CHAPTER Outline

OUTLINE

Incidence, Mortality Trends, and Race, 388

Genetics, Epigenetics, Tumor Microenvironment, and Cellular Signaling in Cancer, 395
- Genetics and Epigenetics, 395
- Tumor Microenvironment, 395
- Cellular Signaling, 395

In Utero and Early Life Conditions, 397

Environmental-Lifestyle Factors, 399
- Tobacco Use, 399
- Diet and Nutrition, Obesity, Alcohol Consumption, and Physical Activity: Impacts on Cancer, 401
- Air Pollution, 409
- Ionizing Radiation, 412
- Non-Ionizing Radiation and Electromagnetic Radiation, 416
- Ultraviolet Radiation, 418
- Infection, Sexual and Reproductive Behavior, 419
- Other Viruses and Microorganisms, 420
- Environmental and Occupational Hazards as Carcinogens, 420

Cancer develops from complex interactions between genes and the environment, including epigenetics, environmental-lifestyle factors, altered metabolism and biologic processes, and exposure to carcinogens (cancer-causing chemical or physical agents (Fig. 13.1).[1–3] According to the World Health Organization (WHO), the causes of specific cancers, aside from those tied with smoking and asbestos and other workplace exposures, are not fully understood.[3] Because the National Cancer Institute estimates that about 10% or fewer of all cancers arise from inherited germ-line mutations, many forms of cancer are preventable.[4]

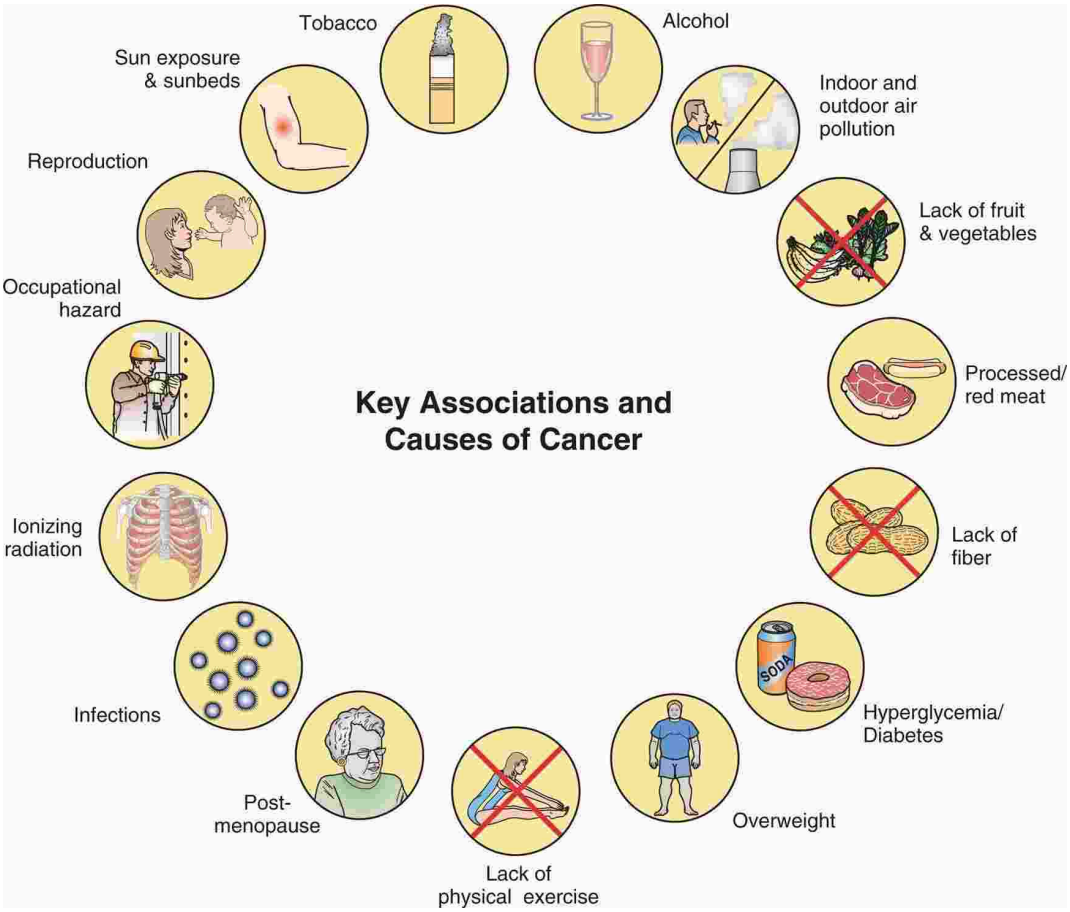

FIG. 13.1 Key Associations and Causes of Cancer. Tobacco, diet and alcohol, obesity, pollution, lack of physical activity, hormones, infections, ionizing radiation, occupational hazards, reproductive factors, and ultraviolet light are key factors for cancer. Although diet is key and known to affect cancer risk, determining specific dietary factors has been very difficult and is emerging.

An illustration lists the key associations and causes of cancer: alcohol, indoor and outdoor pollution, lack of fruit and vegetables, processed or red meat, lack of fiber, hyperglycemia or diabetes, overweight, lack of physical exercise, post-menopause, infections, ionizing radiation, occupational hazard, reproduction, sun exposure and sunbeds, and tobacco.

Contributing factors include high risk activities[5–7] (see Fig. 13.1) such as

- Lifestyle choices, such as smoking, alcohol intake, and diet
- Obesity and lack of physical exercise
- Certain mold, bacterial, and viral infections, parasites, and predisposing sexual practices
- Environmental exposures, including exposure to sunlight; natural and medical ionizing radiation; non-ionizing radiation (NIR); and/or air, water and soil carcinogens, or those in household, pharmaceutical and recreational drugs, personal care products
- Occupational exposures to chemical and physical carcinogens
- Certain prescribed drugs and other hormones, and illicit medications
- Socioeconomic, racial, geographic, and ethnic factors that affect exposures, risk, and detection and treatment

Estimates of the contributions of environmental and occupational factors to cancer development vary considerably and are difficult to calculate. As of 2011, the International Agency for Research on Cancer (IARC) identified more than 100 chemicals, occupations, physical agents, biologic agents and pharmaceuticals, and other agents as human carcinogens.[5] Table 13.1 lists risk factors classified by cancer site within the body based on epidemiological evidence.

Table 13.1

List of Classifications by Cancer Sites With *Sufficient* or *Limited* Evidence in Humans[a]

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
Lip, Oral Cavity, and Pharynx		
Lip		Hydrochlorothiazide Solar radiation
Oral cavity	Alcoholic beverages Betel quid with tobacco Betel quid without tobacco Human papillomavirus type 16 Tobacco, smokeless Tobacco smoking	Human papillomavirus type 18
Salivary gland	X-radiation, γ-radiation	Radioiodines, including iodine-131
Tonsil	Human papillomavirus type 16	
Pharynx	Alcoholic beverages Betel quid with tobacco	Asbestos (all forms) Opium (consumption of) Printing processes

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Human papillomavirus type 16 Tobacco smoking	Tobacco smoke, secondhand
Nasopharynx	Epstein-Barr virus Formaldehyde Salted fish, Chinese style Tobacco smoking Wood dust	
Digestive tract, upper	Acetaldehyde associated with consumption of alcoholic beverages	
Digestive Organs		
Esophagus	Acetaldehyde associated with consumption of alcoholic beverages Alcoholic beverages Betel quid with tobacco Betel quid without tobacco Tobacco, smokeless	Dry cleaning Opium (consumption of) Pickled vegetables (traditional Asian) Rubber production industry Very hot beverages (squamous cell carcinoma)

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Tobacco smoking X-radiation, γ-radiation	
Stomach	*Helicobacter pylori* Rubber production industry Tobacco smoking X-radiation, γ-radiation	Asbestos (all forms) Epstein-Barr virus Lead compounds, inorganic Nitrate or nitrite (ingested) under conditions that result in endogenous nitrosation Opium (consumption of) Pickled vegetables (traditional Asian) Processed meat (consumption of) Salted fish (Chinese style)
Colon and rectum	Alcoholic beverages Processed meat (consumption of) Tobacco smoking X-radiation, γ-radiation	Asbestos (all forms) Night shift work Red meat (consumption of) *Schistosoma japonicum*

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
Anus	Human immunodeficiency virus type 1 Human papillomavirus type 16	Human papillomavirus types 18, 33
Liver and bile duct	Aflatoxins Alcoholic beverages *Clonorchis sinensis* 1,2-Dichloropropane Estrogen-progestogen contraceptives Hepatitis B virus Hepatitis C virus *Opisthorchis viverrini* Plutonium Thorium-232 and its decay products Tobacco smoking (in smokers and in smokers' children) Vinyl chloride	Androgenic (anabolic) steroids Arsenic and inorganic arsenic compounds Betel quid without tobacco Dichlorodiphenyltrichloroethane (DDT) Dichloromethane (Methylene chloride) Human immunodeficiency virus type 1 *S. japonicum* Trichloroethylene X-radiation, γ-radiation

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
Gallbladder	Thorium-232 and its decay products	
Pancreas	Tobacco, smokeless Tobacco smoking	Alcoholic beverages Opium (consumption of) Red meat (consumption of) Thorium-232 and its decay products X-radiation, γ-radiation
Digestive tract, unspecified		Radioiodines, including iodine-131
Respiratory Organs		
Nasal cavity and paranasal sinus	Isopropyl alcohol production Leather dust Nickel compounds Radium-226 and its decay products Radium-228 and its decay products Tobacco smoking Wood dust	Carpentry and joinery Chromium (VI) compounds Formaldehyde Textile manufacturing
Larynx		Human papillomavirus type 16

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Acid mists, strong inorganic Alcoholic beverages Asbestos (all forms) Opium (consumption of) Tobacco smoking	Rubber production industry Sulfur mustard Tobacco smoke, secondhand
Lung	Acheson process, occupational exposures associated with Aluminum production Arsenic and inorganic arsenic compounds Asbestos (all forms) Beryllium and beryllium compounds Bis(chloromethyl) ether; chloromethyl methyl ether (technical grade) Cadmium and cadmium compounds	Acid mists, strong inorganic Art glass, glass containers, and pressed ware (manufacture of) Benzene Biomass fuel (primarily wood), indoor emissions from household combustion of Bitumens, occupational exposure to oxidized bitumens and their emissions during roofing Bitumens, occupational exposure to hard bitumens and their emissions during mastic asphalt work Carbon electrode manufacture α-Chlorinated toluenes and benzyl chloride (combined

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Chromium (VI) compounds Coal, indoor emissions from household combustion Coal gasification Coal-tar pitch Coke production Engine exhaust, diesel Hematite mining (underground) Iron and steel founding MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture) Nickel compounds Opium (consumption of) Outdoor air pollution Painting Particulate matter in outdoor air polution	exposures) Cobalt metal with tungsten carbide Creosotes Diazinon Fibrous silicon carbide Frying, emissions from high temperature Hydrazine Insecticides, nonarsenical, occupational exposures in spraying and application Printing processes 2,3,7,8-Tetrachlorodibenzo-*para*-dioxin

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
	Plutonium Radon-222 and its decay products Rubber production industry Silica dust, crystalline Soot Sulfur mustard Tobacco smoke, secondhand Tobacco smoking Welding fumes X-radiation, γ-radiation	
Bone, Skin, Mesothelium, Endothelium, and Soft Tissue		

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
Bone	Plutonium Radium-224 and its decay products Radium-226 and its decay products Radium-228 and its decay products X-radiation, γ-radiation	Radioiodines, including iodine-131
Skin (melanoma)	Solar radiation Ultraviolet-emitting tanning devices Polychlorinated biphenyls	
Skin (other malignant neoplasms)	Arsenic and inorganic arsenic compounds Azathioprine Coal-tar distillation Coal-tar pitch Cyclosporine Methoxypsoralen plus ultraviolet A	Creosotes Human immunodeficiency virus type 1 Human papillomavirus types 5 and 8 (in individuals with *epidermodysplasia verruciformis*) Hydrochlorothiazide

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
	Mineral oils, untreated or mildly treated Shale oils Solar radiation Soot X-radiation, γ-radiation	Merkel cell polyomavirus (MCV) Nitrogen mustard Petroleum refining, occupational exposures Ultraviolet-emitting tanning devices
Mesothelium (pleura and peritoneum)	Asbestos (all forms) Erionite Fluoro-edenite Painting	
Endothelium (Kaposi sarcoma)	Human immunodeficiency virus type 1 Kaposi sarcoma herpes virus	

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
Soft tissue		Polychlorophenols or their sodium salts (combined exposures) Radioiodines, including iodine-131 2,3,7,8-Tetrachlorodibenzo-*para*-dioxin
Breast and Female Genital Organs		
Breast	Alcoholic beverages Diethylstilbestrol Estrogen-progestogen contraceptives Estrogen-progestogen menopausal therapy X-radiation, γ-radiation	Dieldrin Digoxin Estrogen menopausal therapy Ethylene oxide Night shift work Polychlorinated biphenyls Tobacco smoking
Vulva	Human papillomavirus 16	Human immunodeficiency virus type 1 Human papillomavirus types 18, 33
Vagina	Diethylstilbestrol (exposure in utero)	Human immunodeficiency virus type 1

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Human papillomavirus type 16	
Uterine cervix	Diethylstilbestrol (exposure in utero) Estrogen-progestogen contraceptives Human immunodeficiency virus type 1 Human papillomavirus types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59 Tobacco smoking	Human papillomavirus types 26, 53, 66, 67, 68, 70, 73, 82
Endometrium	Estrogen menopausal therapy Estrogen-progestogen menopausal therapy Tamoxifen	Diethylstilbestrol
Ovary	Asbestos (all forms) Estrogen menopausal therapy Tobacco smoking	Talc-based body powder (perineal use) X-radiation, γ-radiation

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
Male Genital Organs		
Penis	Human papillomavirus type 16	Human immunodeficiency virus type 1 Human papillomavirus type 18
Prostrate		Androgenic (anabolic) steroids Arsenic and inorganic arsenic compounds Cadmium and cadmium compounds Firefighters, occupational exposure Malathion Night shift work Red meat (consumption of) Rubber production industry Thorium-232 and its decay products X-radiation, γ-radiation
Testis		DDT Diethylstilbestrol (exposure in utero)

Cancer Site	**Carcinogenic Agents With *Sufficient Evidence* in Humans**	**Agents With *Limited Evidence* in Humans**
		N,*N*-Dimethylformamide Firefighters, occupational exposure Perfluorooctanoic acid
Urinary Tract		
Kidney	Tobacco smoking Trichloroethylene X-radiation, γ-radiation	Arsenic and inorganic arsenic compounds Cadmium and cadmium compounds Perfluorooctanoic acid Printing processes Welding fumes
Renal pelvis and ureter	Aristolochic acids, plants containing Phenacetin, analgesic mixtures containing Tobacco smoking	Aristolochic acids
Urinary bladder	Aluminum production 4-Aminobiphenyl Arsenic and inorganic arsenic compounds Auramine production	4-Chloro-*ortho*-toluidine Coal-tar pitch Dry cleaning Engine exhaust, diesel

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Benzidine Chlornaphazine Cyclophosphamide Magenta production 2-Naphthylamine Opium (consumption of) Painting Rubber production industry *Schistosoma haematobium* Tobacco smoking *ortho*-Toluidine X-radiation, γ-radiation	Hairdressers and barbers, occupational exposure 2-Mercaptobenzothiazole Pioglitazone Printing processes Soot Tetrachloroethylene Textile manufacturing
Eye, Brain, and Central Nervous System		
Eye	Human immunodeficiency virus type 1 Ultraviolet emissions from welding	Solar radiation

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Ultraviolet-emitting tanning devices	
Brain and central nervous system	X-radiation, γ-radiation	Radiofrequency electromagnetic fields (including from wireless phones)
Endocrine Glands		
Thyroid	Radioiodines, including iodine-131 X-radiation, γ-radiation	
Lymphoid, Hematopoietic, and Related Tissue		
Leukemia and/or lymphoma	Azathioprine Benzene[b] Busulfan 1,3-Butadiene Chlorambucil Cyclophosphamide Cyclosporine Epstein-Barr virus Etoposide with cisplatin and bleomycin	Benzene[b] Bischloroethyl nitrosourea (BCNU) Chloramphenicol DDT Diazinon Dichloromethane (methylene chloride) Ethylene oxide Etoposide

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Fission products, including strontium-90 Formaldehyde *H. pylori* Hepatitis C virus Human immunodeficiency virus type 1 Human T-cell lymphotropic virus type 1 Kaposi sarcoma herpesvirus Lindane Melphalan MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture) Pentachlorophenol Phosphorus-32 Rubber production industry	Firefighters, occupational exposure Glyphosate Hepatitis B virus Magnetic fields, extremely low frequency (childhood leukemia) Malaria (caused by infection with *Plasmodium falciparum* in holoendemic areas) Malathion Mitoxantrone Nitrogen mustard Painting (childhood leukemia from maternal exposure) Petroleum refining, occupational exposures Polychlorinated biphenyls Polychlorophenols or their sodium salts (combined exposures) Radioiodines, including iodine-131 Radon-222 and its decay products

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
	Semustine (methyl-CCNU) Thiotepa Thorium-23 and its decay products Tobacco smoking Treosulfan X-radiation, γ-radiation	Styrene Teniposide 2,3,7,8-Tetrachlorodibenzo-*para*-dioxin Tobacco smoking (childhood leukemia in smokers' children) Trichloroethylene
Multiple or Unspecific Sites		
Multiple sites (unspecified)	Cyclosporine Fission products, including strontium-90 X-radiation, γ-radiation (exposure in utero)	Chlorophenoxy herbicides Plutonium
All cancer sites (combined)	2,3,7,8-Tetrachlorodibenzo-*para*-dioxin	

Cancer Site	Carcinogenic Agents With *Sufficient Evidence* in Humans	Agents With *Limited Evidence* in Humans
Lip, Oral Cavity, and Pharynx		
Lip		Hydrochlorothiazide Solar radiation
Oral cavity	Alcoholic beverages Betel quid with tobacco Betel quid without tobacco Human papillomavirus type 16 Tobacco, smokeless Tobacco smoking	Human papillomavirus type 18
Salivary gland	X-radiation, γ-radiation	Radioiodines, including iodine-131
Tonsil	Human papillomavirus type 16	
Pharynx	Alcoholic beverages Betel quid with tobacco Human papillomavirus type 16 Tobacco smoking	Asbestos (all forms) Opium (consumption of) Printing processes Tobacco smoke, secondhand
Nasopharynx	Epstein-Barr virus Formaldehyde Salted fish, Chinese style Tobacco smoking Wood dust	
Digestive tract, upper	Acetaldehyde associated with consumption of alcoholic beverages	
Digestive Organs		
Esophagus	Acetaldehyde associated with consumption of alcoholic beverages Alcoholic beverages Betel quid with tobacco Betel quid without tobacco Tobacco, smokeless Tobacco smoking X-radiation, γ-radiation	Dry cleaning Opium (consumption of) Pickled vegetables (traditional Asian) Rubber production industry Very hot beverages (squamous cell carcinoma)
Stomach	*Helicobacter pylori* Rubber production industry Tobacco smoking X-radiation, γ-radiation	Asbestos (all forms) Epstein-Barr virus Lead compounds, inorganic Nitrate or nitrite (ingested) under conditions that result in endogenous nitrosation Opium (consumption of) Pickled vegetables (traditional Asian) Processed meat (consumption of) Salted fish (Chinese style)
Colon and rectum	Alcoholic beverages Processed meat (consumption of) Tobacco smoking X-radiation, γ-radiation	Asbestos (all forms) Night shift work Red meat (consumption of) *Schistosoma japonicum*
Anus	Human immunodeficiency virus type 1 Human papillomavirus type 16	Human papillomavirus types 18, 33

Incidence, Mortality Trends, and Race

According to a 2021 report by GLOBOCAN, 1 in 5 people worldwide will develop cancer in their lifetime, and 1 in 8 men and 1 in 11 women will die from the disease.[8] An estimated 19.3 million new cancer cases and 10 million cancer deaths were reported worldwide in 2020 (Fig. 13.2). For the first time, female breast cancer has surpassed lung cancer as the most commonly diagnosed cancer in the world, primarily because of increases in low- and middle-income countries. Lung cancer is the most commonly diagnosed cancer in men, and for both sexes it is the leading cause of cancer death in the world. Prostate cancer is the second most common cancer in men. Other common cancers worldwide arise from the gastrointestinal (GI) tract including colorectum, stomach, and liver cancers.[8]

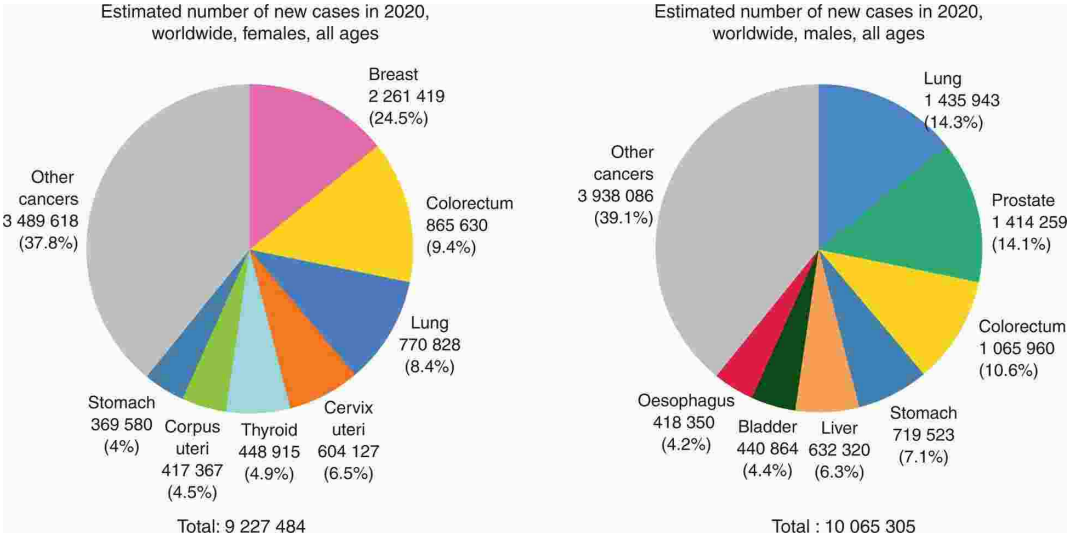

FIG. 13.2 Global Cancer Incidence. (New global cancer data from Globocan 2020.)

Two pie charts show the distribution of estimated number of new cases in 20 20, worldwide, for females and males of all ages. The pie chart for females, representing a total of 9,227,484, shows the following distribution. • Breast, 2,261,419, 24.5 percent. • Colorectum, 865,630, 9.4 percent. • Lung, 770,828, 8.4 percent. • Cervix uteri, 604,127, 6.5 percent. • Thyroid, 448,915, 4.9 percent. • Corpus uteri, 417,367, 4.5 percent. • Stomach, 369,580, 4 percent. • Other cancers, 3,489,618, 37.8 percent. The pie chart for males, representing a total of 10,065,305, shows the following distribution. • Lung, 1,435,943, 14.3 percent. • Prostate, 1,414,259, 14.1 percent. • Colorectum, 1,065,960, 10.6 percent. • Stomach, 719,523, 7.1 percent. • Liver, 632,320, 6.3 percent. • Bladder, 440,864, 4.4 percent. • Esophagus, 418,350, 4.2 percent. • Other cancers, 3,938,086, 39.1 percent.

In the United States, there will be an expected 1.9 million cases of cancer in 2021 and over 600,000 cancer deaths (these estimates exclude basal cell and squamous cell skin cancers).[9] Breast cancer accounts for 30% of all cancer

cases and 15% of cancer deaths in US women, while prostate cancer accounts for 26% of all cancer cases and 11% of cancer deaths in US men. Lung cancer continues to constitute the second highest percentage of new cancer cases (12% to 13%) and the highest number of cancer deaths (22%) in both men and women. Colorectal cancer is the third most common cause of both cancer incidence and cancer deaths in US women and men, and when all major digestive cancer types are combined (colorectal, stomach, esophagus, liver, and pancreas), overall mortality rates exceed that for lung cancer.[9]

The generation in which an individual is born affects the incidence of cancer diagnosis. The concept of generational risk (GR) has been advanced to allow analysis of changes in risk that reflect the impact of a specified time (birth cohort) on cancer risk. Despite the decline in overall cancer mortality rates, adults are experiencing increased incidence of cancers that are not associated with tobacco or screening relative to their parents.[10,11]

For example, white men born in the 1940s had twice as much cancer overall as those born in 1888 through 1897, and the same birth cohort was shown to have more than twice as much cancer not linked to smoking. Comparing the same birth cohorts, women had 50% more cancers overall and 30% more non-smoking related cancers.[11] Steady reductions in colorectal cancer incidence in younger persons occurred between 1969 and 1995; however, recent rates surpassed historical levels and are the highest ever recorded in birth cohorts after 1990. Those born in the United States in the 1990s have a doubled risk of colon cancer (GR = 2) and a fourfold increase in rectal cancer (GR = 4) by the time they reach age 24, as compared to those born six decades ago.[12] Related factors contributing to the increase in colorectal cancer include Western and sugary diet, gut microbiome changes, sedentary lifestyle, smoking, and heavy alcohol consumption.[13] Exposures to non-ionizing radiation (NIR) from cellphones, as well as increased use of pediatric computed tomography (CT) scans and obesity, are additional possible contributing causes for colorectal cancer increases in the younger generation. Studies of colon cells in animals indicate sensitive carcinogenic responses to both NIR and ionizing radiation (IR), while modeling studies note that absorption of microwave radiation into the lower abdomen can be considerable.[12] Despite these increases in incidence, overall US cancer death rates have decreased 31% since 1991, with a notable decline in lung cancer deaths. Unfortunately, the rate of decline in cancer-rated mortality has slowed for prostate, breast, and colorectal cancer since 2018.[9]

Significant racial disparities exist for cancer patterns. For black and brown Americans, the risk of death from some types of cancer is often higher than

for whites, especially at younger ages. For example, although fewer black women are diagnosed with breast cancer, they have a higher mortality rate. Significant racial disparities also are evident for cervical and prostate cancers. The American Cancer Society reports that blacks have the highest mortality rate and shortest survival of any racial and ethnic group in the United States for most cancers. Differences in access to care and treatment, employment in high-risk occupations, residential exposure to hazardous wastes, lack of access to quality nutrition, and other factors may account for the disparities (Box 13.1). Since 1990, the overall cancer mortality rate has declined faster in blacks than whites for both males and females, largely because of more rapid declines in blacks for lung, colorectal, and prostate cancers.[14,15]

Box 13.1

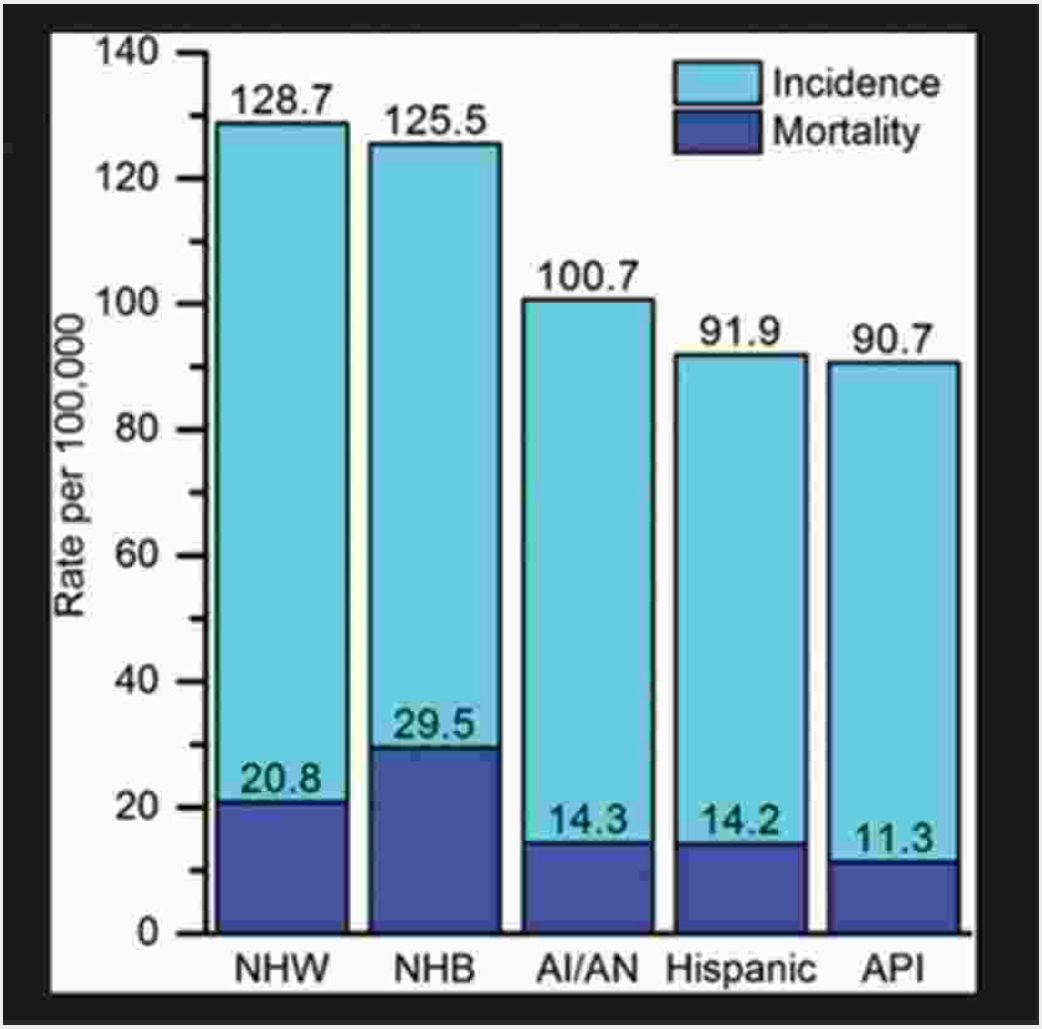
Race: A Social Construction

Race alone is a social construction. Despite years of assumptions that genetic distinctions can consistently be found that differentiate black, brown, and white Americans, aside from sickle cell trait and other relatively rare genetic anomalies, no uniform differences have been identified. Racial groups are not genetically homogenous. African-derived groups in North America incorporated a large proportion of European and some Native American genes. There is more heterogeneity *within* black and brown ethnic groups than *between* these groups and whites. Although it is well accepted that ancestral alleles can affect disease rates, susceptibility, and medication efficacy, these alleles do not fall along any racial categories. Specifically, admixture and migration have produced broad variation so that race categories are in no way comparable to genetic ancestry.

