinone: loading dose, 0.05 mg/kg (50 μg/kg) over 10–60 min; infusion, 0.25–0.75 μg/kg per min	Nonadrenergic inotropic agent that produces phosphodiesterase inhibition and increase in intracellular cyclic adenosine monophosphate (cAMP); intracellular calcium uptake also is delayed; these effects result in improved cardiac contractility and vasodilation	Monitor for arrhythmias (especially accelerated junctional rhythm, junctional tachycardia, and ventricular ectopy); may produce hypotension (especially if person is hypovolemic), liver and GI dysfunction, thrombocytopenia, and abdominal pain; experience in children is limited and recent Reduce dose when renal dysfunction present
Vasodilators		
Nitroglycerin: 0.25–0.5 μg/kg per min; increase as tolerated to maximum 10 μg/kg/min (adolescents, 5 μg/min; Note not per kg per min)	Arterial and venodilator	Is absorbed by polyvinyl chloride tubing; use special infusion set
Nitroprusside: 0.3–0.5 μg/kg per min; titrate up to 8 μg/kg per min (max. infusion dose: 8–10 μg/kg per min)	Arterial and venodilator	Light sensitive; use special infusion set or cover tubing when infusion slow; may produce thiocyanate and cyanide toxicity, particularly for higher doses or prolonged infusion

GI, Gastrointestinal.

St. Louis: Mosby; 2013: p 120 and Kadec KD, McBride ME, et al. 2020 *AHA pediatric advanced life support provider manual*. Dallas, TX: American Heart Association; 2020.

Distributive/Septic Shock

With distributive (septic, anaphylactic, and neurogenic) shock, vasodilation and increased capillary permeability are typically present, and blood flow is unregulated throughout the skin and organ systems, so a normal cardiac output is likely to be inadequate to maintain sufficient perfusion of all tissue beds. **Neurogenic shock** is a form of hypovolemic and vasogenic (maldistributive) shock. It is caused by a loss of vasomotor tone after severe head or spinal cord injury. Massive vasodilation and loss of sympathomimetic tone result in a relative hypovolemia and hypotension. The loss of sympathetic tone prevents compensatory tachycardia.

Sepsis and its complications result from activation of biochemical and physiologic cascades that lead to the formation or activation of cytokines and other mediators that produce vasodilation, increased capillary permeability, maldistribution of blood flow, and cardiovascular and cellular dysfunction.[1] Sepsis and its complications may result in MODS or NPMODS and are leading causes of death in noncoronary intensive care units. In 2005, in the United States, there were more than 75,000 pediatric hospitalizations involving severe sepsis, with an overall mortality of 8.9% to 24%.[30]

In Hartman and colleagues,[30,31] hospital data from seven states provide the most detailed information regarding causes of pediatric sepsis in the United States. In 2013, this group reported data through 2005 and in a subsequent 2019, reported on data from 2005 through 2011.[31] In this data set, an infecting microorganism was identified in less than 40% of infants and children with severe sepsis.[30] The most common sites of identified infection were respiratory tract (roughly 50%) and bacteremia (about 20%).[30] In a more recent series from the Children's Hospital Association of nearly 50,000 children with pediatric severe sepsis from 2004 to 2012,[32] approximately two-thirds of children with severe sepsis had chronic disease. Among these children, bloodstream infections were most common (67.8%), with a high incidence of respiratory (57.2%) sites of infection. Genitourinary infections

were identified in one-fifth, with device infection, cardiovascular infection, and abdominal infections as additional sources.

An international series characterizing children with septic shock has been published by the Pediatric Acute Lung Injury and the Sepsis Investigators Network.[33] In this series, an infectious microorganism was identified in 65% of children, with respiratory (40%) and bloodstream (19%) infections the most frequent sources.

The microorganisms that cause sepsis vary according to age, immune function, and location. In the two large pediatric series from the United States, the most commonly reported infecting microorganisms were staphylococcus, streptococcus, and fungal infections, with fewer gram-negative and viral infections.[30,32] Fungal infections were much more common among children with cancer. When viral infections were documented, concomitant bacterial infections were nearly always present.[30] In the international series of children with severe sepsis, gram-negative (28%) and gram-positive (27%) microorganisms are identified approximately equally, followed by viruses (21%) and fungi (21%).[33]

Prevention of hospital-acquired infections can substantially reduce the risk of infection, sepsis, and its complications.[34] Clinicians must be aware of the common pathogens in various populations.

Factors associated with risk for the development of sepsis include extremes of age (risk highest among infants, young children, and older adults)[1,30,32]; chronic diseases; invasive catheters, surgical incisions, or wounds or burns; immunocompromise; and long-term antibiotic therapy.[32,35] As noted earlier in data from children's hospitals, two-thirds of children with severe sepsis had a chronic disease.[32]

It is now clear that genetic characteristics of the child, as well as of the invading microorganisms, alter the outcome of infections, sepsis, and septic shock.[36,37] Certainly, infectious diseases, such as meningococcal disease, can vary widely in invasiveness and severity of clinical consequences.[38]

Both pro-inflammatory and anti-inflammatory cytokines serve essential protective functions in fighting infection and modulating the immune response. Sepsis is caused by the effects of the invading microorganism and its toxins, and most effects that contribute to septic shock result from a disruption in the balance between *pro-inflammatory* mediators (including tumor necrosis factor-alpha [TNF-α], interleukin [IL]-1, IL-6, and IL-8; platelet-activating factor; arachidonic acid metabolites; nitric oxide; and many kinins) and *anti-inflammatory* mediators (IL-4, IL-10, IL-11, and IL-13;

transforming growth factor-beta; colony-stimulating factors; soluble tumor necrosis factor receptor; IL-1 receptor antagonist; and activated protein C).[1] Extremely high levels of pro-inflammatory mediators, such as TNF, nitric oxide, and platelet-activating factor, can become destructive, even when they eradicate the triggering microorganism.[1,36]

High pro-inflammatory cytokine levels have been implicated in the development of sepsis-induced disseminated intravascular coagulation, pulmonary injury, and microcirculatory disruptions, similar to those observed with burns, severe trauma, shock reperfusion syndromes, post cardiac arrest, and MODS.[36] Tumor necrosis factor levels have been directly related to mortality in newborns and children with meningitis and sepsis,[1] and interleukin-8 levels have been shown to be reliable predictors of pediatric sepsis mortality.[37]

An increase in plasma nitric oxide concentration contributes to vasodilation, hypotension, and decreased myocardial function that develop during adult sepsis. However, infants with sepsis often demonstrate pulmonary vasoconstriction from shock-induced acidosis and hypoxia and may benefit from administration of inhaled nitric oxide or other vasodilators.[39]

During sepsis, the endothelium becomes a secretory organ, changing from the normal profibrinolytic and anticoagulant state to an antifibrinolytic and procoagulant one.[39] This change can lead to the development of microthrombi in some areas of the microcirculation, further contributing to the maldistribution of blood flow. Mediators that regulate coagulation pathways have been implicated in the sepsis process.[39] Activated protein C normally curtails the inflammatory process once the invading microorganism is destroyed, and a deficiency in activated protein C is a marker for severe sepsis in all ages.[40] Although administration of activated protein C improved survival in one study of adults with severe sepsis,[41] subsequent adult studies failed to replicate this result.[42] A study in children was halted because the activated protein C produced excessive bleeding complications.[39,42]

C-reactive protein (CRP) binds to both bacteria and macrophages and activates the complement system. The complement system is a series of proteins that helps macrophages eliminate (opsonize) invading microorganisms; these proteins also participate in the clotting cascade. CRP concentration normally rises with infection and falls when the infection is adequately treated with antibiotics, so it is a useful component to monitor

response to infection. Ferritin is released when macrophages are activated in response to sepsis, injury, and inflammation. In a small sample of children with severe sepsis, mortality was highest (46.5%) among those with both a CRP ≥4.08 mg/dL and a ferritin ≥1980 ng/mL and lowest (0%) among those with a CRP and ferritin below said thresholds.[43]

There is clear interaction among catecholamines, adrenoreceptors, and glucocorticoids contributing to CIH. Endogenous glucocorticoids decrease activation of pro-inflammatory mediators, and the pro-inflammatory mediators contribute to a relative insulin resistance. The glucocorticoids modulate vasomotor tone by enhancing cardiovascular and vasomotor response to catecholamines.[44]

Critically ill children may have absolute or relative adrenal insufficiency, caused by adrenal hemorrhage, decreased renal perfusion, inhibition of corticosteroid production by TNF, or actual adrenal disease, with inadequate adrenal stress response or decreased response to circulating glucocorticoids.[45,46] When sepsis is present and the child fails to respond to initial fluid therapy and vasoactive support, providers should rule out adrenal insufficiency and consider hydrocortisone administration.[47]

Septic shock

Clinical Manifestations

Sepsis and its complications produce a cascade of physiologic and biochemical changes. The clinical progression of sepsis in children was initially defined in 2005 by an international consensus panel (Box 49.3).[48] These definitions have been further refined by the Pediatric Collaborative Group of the Society of Critical Care Medicine, with decreased focus on identification of the SIRS or sepsis, and increased focus on immediate recognition and treatment of septic shock.[47]

Box 49.3

Potential Clinical Findings in Infants and Children With Septic Shock

Potential Alterations in Temperature

Core body temperature of >38.5°C (101.3°F) or <36°C (96.8°F)

Hypotension

Systolic blood pressure less than

- 60 mmHg in infant newborn to 1 months
- 70 mmHg in infant 1 month to 1 year
- 70+2 (age in years) for children 1–10 years of age

Potential Alterations in Heart Rate

Tachycardia in the absence of external stimulus, chronic drugs, or painful stimuli, defined as follows:

- Newborn to 1 year: >180 beats/min
- 2–5 years: >140 beats/min
- 6–12 years: >130 beats/min
- 13 to <18 years: >110 beats/min

Otherwise unexplained persistent elevation in heart rate over a 0.5- to 4-h time period

For children younger than 1 year: bradycardia, in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease, defined by one of the following rates:

- Newborn to 1 month: <100 beats/min
- 1 month to 1 year: <90 beats/min

Otherwise unexplained persistent depression in neonatal heart rate over a 30-minute time period. Lack of neonatal heart rate variability has also been associated with other signs of clinical deterioration.

Potential Alterations in Respiratory Rate

Mean respiratory rate >95th percentile normal for age, as follows:

- Newborn to 1 week: >50 beats/min
- 1 week to 1 month: >40 beats/min
- 1 month to 1 year: >34 beats/min
- 2–5 years: >22 beats/min
- 6–12 years: >18 beats/min
- 13 to <18 years: >14 beats/min

- Mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia

Potential Alterations in Capillary Refill: either prolonged (>2 s) or "flash" (instantaneous)

Potential Alterations in Mental Status: Agitated or with decreased responsiveness

Potential Alterations in Pulse: Decreased/weak or bounding

Potential Alterations in Skin

- Mottled
- Ruddy/red
- Petechiae or purpura

These definitions and criteria have not been validated in newborns and are found in only about half of newborns with culture-positive sepsis.[15]

Systemic inflammatory response syndrome (SIRS) represents a nonspecific response to a variety of insults, including trauma, burns, pancreatitis, or infection. SIRS is present when the child demonstrates two or more of the following as an acute change from baseline: change in temperature, specifically fever (greater than 38.5°C [101.3°F]) or hypothermia (less than 36°C [96.8°F]); change in heart rate (tachypnea or, in infants, bradycardia); change in respiratory rate (or need for mechanical ventilation); or change in white blood cell (WBC) count (including leukocytes, leukopenia, or an increase in the percentage of immature or band forms of WBCs).[48] These clinical signs must be interpreted in light of the child's baseline organ and system function.

Sepsis is a systemic response to infection. It is present when manifestations of SIRS are observed in conjunction with suspected infection.

Positive cultures are not necessary for the diagnosis, but suspicion of infection is required.[48]

Septic newborns are more likely to demonstrate a decrease in heart rate variability rather than overt tachycardia or bradycardia. Fever is uncommon in newborns, and hypothermia may relate more to inadequate temperature support rather than hypothermia. Finally, no complete blood count (CBC) variable has been shown to reliably identify septic newborns.[15]

Severe sepsis is present when the child with sepsis (SIRS+suspected infection) develops cardiovascular or pulmonary dysfunction, or if the child has sepsis and evidence of two or more other organ dysfunctions.[48] The dysfunctional organ should be separate from the site of suspected infection and not explained by effects of drug therapy or other acute effects.[48] This important distinction helps separate signs of severe sepsis from signs of simple pneumonia with respiratory failure.

Septic shock is present when the septic child develops cardiovascular dysfunction characterized by hypotension or three or more signs of altered perfusion.[47]

Experts have proposed simplified consensus criteria for the recognition of pediatric septic shock. Kissoon, Orr, and Carcillo[49] suggested a simplified triad of fever, tachycardia, and vasodilation as diagnostic for pediatric sepsis, with septic shock likely when an altered level of consciousness is added to this triad. Carcillo and colleagues[39,49] distilled the international consensus definitions of septic shock to include suspected infection with hypo- or hyperthermia and clinical signs of inadequate perfusion. These signs of inadequate perfusion include any of the following: decreased level of conscious or change in mental status; prolonged (>2 seconds) capillary refill; abnormal pulses (either diminished or bounding with wide pulse pressure); mottled, cool extremities; or decreased urine output. Hypotension is not required for the diagnosis but, if present, is confirmatory.[39,49]

In 2017, the American College of Critical Care Medicine (ACCM) recommended that every hospital caring for children establish tools for identifying infants and children with the likelihood of septic shock and trigger bundled protocols for immediate resuscitation and stabilization.[47] The ACCM Pediatric Collaborative proposed a simplified sample list of eight potential triggers (Box 49.4) in the child presenting with "concern for infection or temperature abnormality." These eight criteria include: abnormal temperature, hypotension, tachycardia, tachypnea, abnormal capillary refill, abnormal mental status, abnormal pulse, and abnormal skin.

Presence of three or more of these eight criteria, or two or more of these eight in a high-risk individual (i.e., one with malignancy, bone marrow or solid organ transplant, immunodeficiency, immunocompromise, immunosuppression, cerebral palsy, developmental delay, or indwelling catheter) is consistent with sepsis/septic shock and should trigger immediate (within 15 minutes) clinical assessment and activation of the resuscitation bundle of interventions. Hypotension itself is an immediate trigger for such escalation of care.[47]

Box 49.4

Society of Critical Care Medicine Pediatric Collaborative Sample Findings to Trigger Septic Shock Resuscitation and Stabilization Bundles of Care

While assessing vital signs, obtaining history and performing physical examination (including evaluation of mental status, skin perfusion, pulses and capillary refill), identify any of the following potential triggers

- Temperature abnormality
- Hypotension (child immediately requires activation of septic shock resuscitation and stabilization bundle)
- Tachycardia
- Tachypnea
- Capillary refill abnormality
- Mental status abormality
- Pulse abnormality
- Skin abnormality

The child meets criteria for activation of septic shock resuscitation and stabilization bundle if hypotension is present, OR 3 or more of the above triggers are present, OR 2 or more of the above triggers are present in a high-risk individual (i.e., one with malignancy, bone marrow or solid organ transplant, immunodeficiency, immunocompromise, immunosuppression, cerebral palsy, developmental delay, or indwelling catheter).

From Davis AL, Carcillo JA, Aneja RK, et al. American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock. *Critical Care Medicine*, 2017;45(6):1061–1093. doi:10.1097/CCM.0000000000002425; Weiss SL, Peters MJ, Alhazzani W, et al. Executive summary: Surviving sepsis campaign international guidelines for the management of septic shock and sepsis-associated organ dysfunction in children. *Intensive Care Medicine*, 2020;46(suppl 1):1–9. doi:10.1007/s00134-019-05877-7.

Infants and children with septic shock may have a high, normal, or low cardiac output. Preterm newborns may maintain cardiac output but demonstrate severe vasodilation.[50] Unlike adults, who typically present with vasodilation, hypotension, and normal or high cardiac output, approximately half of children with septic shock present with severe peripheral vasoconstriction, high systemic vascular resistance, and low cardiac output.[39,49] Among children with CHD, sepsis is most likely to produce a decrease in cardiac output and perfusion and, postoperatively, is more likely to lead to the development of MODS.[35]

The terms *warm* and *cold septic shock* are imprecise terms and should be used only in conjunction with other descriptions of systemic perfusion and cardiovascular function.[51]

Warm shock is typically associated with peripheral vasodilation, warm skin with flash/immediate capillary refill, bounding pulses, and wide pulse pressure. **Cold shock** is typically associated with peripheral vasoconstriction, cold skin with prolon-ged capillary refill, and decreased peripheral pulses; these characteristics are present in almost half of children who present with septic shock.[51] Cardiac output may be low, normal, or high regardless of skin temperature, perfusion, and pulses; these characteristics alone will not identify the cardiovascular support required.

Evaluation and TreatmentResuscitation and stabilization bundle of care

The child with septic shock has hypovolemia, poor perfusion, and maldistribution of blood flow that requires immediate (within 15 minutes of identification of signs of septic shock) clinician assessment and activation of the *resuscitation bundle of care*. Within the next 5 minutes, providers should establish intravenous or intraosseous access; and within 15 to 30 minutes, clinicians should initiate appropriate bolus fluid resuscitation. Clinicians should also obtain a blood sample for culture and sensitivity *if* it does not delay antibiotic administration and correct hypocalcemia and hypoglycemia.

Within 60 minutes of the septic shock diagnosis, clinicians should administer broad-spectrum empiric antibiotics and, for fluid-refractory

septic shock, initiate and titrate vasoactive drugs.[26,47] Therapeutic goals include restoring systemic perfusion and blood pressure; normalizing heart rate, improving capillary refill, pulses, and urine output; maintaining adequate oxygen delivery; and controlling/eliminating the infection.[3,16,26,47,49,52,53]

For fluid resuscitation, the 2020 Surviving Sepsis International Guidelines now provide caveats regarding recommendations for fluid resuscitation for septic shock based on the presence or absence of hypotension and the availability of critical care resources within the system caring for the infant or child.[16]

> ***For the child in septic shock WITH availability of critical care resources***: Within the first hour, administer up to 2 to 3 fluid boluses of 10 to 20 mL/kg of isotonic crystalloid, titrated to clinical response (e.g., improve blood pressure and systemic perfusion, normalize heart rate, and improve urine output). Assessment is needed after each bolus to determine the tolerance of the bolus and the need for further boluses. Cease fluid bolus administration if new or worsening signs of fluid overload/heart failure (new or worsening rales, crackles, or hepatomegaly) develop.[3,16]
>
> ***For the child with septic shock and hypotension WITHOUT availability of critical care resources*:** In the first hour, begin fluid bolus administration. Provide up to two fluid boluses of 10- to 20 mL/kg of isotonic crystalloid, titrated to patient response, as noted previously. Up to 40 mL/kg can be administered within the first hour. Halt fluid administration if signs of fluid overload/new or worsening heart failure develop.[3,16]
>
> ***For the infant or child with septic shock but no hypotension WITHOUT availability of critical care resources:*** The 2020 Surviving Sepsis International Guidelines recommend against bolus fluid administration for these individuals. Instead, they recommend that providers begin maintenance fluid administration.[3,16] As noted, initiation of vasoactive drug administration is necessary within 60 minutes of the diagnosis of septic shock if shock persists despite bolus fluid administration. The evidence for the selection of an initial vasoactive agent is extremely limited. In a small, randomized prospective trial in children with septic shock, the use of epinephrine was associated with higher survival (14% vs. 7%) than the use of dopamine.[54] However, experts agree that the

doses of epinephrine used in this study were likely to produce a greater physiologic effect than the doses of dopamine used in the study, so many questions remain.[55] The 2017 ACCM review and the 2020 Surviving Sepsis International review identified no evidence regarding the use of norepinephrine in pediatric septic shock.[47]

Considering the evidence limitations, pediatric experts authoring both the ACCM and the Surviving Sepsis International Guidelines reported their clinical preference (e.g., expert opinion) for use of epinephrine in persons with septic shock, myocardial dysfunction and low cardiac output, and their clinical preference for use of norepinephrine for children with septic shock and vasodilation.[16,47] If central venous access is not available, epinephrine and dopamine can be administered via peripheral intravenous catheter with great caution to monitor for tissue extravasation.[47]

In a small, but seminal, 1991 study of children with septic shock, Carcillo, Davis, and Zaritsky[52] showed that rapid fluid resuscitation within the first hour of therapy was associated with significantly higher survival than less aggressive fluid resuscitation. As a result, until recently, clinicians administered multiple (2 to 3 or more) fluid boluses in the first hours of resuscitation to children in septic shock. However, experts now agree that during resuscitation of the child in septic shock, clinicians must focus both on the importance of treating hypovolemia and on the importance of preventing the development of hypervolemia or new or worsening heart failure.[3,16] This is the reason for the modified recommendations to administer *up to* 2 to 3 fluid boluses of 10 to 20 mL/kg (rather than 2 to 3 or more boluses of 20 mL/kg) and re-emphasis on the need for careful evaluation of the child's response to each fluid bolus, halting bolus fluid administration if signs of hypervolemia or new or worsening heart failure develop (e.g., new or worsening signs of respiratory distress, rales, or hepatomegaly).[16]

A positive response includes evidence of improved cardiac output and systemic perfusion. These recommendations are consistent with those of the AHA Pediatric Advanced Cardiac Life Support guidelines.[3]

As noted, clinicians must administer broad-spectrum empiric antibiotics within 60 minutes of identification of septic shock. Note that this 60-minute interval begins as soon as the child is diagnosed; this diagnosis and start of the 60-minute interval may occur in the prehospital setting. Emergency surgical consultation is indicated if infection source control is likely to require surgical intervention.

Within 60 minutes, if the child is at risk for absolute adrenal insufficiency, or the shock is refractory to fluid and vasoactive drug administration, clinicians should consider the administration of hydrocortisone.[47]

The *stabilization bundle of care* requires multimodal monitoring of cardiac and pulmonary function, as well as monitoring and support of other organ system functions to guide fluid, hormone (e.g., hydrocortisone), vasoactive, and renal therapies. Cardiovascular targets include a normal perfusion pressure (i.e., difference between mean arterial pressure and CVP [MAP-CVP] of 55 mmHg+1.5×age in years), an $ScvO_2$ greater than 70%, and/or a cardiac index of 3.3 to 6.0 L/min/m^2.[47]

Frequent monitoring of serum lactate is helpful, as a fall in serum lactate should accompany improvement in systemic perfusion. Early use of renal replacement therapies aids in hemodynamic support and maintenance of appropriate intravascular volume.[1,47]

An algorithm for the treatment of septic shock, based on the recommendations of the ACCM and the Pediatric Advanced Life Support course, is presented in Fig. 49.2.

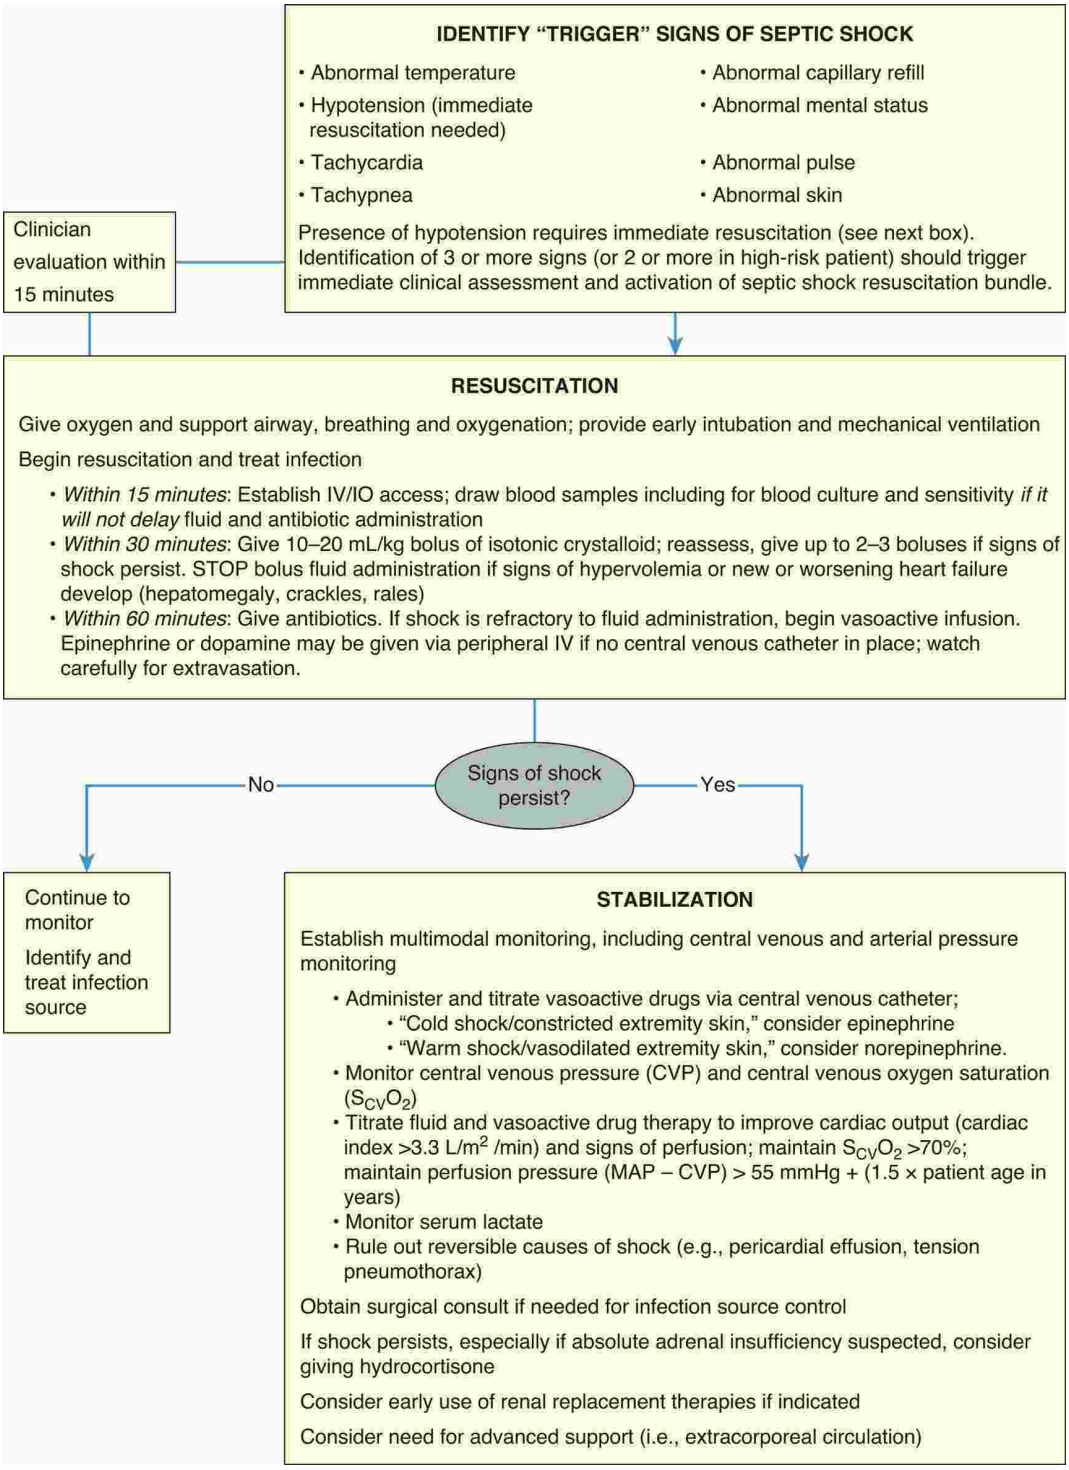

FIG. 49.2 Hemodynamic Support in Pediatric Septic Shock When Critical Care Is Available.
BSA, Body surface area; *IO*, intake/output; *IV*, intravenous. (Modified from Perkin RM, et al. Shock, cardiac arrest and resuscitation. In: Hazinski MF, ed. Nursing care of the critically ill

child, 3rd edition. St. Louis: Mosby; 2013:126. Updated to include information from: Davis AL, Carcillo JA, Deymann AJ, et al. The American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock: Executive summary. *Pediatric Critical Care Medicine*, 2017;18:884–890.)

A flow chart represents an algorithm for treating septic shock, based on the recommendations of the A-C C M and the Pediatric Advanced Life Support course as follows. • Clinician evaluation within 15 minutes includes identifying trigger signs of septic shock and resuscitation. • Identify trigger signs of septic shock includes abnormal temperature; abnormal capillary refill; hypotension (immediate resuscitation needed); tachycardia; tachypnea; abnormal capillary refill; abnormal mental status; abnormal pulse; abnormal skin; Presence of hypotension requires immediate resuscitation (see next box). Identification of 3 or more signs (or 2 or more in high-risk patient) should trigger immediate clinical assessment and activation of septic shock resuscitation bundle. • Resuscitation includes oxygen and support airway, breathing and oxygenation; provide early intubation and mechanical ventilation. Begin resuscitation and treat infection • Within 15 minutes: Establish I V/I O access; draw blood samples including for blood culture and sensitivity if it will not delay fluid and antibiotic administration. • Within 30 minutes: Give 10 to 20 milliliters per kilogram bolus of isotonic crystalloid; reassess, give up to 2 to 3 boluses if signs of shock persist. STOP bolus fluid administration if signs of hypervolemia or new or worsening heart failure develop (hepatomegaly, crackles, rales). • Within 60 minutes: Give antibiotics. If

shock is refractory to fluid administration, begin vasoactive infusion. Epinephrine or dopamine may be given via peripheral IV if no central venous catheter in place; watch carefully for extravasation. • Sign of shock persists?. If yes, stabilization; if no, continue monitoring, identifying, and treating the infection source. • Stabilization includes the Establish multimodal monitoring, including central venous and arterial pressure monitoring. • Administer and titrate vasoactive drugs via central venous catheter; Cold shock/constricted extremity skin," consider epinephrine; Warm shock/vasodilated extremity skin," consider norepinephrine. • Monitor central venous pressure (C V P) and central venous oxygen saturation (S C V O 2); titrate fluid and vasoactive drug therapy to improve cardiac output (cardiac index greater than 3.3 liter per meter square per minute and signs of perfusion; maintain S C V O 2 greater than 70 percent; maintain perfusion pressure (M A P and C V P) greater than 55 millimeters of mercury plus (1.5 into patient age in years). • Monitor serum lactate. • Rule out reversible causes of shock (e.g., pericardial effusion, tension pneumothorax). • Obtain surgical consult if needed for infection source control. • If shock persists, especially if absolute adrenal insufficiency suspected. • Consider giving hydrocortisone. • Consider early use of renal replacement therapies if indicated; Consider need for advanced support (i.e., extracorporeal circulation).

Performance bundle of care

Every system caring for infants and children in septic shock must establish a process of continuous quality of improvement. This requires an organized system to monitor not only the treatment provided but also the interval

required to identify the individual in septic shock and initiate appropriate resuscitation and stabilization. Such continuous quality improvement programs are designed to identify barriers to timely treatment and ensure that treatment adheres to best practice guidelines (e.g., ACCM and AHA PALS Guidelines). Implementation of the ACCM consensus recommendations for hemodynamic support of children with septic shock has been associated with decreased mortality (from 35% to 40% mortality to 2% to 8% mortality).[47,49] In fact, for every hour of delay in the restoration of normal blood pressure for age and restoration of capillary refill less than 3 seconds, mortality from pediatric septic shock can double.[39,47,49] Ames et al. published an excellent editorial summarizing important steps for improving outcomes of septic shock.[56]

Neurogenic Shock

Clinical Manifestations

Signs of neurogenic shock in the child with a recent, severe spinal cord injury include warm skin and hypotension with a low diastolic blood pressure. Signs of poor systemic perfusion also are observed (see Assessment of Shock), although the loss of sympathetic nervous system tone prevents the typical tachycardic response.