There is growing recognition that the tendency to deem race a biological fact may cause clinicians to employ racial signifiers as clinically meaningful without full examination or understanding of their complex origins and significance. This problem appears especially acute with respect to the assumptions with which health care providers of any race treat black and brown women. For example, there has long been the assumption that Americans of African descent retain more salt than those of European ancestry, thus contributing to the higher prevalence of hypertension in blacks. This assumption was based on the hypothesis that survival during the slave trade in the 17th through 19th centuries resulted in black Americans having greater capacity to retain salt, a claim that has been widely disputed. Chrysant and colleagues found no significant differences

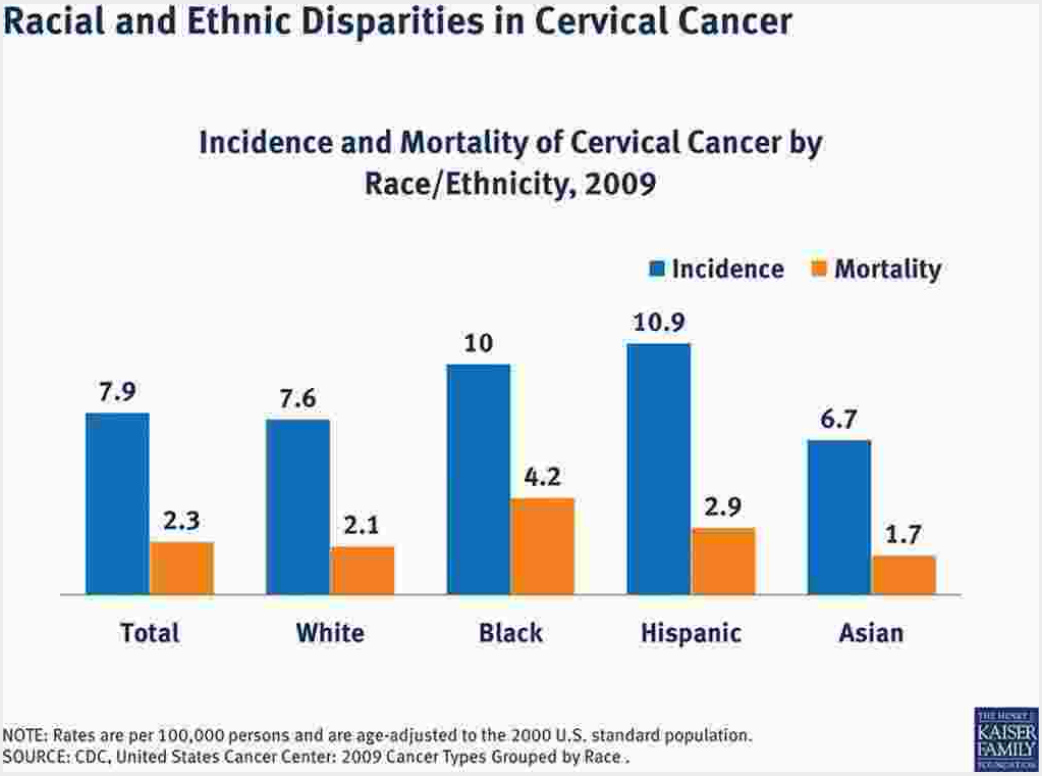
in variations between blood pressure and salt by race, age, sex, or body weight.

Stark evidence of racial, economic, and ethnic disparities in cancer outcomes exist.



Female Breast Cancer Incidence (2012–2016) and Mortality (2013–2017 Rates by Race/Ethnicity, United States.

In 2018, while fewer blacks than whites developed breast cancer, blacks were 50% more likely to die of the disease. Breast cancer statistics. *Cancer Journal for Clinicians*, 2019;69(6), 438–451.)



Patterns of Incidence and Mortality of Cervical Cancer Vary with Race and Ethnicity (From Henry, J. Kaiser Family Foundation. https://www.kff.org/womens-health-policy/slide/racial-and-ethnic-disparities-in-cervical-cancer/)

Academic, governmental, and non-governmental organizations are devoting more resources to elucidating the role of "epigenetics" in the development of common forms of cancer, including the metabolome and the microbiome which can modify expressions of our inherited genomes. Nonetheless, there is vastly more research on genomic mechanisms than on the social factors underlying health. In light of, it is important to develop strategies to address these determinants. Improving efficiencies in health care cannot suffice if the demand for care is also not reduced through primary preventive strategies.

Genetics, Epigenetics, Tumor Microenvironment, and Cellular Signaling in Cancer

Cancer development is a complex process that results from gene mutations, epigenetic and environmental factors, the tumor microenvironment, and changes in both intra- and intercellular signaling (see Chapter 12). This chapter emphasizes the complex interaction between these processes and the environment/lifestyle exposures that influence them.

Genetics and Epigenetics

Gene mutations can be either inherited or acquired. Inherited gene mutations *(germline mutations)* are rare and are passed to the next generation by a parent's sperm or egg. Acquired mutations are more common than inherited mutations and cause most cancers. They occur when the healthy genes, with which we are born, lose the ability to function properly in direct cell signaling and repair, especially during periods of growth. Gene mutations that are acquired after birth are called *somatic mutations*. Somatic mutations occur from exposures to oxidizing agents that directly affect deoxyribonucleic acid (DNA). However, most acquired changes in gene function are not due to direct damage to DNA, but rather are a consequence of the complex effects that lifestyle and environmental exposures have on epigenetic patterns (Fig. 13.3). Epigenetics describes the chemical modulation of gene functions that control cell replication and other cell processes (see Chapter 6). Lifestyle factors, carcinogens, and occupational exposures alter epigenetic patterns, and therefore, may increase susceptibility to cancer (Fig. 13.4A). Epigenetic modifications have many different causes and may take several forms without directly damaging DNA by affecting the production of messenger RNA that directs the translation of proteins (see Fig. 13.4B).

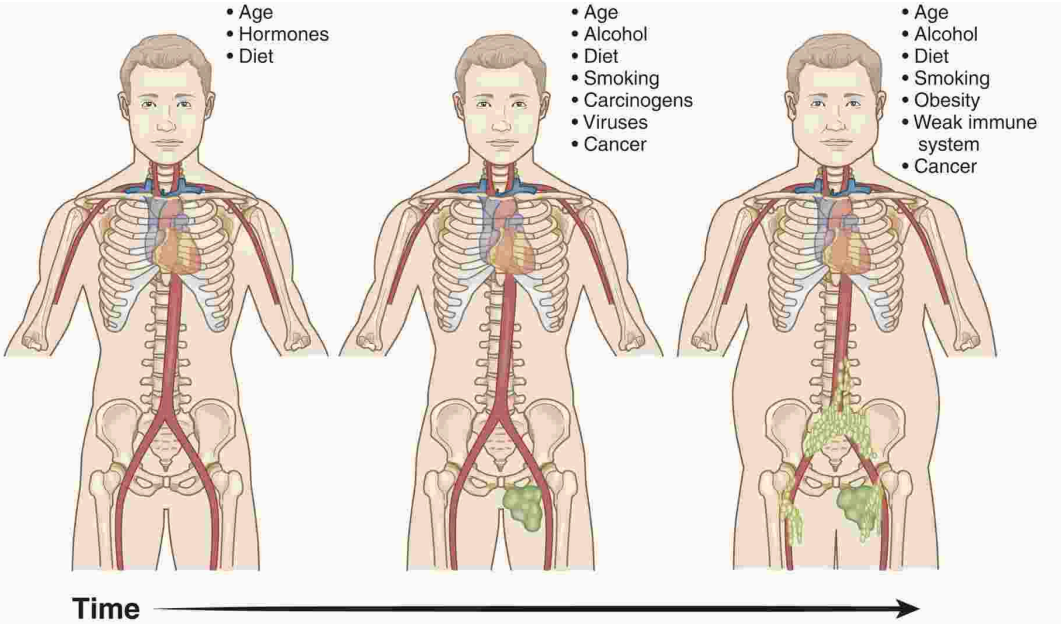

FIG. 13.3 Environmental Factors and Genetic, Epigenetic, and Other Host Factors.
Over time, a person's internal genetic makeup persistently interacts with external or environmental factors. Environmental factors (e.g., diet, smoking, alcohol use, hormones [including xenoestrogens], certain viruses, chemical carcinogens) collectively interact with internal epigenetic factors and genetic mutations to destabilize normal biologic factors including immune factors for balancing growth and maturation. (Adapted from NCI. *Understanding Cancer Series: Cancer: Inside and Outside Factors*. Washington, DC: National Cancer Institute, National Institutes of Health; 2007.)

A timeline, from the left to the right, shows three human illustrations with the skeletal structure and internal organs highlighted, to identify environmental factors and genetic, epigenetic, and other host factors. • Illustration 1. Age, hormones, and diet. • Illustration 2. Age, alcohol, diet, smoking, carcinogens, viruses, and cancer. • Illustration 3.

Age, alcohol, diet, smoking, obesity, weak immune system, and cancer.

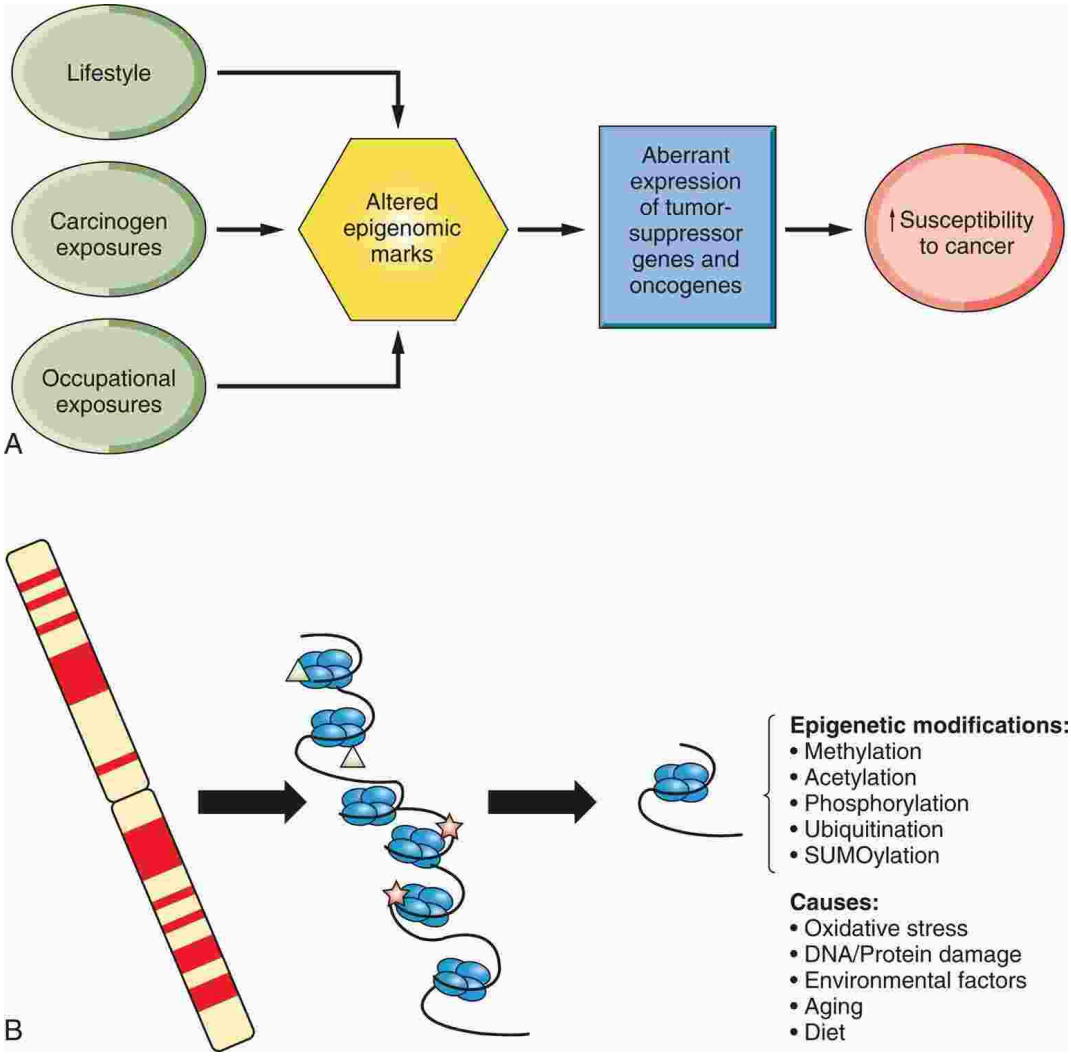

FIG. 13.4 Epigenetic Modulation and Modifications. **(A)** Overview of the potential role of epigenetic modulation by dietary and other environmental factors in cancer development. **(B)** Epigenetic modulation model according to current knowledge. The different types of chemical modifications, such as methylation or acetylation, of promoter regions and/or other regulatory DNA sequences outside the gene can have a severe impact on gene transcription and translation and a resultant high modulation of gene expression and product (protein) functionality. (B, Adapted from Nowsheen S, Aziz K, Tran PT, et al. Epigenetic inactivation of DNA repair in breast cancer. *Cancer Letters*, 2014;342(2):213–222.)

Flowchart A. Lifestyle, carcinogen exposures, and occupational exposures lead to altered epigenomic marks. This leads to aberrant expression of tumor-suppressor genes and oncogenes, resulting in increased susceptibility to cancer. Illustration B shows the epigenetic modifications of D N A: methylation, acetylation, phosphorylation, ubiquitination, and SUMOylation. The causes include: oxidative stress, D N A or protein damage, environmental factors, aging, and diet.

Tumor Microenvironment

At the cellular level, inflammatory, hormonal, and metabolic systems can contribute to a tumor microenvironment that supports growth and metastasis (see Chapter 12). Systemic chronic inflammation is proposed to be the primary cause of most diseases including cancer.[16,17] The inflammatory process leads to the infiltration of inflammatory cells and cytokines into the tissue microenvironment (stroma). Chronic inflammation can *precede* and *initiate* cancer changes (e.g., inflammation-induced colon cancer) and can *promote or exacerbate* chronic processes (e.g., colonic polyposis) that may progress to cancer. When malignant transformation develops, tumor cells continually interact with surrounding stromal cells and, importantly, the infiltrated immune and inflammatory cells (see Chapter 12).

Many environmental and lifestyle factors impact the inflammatory process and may influence cancer development. For example, some nutritional factors such as deficiencies in vitamin D or excesses in refined sugars can induce inflammation. Other environmental factors are significant for lung and respiratory tract cancers where proinflammatory factors include viruses, inhaled tobacco smoke, asbestos fibers, numerous air pollutants, airborne pesticides, radon gas, and industrial sources.[18,19] Such exposures vary greatly with socioeconomics and other factors and influence the degree to which tumors grow, spread, or both. For example, mortality from melanoma is highest in Danish persons from the lowest socioeconomic classes with the lowest educational attainment.[20] In the United States, significant disparities exist between cancer mortality and morbidity for white, brown, and black Americans.[14,15]

Cellular Signaling

Cells must use intracellular communication pathways to connect the messages received from the extracellular environment to the cells' control machinery, which is localized mainly in the DNA (see Chapter 1). Many chronic diseases are formed because of malfunction or dysregulation of these intracellular communication pathways. Internal factors such as dysregulated hormonal systems (see Fig. 13.1) and abnormal glucose or lipid metabolism affect cellular communication and play a significant role in the development of many common diseases, including type 2 diabetes, neurological disorders, and cancer. External factors also play a critical role in cancer development. Humans are constantly exposed to a variety of compounds termed xenobiotics (the Greek word xenos means "foreign"; bios means "life") that include toxic, mutagenic, and carcinogenic chemicals that contribute to inflammation and can affect cellular communication. Examples of xenobiotic stimuli include xenoestrogens[21] and other synthetic hormonal growth factors. Increasingly, several agents that modulate intracellular communication (e.g., antioxidants melatonin and epigallocatechin gallate [EGCG] and antiangiogenic and topoisomerase inhibitors) are being explored as therapeutic drugs that can reduce inflammation and potentially prevent cancer development. Unfortunately, many such agents have been found to have serious side effects and adverse consequences. For example, while the use of EGCG in adults induces cell death in acute myelogenous leukemia, it is contraindicated during pregnancy as prenatal exposure has been linked with neonatal leukemia.[22,23] It is possible that drugs that affect the tissue microenvironment and cell signaling will be tapped to repair precancerous conditions or to avoid or diminish adverse radiation effects of both IR and NIR, especially in electro-hypersensitive individuals.

In Utero and Early Life Conditions

It is widely accepted that a long latency period precedes the onset of most adult cancers. Accumulating data suggest early life events, including prenatal factors, influence later susceptibility to cancer and certain other chronic diseases. The timing of exposure and dose-rate of potential carcinogens can be critically important. Exposures that take place during gestation and early childhood may have greater impacts than those that take place later in life. Developmental plasticity is the degree to which an organism's development is contingent on external cues from its environment. *Plasticity* refers to the ability of genes to organize physiologically or structurally in response to environmental conditions during fetal development. Specifically, the

developmental origins hypothesis postulates that nutrition and other environmental factors affect cellular pathways during gestation, enabling a single genotype to produce a broad range of adult phenotypes.

Maternal nutrition and other environment factors wield significant biologic influences and are therefore more thoroughly evaluated. Persistent epigenetic adaptations, occurring early in development, are believed to be associated with increased susceptibility to cancer and other adult-onset chronic diseases. During *in utero* development, factors such as undernutrition and exposure to toxins and alcohol result in decreased immunity and increased vulnerability to multiple diseases including cancer in adulthood.[24,25] It is estimated that up to 5% of all school-aged children have some form of fetal alcohol syndrome (FASD) that affects multiple health and psychological outcomes.[26]

One of the best examples of early life events that trigger future cancer is *in utero* exposure to diethylstilbestrol (DES), a synthetic estrogen. Originally synthesized and used in Nazi Germany as a hormone that fattened cattle and pigs,[27] DES was prescribed between 1938 and 1971 to avert miscarriage, premature birth, and abnormal bleeding. In 1971, an astute clinician reported an unusual cluster of rare cancers of the vagina (adenocarcinoma) in a group of young teens who had been exposed to DES during gestation.[28] The same clinician showed that the drug did *not* prevent miscarriage. Subsequent monitoring of exposed cohorts found that DES exposure in utero increases the risk of female reproductive tract cancer and of male reproductive impairment throughout childbearing years. Daughters of women who took DES during pregnancy have an increased risk of breast cancer before age 40. A recent meta-analysis demonstrated that prenatally exposed males have a threefold increase in testicular cancer risk.[29]

Evidence is increasing that adverse environmental exposures can affect the genes and epigenetic patterns of reproductive cells in both men and women that are then transmitted to their offspring during conception.[17] For example, maternal smoking during pregnancy has been shown to alter the epigenome of children into adolescence, and has been linked to an increased risk for childhood cancer including retinoblastoma and brain tumors.[30,31] Men who have had preconception exposures to smoking, air pollution, IR, heavy metals, pesticides, and compounds such as bisphenol A, DES, and dioxin have been found to have altered DNA epigenetic methylation patterns in their sperm. As a result, evidence shows that their offspring are more likely to suffer from male-mediated developmental toxicity in the form of spontaneous abortion, low birth weight, developmental delays, and childhood cancer.[32]

Bisphenol A (BPA) and several other endocrine disrupting chemicals (EDCs) (such as those found in pesticides, flame retardants, nonstick coatings) serve as obesogens, agents that stimulate embryonic development of adipose tissue. When exposed to alcohol or other adipose-stimulating agents later in life, prenatally programmed stem cells manufacture more adipocytes and permanently alter germline epigenome in both males and females, enhancing development of obesity across generations.[33] Obesity is a well-recognized risk factor for cancer and is discussed later in this chapter.

In summary, fetal programming influences developmental origins of health and disease. It also may help explain epigenetic transgenerational effects (Tables 13.2 and 13.3).

Table 13.2

Differences Between Multigenerational and Transgenerational Phenotypes

Phenotype	Exposure	Definition
Multigenerational	Direct	Simultaneous exposure of multiple generations to an environmental factor
Transgenerational	Initial germline exposure (ancestral)	Transgenerational phenotype is transmitted to future generations via germline inheritance

Table 13.3

Somatic Versus Germ Cell Inheritance

Cell Type	Biologic Response
Somatic cells	Critical for adult-onset disease in exposed individual; not transmitted to future generations as transgenerational effect
Germ cells	Allows transmission between generations; promotes transgenerational phenotype

Environmental-Lifestyle Factors

Tobacco Use

Smoking remains an important preventable cause of death globally. Smoking causes cancer, heart disease, stroke, lung diseases, diabetes, and chronic obstructive pulmonary disease (COPD) along with many other systemic disorders (Fig. 13.5). Worldwide, tobacco use and secondhand smoke exposure cause more than 8 million deaths per year.[34] More than 16 million Americans are living with a disease caused by smoking. Cigarette smoking accounts for more than 480,000 deaths each year, including more than 41,000 deaths resulting from secondhand smoke.[35]

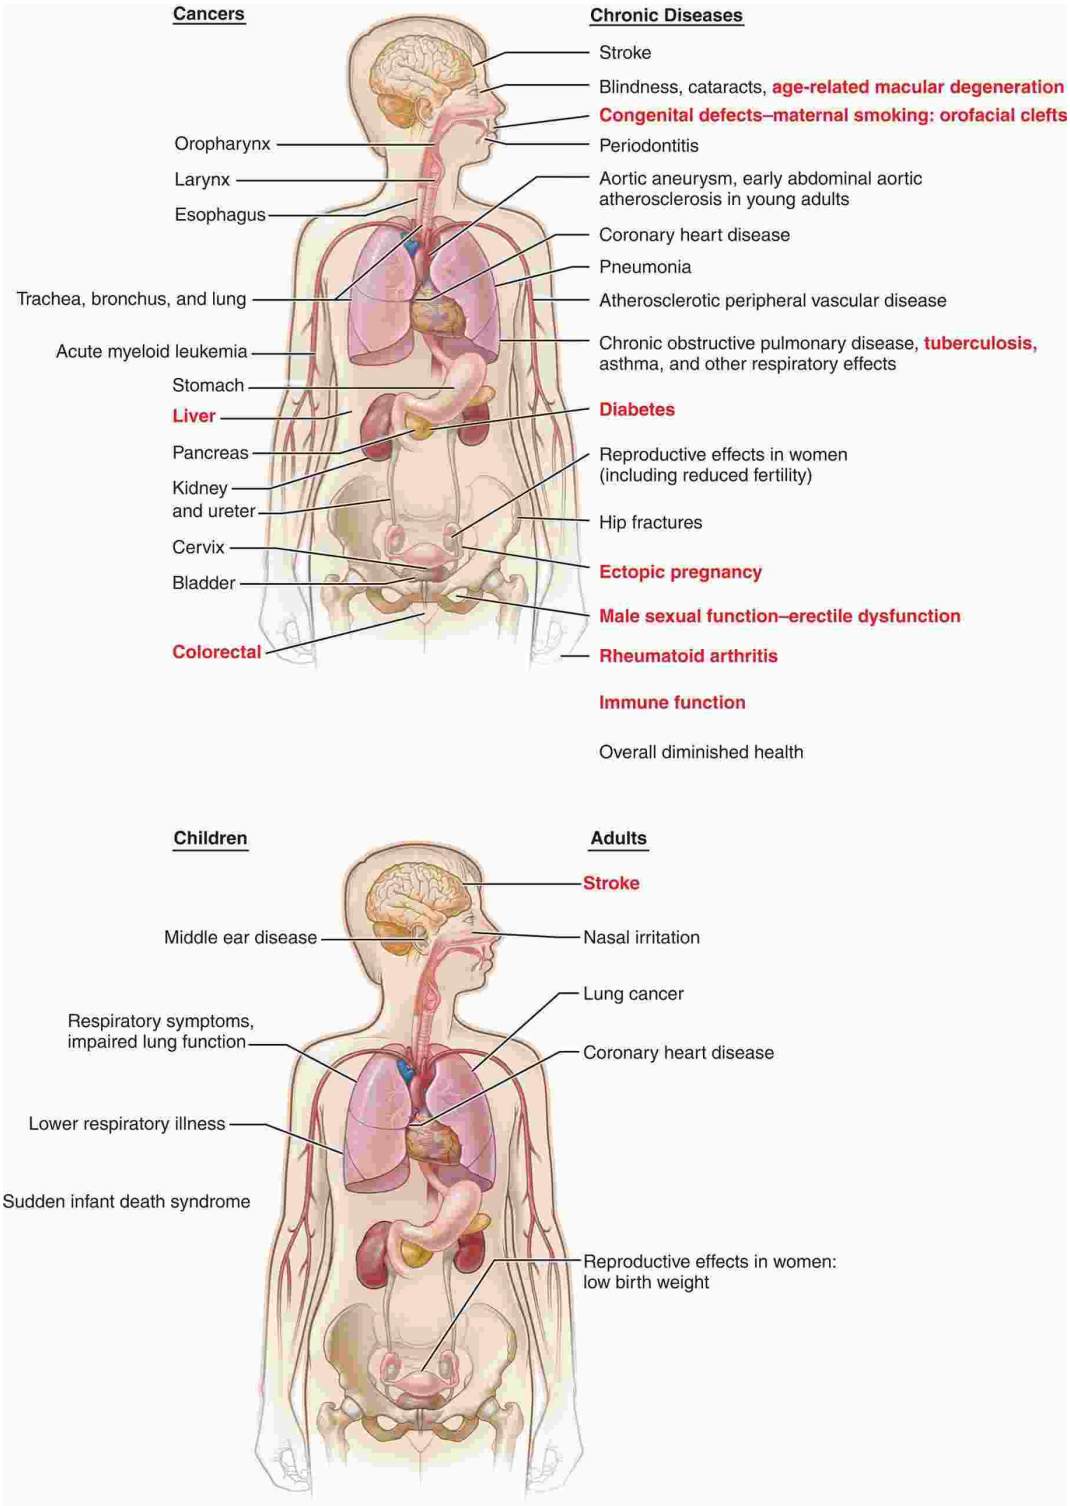

FIG. 13.5 The Health Consequences Linked to Smoking.

NOTE: The conditions in red are new diseases that have been causally linked to smoking. See text for discussion.

Stroke is a new disease causally linked to secondhand smoke. (Reproduced from the World Cancer Research Fund/American Institute for Cancer Research. *Diet, Nutrition, Physical Activity and Cancer: A Global Perspective*. Continuous Update Project Expert Report; 2018. dietandcancerreport.org.)

Two illustrations of the human body with the internal organs identify cancers and chronic diseases in children and adults. The illustration at the top identifies cancers in the following organs: oropharynx; larynx; esophagus; trachea, bronchus, and lung; acute myeloid leukemia; stomach; liver; pancreas; kidney and ureter; cervix; bladder; and colorectal. The illustration also labels the following chronic diseases: • Stroke. • Blindness, cataracts, age-related macular degeneration. • Congenital defects-maternal smoking: orofacial clefts. • Periodontitis. • Aortic aneurysm, early abdominal aortic atherosclerosis in young adults. • Coronary heart disease. • Pneumonia. • Atherosclerotic peripheral vascular disease. • Chronic obstructive pulmonary disease, tuberculosis, asthma, and other respiratory effects. • Diabetes. • Reproductive effects in women (including reduced fertility). • Hip fractures. • Ectopic pregnancy. • Male sexual function-erectile dysfunction. • Rheumatoid arthritis. The illustration at the bottom shows the following conditions in children: middle ear disease; respiratory symptoms, impaired lung function; lower respiratory illness; and sudden infant death syndrome. The illustration also labels the following conditions in adults: stroke, nasal irritation, lung cancer, coronary heart disease, and reproductive effects in women (low birth weight).

The risks associated with smoking are greatest in persons who begin to smoke when young and continue throughout life; however, tobacco smoking is pandemic and affects all ages. Thousands of young people start smoking cigarettes every day.[35] Although rates of smoking in high school students have plummeted, possibly reflecting anti-smoking programs directed at this age group, more young adults are beginning to smoke now than previously. The risks of smoking-related cancer are now equal in men and women.

Secondhand smoke, also called environmental tobacco smoke (ETS), consists of *sidestream smoke* (smoke from the burning end of a cigarette, cigar, or pipe) and *mainstream smoke* (smoke exhaled directly by the smoker). More than 7000 chemicals have been identified in tobacco smoke; hundreds are toxic and can cause cancer in animals, and about 70 are known to cause cancer in humans.[36,37] During 2011 through 2012, about 58 million nonsmokers in the United States were exposed to secondhand smoke.[34]

Smoking tobacco causes cancer in over 15 organ sites and affects nearly every organ of the body:[36,38]

- Cancers of the lung and upper respiratory tract (oral cavity, pharynx, larynx, nasal cavity, paranasal sinuses)
- Cancers of the digestive tract (esophagus, stomach, liver, and colorectum)
- Cancers of the lower urinary tract (renal pelvis, penis, and bladder)
- Cancers of the kidney, pancreas, cervix, and uterus
- Myeloid leukemia

Non-cigarette tobacco use also is hazardous. Cigar or pipe smoking is strongly related to cancers of the oral cavity, oropharynx, hypopharynx, larynx, esophagus, and lung. Cigar smokers who inhale are prone to develop coronary heart disease and COPD. Pipe smokers have an increased risk of cancers of the lung, lip, throat, esophagus, larynx, pancreas, and colon and rectum. Smokeless tobacco is associated with oral cavity, esophageal, and pancreatic cancers.

Electronic cigarettes (e-cigarettes) come in many shapes and sizes, have a battery, a heating element, and a place to hold liquid containing nicotine, flavorings, and other chemicals. Among the more insidious forms of e-cigarettes are those that look like USB drives, highlighters, or pens so they cannot readily be detected in schoolbags. These electronic nicotine delivery systems feature a range of flavors, such as bubble gum, popcorn, peppermint candy, and butterscotch, all tailored to appeal to younger users. In 2020,

nearly 20% of high school students and nearly 5% of middle school students reported current e-cigarette use.[39] E-cigarettes produce a sidestream aerosol that contains more heavy metals than cigarette smoke because of the use of metal coils. They also contain cancer-causing volatile aromatic hydrocarbons, flavoring (diacetyl), and other toxic agents, including nicotine, and ultrafine particles that can be inhaled deeply in the lungs. The smallest of these inhaled particles cross through the lung into the blood. A popular E-cigarette device, called *JUUL*, is shaped like a USB flash drive. The nicotine liquid refills are called pods. Pods come in many flavors, such as cool cucumber, fruit medley, mango, and mint. All *JUUL* e–cigarettes have a high level of nicotine; according to the manufacturer, a single *JUUL* contains as much nicotine as a pack of 20 regular cigarettes. Serious illness and death have occurred in some users of e-cigarettes, possibly due to contaminated fluids such as polyethylene glycol ethers (see Chapter 35).[40]

Tobacco smoke and vapors from e-cigarettes are a type of xenobiotic that can affect genes, the tumor microenvironment, and cell signaling.[41] As with other carcinogens, exposure to tobacco smoke is associated with tissue inflammation and release of toxic oxygen radicals (Fig. 13.6). Resulting mutations and epigenetic changes in key cell cycle genes promote tumor initiation and growth. Inflammation also contributes to a tumor microenvironment that further supports cancer development and spread. These effects may occur not only in the lungs, but throughout the body. Individuals with COPD are at increased risk for lung cancer due to increased inflammation and oxidative stress.[42] The mechanisms of cancer development are described in detail in Chapter 12.

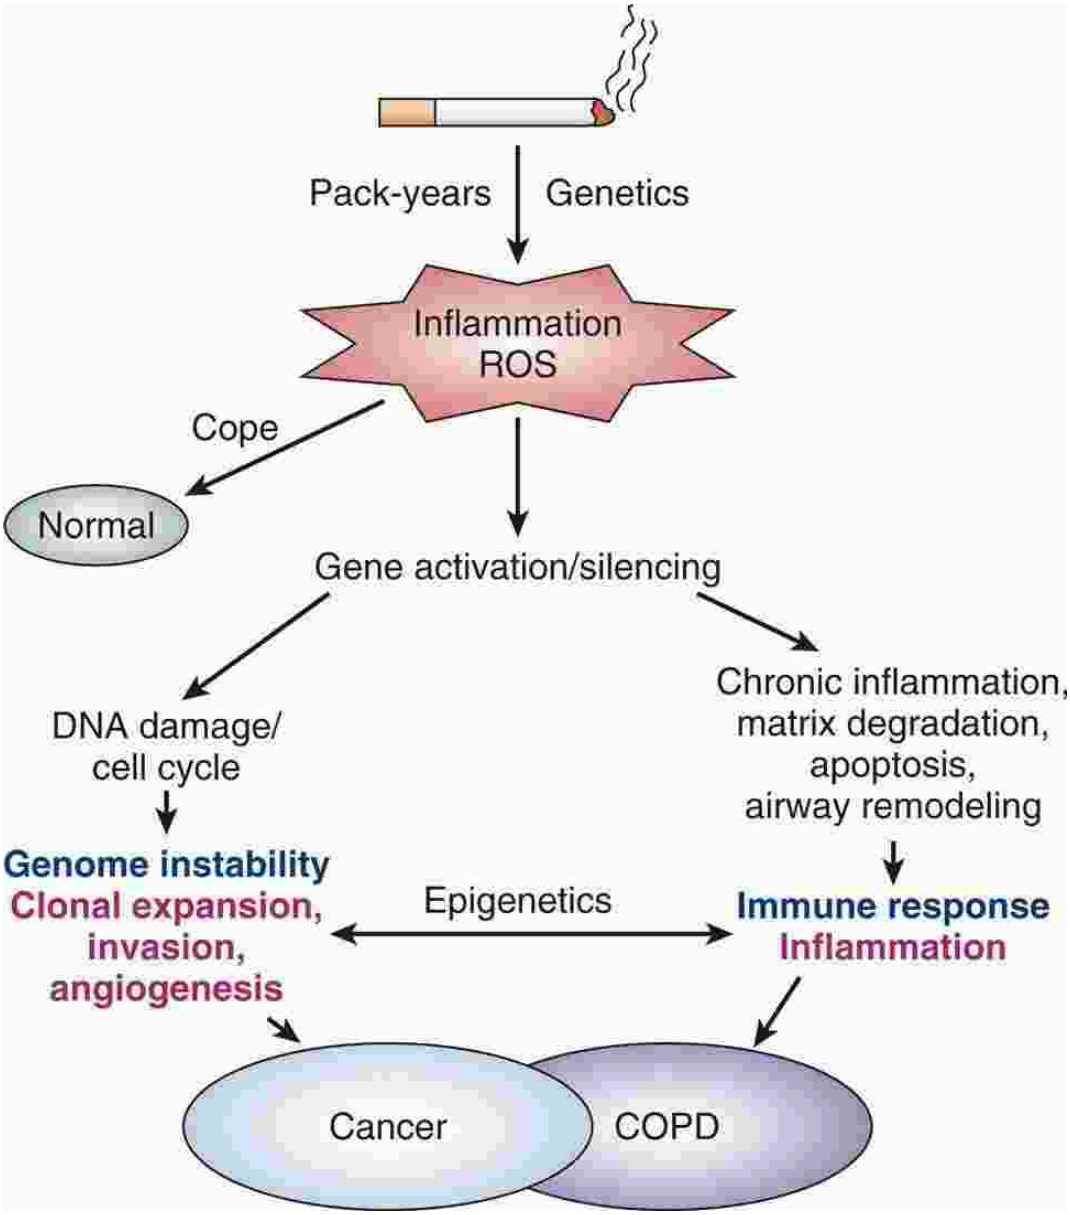

FIG. 13.6 Working Model of Carcinogenesis by Cigarette Smoke.

The main inducer of both lung cancer and chronic obstructive pulmonary disease *(COPD)* is cigarette smoke. Nonsmokers may develop these diseases caused by other environmental or genetic/epigenetic factors. Cigarette smoke induces an inflammatory response and causes an increase in reactive oxygen species *(ROS)*, causing oxidative stress. Oxidative stress is a risk factor for many diseases because it can alter many cellular proteins. A combination of immune-inflammatory signals and

epigenetic events may increase the risk for individuals with COPD developing lung cancer. (From Adcock IM, Caramori G, Barnes PJ. Chronic obstructive pulmonary disease and lung cancer: New molecular insights. *Respiration*, 2011;81(4):265–284.)

A flowchart shows a working model of carcinogenesis by cigarette. Pack-years and genetics lead to inflammation R O S. Coping results in a normal cell. Generic activation or silencing, amplified by epigenetics, leads to the following. • D N A damage or cell cycle. Genome instability includes clonal expansion, invasion, and angiogenesis, leading to cancer. • Chronic inflammation, matrix degradation, apoptosis, and airway remodeling. Immune response include inflammation, leading to C O P D.

Diet and Nutrition, Obesity, Alcohol Consumption, and Physical Activity: Impacts on Cancer

Diet and nutrition, weight, and activity level all influence risks for the development of specific types of cancers (Fig. 13.7).[17] Everyday choices and lifelong habits matter and impact the risk of developing cancer.

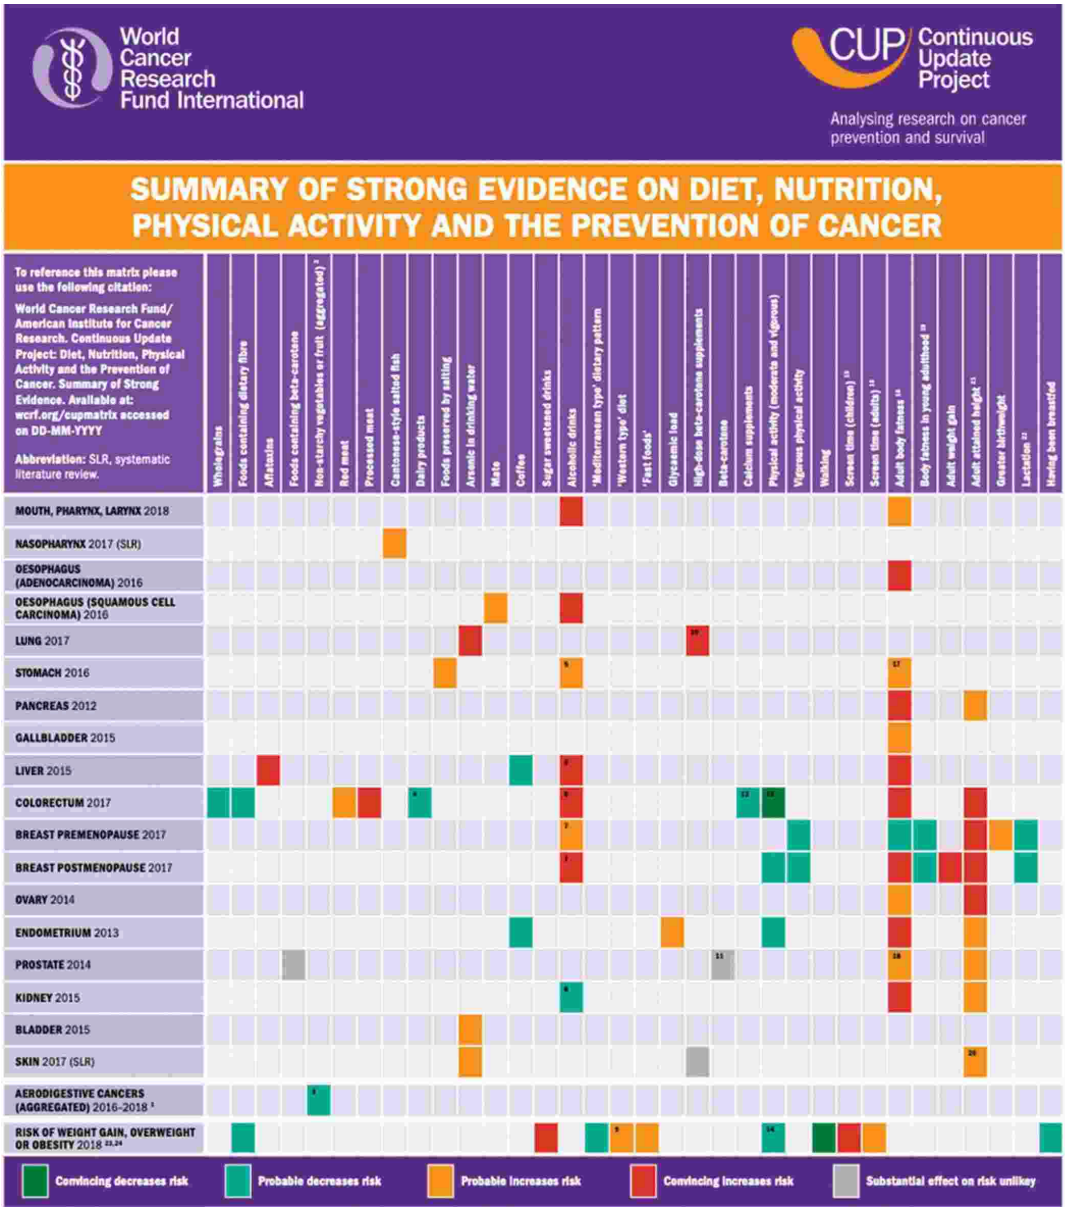

FIG. 13.7 Summary of Strong Evidence on Diet, Nutrition, Physical Activity, and Prevention of Cancer. (This material has been reproduced from the World Cancer Research Fund/American Institute for Cancer Research. Diet, Nutrition, Physical Activity and Cancer: a Global Perspective. Continuous Update Project Expert Report 2018. Available at dietandcancerreport.org.)

An infographic of the summary of strong evidence on diet, nutrition, physical activity, and prevention of cancer shows

each lifestyle, dietary, or environmental component, whether it increases or decreases the risk of specific cancers.

Diet and Nutrition

Researchers targeting associations between diet and nutrition with disease face a variety of challenges, including the difficulty in accurate measurement of specific nutrients, food types, and dietary patterns. Cancer is a disease with long latencies and may depend as much or more on diet in early life as on adult eating practices. Therefore, understanding decades of old dietary patterns is critical to interpreting cancer risks in older adults. Nutrigenomics is the study of the effects of nutrition on genomics, epigenomics, transcription factors (transcriptomics), proteomics, and metabolic factors (metabolomics) and the ways that modifying any one of these factors influences cancer risk (Fig. 13.8). Fig. 3.9 shows cell functions thought to be influenced by diet, weight, and activity level. The impact of diet, nutrition, physical activity and other environmental exposures on the cancer process is illustrated in Fig. 3.10.

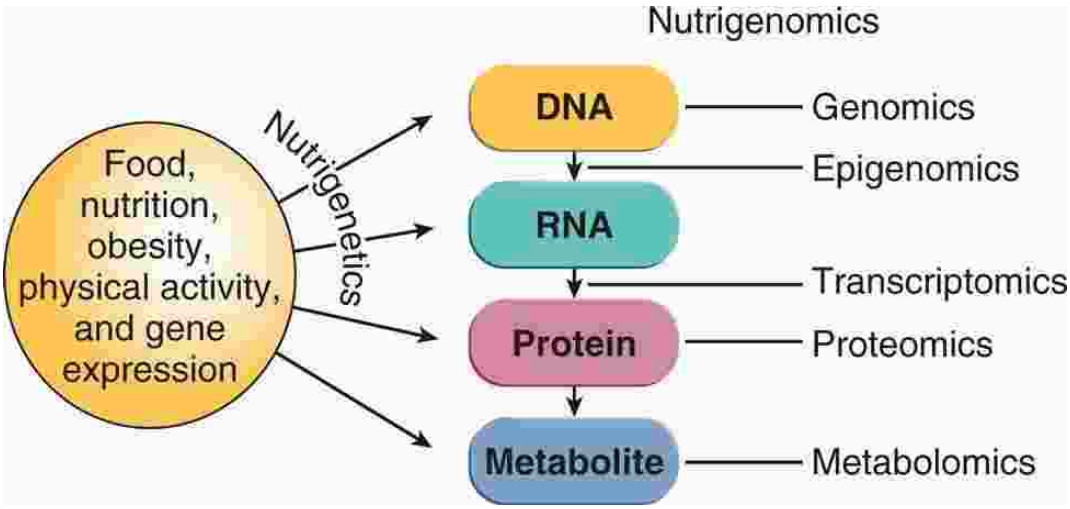

FIG. 13.8 Basis for the Study of Food, Nutrition, Obesity, Physical Activity, and the Cancer Process. The genetic message in the DNA code is translated to RNA, and then into protein synthesis, and so determines metabolic processes. Research methods, called "-omics," address these different stages. (Adapted from World Cancer Research Fund/American Institute for Cancer Research. *Food, Nutrition, Physical Activity, and the Prevention of Cancer: A Global Perspective*. Washington, DC: AICR; 2007.)

An illustration shows the impact of nutrigenetics (food, nutrition, obesity, physical activity, and gene expression) in nutrigenomics. D N A (genomics) leads through epigenomics to R N A, through transcriptomics to protein (proteomics), to metabolite (metabolomics).

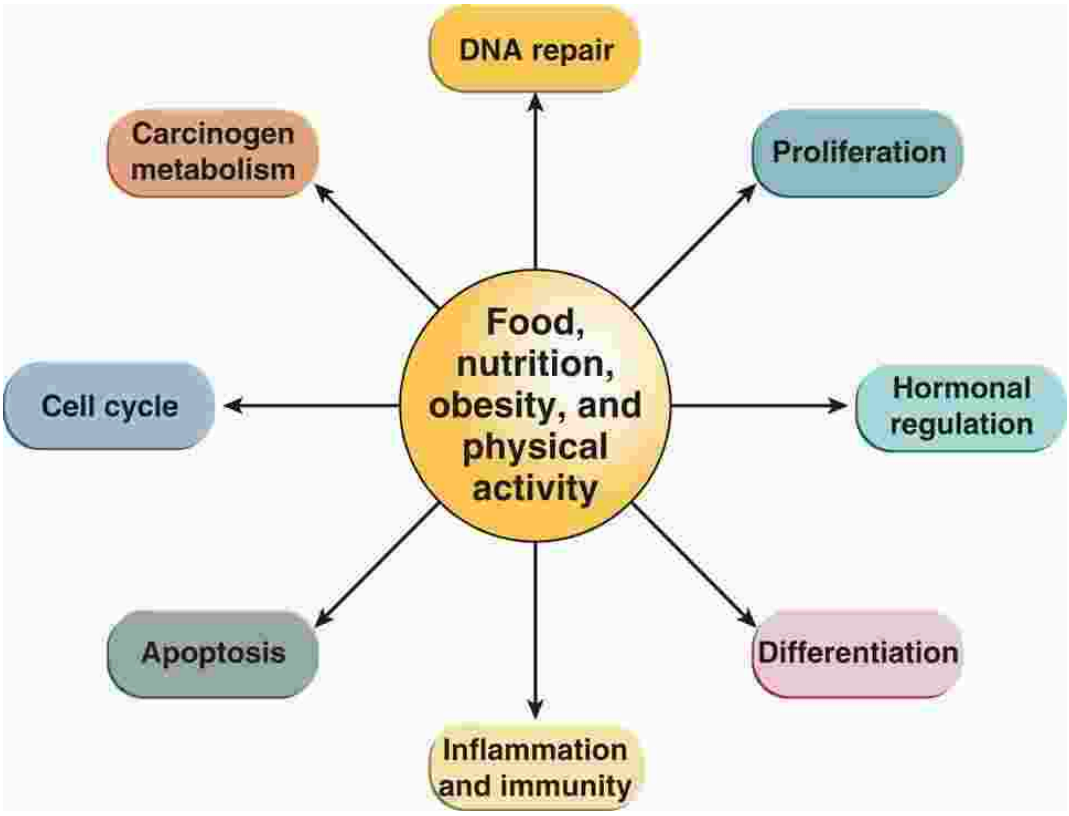

FIG. 13.9 Food, Nutrition, Obesity, Physical Activity, and Cellular Processes Linked to Cancer.
Food, nutrition, and physical activity can influence fundamental processes shown here, which may promote or inhibit cancer development and progression. (This material has been reproduced from the World Cancer Research Fund/American Institute for Cancer Research. Food, Nutrition, Physical Activity, and the Prevention of Cancer: a Global Perspective. Washington DC: AICR, 2007.)

An illustration shows food, nutrition, obesity, and physical activity are linked to the following: D N A repair, proliferation, hormonal regulation, differentiation, inflammation and immunity, apoptosis, cell cycle, and carcinogen metabolism.

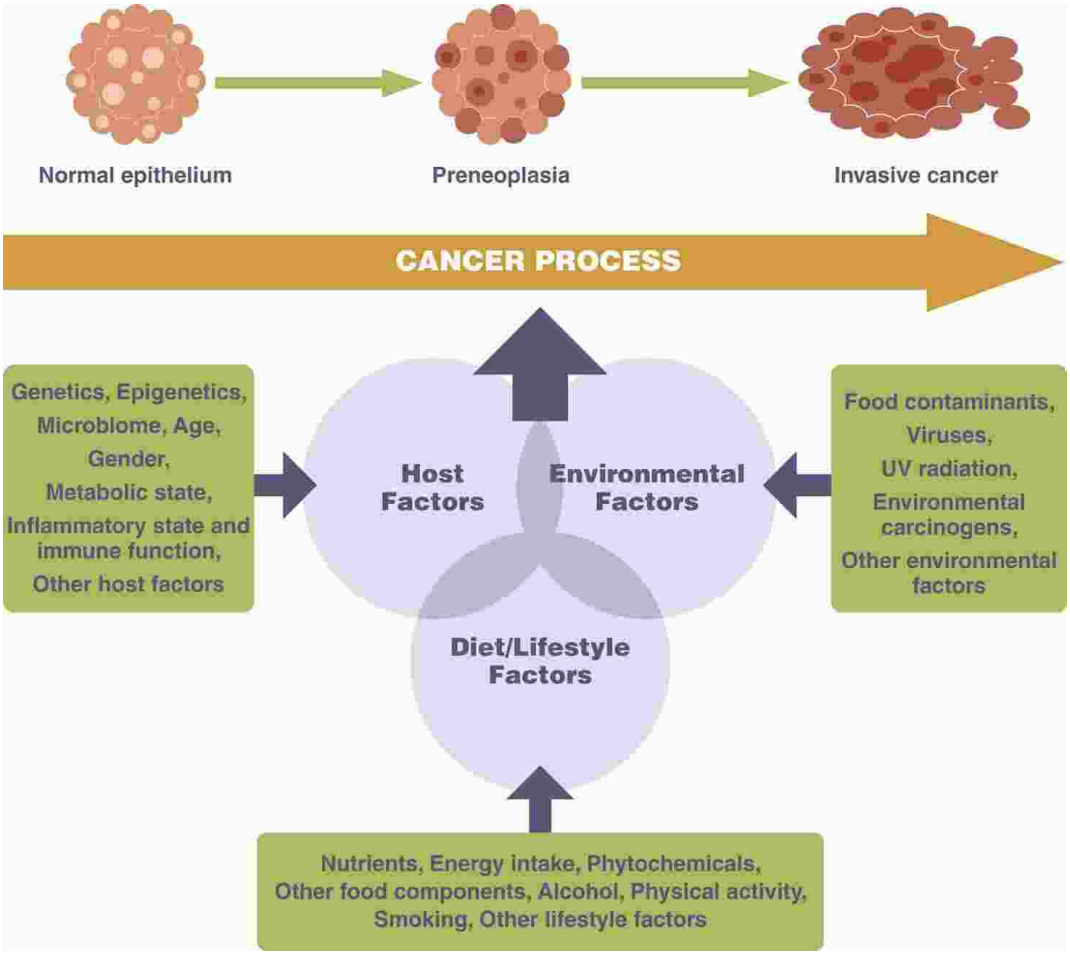

FIG. 13.10 Diet, Nutrition, Physical Activity and Other Environmental Exposures Affect the Cancer Process. It can take many years for a normal cell to transform into invasive cancer cells. Carcinogenesis involves a complex interaction of diet, nutrition, physical activity, and other lifestyle and environmental factors with host factors that are related to inheritance, prior experience, and epigenetic changes. With time, the accumulated genetic damage and impairment of function, for example, DNA repair processes with aging, can all lead to carcinogenesis. Thus critical to this process are everyday lifestyle choices and exposures. (This material has been reproduced from the World Cancer Research Fund/American Institute for Cancer Research. Diet, Nutrition, Physical Activity and Cancer: a Global Perspective. Continuous Update Project Expert Report 2018. Available at dietandcancerreport.org.)

An illustration shows the cancer process progressing as follows: normal epithelium, preneoplasia, and invasive cancer. The following factors impact the cancer process. • Host factors. Genetics, epigenetics, microbiome, age, gender, metabolic state, inflammatory state and immune function, and other host factors. • Environmental factors. Food contaminants, viruses, U V radiation, environmental carcinogens, and other environmental factors. • Diet or lifestyle factors. Nutrients, energy intake, phytochemicals, other food components, alcohol, physical activity, smoking, and other lifestyle factors.

The advocacy of specific dietary recommendations, such as those of the Mediterranean diet (MD), is becoming more common as studies indicate that the MD reduces mortality from several chronic diseases, including cancer, cardiovascular, and neurodegenerative diseases.[43] Culture and geographic location influence patterns of physical activity and diet and play a significant role in health and disease. For example, the incidence of colorectal cancer differs fivefold in various geographic regions and is believed to be tied to differences in the consumption of red or processed meat, fiber, and alcohol. As persons migrate from South Asian areas with lower rates of breast, colorectal, and prostate cancer to western zones, their cancer risks rise, particularly when migrating individuals adopt the so-called Western diet and more sedentary lifestyle. Japan has seen a rapid increase in the incidence of colorectal cancer with the westernization of its diet. However, recent changes in colorectal cancer in younger adults are unlikely to reflect dietary factors alone and may be linked to increased uses of CT scans and NIR from cellphones kept close to the body for hours daily.[12]

As described previously, gene expression is influenced by epigenetic processes, such as DNA methylation or acetylation (addition of an acetyl group) (see Chapters 4, 6, and 12). Dietary sources of methyl groups, including folate, methionine, betaine, serine, and choline, are potential modulators of DNA methylation (Fig. 13.11). The European Prospective Investigation into Cancer and Nutrition (EPIC) found that individuals with high plasma concentrations of methionine, choline, and betaine may be at

reduced risk for colorectal cancer.[44] Other examples of epigenetic changes and diet are presented in Box 13.2.

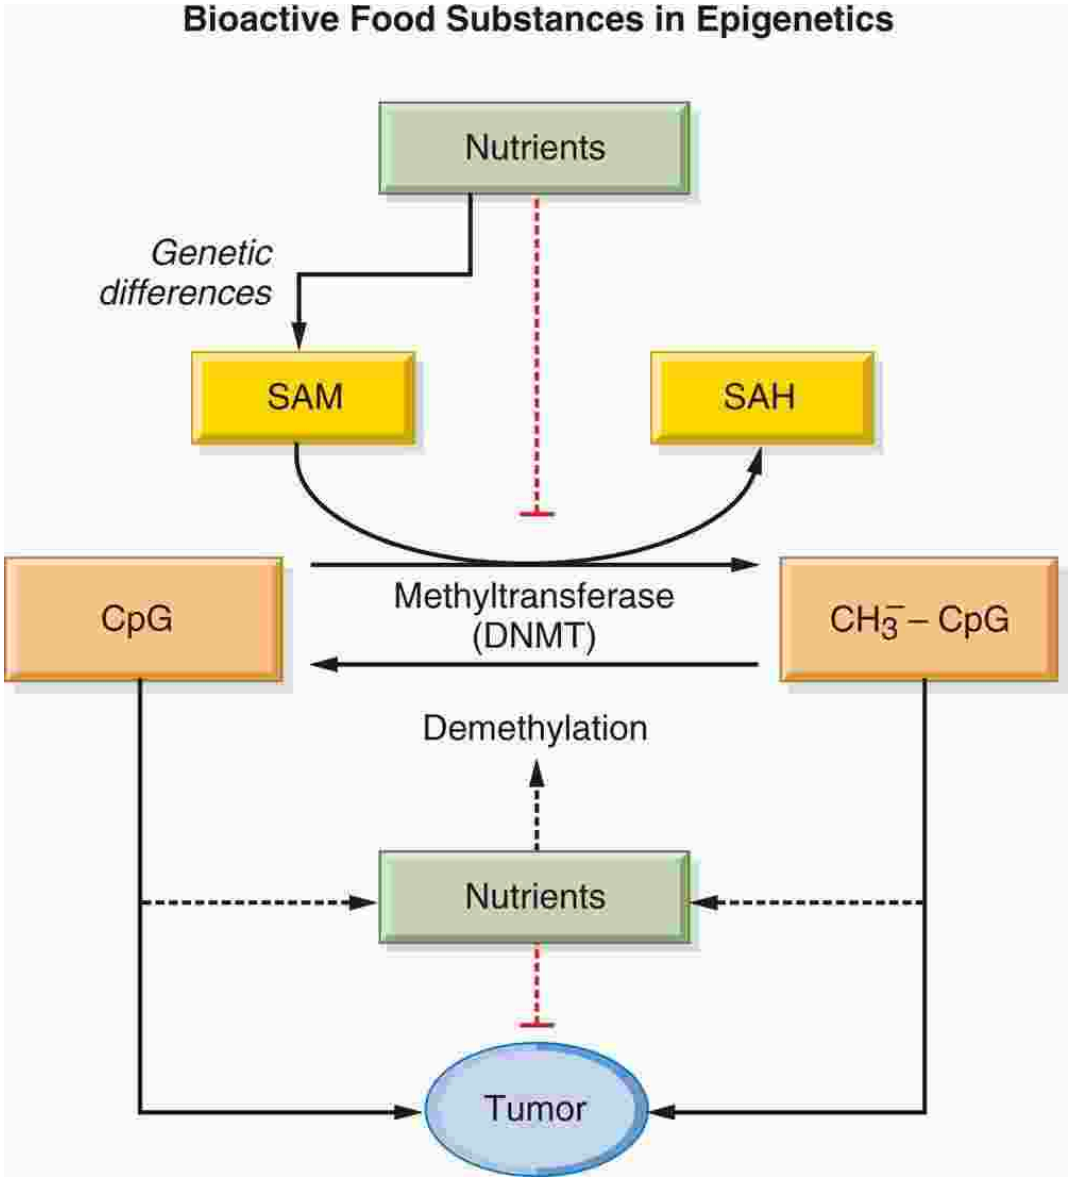

FIG. 13.11 Dietary Factors, DNA Methylation, and Cancer.

Certain dietary factors may supply methyl groups ($+CH_3$) that can be donated through *S*-adenosylmethionine *(SAM)* to many acceptors in the cell (DNA, proteins, lipids, and metabolites). Donation and removal (demethylation) are affected by numerous enzymes, including DNA methyltransferase *(DNMT)*. Increased DNMT activity occurs in many tumor cells. Hypermethylation can inhibit or silence tumor-suppressor genes (see Chapter 12, and DNA methylation inhibitors as anticancer agents can block DNMT, thus reactivating tumor-suppressor genes. DNA

hypomethylation can reactivate and mutate genes, including cancer-causing oncogenes. *SAH, S*-Adenosylhomocysteine; CH_3, methyl group; *CpG site*, cytosine (C) lies next to guanine (G).

A flowchart shows the impact of bioactive food substances in epigenetics. Nutrients, through genetic differences, lead to S A M, which leads to S A H. There is a reversible process, methyltransferase (D N M T), between C p G and C H 3 negative bond C p G, both of which lead to tumor or nutrients which lead to demethylation.

Box 13.2

Examples of Epigenetic Changes and Diet

- B vitamins (B_2, B_6, B_{12}) are modulators of DNA methylation
- Periconceptual maternal supplementation with 400 mcg of folic acid per day was associated with methylation in the offspring
- From the Waterland study, methylation effects were similar in all tissues examined. These data suggest that the methylation mechanism may alter stem cells early in embryogenesis before tissue differentiation and persist throughout life
- Severe folate deficiency, which increases the risk of hepatocellular cancer, induces hypomethylation of the *p53* tumor suppressor gene
- There is strong evidence for the epigenetic effects of organosulfur compounds from garlic and of isothiocyanates from cruciferous vegetables
- Sulforaphane from cruciferous vegetables can act as a histone deacetylase inhibitor to maintain DNA stability or modify transcription
- The potential role of dietary polyphenols, such as curcumin, resveratrol, genistein, epigallocatechin gallate (EGCG), and indole-3-carbinol, may promote antiproliferation and proapoptosis through epigenetic regulation of microRNAs (miRNAs).

- Natural agents in cancer therapies are being investigated in clinical trials

Data from World Cancer Research Fund/American Institute from Cancer Research. *Food, Nutrition, Physical Activity, and the Prevention of Cancer: A Global Perspective*. Washington, DC; 2007; AICR and World Cancer Research Fund/American Institute for Cancer Research. *Diet, Nutrition, Physical Activity and Cancer: A Global Perspective*. Continuous Update Project Report; 2018. dietandcancerreport.org.