Evaluation

and Treatment

Treatment of neurogenic shock includes positioning to enhance venous return, bolus fluid therapy as needed to support cardiac output, and administration of vasopressors to treat fluid-refractory hypotension. Supplementary warming or cooling is likely to be needed to support normothermia.[26]

Obstructive Shock

Pathophysiology

Obstructive shock is inadequate cardiac output caused by an impediment to blood flow to or from the heart into the pulmonary or systemic circulation. Causes of obstructive shock in children include congenital heart defects (such as critical aortic stenosis and those with ductal-dependent pulmonary or systemic blood flow), tension pneumothorax, and pulmonary embolus.

Obstruction to blood flow results in low cardiac output and circulatory collapse, typically with signs of peripheral vasoconstriction as adrenergic stimulation diverts blood flow from the skin, gut, and kidney to the heart and brain. Signs of systemic or pulmonary venous obstruction are observed.

Clinical Manifestations. Additional clinical manifestations of obstructive shock are based on the cause of the obstruction. For example, the newborn with ductal-dependent pulmonary blood flow develops profound hypoxemia when the ductus arteriosus begins to constrict. If a newborn has ductal-dependent systemic blood flow, systemic pulses become faint or absent, extremities become cold and pale, and signs of pulmonary venous congestion can develop when the ductus arteriosus begins to close. Tension pneumothorax produces signs of systemic venous obstruction and congestion, decreased breath sounds and decreased chest expansion on the side of the pneumothorax, and shift of the mediastinum to the contralateral chest. Significant hypoxemia is present. When cardiac tamponade is the cause of the obstruction, signs of systemic or pulmonary edema, or both, develop with low cardiac output. Additional signs can include muffled heart sounds and pulsus paradoxus, although low cardiac output may severely decrease the quality of all pulses. When pulmonary embolus is the cause of the obstruction, hypoxemia, severe respiratory distress/shortness of breath, hypoxemia, and signs of right ventricular failure are observed.[1,23]

Evaluation

and Treatment

Treatment of obstructive shock requires restoration of systemic oxygenation and perfusion with elimination of the obstruction to flow. To support systemic oxygenation and perfusion, providers must establish and maintain an adequate airway and support oxygenation and ventilation. Diagnostic studies are limited to those essential to the establishment of the diagnosis. Elimination of the cause of obstruction may require administration of prostaglandin E_1 (to reopen a constricted ductus arteriosus in newborns with ductal-dependent CHD), interventional cardiac catheterization for treatment of other defects causing obstruction, needle decompression of a tension pneumothorax or cardiac tamponade, or fibrinolytic therapy and fibrinolytics (and possible embolectomy) for treatment of massive pulmonary embolus.[1,26]

If cardiac tamponade is present, bolus fluid administration may transiently improve cardiac output while preparations are made for pericardiocentesis.

However, this should not delay definitive therapy.

Reperfusion and Inflammatory Injury

Reperfusion (reoxygenation) injury is cell damage caused by the restoration of blood flow and oxygen delivery to cells that have been exposed to injurious, but nonlethal, hypoxic conditions.[57]

Pathophysiology. Ischemia causes changes in transmembrane permeability to sodium and calcium and damage to intracellular organelles.[58] This damage triggers a pro-inflammatory and procoagulant response that can be very similar to that caused by septic shock (described previously).

Restoration of oxygen delivery to extremely ischemic tissues produces highly reactive oxygen intermediates (e.g., free oxygen radicals and superoxide) that damage cell membranes, denature proteins, and disrupt chromosomes (see Chapter 2).[58] The amount of free oxygen radicals produced is directly related to the severity and duration of the ischemic period. The reperfusion process is most likely to affect endothelial cells of the microvasculature, compromising organ perfusion after shock resuscitation.[57,58]

An ischemic insult activates WBCs, priming monocytes and macrophages and contributing to the release of inflammatory mediators or cytokines, including TNF, IL-1, IL-6, IL-8, and platelet-activating factors. These cytokines in turn contribute to vasodilation, increased capillary permeability, and altered platelet function. The ultimate result is a maldistribution of blood flow and a compromise in organ perfusion and function.[57,58] The role of these mediators is summarized in Chapter 8; Chapter 48 includes a more comprehensive discussion of MODS.

Clinical Manifestations. Signs of organ dysfunction include, but are not limited to, lactic acidosis, oliguria, and an acute alteration in level of consciousness (e.g., decrease in Glasgow Coma Scale score of 1 point or more from baseline); hypoxemia, hypotension, poor capillary refill, or shock plus signs of coagulopathy; respiratory, renal, or hepatic dysfunction; or neurologic dysfunction. CIH also may be present. Gut injury and inflammation may enable translocation of gram-negative bacteria or endotoxin into the bloodstream and may contribute to GI bleeding.[59]

Several predictive and descriptive scoring systems are available to characterize the severity of illness in critically ill children with organ dysfunction. Outcome scores include the Pediatric Logistic Organ Dysfunction (PELOD) scoring system[60] and the Pediatric Multiple Organ

Dysfunction Score (P-MODS).[60–62] These scoring systems may be useful in conjunction with other factors such as prognostic indicators when they are applied for several days. Important differences exist between neonates and children in terms of mortality associated with specific organ failures and with specific PELOD scores.[61]

Evaluation and Treatment[63] The best available model of pediatric reperfusion injury is the child who survives cardiac arrest. "Bundled" post-cardiac arrest care, including meticulous targeted temperature management (strict continuous monitor-ing and maintaining of central body temperature as either hypothermic [32° to 34°C/89.6° to 93.2°F] or "normothermic," [36°C/96.8°F] with control of temperature to prevent or promptly treat fever), as well as protocol-based support of cardiorespiratory function and function of other organ systems, has been shown to substantially increase neurologically intact survival to hospital discharge in adults who survive cardiac arrest.[64] Such a "bundled" approach is now pursued with children. This care typically requires the transfer of the child to a medical center with appropriate pediatric critical care expertise.[1,63]

Fever typically develops following resuscitation from cardiac arrest and is associated with unfavorable neurologic outcome.[65] Therapeutic hypothermia suppresses pro-inflammatory mediators and may enhance anti-inflammatory mediators.[66,67] Mild to moderate induced hypothermia (to 32° to 34°C [89.6° to 93.2°F]) was associated with increased survival in neurologic outcome in neonates with hypoxic-ischemic encephalopathy[68] and in comatose, hemodynamically stable adults following resuscitation from cardiac arrest.[69] However, the control groups in these neonatal and adult hypothermia studies were febrile, so that may have lowered survival in the control group. Three recent large, multicentered randomized clinical trials comparing strict maintenance of normothermia (36°C [96.8°F]) to moderate therapeutic hypothermia (33°C [91.4°F]) demonstrated neither benefit nor harm to the use of cooling in adults[70] or children with out-of-hospital cardiac arrest[71] or in-hospital cardiac arrest.[72] For this reason, the AHA PALS guidelines recommend strict control of temperature either in the hypothermic (to 32° to 34°C [89.6° to 93.2°F]) or normothermic (36°C [96.8°F]) range for the child who remains comatose following resuscitation from cardiac arrest.[3]

Support of airway, oxygenation, and ventilation includes oxygen administration and intubation and support of ventilation to maintain arterial oxygen saturation at 94% to 99% and avoid hypoxemia. Of course, if cyanotic heart disease is present (e.g., single ventricle), the arterial oxygen saturation

is typically maintained at 65% to 75%. Support of ventilation is titrated to maintain a $PaCO_2$ within the child's normal range.

Continuous monitoring of blood pressure is indicated. Hypotension during post-cardiac arrest care can contribute to a worse neurologic outcome, so it must be promptly detected and aggressively treated. Titration of inotropic and vasoactive drugs is typically required (see Table 49.7), and bolus fluid administration may be needed. Additional treatment of shock has been summarized earlier in this chapter. If the child remains hemodynamically unstable with conventional management of shock, mechanical support of circulation should be considered in the appropriate setting.

Prevention of secondary neurologic insult requires targeted temperature management with strict maintenance of normothermia and prevention or aggressive treatment of fever. In addition to the support of airway, ventilation, and circulation, careful maintenance of fluid and electrolyte balance is imperative. If renal failure develops, early use of renal replacement therapies is indicated. If seizures develop, they must be managed aggressively.[73]

A thorough presentation of pediatric reperfusion injury and post-resuscitation care is beyond the scope of this chapter. The reader is referred to a comprehensive 2019 AHA Scientific Statement, Pediatric Post-Cardiac Arrest Care (see the box Emerging Science Box: Therapies for Shock and Sepsi).[63]

Emerging Science BoxTherapies for Shock and Sepsis

Prevention of shock is important. Prevention of trauma (injury prevention) and treatment of dehydration can eliminate the two leading causes of hypovolemic shock in children. The incidence of septic shock from hospital-acquired infections, such as ventilator-associated pneumonia or catheter-related bloodstream infections, is decreasing with the use of quality improvement approaches.[29]

Advances in shock therapy show promise for continued improvement in treatment. There is a better understanding of resuscitation goals with an appreciation of the need to target adequate, rather than "normal", cardiac output and oxygen delivery during resuscitation. Second, technological improvements are increasing our ability to assess cardiac output.

Trauma resuscitation also has become more targeted in adults and children. In the prehospital setting, prehospital fluid resuscitation is reserved for children with signs of shock. If penetrating trauma is associated with hypovolemic shock, the child requires urgent transport and surgical intervention, rather than attempts to aggressively treat the shock at the site of injury.

Because massive transfusions can produce immunologic and coagulation complications, the surgical approach to trauma has changed to include staged surgical repair of significant injuries (e.g., liver and bowel injuries). The initial surgery is performed to stabilize the child, and, if needed, subsequent procedures repair the injury. This multistage approach, based on battlefield experiences, reduces the volume of blood products administered and has been linked with reduced morbidity and mortality.[24]

Major advances have been made in understanding the pathophysiology of septic shock and MODS in children. These advances are beginning to be applied to modify clinical evaluation and treatment.[75] Patterns of alterations in biomarkers of sepsis—so-called biomarker signatures—may enable the identification of children at high risk for sepsis, in order to provide more careful monitoring and early intervention. In addition, if alterations in concentrations of biomarkers can be identified at the time they occur, modulation of biomarker activity may be possible using strategies such as receptor antagonists.

It soon may be possible to tailor sepsis and other critical therapies through the use of genetic profiling of the microorganism[33] and of the child.[32,75] Prospective identification of genetic markers for risk of sepsis and responsiveness to therapy may enable individual tailoring of surveillance and interventions to maximize survival and minimize risks from those therapies that are unlikely to be effective.

Finally, several devices are available that enable noninvasive or minimally invasive calculation of cardiac output and index, stroke volume, and circulating blood volume in children.[2] As providers gain experience with the use of such devices and more published data are available about their reliability in children, there will be more tools to confirm clinical assessment and monitor response to therapy.

Systems of continuous quality improvement are essential to identify barriers to, or delays in, appropriate treatment and enable improvement in survival from shock, particularly septic shock.

Burns

Management of pediatric burn injuries requires an understanding of the differences that exist in this population related to the etiology of injury, growth and development, physiology, and clinical course. In 1988, the American Burn Association established criteria to guide the transfer of an individual to a specialized burn center (see Chapter 48). These criteria remain a standard in burn care and are based on complex management issues related to the treatment of acute burns within the first 24-hour post-burn injury.

Burn injuries in children often are preventable and are frequently the result of curiosity, inability to escape the burning agent, inadequate supervision, or nonaccidental burn trauma. **Scald injuries** (e.g., hot water and grease) are most common among young children, whereas flame burns are more prevalent among older children.[74] A child exposed to hot tap water at 60°C (140°F) for 3 seconds will sustain a third-degree burn.[75]

A child's skin is thinner and thus more susceptible to injury than an adult's. The extent of injury is determined by the temperature of the burning agent and the duration of exposure. Because very young children may be unable to escape the heat source, the depth of the injury is likely to be greater. The kitchen tends to be a common site for burn injury and often involves pulling over dishes or appliances containing hot liquids. Tap water burns from the bathroom, compared to other scald burns, are likely to be more severe and cover a greater surface area of the body. These are common burn injury sources for children 5 years of age and younger.

Children 3 to 9 years of age are most often injured by flame during fire play. Lighters and matches ignite clothing and cause house fires. Young children may run when clothing ignites and this increases the severity of injury. Inhalation injury significantly increases mortality for pediatric patients with a severe burn injury.[76] Escape from a burning residence or motor vehicle is often delayed because young children cannot cognitively comprehend the circumstances or physically remove themselves from the danger. **Flame burns** involving flammable liquids, especially gasoline, are more common in older children.

Although flame and scald burns account for the majority of thermal injuries in children, **electrical burns** result from direct contact with high- or low-voltage current. Most commonly, these injuries occur as a result of risk-taking behavior on the part of young males. Trauma from contact with electrical energy results from the passage of current through vital organs, muscle compartments, and nerve or vascular pathways. Very young children

are at risk for injury from chewing on electrical cords or inserting objects into electrical outlets (Fig. 49.3). Lightning strikes also account for some electrical injuries. **Chemical burns** occur most often in an industrial setting for the adult. At home, children may be burned by swallowing corrosive agents such as cleaning products. The type of causative agent has important implications for the evaluation, treatment, and prognosis of the child.

FIG. 49.3 Commissure Burn Resulting from Biting an Electrical Wire. (Courtesy Mary Fran Hazinski.)

Although **child abuse** can occur at any age, young children are particularly vulnerable to serious injury. Approximately 3% to 24% of children who have sustained a burn injury are referred to child protective services for suspicion of abuse.[77] Burns that may suggest nonaccidental trauma include (1) patterned burns, (2) forced immersion burn patterns with sharp stocking or glove demarcation and sparing of flexed protected areas, (3) splash/spill burn patterns not consistent with history or developmental level, and (4) contact burns with well-defined margins of the object.[78] Abuse is suggested with (1) historical inconsistencies and physical examination; (2) incompatible burn and developmental level; (3) bilateral or mirror image burns; (4) localized burns to genitals, buttocks, and perineum (especially at

toilet-training stage); (5) evidence of excessive delay in seeking treatment; and (6) presence of other forms of injury.[78] Forced immersion in hot water typically presents with deep symmetric injuries lacking any evidence of splash wounds (Fig. 49.4). By contrast, a pull-down splash burn usually has a triangular pattern with immediate skin contact reflected as the area of greatest burn injury. The burn injury then forms an arrow pointing downward. **Contact burns** also may be intentionally inflicted by contact with cigarettes or other hot objects, such as curling irons. Young children often sustain burns to the palms of their hands while inadvertently grasping a hot object. If a burn occurs to the back of the hand, this lends cause for suspicion. The provider must rule out diseases or conditions that mimic burn injury, such as diaper dermatitis, scalded skin syndrome, or impetigo, when assessing for abuse.

FIG. 49.4 Burn Pattern Typically Seen After Forced Immersion in Hot Water.

Severity of Injury

The severity of burn injury is assessed based on the percentage of the total body surface area (TBSA) involved. Use of the standard Rule of Nines results

in inaccurate calculation of the percentage of TBSA involved in children. Although the infant's trunk and arms are of roughly the same proportion as the adult's, the head and neck make up 18% of TBSA and each lower extremity is 14% of TBSA. A modified Rule of Nines deducts 1% from the head and adds 0.5% to each leg for each year of life after 2 years (Fig. 49.5).[79] Various charts are available that assign body proportions to children of different ages. These are generally used in pediatric burn facilities and accurately compute the extent of burn injury.

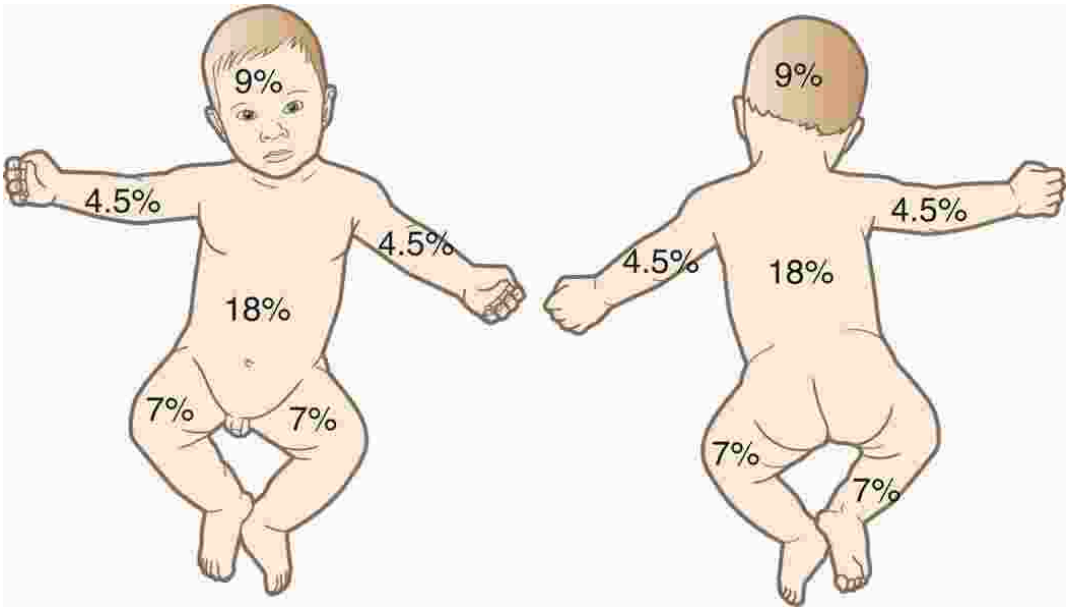

FIG. 49.5 Rule of Nines for Pediatric Burns. (Adapted from American Burn Association. *Pediatric burn injuries. Advanced burn life support provider manual 2018 update*. Chicago, IL: American Burn Association; 2018.)

The body diagram illustrates the percentage of total burned surface area in an infant. The illustration on the left depicts the anterior view of an infant showing the percentage of total burned surface as head 9 percent; body 18 percent; left upper extremity 4.5 percent; right upper extremity 4.5 percent; left lower extremity 7 percent; right lower extremity 7 percent. The illustration on the right depicts the posterior view of an infant showing the percentage of total burned surface as head 9 percent; body 18 percent; left upper extremity 4.5 percent; right upper extremity 4.5 percent; left lower extremity 7 percent; right lower extremity 7 percent.

Because burn trauma represents a three-dimensional wound, the severity of injury is assessed also in relation to the **depth of injury**. The etiology of the burn and the duration of contact with the burning agent are important

considerations in determining the depth of injury. In general, the more intense the heat source and longer the contact, the deeper the resulting injury; however, infant skin is extremely fragile and more likely to sustain a deeper burn. This makes the estimation of the depth of burn difficult in very young children, especially following scald injuries (Fig. 49.6). Intentionally inflicted burns tend to be more severe because contact with the burning agent is prolonged. Electrical injuries also may mask the extent of damage on initial assessment. Visible tissue damage may appear minimal despite severe injury to underlying structures.

FIG. 49.6 Areas of Indeterminate Depth of Injury in a Young Child.

The body diagram illustrates the percentage of total burned surface area in an infant. The illustration on the left depicts the anterior view of an infant showing the percentage of total burned surface as head 9 percent; body 18 percent; left upper extremity 4.5 percent; right upper extremity 4.5 percent; left lower extremity 7 percent; right lower extremity 7 percent. The illustration on the right depicts the posterior view of an infant showing the percentage of total burned surface as head 9 percent; body 18 percent; left upper extremity 4.5 percent; right upper extremity 4.5 percent; left lower extremity 7 percent; right lower extremity 7 percent.

Another important factor in assessing the severity of injury is the victim's age. Children younger than 2 years have a significantly higher risk for associated morbidity and mortality after sustaining a burn injury. They have not achieved maturity of the immune system and are at increased risk for infection and sepsis. In addition, very young children are intolerant of rapid fluid shifts and demonstrate immature renal function, negatively affecting their ability to retain sodium and water (see Shock).

The areas of the body injured are another consideration when assessing the severity of the burn. Burns of the hands, feet, perineum, and across joints carry the potential for scar formation and contracture that may interfere with function as well as growth and development. Specialized care is required to preserve maximal function. In addition, burns to the face and neck may result in airway compromise as well as deformity caused by damage to delicate cartilage of the nose and ears.

Other associated trauma or injuries due to the circumstances of the burn should always be investigated. Initially, burns do not bleed. Bloody drainage to an area of the body, even with a burn, suggests another source of trauma. Fractures may result from jumping from a window to escape a house fire. Electrical injuries and motor vehicle accidents often result in associated trauma. Any suspicion of nonaccidental burns should alert the burn team to assess for other injuries.

Pathophysiology, Clinical Manifestations, and Treatment

Major burn trauma involves all body systems, and the consequences of injury include shock, infection, hypermetabolism, organ failure, and functional limitations. These effects can be magnified in the pediatric population as a result of physiologic immaturity and age-related variation in treatment modalities. Along with recognition of changes in the pathophysiology with a burn injury, clinical manifestations are apparent in all organ systems. Although the cutaneous trauma is the initiator of the chain of responses, it is important to consider all of the likely consequences of the injury. An awareness of the changing patterns of convalescence and the development of complications assists in the identification and early treatment of potential sequelae.

Integument

The local response manifested in the area of trauma includes a reduction of tissue perfusion, cellular destruction, and an inflammatory response.

Progressive injury caused by **dermal ischemia** may result from ineffective initial management, especially inadequate or delayed fluid resuscitation. An increase in the permeability and hydrostatic pressure of the capillaries results in the shift of fluid, proteins, and electrolytes into the interstitial spaces. A diminishing intravascular oncotic pressure further enhances these shifts and results in edema formation. Marked edema can result, not only in the area of injury but also in unburned areas. Complications arising from edema are caused by both local and systemic capillary leak.[80] Loss of substantial areas of skin has immediate and profound physiologic effects. Although these losses are maximal in the immediate post burn period, they persist until wound closure.

Circulatory alterations also occur in the area of injury. Reduced blood flow and capillary stasis result from **hemoconcentration**, the release of thromboplastin and clot-activating factors from heat-damaged cells, reduced cardiac output, and edema formation. Circulation in the area of partial-thickness wounds ceases for 24 to 48 hours after injury, after which it is usually restored. Vascular supply in the area of full-thickness injuries is completely occluded and is not restored until granulation tissue forms or the wound is surgically repaired. The dry, leathery **eschar** provides an ideal environment for bacterial growth. Infection, trauma, or applying ice to the burn area may convert a partial-thickness injury to a full-thickness one, especially in young children, who have thinner, more delicate skin.

Vitamin D, an essential factor for the proper formation of bone during growth and development, is an important nutrient in children to facilitate intestinal absorption of calcium. Even though vitamin D plays no direct role in burn wound healing, a deficiency of this vitamin has been associated with adverse effects on the skeletal system, as well as on the immune system, which can lead to an increased risk of infection. Vitamin D production may be compromised in burned children, demonstrated by a high incidence of low serum vitamin D levels. Burn-wound scarring and lack of sunlight may limit cutaneous vitamin D biosynthesis.[81]

Cardiovascular System

The marked reduction in cardiac output immediately following injury is accompanied by an initial increase in systemic vascular resistance. As fluid is lost into the interstitial spaces, a further reduction in cardiac output occurs, accompanied by vasodilation. Because the infant maintains cardiac output by increasing heart rate preferentially to stroke volume, extremely elevated heart rates result in a decreased filling time and a further reduction in

cardiac output.[82] An adequate resuscitation returns cardiac output to normal levels in approximately 24 to 36 hours. Without fluid replacement, cardiac output continues to decrease and results in organ failure and death.

The inefficient and labile peripheral circulation of the infant further complicates management of the burn shock phase of treatment. Related to circumferential full-thickness burns, the rapid fluid shift to the interstitial space and drying of the eschar results in compromised circulation and a resultant tourniquet effect in the extremities. This fluid shift in the torso results in compromised circulation as well as reduced muscle movement impeding respiratory effort. An **escharotomy** is a procedure that relieves pressure, restores circulation, and improves muscular and respiratory effort (Fig. 49.7). As muscular edema intensifies (frequently seen in electrical injuries) blood vessels and nerves become entrapped because the fascia cannot expand to accommodate the massive edema. Release of pressure is required by a **fasciotomy** to restore blood flow and preserve nerve function (Fig. 49.8).

FIG. 49.7 Escharotomy in a Severely Burned Arm.
(Courtesy Mary Fran Hazinski.)

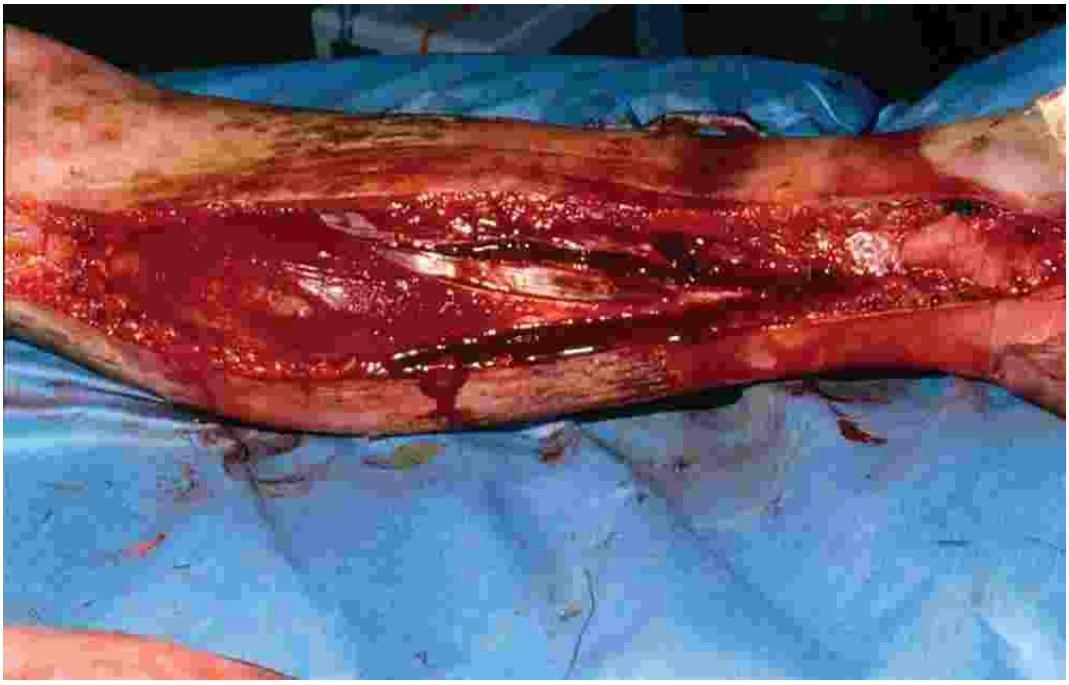

FIG. 49.8 Fasciotomy in a Severely Burned Arm. (Courtesy Mary Fran Hazinski.)

A higher risk of chest constriction and impairment of respiratory excursion may result because of the increased pliability of the rib cage, especially in very young children. Excessive fluid volume and burns to the chest or abdomen decrease compliance and can contribute to a serious complication (increased intra-abdominal pressure) that may have an underestimated incidence in burned individuals. Although children with increased intra-abdominal pressure readings tended to be younger, larger TBSA injuries and full-thickness components were significantly associated with elevated pressures and can result in tissue ischemia.[83] Increased **intra-abdominal pressure** has the potential to impair hemodynamics, renal function, hepatic malperfusion, and pulmonary dysfunction. Despite maintaining cardiac output with fluid replacement, renal function remains impaired in the presence of increased intra-abdominal pressure. Intra-abdominal pressure, as a stressor, can stimulate the neuroendocrine system and elicit stress reactions directed at neutralizing the initial insult of the burn. Increases in the production and release of catecholamines, glucocorticoids, inflammatory mediators such as tumor necrosis factor (TNF-α), and insulin resistance support the clinical finding of profoundly altered cardiovascular, pulmonary, and renal function.[84,85]

Pulmonary System

The clinical manifestations of burn injury related to the pulmonary system include a variety of complications ranging from inhalation injury, pulmonary edema, and respiratory failure to aspiration of gastric contents and pneumonia. Inhalation injury has a negative, prolonged effect on pulmonary function that is associated with, and remains, a major determinant of increased morbidity and mortality.[86]

Anatomic differences in the pediatric airway affect the response to pulmonary complications, as well as therapeutic interventions. The infant airway is positioned anteriorly, making visualization of the cords more difficult. The difficult visualization is further compounded by the relatively large tongue and slanting vocal cords. A small degree of edema results in greatly increased work of breathing in the child (Fig. 49.9). These considerations are particularly important during the resuscitation phase when progressive edema threatens to obstruct the airway. Significant edema results in impairment of respiratory function unless an artificial airway is inserted (Fig. 49.10). Malposition of an endotracheal tube may result in inadvertent extubation, intubation of the bronchi, and atelectasis. Because of the relatively short length of the infant trachea, alterations of the position of the head and neck can affect tube position despite maintenance of the tube position at the teeth.[87–89]

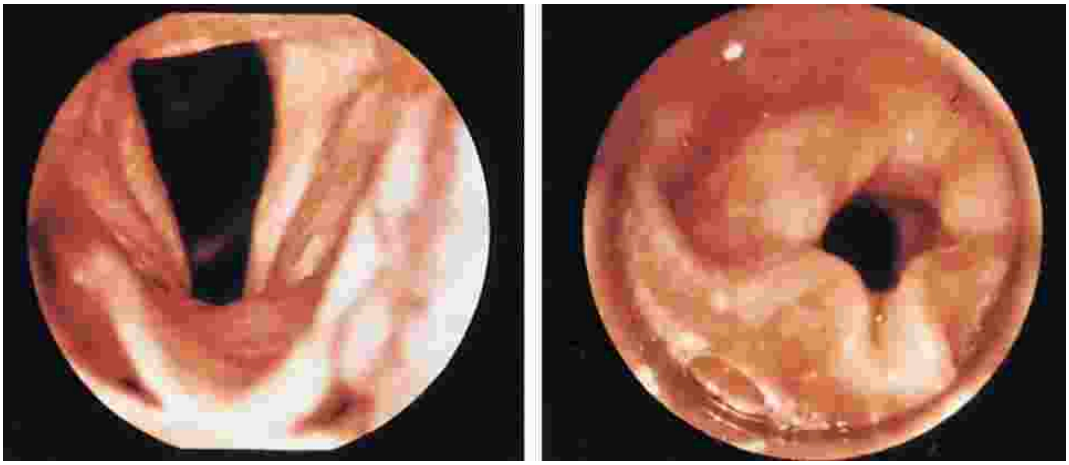

FIG. 49.9 Airways.
Adult airway *(left);* smaller pediatric airway *(right)*.

FIG. 49.10 Severe Facial Edema During Burn Shock.

Infants and children compensate for pulmonary compromise by increasing the respiratory rate. However, because the child possesses fewer type I muscle fibers, fatigue related to the increased work of breathing results in more rapid desaturation than in adults. The soft cartilage of the pediatric airway is prone to collapse in the presence of partial obstruction. Children with burns are at increased risk for these events made more complex by underlying respiratory disease or injury.