Nutritional factors play an important role in cancer development, growth, and responsiveness to treatment. Bioactive xenobiotics found in food have a profound effect on cell differentiation, including the differentiation of cancer stem cells. Cancer stem cells utilize several developmental mechanisms for self-renewal; these mechanisms appear to be fundamental to the initiation, recurrence, and regression or apoptosis of tumors (see Chapter 12). Even if chemotherapy or radiation eliminates cancer cells, it is only when cancer stem cells are destroyed that a full recovery is achievable. Repopulation with radioresistant or chemo-resistant stem cells may significantly contribute to therapy resistance. Evidence from both drug and bioactive food constituents shows that nutritional factors substantially affect cancer stem cell self-renewal capabilities; for example, retinoic acid may promote differentiation of breast cancer stem cells. Increased consumption of specific food compounds, including vitamin A and D, genistein, green tea, epigallocatechin, sulforaphane, theanine, curcumin, choline, and possibly many others, may suppress cancer stem renewal.[45,46] The relationship between diet and cancer is of such great interest that an entire scientific journal is dedicated to the topic (Nutrition and Cancer).

A variety of food constituents also influence the cell cycle and DNA repair (Fig. 13.12). Observational studies suggest that malnutrition can reduce the capacity of DNA to repair damage. Healthy adults consuming kiwifruit, cooked carrots, or supplemental coenzyme Q_{10} improve DNA repair capacity. Lycopene, a plant-based antioxidant, may reduce the risk for lung cancer by preventing DNA damage and improving DNA repair.[47]

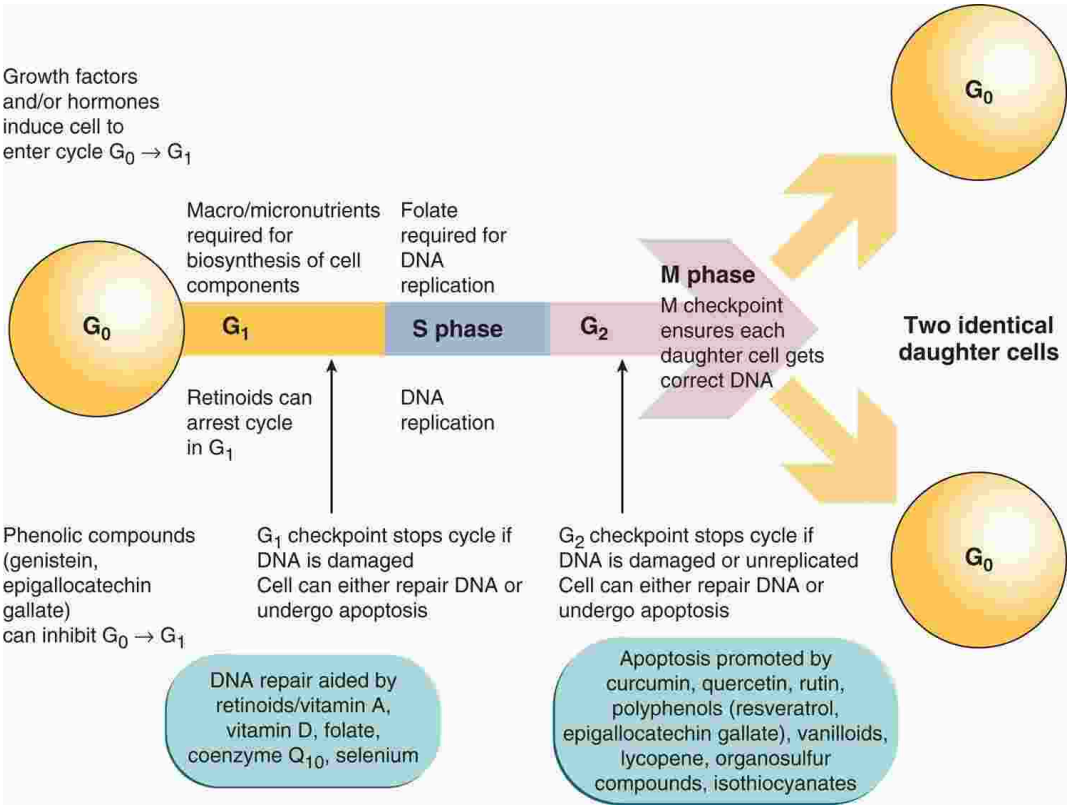

FIG. 13.12 Cell Cycle and Nutrition Regulation. Nutrition may influence the regulation of the normal cell cycle, which ensures correct DNA replication. G_0 represents the resting phase, G_1 the growth and preparation of the chromosome for replication, S the synthesis of DNA, G_2 the preparation of the cell for division, and M mitosis. (Adapted from World Cancer Research Fund/American Institute for Cancer Research. *Food, Nutrition, Physical Activity, and the Prevention of Cancer: A Global Perspective*. Washington, DC: AICR; 2007.)

An illustration shows the cell cycle and nutrition regulation. Growth factors and or hormones induce cell to enter G sub 0 to G sub 1. G sub 0 progresses through the following stages. • G sub 1. Macro or micronutrients required for biosynthesis of cell components. Retinoids can arrest cycle in G sub 1. • S phase. Folate required for D N A replication. D N A replication. • G sub 2, M phase. M checkpoint

ensures each daughter cell gets correct D N A. • Two identical daughter cells: G sub 0. Phenolic compounds (genistein, epigallocatechin gallate) can inhibit G sub 0 leads to G sub 1. G sub 1 checkpoint stops cycle if D N A is damaged. Cell can either repair D N A or undergo apoptosis. D N A repair aided by retinoids or vitamin A, vitamin D, folate, coenzyme Q sub 10, selenium. G sub 2 checkpoint stops cycle if D N A is damaged or unreplicated. Cell can either repair D N A or undergo apoptosis. Apoptosis is promoted by curcumin, quercetin, rutin, polyphenols (resveratrol, epigallocatechin gallate), vanilloids, lycopene, organosulfur compounds, and isothiocyanates.

Humans are constantly exposed to a variety of xenobiotics that include toxic, mutagenic, and carcinogenic chemicals. Many xenobiotics are chemicals found in medications. A surprising number of widely used pharmaceuticals, including popular agents such as gabapentin, azopyrimidine, hydrochlorothiazide, and paroxetine, can also increase cancer risk. Common pharmaceutical agents linked to cancer are listed in Box 13.3. Most xenobiotics are transported in the blood by lipoproteins and penetrate lipid membranes. The body has two main defense systems for counteracting these effects: (1) detoxification enzymes that work through the liver and (2) antioxidant systems (see Chapter 2). When a compound is absorbed through the GI tract, it enters the hepatic circulation through the portal vein. The liver metabolizes dietary or pharmaceutical xenobiotics that are orally ingested through the *first pass effect* that can metabolize and thereby prevent many potentially carcinogenic agents from entering the body. Although the liver is the main site of detoxification, this process occurs to a lesser extent at other sites (i.e., extrahepatic detoxification). Many foods, such as isothiocyanates from cruciferous vegetables, induce detoxification enzymes that enhance the efficiency and degree of detoxification of xenobiotics and thus can serve a protective role in metabolizing carcinogens.

Box 13.3

Common Pharmaceutical Agents Associated With Increased Cancer Risk

Fluoxetine and paroxetine with testicular cancer
Hydrochlorothiazide with renal and lip cancer
Hyoscyamine with non-Hodgkin lymphoma
Nifedipine with lip cancer
Nortriptyline with esophageal and hepatic cancer
Oxazepam with lung cancer
Sulindac with gallbladder cancer and leukemia

Data from https://www.mdlinx.com/article/common-prescription-drugs-you-didn-t-know-could-cause-cancer/5Ts67N8oKAP5GEVMderxUq.

Certain enzymes (glutathione-*S*-transferases [GSH]) are "enzyme housekeepers" that play essential roles in the metabolism of environmental carcinogens and reactive oxygen species (ROS). Individuals who have absent or reduced levels of these protective enzymes may be at higher risk for cancers because of a decreased capacity to effectively neutralize carcinogens by metabolic transformation into less toxic forms. For example, there are fungi that form on certain crops such as peanuts and some grains that produce carcinogenic aflatoxin. The production of this toxin can be counteracted by ascorbate, n-acetylcysteine, or other nutritional components that affect the production of GSH. Activated in the liver, aflatoxins produce adducts with N-7 guanine-DNA that can trigger the formation of malignant cells. Individuals lacking protective enzymes or having lower levels of those enzymes are at higher risk for developing colon, liver, and other types of cancer.

The EPIC trial, which included 478,040 people from 10 countries, reported convincing data linking colon cancer to consumption of meats that contain nitrites, nitrates, or other preservatives in products such as bacon, sausages, bratwursts, frankfurters, and other nitrite-containing meats.[48] The resulting *N*-nitroso compounds increase nitrogenous residues in the colon that can cause DNA damage that increases cancer risk. Observational and experimental studies indicate that supplementation with chlorophyllin, vitamin A, and other antioxidants may reduce the risk of cancer development.

Metabolic reactions that impact cancer development include pro-carcinogenic processes, as well as protective reactions. Other products of normal metabolism produced in adipose tissue (hormones, inflammatory

mediators, adipokines) can contribute to tumor microenvironment. Furthermore, microorganisms in the digestive tract (gut microbiome, see Chapter 7) play an important role in the metabolism of food and produce many small molecules that may impact cancer development.[49] Some reactions activate dietary compounds to form potential carcinogens as with aflatoxin. Other metabolic processes, such as ingested antioxidants, can inactivate ingested carcinogenic components thus preventing DNA damage. Red meat and its preservatives have been the subject of considerable scrutiny. A high intake of red meat may result in the synthesis of higher levels of heme iron, a substance known to activate oxidative stress and inflammation in the colon. Additionally, meat may have certain thermoresistant oncogenic bovine viruses (e.g., polyoma-papilloma) or single-stranded DNA viruses. Cooking meats at high temperatures (pan frying or grilling) may pose additional hazards because it results in the formation of highly mutagenic heterocyclic amines (HCAs) and polycyclic aromatic hydrocarbons (PAHs), both identified as carcinogens in laboratory animals. Future research is needed to define robust biomarkers of cancer risk.

Obesity

Obesity constitutes a special form of poor nutrition that is epidemic over the past 20 years in most developed countries, including the United States, and in urban areas of many rapidly developing countries. The Lancet Commission on the epidemic of obesity, malnutrition, and climate change has documented global patterns where several countries simultaneously have both increased rates of obesity as well as problems of underweight. Over 40% of US adults are obese, affecting nearly half of non-Hispanic Blacks (see Chapter 23).[50] The prevalence of obesity in children has increased significantly in the past decade such that now nearly one in five US children are obese.[51] Worldwide, it is estimated that nearly 2 billion adults are overweight, and of these over 650 million are obese.[52] Criteria for overweight status and obesity are based on the body mass index (BMI) (see Chapter 23).

Obesity constitutes a significant setback to improvements in other areas of health during the past century. Numerous serious chronic health conditions are linked to obesity and physical inactivity, including diabetes, cardiovascular disease, and 13 distinct forms of cancer (liver, advanced prostate, ovarian, gallbladder, kidney, colorectal, esophageal [adenocarcinoma], postmenopausal breast, pancreatic, endometrial, stomach [cardia], multiple myeloma, and meningioma) (Fig. 13.13). The accelerating, long-term costs of obesity for both the individual and society underlie the urgency to accelerate progress in prevention and treatment. IARC has

established a preventive relationship between the absence of excess weight and the risk of cancer in humans.

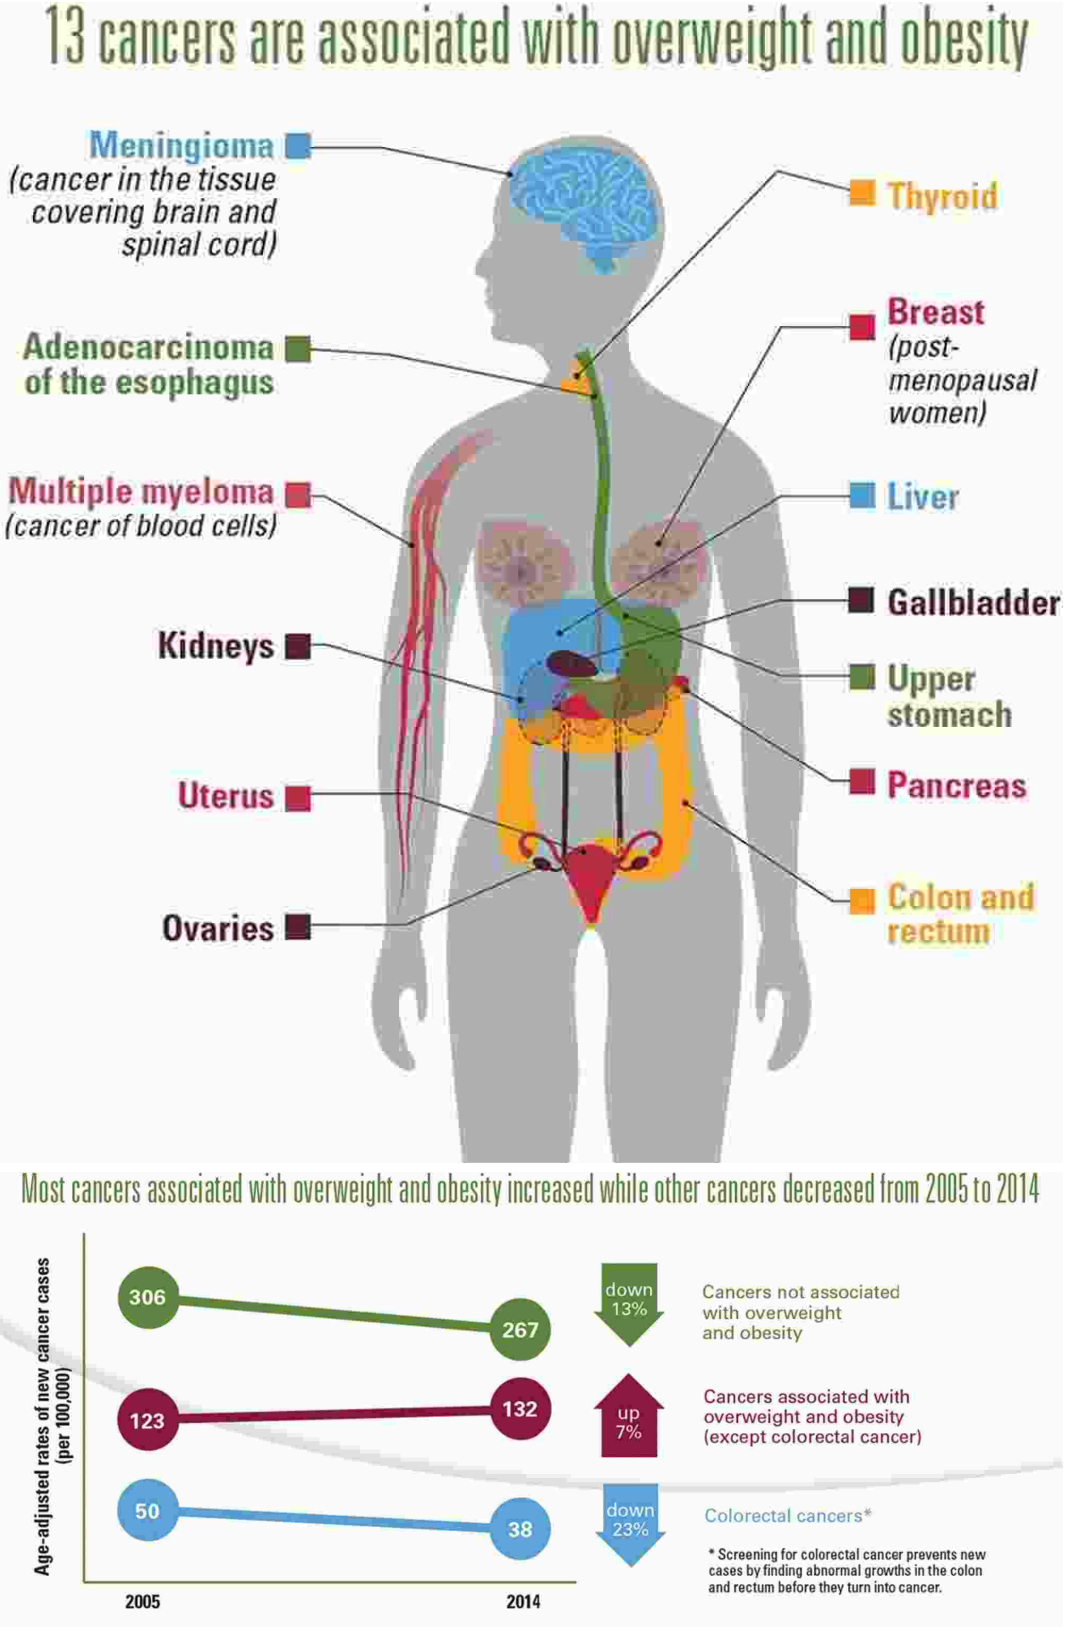

FIG. 13.13 Overweight and Obesity and Increased Risk for 13 Cancers.

(A) Cancers associated with overweight and obesity are meningioma, adenocarcinoma of the esophagus, multiple myeloma, kidneys, uterus, ovaries, thyroid, breast (post-menopausal, liver, gallbladder upper stomach, pancreas, colon and rectum; **(B)** Although most cancers associated with overweight and obesity increased, other cancers decreased from 2005 to 2014. (From CDC Cancer and obesity. *Overweight and Obesity Are Associated With Cancer Vital Signs Centers for Disease Control and Prevention US Department of Health &Human Services*. US Cancer Statistics; 2017.)

Top panel. An illustration of the human figure identifies the 13 cancers associated with overweight and obesity: meningioma (cancer in the tissue covering brain and spinal cord), thyroid, adenocarcinoma of the esophagus, breast (post-menopausal women), multiple myeloma (cancer of blood cells), liver, upper stomach, gallbladder, kidneys, pancreas, colon and rectum, uterus, and ovaries. Bottom panel. A line graph shows how most cancers associated with overweight and obesity increased while other cancers decreased from 2005 to 20 14. The vertical axis represents age-adjusted rates of new cancer cases (per 100,000). The horizontal axis shows years 2005 and 20 14. The data from the graph are as follows. • Cancers not associated with overweight and obesity are down 13 percent from 306 in 2005 to 267 in 20 14. • Cancers associated with overweight and obesity (except colorectal cancer) are up 7 percent from 123 in 2005 to 132 in 20 14. • Colorectal cancers are down 23 percent from 50 in 2005 to 38 in 20 14. Screening for colorectal cancer prevents new cases by finding abnormal growths in the colon and rectum before they turn into cancer.

Obesity has been linked mechanistically to both an increase in cancer risk and cancer progression. Because tumor growth is regulated by interactions between tumor cells and their tissue microenvironment, stromal compartments rich in adipose tissue can promote the development of tumor cells. During cancer progression, cancer-associated adipocytes (CAAs) undergo both structural and functional alterations that create a favorable micro-environment for increased cellular invasiveness and aggression (Fig. 13.14A). Cancer cells alter adipocytes through lipolysis and delipidation leading to CAAs that produce abnormal amounts of adipocyte-derived cytokines (increased leptin and decreased adiponectin), as well as release inflammatory cytokines and protease enzymes. The adipokine leptin increases inflammation and is associated with stromal effects that promote cancer cell proliferation, metabolism, angiogenesis, and invasion.[53] In obese individuals, changes in glucose and lipid metabolism are found in the tumor microenvironment as well as systemically. Obesity causes dysfunctional adipose tissue to produce increased levels of insulin–like growth factor 1 (IGF-1), sex hormones, and adipokines that contribute to obesity-related metabolic changes such as insulin resistance, hyperglycemia, dyslipidemia, hypoxia, and chronic inflammation (see Fig. 13.14B). As described previously, inflammation is an important contributor to both tumor initiation and progression. Excess adipose tissue can become reservoirs of lipophilic organochlorines and other fat-seeking toxic agents that can enhance proinflammatory mediators, which attract macrophages and cancer-associated fibroblasts, all of which are tumor-promoters. Additionally, the associated insulin resistance and hypoxia can trigger compensatory angiogenesis, thus providing an energy reservoir for any embedded cancer cells. Type 2 diabetes, elevated insulin levels, and altered insulin signaling pathways in obese individuals have been linked to cancer risk and progression as well as resistance to cancer therapies.[54]

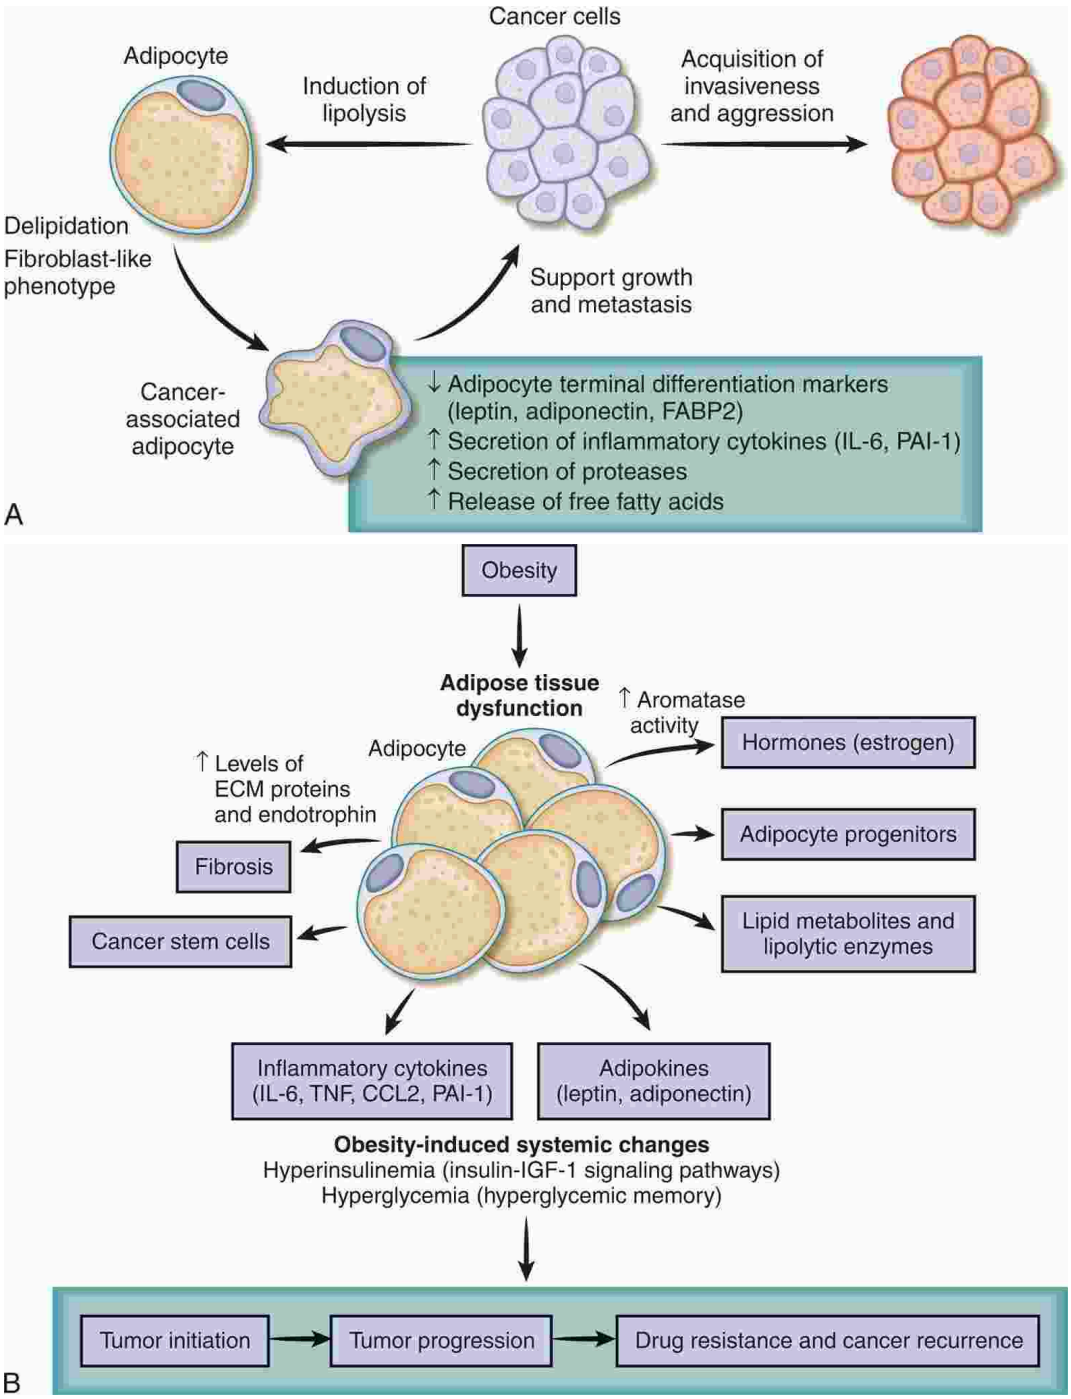

FIG. 13.14 Structural and Functional Changes in Adipocytes and Interaction With the Microenvironment Contribute to Cancer Progression and Metastases: A Working Model.

(A) Signaling interactions occur between cancer cells and cancer-associated adipocytes. This interaction within the tumor microenvironment creates a place or *niche*

permissive for cancer growth. Cancer cells stimulate the breakdown of lipids in adipocytes, leading to *delipidation* and the emergence of a fibroblast-like phenotype in adipocytes. The continuing alterations are associated with functional changes in the cells and include increased secretion of inflammatory mediators (cytokines) and proteases, and increased release of free fatty acids. All of these changes can support tumor growth and invasiveness. **(B)** Obesity leads to excessive levels of proinflammatory cytokines, sex hormones, lipid metabolites, and altered adipokines. The altered adipose tissue becomes a source of various extracellular matrix proteins, cancer stem cells, and cancer-associated adipokines. Collectively these alterations contribute to tumor initiation, growth, and recurrence. The systemic metabolic changes of obesity—hyperinsulinemia and hyperglycemia—can further contribute to a tumor-permissive environment. *CCL2*, Chemokine ligand 2; *ECM*, extracellular matrix; *FABP2*, fatty acid–binding protein 2; *IGF*, insulin-like growth factor; *IL*, interleukin; *TNF*, tumor necrosis factor. (Adapted from Park J, Morley TS, Kim M, et al. Obesity and cancer—Mechanisms underlying tumour progression and recurrence. *Nature Reviews Endocrinology* 2014;10(8):455–465.)

Illustration A represents signaling interactions. Cancerous cells can undergo either of the following processes. • Acquisition of invasiveness and aggression. • Induction of lipolysis leads to adipocyte. This leads to dilapidation and fibroblast-like phenotype, resulting in cancer-associated adipocyte that support growth and metastasis. Cancer-associated adipocyte involves the following. • Decreased adipocyte terminal differentiation markers (leptin, adiponectin, F A B P 2). • Increased secretion of inflammatory cytokines (I L-6, P A I-1). • Increased secretion of proteases. • Increased release of free fatty acids. Illustration B. Obesity leads to adipose tissue dysfunction,

resulting in the following conditions. • Increased aromatase activity. • Hormones (estrogen). • Adipocyte progenitors. • Lipid metabolites and lipolytic enzymes. • Adipokines (leptin, adiponectin). • Inflammatory cytokines (I L-6, T N F, C C L 2, P A I -1). • Cancer stem cells. • Fibrosis. • Increased levels of E C M proteins and endotrophin. Obesity-induced systemic changes include hyperinsulinemia (insulin-I G F-1 signaling pathways) and hyperglycemia (hyperglycemic memory). These can lead to tumor initiation, tumor progression, and drug resistance and cancer recurrence.

Increasing BMI is related to less favorable outcomes for cancer recurrence, survival, and comorbidities (e.g., cardiovascular disease, diabetes, wound healing). Survivors of childhood cancers appear to have an increased risk of developing obesity, diabetes, thyroid cancer, and other cancers throughout the aging process.[55]

Alcohol Consumption

Alcohol is classified by IARC as a human carcinogen and is known to increase circulating unbound hormones as well as obesity. Overall, there are strong data linking alcohol with cancers of the mouth, pharynx, larynx, esophagus, liver, colorectum, and breast (in both males and females) (Table 13.4).[56] The evidence does not support any "safe limit" of intake. The deleterious effects come from the ethanol content and are not affected by the type of drink consumed.

Table 13.4

Alcoholic Drinks and Risk of Cancer[a]

	Decreases Risk		Increases Risk	
	Exposure	**Cancer Site**	**Exposure**	**Cancer Site**
Convincing			Alcoholic drinks	Mouth, pharynx and larynx, esophagus Colorectum (men)[b] Breast (premenopause and postmenopause)
Probable			Alcoholic drinks	Liver[c] Colorectum (women)[b]
Limited—suggestive				
Substantial effect on risk unlikely	Alcoholic drinks (adverse effect): kidney[d]			

	Decreases Risk		Increases Risk	
	Exposure	Cancer Site	Exposure	Cancer Site
Convincing			Alcoholic drinks	Mouth, pharynx and larynx, esophagus Colorectum (men)b Breast (premenopause and postmenopause)
Probable			Alcoholic drinks	Liverc Colorectum (women)b
Limited—suggestive				
Substantial effect on risk unlikely	Alcoholic drinks (adverse effect): kidneyd			

[a]In the judgment of the Panel (WCRF/AICR), the factors listed modify the risk of cancer. Judgments are graded according to the strength of the evidence.

[b]The judgments for men and women are different because there are fewer data for women. Increased risk is only apparent above a threshold of 30 g/day of ethanol for both sexes.

[c]Cirrhosis is an essential precursor of liver cancer caused by alcohol. The International Agency for Research on Cancer has graded alcohol as a class 1 carcinogen for liver cancer. Alcohol alone only causes cirrhosis in the presence of other factors.

[d]The evidence was sufficient to judge that alcoholic drinks are unlikely to have an adverse effect on the risk of kidney cancer; it was inadequate to draw a conclusion regarding the protective effect.

Adapted from World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR). *Second Expert Report: Food, Nutrition, Physical Activity, and the Prevention of Cancer: A Global Perspective*. London: Author.