Smoke inhalation causes pulmonary parenchymal damage, resulting in decreased pulmonary compliance and increased airway resistance. Several ventilator models are found to be used to compensate for this pulmonary damage. However, for conventional models, conflicting evidence exists. In one research study, high tidal volumes decreased ventilator days and atelectasis, but increased pneumothorax, as compared to low tidal volumes. Mortality was not affected. Non-conventional ventilators include high-frequency percussive ventilation (HFPV) and high-frequency oscillatory ventilation (HFOV). HFPV requires high frequency small tidal volumes, low-frequency breathing rates and a low-pressure circuit, which may improve gas exchange and airway pressure. Outcomes, when compared to conventional ventilation, offered less incidence of pneumonia, lower peak inspiratory pressure, and decreased work of breathing. HFOV provides high respiratory rates with low tidal volumes, which generates a high flow of O_2 without a substantial increase in airway pressure. HFOV demonstrates improved oxygenation. Clinicians are vigilant for post-extubation stridor and pulmonary damage due to ventilation during the course of treatment.[76]

Additional non-ventilatory measures include pronation and extracorporeal membrane oxidation (ECMO) of the individual. Pronation reduces the work of breathing because the masses of the heart and bronchial tree are inverted, allowing for better expansion of the lungs.[88] ECMO is a treatment being used more often for persons with burns demonstrating acute hypoxemic respiratory failure and hemodynamic instability when other medical management options have been exhausted. With ECMO, the person's blood from the body is redirected to the device, oxygenated, and CO_2 removed before it is returned to the body. Even though studies on the safety of ECMO in the pediatric population are limited, value has been found in this treatment modality, and it should be considered as an added level of support. After inhalation injury, ECMO may provide time for organ function recovery, therefore increasing the tendency for survival.[89]

The consequences of metabolic and physiologic changes occurring during the acute phase of injury remain apparent during convalescence. Severe

burns result in a decrease in pulmonary function from restrictive and obstructive pulmonary disease evidenced by a reduction in pulmonary volumes and maximum voluntary ventilation lasting up to 8 years. At times, chest wall scarring in children caused by burns severely limits thoracic cage excursion.

Burn Shock

The pathophysiologic responses of burn injury result in **hypovolemia** and extracellular sodium depletion in the burn-injured individual. Manifestations for adults are discussed in Chapter 48. Hypotension is a late sign of shock in the child. A complete circulatory assessment, including heart rate and peripheral parameters, is a more reliable measure. Urine output reflects end-organ perfusion and is therefore the most accurate monitor of adequate fluid resuscitation. A urine output in pediatric patients weighing 30 kg or less is 1 mL/kg per hour, and in children weighing greater than 30 kg is 0.5 mL/kg per hour (the same as in adults), are the suggested endpoints associated with many resuscitation formulas. Fluid is titrated to maintain the output within the parameters.[79]

The fluid of choice for burn shock resuscitation should approximate the fluid lost from the circulating volume, for example, lactated Ringer solution. Children require more fluid resuscitation for smaller burns than do adults as a result of their limited physiologic reserves. The child's relatively greater ratio of body surface area to weight results in increased evaporative water losses and proportionately more fluid during resuscitation. The need for large volumes of fluid during resuscitation causes a decrease in the concentration of plasma proteins and worsening edema formation; therefore, **colloid replacement** during burn shock resuscitation remains controversial.[90] A component for **maintenance fluid***must* be included in the calculation of fluid needs during resuscitation. Maintenance fluids represent the body requirements in the absence of burn injury.

Successful resuscitation depends on the establishment of intravenous access. Although this is usually accomplished by peripheral or central venous cannulation, circulatory collapse may preclude timely administration of fluid replacement. Cannulation of veins in the pediatric population is further complicated by small vessels and increased subcutaneous fat. Children are good candidates for **intraosseous cannulation** when traditional venous access techniques fail. Blood, drugs, and fluids are readily absorbed by red marrow that drains into medullary venous channels and thus to the systemic circulation. This technique is most effective in children younger

than 5 years because red marrow is steadily replaced by yellow marrow in the limbs, making infusion more difficult, hence decreasing the infusion rate.[91] Complications are minimal with proper care and removal as soon as other access is available.

Fluid Resuscitation

Fluid resuscitation is generally required for children with burn injuries of 15% TBSA or greater. Fluid is administered to compensate for fluid and electrolytes extravasating into the interstitial spaces. This replacement restores circulating volume, improves perfusion, and alleviates organ dysfunction associated with impaired circulation.

Various protocols have been proposed as guidelines for fluid administration. It is important to remember that any regimen serves merely as a guideline and will require adjustment based on the individual response of each child. Because the linear relationship between weight and surface area does not exist in children (surface area varies to weight as a two-thirds function), use of adult formulas results in under- or over-resuscitation.[90] A commonly used protocol is a modification of the Parkland formula. Children also tend to require relatively more fluids than adults because children have higher evaporative losses because of their body surface area-to-weight ratio. **Evaporative fluid loss** can be a significant contributor to hypovolemia in the burned child. This evaporative fluid loss continues until the burn wounds are closed. Although there are specific differences in fluid resuscitation principles between adults and children, some aspects are similar. As in adults, inhalation injury increases the magnitude of TBSA injury; therefore, children with burns and inhalation injury require more fluids.[92]

Research suggests that in practice, in the acute phase of the burn injury, children receive far more fluid than calculated by the modified Parkland formula guidelines that can result in a condition called *fluid creep*. Onset may occur from an excess of resuscitation fluids, vasodilation from an increased use of opiates, and a decrease in venous return from an increase in thoracic pressure from ventilator support resulting in increased abdominal pressure. Adequate fluid resuscitation to support organ perfusion and avoidance of over-resuscitation controls fluid creep.[92] With increased intraabdominal pressure, decompressive laparotomy is a procedure that may be used.

Renal System

Loss of circulating volume into the interstitial spaces results in reduced renal blood flow and decreased glomerular filtration. An important measure of the

adequacy of volume replacement is urine excretion. Sufficient volume replacement maintains urine output during resuscitation. Approximately 36 hours after injury, edema fluid begins to mobilize and output increases.

Children younger than 2 years of age lack the ability to concentrate urine because of the immaturity of the renal system and are, therefore, at increased risk for dehydration. In addition, the child has a relatively larger body surface area in relation to weight than the adult. Combined with limited physiologic reserves, increased fluid requirements are necessary for children during burn shock resuscitation and to compensate for evaporative water losses.[93]

Myoglobin, evidence of a pink to red pigment in the urine, is the result of the breakdown of muscle tissue and hemolysis of red blood cells. This is especially common after extensive electrical injuries and destroyed muscle from deep thermal injury. The release of myoglobin may occlude the kidney tubules and result in renal failure.

Gastrointestinal System

The GI system plays an important role in the pathophysiology of burns. Alterations in blood flow result in decreased perfusion to the GI tract. Ischemia may cause erosion and necrosis of GI tissue. The GI response to a burn injury often includes mucosal atrophy, changes in digestive absorption, and increased intestinal permeability. Depending on the proportion of burn size, atrophy of the GI tract mucosa can occur immediately after injury. The atrophy results in gut barrier dysfunction, leading to increased bacterial translocation and ultimately sepsis.[94]

Paralytic ileus occurs often after major burn injuries. Although digestion ceases in the stomach and the large bowel, the small intestine maintains motility and absorptive capacity. Intestinal motility returns as fluid losses are replaced unless irreversible necrosis of the bowel has occurred as a result of insufficient perfusion.

Immune Function

Burn trauma, induced immunosuppression, results in increased susceptibility to infection and sepsis. Although the exact mechanisms responsible for this immunosuppression remain obscure, it is clear that complex interactions of the hypermetabolic response, nutritional support, bacterial translocation, and defects in both innate and acquired immune function are involved (Fig. 49.11). In addition, young children are at

increased risk for microbial invasion caused by an immature immune system and limited antibody production.

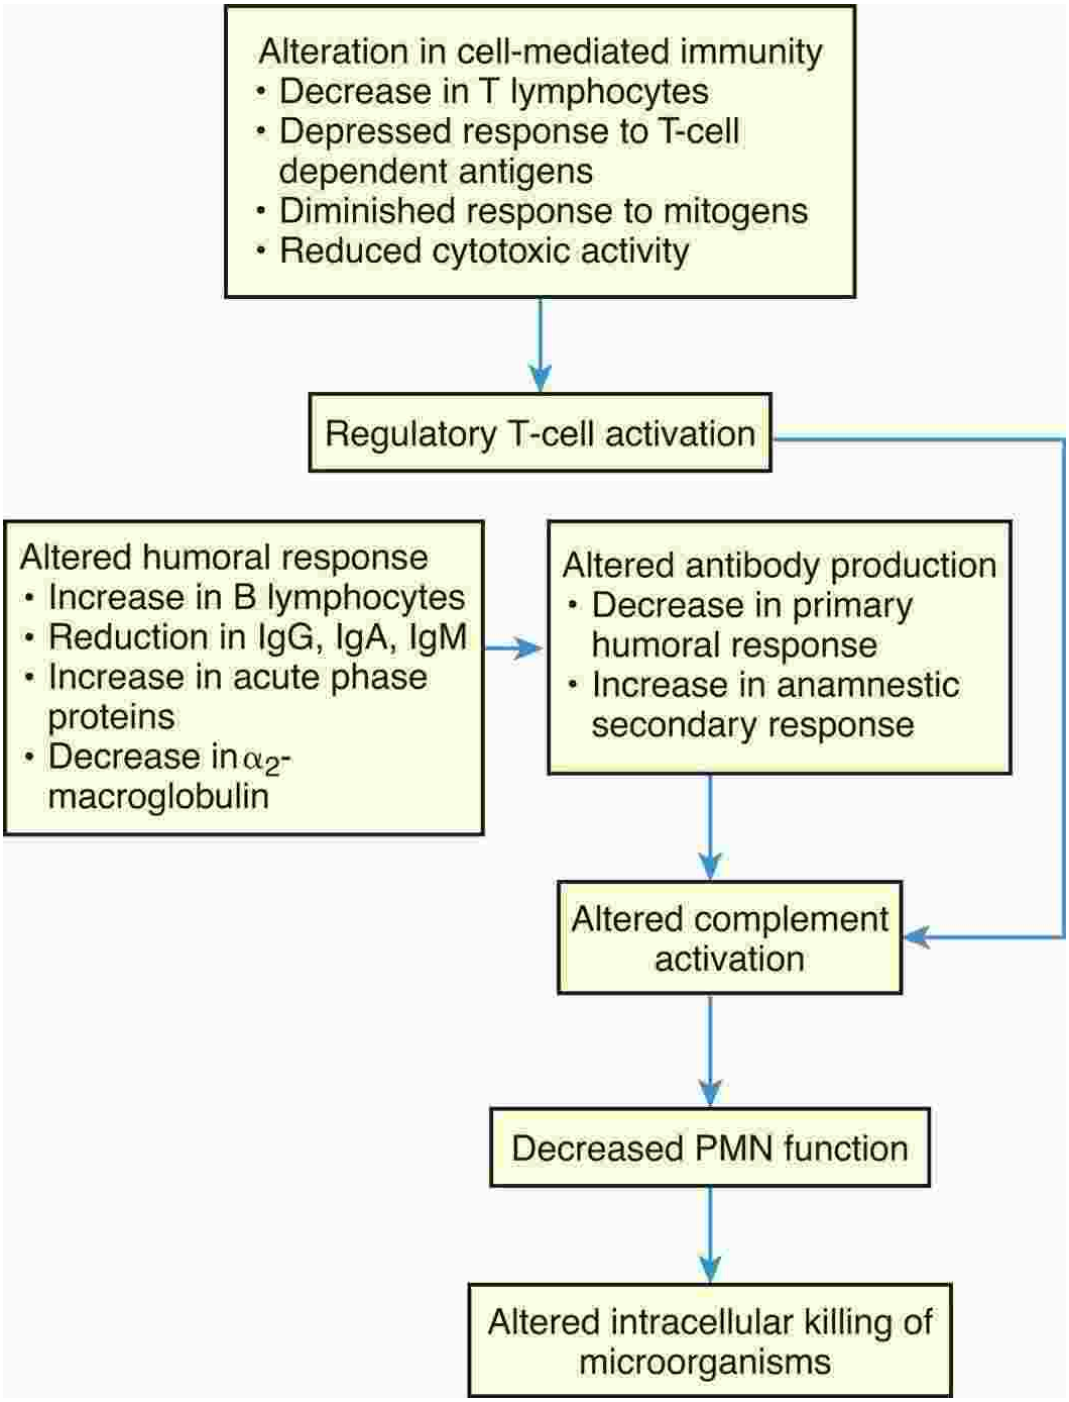

FIG. 49.11 Altered Immune Function After Thermal Injury.
Cell-mediated immunity, antibody production, humoral response. *PMN*, Polymorphonuclear leukocyte.

A flow chart summarizes the altered immune function after thermal injury. • Altered in cell-mediated immunity involves a decrease in T lymphocytes; depressed response to T cell-dependent antigens; diminished response to mitogens; reduced cytotoxic activity. • Altered humoral responses consisting of an increase in B lymphocytes; reduction in I g G, I g A, I g M; increase in acute phase proteins; decrease in alpha two macroglobulins. • Altered antibody production involves decrease in primary humoral response and; an increase in anamnestic secondary response. • Alteration in cell-mediated immunity leads to regulatory T-cell activation. • Regular T-cell activation leads to altered complement activation. • Altered complement activation leads to decreased P M N function. • Decreased P M N function leads to altered intracellular killing of microorganisms.

Deitch reported that wound- or gut-derived endotoxemia may be one of the mediators of the hypermetabolic response observed after thermal injury, and this finding remains undisputed.[95] When bacteria translocate from the gut or from the burn wound, endotoxins may affect immunologic response as inflammatory mediators are released. A further complication in the activation of inflammatory mediators is the formation of toxic metabolites or reactive oxygen species (ROS). These ROS, such as hydrogen peroxide, nitrous oxide, and superoxide anion, are produced in enormous amounts following a burn injury and are harmful.[85]

Factors such as age and the severity of the burn injury may also affect circulating immunoglobulins. Therapeutic interventions such as multiple transfusions, surgical procedures, and antibiotic and anesthetic administration also introduce elements that confound the evaluation of immunosuppressive effects. The immune system is activated systemically after a large burn injury with extensive tissue necrosis and may become ineffective or even self-destructive. Infections in burns may result in the loss of some components of innate immune function.[96] An additional aspect of

the immunopathologic consequence of a burn is the role of immunomodulatory cytokines that are suggested to regulate innate regulatory lymphocytes. The systemic inflammatory response increases pro-inflammatory cytokine production by the peripheral blood mononuclear cells. In children with moderate to severe burn injury, cytokines have been found to increase inflammation by enhancing catabolism and hypermetabolism. In this immunomodulatory process, the pro-inflammatory function of cytokines enhances protection from sepsis recalling that the anti-inflammatory function supports tissue repair.[96]

Infection

Whereas shock and pulmonary compromise present the most immediate threat after burn trauma, local and systemic infections become the primary complication during healing. The burn wound initially is relatively free of pathogens; however, dead, avascular tissue and wound exudate provide a fertile environment for bacterial growth. Colonization of the wound is apparent by the fifth post burn day. Gram-positive microorganisms are usually recovered from cultures first, followed by opportunistic gram-negative bacteria.[97] The impaired vascular supply to burned tissue enhances the proliferation of pathogenic microorganisms. Bacterial invasion results in thrombosis and a further impairment of circulation enough to convert a partial-thickness injury to a full-thickness wound.

Improvements in treatment have resulted in a reduction in wound infection. Aggressive excision and grafting of the wounds, the development of microorganism-specific topical antimicrobials, and improved nutritional support have contributed to this trend. However, the incidence of septicemia remains relatively constant. The burn wound serves as the site of primary invasion for most instances of local or generalized infection. Because the burned child is immunosuppressed for many weeks after injury, maintaining the burn wound at low contamination levels by strict infection control measures, meticulous wound care, and routine quantitative culture samples assists in controlling infection caused by wound flora.[98]

Metabolism

Complex metabolic alterations are observed after burn injury. The extent of metabolic derangement is proportional to the magnitude of TBSA burn sustained. Wilmore demonstrated the linear increase in metabolic rate up to 2½ times normal resting energy expenditure (REE).[99] As the burn injury

approaches 50% TBSA, a plateau is reached, limiting further physiologic response to the trauma or other challenges such as infection.

A biphasic pattern of physiologic response is evident in thermally injured children. The initial **ebb phase** occurs during the immediate post burn period and continues for 3 to 5 days. This phase is characterized by reduced oxygen consumption, impaired circulation, and cellular shock. After the resolution of the shock and the restoration of circulating volume, the metabolic response shifts to a **catabolic (flow) phase** (Table 49.8). A state of **hypermetabolism** ensues, characterized by increased oxygen consumption and elevation of catecholamines, glucocorticoids, and glucagon.

Table 49.8

Metabolic Alterations Following Injury

Response	Dominant Factors	Clinical Findings
Ebb Response	Loss of plasma volume	Hyperglycemia
	Shock Low plasma insulin levels	Decreased oxygen consumption
		Depressed resting energy expenditure
		Decreased blood pressure
		Cardiac output below normal
		Decreased body temperature
Flow Response		
Acute phase	Elevated catecholamines	Catabolic
	Elevated glucagons	Hyperglycemia
	Elevated glucocorticoids	Increased respiratory rate
	Normal or elevated insulin levels High glucagon/insulin ratio	Increased oxygen consumption
		Increased body temperature
		Redistribution of polyvalent cations such as zinc and iron
		Mobilization of metabolic reserves
		Increased urinary excretion of nitrogen, sulfur, magnesium, phosphorus, potassium
		Accelerated gluconeogenesis

Response	Dominant Factors	Clinical Findings
Adaptive phase	Stress hormone response subsiding	Anabolic
		Normoglycemia
		Energy turnover diminished
		Convalescence

From Gottschlich M, Alexander JW, Bower RH. In: Rombeau JL, Caldwell MD, eds. *Enteral and tube feeding*. Philadelphia: Saunders; 1990.

Increased blood flow to the wound supplies additional glucose necessary for tissue repair. Insulin levels are usually normal or even elevated but are inappropriately low in relation to glucagon. Catecholamines and glucocorticoids act as antagonists to insulin. This effect combined with a tissue resistance to insulin stimulates glycogenolysis and gluconeogenesis, thus increasing glucose flow from the liver.[100] In the child, glycogen stores for meeting the increased energy demands of the burn are limited. The initiation of protein and lipid catabolism for glycogenesis is accelerated. This prolonged metabolic dysfunction may lead to loss of lean body mass and increased morbidity.[101] Metabolic rates slowly return to normal with wound

closure. However, a reactivation of the hypermetabolic response may occur with sepsis or organ failure.

Hypermetabolism

The hypermetabolic response after burn injury profoundly alters the production and use of nutrients. Because of these phenomena, caloric requirements increase dramatically. Advances in burn care have allowed the performance of indirect calorimetry and assessment of metabolic rate at the bedside. Nutritional support must have an increased metabolic rate factored in (increased by 10% to 20%) because of fluctuations in energy use associated with activity. Current recommendations suggest 1.5 to 2 g protein/kg/day for adults and up to 2.5 to 4 g protein/kg/day for children.[101]

In addition to age, body composition has been found to significantly affect the post burn course. Studies suggest that obese children with burns have a longer hospital stay, a greater need for ventilatory support, more severe muscle wasting, and greater insulin resistance.[101] However, the heightened nutrient requirements of the burned child preclude a reduction in nutritional support during the acute phase of recovery. Aggressive nutritional therapy is critical to the recovery of these children, and programs designed to achieve ideal body weight should not be instituted until wound healing is achieved.

The metabolism of many micronutrients is greatly affected by burn injury. Micronutrient supplementation is necessary because vitamin and mineral requirements increase with the severity of the burn related to heightened protein synthesis, enhanced caloric expenditure, and increased micronutrient losses. Hypermetabolism results in a rapid turnover in vitamins and trace minerals important in the wound healing and immune response. A deficiency of specific nutrients interferes with carbohydrate and nucleic acid metabolism, collagen formation, and immune function.

The **thermoregulatory response** after burn injury results in an elevation in core body temperature. The ideal resting temperature for burned patients is about 38°C (100.4°F). Due to the loss of the skin barrier, burn injury impairs thermoregulation by reducing the body's ability to retain heat and water. A temperature lower than 38°C (100.4°F) may indicate overwhelming sepsis or a weakened temperature control function. Disproportionate heat loss by convection and evaporation require enhanced methods to preserve body heat.[102]

The pediatric surface area to mass ratios can be nearly three times that of adults, leading to greater evaporative fluid loss in pediatric patients. Neonates, infants, and children also have higher blood volumes relative to

their mass, averaging ~80 mL/kg body weight compared to the adult average of 70 mL/kg. Therefore, fluid resuscitation in the pediatric patient requires larger volumes per unit of body weight. Dextrose is often co-administered to those under 20 kg (44 lb) to avoid hypoglycemia. Enhanced evaporative loss and need for isotonic fluids then increases the risk of hypothermia in this population. Burn-associated fluid and protein loss, a decrease in blood volume, and SIRS can result in renal and hepatic system dysfunction and are significant concerns in both the pediatric and adult burn patient.[102] Therapeutic interventions, such as operative procedures, dressing changes, and transport, present situations requiring increased diligence to prevent inadvertent cooling. Infants are at increased risk for a precipitous drop in core body temperature caused by an inability to regulate heat loss by shivering. Infants and children are especially vulnerable because of the large surface area relative to metabolically active tissue.[93]

Nutritional Support

Compared to sepsis and trauma, burn hypermetabolism (BHM) has an increased degree and extended duration that can persist long after the burn injury. In the immediate post burn state with the "ebb phase," metabolism decreases and tissue perfusion is reduced. A short time afterward, the "flow phase" begins with a state of BHM and hyperdynamic circulation, manifested in an increase in oxygen consumption with an REE of 10% above normal. Unless BHM is reversed with appropriate nutritional intervention, muscle mass is lost, immune response is compromised, and wound healing is delayed.[101] Adenosine triphosphate (ATP) turnover and mitochondrial oxygen consumption account for a substantial part of BHM. Evidence that supports this theory considers the presence of abnormal levels of the uncoupling protein 1, a mitochondrial transmembrane protein and principal mediator of thermogenesis, in the adipose tissue of burn patients.[103] The catecholamines, namely epinephrine, cortisol, and glucagon, mediate BHM. It follows that protein synthesis and lipogenesis are then limited. Protein breakdown becomes a substantial energy source.[101]

Early and ample enteral feeding (EF) is particularly essential to prevent the complications of BHM such as weight loss, particularly muscle mass loss and immune dysfunction. EF supports GI mucosa function, reducing the risk of Curling's ulcer. Considered together, these factors support a reduced length of stay. The metabolic state in severe burns is extremely complex and requires additional investigation.[101]

Wound Management

The goals of wound management include prevention of infection, removal of devitalized tissue, and closure of the wound (see Emerging Science Box: Advances in Burn Wound Care). Burns that are clearly deep dermal or full-thickness injuries are surgically excised as soon as the child is hemodynamically stable after resuscitation. Early excision reduces the incidence of wound infection and systemic sepsis.[104] Coverage of the excised wound is necessary to achieve wound closure. The choice of a coverage technique depends on the availability of donor skin.

Emerging Science BoxAdvances in Burn Wound Care

Although advances in burn care have led to a decrease in morbidity and mortality for the burn patient, those with deep partial and full thickness injuries may still require excision and surgical intervention. With large burns, donor site availability may be limited. In an effort to address this limitation, novel developments and techniques for approaching epidermal replacement shows promise. Recent studies of skin grafting with the use of an autologous skin cell suspension (ASCS) using a harvesting and processing device (ReCell, Avita Medical, Valencia, CA) have resulted in positive outcomes for these persons in the arena of skin repair. With the use of the ReCell device, the ASCS promotes rapid epidermal regeneration and re-epithelialization while requiring significantly less donor site skin. During surgery, the ReCell device is used to prepare a solution of the person's harvested skin. The regenerative epidermal suspension is then immediately applied without having to culture the skin cells. It is sprayed directly on the acute partial thickness wound or used in combination with a meshed autograft for full thickness burn wounds. It is FDA approved for individuals over 18 years of age. Pediatric patients bring a set of challenges to skin grafting and morbidity of donor sites. ReCell is approved under "compassionate use" for the pediatric patient who has sustained burn injuries and does not have available donor sites for autologous split thickness skin grafting.

Data from Holmes Iv JH, et al. A comparative study of the ReCell® device and autologous split-thickness meshed skin graft in the treatment of acute burn injuries. Journal of Burn Care & Research, 2018;39(5):694–701; Nannassay AD, et al.: The use of an autologous cell harvesting and processing device to decrease surgical procedures and expedite healing in two pediatric patients. Wounds, 2019;31(12): 316–321.

Split-thickness sheet grafts are selected for areas of maximal functional and cosmetic results (Fig. 49.12). Children with very large burn injuries often do not have enough unburned skin available to facilitate the use of the sheet graft. In these cases, the surgeon uses a meshing technique to expand the available skin and increase the size of the graft. The pattern created heals by the migration of epithelium from the meshed edges. Scar formation is increased, and the mesh pattern remains clearly visible (Fig. 49.13). The color, texture, vascularity, thickness, and hair-bearing nature of the skin vary from one area to another. Site selection and depth of donor sites require careful consideration. Skin grafts for the face should be taken, if possible, from above the nipple line or from the scalp for best color match.[105]

FIG. 49.12 Split-Thickness Sheet Graft.

FIG. 49.13 Meshed Autograft. (Courtesy Mary Fran Hazinski.)

Scar Maturation

In normal epidermal healing, minimal disruption in skin color, texture, and thickness occurs. However, burn wounds that extend into the dermis are repaired through **scar formation** and may result in an overgrowth of dermal constituents (Fig. 49.14A). Accelerated collagen synthesis most likely begins with high levels of activity in granulation tissue. The **hypertrophic scar** consists of hypercellular and disorganized connective tissue that is erythematous, raised, and pruritic. Normal dermis contains thick fibers and fiber bundles running parallel to the surface. In the hypertrophic scar, the collagen is degraded, resulting in disorganized bundles that are cross-linked tightly and lack pliability.[106] As the hypertrophic scar matures, collagen begins to orient in a more parallel fashion, and vascularity decreases (see Fig. 49.14B). Collagen synthesis is very active soon after wound closure, and alteration of the scar can be accomplished before strong cross-linking of the collagen is established.

FIG. 49.14 Scar Maturation.
(A) Immature hypertrophic scar. **(B)** Flat, mature scar after pressure therapy.

Although the duration of wound healing varies among individuals, the length of time required to achieve wound closure is the most reliable predictor of hypertrophic scarring. Deeper burns demonstrate increased scarring caused by the formation of granulation tissue and prolonged healing time. Scarring that extends beyond the edges of the initial wound is termed **keloids**. While keloids can develop in any burn wound, it more commonly develops in darker-pigmented skin.[106] Although age has not been found to be a predictor of hypertrophic scar formation, younger individuals are more susceptible to trauma and have greater skin tension and an accelerated rate of collagen synthesis. Increased tension with resultant trauma stimulates inflammation, which in turn results in the formation of additional collagen.

Scar tissue is metabolically active and highly vascular. Collagen is deposited in random patterns, and contraction of the scar can result in disabling deformities. The scar is active as long as it is raised, red, and firm. **Scar maturation** requires 1 to 2 years and depends on individual differences and compliance with the rehabilitation program. The mature scar is characterized by increased suppleness, flattening, and pigmented color.

Scar tissue does not grow and expand like normal tissue. Although massage therapy offers some benefit in stretching, functional limitation may develop as the child grows. This is particularly evident over joints. Reconstructive surgery is often necessary to restore anatomic integrity and to promote independent function.

Itching may occur at any time during burn wound healing and may last for many years after the burn has healed. As a complication, it can lead to graft loss and skin breakdown since the area may be scratched away in an effort to obtain relief. Moisturizing lotions, silicone gel sheets, and massage may lend relief. When examining medication, the combination of H_1 and H_2 antagonists may be used to control itching.[107]

Comfort Management

Pain is multidimensional and includes physical, emotional, cognitive, and cultural factors. Emotional factors are more important in the child's perception of pain than in adults. When considering pain and anxiety management, background pain and fear of pain are important considerations. Fear or anxiety may exponentially increase the sensation of pain in children. Also important is the challenge for a pediatric burn patient because children have distinct anatomic, physiological, and psychological characteristics. Post-traumatic stress disorder is demonstrated in 30% of

severely burned children six months after injury. In combination with the previously mentioned characteristics, burn injury can affect medication response and elimination in children.[108] Both pharmacologic and nonpharmacologic interventions are important in treating persons with burns. The measurement of pain is particularly challenging in young infants, who lack the language skills to express pain. A variety of tools, from physiologic monitors to behavioral analyses, functional ability assessments, and analog scales have been developed to measure pediatric pain. The quality of pain control in burn centers has improved along with the ability to assess pain in the pediatric population.

Recovery from Burn Injury

Rehabilitation becomes the major focus of care once wound coverage has been achieved and continues until all reconstructive procedures have been completed. This phase may extend over many years in the pediatric population. Children require specialized management to ensure optimal functional and cosmetic results. Scar and contracture management is necessary for prolonged periods because of changes in body composition as the child grows and matures. Very young children present unique challenges because the small body size can be difficult to fit with pressure garments and splints, growth is rapid, and cooperation with the rehabilitation program is limited.

Infant skin is thinner, and the epidermis is more loosely connected to the dermis. This increases the risk of blistering, chafing, and rash formation. The infant also produces less sebum and sweat, further exacerbating the propensity to skin irritation. Because scar tissue contains no sweat glands, these characteristics of the skin in growing children compound the difficulty in maintaining pressure on maturing scars while cooling the body.

Positioning and splinting to prevent contracture formation, as well as rehabilitative aspects of therapy, are instituted on admission and continue throughout the hospitalization. Physical therapy and occupational therapy provide exercise to maintain range of motion and function. Psychosocial support is very important for the child and the family. The information provided should be consistent and honest to allow clarification of concerns. In addition to the functional aspects of rehabilitation, attention must be directed to psychosocial needs and community reintegration.

A method to facilitate the transition from the hospital to the community is a school reentry program offered by many burn centers. These programs

provide education for teachers and peers about the injury, appearance, and abilities of the returning child.

Summary Review

Shock and Multiple Organ Dysfunction Syndrome

1. Shock in children is present when there are signs of poor systemic perfusion, regardless of blood pressure.
2. Hypovolemic shock is the most common type of shock in children and most frequently results from dehydration and trauma. Hypovolemic shock also may result from expansion of the vascular space, producing inadequate intravascular volume relative to the vascular space.
3. Hypotension is a sign of severe (preterminal), decompensated shock, referred to as *hypotensive shock*.
4. Clinical manifestations of hypovolemic shock include inadequate systemic perfusion associated with intravascular fluid loss. Adrenergic compensatory mechanisms can produce tachycardia, redistribution of blood flow, peripheral vasoconstriction, cool extremities, delayed capillary refill, and oliguria.
5. Neurogenic shock is caused by a loss of vasomotor tone after severe injury to the spinal cord.
6. Clinical manifestations of neurogenic shock include warm skin, hypotension with a low diastolic blood pressure, and poor systemic perfusion. Tachycardia is not present.
7. Cardiogenic shock, with decreased cardiac output, is observed most commonly after cardiovascular surgery or with inflammatory diseases of the heart, such as cardiomyopathy and myocarditis. It is also found in children with obstructive CHD and those with drug toxicity or severe electrolyte or acid-base imbalances.
8. Clinical manifestations of cardiogenic shock include inadequate systemic perfusion despite adequate intravascular volume. Cardiac output is typically low. Adrenergic compensatory mechanisms, including peripheral vasoconstriction and decreased urine volume, are similar to those found in hypovolemic shock.
9. Once septic shock is present, immediate treatment is urgently needed. Therapy in the first hour includes rapid identification, resuscitation, and stabilization including fluid resuscitation (up to 2 to 3 boluses of 10 to 20 mL/kg administered in the first hour of therapy, if critical

care resources are present). If the child does not respond to volume administration alone, vasoactive support must be initiated within the first hour of treatment. Antibiotics also must be administered within the first hour. Goals of therapy are to rapidly normalize the heart rate and blood pressure for age and to normalize capillary refill to less than 3 seconds. Fluid and vasoactive therapy should support high cardiac output and oxygen delivery, maintaining the $S_{CV}O_2$ at approximately 70%.

10. Sepsis is a systemic response to infection. It is present when manifestations of SIRS are observed. SIRS is present when the child demonstrates two or more of the following as an acute change from baseline values: altered temperature, altered heart rate, altered respiratory rate, and alteration in the WBC count. The newborn often develops hypothermia rather than fever as a sign of infection and may develop bradycardia instead of tachycardia.
11. Severe sepsis is present when there is evidence of SIRS and signs of organ dysfunction, hypoperfusion, or hypotension.
12. The development of septic shock is heralded when the child with severe sepsis develops signs of cardiovascular dysfunction. The child may become hypotensive despite adequate fluid resuscitation or require vasopressors to maintain blood pressure.
13. Reperfusion and inflammatory injury stimulate free oxygen radicals that can damage cell membranes, denature proteins, and disrupt chromosomes. This process likely affects endothelial cells and the microvasculature, causing MODS.
14. Lactic acidosis (i.e., rise in serum lactate) may be the most sensitive indicator of inadequate systemic perfusion in children; effective shock therapy should eliminate lactic acidosis.
15. The general goals of treatment for shock are maximization of oxygen delivery and minimization of oxygen demand. This requires the support of airway, oxygenation, and ventilation. Support of cardiovascular function requires support of appropriate heart rate and rhythm, adequate intravascular volume, good myocardial function, and appropriate vascular resistance and distribution of blood flow. The child should be kept warm, but fever must be treated promptly.
16. The signs of shock should lessen or disappear if management of shock is effective. The warmth of the child's extremities, briskness of capillary refill, quality of peripheral pulses, level of consciousness

and responsiveness, urine volume, oxygenation, ventilation, and acid-base status should improve throughout shock therapy.

Burns

1. Burns in children are often the result of curiosity, inability to escape the burning agent, inadequate supervision, or nonaccidental trauma.
2. Scald injuries are commonly seen in young children and result from exposure to hot water, grease, or other hot liquids, whereas flame burns are more prevalent among older children.
3. A child's skin is thinner and thus more susceptible to injury than adult skin. The kitchen and bathroom are common sites of burn injury.
4. Approximately 3% to 24% of children who have sustained a burn injury are referred to child protective services for suspicion of abuse.
5. Flame burns involving flammable liquids, most notably gasoline, are more common in older children. Risk-taking behaviors in young males can lead to electrical burns. Children may be exposed to chemical injury by swallowing caustic agents at home.
6. Use of the standard Rule of Nines results in inaccurate calculation of the percentage of TBSA in children. A modified Rule of Nines deducts 1% from the head and adds 0.5% to each leg for each year of life after 2 years of age.
7. Major burn trauma involves all body systems, and the consequences of injury include shock, infection, hypermetabolism, organ failure, and functional limitations. These effects can be magnified in the pediatric population as a result of physiologic immaturity and age-related variation in treatment modalities.
8. Applying ice, infection, or trauma to the burn area may convert a partial-thickness injury to a full-thickness one, especially in young children, who have thinner, more delicate skin.
9. Marked reduction in cardiac output occurs immediately after injury and is accompanied by an initial increase in systemic vascular resistance. The inefficient and labile peripheral circulation of the infant complicates management of the burn shock phase of treatment. A higher risk of chest constriction and impairment of respiratory excursion may result because of the increased pliability of the rib cage, especially in very young children. Younger children are also more susceptible to developing increased intra-abdominal pressure.

10. Inhalation injury significantly increases mortality for pediatric patients with a severe burn injury.
11. Children require more fluid resuscitation for smaller burns than does the adult population as a result of limited physiologic reserves. The child incurs increased evaporative water loss, leading to proportionately more fluid during resuscitation. Large volumes of fluid during resuscitation worsen edema formation; therefore, colloid replacement during burn shock resuscitation remains controversial.
12. Children younger than 2 years lack the ability to concentrate urine because of the immaturity of the renal system and are therefore at increased risk for dehydration. Because children have a relatively larger body surface area in relation to weight than adults, they require proportionately increased fluid during burn shock resuscitation to compensate for evaporative water losses.
13. A biphasic pattern of physiologic responses is evident in the burn-injured child. The initial ebb phase occurs during the immediate post burn period and continues for 3 to 5 days. This phase is characterized by reduced oxygen consumption, impaired circulation, and cellular shock. After this phase and the restoration of volume, the metabolic response shifts to a catabolic, or flow, phase. This phase is characterized by hypermetabolism with an increased oxygen consumption and elevation of catecholamines, glucocorticoids, and glucagon.
14. Limited glycogen stores in burn injured children affect the ability to meet increased energy demands. This prolonged metabolic dysfunction may lead to loss of lean body mass and increased morbidity.
15. Although age was not found to be a predictor of hypertrophic scarring, children have greater skin tension and an accelerated rate of collagen synthesis that produces scarring easier. While the duration of burn healing varies among individuals, time to healing has been found as a predictor of hypertrophic scarring.
16. Children require specialized management to ensure optimal functional and cosmetic results. Long-term scar and contracture management is necessary because of changes in body composition as the child grows and matures.

Glossary

A

Absolute polycythemia Excessive red blood cell production; a physiologic response resulting from increased erythropoietin secretion in response to chronic hypoxia or as a symptom of polycythemia vera.

Absorption atelectasis See Atelectasis.

Acid maltase deficiency (glycogen storage disease type II or Pompe disease) An autosomal recessive metabolic disorder that damages muscle and nerve cells throughout the body by an accumulation of glycogen in the lysosome attributable to deficiency of the lysosomal acid α-glucosidase enzyme. The buildup of glycogen causes progressive muscle weakness (myopathy) throughout the body and affects various body tissues, particularly in the heart, skeletal muscles, liver, and nervous system.

Acne A common skin disease characterized by pimples on the face, chest, and back. It occurs when the pores of the skin become clogged with oil, dead skin cells, and bacteria.

Acne conglobate Severe cystic acne characterized by cystic lesions, abscesses, communicating sinuses, and thickened, nodular scars; usually does not affect the face.

Acne rosacea A chronic form of dermatitis of the face in which the middle portion of the face appears red with small red lines caused by dilation of capillaries.

Acne vulgaris An inflammatory eruption of the sebaceous follicles usually occurring on the face, upper back, and chest that consists of blackheads, cysts, papules, and pustules.

Noninflammatory acne Open comedones caused by the enlargement and dilation of a plug resulting from the accumulation of oil and dead skin cells inside the hair follicle and by closed comedones that form if the hair follicle pore remains closed; they appear as a tiny, sometimes pink bump in the skin.

Acquired immunodeficiency syndrome (AIDS) See Immune deficiency.

Acquired sideroblastic anemia See Anemia.

ACTH deficiency A condition characterized by decreased or absent production of adrenocorticotropic hormone (ACTH) by the pituitary gland, resulting in a reduction in the secretion of adrenal hormones and subsequent weight loss, lack of appetite, weakness, nausea, vomiting, and low blood pressure.

Actinic keratosis A condition in which a premalignant small, reddish, rough spot appears on skin chronically exposed to the sun.

Acute chest syndrome A syndrome occurring in association with sickle cell disease defined by a new infiltrate on chest radiograph; associated with one or more new symptoms: fever, cough, sputum production, dyspnea, or hypoxia. It occurs most

commonly in the 2- to 4-year-old age group and declines in incidence with age.

Acute colonic pseudo-obstruction (Ogilvie syndrome) A massive dilation of the large bowel that occurs in critically ill persons and immobilized older adults. It is characterized by significant dilation of the cecum and absence of mechanical obstruction and is related to excessive sympathetic motor input or decreased parasympathetic motor input.

Acute confusional state (ACS) A form of delirium caused by interference with the metabolic or other biochemical processes essential for normal brain functioning. Symptoms may include disturbances in cognition and levels of awareness, short-term memory deficit, retrograde and anterograde amnesia, and disturbances in orientation, accompanied by restlessness, apprehension, irritability, and apathy. The condition may be associated with an acute physiologic state, delirium, toxic psychosis, or acute brain syndrome.

Acute coronary syndrome A classification encompassing clinical presentations ranging from unstable angina through infarction.

Acute cystitis An inflammation of the bladder, which is the most common site of urinary tract infection.

Acute epiglottitis An infection that causes inflammation of the epiglottis and surrounding tissues and may lead to upper airway blockage.

Acute gastritis An inflammatory disorder of the gastric mucosa, usually caused by injury of the protective mucosal barrier by

drugs, chemicals, or *Helicobacter pylori* infection.

Acute glomerulonephritis See Glomerulonephritis.

Acute gouty arthritis An abrupt pain of a joint, most often the great toe, which is swollen, hot, and shiny secondary to an attack of gout.

Acute idiopathic thrombotic thrombocytopenic purpura (TTP) See Thrombocytopenia.

Acute leukemia See Leukemia.

Acute liver failure (fulminant liver failure) A rare clinical syndrome resulting from severe impairment or necrosis of liver cells without preexisting liver disease or cirrhosis. Acetaminophen overdose is the leading cause.

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) A spectrum of acute lung inflammation and diffuse alveolocapillary injury.

Acute lymphoblastic leukemia (ALL) See Leukemia.

Acute mesenteric ischemia Caused by acute occlusion of the mesenteric artery that results in a significant reduction in mucosal blood flow to the large and small intestines. Aortic aneurysms, arterial thrombi, or emboli can be causes.

Acute mountain sickness (AMS) The presence of a combination of nonspecific symptoms that appear within a few hours after ascent to altitude, and may include headache, loss of appetite, nausea, vomiting, weakness, lassitude, dizziness, and difficulty sleeping.

Acute myelogenous leukemia (AML) See Leukemia.

Acute orthostatic hypotension An abnormal decrease in blood pressure when a person stands. This may lead to fainting.

Acute otitis media (AOM) An infection of the middle ear space, behind the eardrum (tympanic membrane); characterized by pain, dizziness, and partial loss of hearing.

Acute pancreatitis Inflammation of the pancreas resulting from obstruction to the outflow of pancreatic digestive enzymes caused by bile duct or pancreatic duct obstruction (e.g., gallstones). Usually a mild disease and resolves spontaneously.

Acute poststreptococcal glomerulonephritis (PSGN) See Glomerulonephritis.

Acute pyelonephritis Acute inflammation of the renal parenchyma and pelvis characterized by small cortical abscesses and yellowish streaks in the medulla resulting from the accumulation of pus in the collecting tubules and interstitial tissue.

Acute renal failure (acute renal injury) A sudden decline in kidney function with a decrease in glomerular filtration and accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels.

Acute respiratory distress syndrome (ARDS) Capillaries or alveoli of the lungs are damaged as a result of infection, injury, blood loss, or inhalation injury-causing fluid to leak from the capillaries into the alveoli, resulting in pulmonary edema and collapse of some alveoli.

Acute tubular necrosis (ATN) The kidney undergoes ischemic or nephrotoxic injury because of severe hypotension, aminoglycosides, or radiocontrast agents and produces granular and epithelial cell casts in urine.

Acute urethral syndrome The bladder is irritated and the typical symptoms of a urinary tract infection are present in the absence of an infection.

Adenocarcinoma Tumor arising from epithelial cells with a glandular or glandlike pattern.

Adenocystic tumor (cylindroma) Rare bronchial gland tumors that arise predominantly in the trachea or large airways and cause obstruction.

Adenomyosis The presence of islands of endometrial glands surrounded by benign endometrial stroma within the uterine myometrium.

Adenosine deaminase (ADA) deficiency See Immune deficiency.

Adrenarche Growth of axillary and pubic hair and other physiologic changes induced by hyperactivity of the suprarenal cortex and adrenocortical secretion of androgenic hormones in early puberty.

Agammaglobulinemia See Immune deficiency.

Ageusia Loss of the sense of taste.

Agoraphobia A mental disorder characterized by an irrational fear of leaving the familiar setting of home, or venturing into the open; it is so pervasive that a large number of external life situations are entered into reluctantly or are avoided; often associated with panic attacks.

Agranulocytosis See Immune deficiency.

Akinesia Slowness or loss of normal motor function resulting in impaired muscle movement.

Akinetic mutism (AM) A syndrome characterized by the inability to speak, loss of voluntary movement, and apparent loss of emotional feeling. It is related to lesions of the upper brainstem.

Albright syndrome (Albright–McCune–Sternberg syndrome) A syndrome characterized by polyostotic fibrous dysplasia, patchy dermal pigmentation, and endocrine dysfunction.

Alcoholic cirrhosis See Cirrhosis.

Alcoholic fatty liver (steatosis) The mildest form of alcoholic liver disease; can be caused by chronic ingestion of relatively small amounts of alcohol, may be asymptomatic, and is reversible with cessation of drinking.

Alcoholic hepatitis (steatohepatitis) A precursor of cirrhosis characterized by inflammation; degeneration and necrosis of hepatocytes; infiltration of neutrophils, macrophages, and lymphocytes; immunologic alterations; and lipid peroxidation.

Algor mortis Postmortem reduction of body temperature.

Alkaline reflux gastritis Inflammation of the stomach caused by reflux of bile and alkaline pancreatic secretions that contain proteolytic enzymes and disrupt the mucosal barrier in the remnant stomach.

Allergic contact dermatitis Contact dermatitis attributable to allergic sensitization.

Allodynia A condition in which pain arises from a stimulus that would not normally be experienced as painful.

Allostasis Long-term or chronic exaggerated responses to stress.

Alogia Inability to speak because of mental deficiency, mental confusion, or aphasia.

Alopecia Loss of hair.

Alopecia areata An autoimmune T-cell-mediated chronic inflammatory disease directed at hair follicles that results in baldness, usually in round patches.

Alpha-thalassemia major See Anemia.

Alpha-thalassemia minor See Anemia.

Alzheimer disease (dementia of Alzheimer type [DAT], senile disease complex) A degenerative disease characterized by amyloid plaques and fibrillary tangles in the cortex and atrophy and widened sulci in the frontal and temporal lobes.

Amblyopia Poor vision caused by abnormal development of visual areas of the brain in response to abnormal visual stimulation during early development.

Amenorrhea Lack of menstruation; most common causes (aside from pregnancy) are chromosomal abnormalities, hypothalamic dysfunction, polycystic ovarian syndrome, hyperprolactinemia, hypothyroidism, malnutrition, and ovarian failure.

Amyotrophic lateral sclerosis (ALS) (sporadic motor system disease, sporadic motor neuron disease, motor neuron disease, Lou Gehrig disease) A disease that breaks down tissues in the

nervous system (a neurodegenerative disease); it is of unknown cause and affects the nerves responsible for movement.

Anaphylactic shock A state of shock caused by a severe allergic reaction that lowers blood pressure and results in urticaria, breathing difficulties, and possibly death.

Anaphylactoid purpura (allergic purpura, Henoch–Schönlein purpura) Nonthrombocytopenic purpura attributable to immune hypersensitivity to foods, drugs, and insect bites.

Anemia Hemoglobin concentration is less than normal because of a deficiency in red blood cells, a low level of hemoglobin in cells, or both; it manifests as pallor of the skin and mucous membranes, weakness, dizziness, easy fatigability, and drowsiness caused by oxygen deficiency.

Hereditary spherocytosis (congenital hemolytic anemia, congenital acholuric jaundice) A defect in the cell membrane of red blood cells that causes thickened, fragile red blood cells that are susceptible to spontaneous hemolysis and results in chronic anemia, jaundice, fever, and abdominal pain.

Congenital hemolytic anemias .

Alpha-thalassemia major Thalassemia in which all four α chains of hemoglobin are defective, resulting in a fatal condition because oxygen cannot be released to the tissues.

Alpha-thalassemia minor Thalassemia in which two α chains of hemoglobin are defective.

Beta-thalassemia major (Cooley anemia) Thalassemia in which α-chain synthesis and β-chain synthesis are uncoupled; β-chain

production is depressed moderately in the heterozygous form, beta-thalassemia minor, and severely in the homozygous form, beta-thalassemia major, resulting in erythrocytes that have a reduced amount of hemoglobin and accumulations of free α chains.

Beta-thalassemia minor See above.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency An inherited condition that is asymptomatic in the absence of exposure to particular substances such as certain medicines, mothballs, or severe infections; with exposure the red blood cells undergo destruction, producing excessive bilirubin that overloads the liver and causes jaundice.

Hemoglobin H disease A form of alpha-thalassemia in which a hemoglobin H gene is expressed but cannot bind oxygen.

Sickle cell anemia (sickle cell disease [SCD]) An inherited autosomal recessive disorder of the blood caused by abnormal hemoglobin that distorts red blood cells and makes them fragile and prone to rupture and can cause anemia, joint pain, fever, leg ulcers, and jaundice.

Sickle cell trait An inherited condition in which an individual carries only one gene for sickle cell disease and is without symptoms.

Sickle cell–Hb C disease A heterozygous form in which the child simultaneously inherits a hemoglobin C gene from another parent.

Sickle cell–thalassemia disease A heterozygous form in which the child simultaneously inherits a thalassemia gene from another parent.

Thalassemia A potentially fatal genetic disorder in which hemoglobin molecules are abnormal, resulting in severe anemia; enlarged heart, liver, and spleen; and skeletal deformation.

Macrocytic anemia (megaloblastic anemia) A condition characterized by erythrocytes that are larger than normal; associated with deficiency of vitamin B_{12} or folic acid caused by inadequate intake or insufficient absorption secondary to alcoholism or drugs that inhibit DNA replication.

Pernicious anemia An autoimmune disorder that causes a deficiency in intrinsic factor, resulting in the inability to absorb vitamin B_{12} and a subsequent increase in the production of abnormal erythrocytes.

Microcytic-hypochromic anemia A condition in which red blood cells are smaller than normal as a result of iron deficiency.

Acquired sideroblastic anemia A heterogeneous group of disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs as a primary disorder with no known cause (idiopathic) or is associated with other myeloproliferative or myelodysplastic disorders.

Hereditary sideroblastic anemia Heterogeneous group of rare disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs almost exclusively

in males, suggesting a predominant recessive X-linked transmission.

Hypoplastic anemia A condition in which anemia results from greatly depressed, inadequately functioning bone marrow and smaller-than-normal erythrocytes.

Iron deficiency anemia (IDA) An insufficient dietary intake or absorption of iron, resulting in decreased incorporation of hemoglobin into red blood cells and subsequent feelings of fatigue, weakness, and shortness of breath as well as pale earlobes, palms, and conjunctivae.

Reversible sideroblastic anemia Associated with alcoholism; results from nutritional deficiencies of folate.

Sideroblastic anemia (SA) Refractory anemia of varying severity that is caused by altered mitochondrial metabolism and is marked by sideroblasts in the bone marrow.

Normocytic-normochromic anemia (NNA) Erythrocytes are of normal size and hemoglobin content but of insufficient number; usually caused by hereditary spherocytosis, drug-induced anemia, and anemia secondary to malignancies.

Anemia of chronic disease (ACD) A mild to moderate anemia resulting from decreased erythropoiesis in individuals with conditions of chronic systemic disease or inflammation.

Aplastic anemia Decreased bone marrow production of adequate amounts of new red blood cells; results from an autoimmune disorder or exposure to radiation or substances such as benzene or certain drugs.

Aplastic crisis Temporary loss of bone marrow causes erythropoiesis, resulting in an acute fall in hemoglobin levels and subsequent anemia.

Atrial septal defect (ASD) An abnormal communication between the atria; isolated ASD occurs in about 5% to 10% of all congenital cardiac defects.

Autoimmune hemolytic anemia (AIHA) A form of hemolytic anemia involving autoantibodies against red blood cell antigens.

Cold agglutinin autoimmune hemolytic anemia Acquired disorder caused by autoantibodies against antigens normally on the surface of erythrocytes; mediated by immunoglobulin M (IgM) antibodies that optimally bind to and agglutinate erythrocytes in colder portions of the body (e.g., fingers, toes), and occurs less often than warm antibody hemolysis, affecting mostly middle-aged and older adults.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) A disorder in which exposure to cold initiates acute and severe intravascular hemolysis that, unlike cold agglutinin anemia, results in hemoglobinuria. The chronic form of this anemia is extremely rare, but an acute form of paroxysmal cold hemoglobinuria is frequently observed in autoimmune hemolytic anemia of childhood.

Drug-induced hemolytic anemia A form of immune hemolytic anemia usually resulting from an allergic reaction against foreign antigens (e.g., antibiotics) that have attached to the surface of red blood cells.

Fanconi anemia A genetic disease affecting bone marrow that is characterized by pancytopenia, hypoplasia of the bone marrow, congenital anomalies, and pigment changes of the skin and that predisposes the individual to myelodysplasia and to acute myeloid leukemia or cancers of the mouth, esophagus, intestinal and urinary tracts, and reproductive organs.

Hemolytic anemia A condition in which red blood cells are destroyed in response to certain toxic or infectious agents or in certain inherited blood disorders and the rate of breakdown exceeds the body's ability to compensate.

Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis) A condition that affects a fetus or newborn in which red blood cells break down because of antibodies made by the mother that are directed against the infant's red cells, potentially resulting in anemia, heart failure, jaundice, and brain damage.

Posthemorrhagic anemia A type of normocytic-normochromic anemia that is caused by sudden blood loss in an individual with normal iron stores and triggers a compensatory response in which water and electrolytes from tissues and interstitial spaces are used to expand plasma volume and accelerate the formation and development of blood cells.

Warm autoimmune hemolytic anemia The most common form of autoimmune hemolytic anemia; caused by IgG that binds to erythrocytes at normal body temperature; often secondary to other diseases, especially lymphomas, chronic lymphocytic leukemia, other neoplastic disorders, or systemic lupus erythematosus.

Anencephaly Anomaly in which the soft, bony component of the skull and much of the brain are missing.

Angelman syndrome (happy puppet syndrome) An inherited syndrome of jerky puppet like movements, frequent laughter, mental and motor retardation, peculiar open-mouthed facies, and seizures.

Angina pectoris Chest pain caused by reduced cardiac blood flow and myocardial ischemia.

Anhedonia Absence of pleasure from the performance of acts that would ordinarily be pleasurable.

Ankylosing spondylitis (AS, spondyloarthritis) Chronic inflammation of the spine and sacroiliac joints with gradual fusion of the vertebrae that immobilizes the spine.

Anorexia nervosa (AN) A disorder with both psychologic and physiologic components that begins with dieting to lose weight and manifests into an inappropriate self-control behavior; continued restrictive eating may lead to starvation and eventually death.

Anorgasmia (orgasmic dysfunction) The inability of the woman to reach or achieve orgasm.

Anuria Urine output less than 50 mL/day.

Anxiety disorder A group of disorders involving various manifestations of anxiety that are grouped together and include panic disorder, specific phobia, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder, generalized anxiety disorder

(GAD), and anxiety disorders secondary to medical conditions or substance-induced or not otherwise specified.

Aplastic anemia See Anemia.

Aplastic crisis See Anemia.

Appendicitis Inflammation of the appendix as a result of blockage of the opening from the appendix into the cecum; the appendix wall becomes infected and ruptures, allowing the infection to spread throughout the abdomen and cause pain, anorexia, fever, nausea, vomiting, and diarrhea.

Apraxia A disorder of voluntary movement consisting of impairment of the performance of skilled or purposeful movements; results from acquired cerebral disease.

Arcus senilis A gray to white ring at the periphery of the cornea; caused by deposits of cholesterol in the cornea or hyaline degeneration and occurs primarily in older persons.

Areflexia Absence of reflexes.

Arterial ischemic stroke (pediatric arterial ischemic stroke) A rare disorder in children resulting from embolism, arteriopathy, or, rarely, sinovenous thrombosis and leading to a decreased flow of blood and oxygen to areas of the brain.

Asbestosis Pulmonary inflammation and fibrosis resulting from inhalation of hydrous silicates of various metals in fibrous form.

Aseptic meningitis A form of inflammation of the meninges and subarachnoid space surrounding the brain and spinal cord without evidence of bacterial infection; may be associated with viral infection, systemic disease, or drugs.

Aspiration pneumonitis A condition caused by the abnormal entry of fluids, particulate matter, or secretions into the lower airways that can lead to chemical pneumonitis from entry of toxic material such as gastric acid, from bacterial infection, or by mechanical obstruction of the lower airways.

Asthma A chronic inflammatory disorder of the airways involving bronchial hyper responsiveness and airway obstruction marked by periodic attacks of wheezing, shortness of breath, a tight feeling in the chest, and a cough that produces mucus because of an allergic reaction triggered by certain drugs, irritants, viral infection, exercise, or emotional stress.

Asymptomatic bacteriuria The presence of bacteria in the urine without evidence of infection.

Ataxia-telangiectasia (AT) See Immune deficiency.

Ataxic cerebral palsy A form of cerebral palsy associated with damage to the cerebellum and resulting in gait disturbances and instability; at birth the infant may have hypotonia, but develops stiffness of the trunk muscles later in infancy.

Atelectasis Part of or an entire lung collapses and the alveoli deflate as a result of surgery, smoking, or blockage of a bronchiole.

Absorption atelectasis Collapse of lung tissue resulting from gradual absorption of air from obstructed or hypoventilated alveoli or from inhalation of concentrated oxygen or anesthetic agents.

Compression atelectasis Air pressure in the pleural space pushes against the already recoiled lung, causing compression atelectasis,

and against the mediastinum, compressing and displacing the heart and great vessels.

Surfactant impairment Decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and causes lung collapse during expiration; can occur because of premature birth, acute respiratory distress syndrome, anesthesia, or mechanical ventilation.

Atherosclerosis A type of arteriosclerosis in which the inflammatory changes of thickening and hardening of the walls of large- and medium-sized arteries are caused by an atheroma or plaque of lipids, cells, and connective tissue in the tunica intima.

Atopic dermatitis (AD) (allergic dermatitis) A chronic hereditary skin disease characterized by intense itching and inflamed skin that causes redness, swelling, cracking, crusting, and scaling.

Atrial septal defect (ASD) A congenital heart disease involving the interatrial septum of the heart that separates the right and left atria, resulting in misdirected blood flow between the two sides of the heart.

Atrioventricular canal (AVC) defect A large hole is present in the center of the heart where the wall between the atria joins the wall between the ventricles, and the tricuspid and mitral valves are formed into a single large valve that crosses the defect.

Atypical ductal hyperplasia (ADH) Abnormal proliferating cells in breast ducts.

Atypical hyperplasia Increased number of cells with some variation in cellular structure but without sufficient qualitative or

quantitative features of carcinoma.

Atypical lobular hyperplasia (ALH) Abnormal proliferating cells in breast lobules.

Autoimmune hemolytic anemia (AIHA) See Anemia.

Autoimmune neonatal thrombocytopenia See Thrombocytopenia.

Autoimmune vascular purpura (allergic purpura) Purpura caused by antibody-mediated injury of blood vessel walls, typically arterioles and capillaries. The reaction is directed to foreign proteins or chemicals in the blood (microorganisms, drugs, or other chemicals) that deposit on the vessel walls.

Autonomic hyperreflexia (dysreflexia) A syndrome resulting from afferent stimuli that cause intense sympathetic discharge originating with spinal cord injury above the major splanchnic outflow; characterized by hypertension, bradycardia, sweating of the forehead, severe headache, and piloerection on distention of the bladder and rectum.

Autosomal agammaglobulinemia See Immune deficiency.

Autosomal dominant polycystic kidney disease (ADPKD) A progressive disease characterized by the formation of multiple cysts of varying size scattered diffusely throughout both kidneys, resulting in compression and destruction of renal parenchyma, usually with hypertension, gross hematuria, and uremia leading to progressive renal failure.

Autosomal hyper-IgM syndrome See Immune deficiency.

Azotemia Kidney dysfunction characterized by increased serum urea levels and frequently associated with increased creatinine

levels.

B

Bacterial pneumonia An acute or chronic disease marked by inflammation of the lungs caused by bacterial infection.

Bacterial tracheitis A condition in which the larynx, trachea, and bronchi are inflamed and present with signs similar to those of epiglottitis and croup; may result in airway obstruction secondary to subglottic edema or sloughing of the epithelial lining or the mucopurulent membrane within the trachea.

Bacterial vaginosis (BV) A condition caused by an overgrowth of normal vaginal bacteria, causing vaginal discharge with a foul odor.

Balanitis Inflammation of the glans penis caused by irritation by environmental substances, physical trauma, or infection.

Bare lymphocyte syndrome See Immune deficiency.

Barrett esophagus Chronic peptic ulceration of the esophagus; formation of precancerous lesions with possible progression to adenocarcinoma.

Bartholinitis (Bartholin cyst) Inflammation of one or both ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands.

Basal cell carcinoma A surface epithelial tumor of the skin originating from undifferentiated basal or germinative cells.

B-cell neoplasm See Lymphoma.

Becker muscular dystrophy A general term for a number of late-onset X-linked recessive hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

Beckwith–Wiedemann syndrome An inherited disorder characterized by exomphalos, macroglossia, and gigantism; often associated with visceromegaly, adrenocortical cytomegaly, and dysplasia of the renal medulla.

Benign breast disease (BBD) A spectrum of noncancerous changes in ducts and lobules of the breast, including irregular lumps, cysts, sensitive nipples, and itching.

Benign prostatic hyperplasia (BPH) Enlargement of the prostate gland, which may press against the urethra and bladder, interfering with urine flow.

Beta-thalassemia major (Cooley anemia) See Anemia.

Beta-thalassemia minor See Anemia.

Biliary atresia A condition in newborn children in which the biliary tract is blocked or absent, causing bile accumulation and progressive liver failure.

Biliary cirrhosis See Cirrhosis.

Bipolar disorder Psychiatric disorder characterized by alternating mania or hypomania and depression, often with periods of normal mood in between, and changes in energy and behavior according to mood.

Blast injury Tissue damage from compressive waves of air against the body followed by waves of decreased pressure.

Blepharitis Inflammation of the eyelids.

B-lymphocyte deficiency See Immune deficiency.

Bradycardia An abnormally low heart rate, which can cause a fall in cardiac output or can be a symptom of deterioration.

Bradykinesia Decreased spontaneity and movement; a feature of extrapyramidal disorders, such as Parkinson disease.

Brainstem gliomas A group of tumors located in the brainstem that are usually classified as high grade and result in the sudden onset of symptoms including headaches, vomiting, and visual disturbances.

Bronchial carcinoid tumor An obstructing tumor of the trachea or large bronchi that may cause paraneoplastic symptoms.

Bronchiectasis Dilation of the bronchi in response to obstruction, necrotizing pneumonias, cystic fibrosis, or Kartagener syndrome (a hereditary syndrome consisting of dextrocardia, bronchiectasis, and sinusitis).

Bronchiolitis Inflammation of the bronchioles usually caused by viral infection.