Gene variations among alcohol users may increase the likelihood of alcohol-related toxicities. For example, genes that encode for ethanol metabolism affect the ability of the body to convert acetaldehyde to acetate. Acetaldehyde is the most toxic metabolite of alcohol and is the chief cause of alcohol-related carcinogenesis. Other toxic effects of alcohol result from the induction of cytochrome P-450 2E1 (genetic variant CYP2E1) leading to the generation of ROS and oxidative stress.[57] Some factors that can enhance the carcinogenicity of ethanol include an increase in pro-carcinogens (e.g., nitrosamines from preserved meats) and viral co-factors, such as hepatitis, that weaken the capacity of the liver to induce protective enzymes. Such changes predispose the individual to enzyme and metabolic dysfunction, as well as structural abnormalities (e.g., altered mucosal integrity). Associated nutritional deficiencies in cancer-protective agents, such as retinol, retinyl esters, folic acid, and other vitamins also contribute to tumor initiation and progression. For example, deficiencies in folate cause epigenetic changes in DNA methylation that promote tumor cell proliferation.[58]

Physical Activity

Regular exercise is reported to decrease the risk of breast cancer, colon cancer (men), and endometrial cancer independent of weight changes. Data are showing the vital importance of regular exercise in the primary and secondary prevention of several other chronic diseases, including cardiovascular disease, hypertension, diabetes, obesity, depression, osteoporosis, and premature death.[17,59] Millions of deaths in the United States are attributable to physical inactivity.[60] In a recent study, those with high levels of sedentary behavior were found to have a 28% to 44% increased risk of colon cancer, an 8% to 17% increased risk for breast cancer, and a 28% to

36% risk for endometrial cancer.[61] Several biologic mechanisms have been proposed to account for the protective effect of exercise against many forms of cancer, including

- Decreasing insulin and IGF levels
- Decreasing obesity
- Increasing free radical scavenger systems
- Altering inflammatory mediators
- Decreasing levels of circulating unbound sex hormones and metabolic hormones
- Improving immune function
- Decreasing oncogenes
- Enhancing cytochrome P-450 and thereby modifying carcinogen activation
- Increasing gut motility and excretion of carcinogens
- Increasing antitumor effects from the release of myokines or proteins from contracting muscles (see Emerging Science Box: Exercise and Anticancer Effects of Myokines)

Many questions remain unanswered concerning the ideal frequency, intensity, and duration of exercise. According to the US Department of Health and Human Services, significant health benefits are achieved when adults engage weekly in at least 150 minutes (2 hours and 30 minutes) to 300 minutes (5 hours) of moderate-intensity aerobic physical activity, 75 minutes (1 hour and 15 minutes) to 150 minutes (2 hours and 30 minutes) of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity activity.[62] The guidelines recommend at least 60 minutes of physical activity everyday (mostly moderate- or vigorous-intensity aerobic) for children and adolescents. Being physically active after a cancer diagnosis is linked to improved quality of life and increased survival for several cancer types. A Cochrane review found that aerobic exercise was beneficial for adults with cancer-related fatigue both during and after cancer treatment.[63] Another Cochrane review found exercise in children with cancer associated with improved body composition, flexibility, and cardiorespiratory fitness.[64]

Air Pollution

The US Environmental Protection Agency, WHO, the Institute for Health Metrics and Evaluation (IHME) of the University of Washington, and others report that long-term exposure to air pollution increases morbidity from

respiratory disease, lung cancer, and bronchitis, as well as a wide range of other chronic diseases. Air pollution also shortens life expectancy from cardiovascular disease, respiratory disease, lung cancer, and possibly neurodegenerative diseases and other forms of cancer.[65] Worldwide, air pollution is the fifth leading cause of death, and is the leading known environmental cause of death.[66,67] Indoor air pollution from burning coal, charcoal, wood, dung, or other biomass also poses a significant health burden.

IARC has concluded that outdoor air pollution is carcinogenic to humans (IARC Group 1) and causes lung cancer.[68] A recent systematic review found that leukemia is also linked to air pollution exposure.[69] Specific constituents of polluted air are highly mutagenic and carcinogenic.[70] Outdoor air pollution consists of fine particulates, gases of nitrogen and sulfur, heavy metals, volatile organic compounds, and combustion exhausts that form ozone in the presence of sunlight. It is the only carcinogen in IARC Group 1 that is a mixture of components, some of which exhibit high toxicity and carcinogenic potential when isolated, whereas other components do not. Studies of this mixture sometimes reveal no effects compared to the effects caused by toxic compounds tested individually. Thus, the mechanism of carcinogenicity induced by air pollution is a mixture of multiple cellular responses, revealing synergies and antagonisms between components.[71]

Some of the compounds in air pollution are classified by the IARC as carcinogens including benzo[a]pyrene and benzo[a]anthracene. IARC classifies diesel engine exhaust as carcinogenic with sufficient evidence that it is linked to an increased risk of lung cancer and an association with bladder cancer. The most significant association, however, between air pollution and cancer involves exposures to particulate matter (PM) (see Chapter 2). PM is a mixture of extremely small particles, including heavy metals and liquid droplets, that are a complex mix of acids (nitrates and sulfates), organic chemicals, metals, and soil or dust particles. PM varies in size categorized as PM_{10} (particles with an aerodynamic diameter equal to or less than 10 μm), $PM_{2.5}$ (particles with an aerodynamic diameter equal to or less than 2.5 μm), and ultrafine particles (Fig. 13.15). The size of the particles determines where they are distributed in the respiratory tract, with large particles deposited in upper airways, while fine particles are deposited in deeper airways.

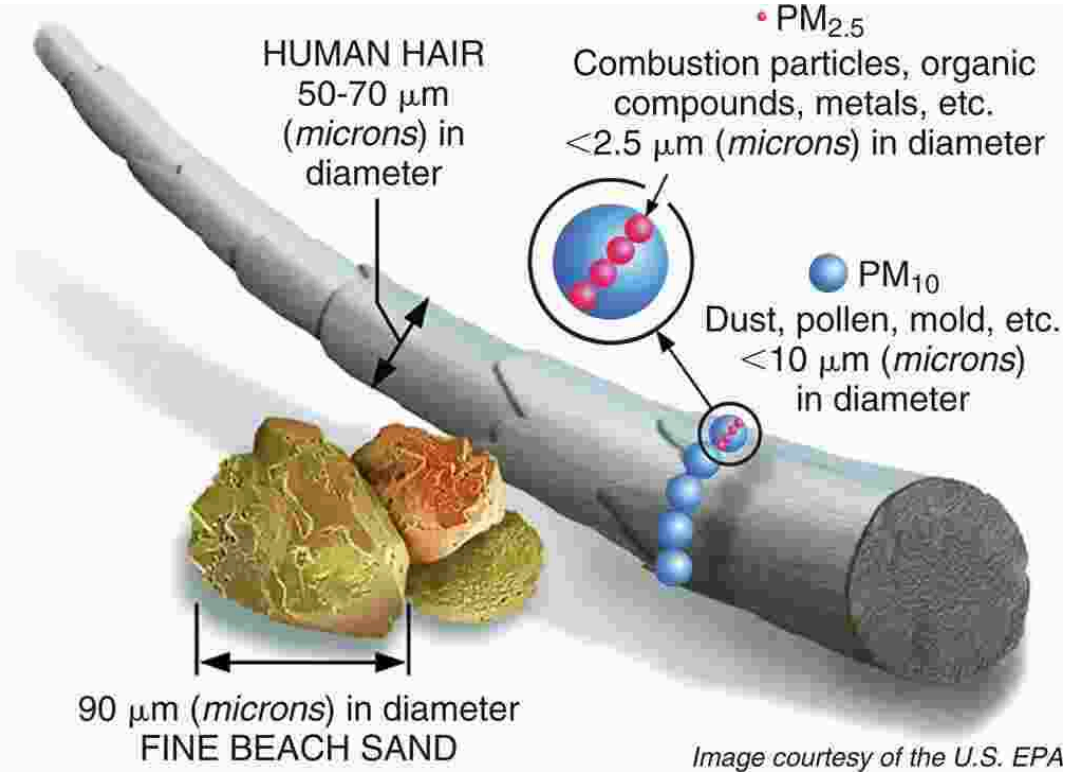

FIG. 13.15 Particle Sizes and Pollution. (From Environmental Protection Agency. *Particulate Matter Updated March 18, 2013*. Washington, DC: Author; 2013.)

An illustration compares the sizes of fine beach sand and human hair. Human hair is 50 to 70 micrometers or microns in diameter. Fine beach sand is 90 micrometers or microns in diameter. P M 10 substances on a hair stand include dust, pollen, and mold that are less than 10 micrometers or microns in diameter. P M 2.5 substances, on P M 10 substances, include combustion particles, organic compounds, and metals that are less than 2.5 micrometers or microns in diameter.

The mechanisms of adverse effects of PM include (1) oxidative stress, (2) ROS generation, (3) DNA oxidative damage, (4) mutagenicity, (5) stimulation of proinflammatory factors, and (6) induction of senescence. $PM_{2,5}$ or smaller particles are easily absorbed by the lungs Within the blood, these tiny

particles are phagocytosed by macrophages and neutrophils that release tissue-damaging inflammatory mediators. PM causes pulmonary inflammation, which leads to oxidative stress and oxidation of DNA, sustained cellular proliferation, and tissue remodeling progressing to fibrosis and tumor development. $PM_{2.5}$ inhalation has an antiapoptotic effect that sustains cell division in damaged cells, induces angiogenesis, and activates invasion and metastasis of cancer cells.[71]

Levels of ozone, another common outdoor air pollutant, are rising around the world in both higher income and lower/middle income regions contributing to about 365,000 annual deaths from chronic lung disease and lung cancer. Over 70% of these deaths occurred in India and China. In the United States, it is estimated that there were 12,800 deaths in 2019 attributable to ozone exposure.[66]

Living close to petrochemical and other industries is a recognized cancer risk factor in India, Brazil, China, and the United States. *Cancer Alley* is the term used to depict an array of historically black and brown and impoverished small factory towns situated on an 85-mile stretch of industrial plants along the banks of the Mississippi River that extends from New Orleans to Baton Rouge. Similar phenomena can be found in many rapidly industrializing zones across the globe, where the economically and ethnically disadvantaged incur far greater burdens of pollution and poor health. In India, up to half of all lung cancer occurs in non-smokers and is believed to reflect levels of both indoor (from cooking fuels) and outdoor air pollution that are without historic precedence.

Levels of pollutants, such as cigarette smoke and fuel byproducts, can easily become concentrated indoors. Both active and passive smoking (secondhand smoke) and fuel combustion lead to the formation of ROS and damaging free radicals. These byproducts can remain airborne for weeks, inducing cell death (apoptosis) in the lungs, promoting inflammation, and increasing biochemical markers known to increase DNA damage and the risk of cancer. Non-smokers in some regions in China and India have high levels of lung cancer from exposures to cooking fumes, as well as domestic coal byproducts that can produce indoor particulate levels many times greater than outdoor pollution or tobacco smoke.[72]

Another significant indoor air pollutant is radon gas, which is considered the leading indoor cause of lung cancer in nonsmokers in the United States.[73,74] Radon is a natural radioactive decay product of uranium that can become trapped indoors after it is released from rock and soil. Exposure levels are greater in underground mines as compared to houses. Radon gas in the

air breaks down into tiny radioactive elements that are inhaled directly into the lungs or attach to small dust particles that are then inhaled and lodge in the bronchi. Here, they can give off radiation that damages lung cells and may eventually lead to lung cancer. Non-smokers with polymorphisms of genes for DNA-repair are most susceptible to developing radon-associated lung cancer.[75] Houses with carcinogenic radon hazards can be identified by testing basements when doors and windows are kept closed. If levels are above 4 μg/dL, the Environmental Protection Agency advises that they should be mitigated.

Ionizing Radiation

Much of the knowledge of the effects of IR on human cancer has stemmed from observations of cancer patterns in survivors of the Hiroshima and Nagasaki atomic bombs from 1945 who were exposed over the dose range from 20 to 250 centigray (cGy), which includes low linear energy transfer (LET) radiation, like that from x-rays or γ-rays. Other evidence is derived from groups exposed to IR for medical reasons or various occupational exposures (Table 13.5). Within the first decade after the bombings in Japan, increased risks of acute leukemia were evident in children as were increased frequencies of thyroid and breast carcinomas. Other cancers later added to the list include lung, stomach, colon, esophageal, urinary tract cancers, and multiple myeloma. At Nagasaki and Hiroshima, the leukemia incidence in individuals 15 years or younger reached its peak 6 to 7 years after the explosions and has declined steadily since 1952. Those 45 years or older at the time of exposure had a longer latent period of 20 years before developing acute leukemia.

AB, Atomic bomb survivors; *AS*, ankylosing spondylitis individuals; *PM*, postpartum mastitis individuals; *RD*, radiologists; *RP*, radium dial painters; *TC*, tinea capitis individuals; *TH*, individuals receiving Thorotrast; *UM*, underground miners.

Data from Jones JA, et al. Ionizing radiation as a carcinogen. In: McQueen E, ed. *CA comprehensive toxicology*, 2nd edition. St Louis: Elsevier; 2010.

Age at the time of exposure is one of the main determinants of the type of radiation-induced cancer that is likely to develop. Susceptibility to cell damage is a function of the rate of cell replication; thus radiation exposures at early ages are the most carcinogenic. Sensitivity to radiation decreases until maturity but increases again at older ages when exposures can promote previously tumor-initiated cells and immune systems are more compromised.[76] Studies of Japanese atomic bomb survivors and Oak Ridge Y-12 uranium-processing plant workers suggest that this bimodal distribution indicates that radiation risks from early age exposures are related to *initiation* of cancer processes; whereas radiation exposures at later ages are mostly associated with the *promotion* of preexisting premalignant cells or exposures to chemical or physical agents that function as co-carcinogens.[77,78]

Human exposure to IR includes environmental emissions (e.g., radon), as well as diagnostic or therapeutic medical exposures (x-rays, CT scans, radioisotopes), and other radioactive sources. Studies of the childhood cohort treated with radiation to the skull to treat tinea capitis (ringworm) also show increased risks of brain cancer later in life along with elevations in thyroid cancer risk.[79,80] More recent pooled analyses reaffirm a linear relationship between dose and increased risk of thyroid cancer. This association persisted greater than 45 years after exposure, was greater at younger age of exposures, and was similar by sex and number of treatments.[81] Radiation-induced damage depends not only on dose, fractionation, and mechanism of the radiation delivery but also on critical indices of vulnerability that affect inherent repair mechanisms of the organism.

Radiation health risks involve not only neoplastic diseases but also cardiovascular disease. Cardiac and blood vessel damage causes fibrosis of the heart and blood vessels resulting in increased risk for coronary artery disease, valvular disease, cardiomyopathy, arrhythmias, and pericardial disease.[82] Other risks from IR even at low doses include somatic mutations and tissue alterations that contribute to other diseases, such as respiratory diseases, birth defects, and eye maladies, and may affect future generations. Fetal radiation exposure increases the risk for growth restriction, major malformations, death, and postnatal development of cancer.[83] In 2009, the National Council on Radiation Protection and Measurements (NCRP) reported Americans were exposed to more than seven times as much IR from medical procedures as compared with the 1980s (see Emerging Science Box: Increasing Use of Computed Tomography Scans and Risks).[84] In another study, the use of CT scans increased by 7.8% per year between 1996 and 2010 resulting in a doubling of the average per-person dose of radiation exposure

for study subjects during that period.[85] In an effort to reduce pediatric exposure, the concept of "as low as reasonably achievable (ALARA)" levels of radiation from diagnostic or therapeutic procedures was introduced in the 1980s. An international program called "Image Gently" has since been successful in reducing unnecessary radiation exposure to children.[86]

Radiation-Induced Cancer

IR is a potent mutagen and carcinogen. It can penetrate cells and tissues, depositing random energy within tissues in the form of ionizations (e.g., excitation or removal of an electron from the target atom). Such ionization can lead to irreversible or indirect damage secondary to the formation of water-based free radicals (radiolysis). The *general* characteristics of IR-induced carcinogenesis are well established. Research over the past two decades has focused on *specific* cellular and molecular mechanisms which impact cancer development and other chronic illnesses. Considerations include dose-response relationships for mutations, chromosome aberrations, cell transformation, and both genetic and epigenetic expression that vary with host conditions. Other important areas of investigation include effects on the microenvironment and nontargeted cells, which are the biologic effects that occur in nonirradiated bystander cells.

IR is a potent DNA-damaging agent causing cross-linking, nucleotide base damage, and single- or double-strand DNA breaks thus disrupting cellular regulation processes leading to carcinogenesis. The double-strand break (DSB) (Fig. 13.16) is considered one hallmark lesion. This type of DNA damage commonly can be repaired by the *nonhomologous end joining (NHEJ) pathway* that efficiently joins broken ends of DNA. However, repair errors can occur and increase with age and malnutrition. Irradiated human cells that are unable to execute the NHEJ pathway are extremely vulnerable to large-scale mutations and chromosomal aberrations.[87]

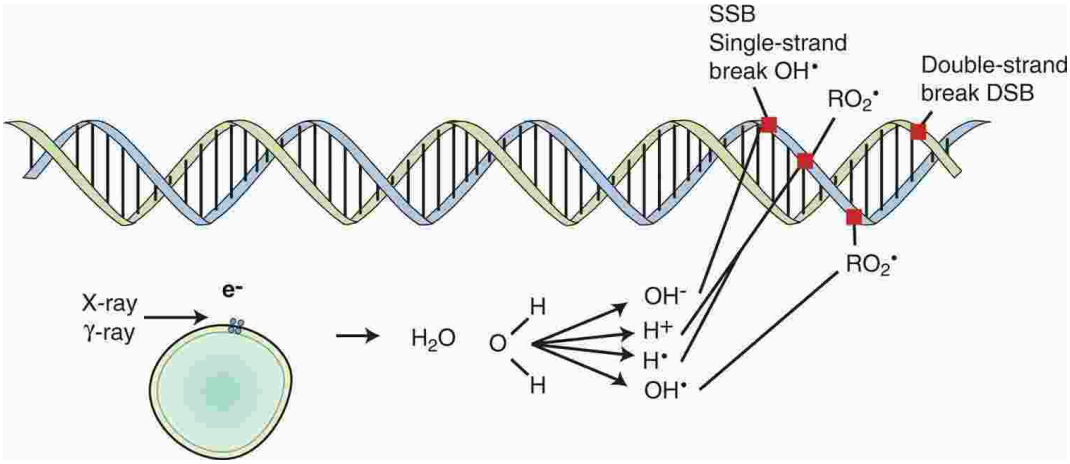

FIG. 13.16 Free Radicals.
Free radicals formed by water nearby and around DNA cause indirect effects. These free radicals have a short life as single free radicals. Oxygen can modify the reaction, enabling longer lifetimes of oxidative free radicals.

An illustration of a D N A helical structure has S S B single-strand break is caused by O H and R O 2 free radicals, and double-strand break is caused by D S B. X-ray and gamma-ray impact the electron, which converting water to free radicals: hydroxide and oxygen.

Although evidence suggests that interindividual differences in radiation responses may be attributed to certain genes and epigenetic conditions (see Chapter 6, Epigenetics and Disease), IR can activate oncogenes, resulting in uncontrolled cell growth (see Chapter 12). Several sensitive tumor-suppressor genes have been identified that are deactivated by IR and promote carcinogenesis after low doses of radiation. For example, IR has been shown to disrupt the p53 gene, which is the most commonly mutated gene in human cancers and is responsible for DNA repair and for inducing apoptosis in irreparably damaged cells (see Chapter 12). In women with breast cancer who have an inherited mutation in the p53 gene at one allele, treatment with radiation can induce mutations in the other p53 allele leading to enhanced carcinogenesis in cells that survive the treatment.[88] Gene expression can change as a function of radiation dose, timing, and type of exposure.[89]

Nontargeted Effects

Nontargeted effects (NTEs) occur in cells not directly traversed by a radiation particle but in the vicinity of a cell that has been exposed or has received signals (cell-to-cell communication) from irradiated cells. Contradicting a long-held assumption that direct exposures are required to produce aberrant responses, it is now understood that cells can participate in the final damage response even though they are not directly exposed. In addition, cells that are the progeny of irradiated cells may express a high level of gene mutations, cell lethality, and chromosomal aberration. These deleterious effects, stemming from previous generations of irradiated cells, constitute genomic instability that may contribute to secondary cancers and can lead to effects in nearby cells, termed bystander cells.[90]

Radiation-induced bystander effects (RIBEs) can occur in cells not directly exposed to IR and show heritable changes that include DNA damage, mutations, chromosomal aberrations, chromosomal instability, senescence, apoptosis, and oncogenic transformation.[91,92] Both DSBs and apoptotic cell death can be induced by bystander effects, supporting a signaling role between the irradiated cells (the targeted cells) and nonirradiated cells (the nontargeted or bystander cells) (Fig. 13.17). Emerging data indicate the importance of exosomes mediating microRNA transfer and the cellular communication between the directly irradiated cells and the nonirradiated cells (see Chapters 1,12 and Fig. 13.18).[93] Investigators reported that cell-free chromatin (cfCh) particles released from dying cells can integrate into genomes of surrounding healthy cells to induce DNA damage and inflammation.[94]

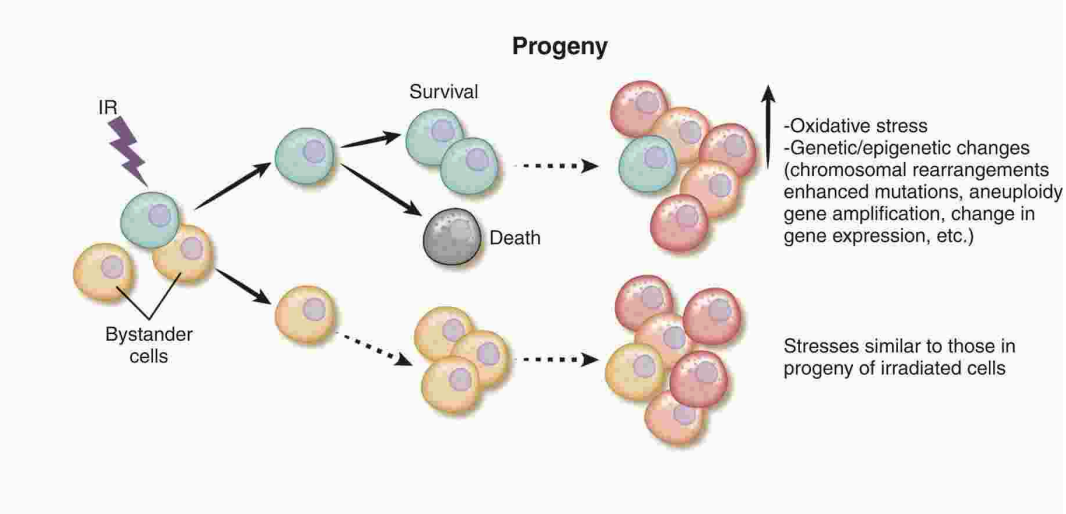

FIG. 13.17 Radiation: Targeted and Nontargeted or Bystander Effects.
Signaling from cells exposed to irradiation causes stressful effects, including oxidative stress, to those cells not directly irradiated (called *bystander cells*) and their progeny. These induced effects may be similar to those reported in the progeny of irradiated cells. (Adapted from Azzam EI, Jay-Gerin JP, Pain D. Ionizing radiation-induced metabolic oxidative stress and prolonged cell injury. *Cancer Letters*, 2012;327(1–2):48–60.)

An illustration shows the effect of radiation on targeted and nontargeted cells. Irradiation on a targeted cell results in the survival or death of the cell. In case of survival, the cell generates progenies, causing oxidative stress and genetic or epidemic changes (chromosomal rearrangements enhanced mutations, aneuploidy gene amplification, change in gene expression, etcetera). Irradiation on bystander cells leads to survival and progeny, causing stresses similar to those in progeny of irradiated cells.

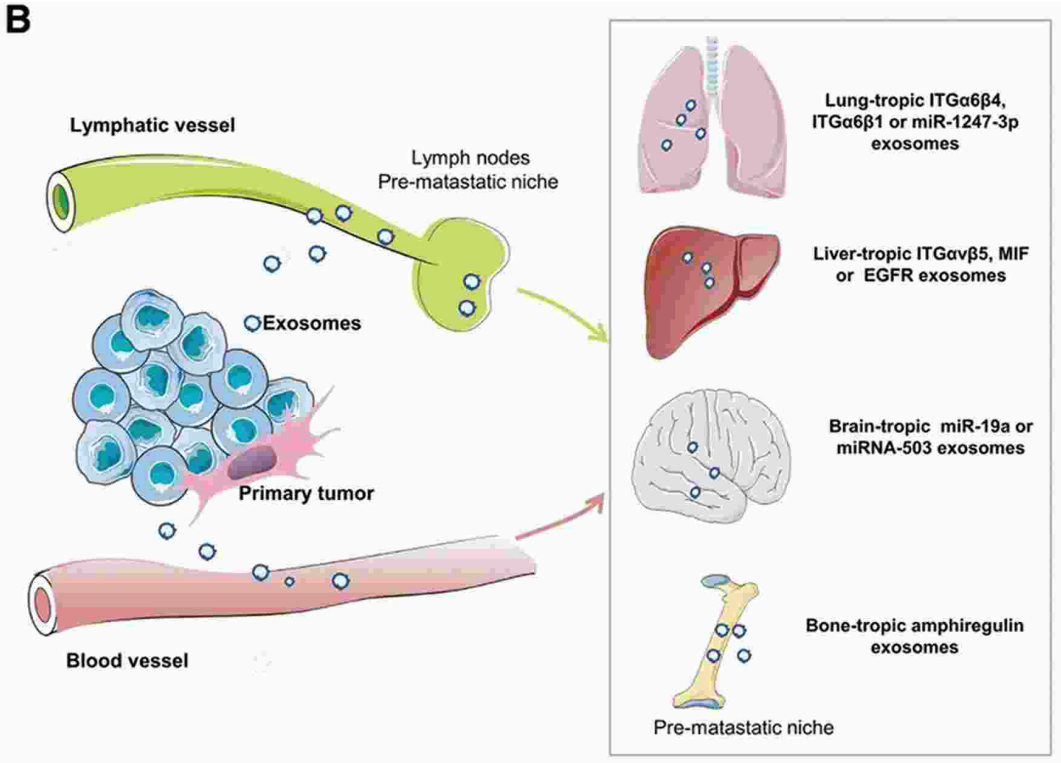

FIG. 13.18 Exosomes in Cancer.
(A) Exosomes are vesicles that carry cargo. Tumor-derived exosomes can be released into extracellular sites. These vesicles carry oncoproteins and nucleic acids that induce different signaling pathways and activation of different immune cells. This communication can promote a cancer-favorable inflammatory microenvironment that promotes metastatic initiation and progression. Tumor derived exosomes are involved in the epithelial-to-mesenchymal transition (EMT), angiogenesis, increase of vascular permeability, alteration of the immune system, transformation of recipient cells and reprogramming of energy metabolism. **(B)** Exosomes are involved in organotropic metastasis (see Chapter 12). (From Wu M, Wang G, Hu W, et al. Emerging roles and therapeutic value of exosomes in cancer metastasis. *Mol Cancer*. 2019;18[1]. https://doi.org/10.1186/s12943-019-0964-8.)

An illustration shows the effect of exosomes in cancer. Cells with a primary tumor release exosomes into the lymphatic vessel which travel to the lymph nodes. It's results in

following pre-metastatic niche. • Lungs. Lung-tropic I T G alpha 6 beta 4, I T G alpha 6 beta 1 or m i R-1247-3 p exosomes. • Liver. Liver-tropic I T G alpha v beta 5, M I F or E G F R exosomes. • Brain. Brain-tropic m i R-19 a or m i R N A-503 exosomes. • Bone. Bone-tropic amphiregulin exosomes.

Numerous intercellular and intracellular signaling pathways are implicated in the bystander response, and these effects have been shown to be transmitted to cell descendants. Importantly, exosome communication is being studied for the capacity to induce a favorable inflammatory microenvironment that promotes cancer cell metastasis.[95–97] In contrast, therapeutic interference with specific signaling pathways may result in genome stabilization and the generation of novel therapeutics.

These bystander effects, demonstrated in vivo, reflect an ongoing inflammatory response (oxidative stress response) to the initial radiation-induced injury (see Emerging Science Box: Paradigm Shift? Responses to Ionizing Radiation Mediated by Inflammatory Mechanisms).

Acute, Latent, and Microenvironmental Effects

IR causes both acute and persistent effects. Acute exposure to IR can cause damage to multiple organ systems, especially those with highly proliferative cells, such as the hematopoietic and reproductive systems, the skin, and the GI system. Investigators have postulated that radiation's carcinogenic potential persists as a direct result of nontargeted radiation effects, which are known to alter cell signaling and induce changes in the microenvironment. Investigators report the brain's innate immune system is especially vulnerable to cranial irradiation, especially at young ages when the skull is thin and neurons poorly myelinated. The radiation alters the microenvironment and induces the recruitment of macrophages, which infiltrate the region. With improvements in pediatric cancer survival, the long-term risks of a second cancer developing from radiation or chemotherapeutic treatments become increasingly important.

Radiation-induced cancer in humans has latent periods, usually 5 to 10 years, but latency for some radiation-related tumors can span decades. British investigators have reported that for solid tumors, except brain tumors, radiation-related excess risk begins to appear about 5 years after exposure in therapeutically irradiated groups. For leukemia, it appears within 5 years of

exposure.[98] Using US Surveillance Epidemiology and End Results (SEER) data, the estimated excess of secondary cancers that could be related to radiotherapy is about 8%.[99] Data from the United Kingdom, which included diagnostic procedures but excluded therapeutic irradiation, yielded an estimation of 15%.[98]

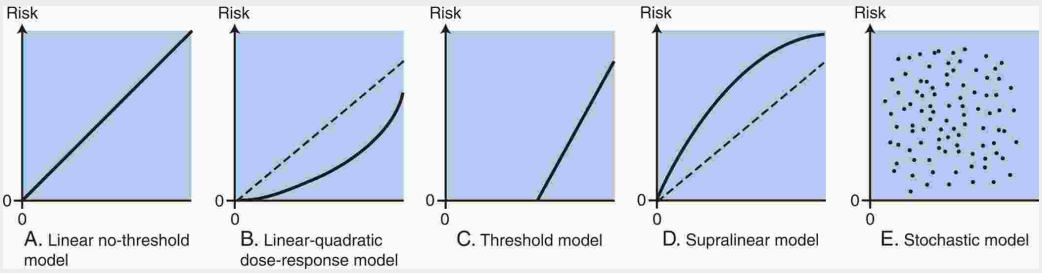
Low Dose and Dose Rate

Recent events, including the 2011 Fukushima and Chernobyl nuclear accidents, terrorist attacks, and exposure to radiation from medical procedures, have increased the need to identify risks from low-level IR exposures. Because reliable surveillance of large populations cannot easily be accomplished, simulation models also may provide reasonable approximations that employ theoretic models to estimate response curves (Box 13.4).