Bronchiolitis obliterans Partial or complete obliteration of bronchioles and some bronchi by granulation and fibrotic tissue masses.

Bronchiolitis obliterans with organizing pneumonia (BOOP) Obstruction of the bronchioles and alveolar ducts by fibrous granulation tissue that is further complicated by the development of pneumonia.

Bronchopulmonary dysplasia (BPD) A condition most often found in premature infants in which chronic pulmonary insufficiency occurs because of long-term artificial pulmonary ventilation.

Bruton agammaglobulinemia See Immune deficiency.

Bulbar palsy A form of palsy resulting from impaired function of the cranial nerves from degeneration of the motor neurons of primarily the brainstem; manifested as weakness and wasting of the various bulbar muscles, resulting in difficulty articulating words (dysarthria) and difficulty swallowing (dysphagia); fluid regurgitation is a major symptom and can cause aspiration.

Bullous pemphigoid (BP) A more benign autoimmune disease than pemphigus vulgaris, with blistering of the subepidermal skin layer.

Burkitt lymphoma See Lymphoma.

Burn shock A phenomenon consisting of both a hypovolemic cardiovascular component and a cellular component; results from massive fluid losses from the circulating blood volume.

Bursitis A trauma or overuse injury that can cause painful inflammation in the bursal sacs.

C

C1 deficiency See Immune deficiency.

C2 deficiency See Immune deficiency.

C3 deficiency See Immune deficiency.

C3 receptor deficiency See Immune deficiency.

C4 deficiency See Immune deficiency.

C9 deficiency See Immune deficiency.

Cachexia Illness and malnutrition seen in individuals with cancer that results in wasting and eventual death.

Calculi or urinary stone (urolithiasis) Masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults.

Candidiasis A fungal infection caused by an overgrowth of normal *Candida albicans* found in the skin and mucous membranes of the mouth, respiratory tract, or vagina.

Caplan syndrome Formation in coal workers of intrapulmonary nodules in pneumoconiosis that are histologically similar to subcutaneous rheumatoid nodules associated with rheumatoid arthritis.

Carbuncles A condition in which a bacterial infection of the hair follicle or sebaceous gland ducts becomes painful and discharges pus through various openings.

Carcinoma in situ (CIS) Preinvasive epithelial malignant tumors of glandular or squamous cell origin.

Carcinoma Epithelial cell tumor.

Cardiogenic shock A condition resulting from decreased cardiac output caused by heart disease in which the heart is unable to pump blood through the body, usually because of myocardial infarction.

Cardiomyopathy(ies) A diverse group of diseases primarily affecting the myocardium and resulting from tissue remodeling caused by myocardial and neurohumoral responses to ischemic and hypertensive alterations.

Cavernous (congenital) hemangioma A birthmark that is similar to the strawberry hemangioma but is more deeply rooted and may appear as a red-blue spongy mass of tissue filled with blood.

Cellulitis An infection of the dermis and subcutaneous tissue usually caused by *Staphylococcus*, CA-MRSA, or group B streptococci.

Central core disease (CCD) An autosomal dominant congenital myopathy characterized by hypotonia, delay of motor development in infancy, and nonprogressive or slowly progressive muscle weakness; on biopsy the central core of muscle fibers stains abnormally, myofibrils are abnormally compact, and there is virtual absence of mitochondria and sarcoplasmic reticulum; histochemically, the cores are devoid of oxidative enzyme, phosphorylase, and ATPase activity.

Central precocious puberty A condition in which puberty begins prematurely with normal changes in the hypothalamus-pituitary-gonad (HPG) axis and with premature development of secondary sexual characteristics and premature closure of the epiphysis of long bones, resulting in lifelong short stature.

Centriacinar emphysema See Emphysema.

Cerebellar astrocytoma Brain tumor of the right or left cerebellar hemisphere that causes motor symptoms on the same side as the

tumor.

Cerebral palsy (CP) A developmental brain injury that occurs before or shortly after birth and causes muscular impairment affecting motor function and also may alter speech and learning abilities.

Cerebrovascular accidents (CVAs) The leading cause of disability, the third leading cause of death in women, and the fifth leading cause of death in men in the United States; classified pathophysiologically as ischemic, hemorrhagic, or cryptogenic.

Cervical dysplasia (cervical intraepithelial neoplasia [CIN]) A condition characterized by the appearance of abnormal cervical cells that are considered precancerous.

Cervicitis Inflammation of the mucous membrane of the uterine cervix caused by infection, typically by chlamydia, genital herpes, or gonorrhea.

Chediak-Higashi syndrome See Immune deficiency.

Cheyne-Stokes respiration An abnormal pattern of breathing in which tidal volume gradually increases followed by a gradual decrease and a period of apnea before returning to a normal respiratory pattern.

Chickenpox An infectious viral disease that is spread by direct contact or through the air by coughing or sneezing; it causes a blister-like rash that first affects the face and trunk and then can spread over the rest of the body; symptoms include severe itching, fatigue, and fever.

Childhood absence epilepsy (petit mal seizures, nonconvulsive epilepsy) A type of generalized epilepsy; age of onset is 4 to 10

years.

Chlamydia A sexually transmitted bacterial infection that can cause infertility and blindness.

Choking asphyxiation Obstruction of the internal airways.

Cholangiocellular carcinoma (cholangiocarcinoma) Primary carcinomas of the liver that develop in the bile ducts.

Cholecystitis Inflammation of the gallbladder commonly caused by impaction of a gallstone that causes right upper quadrant pain and possibly a rupture and abscess in the gallbladder.

Cholelithiasis The presence or formation of gallstones in the gallbladder or bile ducts.

Chondrosarcoma A cancer of the cartilage that usually occurs in the pelvic bones, shoulder bones, and the upper part of the arms and legs.

Chronic active hepatitis The persistence of clinical manifestations and liver inflammation after the acute stages with consistently abnormal liver function tests and persistent hepatitis B surface antigen (HBsAg) creating a predisposition to cirrhosis and primary hepatocellular carcinoma.

Chronic bronchitis Particularly as a cause of chronic cough in smokers.

Chronic gastritis Tends to occur in older adults with chronic inflammation, mucosal atrophy, and epithelial metaplasia; may be immune (fundal) or nonimmune (antral), depending on the pathogenesis and location of the lesions.

Chronic glomerulonephritis See Glomerulonephritis.

Chronic granulomatous disease (CGD) See Immune deficiency.

Chronic kidney disease (CKD) Progressive loss of renal function associated with systemic diseases such as hypertension, diabetes mellitus, systemic lupus erythematosus, or intrinsic kidney disease, including kidney stones, acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders.

Chronic leukemia See Leukemia.

Chronic lymphocytic leukemia (CLL) See Leukemia.

Chronic mesenteric ischemia Development of regions of compromised blood flow in the mesenterium secondary to atherosclerosis (most common), congestive heart failure, dysrhythmias, hemorrhage, thrombus formation, aortic aneurysm, or any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by formation of collateral circulation that may be able to nourish the resting intestine.

Chronic mucocutaneous candidiasis See Immune deficiency.

Chronic myelogenous leukemia (CML) See Leukemia.

Chronic obstructive pulmonary disease (COPD) Any of a group of irreversible respiratory diseases (chronic bronchitis, emphysema, α_1-antitrypsin deficiency) that are characterized by airflow obstruction or limitation.

Chronic pancreatitis Inflammation of the pancreas resulting from repeated exacerbations of acute pancreatitis that lead to chronic

changes; associated with obstruction from gallstones, autoimmune disease, gene mutations, smoking, occupational chemical exposure, and obesity.

Chronic pyelonephritis Persistent or recurrent infection of the kidney leading to scarring.

Chronic relapsing thrombotic thrombocytopenic purpura (TTP) See Thrombocytopenia.

Chronic venous insufficiency (CVI) Persistent ambulatory lower extremity venous hypertension.

Cirrhosis Degeneration of liver tissue resulting in fibrosis with nodule and scar formation that compromises liver function.

Alcoholic cirrhosis Destructive inflammation of the liver caused by the toxic effects of alcohol metabolism, immunologic processes, lipid peroxidation, and malnutrition.

Biliary cirrhosis A form of alcoholic cirrhosis in which damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes.

Primary biliary cirrhosis A T-lymphocyte- and antibody-mediated destruction of the small intrahepatic bile ducts.

Cloacal exstrophy Family of congenital anomalies with two exstrophied bladder units separated by an exstrophied segment of intestine, which is usually cecum, receiving the ileum superiorly and continuing distally to a blind-ending microcolon.

Clubfoot Describes a range of foot deformities in which the foot turns inward and downward.

Cluster headache One of a group of rare disorders referred to as *trigeminal autonomic cephalalgia*; they occur in clusters (up to eight attacks per day) on one side of the head primarily, with pain that is severe, stabbing, and throbbing.

Coal worker pneumoconiosis (coal miner lung, black lung) Mild to severe pneumoconiosis (pulmonary fibrosis) caused by coal dust (coal, silica, quartz) deposits in the lung; symptoms initially present as a productive cough and wheezing but may advance to chronic bronchitis and emphysema.

Coarctation of the aorta (COA) A condition in which the aorta narrows in the area where the ductus arteriosus inserts; narrowing usually occurs preductal in children and postductal in adults.

Cold agglutinin autoimmune hemolytic anemia See Anemia.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) See Anemia.

Combined T- and B-lymphocyte deficiency See Immune deficiency.

Common variable immune deficiency See Immune deficiency.

Communicating (extraventricular) hydrocephalus A disorder in which the cerebrospinal fluid pathways are intact but cerebrospinal fluid absorption is impaired.

Community-acquired pneumonia (CAP) A major cause of morbidity and mortality in children, particularly in developing countries.

Complement deficiency See Immune deficiency.

Complete precocious puberty Refers to the early onset and progression of all pubertal features (i.e., thelarche, pubarche, and menarche).

Complex febrile seizure Seizures with characteristic features similar to those of simple febrile seizure with a longer duration and focal characteristics; occur more than once in a 24-hour period.

Complex regional pain syndrome (CRPS) Diffuse persistent pain usually in an extremity often associated with vasomotor disturbances, trophic changes, and limitation or immobility of joints; frequently follows a local injury.

Compression atelectasis See Atelectasis.

Compressive syndrome (sensorimotor syndrome; crush syndrome) A shocklike state that follows release of a limb (or limbs) or the trunk and pelvis after a prolonged period of compression, such as by a heavy weight; characterized by suppression of renal function, probably the result of damage to the renal tubules by myoglobin from the damaged muscles.

Congenital (infantile) nephrotic syndrome (Finnish type) A very rare form of nephrotic syndrome caused by a defect in a kidney protein resulting in excessive amounts of protein excreted in the urine.

Congenital adrenal hyperplasia A group of autosomal recessively inherited disorders associated with a deficiency of one of the enzymes involved in cortisol biosynthesis, resulting in elevation of ACTH levels and overproduction and accumulation of cortisol precursors proximal to the block; androgens are produced in

excess, causing virilization. The most common disorder is the 21-hydroxylase deficiency, caused by mutation in the cytochrome P450 21-hydroxylase gene *(CYP21)* on chromosome 6p.

Congenital aganglionic megacolon (Hirschsprung disease) A congenital defect in which the nerves that innervate the anus through the wall of the bowel are absent, resulting in enlargement of the bowel superior to the point where the nerves are missing and a subsequent decrease in peristalsis that results in chronic constipation.

Congenital hydrocephalus Excessive accumulation of cerebrospinal fluid present at birth and characterized by increased intracranial pressure (ICP). This increase may be caused by a blockage within the ventricular system in which the cerebrospinal fluid (CSF) flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF that results in ventricular enlargement and increased ICP.

Congenital hydrocephalus Lack of secretion of thyroid hormone.

Congestive splenomegaly Enlargement of the spleen accompanied by ascites, portal hypertension, and esophageal varices; most commonly seen in those with hepatic cirrhosis.

Consumptive thrombohemorrhagic disorders Heterogeneous group of conditions that demonstrate the entire range of hemorrhagic and thrombotic pathologic conditions.

Contact dermatitis An allergic response to an environmental antigen binding to specific carrier proteins contained in an individual's skin.

Contrecoup injury Brain injury resulting from the brain hitting the inside of the skull on the side opposite the site of blunt force trauma.

Cor pulmonale Right-sided heart failure caused by prolonged pulmonary hypertension.

Coronary artery disease (CAD) Narrowing of the lumen of one or more of the coronary arteries, usually attributable to atherosclerosis, leading to myocardial ischemia; can cause congestive heart failure, angina pectoris, or myocardial infarction.

Craniopharyngioma A brain tumor that develops in the pituitary gland and most often affects children, causing headache, seizure, diabetes insipidus, early onset of puberty, and delayed growth.

Craniosynostosis (craniostenosis) (see Syndromic craniosynostosis) Premature ossification of the skull and closure of the sutures, resulting in abnormal skull expansion and asymmetrical skull growth.

Cri du chat syndrome A hereditary congenital syndrome characterized by hypertelorism, microcephaly, severe mental deficiency, and a plaintive catlike cry; caused by deletion of the short arm of chromosome 5.

Crohn disease (CD) An autoimmune condition in which the intestines and possibly other regions of the digestive system are chronically inflamed and ulcerated, causing chronic diarrhea, disrupted digestion, and subsequent difficulty eating and digesting food.

Croup A viral infection that involves the larynx, trachea, and the airways leading to the lungs and that can result in serious breathing difficulties, hoarseness, sore throat, and a hacking cough.

Cryptorchidism The scrotum of one or both testes is absent because of failure of the testis to descend from the abdominal position during fetal development.

Curling ulcer Ischemic ulcers of the stomach and duodenal mucosa that develop within hours after an event, such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis.

Cushing disease Adrenal hyperplasia caused by an ACTH-secreting basophil adenoma of the pituitary.

Cushing syndrome Increased synthesis and secretion of cortisol from a tumor of the adrenal cortex; caused by administration of glucocorticoid drugs or by the presence of an ACTH-secreting tumor of the anterior lobe of the pituitary gland (Cushing disease), resulting in weight gain, glucose intolerance, and muscle wasting.

Cushing ulcer A stress ulcer associated with severe head trauma or brain surgery.

Cyclic neutropenia See Immune deficiency.

Cylindrical bronchiectasis A reversible bronchial dilation with symmetrically dilated airways, as can be seen after pneumonia.

Cystic fibrosis (CF) A genetic disorder of the exocrine glands caused by a mutation in the CF transmembrane regulator gene, resulting in impairment in chloride transfer across cell membranes and

subsequent chloride and water accumulation in organs and in thickened secretions that block ducts and form cysts.

Cystitis A condition characterized by acute or chronic inflammation of the urinary bladder, usually caused by bacterial infection of the urethra; symptoms include frequent burning on urination, blood in the urine, pain in the pubic area, chills and fever, back pain, and nausea. See Painful bladder syndrome/interstitial cystitis (PBS/IC) for further information.

D

Dandy–Walker malformation Congenital defect of midline cerebellar structures and the fourth ventricle in which hydrocephalus is caused by atresia of the foramina of Luschka or Magendie, which normally allow the fourth ventricle to empty into the areas surrounding the brain, leading the ventricular flow of CSF into a "blind pouch."

Dawn phenomenon Abrupt increases in fasting levels of plasma glucose between 5 and 9 AM, in the absence of antecedent hypoglycemia; occurs in diabetic persons receiving insulin therapy.

Decompression sickness (DCS) (caisson disease) Gas embolism created when a person under water returns to the surface too quickly, resulting in cellular hypoxia, joint and muscle pain, and tissue necrosis.

Deep venous thrombosis (DVT) A blood clot or thrombus in a deep vein, usually of the leg.

Degenerative disk disease (DDD) Intervertebral disk tissue is replaced by fibrocartilage during aging; functional capacity is rarely altered.

Demyelinating polyneuropathy A type of polyneuropathy in which the peripheral nerve myelin is primarily affected; can be familial (Charcot-Marie-Tooth disease, type 1) or acquired (Guillain-Barré syndrome); motor nerve conduction is slowed or blocked.

Dermatitis herpetiformis Pruritic chronic dermatitis with successive groups of symmetrical, erythematous, papular, vesicular, eczematous, or bullous lesions; usually associated with asymptomatic gluten-sensitive enteropathy.

Detrusor areflexia A lower motor neuron disorder that results in underactive, hypotonic, or atonic bladder function with retention of urine and distention.

Detrusor hyperreflexia (uninhibited or reflex bladder) Upper motor neuron disorders in which the bladder empties automatically when it becomes full and the external sphincter functions normally.

Developmental dysplasia of the hip (DDH) A condition in which the hip joint of babies or young children is malformed, with the ball being completely out of the socket or the socket being too shallow to support the ball.

Diabetes Diseases having in common the triad of symptoms of polyuria, weight loss, and significant glucosuria.

Diabetes insipidus A disease caused by a deficiency in or resistance to antidiuretic hormone that is characterized by excretion of large

amounts of dilute urine because of a decrease in water reabsorption in the kidney.

Gestational diabetes mellitus (GDM) Carbohydrate intolerance of variable severity with onset during pregnancy.

Maturity-onset diabetes of youth (MODY) A non–insulin-requiring diabetes in lean individuals typically younger than 25 with evidence of autosomal dominant inheritance.

Type 1 diabetes mellitus A disorder of carbohydrate metabolism characterized by a decrease in insulin production, resulting in hyperglycemia, ketoacidosis, and eventually renal failure and coronary artery disease.

Type 2 diabetes mellitus A condition of glucose intolerance that normally appears first in adulthood and is exacerbated by obesity and an inactive lifestyle.

Diabetic nephropathy A progressive kidney disease caused by diabetes-induced angiopathy of capillaries in the glomeruli that causes nodular glomerulosclerosis.

Diabetic neuropathy Combined sensory and motor disorder often seen in older diabetic persons as a result of microvascular injury involving small blood vessels that supply nerves.

Diabetic retinopathy Damage to the retina caused by an over accumulation of glucose or fructose that damages the blood vessels in the retina; in advanced stages, lack of oxygen in the retina causes fragile blood vessels to grow along the retina and in the vitreous fluid of the eye that may bleed and cause blurred vision.

Diaper dermatitis A type of dermatitis characterized by inflammation of the skin in the diaper area in infants caused by exposure of the skin to feces and urine.

Diastolic heart failure A condition in which heart contractions are normal but the ventricle does not relax completely; therefore less blood enters the heart.

Diffuse brain injury (diffuse axonal injury) Injury to neuronal axons in many areas of the brain caused by stretching and shearing forces received during brain injury.

DiGeorge syndrome See Immune deficiency.

Dilated cardiomyopathy (congestive cardiomyopathy) A condition in which all four chambers of the heart are enlarged and weakened, resulting in progressive congestive heart failure and the need for heart transplantation.

Discoid (cutaneous) lupus erythematosus (DLE) See Lupus erythematosus.

Dislocation The temporary displacement of a bone from its normal position in a joint.

Disorders of desire (hypoactive sexual desire, decreased libido) The most common sexual dysfunction in women; prevalence increases with age and may be a biologic manifestation of depression, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency.

Disseminated intravascular coagulation (DIC) An acquired clinical syndrome characterized by widespread activation of coagulation

resulting in the formation of fibrin clots in medium and small vessels (microvasculature) throughout the body.

Distal intestinal obstruction syndrome (DIOS) A syndrome seen in cystic fibrosis secondary to impaction with feces and inspissated mucus.

Diverticulitis Inflammation of the herniations or saclike outpouchings of mucosa through the muscle layers of the colon wall.

Diverticulosis The presence of multiple bulging sacs pushing outward from the wall of the large intestine that may become infected and rupture, causing abdominal pain, tenderness, and fever.

Down syndrome Trisomy or translocation of chromosome 21, resulting in intellectual disability; distinctive facial appearance with a low nasal bridge, epicanthal folds, protruding tongue, and flat, low-set ears; poor muscle tone (hypotonia); and short stature. Congenital heart defects, reduced ability to resist respiratory tract infections, and increased risk for leukemia are common.

Drug-induced hemolytic anemia See Anemia.

Duchenne muscular dystrophy (DMD) An X-linked genetic disorder in which fat and fibrous tissue infiltrate and weaken muscle tissues such as in the legs and pelvis, lungs, and heart; usually results in death before adulthood.

Dumping syndrome Rapid emptying of hypertonic chyme from a surgically created residual stomach causing nausea, vomiting, bleeding, and diarrhea about 20 minutes after a meal.

Duodenal ulcer Most common type of peptic ulcer; usually associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.

Dysfunctional uterine bleeding (DUB) Heavy or irregular bleeding in the absence of organic disease, such as submucous fibroids, endometrial polyps, blood dyscrasias, pregnancy, infection, or systemic disease.

Dyskinetic cerebral palsy Extreme difficulty in fine motor coordination and purposeful movements resulting from injury to the basal ganglia or thalamus.

Dysphoric mood Mood of general dissatisfaction, restlessness, depression, and anxiety; a feeling of unpleasantness or discomfort.

Dysplasia (atypical hyperplasia) Abnormal changes in the size, shape, and organization of mature cells; considered a form of atypical hyperplasia.

Dyspraxia The partial inability to perform purposeful or skilled motor acts in the absence of paralysis, sensory loss, abnormal posture and tone, abnormal involuntary movement, incoordination, or inattentiveness.

Dysrhythmias (arrhythmias) Disturbances of cardiac rhythm and the most common complication of acute MI.

Dyssynergia Development of lesions in the upper motor neurons of the brain and spinal cord; results in loss of coordinated

neuromuscular contraction and overactive or hyper reflexive bladder function.

E

Eczema Most common inflammatory disorder of the skin; generally characterized by pruritus, lesions with indistinct borders, and epidermal changes.

Eisenmenger syndrome A progressively developing condition in which a congenital heart defect such as ventricular septal defect is left untreated and causes a reversed right-to-left shunt secondary to increased pressures on the right side of the heart because of pulmonary hypertension.

Embryonic tumor A tumor originating in the gestational period that contains predominantly immature blast cells that cannot differentiate into mature functional cells.

Emphysema Pulmonary inflammation resulting in increased work of breathing or physiologic dead space and abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis.

Centriacinar emphysema Diminished pulmonary function resulting from septal destruction in the respiratory bronchioles and alveolar ducts, usually in the upper lobes of the lung.

Panacinar emphysema Destruction of the entire acinus, with damage more randomly distributed and involving the lower lobes of the lung. It tends to occur in older adults and in those with α_1-antitrypsin deficiency.

Empyema (infected pleural effusion) A condition in which purulent fluid is persistently discharged into the pleural space as a result of complications of bacterial infections.

Encephalitis Inflammation of the brain usually caused by a virus.

Endometriosis A condition that is common in women of reproductive age in which the tissue lining the uterus is found outside of the uterus, resulting in pain and infertility.

End-stage kidney disease (ESKD) A condition in which there is significant loss of renal function; usually less than 10% of renal function remains.

Eosinophilic esophagitis Rare, idiopathic inflammatory disease of the esophagus characterized by infiltration of eosinophils; associated with atopic disease, including asthma and food allergies.

Ependymoma Intracranial tumor that is most commonly found in children and typically arises from the inner lining of the fourth ventricle and the spinal canal.

Epididymitis A painful condition in which the epididymis becomes inflamed, usually because of a secondary bacterial infection that is triggered by a variety of underlying conditions such as urinary tract or sexually transmitted infections.

Epilepsy A group of chronic neurologic disorders with paroxysmal brain dysfunction from excessive neuronal discharge; symptoms vary widely from complex behavioral abnormalities to focal convulsions, to momentary spells of impaired consciousness.

Epispadias A birth defect in which the urethra opens on the upper penile surface.

Erysipelas A highly contagious bacterial infection that produces shiny, red, swollen areas and fever and can lead to blood poisoning and pneumonia.

Erythema multiforme A skin disease that is caused by allergies, seasonal changes, or drug sensitivities, resulting in the formation of red macules, papules, or subdermal vesicles on the skin and mucous membranes.

Erythema toxicum neonatorum A temporary eruption of redness of the skin, small papules, and occasionally pustules in newborns that is associated with contact dermatitis or hypersensitivity to milk or other allergens.

Erythrodermic (exfoliative) psoriasis See Psoriasis.

Erythromyalgia Chronic disorder characterized by warmth, pain, and redness, occurring primarily in the feet and lower legs.

Essential (primary) thrombocythemia (ET) Excessive production of platelets (platelet count greater than 400,000/mm^3 of blood); may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/mm^3 of blood when intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

Ewing sarcoma A malignant neoplasm of bone, primarily those of the extremities, including the shoulder girdle, with a predilection for the metaphysis; histologically presents as conspicuous foci of

necrosis in association with irregular masses of small, regular, rounded, or ovoid cells.

Exstrophy of the bladder A congenital defect in which the lower abdominal wall is malformed and ruptures.

Extrapyramidal/nonspecific cerebral palsy Any of a group of clinical disorders considered to be due to malfunction in the extrapyramidal system and marked by abnormal involuntary movements; included are parkinsonism, athetosis, and chorea.

F

Facioscapulohumeral muscular dystrophy (FSHD) An autosomal dominant genetic disorder that begins in childhood and causes muscle wasting and weakness, primarily in the face, shoulder, and arms.

Factor H deficiency See Immune deficiency.

Factor I deficiency See Immune deficiency.

Failure to thrive (FTT) Also called *growth faltering*, it is a physical sign demonstrating that a child is receiving inadequate nutrition for optimal growth and development. FTT is manifested as a deceleration in weight gain, a low weight/height ratio, a low weight/height/head circumference ratio, or a low body mass index (BMI).

Fanconi anemia See Anemia.

Fetal alcohol syndrome (FAS) A syndrome of altered prenatal growth and morphogenesis that occurs in infants born to women who were chronically alcoholic during pregnancy; it includes

maxillary hypoplasia, prominence of the forehead and mandible, short palpebral fissures, microphthalmia, epicanthal folds, severe growth retardation, intellectual disability, and microcephaly.

Fibromyalgia A condition in which muscles, tendons, and joints are painful, stiff, and tender; often accompanied by restless sleep, fatigue, anxiety, depression, and disturbances in bowel function.

Fibrosarcoma A malignant tumor of fibrous connective tissue that usually is derived from immature proliferating fibroblasts.

Fibrous dysplasia (FD) A genetic disorder in which tumor-like growths or lesions form in one or more bones and replace the medullary bone with fibrous tissue, resulting in expansion and weakening of the bone.

Florid hyperplasia Rapid and unexpected cell growth in the lining of the breast ducts.

Focal segmental glomerulosclerosis (FSGS) A condition in which glomerular capillaries with thickened basement membranes and increased mesangial matrix collapse in segments. Usually presents as nephrotic syndrome.

Frontotemporal dementia (FTD) (Pick disease) Progressive circumscribed cerebral atrophy; a rare type of cerebrodegenerative disorder manifested primarily as dementia, in which there is striking atrophy of portions of the frontal and temporal lobes.

FSH deficiency A condition characterized by decreased or absent production of follicle-stimulating hormone (FSH), resulting in a decline in spermatogenesis/oogenesis and associated infertility.

Furuncles A staphylococcal infection produces painful pus-filled inflamed hair follicles and involves surrounding skin and subcutaneous tissue.

Fusiform aneurysm (giant aneurysm) A large aneurysm that stretches to affect the entire circumference of the arterial wall.

G

Galactorrhea (inappropriate lactation) A condition in which milk-like fluid is secreted from the breast because of hormonal alterations that are not associated with childbirth or nursing.

Ganglioneuroblastoma An embryonal aggressive tumor of intermediate cellular differentiation that originates outside the central nervous system (CNS) in the developing sympathetic nervous system.

Ganglioneuroma A benign neoplasm composed of mature ganglionic neurons scattered within a stroma of neurofibrils and collagenous fibers.

Gangliosidosis Any disease characterized by abnormal accumulation of specific gangliosides within the nervous system (e.g., Tay-Sachs disease).

Gastroesophageal reflux disease (GERD) The reflux of acid and pepsin from the stomach to the esophagus that causes esophagitis.

General adaptation syndrome (GAS) The sum of all nonspecific reactions of the body to prolonged systemic stress, comprising alarm, resistance, and exhaustion.

Generalized anxiety disorder (GAD) An anxiety disorder characterized by an excessively anxious mood lasting at least 1 month that interferes with daily functioning and may be accompanied by jitteriness, sweating, feelings of catastrophe concerning one's family or self, and irritability.

Generalized neuropathy A functional disturbance or pathologic change in the cell body of one type of peripheral neuron.

Genital herpes A sexually transmitted viral infection that is caused primarily by herpes simplex virus type 2 and is characterized by painful lesions in the genital and anal regions.

Gestational diabetes mellitus (GDM) See Diabetes.

GH deficiency A condition characterized by decreased or absent production of growth hormone (GH), resulting in a decline in insulin-like growth factor 1 and dwarfism if the deficiency is prepubertal.

Glaucoma A disease of the eye characterized by increased intraocular pressure, excavation, and atrophy of the optic nerve; produces defects in the field of vision and eventual blindness.

Glomerulonephritis Inflammation of the renal glomeruli that may not produce symptoms or may present with hematuria and proteinuria.

Acute glomerulonephritis An inflammatory disease of both kidneys predominantly affecting children from ages 2 to 12.

Acute poststreptococcal glomerulonephritis (PSGN) A kidney disease secondary to infection with Streptococci in which bacterial antigens complex with antibodies in the blood, deposit

in the kidneys, and initiate an immune complex–mediated hypersensitivity reaction.

Chronic glomerulonephritis A slowly progressive glomerulonephritis most often associated with other systemic disease, including diabetes, malaria, hepatitis, or systemic lupus erythematosus, that generally leads to irreversible renal failure.

Membranoproliferative glomerulonephritis (MPGN) A chronic, slowly progressive glomerulonephritis in which the glomeruli are enlarged as a result of proliferation of mesangial cells and irregular thickening of the capillary walls, which narrows the capillary lumina.

Membranous glomerulonephritis A slowly progressive disease of unknown origin or that occurs secondary to autoimmune conditions, infections, specific drugs, or malignant tumors that is caused by immune complexes formed from the binding of antibodies to antigens of the glomerular basement membrane (GBM) or antigens transported from the systemic circulation and implanted in the GBM.

Membranous nephropathy (membranous glomerulonephritis) Membranous nephropathy is caused by subepithelial deposition of antibodies (IgG4 subclass) to antigens (M-type phospholipase A2 receptor [PLA2R] protein) located on glomerular podocytes and activation of complement-mediated inflammation with injury and release of inflammatory mediators by mesangial and epithelial cells, resulting in increased membrane permeability, thickening of the glomerular membrane, and ultimately glomerular sclerosis.

Mesangial proliferative glomerulonephritis Deposition of immune complexes in the mesangium with mesangial cell proliferation and expansion reducing blood flow and altering filtration membrane permeability with development of hematuria, proteinuria, hypertension, and uremia (nephritic syndrome); associated with IgA nephropathy, lupus nephritis, or early diabetic nephropathy.

Rapidly progressive (crescentic) glomerulonephritis (RPGN) (subacute or extracapillary glomerulonephritis) Develops over days to weeks, primarily affects adults in their fifties and sixties, and may be idiopathic or associated with a proliferative glomerular disease (diffuse proliferation of extracapillary cells), such as lupus or poststreptococcal glomerulonephritis.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency See Anemia.

Gluten-sensitive enteropathy (celiac sprue) A condition characterized by mucosal inflammation and villous atrophy in the gastrointestinal tract formed in response to a genetic predisposition for an immune response to gluten and similar proteins.

Gonorrhea A sexually transmitted disease caused by the bacteria gonococci that invade the mucous membranes of the genitals and urinary tract and in women the cervix, fallopian tubes, and ovaries, causing chronic pelvic pain or infertility.

Gout A disorder of uric acid metabolism that causes painful inflammation of the joints, commonly the big toe, and arthritic

attacks resulting from elevated levels of uric acid in the blood and the deposition of negatively birefringent urate crystals around the joints.

Gouty arthritis Inflammation of the joints in gout.

Graft rejection Immunologic rejection of transplanted tissue or organs based on antigen differences between the donor and recipient.

Acute graft rejection Cell-mediated immune rejection that occurs within days to months after transplantation; immune response is usually against unmatched human leukocyte antigen (HLA) antigens and develops after transplantation.

Chronic graft rejection Slow, progressive organ failure after a period of months or years of normal function by a developing weak cell-mediated immune response against minor histocompatibility antigens on the endothelial cells lining the blood vessels of the grafted tissue.

Hyperacute graft rejection Immediate rejection of a graft because of preexisting antibodies against antigens expressed on the grafted tissue or organ.

Graft-versus-host disease (GVHD) Condition in which mature T cells in a transplanted graft (e.g., transfused blood) are capable of a destructive cell-mediated reaction against unmatched histocompatibility antigens on the tissues in the graft recipient.

Granuloma inguinale A bacterial-induced disease, also called *donovanosis*, that is thought to be transmitted primarily by anal rather than vaginal intercourse and causes painless genital ulcers

like syphilis but progresses to destroy the internal and external genital tissue.

Graves disease Autoimmune hyperthyroidism caused by antibodies that continuously activate thyroid-stimulating-hormone receptors, resulting in uncontrolled production of thyroxine and characterized by an enlarged thyroid gland, protrusion of eyeballs, a rapid heartbeat, and nervous excitability.

Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory polyradiculopathy, acute autoimmune neuropathy) An acute, immune-mediated disorder of peripheral nerves, spinal roots, and cranial nerves that commonly presents as a rapidly progressive, areflexic, relatively symmetrical ascending weakness of the limb, truncal, respiratory, pharyngeal, and facial musculature, with variable sensory and autonomic dysfunction; typically reaches its peak activity within 2 to 3 weeks, followed by a plateau period of similar duration, and gradual but complete recovery in most cases; often preceded by a respiratory tract or gastrointestinal tract infection and is associated with albuminocytologic dissociation of the cerebrospinal fluid.

Guttate psoriasis See Psoriasis.

Gynecomastia Abnormal breast tissue development on adolescent boys or men as a result of an imbalance in hormones.

H

Heat exhaustion Occurs when sufficient salt and water loss results in hemoconcentration with hypotension occurring secondary to

fluid loss (hypovolemia), and the individual feels weak, is nauseated, and can suddenly collapse.

Heat stroke A life-threatening condition associated with high environmental temperatures and humidity causing core body temperature to rise as a result of thermoregulatory failure.

Hematemesis Accumulation of blood in the gastrointestinal tract causing irritation, increased peristalsis, and vomiting.

Hematochezia Rapid bleeding from the upper GI tract producing bright red stools.

Hemochromatosis Disorder of iron metabolism characterized by excessive absorption of ingested iron, saturation of iron-binding protein, and deposition of hemosiderin in tissue, particularly in the liver, pancreas, and skin; cirrhosis of the liver, diabetes (bronze diabetes), bronze pigmentation of the skin, and eventually heart failure may occur; also can result from administration of large amounts of iron orally, by injection, or in forms of blood transfusion therapy.

Hemoglobin H disease See Anemia.

Hemolytic anemia See Anemia.

Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis) See Anemia.

Hemolytic jaundice (prehepatic jaundice, nonobstructive jaundice) Jaundice resulting from excessive hemolysis of red blood cells.

Hemolytic-uremic syndrome (HUS) A condition in which platelets aggregate within the kidney's small blood vessels, resulting in reduced blood flow to the kidney and subsequent kidney failure

and destruction of the red blood cells; occurs usually after exposure to Shiga-like toxin from a strain of *E. coli*.

Hemophilia A (classic hemophilia) A genetic disorder in which a mutation in factor VIII causes prolonged clotting time, decreased formation of thromboplastin, and diminished conversion of prothrombin.

Hemophilia B (Christmas disease) A genetic disorder similar to hemophilia A in terms of symptoms but with a mutation in the factor IX gene.

Hemophilia C (factor XI deficiency) A genetic disorder characterized by a deficiency in factor XI, resulting in a mild form of hemophilia.

Hemorrhagic stroke (spontaneous intracranial hemorrhage) Stroke usually caused by hypertension that results in bleeding in the brain and typically increases intracranial pressure and may lead to death.

Henoch–Schönlein purpura nephritis Inflammation of the blood vessels causing bleeding into the skin, mucous membranes, internal organs, and other tissues; pain and inflammation in the joints; abdominal pain; gastrointestinal bleeding; inflammation of the kidneys; subcutaneous edema; encephalopathy; and inflammation of the testis.

Heparin-induced thrombocytopenia (HIT) See Thrombocytopenia.

Hepatic encephalopathy A condition that is usually caused by liver cirrhosis and portal hypertension in which toxins produced by the gut pass into the systemic circulation and damage brain cells,

resulting in impaired cognition, tremor, and a decreased level of consciousness.

Hepatitis B virus One of six types of hepatitis virus that cause liver infection; it is most commonly sexually transmitted.

Hepatocellular carcinoma (hepatocarcinoma; HCC) Primary carcinoma of the liver developing in hepatocytes.

Hepatopulmonary syndrome Intrapulmonary vasodilation, intrapulmonary shunting, and hypoxia and portopulmonary hypertension (pulmonary vasoconstriction and vascular remodeling) are common respiratory complications of advanced liver disease and portal hypertension.

Hepatorenal syndrome (HRS) Acute renal failure occurs because of a decrease in renal blood flow secondary to liver disease.

Hereditary angioedema An inherited, autosomal dominant disease characterized by the episodic appearance of nonpitting edema, most often affecting the limbs, but capable of involving other parts of the body, including mucosal surfaces such as those of the intestine (causing abdominal pain) or respiratory tract (causing asphyxia); associated with deficiency of inhibitor of the first component of complement pathway (C1 esterase inhibitor).

Hereditary hemochromatosis (HH) Autosomal recessive chronic liver disease caused by excessive intestinal absorption of elemental iron; characterized by elevated serum iron saturation, transferrin, and ferritin levels; improves with phlebotomy; increased risk of developing cirrhosis, liver cancer, and liver failure.

Hereditary sideroblastic anemia See Anemia.

Hereditary spherocytosis See Anemia.

Hiatal hernia An anatomic abnormality in which the esophageal hiatus is larger than normal, causing part of the stomach to protrude through the diaphragm and up into the esophagus or chest.

High altitude cerebral edema (HACE) An increase in severity of symptoms or signs of neurologic dysfunction, such as ataxia or altered consciousness, related to high altitude.

High altitude pulmonary edema (HAPE) A noncardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure related to high altitude illness.

Hirsutism Abnormal growth and distribution of androgen-sensitive hair growth on the face, body, and pubic area in a male pattern that occurs in women.

Hodgkin lymphoma (HL) See Lymphoma.

Hormonal hyperplasia Growth of cellular layers chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken for reception of the fertilized ovum.

Huntington disease (HD) An autosomal dominant disease causing a progressive increase in involuntary, jerky, dyskinetic movements; mental deterioration; and premature death.

Hyaline membrane disease (HMD) A type of respiratory distress syndrome of the newborn in which there is formation of a

hyaline-like membrane lining the terminal respiratory passages; extensive atelectasis is attributed to lack of surfactant.

Hydrocele A collection of fluid within the tunica vaginalis that is the most common cause of scrotal swelling.

Hydrocephalus ex vacuo Hydrocephalus attributable to loss or atrophy of brain tissue; less commonly associated with raised intracranial pressure and dilation of the cerebral ventricles.

Hydrops fetalis Edema formation in the fetal subcutaneous tissue because of an enzyme deficiency or any one of several other disorders.

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS) A complication seen in diabetes mellitus in which very marked hyperglycemia occurs, causing osmotic shifts in water in brain cells, and resulting in coma. It can be fatal or lead to permanent neurologic damage.

Hypersensitive pneumonitis (extrinsic allergic alveolitis) An allergic, inflammatory disease of the lungs caused by inhalation of organic particles or fumes.

Hypertrophic cardiomyopathy A genetic disorder caused by various mutations that thicken the heart muscle, possibly leading to obstruction of blood flow and heart dysfunction; this is a common cause of sudden death in young athletes.

Hypogammaglobulinemia See Immune deficiency.

Hypoplastic anemia See Anemia.

Hypoplastic left heart syndrome (HLHS) A condition in which the left side of the heart, including the aorta, aortic valve, left

ventricle, and mitral valve, is underdeveloped and blood returning from the lungs flows through an opening in the atrial septum and the right ventricle pumps the blood into the pulmonary artery and then into the aorta.

Hypospadias A birth defect in which the urethral opening is abnormally placed, opening anywhere from the tip of the glans penis to the shaft, or to the junction of the penis and scrotum or perineum in males; usually opens in the vagina in females.

Hypotonia Decreased muscle tone; a condition in which passive movement of a muscle occurs with little or no resistance. A symptom of cerebellar and pure pyramidal tract damage, it is thought to be caused by decreased muscle spindle activity secondary to decreased excitability of neurons.

Hypovolemic shock Caused by loss of whole blood (hemorrhage), plasma (burns), or interstitial fluid (diaphoresis, diabetes mellitus, diabetes insipidus, emesis, or diuresis) in large amounts.

Hypoxemia Reduced oxygen levels in the blood, which contributes to cardiovascular dysfunction by causing dilation of arterioles, capillaries, and venules and leads to decreased vascular resistance and increased flow.

I

Iatrogenic pneumothorax See Pneumothorax.

Icterus neonatorum (neonatal jaundice) Jaundice in newborn infants caused by functional immaturity of the liver; usually subsides within the first few days of life.

Idiopathic pulmonary fibrosis (IPF) An excessive amount of fibrous or connective tissue in the lung.

Idiopathic thrombocytopenic purpura (autoimmune or primary thrombocytopenic purpura) See Thrombocytopenia.

IgA nephropathy (Berger disease) The most common form of idiopathic acute glomerulonephritis in developed countries, especially Asia; cause is unknown.

IgA pemphigus The most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis.

IgG subclass deficiency See Immune deficiency.

IL-7 receptor deficiency See Immune deficiency.

Immune deficiency A group of disorders in which one or more components of the immune or inflammatory response is impaired, resulting in increased susceptibility to infections. Primary (congenital) immune deficiencies result from genetic defects, and secondary immune deficiencies result from nongenetic factors, such as infections and other physiologic or pathophysiologic conditions. Primary immune deficiencies include:

B-lymphocyte deficiency A group of disorders in which B-cell development is defective, resulting in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism. These include:

Agammaglobulinemia A condition in which no antibodies are produced.

Autosomal agammaglobulinemia An autosomal recessive form of agammaglobulinemia resulting from mutations in the B-cell receptor.

Autosomal hyper-IgM syndrome Inability to class-switch resulting from mutations in CD40 on B cells.

Bruton agammaglobulinemia A defect in B-cell development results in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism.

Common variable immune deficiency The most commonly diagnosed immune deficiency; hypogammaglobulinemia of IgG and other antibody classes; normal numbers of B cells, with or without associated T-cell defects.

Hypogammaglobulinemia A condition in which immunoglobulin levels are much lower than normal.

IgG subclass deficiency Deficiencies in certain subclasses of antibody.

Selective IgA deficiency Failure to produce IgA, with or without diminished production of other classes of antibody.

X-linked hyper-IgM syndrome Inability to class-switch resulting from a defect in activation-induced cytidine deaminase (AICD).

Combined T- and B-lymphocyte deficiency A group of immune deficiencies in which both T and B lymphocytes are defective. The

most severe of these deficiencies is called *severe combined immune deficiency (SCID)*. These include:

Adenosine deaminase (ADA) deficiency A form of SCID caused by an autosomal recessive mutation in the enzyme ADA, leading to death of rapidly dividing cells, particularly lymphocytes.

Ataxia-telangiectasia (AT) An autosomal recessive disorder resulting from a large variety of sporadic mutations in the *ATM* gene; often associated with ataxia (unsteady gait), telangiectasia (dilation of capillaries), and variable effects on both B and T cells.

Bare lymphocyte syndrome Forms of SCID characterized by an inability of lymphocytes and macrophages to present antigen because of defects in class I (major histocompatibility complex (MHC) class I deficiency) or class II (MHC class II deficiency) MHC antigen expression.

IL-7 receptor deficiency A form of SCID resulting from mutations in the IL-7 receptor, which is necessary for maturation of T cells.

JAK3 deficiency A form of SCID resulting from mutations in JAK3, which encodes an enzyme (a tyrosine kinase) associated with the receptor for IL-2.

Purine nucleoside phosphorylase (PNP) deficiency A form of SCID resulting from a mutation in the enzyme PNP.

RAG-1 and RAG-2 deficiencies Autosomal recessive mutations in recombination-activating gene (RAG-1 or RAG-2) enzymes that are necessary for genetic rearrangement of antibody and T-cell receptor variable regions.

Reticular dysgenesis The most severe form of SCID in which a common stem cell for all white blood cells is absent; therefore T cells, B cells, and phagocytic cells never develop.

Wiskott-Aldrich syndrome (WAS) An X-linked recessive trait resulting in chronic eczema with chronic suppurative otitis media, anemia, thrombocytopenic purpura, poor antibody response to polysaccharide antigens, and dysfunctions of cell-mediated immunity.

X-linked SCID A form of SCID with arrested maturation of T and natural killer (NK) cells and the production of immature B cells as a result of a defect in the IL-2 receptor gamma chain (IL-2Rγ), which is shared with many other cytokine receptors.

Complement deficiency A group of conditions in which specific proteins of the complement system are absent or suboptimal, resulting in diminished complement activity. These include:

C1 deficiency A deficiency of the first component of the classical pathway.

C2 deficiency A deficiency with an increased risk for recurrent respiratory tract infections with encapsulated bacteria and a systemic lupus erythematosus–like syndrome that may be complicated by kidney disease (glomerulonephritis).

C3 deficiency The most severe complement defect; an associated deficit of C3b, which is a major opsonin, results in a risk for recurrent life-threatening infections with encapsulated bacteria.

C3 receptor deficiency Deficiencies in the complement receptor for C3 result in recurrent bacterial infections, particularly of the skin.

C4 deficiency Results in an increased risk for recurrent respiratory tract infections with encapsulated bacteria and a systemic lupus erythematosus–like syndrome that may be complicated by kidney disease (glomerulonephritis).

C9 deficiency The most common terminal pathway defect and generally asymptomatic.

Factor H deficiency A deficiency of complement factor H resulting in increased destruction of C3 and a secondary C3 deficiency.

Factor I deficiency A deficiency of complement factor I resulting in increased destruction of C3 and a secondary C3 deficiency.

Mannose-binding lectin (MBL) deficiency A defect of the lectin pathway of complement activation resulting in an increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose.

Properdin deficiency An X-linked defect in the alternative pathway of complement activation resulting in recurrent meningococcal infections.

Phagocytic deficiency A group of conditions in which phagocytes are diminished, resulting in increased bacterial infections. These include:

Chediak-Higashi syndrome A lethal, progressive, autosomal recessive, systemic disorder associated with oculocutaneous albinism, massive leukocyte inclusions (giant lysosomes), histiocytic infiltration of multiple body organs, development of pancytopenia, hepatosplenomegaly, and recurrent or persistent bacterial infections.

Chronic granulomatous disease (CGD) Both X-linked and autosomal forms of mutations of the nicotinamide adenine dinucleotide phosphate + hydrogen (NADPH) oxidase complex, resulting in diminished production of hydrogen peroxide and other oxygen products necessary for the bactericidal activity of myeloperoxidase.

Cyclic neutropenia An autosomal dominant mutation in the *ELA2* gene resulting in periods of neutropenia lasting a few days to

weeks.

Severe congenital neutropenia Inadequate numbers of neutrophils resulting in a variety of recurrent and severe bacterial infections beginning early in life.

Secondary immune deficiencies .

Acquired immunodeficiency syndrome (AIDS) An epidemic, transmissible retroviral disease caused by infection with the human immunodeficiency virus (HIV), resulting in destruction of T-helper cells, suppression of both antibody and cellular immune responses, and development of life-threatening infections with opportunistic organisms.

Agranulocytosis Complete absence of granulocytes in the blood is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation.

Qualitative leukocyte disorder A group of conditions with various disruptions of leukocyte function.

Quantitative leukocyte disorder A group of conditions, frequently associated with infections and leukemias, with decreased production of leukocytes in the bone marrow or accelerated destruction of leukocytes in the circulation.

Transient hypogammaglobulinemia of infancy A period at 6 to 8 months when the newborn may not have produced adequate amounts of antibody to replace maternal antibody; in some infants this may lead to a period of increased susceptibility to infections.

T-lymphocyte deficiency A group of disorders in which T-cell development is defective, resulting in lower levels of cellular immunity. Diminished T-helper cell function may also decrease the production of antibody. These include:

Chronic mucocutaneous candidiasis A primary defect of T-lymphocyte response to a specific infectious agent, the yeast *C. albicans*.

DiGeorge syndrome A genetic disorder caused by deletion of a piece of chromosome 22 that results in cardiac defects, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia.

Immune thrombocytopenic purpura See Thrombocytopenia.

Imperforate anus A congenital defect in which the anal opening is absent because of the presence of a membranous septum or complete absence of the anal canal.

Impetigo A contagious bacterial infection that produces superficial red blisters that rupture and produce thick yellow crusts that commonly occur on the face but can spread to other regions of the body easily.

Infectious mononucleosis (IM) A disease caused by the Epstein-Barr virus or the cytomegalovirus that is transmitted by exchanging saliva or blood or by coughing and sneezing and acts by infecting the B cells and atypical T cells, resulting in fever, sore throat, and fatigue.

Infective endocarditis (IE) A general term used to describe infection and inflammation of the endocardium, especially the cardiac valves.

Infertility The inability to conceive after 1 year of unprotected intercourse with the same, opposite-sex partner.

Intracerebral hematoma (intraparenchymal hemorrhage) Blood accumulation that partially clots inside the brain, usually in the frontal and temporal lobes.

Intraductal papilloma Array of papillary cells that grow from the wall of a cyst into the lumen of the duct; growth occurs within a dilated duct often near or beside the nipple, causing benign nipple discharge.

Intrarenal (intrinsic) acute kidney injury (AKI) A sudden decline in kidney function with a decrease in glomerular filtration and an accumulation of nitrogenous waste products in the blood (elevation in plasma creatinine and blood urea nitrogen levels); may result from ischemic acute tubular necrosis (ATN), nephrotoxic ATN (i.e., exposure to radiocontrast media or antibiotics), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth).

Invasive breast carcinoma A malignant invasive epithelial lesion derived from the terminal duct lobular area.

Invasive carcinoma of the cervix Invasion of cervical carcinoma into adjacent tissues, such as ureters and structures of the lateral pelvic wall, the vaginal stroma and epithelium, and the lower uterine segment and myometrium.

Inverse psoriasis See Psoriasis.

Iron deficiency anemia (IDA) See Anemia.

Irritable bowel syndrome (IBS) A chronic noninflammatory disease with a psychophysiologic basis; characterized by abdominal pain, diarrhea or constipation, or both; no detectable pathologic change.

Irritative syndrome (radicular syndrome) A combination of changes usually seen with compromise of a spinal root within the intraspinal canal; these include neck or back pain and, in the affected root distribution, dermatomal pain, paresthesias, or both; decreased deep tendon reflexes; and occasionally myotomal weakness.

Isolated systolic hypertension Loss of elasticity of the arteries resulting in an increase in cardiac output or stroke volume, a systolic blood pressure consistently greater than 160 mmHg, and a diastolic pressure less than 90 mmHg.

J

JAK3 deficiency See Immune deficiency.

Jaundice (icterus) Yellowish brown staining of the skin and the conjunctivae caused by high bilirubin levels in blood secondary to excessive erythrocyte breakdown, obstruction in or around the liver, or liver disease.

Juvenile idiopathic arthritis (JIA) Chronic pauciarticular arthritis and destruction of joints beginning in childhood and often going into remission at puberty.

Juvenile myoclonic epilepsy A type of epilepsy that occurs in adolescents and young adults, usually on awakening, and is characterized by jerks of the neck, shoulders, and arms and by clonic-tonic seizures.

K

Kaposi sarcoma (KS) A rare cancer of connective tissue caused by herpesvirus 8 (HHV8) in which many bluish red nodules appear on the skin, especially skin of the lower extremities; occurs in a particularly virulent form in individuals with AIDS.

Kawasaki disease A vascular disease characterized by an inflamed heart and vessels; a coronary artery aneurysm, thickening, and stenosis; a fever that lasts at least 5 days; and at least four of the following: inflammation with reddening of the whites of the eyes; red, swollen hands or feet or peeling skin; rash; swollen lymph glands in the neck; inflamed lips or throat; or red "strawberry" tongue.

Klinefelter syndrome Smallness of testes with fibrosis and hyalinization of seminiferous tubules, variable degrees of masculinization, azoospermia, infertility, and increased levels of urinary gonadotropins; associated typically with an XXY chromosome complement although variants include XXYY, XXXY, and XXXXY.

Kwashiorkor A condition in which children do not receive enough protein in their diet, resulting in a swollen and severely bloated abdomen secondary to decreased albumin levels in the blood, skin changes resulting in a reddish discoloration of the hair and

skin in dark-skinned children, severe diarrhea, fatty liver, muscle atrophy, and restricted development.

L

Lactase deficiency A condition in which insufficient lactase is present in the small intestine to digest lactose, resulting in lactose intolerance characterized by diarrhea, bloating, and gas in response to exposure to lactose.

Lactose intolerance A condition caused by lactase deficiency in which lactose is not metabolized, making it impossible for the small intestine to absorb it and causing excessive gas production and diarrhea when exposed to lactose-containing foods.

Lambert-Eaton myasthenic syndrome A generalized disorder of neuromuscular transmission caused by a defect in the release of acetylcholine from the presynaptic nerve terminals; often associated with small cell carcinoma of the lung, particularly in elderly men with a long history of cigarette smoking; weakness tends to affect solely axial muscles, girdle muscles, and less often the limb muscles; autonomic disturbances, dry mouth, and impotence are common; the deep tendon reflexes are unelicitable; caused by loss of voltage-sensitive calcium channels located on the presynaptic motor nerve terminal.

Laryngomalacia A congenital anomaly caused by a developmental delay in the laryngeal cartilage and supporting structures of the larynx that causes the cartilage to be floppy and fold in on itself during inspiration, producing high-pitched, coarse, and low-pitched sounds.

Left heart failure (congestive heart failure) Inability of the left ventricle to maintain its circulatory load, with a corresponding rise in pressure in the pulmonary circulation usually with pulmonary congestion and ultimately pulmonary edema.

Legg-Calvé-Perthes disease Blood supply to the head of the femur near the hip joint is interrupted, resulting in osteonecrosis of the corresponding epiphysis.

Lennox-Gastaut syndrome A generalized myoclonic epilepsy that occurs in children between 1 and 5 years of age as a result of various cerebral afflictions such as perinatal hypoxia, hemorrhage, encephalitis, and metabolic disorders of the brain; it is characterized by mental retardation, personality disorders, and generalized tonic seizures.

Leukemia A clonal malignant disorder of leukocytes in the bone marrow and usually, but not always of the blood; uncontrolled proliferation of malignant leukocytes, causing an overcrowding of bone marrow and decreased production and function of normal hematopoietic cells.

Acute leukemia Characterized by undifferentiated or immature cells, usually a blast cell, and the onset of disease is abrupt and rapid.

Acute lymphoblastic/lymphocytic leukemia (ALL) Excessive production and proliferation of malignant and immature white blood cells (lymphoblasts) in the bone marrow that progresses rapidly if left untreated.

Acute myelogenous leukemia (AML) Excessive number of immature myeloid cells (myeloblasts) in the blood and bone marrow, overcrowding the marrow and decreasing the function of other cells.

Chronic leukemia Slow-growing cancer with many immature lymphocytes in the blood and bone marrow; the predominant cell is more differentiated but does not function normally.

Chronic lymphocytic leukemia (CLL) Malignant transformation and progressive accumulation in the marrow of monoclonal B lymphocytes; rarely are CLL malignancies of T-cell origin.

Chronic myelogenous leukemia (CML) Production of heterogeneous myeloid cells in the bone marrow, the majority of which express the Philadelphia chromosome; CML is considered a myeloproliferative disorder.

Leukocytosis A leukocyte count that is higher than normal.

LH deficiency A condition characterized by decreased or absent production of luteinizing hormone (LH), resulting in a decline in sex steroid production in testes/ovaries and associated infertility.

Lichen planus A recurrent rash of small, flat-topped bumps and rough scaly patches appearing on the skin, in the lining of the mouth, and in the vagina in response to inflammation or an allergy to a specific medication.

Localized scleroderma (morphea) Rare and idiopathic sclerosis of the skin, usually with childhood onset.

Locked-in syndrome Quadriplegia and mutism with intact consciousness and preservation of some eye movements; usually

results from a vascular lesion of the anterior pons.

Lupus erythematosus Any of a group of autoimmune connective tissue disorders that commonly produce red scaly lesions and are accompanied by fever, malaise, myalgia, fatigue, and weight loss.

Discoid (cutaneous) lupus erythematosus (DLE) Lupus erythematosus limited to the skin; can progress to systemic lupus erythematosus.

Systematic lupus erythematosus A chronic, multisystem, inflammatory disease; is one of the most common, complex, and serious of the autoimmune disorders.

Lyme disease (borreliosis) Tick-borne spirochete bacterial infection that is characterized by a rash in the area of the bite, headache, neck stiffness, chills, fever, myalgia, arthralgia, malaise, fatigue, and possible development of arthritis in large joints.

Lymphadenopathy An alteration of lymphoid function characterized by enlarged lymph nodes.

Lymphoblastic lymphoma (LL) See Lymphoma.

Lymphogranuloma venereum (LGV) A sexually transmitted bacterial infection that enters the body through breaks in the skin or across the epithelial cell layer of mucous membranes and primarily targets the lymphatics and lymph nodes.

Lymphoma Diverse group of neoplasms arising from cell proliferation in lymphoid tissue.

B-cell neoplasm A group of lymphomas including myelomas that originate from B cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

Burkitt lymphoma An aggressive malignancy of the B lymphocytes characterized by a large osteolytic lesion in the facial bones and associated with Epstein-Barr virus infection.

Hodgkin lymphoma (HL) A neoplasm of lymphoid tissue that progresses from one group of lymph nodes to another; the lymph nodes, spleen, and liver become enlarged with the presence of Reed–Sternberg cells and is often accompanied by anemia, fever, and eventually death if not treated at an early stage; also referred to as *Hodgkin disease*.

Lymphoblastic lymphoma (LL) A progressive neoplasm arising in the thymus; most are of T-cell origin; a variant of acute lymphoblastic leukemia; common cause of non-Hodgkin lymphoma (NHL) in children.

Lymphoplasmacytic lymphoma Also called *Waldenström macroglobulinemia*.

Mucosa-associated lymphoid tissue (MALT) lymphoma A low-grade B-cell lymphoma linked to infection with *H. pylori*.

Mycosis fungoides Most common cutaneous T-cell lymphoma; present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors.

NK-cell neoplasm A group of lymphomas that originate from natural killer (NK) cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

Non-Hodgkin lymphoma (NHL) A group of malignancies of lymphoid tissue reclassified as B-cell, T-cell, and NK-cell lymphomas with varied biologic and clinical features.

T-cell neoplasm A variety of lymphomas that originate from T cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

Waldenström macroglobulinemia A rare type of slow-growing plasma cell tumor that secretes a monoclonal IgM molecule; also called *lymphoplasmocytic lymphoma*.

Lymphoplasmacytic lymphoma See Lymphoma.

Lysosomal storage diseases A group of more than 30 disorders that result from impaired lysosomal function, leading to mucopolysaccharidoses, lipid storage disorders, mucolipidoses, leukodystrophies, and glycoprotein storage disorders.

M

Macrocytic anemia (megaloblastic anemia) See Anemia.

Major (unipolar) depression Severely depressed mood and loss of pleasure that may begin suddenly or slowly; it persists for at least 2 weeks and may recur throughout life.

Malignant hyperthermia An inherited life-threatening disorder that causes muscle rigidity, a hypermetabolic state, tachycardia, and increased body temperature in response to administration of general anesthesia.

Malnutrition Lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals; caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors.

Mannose-binding lectin (MBL) deficiency See Immune deficiency.

Marasmus A childhood disorder characterized by protein and energy malnutrition, resulting in dry skin, loss of adipose tissue from normal areas of fat deposits such as buttocks and thighs, and behavior that is fretful and irritable.

Maturity-onset diabetes of youth (MODY) See Diabetes mellitus.

McArdle disease A metabolic disorder involving an enzyme defect that causes deficiency of muscle phosphorylase, which helps break down glycogen, and consequently this disorder causes an energy deficit in the muscles, resulting in muscle pain and cramping.

Meconium ileus Obstruction with thickened meconium in the intestine of a newborn child as a result of a lack of trypsin and associated with cystic fibrosis of the pancreas.

Medulloblastoma A malignant cerebellar tumor near the fourth ventricle that is most often found in children and consists of neoplastic cells that resemble the undifferentiated cells of the neural tube.

Melanoma A malignant tumor of the skin originating from the transformation of melanocytes.

Membranoproliferative glomerulonephritis (MPGN) See Glomerulonephritis.

Membranous glomerulonephritis See Glomerulonephritis.

Membranous nephropathy (membranous glomerulonephritis) See Glomerulonephritis.

Ménière disease (endolymphatic hydrops) Dilation of the membranous labyrinth of the inner ear that is thought to be due

to impaired absorption of endolymph in the endolymphatic sac; the pathologic finding in Ménière disease.

Ménière syndrome An affliction characterized clinically by vertigo, nausea, vomiting, tinnitus, and fluctuating and progressive sensory hearing loss associated with endolymphatic hydrops.

Meningioma A slow-growing mass of the meninges that is usually benign but increases intracranial pressure.

Meningocele Neural tube defect in the skull or spinal column that forms a cyst filled with cerebrospinal fluid through which the meninges of the brain protrude.

Mesangial proliferative glomerulonephritis See Glomerulonephritis.

Mesenteric venous thrombosis A condition in which a blood clot obstructs one of the mesenteric veins and compromises the intestinal blood supply; can result in intestinal gangrene and tissue death.

Mesothelioma A type of cancer that is usually associated with previous exposure to asbestos, which affects the pleura, the lining of the abdominal cavity, the pericardium, and most internal organ coverings.

Metabolic acidosis A condition in which the concentration of non–carbonic acids increases or bicarbonate (base) is lost from the extracellular fluid or cannot be regenerated by the kidney.

Metabolic syndrome A condition of unknown cause that presents with symptoms of insulin resistance, obesity, hypertension, dyslipidemia, and systemic inflammation.

Metatarsus adductus A foot deformity in which the front half of the foot bends inward, possibly because of the infant's position in the uterus.

Methicillin-resistant *Staphylococcus aureus* (MRSA) An infection that carries the extrachromosomal gene *mecA* for resistance to methicillin and has less sensitivity to inhibition by antibiotics.

MHC class I deficiency See Immune deficiency.