Box 13.4

Theoretical Models to Understand Low-Dose Radiation

Several models include the linear no-threshold (LNT) relationship, in which any dose, including very low doses, has the potential to cause mutations (see A). Another model, the linear-quadratic relationship, proposes there is a risk mathematical term that is directly proportional to the dose (linear term) and another term proportional to the square of the dose (quadratic term) (see B). The threshold model proposes a threshold dose below which radiation may not cause cancer in humans (see C). Proponents of this model argue that such thresholds are derived, for example, from the ability to repair damage caused by lower doses of radiation. There is some evidence that low doses may actually produce a higher level of risk per unit of dose, which is called the *supralinear hypothesis* (see D). E, Stochastic or random probability is a major model for understanding low-dose radiation. Currently, the shape of the response curve for the low-dose region is unknown.



Theoretic Models for Estimating Risk of Low-Dose Ionizing Radiation.
Collective population dose is expressed as a person-rem (roentgen equivalent, man). Estimating a collective dose then enables an application of a "constant risk factor" to obtain a statistical estimate of the number of additional cancers (above background radiation) from that exposure. These computations apply to low doses–low dose rates only (A). Many propose the best fit is the linear no-threshold (LNT) model (B). The most common alternative to the LNT model is the linear-quadratic model. The quadratic term is the square of the dose. The linear term is equal to zero (C). The threshold model is a threshold below which there is *no* increase in cancer risk. Proponents of this model argue that because some toxic chemicals/materials exhibit such thresholds, radiation must also have a threshold. Their arguments are related to repair of the radiation damage caused by lower doses of radiation (D). Some evidence exists that low levels of radiation produce a higher level of risk per unit dose, which is called the supralinear model. The stochastic model describes effects that are random, and the events cannot be predicted (E). (Adapted from Makhijani A, Smith B, Thorne MC. Science for the vulnerable: Setting radiation and multiple exposure environmental health standards to protect those at most risk. Takoma Park, MD: Institute for Energy and Environmental Research; 2006.)

Non-Ionizing Radiation and Electromagnetic Radiation

NIR includes electromagnetic radiation and differs from IR in the way it acts on materials like air, water, and living tissue. NIR includes the spectrum of ultraviolet (UV), visible light, infrared (IR), microwave (MW), radio frequency

(RF), and extremely low frequency (ELF) (Box 13.5). NIR is found in a wide range of occupational settings and can pose a health risk to potentially exposed workers if not adequately controlled.

Box 13.5

Terms Used for Non-Ionizing Radiation and Electromagnetic Radiation

Non-Ionizing Radiation=NIR
Electromagnetic Radiation=EMR(EM)
Radiofrequency Radiation=RFR (RF)
Radiofrequency Electromagnetic Radiation=RF-EMR
Ultraviolet=UV
Infrared Radiation=IR
Microwave=MW
Extremely low frequency=ELF

From Flores-McLaughlin J, Runnells J, Gaza, R. Overview of non-ionizing radiation safety operations on the International Space Station. *Journal of Space Safety Engineering*, 2017;4(2):6–63. doi:10.1016/j.jsse.2017.02.007. ISSN 2468-8967. http://www.sciencedirect.com/science/article/pii/S2468896717300204.

Electromagnetic radiation (EM or EMR) is produced by coupled electric and magnetic fields that propagate as waves through materials and air. Its frequency range is usually defined from radio waves (10 kHz and above, such as AM broadcasts), through microwaves (1 to 10 GHz) up to visible light, and beyond to diagnostic x-rays and even gamma rays originating in deep space (see Box 13.5). EMR originating in the UV part of the spectrum and above can interact with materials leading to the direct ionization of atoms and molecules. Health risks associated with the non-ionizing part of the spectrum (termed electromagnetic fields [EMFs]) have been a concern for many decades. The impact of EMR on human health or the physical environment has not been fully assessed. In addition, with competing priorities (convenience, financial interest, and health necessity) and the limited availability of independent research on the topic, a consensus on the risks and benefits of different types of EMR exposure may be difficult to achieve. Safety standards vary significantly among countries. The National Institute of Environmental Health Sciences Electric and Magnetic Fields Working Group

and the Environmental Protection Agency have recommended that low-frequency EMFs be classified as possible carcinogens.

Recent research has addressed low-intensity or low power fields and radiofrequency radiation (RFR, also termed *microwave radiation*) from devices such as phones, broadcast antennas, Wi-Fi, security monitors, baby monitors, wireless charging stations, routers, antennas, and others. Typically, these emissions are in the frequency range of 10^8 to 10^{10} Hz. Exposure to electric and magnetic fields is widespread. Electric fields are blocked by or weakened by walls and other objects, but magnetic fields are not. EMFs affect cardiac and neural functioning. The most common sources of radiofrequency electromagnetic radiation (RF-EMR) are wireless telecommunication devices and equipment, including cell phones, smart meters, and portable wireless devices (laptop computers and tablets). It is projected that 50 billion wireless radiating devices will be connected through the Internet of Things (IoT) in the next few years. Exposures to microwave or radiofrequency-radiation EMF associated with increased human brain cancers led to its classification as a possible cause of cancer by the IARC in 2011. Studies published since then have strengthened the evidence.[100] The most extensively studied public exposure to microwave radiation is from use of wireless telephones (mobile and cordless). Other exposures include occupational and military settings and sources from the general environment where few studies have been done. Recent studies from the National Toxicology Program (NTP) exposing rodents in their 2-year lifetimes to the same levels of RFR humans can receive in 70 years, resulted in what independent peer-reviewers deemed "clear evidence" of tumors in tissues surrounding the nerves in the hearts (schwannomas) of male rats, "some evidence" of glioma, "some evidence" of an association with tumors in the adrenal glands of male rats, hyperplasia, and DNA damage in multiple organs in rats and mice.[101,102] The report also noted statistically significant increases in tumors found in other organs at one or more of the exposure levels studied, including the brain, prostate gland, pituitary gland, adrenal gland, liver, and pancreas. Potential mechanisms underlying these findings included genotoxicity, effects on immune function, gene and protein expression, DNA repair mechanisms, cell signaling, oxidative stress, decreased melatonin, and apoptosis. Long-term exposure to elevated magnetic fields may lead to increased free radical concentrations, which are associated with aging, cancers, and neurodegenerative diseases. The NTP studies took more than 10 years to complete and are the most comprehensive assessment to date of health effects in animals exposed to RFR.

Children are now spending up to 9 hours a day with wireless radiating devices that are often held much closer to young bodies than manufacturers advise. The effects of exposure may be compounded because of increased vulnerability of young, rapidly growing cells to radiation and children's longer lifetime use of cell phones. In response to the NTP study discussed earlier, the American Academy of Pediatrics issued specific recommendations to reduce wireless cell phone exposure (Box 13.6). Chapter 14 discusses cancer in children. Low intensity NIR exposure in children can damage DNA, induce cancer, and impair reproductive health.[103] Senior investigators have noted that 13 epidemiological studies published since 2011 associate mobile phone use with increased tumors. Nine studies specifically report increased risk of brain cancer from mobile phone use, and four case-control studies report increased risk of vestibular nerve tumors from mobile phone use.[101]

Box 13.6

Cell Phone Radiation and Children's Health: What Parents Need to Know

Use text messaging when possible and use cell phones in speaker mode or with the use of hands-free kits.
When talking on the cell phone, try holding it an inch or more away from the head.
Make only short or essential calls on cell phones.
Avoid carrying your phone against the body, such as in a pocket, sock, or bra; cell phonemanufacturers cannot guarantee that the amount of radiation absorbed will be at a safe level.
Do not talk on the phone or text while driving; this increases the risk of automobile crashes.
Exercise caution when using a phone or texting while walking or performing other activities; "distracted walking" injuries also are on the rise.
If you plan to watch a movie on your device, download it first, then switch to airplane mode while watching it to avoid unnecessary radiation exposure.
Keep an eye on signal strength (i.e., how many bars); the weaker your cell signal, the harder the phone has to work and the more radiation it gives off; it is better to wait until there is a stronger signal before using the device.

Avoid making calls in cars, elevators, trains, and buses; the cell phone works harder to get a signal through metal, so the power level increases.

Remember that cell phones are not toys or teething items.

Data from *American Academy of Pediatrics*; June 13, 2016. Available at http://www.healthychildren.org.

As is evident from the atomic bomb survivors' studies, cancers that stem from environmental exposure to radiation can take four decades to be evident in the general population. With the unprecedented demand for computer-based schooling and pandemic-fueled increases in uses of all wireless radiating devices, the intensity and frequency of RFR exposures has changed exponentially in the past year alone. Controversies also are growing regarding the untested 5 G technology network and its potential to affect cancer by altering growth factors and the immune system, along with important environmental impacts on insects, trees, and animals. When considering the totality of the evidence at hand, current evidence is strong enough to go from precaution concerning possible risk to prevention of known risks. A concerted program of public and health professional education is needed to promote safer technology. Every attempt should be made to reduce exposure to RFR in schools, as well as homes.[101] Lingering controversies exist about how best to set standards for RFR. The Federal Communications Commission (FCC) relies on 24-year-old scientific evidence and insists that only thermal effects are to be avoided, dismissing findings from the NTP. Many authorities dispute this FCC determination noting that it relies heavily on the International Commission on Non-ionizing Radiation Protection (ICNIRP), a small, self-appointed, self-monitored group with no independent oversight. "In adopting ICNIRP positions of a group of 13 scientists, many of whom have close ties to industry, the agency ignores the fact that the majority, including several hundred experts in the fields of bioelectromagnetics and related matters, strongly dissent from the conclusions of ICNIRP."[104]

Ultraviolet Radiation

Ultraviolet (UV) radiation is produced naturally from sunlight and artificially from electric lights, black lights, and tanning lamps. UV radiation is divided into three major wavelengths: UVA, UVB, and UVC radiation. Most of the UV radiation received on earth is UVA; some is UVB. UVA radiation is weaker than UVB but penetrates more deeply into the skin and is more constant

throughout the year regardless of weather conditions. UVB primarily affects the outer layer of the skin. UVC radiation effects do not increase health risks as much as UVB radiation. UV radiation also can be important to health as it promotes the synthesis of di-hydroxy vitamin D metabolism in the liver, which is essential for the absorption of calcium and phosphorus from food for bone development. Skin color greatly influences natural metabolism. The WHO generally recommends 5 to 15 minutes of sun exposure two to three times a week, but darker skinned people may require more. Overexposure, however, can result in acute and chronic health effects, including melanoma and other forms of cancer of the skin and eyes, as well as impacts on the immune system.

There are three main types of skin cancer (see Chapter 46):

- Basal cell carcinoma (BCC): cancer in the lower part of the epidermis or outer layer of the skin
- Squamous cell carcinoma (SCC): cancer in the flat cells that form the surface of the skin
- Melanoma: cancer that forms in melanocytes (i.e., pigment cells)

In the United States, skin cancer is the most commonly diagnosed malignancy; however, the actual number of non-melanoma skin cancers is unknown because they are not reported to cancer registries. BCC commonly occurs on the head and neck. SCC typically occurs on sun-exposed areas of the skin, including the forehead, nose, ears, lower lip, and dorsa of the hand. The incidence of BCC and SCC is strongly correlated with lifetime sunlight exposure (i.e., photocarcinogenesis). Specific patterns of sunlight exposure, intermittent or chronic, confer different host effects. Intense intermittent recreational sun exposure has been associated with melanoma and BCC. Chronic occupational sun exposure has been associated with SCC. Tanning bed exposure is associated with an increased risk of all forms of skin cancer, with higher risks when exposure took place at younger ages.[105] Other skin cancer risk factors include IR, use of photosensitive medications (e.g. tetracycline, thiazide diuretics, and retinoids), immunosuppression, and genetic factors.[106] In general, skin cancers have a higher incidence among people with a light or fair skin tone, but they can occur in anyone, including those who do not usually burn from exposure to sunlight. The pathogenesis of non-melanoma skin cancers involves specific gene mutations, epigenetic alterations, oxidative stress, inflammation, and reduced immune surveillance (see Chapter 46 for a more complete discussion of skin cancers).[106]

In 2021, the estimated number of new cases of melanoma of the skin will be 106,110 with an estimated 7180 deaths.[107] Melanoma can occur at many sites, many of which are not usually exposed to sunlight. *Intermittent acute* sun exposure causing sunburn early in life is associated with an increased risk of melanoma. Germline mutations have been identified in melanoma cells, as well as numerous somatic mutations that include several different types of oncogenes and tumor suppressor genes (see Chapter 12).[108] Low levels of melanin in white skin result in significant vulnerability to UV-mediated genetic alterations and a higher risk of melanoma formation, especially in persons with fair, freckled skin or immune deficiencies.[109] Although rare in people with dark skin, melanoma may be found under the fingernails or toenails or on the palms of the hands and soles of the feet.

The US Preventive Services Task Force (USPSTF) concludes that the current evidence is insufficient to justify screening for early detection of skin cancer. Moreover, the risks of overdiagnosis and overtreatment appear considerable relative to the benefits of annual visual skin examination by a clinician to screen for skin cancer in asymptomatic adults.[110] White men and women are more likely to die of melanoma than any other group. Risk factors vary for different types of skin cancer. Box 13.7 identifies the main risk factors for skin cancers.

Box 13.7

Common Risk Factors for Skin Cancers

Lighter natural skin color
Family history of skin cancer
A personal history of skin cancer
Exposure to sun through work and play
History of sunburns, especially early in life
History of indoor tanning
Skin that burns, reddens easily, or becomes painful in the sun
Freckles
Blue or green eyes
Blonde or red hair
Certain types of moles and a large number of moles

Higher coffee intake was associated with a modest decrease in melanoma (large cohort study)

Infection, Sexual and Reproductive Behavior

Infections with certain viruses, bacteria, and parasites are important contributors to or co-factors for cancer worldwide. The number of cases varies widely by region, with less developed areas having three times more infection-related cancers than more developed countries.[111] Among the more notable infections contributing to new cancer cases are *Helicobacter pylori (H. pylori)*, human papillomavirus (HPV), hepatitis B virus (HBV), hepatitis C virus (HCV), and Epstein–Barr virus (EBV). *H. pylori* contributes to about 75% of stomach cancers. HPV, HBV, and HCV infect the liver and together account for the preponderance of liver cancer cases (see Chapter 41). EBV is linked to nasopharyngeal carcinoma, Hodgkin lymphoma, diffuse large B-cell lymphoma (DLBCL), Burkitt lymphoma, EBV-associated malignant B-cell lymphoma, other lymphomas, and gastric adenocarcinoma.

HPV is the most common sexually transmitted virus in the United States and accounts for more than half of the total infection-attributable cancers in women worldwide. When detected through regular screening at an early stage, cervical cancer is treatable and curable. However, many national screening programs fail to reach poor women; sex-workers; black, brown, and native Americans; and those who are marginalized in society.[112]

Many sexually active women and men will be infected with HPV at some point in their lifetime, and some repeatedly. Although the main mode of HPV transmission is sexual contact, HPV can be contracted through contact with contaminated fomites, fingers, and mouth, as well as vertical transfer to infants at birth.[113] HPVs are a group of more than 200 related viruses, and at least 13 are cancer causing. *Low-risk HPVs* are not associated with cancer but can cause skin warts, called *condylomata acuminata*. *High-risk*, or oncogenic. HPV types 16 and 18 are responsible for most cancers. Most high-risk HPV infections cause cytologic abnormalities or abnormal cell changes that regress spontaneously. According to the National Cancer Institute, most HPV infections will be suppressed by an individual's immune system.[114] Persistence of infection with high-risk HPV is a precursor to the development of cervical intraepithelial neoplasia (CIN) (see Chapter 25), lesions, and invasive cervical cancers. HPV infection also has been identified as a definite carcinogen for several other types of cancer: penis, vulvar, vaginal, anal, and some oropharyngeal cancers (OPCs). Half of the OPCs most commonly linked to HPV-16 include the base of the tongue, tonsils, and pharynx. The incidence

of HPV-associated OPC has increased during the past 20 years, especially among men, and may reflect persistent chronic inflammation. Co-factors that may increase the risk of developing cancer following a high-risk HPV infection include alcohol, smoking, decreased immunity, having many children (cervical cancer), long-term oral contraceptive use (cervical cancer), poor oral hygiene (OPC), and chronic inflammation.

Current guidelines recommend that sexually active women should have a Pap test every 3 years beginning at age 21 to 29. Women 30 to 65 years of age may receive Pap testing with HPV screening every 5 years (preferred) or Pap testing alone every 3 years. After age 65, Pap testing and HPV screening are no longer recommended for women with previous normal testing results since the risk of new malignancy is low. Women who had a hysterectomy with removal of the uterine cervix for a noncancerous condition also do not need Pap smears or HPV testing the rest of their lives. Currently, although the HPV vaccine does reduce the risk for cervical cancer, it does not change the frequency or need for Pap and HPV testing (see Chapters 25 and 27).

Other Viruses and Microorganisms

The relationship between viruses, bacteria, and cancer is discussed in Chapter 12. Human herpesvirus type 8 is linked to Kaposi sarcoma, and human T-cell lymphotropic virus type 1 is linked to leukemia and lymphoma. Other microorganisms involved in carcinogenesis include parasites such as *Opisthorchis viverrini* (bile duct cancer) and *Schistosoma haematobium* (bladder cancer). Their specific roles in carcinogenesis are thought to be related to functioning as cofactors or as direct carcinogens, or both.

Environmental and Occupational Hazards as Carcinogens

According to the Center for Disease Control Agency for Toxic Substances and Disease Registry, there are tens of thousands of synthetic chemicals that are widely used in the United States, of which only a fraction have been tested for their health effects.[115] Despite the 1976 US Toxic Substances Control Act and the 2016 Frank R. Lautenberg Chemical Safety for the 21st Century Act, widespread and low-level exposure to multiple toxic chemicals occurs every day in air, soil, food, water, household products, toys, personal care products, workplaces, and homes. Several hundred chemicals have been found to be carcinogens in controlled studies of experimental animals. According to IARC and the NTP, experimental chemical carcinogens should be regarded as

potentially carcinogenic in humans. Table 13.1 provides a summary of a limited number of chemicals for which IARC judges there to be sufficient or limited evidence in humans by cancer site. A simplified overview of the Occupational Safety and Health Administration (OSHA) listing of carcinogenic factors is presented in Table 13.6.

Table 13.6

Overview of Occupational Safety and Health Administration-Relevant Carcinogenic Factors

Group	Example
Chemicals	
Gases	Vinyl chloride Formaldehyde
Liquids, volatile	Trichloroethylene Tetrachloroethylene Methylchloride Styrene Benzene Xylene
Liquids, nonvolatile	Metalworking fluids Mineral oils Hair dyes
Solids, dust	Silica Wood dust Talc containing asbestiform fibers
Solids, fibers	

Group	Example
	Asbestos Man-made mineral fibers, for example, ceramic fibers
Solids	Lead Nickel compounds Chromium VI compounds Arsenic Beryllium Cadmium Carbon black Bitumen
Fumes, smoke	Welding fumes Diesel emissions Coal tar fumes Bitumen fumes Fire, combustion emissions PAHs Tobacco smoke
Mixtures	Solvents
Pesticides	

Group	Example
Halogenated organic compounds	DDT Ethylene dibromide
Others	Amitrole
Pharmaceuticals	
Antineoplastic drugs	MOPP (Mustargen, oncovin, procarbazine, and prednisone, a combination chemotherapy regimen used to treat Hodgkin disease) and other combined chemotherapies, including alkylating agents
Anesthetics	There is evidence from in vitro experiments that isoflurane increases cancer cells' potential to grow and migrate
Emerging Factors	
Air pollution and fine particulate matter	Emissions from motor vehicles, industrial processes, power generation, and other sources polluting the ambient air
Endocrine-disrupting compounds	Certain pesticides Certain flame retardants
Biologic Factors	
Bacteria	*Helicobacter pylori*
Viruses	Hepatitis B Hepatitis C
Mycotoxin-producing fungi	Bulk handling of agricultural foodstuffs (nuts, grain, maize, coffee), animal-feed production, brewing/malting, waste management,

Group	Example
	composting, food production, working with indoor molds, horticulture
Aspergillus flavus, A. parasiticus	Aflatoxin (A1)
Penicillium griseofulvum	Griseofulvin (IARC group 2B)
A. ochraceus, A. carbonarius, P. verrucosum	Ochratoxin A (group 2B)
A. versicolor, Emericella nidulans, Chaetomium spp., A. flavus, A. parasiticus	Sterigmatocystin (group 2B)
Fusarium spp.	Fumonisin B1 (group 2B)
Physical Factors	
Ionizing radiation	Radon X-rays
Ultraviolet radiation (UVR)	Solar radiation Artificial UVR
Ergonomics	Sedentary work
Other	
Work organization	Shift work that involves circadian disruptionStatic workProlonged sitting and standing
Lifestyle factors	Stress-related obesity, smoking, drinking, drug consumption
Combinations of Various Factors	

Group	Example
Chemicals and radiation	Methoxsalen and UVA radiation Some chemicals, called *promoters*, can increase the cancer-causing ability of UVR. Conversely, UVR can act as a promoter and increase the cancer-causing ability of some chemicals, particularly coal tar and pitch.
Work organization and chemicals	Shift work and solvents

DDT, Dichlorodiphenyltrichloroethane; *IARC*, International Agency for Research on Cancer; *PSHs*, polycyclic aromatic hydrocarbons; *UVA*, ultraviolet A.

Data from European Agency for Safety and Health at Work. *Exposure to Carcinogens and Work-related Cancer: A Review of Assessment Methods European Risk Observatory Report*. Luxembourg: European Agency for Safety and Health at Work Eu-OSHA. http://europa.eu.OSHA, Occupational Safety and Health Administration.

Chemical carcinogenesis can arise from genotoxic and nongenotoxic or epigenetic mechanisms (Fig. 13.19). Genotoxic mechanisms create genetic damage directly and nongenotoxic mechanisms (inflammation, immunosuppression, ROS, receptor activation, epigenetic silencing) alter signal transduction and the reduce the potential for repair of damage.

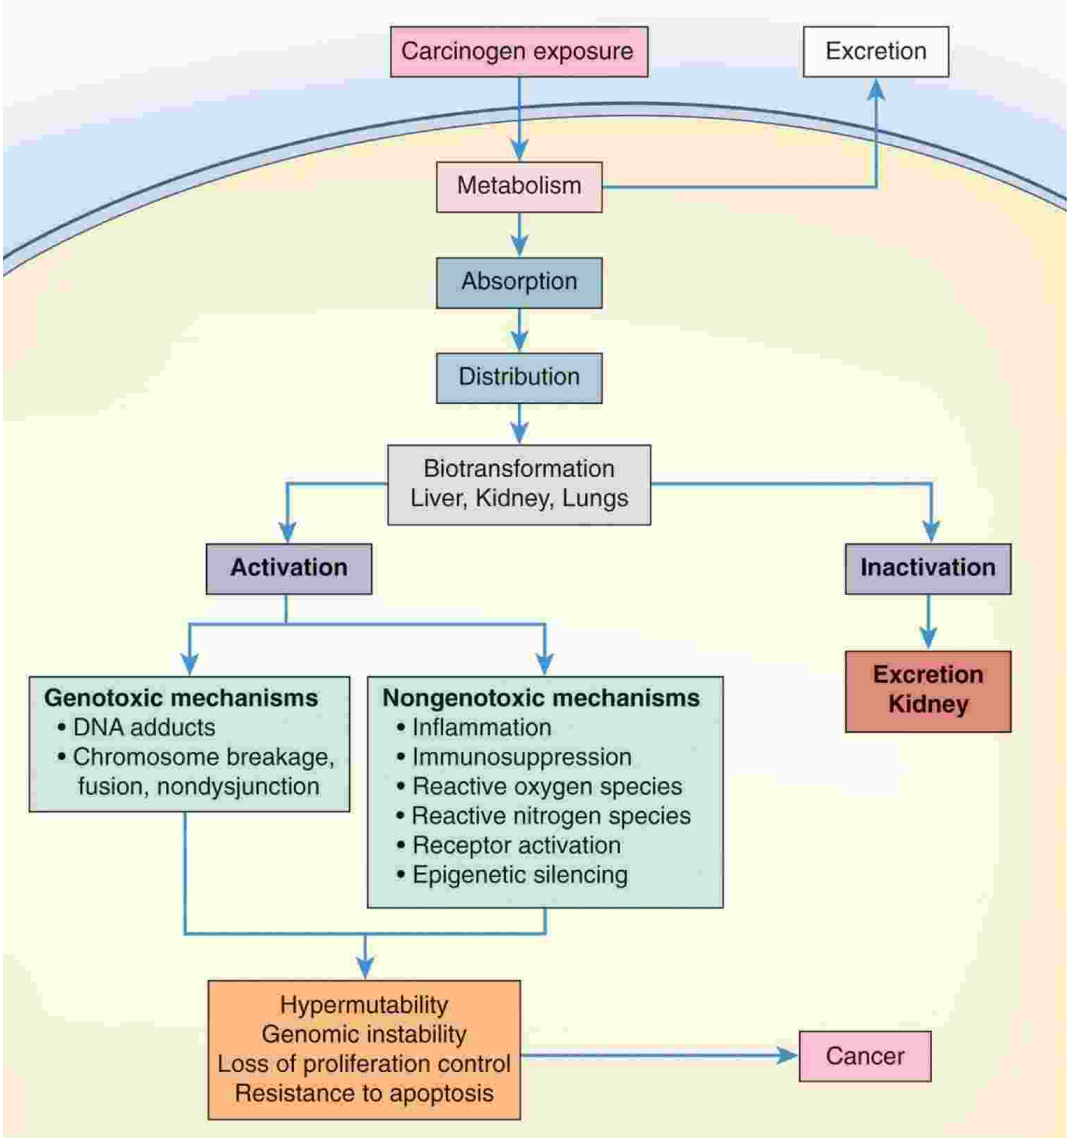

FIG. 13.19 Mechanisms of Chemical Carcinogenesis. Cellular internalization of chemical carcinogens results in metabolic products that are either excreted or retained by the cell. Within the cell, carcinogens or their metabolic products can directly or indirectly affect the regulation and expression of genes involved in cell cycle control, DNA repair, cell differentiation, or apoptosis. Some chemical carcinogens act by *genotoxic* mechanisms, such as DNA adducts, chromosomal breakage, fusion, deletion, missegregation, and nondisjunction. Other carcinogens act by *nongenotoxic* mechanisms, such as induction of inflammation, immunosuppression, formation of reactive oxygen species (oxidative stress), activation of receptors,

and epigenetic mechanisms, such as silencing. Both genotoxic and nongenotoxic mechanisms can alter signal transduction pathways that result in many features of cancer cells (Adapted from Luch A. Nature and nurture–Lessons from chemical carcinogenesis. *Nature Reviews: Cancer*, 2005;5(2):113–125.)

A flowchart shows the mechanisms of chemical carcinogenesis. • Carcinogen exposure. • Metabolism (can also lead to excretion). • Absorption. • Distribution. • Biotransformation: liver, kidney, and lungs. Inactivation of biotransformation leads to excretion from the kidney. Activation of biotransformation leads to the following: • Genotoxic mechanisms: D N A adducts; chromosome breakage, fusion, nondysfunction. • Nongenotoxic mechanisms: inflammation, immunosuppression, reactive oxygen species, reactive nitrogen species, receptor activation, and epigenetic silencing. Both genotoxic and nongenotoxic mechanisms lead to cancer as a result of the following: • Hypermutability. • Genomic instability. • Loss of proliferation control. • Resistance to apoptosis.

A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors; however, the contributing role of smoking is often not easily evaluated in studies of workplace cancer. Millions of US workers, and even more of those in rapidly developing regions that lack regulatory controls, are regularly exposed to substances tested as carcinogens in animal studies. It has been estimated that 4% of all cancer deaths and 12.5% of all lung cancer deaths are caused by workplace exposures to carcinogens.[116] Some groups of workers are especially vulnerable and face much higher risks, such as those working with aromatic hydrocarbons, butadiene, and some pesticides. For close to a century, it has been known that textile industry workers can be continuously exposed to different kinds of carcinogenic chemicals (dyes, solvents, fiber dusts, others) and face greater cancer risks as a result.[117]

One notable occupational cause of cancer is asbestos, a heat-resistant, fibrous silicate mineral found in cementitious products, plaster, flooring, house siding, or woven into fabrics and fire-resistant and insulating materials, such as brake linings and vehicle components such as clutches. Asbestos increases the risk of mesothelioma and lung cancer (see Chapter 35), and is implicated in ovarian and other cancers as well (see Chapter 35). Noncancerous disorders related to asbestos exposures include pleural plaques, diffuse pleural thickening, and pulmonary fibrosis. These asbestos-related disorders (ARDs) represent a significant occupational and public health concern. In Western Europe, because of the long latency of disease onset, the epidemic of mesothelioma in building workers born after 1940 did not become apparent until the 1990s. Building materials containing asbestos have been banned in most developed countries, but such materials are still used in many developing countries, where the incidence of cases of ARDs is rising. No exposure to asbestos is without risk.

For nearly a century, carcinoma of the bladder has been linked with the manufacture of dyes, rubber, paint, and aromatic amines, especially β-naphthylamine and benzidine. Benzene inhalation is linked to leukemia in shoemakers and in workers employed in the rubber cement, explosives, and dye-manufacture industries. Other notable occupational hazards include heavy metals (high-nickel alloy, chromium VI compounds, inorganic arsenic), silica, PAHs, sulfuric acid, and chloromethyl ether. Disentangling data related to lung cancer, air pollution, and occupational risks is challenging, especially in combination with risk factors, such as active and passive smoking, other environmental factors, and genetic polymorphisms at multiple loci.

Summary Review

Genetics, Epigenetics, and Tissue

1. Cancer arises from a complicated and interacting web of multiple etiologies, with fewer than 10% of all cases stemming from inherited germline factors. All cancer develops when the healthy genes with which we are born lose their ability to enhance DNA repair, direct proteins to induce cell death at appropriate times, or promote beneficial cell signaling. Avoiding high-risk behaviors and exposure to carcinogens can prevent many types of cancers.
2. Risk factors for cancer include lifestyle behaviors (smoking, alcohol intake, diet), lack of physical exercise and obesity, certain infections, environmental factors (exposure to sunlight, ionizing or non-ionizing

radiation as well as drinking water contaminants), occupational exposure to carcinogens, and certain medications or common contaminants in pharmaceuticals that can turn on malignant processes through chromosome rearrangements or other processes.