MHC class II deficiency See Immune deficiency.

Microcephaly A defect in which failure of normal brain growth causes delayed skull growth and production of a small head.

Microcytic-hypochromic anemia See Anemia.

Microscopic colitis A relatively common cause of diarrhea; occurs primarily in females and older adults.

Migraine headache A headache that usually begins in the temporal region unilaterally after vascular changes of cranial arteries and may cause irritability, nausea, vomiting, constipation or diarrhea, and photophobia.

Mild concussion (mild traumatic brain injury) Temporary axonal disturbances without the loss of consciousness in response to a violent blow, jarring, shaking, or other closed-head injury.

Miliaria A skin disease caused by partially obstructed sweat glands that results in small and itchy rashes usually located in skinfolds and on areas of the body that may rub against clothing, such as the back, chest, and stomach.

Minimal change nephropathy (MCN) The foot processes of the renal capillary basement membrane are fused and deformed because of a T-cell disorder that reduces the anion component of the basement membrane and allows proteins to leak into the renal tubule.

Minimally conscious state (MCS) A condition in which a severely brain-damaged person is capable of deliberate behavior distinguishable from unconscious reflexive actions.

Mitral valve prolapse syndrome The mitral valve cannot close properly because of one or both flaps being too large, possibly resulting in mitral valve regurgitation.

Mixed precocious puberty Development of some secondary sex characteristics of the opposite sex (virilization of a girl or feminization of a boy); usually evident at birth and rare in older children.

Molluscum contagiosum A viral infection of the skin occurring in young children that affects the body, arms, and legs; it is spread through direct contact, saliva, or shared articles of clothing and is considered a sexually transmitted disease in adults, affecting the genitals, lower abdomen, buttocks, and inner thighs.

Monoclonal gammopathy of undetermined significance (MGUS) Production of monoclonal antibodies by noncancerous plasma cells that accumulate in the blood.

Motility diarrhea Diarrhea caused by excessive motility decreases transit time, mucosal surface contact, and fluid absorption secondary to resection of the small intestine (short bowel

syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, irritable bowel syndrome–diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse.

Moyamoya disease An abnormality of the blood vessels that supply the frontal region of the brain in which vessels constrict or become completely occluded, resulting in diminished blood flow. The body attempts to compensate by growing new vessels at the base of the brain, which appear as a puff of smoke on angiography.

Mucoepidermoid carcinoma A tumor of the main or lobar bronchi lumen that may extend into the peribronchial tissue.

Mucolipidosis (ML) Accumulation of both carbohydrates and lipids.

Mucopolysaccharidosis Carbohydrate excess disorders.

Mucopurulent cervicitis (MPC) Inflammation of the cervix with purulent endocervical exudate that may be asymptomatic or cause abnormal vaginal discharge and vaginal bleeding.

Mucosa-associated lymphoid tissue (MALT) lymphoma See Lymphoma.

Multiple myeloma (MM) Most common and most aggressive plasma cell tumor; a clonal plasma cell cancer characterized by the slow proliferation of malignant cells as tumor cells form masses in the bone marrow that usually result in destruction of the bone; most secrete large amounts of monoclonal proteins that resemble intact immunoglobulins.

Multiple organ dysfunction syndrome (MODS) Progressive disease often involving the ultimate failure of two or more organ systems after a severe illness or injury; disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyper dynamic state that persists as organ dysfunction develops.

Multiple papilloma (diffuse papillomatosis) A minimum of five papillomas within a localized segment of breast tissue.

Multiple sclerosis (MS) Chronic demyelinating disease of the central nervous system that causes inflammation and scarring of myelin sheaths.

Muscular dystrophy A general term for a number of hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

Myasthenia gravis Neuromuscular disorder caused by an autoimmune response in which antibodies to acetylcholine receptors impair neuromuscular transmission.

Mycosis fungoides See Lymphoma.

Myelodysplastic syndrome (MDS) A group of hematologic conditions characterized by ineffective production of blood cells, resulting in anemia that requires chronic blood transfusion.

Myoadenylate deaminase deficiency (MDD) A genetic disorder in which an enzyme deficiency prevents the conversion of adenosine monophosphate (AMP) to inosine monophosphate, resulting in increased AMP loss and the inability to synthesize adenosine triphosphate for energy.

Myocardial infarction A heart condition of sudden onset in which muscle tissue dies because of a lack of blood flow, resulting in varying degrees of chest pain or discomfort, weakness, sweating, nausea and vomiting, and possibly loss of consciousness.

Myositis ossificans A condition in which bone is deposited in muscle tissue, causing pain and swelling.

Myositis Inflammation of a muscle, usually a voluntary muscle, resulting in pain, tenderness, and sometimes spasm in the affected area.

Myxedema Cutaneous edema caused by deposition of connective tissue (e.g., glycosaminoglycans and hyaluronic acid) and associated with hypothyroidism and Graves disease; characterized by dry skin, pretibial myxedema, swelling around the lips and nose, mental deterioration, and a decrease in basal metabolic rate.

N

Necrotizing enterocolitis (NEC) A condition of extensive ulceration and necrosis of the ileum and colon in premature infants during the neonatal period.

Necrotizing fasciitis A rare, rapidly spreading inflammation starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin; it is initiated by bacterial infection and treated with antibiotics; often requires surgical débridement.

Neonatal alloimmune thrombocytopenic purpura (NATP) See Thrombocytopenia.

Neonatal purpura fulminans A fatal syndrome found in neonates who are homozygous or double heterozygous for types I and II protein deficiency.

Nephritic syndrome A disorder of the glomerular filtration membrane in which plasma proteins and red blood cells pass into the urine, resulting in mild proteinuria, hematuria, and mild hypertension.

Nephroblastoma (Wilms tumor) A malignant renal tumor of young children that compresses the normal kidney parenchyma, causing an abdominal mass, blood in the urine, and fever and may be associated with anorexia, vomiting, and malaise; often inherited as an autosomal dominant trait.

Nephrotic syndrome A disorder of the glomerular filtration membrane that permits proteins to pass into the urine, resulting in proteinuria, hypoalbuminemia, hyperlipidemia, and systemic edema.

Neural tube defect (NTD) Lack of closure of the neural groove caused by an arrest of the normal development of the brain and spinal cord during the first month of embryonic development.

Neuroblastoma A malignant tumor containing neuroblast cells that originate in the autonomic nervous system or the adrenal medulla; is most common in infants and young children.

Neurogenic shock (vasogenic shock) A type of shock caused by the sudden loss of the sympathetic nervous system signals to the

smooth muscle in vessel walls, causing the vessels to relax and a decrease in peripheral vascular resistance and blood pressure.

Neuroleptic malignant syndrome Hyperthermia with autonomic and extrapyramidal side effects caused by the administration of neuroleptic drugs.

NK-cell neoplasm See Lymphoma.

Nonalcoholic fatty liver disease (NAFLD) Accumulation of fat in hepatocytes, primarily in the form of triglycerides, occurring either in the absence of alcohol or with little alcohol intake; causes progressive inflammation and scarring that is usually asymptomatic for years.

Nonalcoholic steatohepatitis (NASH) A more serious form of nonalcoholic fatty liver disease resulting from hepatocellular injury, inflammation, and fibrosis; this condition is difficult to distinguish from alcohol-induced liver fibrosis; may progress to cirrhosis, end-stage liver disease, and an increased risk for hepatocellular carcinoma.

Nonbacterial infectious cystitis See Painful bladder syndrome/interstitial cystitis (PBS/IC).

Nonbacterial prostatitis Prostatitis causes chronic pain that disappears and returns without warning but shows no signs of bacterial infection in the prostatic fluid even though the semen and other fluids from the prostate contain immune cells that the body produces in response to infection.

Non-Hodgkin lymphoma (NHL) See Lymphoma.

Noninfectious cystitis See Painful bladder syndrome/interstitial cystitis (PBS/IC).

Noninflammatory acne See Acne.

Noninflammatory joint disease A disease in which alterations in the structure or mechanics of the joint result in pain during motion.

Nonoliguric renal failure Excretion of more than 500 mL/day of urine concurrent with renal failure; although adequate volume of urine is excreted, renal tubules have impaired reabsorption and concentration and dilution function so that filtration is defective, resulting in accumulation of uremic toxins in the blood.

Nonossifying fibroma (fibrous cortical deficit) A benign fibrous tissue tumor forms in the metaphysis of any of the long bones but usually occurs in the thigh and shin bones in children and adolescents.

Nonpuerperal hyperprolactinemia The presence of excessive amounts of prolactin (the pituitary hormone that stimulates milk production) in the blood not related to pregnancy or childbirth; most common cause of galactorrhea.

Nonsyndromic craniosynostosis (see Craniosynostosis) The premature closure of one or more of the cranial sutures during the first 18 to 20 months of an infant's life, but an isolated defect unrelated to syndrome.

Normocytic-normochromic anemia (NNA) See Anemia.

O

Obesity hypoventilation syndrome (pickwickian syndrome) A condition of severely overweight individuals related to the inability to breathe rapidly or deeply enough to maintain adequate blood oxygen levels; characterized by obstructive sleep apnea, somnolence, hypoventilation, erythrocytosis, and heart failure.

Obsessive-compulsive disorder (OCD) An anxiety disorder characterized by obsessive thoughts and repetitive compulsive actions, such as cleaning, checking, or counting.

Obstructive jaundice Jaundice related to extrahepatic or intrahepatic obstruction.

Obstructive pulmonary disease Airway obstruction that is worse with expiration so that more force or more time is required to expire a given volume of air and emptying of the lungs is slowed; characterized by shortness of breath (dyspnea) and wheezing.

Obstructive sleep apnea syndrome (OSAS) A disorder of sleep characterized by airway obstruction and episodes of apnea accompanied by snoring.

Obstructive uropathy The blockage of urine flow, often by ureteral or kidney stones, resulting in the reflux of urine and subsequent injury to kidneys.

Onychomycosis A fungal infection of the fingernails or toenails that causes thickening, roughness, and splitting of the nails.

Oophoritis Inflammation of the ovaries.

Open pneumothorax (communicating pneumothorax) See Pneumothorax.

Optic glioma Tumor originating from glial cells in the brain that affects the optic nerve; commonly seen in children with neurofibromatosis.

Organic brain syndrome A constellation of physical brain disorders with psychologic or behavioral signs and symptoms and grouped according to symptoms rather than etiology.

Orthopnea Shortness of breath (dyspnea) that occurs when an individual lies flat and is common in individuals with heart failure.

Orthostatic (postural) hypotension A sudden drop in blood pressure when a person assumes a standing position, resulting in dizziness, lightheadedness, blurred vision, and temporary loss of consciousness.

Osmotic diarrhea Nonabsorbable substance in the intestine draws water into the lumen by osmosis, resulting in large-volume diarrhea; caused by drinking solutions with excessive sugars, salt, or vitamin C; maldigestion syndromes.

Osteoarthritis (OA) Inflammatory degenerative joint disease in which synthesis and degradation of the articular cartilage in the movable joints are altered, resulting in wearing and destruction of cartilage.

Osteochondrosis (Osgood-Schlatter disease) A condition in children that results from the tendons pulling on the epiphysis of long bones, causing pain just below the knee, irritation and swelling, and possibly abnormal bone growth.

Osteogenesis imperfecta (brittle bone disease) A genetic disease in which collagen production is deficient, making the bones abnormally fragile and causing recurring fractures with only minimal trauma, deformity of long bones, a bluish coloration of the sclerae, and often the development of otosclerosis.

Osteoid osteoma A benign tumor in one of the bones of the lower extremities that is painful and is characterized by vascularized connective tissue and osteoid material that is surrounded by a large zone of thickened bone.

Osteomalacia A disease in which vitamin D or calcium deficiency or excessive renal phosphate loss causes a softening of the bones with accompanying pain and weakness.

Osteomyelitis A bacterial infection of the bone and bone marrow that occurs through open fractures, penetrating wounds, surgical operations, or by infiltration of the bloodstream; causes pain, high fever, and formation of an abscess at the site of infection.

Osteoporosis A disease in which the bones become porous and weakened, making bones easily fracture and slow to heal.

Overactive bladder syndrome (OAB) A chronic syndrome of overactivity of the detrusor muscle; characterized by urgency with involuntary detrusor contractions during the bladder filling phase.

Oxygen toxicity An iatrogenic inflammatory condition caused by prolonged exposure to high concentrations of supplemental oxygen resulting from damage to alveolocapillary membranes,

disruption of surfactant production, and interstitial and alveolar edema; caused by oxygen free radicals.

P

Paget disease of bone (PDB or osteitis deformans) A bone disorder in which excessive bone remodeling causes enlarged, deformed bones that can weaken the bone integrity and result in bone pain, arthritis, deformities, or fractures.

Painful bladder syndrome/interstitial cystitis (PBS/IC) (see Cystitis) A condition occurring in women ages 20 to 40 years who have symptoms of cystitis, such as frequency, urgency, dysuria, and nocturia, for more than 6 weeks' duration; usually related to bacterial infection.

Nonbacterial infectious cystitis Cystitis with negative urine cultures and no other known etiology; most common in immunocompromised individuals and related to viral, mycobacterial, chlamydial, or fungal infection.

Noninfectious cystitis Cystitis without evidence of infection; usually autoimmune or related to exposure to radiation or chemotherapy treatment for pelvic or urogenital cancers.

Panacinar emphysema See Emphysema.

Pancreatic insufficiency A condition in which the pancreas does not secrete enough hormones and digestive enzymes for normal digestion to occur, resulting in malabsorption, malnutrition, vitamin deficiencies, and weight loss.

Pancreatitis Inflammation of the pancreas, usually resulting in abdominal pain.

Panhypopituitarism A condition in which the secretion of all anterior pituitary hormones is inadequate or absent; caused by a variety of disorders that result in destruction or loss of function of all or most of the anterior pituitary gland.

Panic disorder A psychologic disorder that is characterized by recurrent attacks of anxiety or terror and usually results in the development of one or more phobias.

Papulosquamous disorder Collective reference to inflammatory disorders characterized by papules, scales, plaques, and erythema, including psoriasis, pityriasis rosea, and lichen planus.

Paraesophageal hiatal hernia Herniation of the greater curvature of the stomach through a secondary opening in the diaphragm.

Paralytic ileus Also known as *functional obstruction*, it is a failure of motility after intestinal or abdominal surgery, acute pancreatitis, or hypokalemia.

Paraneoplastic pemphigus See Pemphigus.

Paraphimosis A condition in which the foreskin becomes trapped behind the glans penis and cannot return to its normal flaccid position covering the glans penis.

Parkinson disease Degeneration of the basal ganglia dopaminergic nigrostriatal pathway that causes hypokinesia, tremor, and muscular rigidity.

Parkinsonism (Parkinson syndrome, parkinsonian syndrome) A neurologic condition characterized by tremors, rigidity,

hypokinesia, and postural instability as a result of degeneration of the corpus striatum or substantia nigra caused by Parkinson disease and other conditions related to toxins or metabolic conditions.

Paronychia An acute or chronic infection of the cuticle. One or more fingers or toes may be involved.

Paroxysmal nocturnal dyspnea (PND) Attacks of breathing discomfort, shortness of breath, and coughing that occur at night with varying intensity so that individuals must sit up or stand to relieve dyspnea; may occur in individuals with heart failure or lung disease.

Partial obstruction of the bladder outlet or urethra Partial obstruction related to deposition of collagen within the smooth muscle bundles of the detrusor muscle; causes an increase in the force of detrusor contraction.

Partial precocious puberty The partial development of appropriate secondary sex characteristics alone or in combination.

Pediculosis pubis A contagious condition, also known as *crabs* or *crab lice*, that is an infestation of the pubic hair in which the louse feeds on human blood and multiplies rapidly.

Pelvic inflammatory disease (PID) Inflammation of the female genital tract caused by microorganisms, typically those that are sexually transmitted such as chlamydia and gonococci; characterized by severe abdominal pain, high fever, vaginal discharge, and possibly infertility.

Pelvic organ prolapse (POP) Bladder outlet obstruction in women caused most commonly by a cystocele (the downward protrusion of the bladder into the vagina) that descends below the level of the urethral outlet.

Pemphigus A category of autoimmune skin diseases marked by groups of itching blisters and raw sores on the skin and mucous membranes.

Paraneoplastic pemphigus The most severe form of pemphigus; is associated with lymphoproliferative neoplasms and affects internal organs, including lungs, thyroid, kidney, smooth muscle, and gastrointestinal tract.

Pemphigus foliaceus A milder form of pemphigus involving loss of cell-to-cell adhesion (acantholysis) at the subcorneal level with blistering, erosions, scaling, crusting, and erythema usually of the face and chest.

Pemphigus vulgaris The most common form of pemphigus with acantholysis at the suprabasal level and initiated by IgG autoantibodies against the desmoglein adhesion molecules, resulting in acantholysis in the epidermis with fluid accumulation and blister formation; oral lesions precede the onset of skin blistering.

Pericarditis The pericardium is infected by a virus, bacteria, parasite, or fungus and becomes inflamed, resulting in pain and fluid and blood components entering into the pericardial space.

Perihepatitis (Fitz-Hugh–Curtis syndrome) A complication of pelvic inflammatory disease secondary to gonococci bacteria

traveling up the peritoneum to the upper abdomen and causing inflammation.

Periodic paralysis One of a group of diseases in which muscular weakness or flaccid paralysis occurs without loss of consciousness, speech, or sensation.

Peripheral artery disease (PAD) Any of a group of diseases caused by the obstruction of large peripheral arteries secondary to atherosclerosis, inflammatory processes, embolism, or thrombus formation that causes ischemia.

Pernicious anemia See Anemia.

Pes planus (flatfoot) A condition in which the arch of the foot never develops or it collapses and contacts the ground.

Peyronie disease (bent nail syndrome) A condition in which fibrous plaques grow in the soft tissue of the penis because of injury of the internal cavity of the penis that is accompanied by bleeding and scar tissue formation at the tunica albuginea of the corpora cavernosa.

Phagocytic deficiency See Immune deficiency.

Phenylketonuria (PKU) A genetic disorder in which the body lacks the enzyme necessary to metabolize the amino acid phenylalanine to tyrosine, resulting in accumulation of phenylalanine and subsequent brain damage and progressive mental retardation.

Pheochromocytoma A tumor of the adrenal medulla that causes the chromaffin cells to secrete increased amounts of epinephrine or norepinephrine.

Phimosis The foreskin of the penis of an uncircumcised male cannot be fully retracted.

Pick disease Progressive atrophy of the cerebral convolutions in a limited area (lobe) of the brain, with clinical manifestations and course similar to those of Alzheimer disease.

Pityriasis rosea A skin disorder, thought to be caused by a virus, in which patches of ovular pink rash appear primarily on the trunk and extremities.

Plaque psoriasis See Psoriasis.

Pneumoconiosis A chronic disease of the lungs typically seen in miners, sandblasters, and metal grinders that is caused by repeated inhalation of dust particles, including iron oxides, silicates, and carbonates, that collect in the lungs and become sites for the formation of fibrous nodules that eventually replace lung tissue.

Pneumonia An infection of one or both lungs caused by a bacterium, virus, fungus, or other organism that enters the body through respiratory passages and causes high fever, chills, chest pain, difficulty breathing, cough with sputum, and possibly bluish skin from insufficiently oxygenated blood.

Pneumothorax The collapse of a lung and subsequent escape of air into the pleural cavity between the lung and the chest wall that is caused by trauma, environmental factors, or spontaneous occurrence and results in a sudden pain in the chest.

Iatrogenic pneumothorax The presence of air or gas in the pleural space caused by a rupture in the visceral pleura (which surrounds

the lungs) or the parietal pleura and chest wall; is most commonly caused by transthoracic needle aspiration.

Open pneumothorax (communicating pneumothorax) Spontaneous and traumatic pneumothorax in which air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced out during expiration.

Primary (spontaneous) pneumothorax Occurs unexpectedly in healthy individuals (usually men) between ages 20 and 40 years; is most often caused by the spontaneous rupture of blebs on the visceral pleura.

Secondary (traumatic) pneumothorax Spontaneous or secondary pneumothorax beginning with sudden pleural pain, tachypnea, and possibly mild dyspnea.

Tension pneumothorax The site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration, but preventing its escape by closing during expiration and leading to air pressure in the pneumothorax exceeding barometric pressure.

Polycystic ovary syndrome (PCOS) A hormonal condition in which multiple ovarian cysts form because of elevated levels of androgens, resulting in hirsutism, obesity, menstrual abnormalities, infertility, and enlarged ovaries.

Polycythemia vera A chronic, progressive disease that is characterized by overgrowth of the bone marrow, excessive red blood cell production, and an enlarged spleen and causes

headache, inability to concentrate, and pain in the fingers and toes.

Pompe disease See Acid maltase deficiency.

Port-wine (nevus flammeus) stain A birthmark caused by superficial and deep dilated capillaries in the skin that produce a reddish to purplish discoloration of the skin, usually on the face, but can occur anywhere on the body.

Postconcussive syndrome Physical and personality changes that may occur after concussion of the brain, including amnesia, headache, dizziness, tinnitus, irritability, fatigability, sweating, heart palpitations, insomnia, and difficulty concentrating.

Posthemorrhagic anemia See Anemia.

Postobstructive pulmonary edema (POPE) (negative pressure pulmonary edema) A rare life-threatening complication that can occur after relief of upper airway obstruction (e.g., postextubation laryngospasm after anesthesia induction, epiglottitis, laryngeal tumor, or obstructive tonsils).

Postrenal acute kidney injury Rare complication of urinary tract obstruction that affects the kidneys bilaterally (e.g., bilateral ureteral obstruction, bladder outlet obstruction–prostatic hypertrophy, tumors or neurogenic bladder, and urethral obstruction); obstruction causes an increase in intraluminal pressure upstream from the site of obstruction.

Postthrombotic syndrome (PTS) A syndrome that follows a vascular thrombosis, such as persistent edema.

Posttraumatic stress disorder (PTSD) A psychologic disorder that may develop in individuals who have experienced or witnessed traumatic events; is characterized by recurrent flashbacks of the traumatic event, nightmares, irritability, anxiety, fatigue, forgetfulness, and social withdrawal.

Potter syndrome A syndrome of renal agenesis with hypoplastic lungs and associated neonatal respiratory distress, hemodynamic instability, acidosis, cyanosis, edema, and characteristic (Potter) facies; death usually occurs from respiratory insufficiency, which develops before uremia.

Poverty of content A disorder, also called *poverty of speech content*, that is characterized by disorganized speech that conveys little information and may be vague or contain repetitive or obscure phrases.

Prader-Willi syndrome A rare genetic disorder caused by gene deletions on paternal chromosome 15 that result in short stature, hypotonia, small hands and feet, obesity, mild to moderate mental retardation, and hypogonadism.

Precocious puberty A condition in which a boy or girl undergoes the changes associated with puberty at an unexpectedly early age; often caused by a pathologic process that increases the secretion of estrogens or androgens.

Premenstrual dysphoric disorder (PMDD) Recurrence in the luteal phase of the menstrual cycle of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities.

Premenstrual syndrome (PMS) A group of symptoms that occur in many women from 2 to 14 days before menstruation begins, including abdominal bloating, breast tenderness, headache, fatigue, irritability, depression, and emotional distress.

Prerenal acute kidney injury Rapid development of renal hypoperfusion with the elevation of serum creatinine and urea levels.

Presbyopia A form of farsightedness usually accompanying advanced age in which the lens loses elasticity and becomes unable to accommodate and focus light for near vision.

Priapism A painful condition in which the erect penis maintains an erection in the absence of physical and psychologic stimulation.

Primary (congenital) immune deficiency See Immune deficiency.

Primary (spontaneous) pneumothorax See Pneumothorax.

Primary accidental hypothermia Unintentional drop in core body temperature below 35°C (95°F) of a previously healthy person attributable to the changes that occur with cold temperatures.

Primary adrenal insufficiency (Addison disease) Adrenal hypofunction resulting in bronzelike pigmentation of the skin, severe prostration, progressive anemia, low blood pressure, diarrhea, and digestive disturbance.

Primary amenorrhea Continued absence of menarche and menstrual function by 14 years of age without the development of secondary sex characteristics or by age 16 years if these changes have occurred.

Primary biliary cirrhosis See Cirrhosis.

Primary dysmenorrhea Painful menstruation because of a functional disturbance rather than because of inflammation, growths, or anatomic factors.

Primary gout Acute episodes of urate crystal–induced synovitis resulting from abnormality of purine metabolism; lower-than-normal urinary excretion of urate leads to hyperuricemia and acute episodes of joint inflammation.

Primary hyperaldosteronism (Conn disease, primary aldosteronism) An adrenocortical disorder caused by excessive secretion of aldosterone and characterized by headaches, nocturia, polyuria, fatigue, hypertension, potassium depletion, hypokalemic alkalosis, hypervolemia, and decreased plasma renin activity; may be associated with small benign adrenocortical adenomas.

Primary hyperparathyroidism Usually the result of a benign parathyroid tumor that secretes parathyroid hormone and increases circulating calcium levels; this condition is accompanied by hypercalcemia, nausea, vomiting, lethargy, depression, muscular weakness, and an altered mental state.

Primary hypertension (essential hypertension, idiopathic hypertension) Elevated blood pressure of unknown etiology accompanied by increased total peripheral vascular resistance as a result of vasoconstriction, increased cardiac output, or both.

Primary multiple organ dysfunction syndrome (MODS) Multiple organ injury directly associated with a specific insult, most often ischemia or impaired perfusion from an episode of shock or

trauma, thermal injury, soft tissue necrosis, or invasive infection with decreased local perfusion in the injured organs.

Primary syphilis A stage of syphilis infection that occurs after an incubation period of 10 to 90 days and is characterized by a primary sore or chancre that develops at the point of initial exposure and lasts 4 to 6 weeks.

Prinzmetal angina A form of angina pectoris characterized by pain that is not precipitated by cardiac work; it is of longer duration and usually more severe and is associated with unusual electrocardiographic results including elevated ST segments.

Progressive bulbar palsy (see Bulbar palsy) A slowly progressive neurodegenerative disorder of the motor neurons of the cerebral cortex, spinal cord, and brainstem, resulting in progressive symptoms of bulbar palsy that may advance to loss of ability to manipulate food in the mouth, inability to swallow, choking, and emotional changes; may lead to aspiration of food and fluid and death from pneumonia.

Progressive spinal muscular atrophy A progressive degenerative disorder of the motor neurons of the spinal cord causing muscular weakness and wasting, typically beginning in the distal portions of the limbs and spreading proximally.

Prolactinoma The most common type of anterior pituitary tumor; produces visual disturbances and prolactin excess that results in infertility and changes in menstruation in females and in impotence, loss of libido, and infertility in males.

Properdin deficiency See Immune deficiency.

Prostatitis Inflammation of the prostate gland caused by urinary tract infection.

Protein C deficiency A disorder characterized by a lack of anticoagulant activity and an increased tendency to form blood clots because of decreased degradation of factor Va and factor VIIIa secondary to thrombosis, deep vein thrombosis, pulmonary embolism, thrombophlebitis, neonatal purpura fulminans, and disseminated intravascular coagulation.

Protein S deficiency A disorder characterized by a lack of anticoagulant activity and an increased tendency to form blood clots because of decreased degradation of factor Va and factor VIIIa.

Pseudothrombocytopenia See Thrombocytopenia.

Psoriasis A noncontagious autoimmune skin disorder in which the skin becomes scaly and inflamed when cells in the outer layer of skin reproduce faster than normal and accumulate as plaques on the skin surface.

Erythrodermic (exfoliative) psoriasis Widespread red, scaling lesions that cover a large body surface area; often accompanied by itching or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.

Guttate psoriasis Sudden appearance of small papules on the trunk and extremities, occasionally after a streptococcal respiratory tract infection in children.

Inverse psoriasis Rare development of large, smooth, dry, and deep red lesions in skinfolds (i.e., axilla or groin).

Plaque psoriasis Most common form of psoriasis; begins with well-demarcated, thick, silvery, scaly erythematosus inflammatory lesions with epidermal hyper proliferation and the presence of activated T lymphocytes that may become mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions.

Pustular psoriasis Blisters of noninfectious pus that develop over areas of plaque psoriasis.

Pulmonary artery hypertension (PAH) Increased blood pressure in the pulmonary artery attributable to vasoconstriction that may eventually lead to fibrosis, increased workload, hypertrophy of the right ventricle, and right heart failure; etiology may be idiopathic, familial, or associated with other diseases.

Pulmonary embolism (PE) Dislodgement of a blood clot from its site of origin and embolization to the arterial blood supply of one of the lungs, resulting in shortness of breath and difficulty breathing, rapid breathing that is painful, cough, and (in severe cases) hypotension, shock, loss of consciousness, and death.

Pulmonary stenosis A condition in which the opening into the pulmonary artery from the right ventricle narrows.

Pure red cell aplasia (PRCA) An acquired or congenital condition in which the bone marrow lacks red blood cell precursors even though megakaryocytes and white blood cell precursors are usually present at normal levels.

Purine nucleoside phosphorylase (PNP) deficiency See Immune deficiency.

Pustular psoriasis See Psoriasis.

Pyloric stenosis A congenital abnormality in which the pylorus is narrow, resulting in poor feeding, weight loss, and progressively worsening vomiting.

Pyramidal/spastic cerebral palsy Palsy resulting from damage or defects in the brain's corticospinal pathways (upper motor neuron) in either one or both hemispheres.

Q

Qualitative leukocyte disorder See Immune deficiency.

Quantitative leukocyte disorder See Immune deficiency.

R

RAG-1/RAG-2 deficiencies See Immune deficiency.

Rapidly progressive (crescentic) glomerulonephritis (RPGN) See Glomerulonephritis.

Raynaud disease A condition in which the blood vessels spasm because of inadequate blood supply, resulting in discoloration of the fingers and/or toes after exposure to changes in temperature or emotional events.

Raynaud phenomenon A condition caused by the temperature-dependent deposition of immune complexes in the capillary beds of the peripheral circulation, which blocks the circulation and causes localized pallor and numbness, followed by cyanosis and eventually gangrene if the circulation is not restored.

Rectocele A condition caused by childbirth or hysterectomy in which the region between the rectum and vagina bulges toward the vagina, resulting in a sense of pressure or protrusion within the vagina, the feeling of incomplete emptying of the rectum, difficulty passing stool, discomfort or pain during evacuation or intercourse, constipation, vaginal bleeding, fecal incontinence, prolapse of the bulge through the opening of the vagina, or rectal prolapse through the anus.

Refeeding syndrome Metabolic disturbances that occur upon initiating parenteral or enteral nutritional therapy to individuals who are severely malnourished; starvation results in movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma and refeeding increases insulin levels and stimulates movement of glucose and these ions back into the cells, resulting in dangerously low levels in the plasma (hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency) and other potentially fatal metabolic complications.

Relative polycythemia A relative increase in the number of red blood cells caused by loss of the fluid portion of the blood.

Renal agenesis Only one functional kidney is present at birth.

Renal calculi (nephrolithiasis) Also called *urinary stones (urolithiasis)*; masses of crystals, protein, or other substances that can be located in the kidneys, ureters, and urinary bladder and are a common cause of urinary tract obstruction in adults.

Renal cell carcinoma (RCC) The most common renal neoplasm (approximately 80% of all renal neoplasms).

Renal dysplasia Abnormal tissue development in one or both kidneys.

Respiratory acidosis occurs when there is alveolar hypoventilation. Carbon dioxide is retained, increasing $[H^+]$ (as H_2CO_3), thus decreasing the ratio of to P_{CO_2} and producing acidosis.