3. Cancers are caused by interactions between environmental-lifestyle factors and inherited or acquired genetic/epigenetic factors. Contributing factors include weaker immune systems, variations in detoxifying enzymes or DNA repair genes, differences in hormone levels, and metabolic factors such as disordered glucose and lipid metabolism.
4. Cancer-causing factors are influenced by the surrounding microenvironment or stroma. Once malignant phenotypes have developed, complex interactions occur between the tumor, the surrounding stroma, and cells of the immune and inflammatory systems.
5. Globally, cancer is reported to remain a major cause of morbidity and mortality in the coming decades in both developed and developing regions.
6. For the first time, female breast cancer has surpassed lung cancer as the most commonly diagnosed cancer in the world, primarily because of increases in low- and middle-income countries. Lung cancer is the most commonly diagnosed cancer in men, and for both sexes it is the leading cause of cancer death in the world. Prostate cancer is the second most common cancer in men. Other common cancers worldwide arise from the gastrointestinal tract including colorectum, stomach, and liver cancers. Despite these increases in incidence, overall US cancer death rates have decreased 31% since 1991, especially due to a decline in lung cancer deaths. The rate of decline in cancer-rated mortality has slowed for prostate, breast, and colorectal cancer since 2018.
7. Increased Generational Risk (GR) is evident in trends in cancer not related to smoking or diagnostic ascertainment, with persons born after 1940 experiencing up to twice as much cancer as those born earlier. Explanations for increases in specific subtypes of non-smoking related cancer need to be sought.
8. Race, ethnicity, and social class are major determinants of the risk of developing and dying of cancer around the world, reflecting largely socioeconomic factors that affect access to care, good nutrition, workplace, and environmental exposures.

In Utero and Early Life Conditions

1. Emerging data suggest prenatal and early life events influence later susceptibility to cancer and other chronic diseases.
2. Developmental plasticity is the degree to which an organism's development is contingent on its environment. Plasticity refers to the ability of genes to organize physiologically or structurally in response to environmental conditions during fetal development.
3. The developmental origins hypothesis suggests that nutrition and other environmental factors affect cellular pathways during gestation, enabling a single genotype to affect a broad range of adult phenotypes. Maternal nutrition, as well as environment factors, are proposed as significant biological influences.
4. Undernutrition in utero is linked to increased heart disease, metabolic disorders, and possibly breast cancer decades later. Deficiencies that occur in the first trimester are far more influential than those that take place in the last trimester in affecting disease outcome in adulthood.

Environmental-Lifestyle Factors

Tobacco Use

1. Cigarette smoking is carcinogenic and the most important known avoidable cause of cancer that is controlled by individual behaviors. Tobacco smoking causes cancer in more than 15 organ sites, and exposure to secondhand smoke and parental smoking causes cancer in children and in other nonsmokers. The risk is greatest in those who begin to smoke when young and continue throughout life. Smoking is, however, a pandemic affecting all ages.
2. Worldwide, tobacco use causes more than 7 million deaths per year.
3. Environmental tobacco smoke (i.e., secondhand smoke) is a cause of stroke; increases the risk of death in people with cancer and cancer survivors as well as those with macular degeneration, tuberculosis, ectopic pregnancy, and diabetes mellitus. Secondhand smoke exposure increases inflammation, impairs immunity, and is a cause of rheumatoid arthritis.
4. Smoking tobacco is linked to cancers of the lung, upper aerodigestive tract, stomach, lower urinary tract, kidney, pancreas, cervix, uterus, and myeloid leukemia. Recently added to the list of smoking-related cancers are liver and colorectal cancer. Smoking causes even more

deaths from respiratory, vascular, and other diseases than from cancer.

5. Cigar or pipe smoking is related to cancers of the oral cavity, oropharynx, hypopharynx, larynx, esophagus, and lung. Pipe smokers have an increased risk of cancers of lung, lip, throat, esophagus, larynx, pancreas, and colon and rectum.
6. Electronic cigarettes can contain harmful, highly-addictive, and potentially cancer-causing substances and have been extensively marketed to young teens and are targeted by public health authorities as potential gateways to tobacco smoking.

Diet

1. The influence of diet on cancer development is complicated. Cancer risks in older adults may depend as much or more on diet in early life as on current eating practices.
2. Nutrigenomics is the study of the effects of nutrition on the phenotypic variability of individuals based on genomic differences.
3. Nutrition, obesity, alcohol consumption, and physical activity all influence risks for cancer development and can interact synergistically.
4. As a tool for preventive medicine aimed at reducing disease, dietary recommendations, such as the Mediterranean diet, are becoming more widespread.
5. The importance of diet has been illustrated by data showing changes in cancer risk among migrants that move from countries with low-cancer risk to those with high-cancer risk countries. With geographic migration, particularly with the adoption of the Western diet, cancer risks approximate those of the new region within a generation.
6. Bioactive components have a profound effect on differentiation, potentially including differentiation of cancer stem cells. Intake of a broad range of specific food compounds may suppress cancer stem renewal.
7. A variety of food compounds may serve as antioxidants and influence cell signaling and DNA repair.
8. Xenobiotics can be toxic, mutagenic, and carcinogenic chemicals that humans are constantly exposed to. The body has several immunological systems for counteracting these effects, including enhanced production of Natural Killer cells and other anticarcinogens. Many foods enhance the efficiency and degree of detoxification of

xenobiotics and thus serve a protective role in metabolizing carcinogens.

9. Diets high in red meat or processed meat may lead to increased risks of colorectal cancer. Meats containing nitrites, nitrates, or other preservatives can leave residues in the colon that cause DNA damage.
10. Obesity is an epidemic in both developed and developing countries. Obesity is a form of poor nutrition or overnutrition, that impacts energy balance, cancer risk, cancer recurrence, and survival.
11. Obesity is a risk factor for 13 cancers: liver, advanced prostate, ovarian, gallbladder, kidney, colorectal, esophageal, breast (postmenopausal), pancreatic, endometrial, meningioma, multiple myeloma, and stomach.
12. Understanding the mechanisms of obesity-associated cancer risks is evolving and varies by type of tumor and distribution of body fat. Emerging data point to three main factors: (1) insulin-insulin-like growth factor (IGF-1) axis, (2) sex hormones, and (3) adipokines.
13. Metabolic changes in adipose tissue from obesity result in several alterations and include insulin resistance, hyperglycemia, dyslipidemia, hypoxia, and chronic inflammation. Tumor growth is regulated by interactions between tumor cells and their tissue microenvironment, so stromal compartments that are rich in adipose tissue can promote the development of tumor cells.
14. Alcohol is classified as a human carcinogen. Strong data link alcohol with cancers of the mouth, pharynx, larynx, esophagus, liver, colorectum, and breast.
15. Evidence does not show any safe limit of alcohol and the health effects are from ethanol regardless of the type of drink.
16. Alcohol-related carcinogenesis involves acetaldehyde, reactive oxygen species (ROS), pro-carcinogen activation, cellular regeneration, nutritional deficiencies, and enzyme and metabolic dysfunction.
17. Physical activity, independent of weight changes, reduces the risk for breast cancer, colon cancer (in men), and endometrial cancer.
18. Biologic mechanisms for the protective effects of physical activity include decreasing insulin and IGF levels, decreasing obesity, increasing free radical scavenger systems, altering inflammatory mediators, decreasing levels of circulating unbound sex hormones and metabolic hormones, improving immune function, decreasing oncogenes, enhancing cytochrome P-450 activity (thus modifying carcinogen activation), increasing gut motility, and increasing release

of myokines (proteins from contracting muscles with antitumor effects).

19. Many unanswered questions remain regarding frequency of exercise, intensity, and duration.
20. Recent data encourage 150 minutes of moderate-intensity aerobic or 75 minutes of vigorous-intensity aerobic physical activity each week for adults. Children and adolescents should get at least 60 minutes of physical activity daily.

Air Pollution

1. Air pollution, indoor and outdoor, is the leading environmental cause of death worldwide. Long-term exposure to air pollution increases mortality and morbidity and shortens life expectancy from cardiovascular, respiratory disease, and lung cancer.
2. There is a significant association between increased rates of lung cancer and exposure to particulate matter, a mixture of small particles and liquid droplets. Primary particles are emitted directly from a source, for example, construction sites, unpaved roads, fields, or smokestacks. Secondary particles are emitted from power plants, industries, and automobiles.
3. Diesel exhaust is carcinogenic and causes lung cancer. Acute exposure to diesel exhaust that contains particles is linked to lung, throat, and eye irritations; asthma attacks; and myocardial ischemia.
4. The mechanisms of adverse effects of particulate matter include (1) oxidative stress, (2) ROS generation, (3) DNA oxidative damage, (4) mutagenicity, (5) stimulation of proinflammatory factors, and (6) induction of senescence.
5. Fine particle pollution also is linked to (1) premature death in people with heart or lung disease, (2) nonfatal heart attacks, (3) irregular heartbeat, (4) aggravated asthma, (5) decreased lung function, and (6) respiratory symptoms.
6. Indoor air pollution is generally considered worse than outdoor pollution. Sources of indoor air pollution include tobacco smoke, heating and cooking combustion sources, radon, and coal use.

Ionizing Radiation

1. Much of the knowledge of the effects of ionizing radiation on human cancer has come from Hiroshima and Nagasaki atomic bomb

exposures, particularly the Life Span Study. Other evidence is from exposure to radiation for medical reasons, underground miners, and other occupational exposures. Human exposure includes emissions from the environment, x-rays, CT scans, radioisotopes, and other radioactive sources.

2. Atomic bomb exposures in Japan caused acute leukemias and increased frequencies of thyroid, breast, lung, stomach, colon, esophageal, and brain, urinary tract cancers and multiple myeloma.
3. Excess relative risks (ERRs) for radiation-induced cancers at a given age are much higher for individuals exposed during childhood or over age 40.
4. The bimodal age distribution of radiation-induced cancer risk means that radiation exposure in early ages is related to initiation of cancer processes, whereas exposure in later ages is associated with promotion of pre-existing premalignant cells.
5. Other health risks from radiation include cardiovascular and neurodegenerative effects and somatic mutations that may contribute to other diseases. These effects may manifest years after radiation exposure.
6. There is concern about the increased IR exposure from medical procedures, particularly CT scans.
7. IR is a potent mutagen and carcinogen; it can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations.
8. IR affects DNA by causing cross-linking, nucleotide base damage, and single- and double-strand DNA breaks. Disrupted cellular regulation processes can lead to carcinogenesis. The double-strand break is considered the hallmark lesion associated with IR.
9. It is now known that radiation may induce genomic instability to the progeny of the directly irradiated cells over many generations of cell divisions and can affect so-called bystander cells. Investigators are studying genomic instability as it may contribute to secondary cancers.
10. The risks from low-dose radiation are difficult to calculate because they require monitoring of large populations, and this is not regularly done.

Ultraviolet Radiation

1. Ultraviolet (UV) radiation comes from sunlight, electric lights, black lights, and tanning lamps. Most of the UV radiation received on earth

is UVA and some UVB. UVA radiation is weaker than UVB, but UVA penetrates more deeply into the skin and is more constant throughout the year despite the weather.
2. The incidence of basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) is strongly correlated with lifetime sunlight exposure. Intense intermittent recreational sun exposure has been associated with melanoma and BCC. Chronic occupational sun exposure has been associated with SCC. Tanning bed use has been associated with an increased risk of BCC, especially in women.
3. Skin cancer risk factors include cumulative sun exposure (the additive effects of intermittent sun exposure, chronic sun exposure, or both), ionizing radiation, chronic arsenic ingestion and other chemical exposures, immunosuppression, and genetic factors.
4. The pathogenesis of nonmelanoma skin cancers involves specific gene mutations, epigenetic alterations, oxidative stress, inflammation, and reduced immune surveillance.

Electromagnetic Radiation

1. EMR occurs in the form of magnetic and electric fields, and varies with power, frequency, polarity, information content, wave form, and other variables. Exposures are widespread and growing exponentially in recent years, especially for toddlers and young children who must rely on wireless devices for education during the pandemic. Wireless telecommunication devices (e.g., cell phones, wireless laptops, smart meters) are the most common sources of radiofrequency electromagnetic radiation (RF-EMR).
2. Competing priorities (convenience, financial interest, and health necessity) may make a consensus on the risk/benefit ratio of EMR difficult to achieve.
3. Low-frequency electromagnetic fields (EMFs) and higher-frequency EMFs (from cellphones and other wireless transmitting devices) have been classified as possible carcinogens by several expert groups, including the EPA, and the IARC of the WHO in 2011. More recently, experimental and epidemiological evidence amassed in the past decade reveal that EMF/RF constitutes a known cause of cancer in humans.
4. Importantly, exposures from numerous wireless transmitting devices have expanded dramatically, especially for children.

5. Children are a main concern since the effects of exposure may be compounded because of their increased vulnerability to both IR and NIR/EMF radiation, their immature immune systems, thinner skulls, and immature nervous systems and their longer use of cell phones and other wireless transmitting devices throughout their lifetimes.
6. Exposures from the proposed 5 G system are poorly understood but involve beam-forming from closely placed antennas that will also send and receive 3 G and 4 G frequencies to connect billions of existing devices; the millions of new antennas that are needed for this system have not been adequately evaluated for impacts on public health or the environment according to the US Government Accountability Office, 2020, and the European Union, 2020.

Infection, Sexual and Reproductive Behavior

1. Infection with certain viruses, bacteria, and parasites are an important contributor to cancer worldwide. The most notable infections implicated in new cancer cases include Epstein-Barr virus (EBV), *Helicobacter pylori*, hepatitis B and C viruses (HBV and HCV), and human papillomavirus (HPV).
2. *H. pylori* is the cause of about 75% of stomach cancers. EBV is linked to nasopharyngeal carcinoma, Hodgkin lymphoma, diffuse large B-cell lymphoma, Burkitt lymphoma, EBV-associated malignant B-cell lymphoma, other lymphomas, and gastric adenocarcinoma. HBV and HCV infect the liver and together account for the large majority of liver cancer cases.
3. HPV is the most common sexually transmitted virus in the United States and accounts for more than half of the total infection-attributable cancers in women worldwide. HPV types 16 and 18 are responsible for the majority of cancers. Persistence of infection with high-risk HPV is a prerequisite for the development of cervical intraepithelial neoplasia, lesions, and invasive cancer.
4. HPV infection has been identified as a definite carcinogen for several types of cancer: cervical, penis, vulvar, vaginal, anal, and some oropharyngeal (including the base of the tongue, tonsils, and pharynx).
5. The incidence of HPV-associated oropharyngeal cancer has increased during the past 20 years, especially among men.
6. Biologic factors that may interact with HPV infection to increase cancer risk include smoking, decreased immunity, having many children,

long-term oral contraceptive use, poor oral hygiene and nutrition, and chronic inflammation.

7. HPV may be transmitted by genital contact (oral, touching, or sexual intercourse). The possible modes of transmission in children are controversial; however, it is thought that newborn babies can be exposed to cervical HPV infection from the mother.
8. Although the HPV vaccine reduces the risk for cervical cancer, women should still get Pap tests and HPV screening at regular intervals.

Other Viruses and Microorganisms

1. Human herpes virus type 8 and HIV-AIDs are linked to Kaposi sarcoma, and human T-cell lymphotropic virus type 1 is linked to leukemia and lymphoma.
2. Microorganisms involved in carcinogenesis include parasites such as *Opisthorchis viverrini* (bile duct cancer) and *Schistosoma haematobium* (bladder cancer).

Chemicals and Occupational Hazards as Carcinogens

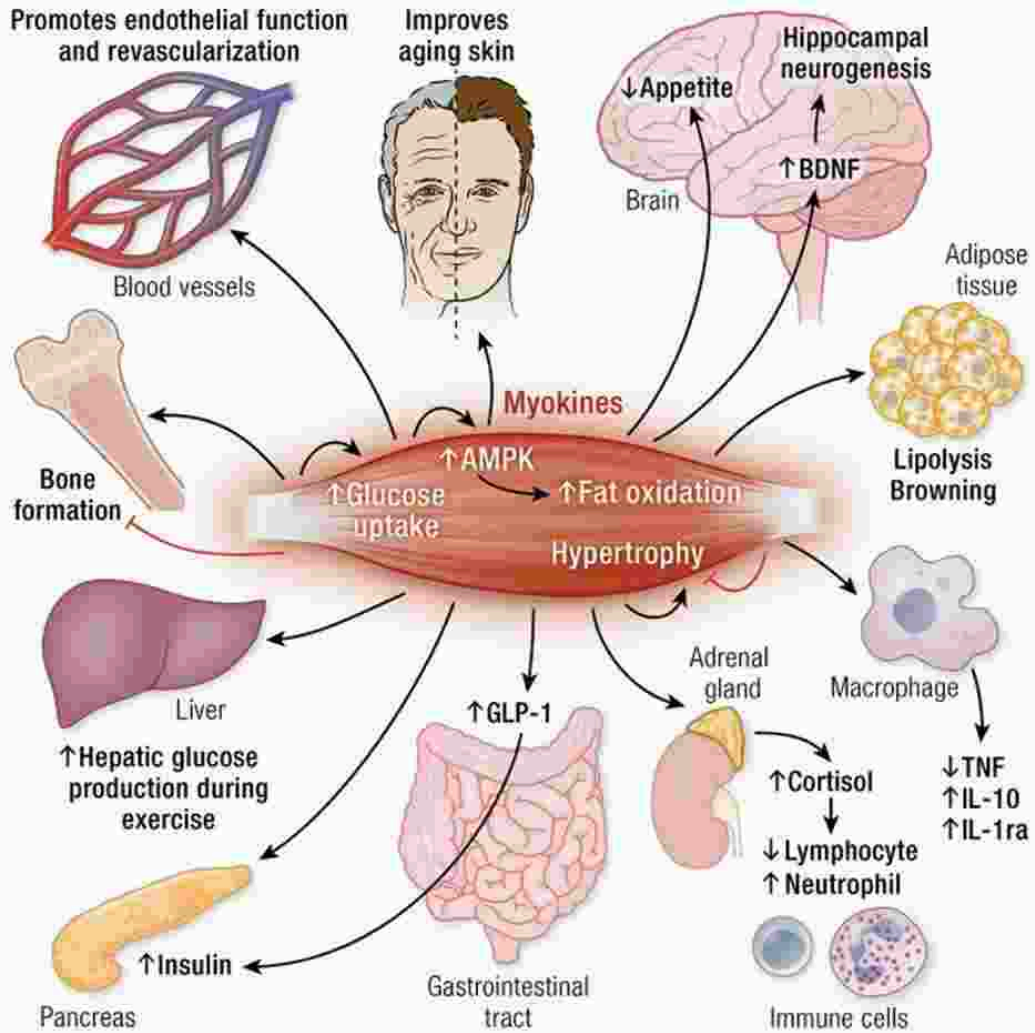
1. Synthetic chemicals are widely used in the United States, of which only a fraction have been tested for their health.
2. Exposure to chemicals occurs from air, soil, food, water, personal care products, toys, household products, medications, workplaces, and homes
3. A large number of chemicals are known carcinogens in experimental animals, and it is suspected that most of these are potentially carcinogenic in humans. When adequately tested, all agents known to cause cancer in humans also produce it in experimental animals when adequately evaluated.
4. Chemical carcinogenesis involves genotoxic mechanisms (create genetic damage) and nongenotoxic mechanisms (alter signal transduction).
5. A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors. Notable occupational hazards include dyes, rubber, paint, aromatic amines, benzol, heavy metals, silica, polycyclic aromatic hydrocarbons, sulfuric acid, and chloromethyl ether. Asbestos is linked to an epidemic of mesothelioma and asbestos usage has been banned in most developed countries.

Emerging Science BoxExercise and Anticancer Effects of Myokines

A newly identified anticancer mechanism of exercise is the release of proteins called myokines into the bloodstream. Myokines have beneficial effects, such as increasing insulin sensitivity of many systems (see first figure below). Additionally, myokines can induce apoptosis in breast cancer and colon cancer cells. Other investigators have found antitumorigenic effects of another myokine, interleukin-6 (IL-6), from working muscles. Epinephrine from the adrenal glands also increases mobilization of natural killer (NK) cells, which migrate into tumors and destroy tumor cells (see second figure below).

Biological Roles of Myokines

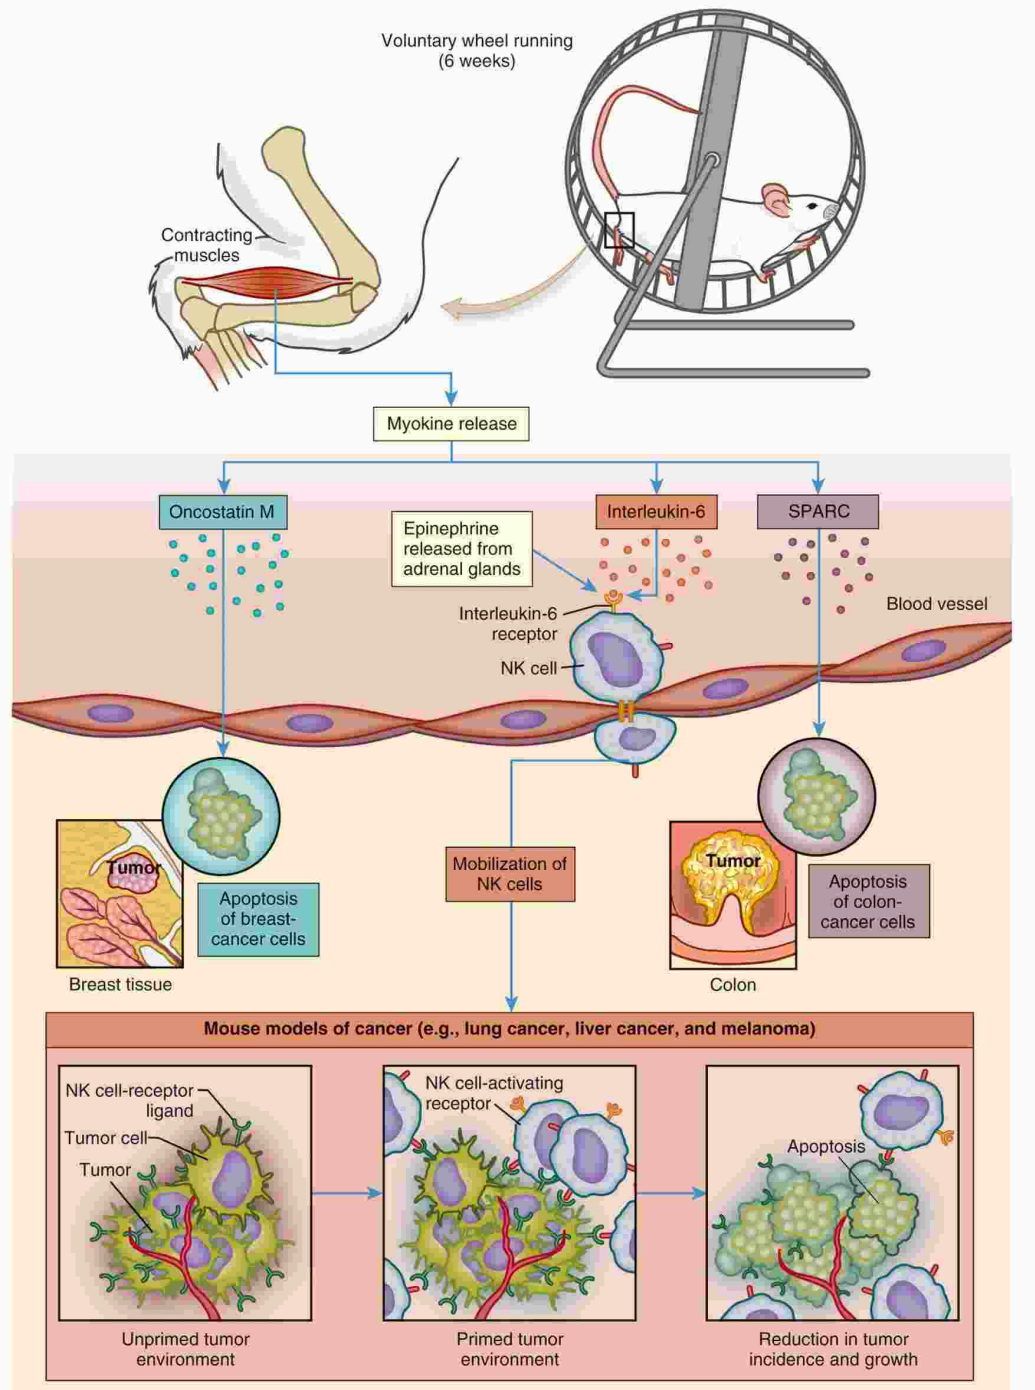
Only a few myokines have been allocated to specific function in humans. The biological roles of myokines include, for example, effects on cognition, lipid and glucose metabolism, browning of white fat, bone formation, endothelial cell function, hypertrophy, skin structure, and tumor growth.



(From Severinsen M, Pedersen BK. Muscle-organ crosstalk: The emerging roles of myokines. Endocrine Reviews, 2020;41(4):594–609. https://doi.org/10.1210/endrev/bnaa016.)

An illustration shows the following exercise and anticancer effects of myokines: • Improves aging skin. • Brain: decreased appetite; increased B D N F and hippocampal neurogenesis. • Lipolysis browning in adipose tissue. • Macrophage leads to decreased T N F, increased I L-10, and increased I L-1 r a. • Adrenal gland leads to increased cortisol, which results in decreased lymphocyte and increased neutrophil. • Gastrointestinal

tract. Increased G L P-1 leads to increased insulin. • Increased insulin occurs in pancreas. • Liver. Increased hepatic glucose production during exercise. • Bone formation. • Blood vessels. Promotes endothelial function and revascularization. • Increased A M P K leads to increased fat oxidation.



Antitumor Effects of Myokines (Adapted from Lucia A, Ramírez M. (2016). Muscling in on cancer. *New England Journal of Medicine*, 2016;375(9):892–894; Pedersen L, Idorn M, Olofsson GH, et al. Voluntary running suppresses tumor growth through epinephrine-and IL-6-dependent NK cell mobilization and redistribution. *Cell Metabolism*, 2016;23(3):554–562.)

An illustration of a mouse inside a wheel represents voluntary running (6 weeks). An accompanying illustration shows the contracting muscles in the hind legs of the mouse. This releases myokine: • Oncostatin M. Apoptosis of breast-cancer cells. An accompanying illustration shows a tumor in breast tissue. • Interleukin-6. Epinephrine is released from adrenal glands that are locked on to the interleukin-6 receptors on the N K cell. Mobilization of N K cells. • S P A R C. Apoptosis of colon-cancer cells. An accompanying illustration shows a tumor in the colon. There are three illustrations of mouse models of cancer (example, lung cancer, liver cancer, and melanoma). • Unprimed tumor environment. The illustration shows N K cell-receptor ligand, tumor cell, and tumor. • Primed tumor environment. The illustration identifies N K cell-activating receptors on the cells around the tumor cells. • Reduction in tumor incidence and growth. The illustration shows apoptosis.

DOI: 10.3389/fphys.2020.00091; Severinsen MCK, Pedersen BK. Muscle–organ crosstalk: the emerging roles of myokines. Endocr Rev. 2020;41(4):594–609.; Son JS, Chae SA, Testroet ED, et al. Exercise-induced myokines: A brief review of controversial issues of this decade. Expert Review of Endocrinology and Metabolism, 2018;13(1):51–58.

Emerging Science Box Increasing Use of Computed Tomography Scans and Risks

An analysis of computed tomography (CT) patterns by radiology researchers at Columbia University confirmed that the sevenfold increase in both diagnostic and therapeutic radiation from CT scans in the past 4 decades has contributed to major increases in cancer risks especially for

those exposed as children. Where adult CT scanners are not adjusted to smaller bodies, infants can incur up to 4000 chest x-rays from a single whole-body CT scan. Based on data from Japanese survivors of atomic bombs, the authors estimated that 1.5% to 2.0% of all cancers in the United States in the next decades might be attributable to CT radiation. The researchers also note that pediatric, young adult, and adult CT scans are sometimes ordered excessively and repeated unnecessarily because of defensive medicine. Finally, they advocate three ways to reduce radiation exposures: (1) reduce radiation doses in individual studies (i.e., use modern scanners adjusted to smaller bodies), (2) whenever possible substitute ultrasonography with magnetic resonance imaging (MRI) for CT, and (3) order CT scans only when absolutely necessary. The NCRP reports that most radiation exposures today are because of diagnostic procedures. In 2006, 67 million CT scans (compared with 3 million in 1980), 18 million nuclear medicine procedures, 17 million interventional fluoroscopy procedures, and 18 million nuclear medicine procedures were performed in the United States. Davis calculated that a single, unadjusted pediatric head CT can be equivalent to as many as 4000 chest x-rays.

Progress is being made in reducing pediatric CT procedures as a result of major educational efforts to promote awareness that as many as a third of CT scans are medically unnecessary and that the highest 25% of doses can be substantially reduced. If both these radiation-reducing strategies are undertaken, it is estimated that 62% of projected radiation-induced cancers could be averted in the next two decades.

Median Effective Radiation Dose for Each Type of Computed Tomography Study

Anatomic Area, Study Type	Median (mSv)	Range (mSv)	Dose Equivalent (No. of Chest X-rays)
Head and Neck			
Routine head	2	0.3–6	30
Routine neck	4	0.7–9	55
Suspected stroke	14	4–56	199
Unadjusted pediatric head	240	70-400	4000
Chest			
Chest, no contrast	8	2–24	117
Chest, with contrast	8	2–19	119
Suspected pulmonary embolus	10	2–30	137
Coronary angiogram	22	7–39	309
Abdomen-Pelvis			
Routine abdomen-pelvis, no contrast	15	3–43	220
Routine abdomen-pelvis, with contrast	16	4–45	234
Multiphase abdomen-pelvis	31	6–90	442
Suspected aneurysm or dissection	24	4–68	347

Anatomic Area, Study Type	Median (mSv)	Range (mSv)	Dose Equivalent (No. of Chest X-rays)

Emerging Science Box A Paradigm Shift? Responses to Ionizing Radiation Mediated by Inflammatory Mechanisms

Many observations have not been supportive of the conventional paradigm of biologic responses to ionizing radiation (IR). The conventional paradigm is that the consequences of exposure to IR have been attributed solely to mutational DNA damage or cell death induced in irradiated cells at the time of exposure. The challenges to this paradigm come from three types of published data: (1) **abscopal**, or "out-of-field," effects, where radiation treatment to one local area of the body results in an antitumor effect distant

to the radiation site; (2) detection of plasma factors in vivo (clastogenic [or capable of chromosome damage] factors) that can affect the survival and function of irradiated cells; and (3) effects in nonirradiated cells that are in the vicinity of irradiated cells (bystander effects) or in the descendants of irradiated cells several generations after the initial radiation exposure (genomic instability). These nontargeted effects are different than the targeted effects that arise in cells upon immediate deposition of energy at the time of radiation exposure. The nontargeted effects arise as a result of intracellular signaling and appear to represent a genotype-dependent balance (and various epigenetic influences) of toxic factors and cellular responses that can involve both oxidative stress and inflammatory type processes (see Fig. 13.17). The continuous activation and increase in endogenous and exogenous ROS damages the body's antioxidant system, stimulates more ROS, and forms a cascade of amplified inflammatory responses which eventually leads to cell death. The interconnected network of inflammatory and immune response pathways activated by IR include (1) cytokines, growth factors, adhesion molecules, (2), DNA damage, ER stress, ROS/RNS, hypoxia (3) inflammasomes, (4) cell death and senescence and (5) coagulation and fibrinolysis.