Respiratory alkalosis Occurs when there is alveolar hyperventilation and decreased concentration of plasma carbon dioxide (termed *hypocapnia*), thus increasing the ratio of to P_{CO_2} (H_2CO_3).

Respiratory distress syndrome (RDS) of the newborn A condition, also known as *hyaline membrane disease (HMD)*, that is a type of respiratory distress in newborns, most often in prematurely born infants, those born by cesarean section, or those having a diabetic mother; the immature lungs do not produce enough surfactant to retain air so the air spaces empty completely and collapse after exhalation.

Reticular dysgenesis See Immune deficiency.

Retinoblastoma An autosomal dominant or sporadic disorder in which a malignant tumor forms in the retina of one or both eyes; typically found in infants.

Reversible sideroblastic anemia See Anemia.

Rhabdomyolysis A potentially fatal condition in which skeletal muscle breaks down as a result of injury such as physical damage

to the muscle, high fever, metabolic disorders, excessive exertion, convulsions, or anoxia of the muscle for several hours; large amounts of myoglobin are usually excreted.

Rheumatic fever An inflammatory disease that is associated with recent streptococcal infection and causes inflammation of the joints, fever, jerky movements, nodules under the skin, and skin rash and often is followed by serious heart damage or disease secondary to antibodies that react both with streptococcal antigens and with those of the heart valve.

Rheumatic heart disease (RHD) Sequela to rheumatic fever in which heart valves are repeatedly inflamed, developing fibrosis and thickening that can result in valve deformities, stenosis, or regurgitation.

Rheumatoid arthritis An autoimmune disease that causes chronic inflammation of the joints and the tissue around the joints and other organs.

Rickets A bone disease that is caused by a deficiency of vitamin D or calcium and manifests in children as softening of bones, abnormal growth of bones, and enlargement of cartilage at the ends of long bones.

Ringed sideroblast An erythroblast in which one-third or more of the nucleus is encircled by 10 or more siderotic granules that may be caused by antituberculous drugs and alcohol abuse.

Roseola A viral disease in infants and young children that causes fever and a spotty rash that appears shortly after the fever has subsided.

Rotavirus A viral infection seen in young children that causes diarrhea by attacking the lining of the small intestine, resulting in the inability to absorb fluid and electrolytes.

Rubella An infectious viral disease of children and young adults that is spread by a droplet spray from the respiratory tract of an infected individual; the disease causes a rash that lasts about 3 days with tender and swollen lymph nodes behind the ears.

Rubeola An infectious viral disease of young children, also known as *measles*, that is spread by a droplet spray from the nose, mouth, and throat of individuals in the infective stage and causes a rash, white spots in the mouth, a rash on the face that spreads to the rest of the body, and fever.

Russell-Silver syndrome (Russell-Silver dwarfism) A growth disorder manifesting as retardation, proportionate short stature, leg length discrepancy, and a small, triangular-shaped face.

S

Saccular aneurysm (berry aneurysm) A localized, progressively growing sac that affects only a portion of the circumference of the arterial wall and may be the result of congenital anomalies or degeneration.

Saccular bronchiectasis (see Bronchiectasis) Bronchiectasis resulting in dilated bronchi that become balloon-like.

Salmon patches (nevus simplex) Patches, also known as *stork bites*, of small, pink, flat spots that are small, dilated blood vessels visible through the skin and are usually found on the forehead,

eyelids, and upper lip; between the eyebrows; and on the back of the neck.

Salpingitis Inflammation of one of the two fallopian tubes caused by infection spreading from the vagina or uterus.

Sarcoma Tumor of the connective tissue cells.

Sarcopenia Age-related loss in skeletal muscle, which is a direct cause of the age-related decrease in muscle strength.

Scabies Skin infestation with the itch mite, *Sarcoptes scabiei*, acquired through close contact with an infected person or contaminated clothing that produces intense itching.

Schizophrenia A psychotic disorder characterized by delusions, hallucinations, loosening of associations, disturbances in mood and sense of self and relationship to the external world, and bizarre, purposeless behavior.

Sclerosing adenosis A condition in which the number of acini per terminal duct is more than twice the number of normal terminal ducts and is associated with a significantly increased risk of subsequent breast carcinoma.

Scoliosis A condition in which the spine is curved sideways to varying degrees; occurs because of either physiologic curvature or functional curvature in which contraction of the paraspinal muscles of the back creates a vertebral curve.

Seborrheic dermatitis Scaly, flaky, itchy, and red skin on the scalp, face, and trunk because of a yeast infection.

Seborrheic keratosis A benign proliferation of cutaneous basal cells that produces smooth or warty elevated lesions; seen primarily in

older people and presents as multiple lesions on the chest, back, and face.

Secondary (acquired) immune deficiency See Immune deficiency.

Secondary (traumatic) pneumothorax See Pneumothorax.

Secondary amenorrhea Menstruation begins at puberty but then is subsequently suppressed for three or more cycles or for 6 months in women who previously menstruated.

Secondary dysmenorrhea Altered menstruation because of inflammation, infection, tumor, or anatomic factors.

Secondary generalization The process by which a simple partial seizure involving one hemisphere becomes a generalized seizure involving the second hemisphere.

Secondary hyperparathyroidism A condition of elevated levels of parathyroid hormone resulting from disease such as renal failure in which parathyroid hormone concentration is elevated in response to vitamin D deficiency.

Secondary hypertension A condition of elevated blood pressure that is associated with other conditions, primarily with renal disease by a renin-dependent mechanism or a fluid volume-dependent mechanism.

Secondary hypothermia Depressed body temperature as a consequence of a serious systemic disorder, for example, endocrine disorders.

Secondary MODS The result of an excessive inflammatory reaction, after a latent period following the initial injury, in organs distant from the site of the original injury. It is postulated that the

resulting organ trauma is caused by the host response to a second insult rather than being a direct result of the primary injury.

Secondary septic arthritis A bacterial infection in the joints, causing them to become inflamed and the bacteria to proliferate.

Secondary syphilis The most contagious stage of syphilis infection; characterized by a skin rash that appears on the trunk and extremities 1 to 6 months after the primary infection and possibly mucous patches on the genitals or inside the mouth.

Selective IgA deficiency See Immune deficiency.

Sepsis Severe physiologic stress typically caused by an infection; its complications result from activation of biochemical and physiologic cascades that lead to the formation or activation of cytokines and other mediators that produce vasodilation, increased capillary permeability, maldistribution of blood flow, and cardiovascular and cellular dysfunction.

Septic shock A condition caused by systemic infection that results in decreased tissue perfusion and oxygenation and can lead to multiple organ dysfunction syndrome and death.

Serum sickness A form of hypersensitivity caused by injection of soluble antigen such as antiserum, which activates a type III hypersensitivity response (formation of soluble circulating antigen-antibody [IgG or IgM] complexes) that activates the complement system.

Severe combined immune deficiency (SCID) See Immune deficiency.

Severe congenital neutropenia See Immune deficiency.

Shock A condition in which the circulatory system is unable to provide adequate circulation to the body tissues because of inadequate pumping by the heart, a reduction in blood volume, or a reduction in blood pressure; it results in slowing of vital functions and possibly death.

Short bowel syndrome A group of malabsorption conditions resulting from massive resection of the small bowel, the degree and kind of malabsorption depending on the site and extent of the resection; it is characterized by diarrhea, steatorrhea, and malnutrition.

Sickle cell anemia See Anemia.

Sickle cell disease (SCD) See Anemia.

Sickle cell trait See Anemia.

Sickle cell–Hb C disease See Anemia.

Sickle cell–thalassemia disease See Anemia.

Sideroblastic anemia (SA) See Anemia.

Silicosis Inflammation of the lung resulting from the inhalation of free silica (silicon dioxide) and silica-containing compounds, which occurs in mining and related industries.

Simple febrile seizure Benign and most common form of childhood seizure.

Simple fibroadenoma Benign solid tumors composed of both fibrous and glandular tissue.

Sliding hiatal hernia The most common type of hernia, occurring when the proximal portion of the stomach moves into the thoracic

cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves.

Small cell lung carcinoma (SCLS) The most common type of neuroendocrine lung tumor; mostly arise from the central part of the lung.

Smallpox (variola) An infectious viral disease that is caused by a poxvirus and result in high fever, aches, and widespread eruption of large sores that leave scars.

Smoldering myeloma A condition in which abnormal plasma cells produce a monoclonal protein, but no symptoms or complications of myeloma are present and may not be present for several years.

Solitary plasmacytoma A solitary tumor of malignant plasma cells that may result in a single lytic bone lesion or may be in the tissues (extramedullary plasmacytoma).

Spina bifida occulta The mildest form of congenital disorder of incomplete closure of the embryonic neural tube; the outer part of some vertebrae may not be completely closed, but the defect is not apparent to the unaided eye and usually causes no serious neurologic dysfunctions.

Spinal stenosis Narrowing of the spinal canal as a result of congenital anomaly or spinal degeneration, resulting in pain, paresthesias, and neurogenic claudication.

Spondylolisthesis Forward displacement of one of the lower lumbar vertebrae over the vertebra below it or over the sacrum.

Sprain A ligament tear, which occurs most commonly in the wrist, ankle, elbow, and knee joints.

Squamous cell carcinoma (SCC) A tumor of the epidermis and the second most common human cancer.

Stable angina A condition in which ischemic attacks occur at predictable frequencies and duration after activities that increase myocardial oxygen demands such as exercise and stress.

Staphylococcal scalded-skin syndrome (SSSS) A disease in infants that is caused by a staphylococcal infection with release of an exfoliative toxin that results in peeling of large areas of skin.

Stevens–Johnson syndrome An inflammatory eruption of circular lesions that can cover the majority of the skin and mucous membranes and usually occurs after a respiratory tract infection or as an allergic reaction to drugs or other substances.

Strabismus The deviation of one eye from the other when a person is looking at an object; it results in failure of the two eyes to simultaneously focus on the same image and therefore loss of binocular vision.

Strawberry hemangioma A red birthmark caused by densely packed blood vessels that usually appears on the face, scalp, back, and chest and disappears during childhood.

Stress ulcer Acute peptic ulcer that occurs in association with various other pathologic conditions, including burns, cor pulmonale, intracranial lesions, and surgical operations.

Structural scoliosis A side-to-side curvature of the spine.

Subacute thyroiditis (subacute granulomatous thyroiditis, de Quervain thyroiditis) A painful inflammation of the thyroid that develops suddenly in a person who has had a viral infection, such

as mumps or an upper respiratory tract illness. Pain radiates throughout the neck and individuals feel ill and feverish.

Subglottic stenosis Narrowing of the airway below the larynx caused by a congenital anomaly or acquired narrowing secondary to injury, possibly resulting in respiratory distress, cyanotic episodes, or recurrent lung infections.

Subluxation An injury in which the contact between two joint surfaces is only partially lost.

Sudden infant death syndrome (SIDS) A syndrome, also known as *crib death*, that is characterized by the sudden, unexpected, and unexplained death of an apparently healthy infant less than 1 year of age.

Superior vena cava syndrome (SVCS) Restriction of the blood flow through the superior vena cava secondary to compression by malignancies or lymphadenopathy.

Sydenham chorea (St. Vitus dance) A postinfectious chorea appearing several months after a streptococcal infection with subsequent rheumatic fever. The chorea typically involves the distal limbs and is associated with hypotonia and emotional lability.

Symphysis Fibrocartilaginous joint; a type of joint in which the apposed bony surfaces are firmly united by a plate of fibrocartilage.

Synchondrosis A cartilaginous joint creating a union between two immovable bones, such as the synchondroses of the cranium, the pubic symphysis, the sternum, and the manubrium.

Syndesmosis A fibrous union in which two bones are connected by interosseous ligaments, such as the anterior and the posterior ligaments in the radioulnar and tibiofibular articulations; is usually converted into bone before adult life.

Syndrome of inappropriate antidiuretic hormone (ADH) secretion (SIADH) A condition in which the release of ADH from the posterior pituitary is elevated relative to serum sodium levels, resulting in increased water reabsorption by the kidneys and fluid overload.

Syndromic craniosynostosis (see Craniosynostosis) Synostosis that occurs as part of a genetic syndrome; usually associated with various dysmorphisms involving the face, skeleton, and nervous system and usually accompanied by developmental delay.

Syphilis A chronic infectious disease that is transmitted by direct contact, usually in sexual intercourse, or passed from mother to child in utero, and progresses through three stages characterized by chancres, ulcerous skin eruptions, and systemic infection that leads to damage to the cardiovascular and nervous systems.

Systemic inflammatory response syndrome (SIRS) A generalized inflammatory response that may lead to depressed cardiac function and decreased organ perfusion.

Systemic lupus erythematosus (see Lupus erythematosus) A chronic, multisystem, inflammatory disease and one of the most common, complex, and serious of the autoimmune disorders.

Systolic heart failure A condition in which the heart muscle contracts so weakly that insufficient oxygenated blood is pumped

throughout the body.

T

Tay-Sachs disease (GM2 gangliosidosis) A fatal autosomal recessive lysosomal storage disorder in which the lysosomal enzyme hexosaminidase A (HexA) is deficient, leading to accumulation of gangliosides in the brain and nerve tissue, mental retardation, convulsions, blindness, and premature death.

T-cell neoplasm See Lymphoma.

Tension pneumothorax See Pneumothorax.

Tertiary syphilis The most severe stage of syphilis, which can begin as early as 1 year after the initial infection but can take up to 10 years to manifest and is characterized by gummas—soft, tumor-like growths found in the skin and mucous membranes and often in the skeleton—joint deformity, neurosyphilis, and cardiovascular syphilis.

Tethered cord syndrome A group of neurologic disorders related to malformation of the spinal cord in which the cord becomes abnormally attached or tethered as a result of scar tissue that develops as the cord transcends the vertebral canal with growth; tethering may decrease blood flow.

Tetralogy of Fallot A congenital condition that is characterized by four malformations including ventricular septal defect, misplacement of the origin of the aorta, narrowing of the pulmonary artery, and enlargement of the right ventricle.

Thalassemia See Anemia.

Thromboangiitis obliterans (Buerger disease) Inflammation of the medium-sized arteries and veins because of thrombotic occlusion, resulting in ischemia and gangrene.

Thrombocythemia A chronic disorder of sustained megakaryocyte proliferation that increases the number of circulating platelets and results in megakaryocytic hyperplasia, splenomegaly, and complications by hemorrhagic and thrombotic episodes.

Thrombocytopenia A reduced number of circulating platelets.

Acute idiopathic thrombotic thrombocytopenic purpura A form of thrombocytopenic purpura (TTP) characterized by thrombotic microangiopathy in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation, leading to increased platelet consumption and organ ischemia.

Autoimmune neonatal thrombocytopenia Destruction of platelets in a fetus/neonate by antiplatelet antibodies produced in the mother against her own platelet antigens (autoimmune) that are shared with the child, and the antibodies are transported across the placenta and destroy the child's platelets.

Chronic relapsing thrombotic thrombocytopenic purpura A rare familial form of TTP characterized by recurring episodes of thrombocytopenia; usually seen in children.

Heparin-induced thrombocytopenia (HIT) A form of drug-induced thrombocytopenia caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation and thrombocytopenia.

Idiopathic thrombocytopenic purpura (autoimmune or primary thrombocytopenic purpura) The most common cause of thrombocytopenia, secondary to increased immune-mediated platelet destruction; can be acute or chronic.

Immune thrombocytopenic purpura A condition in which the number of platelets in the blood is reduced by the production of antibodies against platelets, resulting in ecchymoses and hemorrhage from mucous membranes, anemia, and extreme weakness.

Neonatal alloimmune thrombocytopenic purpura (NATP) A condition in which fetal platelets have an antigen from the father that is absent in the mother, and the mother forms antibodies that cross the placenta and destroy the fetal platelets.

Pseudothrombocytopenia An artificially low platelet count in anticoagulated blood caused by cooling of the blood and autoagglutination of platelets.

Thrombotic thrombocytopenic purpura (TTP) Altered blood coagulation caused by an enzymatic deficiency that is characterized by a reduced number of platelets in the blood, the formation of blood clots in tissue arterioles and capillaries, and neurologic damage.

Thrombophilia Genetic or acquired abnormality of the coagulation system with an increased risk for thrombosis.

Thrombotic thrombocytopenic purpura (TTP) See Thrombocytopenia.

Thrush A yeast infection of the mouth and throat that presents as creamy white curdlike patches on the tongue, inside the mouth, and on the back of the throat and that is commonly associated with yeast infection of the esophagus.

Thyrotoxicosis Excessive concentrations of thyroid hormones in the body that are marked by increased metabolic rate, heat intolerance, goiter, reproductive disorders, excessive sweating, and other alterations in systemic function.

Tinea capitis Fungal infections of the skin classified according to their location on the body.

Tinea corporis (ringworm) A fungal infection of the scalp; much more common in children than in adults.

Tinea infection One of a group of fungal skin infections that include athlete's foot, folliculitis, jock itch, ringworm, and pityriasis versicolor.

Tinea pedis Chronic, superficial fungal infection of the skin of the foot common in adults.

Tinea unguium A fungal infection of the nails.

Tinnitus A condition in which the person hears ringing, buzzing, or other sounds without an external cause.

T-lymphocyte deficiency See Immune deficiency.

Tophaceous gout A form of purine metabolism disorder characterized by the formation of chalky deposits of sodium biurate under the skin and in the joints.

Toxic epidermal necrolysis (TEN) A rare adverse reaction to certain drugs in which a large portion of the skin becomes intensely red, may develop blisters, and exfoliates.

Toxoplasmosis A protozoan infection that is the most common opportunistic infection and occurs in one-third of persons with HIV.

Tracheomalacia (tracheobronchomalacia) A congenital or acquired condition characterized by weakness of the tracheal support cartilage, resulting in tracheal collapse when increased airflow is needed.

Trachoma (granular conjunctivitis or Egyptian ophthalmia) A contagious, chronic inflammation of the mucous membranes of the eyes, caused by *Chlamydia trachomatis*.

Transcortical dysphasia (transcortical sensory dysphasia, mixed transcortical dysphasia, isolated speech center) A type of aphasia with poor comprehension, but fluent grammatically correct speech. Those with transcortical dysphasia can communicate well and are capable of good repetition.

Transient hypogammaglobulinemia of infancy See Immune deficiency.

Transient ischemic attack (TIA) A brief episode in which the brain receives insufficient blood supply; symptoms depend on the site of the blockage.

Transposition of the great arteries (TGAs) The aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle.

Traumatic (dissecting) aneurysm Aneurysm caused by weakening of arterial walls, by a penetrating missile, or after neurosurgery or neuroimaging following an injury.

Trichomoniasis A sexually transmitted bacterial infection of the urethra in males and the vagina in females that can cause urethral and bladder infection in males and urinary tract infection and painful, malodorous vaginitis in women.

Tricuspid atresia Congenital absence of the tricuspid orifice, circulation being made possible by the presence of an atrial septal defect.

True aneurysm Localized dilation of an artery with an expanded lumen lined by stretched remnants of the arterial wall.

Truncus arteriosus A congenital defect in which a large great vessel arises from a ventricular septal defect and does not divide into the aorta and pulmonary artery, resulting in one vessel carrying blood both to the body and to the lungs.

TSH deficiency A condition characterized by decreased or absent production of thyroid-stimulating hormone (TSH), resulting in a decline in thyroid hormone level and subsequent symptoms such as fatigue, cold intolerance, weakness, depression, muscle aches, weight gain, and constipation.

Tuberculosis (TB) An infectious disease of humans caused by *Mycobacterium tuberculosis* that results in the formation of tubercles on the lungs and other tissues of the body.

Tuberous sclerosis complex (TSC) An inherited disease caused by mutation of the *hamartin* and *tuberin* genes and resulting in

malformation of the brain, retina, and viscera and development of epileptic seizures, mental retardation, and skin nodules on the face.

Turner syndrome Gonadal dysgenesis with short stature, undifferentiated (streak) gonads, and variable abnormalities such as webbing of the neck, low posterior hair line, increased carrying angle of elbow, cubitus valgus, and cardiac defects. The genotype is XO (45, X) or X/XX or X/XXX mosaic. The phenotype is female.

Type 1 diabetes mellitus See Diabetes.

Type 2 diabetes mellitus See Diabetes.

U

Ulcerative colitis Chronically inflamed and ulcerated mucosal and submucosal lining of the large intestine, resulting in abdominal pain, diarrhea, and rectal bleeding.

Unclassified epileptic seizure Seizure disorders that do not fit neatly into a classified grouping. These seizures characteristically have a wide variety of abnormal clinical activity. Examples of this activity include rhythmic eye movements, chewing, and swimming movements. These activities are commonly seen in neonatal seizures.

Undifferentiated large cell anaplastic cancer A cancer of epithelial origin that has lost all evidence of differentiation and may have arisen from a stem cell.

Unilateral neglect syndrome Hemiapraxia with failure to pay attention to body grooming and stimuli on one side but not the

other; usually caused by a lesion in the central nervous system.

Unstable angina A condition in which unprovoked ischemic attacks occur at unpredictable frequencies and may increase in severity.

Upper airway obstruction (UAO) Infections, foreign body aspiration, angioedema, obstructive sleep apnea, and trauma in children.

Uremia Syndrome of renal failure resulting in elevated blood urea and creatinine levels.

Uremic syndrome A complex of symptoms resulting from the accumulation of urea and other nitrogenous compounds and toxins in the blood, leading to alterations in levels of fluid and electrolytes, metabolic acidosis, anemia, hyperphosphatemia, and hypocalcemia; symptoms include hypertension, anorexia, nausea, vomiting, diarrhea or constipation, malnutrition and weight loss, pruritus, edema, anemia, and neurologic, cardiovascular disease, and skeletal changes.

Ureterohydronephrosis Dilation of both the ureter and the pelvicaliceal system.

Ureteropelvic junction (UPJ) obstruction An impediment to the drainage of urine from the kidney, usually attributable to partial or intermittent blockage of the renal collecting system at the junction of the renal pelvis and ureter.

Urethral atresia Congenital absence or closure of a normal body opening or tubular structure; congenital imperforation of the urethra.

Urothelial (transitional cell) carcinoma The most common bladder malignancy, appearing on the inner lining of the bladder.

Urticaria Hives; a dermal (skin) manifestation of type I allergic reactions.

Usual ductal hyperplasia (UDH) Description of normal hyperplasia of cells that line the ducts in the normal breast; additional layers of benign cells are present, but with normal cellular structure and arrangement.

Uterine prolapse Descent or herniation of the uterus into or beyond the vagina because of weakness of the pelvic musculature, ligaments, and fascia or obstetric trauma and lacerations sustained during labor and delivery.

V

Vacuolar myelopathy HIV-induced loss of myelin and spongy degeneration of the spinal cord that may cause spastic paraparesis, sensory ataxia in lower limbs, and unsteady gait.

Vaginismus A form of sexual dysfunction that is caused by a psychologic disorder or vaginal inflammation in which the muscles at the entrance to vagina contract and prevent sexual intercourse.

Vaginitis Infection of the vagina usually caused by a fungus that may cause itching or burning and a discharge.

Vaginosis Vaginal irritation without white blood cells or other indication of infection.

Varicocele A painful condition in which the veins in the scrotum that develop in the spermatic cord enlarge, and if the valves that regulate blood flow from these veins become dysfunctional, blood does not leave the testis, thereby causing swelling in the veins above and behind the testis.

Varicose bronchiectasis A condition in which the bronchi become large and balloon-like.

Venous angioma Abnormal veins, usually near the ventricular wall, that form as a congenital anomaly.

Venous stasis ulcer A condition affecting the lower leg in which leaky valves, obstructions, or regurgitation in veins impairs blood flow back to the heart, resulting in pooling of blood in the lower leg and subsequent tissue damage.

Ventricular septal defect (VSD) A congenital malformation in which the wall between the left and right ventricles has a hole that allows blood to travel between the left and right ventricles, potentially leading to congestive heart failure.

Vesicoureteral reflux (VUR) Reflux of urine from the bladder into the ureter.

Vestibular nystagmus Involuntary rapid movement of the eyeball that is due to disturbance of the vestibular system; eye movements are rhythmic, with slow and fast components.

Vitiligo An autoimmune-related loss of melanocytes resulting in the depigmentation of patches of skin.

von Willebrand disease An inherited disease in which the von Willebrand factor proteins that are made in the blood vessel walls

and function to control platelet activity are abnormal or absent, resulting in a tendency to hemorrhage.

Vulvodynia Also referred to as *vulvitis, vestibulitis*, or *vulvovestibulitis*; chronic pain and inflammation of the vulva or vestibule, or both.

W

Waldenström macroglobulinemia See Lymphoma.

Wallerian degeneration The degeneration of a nerve fiber that has been separated from its nutritive center by injury or disease; characterized by segmentation of the myelin and resulting in atrophy and destruction of the axon.

Warm autoimmune hemolytic anemia See Anemia.

Wilms tumor See Nephroblastoma.

Wilson disease A genetic disease in which the ability to metabolize copper is impaired, resulting in an accumulation of copper deposits in organs such as the brain, liver, and kidneys and subsequent organ dysfunction and failure.

Wiskott–Aldrich syndrome (WAS) See Immune deficiency.

X

Xanthelasma A planar xanthoma involving the eyelid(s).

X-linked hyper-IgM syndrome See Immune deficiency.

X-linked SCID See Immune deficiency.

Z

Zika virus A single-stranded RNA virus from the Flaviviridae family, genus *Flavivirus*, that is predominantly transmitted through bites from infected mosquitos; infection during pregnancy has been associated with severe fetal infection and associated CNS abnormalities.

Zollinger–Ellison syndrome The association of atypical, intractable, sometimes fulminating peptic ulcers with extreme gastric hyperacidity and benign or malignant gastrinomas in the pancreas.

Common Laboratory Values

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
Electrolytes	Total, 1% of plasma weight	
Na^+	136–145 mEq/L	136–145 mmol/L
K^+	3.5–5 mEq/L	3.5–5 mmol/L
Ca^{++} (serum)	9–10.5 mg/dL	2.25–2.62 mmol/L
Mg^{++}	1.3–2.1 mg/dL	0.65–1.05 mmol/L
Cl^-	98–106 mEq/L	98–106 mmol/L
HCO_3^- (venous)	23–29 mEq/L	23–29 mmol/L
Phosphate (mostly HPO_4^-)	3–4.5 mg/L	1–1.5 mmol/L
Proteins		
Total Proteins	6.4–8.3 g/dL	64–83 g/L
Albumin	3.5–5 g/dL	35–50 g/L
Gamma globulin	0.7–1.7 g/dL	7–17 g/L
Globulins	2.3–3.4 g/dL	23–34 g/L
Fibrinogen	200–400 mg/dL	2–4 g/L
Troponin I	< 0.03 ng/mL	< 0.03 ng/mL
C-Reactive Protein (CRP)	<1.0 mg/dL	<10.0 mg/L
Procalcitonin[a] (PCT)		
Blood Gases		
pH (arterial)	7.35–7.45	7.35–7.45

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
PCO_2 content (arterial)	35–45 mmHg	35–45 mmHg
PO_2 content (arterial)	80–100 mmHg	80–100 mmHg
HCO3− (arterial)	21–28 mEq/L	21–28 mmol/L
Lipids		
Total Cholesterol	<200 mg/dL	<5.20 mmol/L
LDL	<130 mg/dL	
HDL	>45 mg/dL	>0.75 mmol/L (males)
	>55 mg/dL	>0.91 mmol/L (females)
Triglycerides (after 12 hr fast)	<180 mg/dL	0.45–1.81 mmol/L (males)
		0.40–1.52 mmol/L (females)
Waste Products		
Urea (BUN)	10–20 mg/dL	3.6–7.1 nmol/L
Uric acid (serum)	2.7–8.5 mg/dL	0.16–0.51 μmol/L
Creatinine	0.6–1.2 mg/dL	53–106 μmol/L
Creatinine clearance	107–139 mL/min	1.78–2.32 mL/s (males)

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
	87–107 mL/min	1.45–1.78 mL/s (females)
Bilirubin (total)	0.3–1.0 mg/dL	5.1–17 μmol/L
Bilirubin, direct (conjugated)	0.1–0.3 mg/dL	1.7–5.1 μmol/L
Bilirubin, indirect (unconjugated)	0.2–0.8 mg/dL	5.1–17 μmol/L
Hematology Values		
Leukocyte (white blood cell count)	5000–10,000/mm^3	5–10 × 10^9/L
Lymphocyte	20%–40% of leukocyte differential	1000–4000 × 10^6/L
Monocyte and macrophage	2%–8% of leukocyte differential	100–700 × 10^6/L
Eosinophil	1%–4% of leukocyte differential	50–500 × 10^6/L
Neutrophil (segmented)	55%–70% of leukocyte differential	2500–8000 × 10^6/L
Basophil	0.5–1% of leukocyte differential	25–100 × 10^6/L

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
Platelet	150,000–400,000/mm^3	150–400 × 10^9/L
Erythrocyte (red blood cell count)	4.2–6.1 million/mm^3	4.2–6.1 × 10^{12}/L
Hematocrit	36%–52%	0.40–0.54 g/L
Hemoglobin	12–18 g/dL	7.4–11.2 mmol/L
Mean corpuscular volume	80–96 mcm^3	80–96 fL
Individual Hormones		
Prolactin	3–27 ng/mL	3–27 μg/L
Thyroid tests		
T_3	75–220 ng/dL	975 nmol/L
Free thyroxine (T_4)	0.8–2.8 ng/dL	10–36 pmol/L
Total thyroxine (T_4)	4–12 μg/mL	59–135 nmol/L
TSH	0.4–4.0 μIU/L	0.4–4.0 μIU/L
Serum Enzymes		
Lactic dehydrogenase (total)	100–190 units/L	100–190 units/L
Isoenzymes:		
LDH-1 (heart)	17%–27%	
LDH-2 (reticuloendothelial system)	27%–37%	

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
LDH-3 (lungs)	18%–25%	
LDH-4 (kidney, placenta, pancreas)	3%–8%	
LDH-5 (liver, striated muscle)	0%–5%	
	30–120 units/L	0.5–2.0 μKat/L
Aspartate aminotransferase (AST)	0–35 units/L	0–0.58 μKat/L units/L
Alanine aminotransferase (ALT)	4–36 units/L	4–36 units/L
Creatine kinase	20–200 units/L	20–200 units/L
Amylase	60–120 Somogyi units /dL	30–220 units/L
Lipase	0–160 units/L	0–160 units/L
Other		
Bile acids	0.3–3.0 mg/dL	0.8–7.6 mmol/L
Glucose (fasting)	74–106 mg/dL	4.1–5.9 nmol/L
Hemoglobin A1c	4–5.9% of total	0.04–0.06 of total
Iron, total(s)	60–180 mg/dL	11–32 μmol/L
Iron-binding capacity(s)	250–460 mg/dL	45–82 μmol/L
Prothrombin time	11–12.5 sec	
International normalized ratio (INR)	.8–1.1	

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
Partial thromboplastin time	30–40 sec	
Erythrocyte sedimentation rate (ESR or sed rate) Westergren method		
Male	≤15 mm/hr	
Female	≤20 mm/hr	

Constituent	Normal Mean Value and Some Ranges	Normal Range in SI Units
Electrolytes	Total, 1% of plasma weight	
Na^+	136–145 mEq/L	136–145 mmol/L
K^+	3.5–5 mEq/L	3.5–5 mmol/L
Ca^{++} (serum)	9–10.5 mg/dL	2.25–2.62 mmol/L
Mg^{++}	1.3–2.1 mg/dL	0.65–1.05 mmol/L