Recently, an increasing number of studies have been focusing on the underlying mechanisms involved in hematopoietic stem cell (HSC) fate after radiation exposure. The mechanisms include DNA damage response (DDR), including DNA-damage repair, cell cycle arrest, apoptosis and senescence, or bone marrow (BM) microenvironmental effects. Exposure to radiation not only causes acute myelosuppression but can lead to long-term residual hematopoietic problems because of the induction of HSC senescence. Caution is required from extrapolation of animal studies to humans. ROS, reactive oxygen species; RNS, reactive nitrogen species. ROS, reactive oxygen species; RNS, reactive nitrogen species.

Cancer in Children and Adolescents

Lauri A. Linder

http://evolve.elsevier.com/Rogers/pathophysiology/

Chapter Outline

OUTLINE

Incidence and Types of Childhood Cancer, 430

Etiology, 433
- Genetic and Genomic Factors, 433
- Environmental Factors, 435

Prognosis, 437

Although cancer in children and adolescents is rare, it is the leading cause of death resulting from disease in this age group.[1] Five-year survival rates among children and adolescents with cancer have dramatically improved from 59% in the 1960s to nearly 85% today.[2] Factors leading to improved cure rates include combination chemotherapy; multimodal treatment for children with solid tumors; targeted therapies, including immunotherapy; and participation in multisite clinical trials.

Incidence and Types of Childhood Cancer

More than 16,500 children and adolescents 19 years of age and younger are anticipated to be diagnosed with cancer in the United States in 2020.[3] The overall incidence of childhood and adolescent cancer is 18.7 per 100,000 (Fig. 14.1).[4] Childhood cancer demonstrates a bimodal distribution, with peaks among children <5 years of age and adolescents 15 to 19 years of age. In the United States, childhood cancer is also slightly more common in boys than in girls. The male/female ratio for childhood cancers is 1.2:1.0.[4] In the United States, cancer is more common in white children relative to other racial groups (Table 14.1); however, incidences can vary across racial/ethnic groups.[3] For example, the overall incidence of acute lymphocytic leukemia (ALL) is 1.6 times greater among white children than black children, yet the overall incidence of leukemia is greatest among Hispanic children.[4]

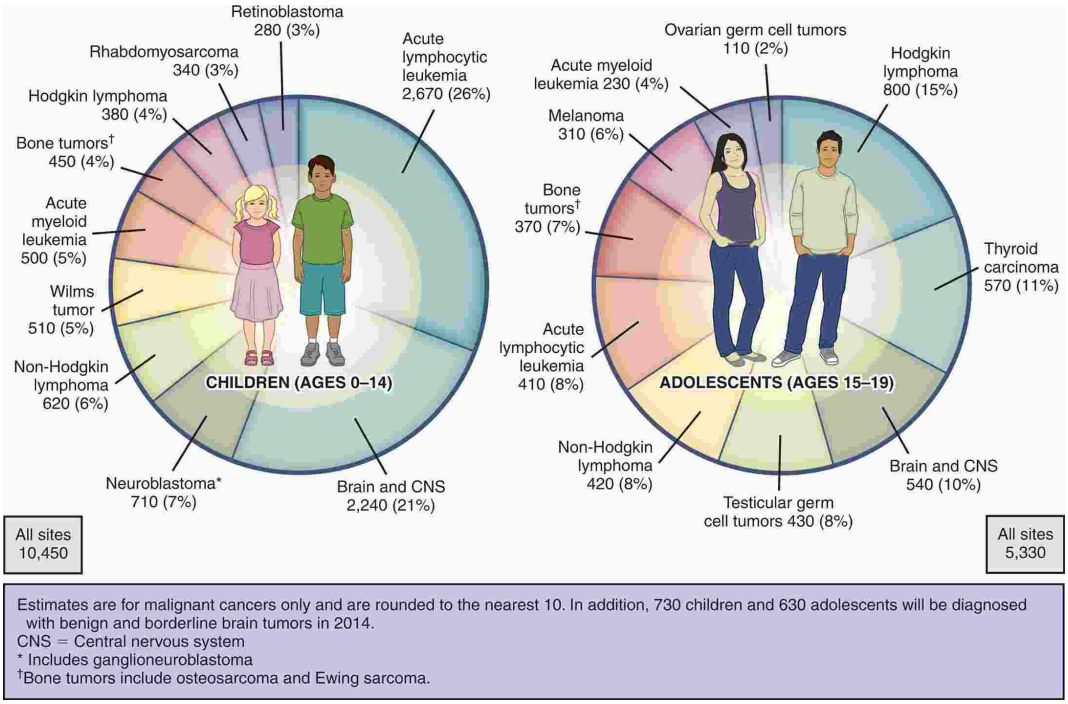

FIG. 14.1 Estimated Cases for Childhood and Adolescent Cancers, United States, 2014. (Data from American Cancer Society, Atlanta, GA, 2014.)

Two pie charts show the distribution of estimated cases for childhood and adolescent cancers in the United States in 20 14. The first chart represents a total of 10,450 sites and shows the following distribution in children between the ages 0 and 14. • Acute lymphocytic leukemia, 2,670 (26 percent). • Brain and C N S, 2,240 (21 percent). • Neuroblastoma, 710 (7 percent). Includes ganglioneuroblastoma. • Non-Hodgkin lymphoma, 620 (6 percent). • Wilms tumor, 510 (5 percent). • Acute myeloid leukemia, 500 (5 percent). • Bone tumors, 450 (4 percent). Includes osteosarcoma and Ewing sarcoma. • Hodgkin lymphoma, 380 (4 percent). • Rhabdomyosarcoma, 340 (3 percent). • Retinoblastoma, 280 (3 percent). The second chart represents a total of 5,330 sites and shows the following distribution in adolescents between the ages 15

and 19. • Hodgkin lymphoma, 800 (15 percent). • Thyroid carcinoma, 570 (11 percent). • Brain and C N S, 540 (10 percent). • Testicular germ cell tumors, 430 (8 percent). • Non-Hodgkin leukemia, 410 (8 percent). • Bone tumors, 370 (7 percent). Includes osteosarcoma and Ewing sarcoma. • Melanoma, 310 (6 percent). • Acute myeloid leukemia, 230 (4 percent). • Ovarian germ cell tumors, 110 (2 percent).

Table 14.1

Childhood Age-Adjusted Cancer Incidence Rates for Children Younger Than 19 Years of Age by Primary Site, Race, and Ethnicity, United States[a]

Cancer Site	Non-Hispanic White	Non-Hispanic Black	Asian/Pacific Islander	American Indian/Alaska Native	Hispanic
All cancer sites combined	18.5	14.6	15.3	9.7	17.1
Brain and other nervous systems	5.9	3.7	3.4		4.5
Leukemia	5.5	3.8	4.3		6.5
Lymphoma	3.1	2.4	2.1		2.7
Other	6.5	4.1	4.3		5.3

Cancer Site	Non-Hispanic White	Non-Hispanic Black	Asian/Pacific Islander	American Indian/Alaska Native	Hispanic
All cancer sites combined	18.5	14.6	15.3	9.7	17.1
Brain and other nervous systems	5.9	3.7	3.4		4.5
Leukemia	5.5	3.8	4.3		6.5
Lymphoma	3.1	2.4	2.1		2.7
Other	6.5	4.1	4.3		5.3

[a]Rates are per 100,000 persons and are age-adjusted to the 2000 US standard population (19 age groups—Census P25-1130).

Data from National Cancer Institute. Surveillance Epidemiology and End Results Program. *SEER Cancer Statistics Review 1975-2017*. https://seer.cancer.gov/csr/1975_2017/browse_csr.php?sectionSEL=28&pageSEL=sect_28_zfig.03#table1; https://seer.cancer.gov/csr/1975_2017/browse_csr.php?sectionSEL=28&pageSEL=sect_28_table.02. Accessed December 16, 2021.

Although death rates from childhood and adolescent cancers are declining, approximately 1,730 cancer-related deaths among children and

adolescents in the United States are anticipated in 2020.[3] Childhood cancer-related deaths are most frequently attributed to brain tumors followed by leukemias; however, survival further varies based on cancer type and age at diagnosis.[3] Between 2013 and 2017, the cancer-related death rates among children and adolescents, from birth to age 19 years, were 2.5 per 100,000 for males and 2.0 per 100,000 for females.[4] By comparison, the cancer-related mortality rate in adults was 183.9 per 100,000 in 2017.[5]

Childhood cancers differ greatly from those in adults in relation to the site and type of the malignancy, as well as the role of environmental exposures. The most common types of cancer among adults include prostate, breast, lung, and colon cancers. Many adult cancers have associated lifestyle factors that could theoretically be avoided, thereby preventing the development of cancer, such as smoking and exposure to the sun.

Among children up to 14 years of age, leukemias and brain tumors account for 61% of childhood cancers; solid tumors, such as neuroblastoma and soft tissue or bone sarcomas, are less common.[3] Lymphomas (including Hodgkin and non-Hodgkin subtypes) are the most common type of cancer among adolescents (15 to 19 years of age). Leukemia, thyroid carcinoma, brain tumors, and germ cell tumors also are among the most common adolescent cancers.[2,3,6] Although very few environmental factors have been linked to pediatric and adolescent malignancies, more data are emerging that the developing child may be affected by both maternal and paternal exposures before conception, exposures in utero, and the contents of breast milk. These exposures may result in epigenetic changes, creating an increased vulnerability to the development of childhood cancer.[7–9]

Most childhood cancers originate from the **mesodermal germ layer**. This layer develops into connective tissue, bone, cartilage, muscle, blood, blood vessels, gonads, kidney, and the lymphatic system (Fig. 14.2). As a result, the most common childhood cancers include leukemias, sarcomas, and embryonic tumors. In general, childhood cancers are fast-growing, resulting in a relatively short latency period—that is, the time from the initial exposure to the onset of symptoms. Additionally, childhood and adolescent cancers tend to be fast growing, with 80% having distant spread (metastases) at diagnosis.

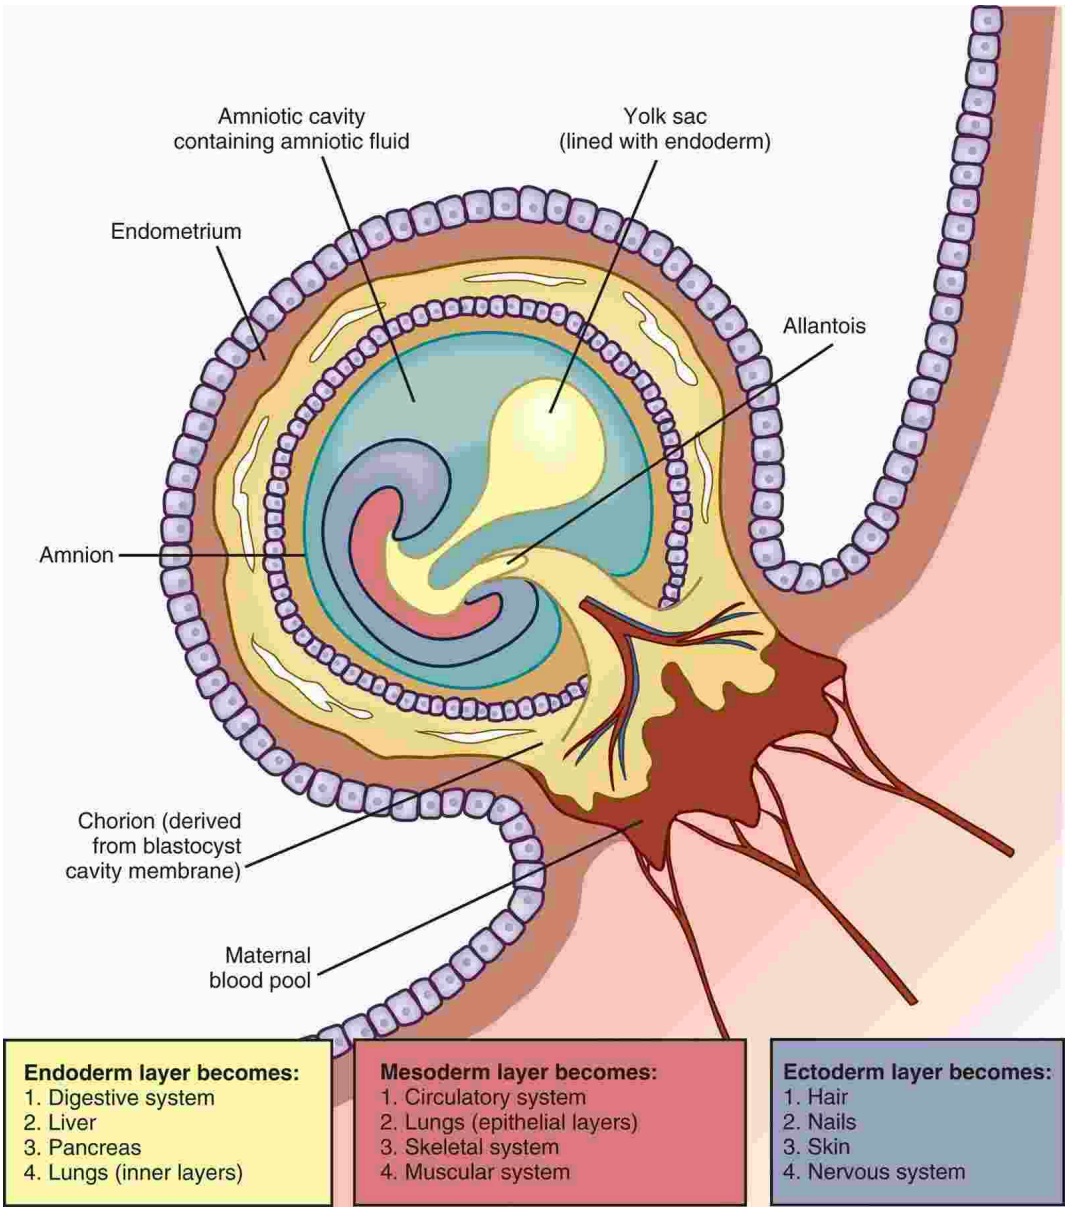

FIG. 14.2 Mesodermal Germ Layer.

An illustration of a mesodermal germ layer shows and labels the followings structures from the inside to the outside: allantois, yolk sac (lines with endoderm), amniotic cavity containing amniotic fluid, amnion, chorion (derived from blastocyst cavity membrane), endometrium, and maternal blood pool. The transformation of layers is as follows. • Endoderm layer: digestive system, liver,

pancreas, and lungs (inner layers). • Mesoderm layer: circulatory system, lungs (epithelial layers), skeletal system, and muscular system. • Ectoderm layer: hair, nails, skin, and nervous system.

Childhood cancers are often diagnosed during peak times of physical growth and maturation and are likely influenced by altered cellular regulatory mechanisms at given times in the child or adolescent's development. These underlying processes associated with growth and development likely account for the bimodal distribution in their incidence, with peak incidences among children age <6 years and then again during adolescence.

The distribution of cancer types also changes during childhood and adolescence. Leukemia is the most common malignancy in children, with most cases occurring in children between 2 and 5 years of age. The most common type of leukemia is ALL, which represents approximately 75% of all childhood and nearly half of all adolescent leukemia cases.[3] Although the presenting signs of the various types of leukemia may be similar, the treatment and response to treatment of childhood leukemias vary greatly (see Chapter 30).

Central nervous system (CNS) tumors are the most common types of solid tumors in children and account for 26% of all childhood cancers and 20% of adolescent cancers[3] (see Chapter 20). The peak incidence of these tumors is among children age <15 years; however, the incidence of specific subtypes of brain and CNS tumors varies across childhood and adolescence. Not all brain tumors are diagnosed malignant by histologic studies; however, even a benign tumor can have devastating effects, depending on the anatomic location. The treatment for brain tumors in children often presents difficulties because therapies, such as radiation, may have debilitating effects on the developing brain, particularly in children younger than 3 years of age.

Lymphomas, both Hodgkin and non-Hodgkin types, are the third most common type of childhood cancer. Lymphoma is rare in children age <5 years. It occurs most frequently in children and adolescents 10 years of age and older; however, the incidence of the subtypes differs across the lifespan (see Chapter 13).

Embryonal tumors begin during intrauterine life. These tumors contain abnormal cells that appear to be immature embryonic tissue; they are unable to mature or differentiate into fully developed cells. Embryonal tumors are most often diagnosed early in life, usually before the child is 5 years of age. They are rare in older children, adolescents, and adults. The names of these tumors often include the root term *blast* (e.g., neuroblastoma, retinoblastoma), which indicates the embryonal stage of development of the involved cells.

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood. This tumor has a bimodal age distribution. Two-thirds of cases occur in children age <6 years, and one-third occur in children and adolescents 10 years of age and older. The two most common types of bone tumors are osteosarcoma and Ewing sarcoma. These cancers are more likely to occur in adolescents age ≥15 years (Table 14.2).

Table 14.2

Childhood Age-Adjusted Invasive Cancer Incidence Rates by Primary Site and Age, United States[a]

Site	Birth to 14 Years	Birth to 19 Years
All sites	16.0	18.1
Leukemia (all types)	5.3	4.8
Acute lymphocytic leukemia	4.1	3.4
Brain and other nervous system	3.2	3.1
Soft tissue	1.1	1.1
Kidney and renal	0.8	0.7
Bones and joints	0.7	0.9
Non-Hodgkin lymphoma	1.0	1.4
Hodgkin lymphoma	0.6	1.1

[a]Rates are per 100,000 persons and are age-adjusted to the 2000 US standard population (19 age groups—Census P25-1130).

Data from National Cancer Institute. Age-adjusted SEER Cancer Incidence Rates, 1975–2017 by primary cancer site and year of diagnosis. https://seer.cancer.gov/csr/1975_2017/browse_csr.php?sectionSEL=28&pageSEL=sect_28_table.02

Although sarcomas, leukemias, and lymphomas are cancers observed in childhood, they also occur in adults. Most adult cancers develop from epithelial tissue and are therefore carcinomas. Because carcinomas most often result from environmental exposures to carcinogens, they rarely occur in children. A long period (up to decades) of exposure is required until the development of carcinoma. The incidence of carcinomas increases between ages 15 and 19 years. Carcinoma is the most common cancer tissue type observed after adolescence.[3]

Etiology

The causes of cancer in children are largely unknown. A few environmental factors can predispose a child to cancer; however, causal factors have not been established for most childhood cancers. A number of host factors, many of which are genetic risk factors or congenital conditions, have been implicated in the development of childhood cancer (Table 14.3). The interaction of many factors most likely produces cancer, a concept referred to as multiple causation or **multifactorial etiology**. According to this premise, cancer develops because of the predisposing characteristics of the person and the interaction with environmental factors.

Table 14.3

Congenital Factors Associated With Childhood Cancer

Syndrome	Associated Childhood Cancer
Chromosome Alterations	
Down syndrome	Acute leukemia
13q syndrome	Retinoblastoma
Chromosome Instability	
Ataxia-telangiectasia	Lymphoma
Bloom syndrome	Acute leukemia, lymphoma, Wilms tumor
Fanconi anemia	Acute myelogenous leukemia, myelodysplastic syndrome, hepatic tumors
Hereditary Syndromes	
Beckwith-Wiedemann syndrome	Wilms tumor, sarcoma, brain tumors, neuroblastoma, hepatoblastoma
Neurofibromatosis type I	Brain tumor, sarcomas, neuroblastomas, Wilms tumor, nonlymphocytic leukemia
Neurofibromatosis type II	Meningioma (malignant or benign), acoustic neuroma/schwannoma, gliomas, ependymomas
Tuberous sclerosis	Glial tumors
Li-Fraumeni syndrome	Sarcoma, adrenocortical carcinoma
Von Hippel-Lindau disease	Cerebellar hemangioblastoma, retinal angioma, renal cell carcinoma, pheochromocytomas
Ataxia-telangiectasia	Leukemia, lymphoma, brain tumors
Gorlin syndrome	Medulloblastoma, skin tumors

Syndrome	**Associated Childhood Cancer**
Immunodeficiency Disorders	
Congenital	
Agammaglobulinemia	Lymphoma, leukemia, brain tumors
Immunoglobulin A (IgA) deficiency	Lymphoma, leukemia, brain tumors
Wiskott-Aldrich syndrome	Leukemia, lymphoma
Acquired	
Aplastic anemia	Leukemia
Human immunodeficiency virus/Acquired immunodeficiency syndrome (HIV/AIDS)	Non-Hodgkin lymphoma, leiomyosarcoma
Organ transplantation	Leukemia, lymphoma
Congenital Malformation Syndromes	
Aniridia, hemihypertrophy, hamartoma, genitourinary anomalies	Wilms tumor
Cryptorchidism	Testicular tumor
Gonadal dysgenesis	Gonadoblastoma
Family Susceptibility	
Twin or sibling with leukemia	Leukemia

Syndrome	Associated Childhood Cancer

Cryptorchidism	Testicular tumor
Gonadal dysgenesis	Gonadoblastoma
Family Susceptibility	
Twin or sibling with leukemia	Leukemia

Most children who are diagnosed with cancer do not have known predisposing environmental or host factors. Because of their relatively short latency period, most childhood cancers do not lend themselves to early cancer warning signs. The American Cancer Society's seven warning signs are less relevant for children. These warning signs describe manifestations of environmentally caused carcinomas that are much more common among adults. Efforts to establish early population-based screening strategies for childhood cancers have not been effective. Children with a family history of cancer and who are known to have mutations associated with cancer, such

as those involving the *TP53* gene, however, will receive additional screening.[10–12]

A **multiple causation model** is useful when the results of epidemiologic studies are interpreted. For example, laboratory and epidemiologic studies may indicate that exposure to a certain chemical or ionizing radiation can cause leukemia, but not all children exposed to that chemical will develop leukemia. Additional studies will be needed to determine what other factors, including underlying genetic risk factors, must interact with chemical exposure to cause the disease.

Genetic and Genomic Factors

Acquired or inherited mutations in individual genes may contribute to the development of cancer in children and adolescents. In general, children who develop cancer have a greater frequency of mutations in germline cancer predisposition genes compared with children who do not develop cancer.[13–15] Genes associated with childhood cancers also tend to differ from those associated with adult cancers.[16,17]

Mutations in proto-oncogenes, tumor-suppressor, and mismatch repair genes are associated with the development of childhood cancer (see Chapter 12). **Proto-oncogenes** code for proteins that help regulate normal cell growth and differentiation. If mutated, proto-oncogenes become oncogenes that help to turn normal cells into cancer cells. Changes produced by specific oncogenes cause the cell cycle to become dysregulated. An example of an oncogene identified in pediatric cancer is *MYCN*, which is involved in neuroblastoma and glioblastoma. Tumor-suppressor genes are protective genes that normally suppress cancer cell proliferation but have lost their suppressor function. When both copies of a tumor-suppressor gene acquire mutations, normal cell function is lost, and cancer can develop. Some childhood and adolescent cancers identified with tumor-suppressor genes include leukemia, osteosarcoma, rhabdomyosarcoma, retinoblastoma, and Wilms tumor.[18] Mismatch repair genes recognize and repair errors in the DNA base sequence that can arise during DNA replication and recombination. Mismatch repair genes also repair some types of DNA damage. Mutations in both alleles of a mismatch repair gene are associated with a distinct phenotype termed constitutional mismatch repair deficiency syndrome (CMMMRD). Children affected with CMMRD, a highly penetrant cancer predisposition syndrome, can develop highly aggressive cancers, including lymphoma, leukemia, and sarcoma.[19]

An underlying single gene, multifactorial, and chromosomal conditions may increase a child's risk for the development of childhood cancer. Fanconi anemia and Bloom syndrome are single-gene autosomal recessive conditions that are risk factors for the development of cancer. Fanconi anemia results in altered DNA repair, and many affected individuals develop acute myelogenous leukemia. Bloom syndrome results in chromosomal fragility leading to increased mutations. It is associated with a spectrum of cancers, including leukemias, lymphomas, and carcinomas.

Li-Fraumeni syndrome (LFS) is an autosomal dominant disorder involving mutations in the tumor protein p53 *(TP53)* gene, a tumor-suppressor gene on the short arm of chromosome 17. For individuals carrying a TP53 mutation, the risk of developing cancer as a child or adult is significantly higher than that seen in the unaffected population. Children and adults in these families are at risk for soft tissue sarcoma, breast cancer, leukemia, osteosarcoma, melanoma, and cancer of the colon, pancreas, adrenal cortex, and brain. Individuals with LFS are also at increased risk for developing multiple primary cancers.[10,20]

Retinoblastoma, a malignant embryonal tumor of the eye, results from deletions in the long arm of chromosome 13, which is the locus for the *RB1* gene, a tumor-suppressor gene. Deletions may occur as germline or acquired mutations. Germline deletions are associated with familial retinoblastoma, whereas acquired deletions are associated with sporadic cases (see Chapter 20).

An increased familial risk has been observed in some pediatric cancers. Although the majority of pediatric cancers are not genetically transmitted as single-gene disorders, shared genetic and environmental risk factors may contribute to an increased familial risk. A child who has a sibling with leukemia has a risk for the development of leukemia that is 2 to 4 times greater than that for children with healthy siblings. The occurrence of leukemia in monozygous twins is estimated as being as high as 25%. Although susceptibility gene loci have been identified for ALL, they explain only a relatively small portion of the familial risk for recurrence of ALL among siblings. Additional currently unidentified genetic loci are likely to contribute to the additional familial risk.[21,22] The heritability of adult cancers across the lifespan also is increased among both monozygotic and dizygotic twins.[23,24]

Chromosomal abnormalities also may contribute to the development of childhood cancer. These may include abnormalities in the number (e.g., aneuploidy) or in the structure (e.g., deletions, amplifications, translocations,

and fragility) of chromosomes (see Chapter 4). Abnormalities may occur within the affected cancer cells as a result of malignant transformation.

A chromosomal translocation results from the rearrangement of two nonhomologous chromosomes. Translocations may result in the creation of a fusion gene, in which the two previously separate gene regions unite. Two fusion genes associated with ALL in children are the *BCR-ABL* gene, resulting from a translocation between chromosomes 9 and 22, and the *TEL-AML1* gene, resulting from a translocation between chromosomes 12 and 21.

Translocations, or the exchange of chromosomal material between nonhomologous chromosomes, also are associated with childhood and adolescent cancers. A well-known chromosomal translocation is the Philadelphia chromosome, which involves chromosomes 9 and 22. The Philadelphia chromosome results in the production of the BCR-Abl fusion protein, which accelerates cell division and inhibits DNA repair. It is commonly found in chronic myelogenous leukemia and some cases of acute lymphoblastic leukemias.[25] Chromosomal translocations also are commonly observed in sarcomas.

Chromosomal abnormalities associated with cancer development may also be present in congenital syndromes. One of the more recognized syndromes is trisomy 21 (Down syndrome), which is the most common genetic condition associated with the development of acute leukemia. Children with Down syndrome have a 10- to 20-fold increased risk of developing acute lymphoblastic and myelogenous leukemias and a higher risk of developing acute megakaryocytic leukemia.[26] The risk is highest in early childhood, and the age distribution for developing ALL among children with Down syndrome is similar to that of children without Down syndrome. The risk of leukemia also is increased for children with congenital malformations involving the circulatory system.[27]

Several other syndromes associated with specific congenital malformations are associated with a higher incidence of cancer development. The mechanisms associated with cancer development, however, are not fully understood.

Wilms tumor, a malignant tumor of the kidney, may occur in combination with other congenital anomalies, including aniridia or congenital absence of the iris of the eye, ambiguous genitalia, and intellectual disability (WAGR syndrome). WAGR syndrome is caused by a mutation on the short arm of chromosome 11. This region includes the Wilms tumor gene *(WT1)* as well as the *PAX6* gene that is associated with ocular development. Wilms tumor also is associated with neurofibromatosis and Beckwith-Wiedemann

syndrome, a condition associated with hemihypertrophy (muscular overgrowth of half of the body and/or face).[28] Most cases of Wilms tumor, however, do not occur in children with underlying congenital syndromes. Approximately 17% of children with Wilms tumor have identifiable malformations and congenital predisposition syndromes.[29] This subset of children is likely to receive additional early cancer screening.

Children with congenital anomalies not associated with a known chromosomal syndrome may also have an increased risk of developing childhood cancer. Compared with healthy children, children with ventricular septal defects have a 10 times greater risk of developing hepatoblastoma.[30] Population-based studies indicate that children with CNS birth defects have a 10 to 20 times increased risk of developing some types of brain tumors.[31] Additionally, the siblings of children with congenital malformations involving the central nervous system, eye, ear, face, or neck are at an increased risk for cancer compared with the siblings of unaffected children.[32]

Cancers in children and adolescents are associated with fewer genetic mutations compared with adult cancers; however, efforts to understand the scope of predisposing mutations in pediatric cancer are ongoing. Recent studies have identified a greater frequency of germline mutations in cancer predisposition genes among children and adolescents with cancer compared with individuals who do not have cancer. More than one-half of the children and adolescents with germline mutations did not have a family history of cancer[13,14] (see Emerging Sciences Box: Cancer Predisposition Genes and Pediatric Cancer).

Mutations in individual genes also may result in epigenetic modifications that, in turn, increase an individual's vulnerability to cancer. For example, mutations in genes encoding histone proteins can decrease the expression of other genes without changing the sequence of these genes. This subsequent decreased gene expression can alter cell differentiation, leading to cancer development. Such epigenetic changes are being investigated in relation to the development of diffuse intrinsic pontine glioma (DIPG), an incurable brain tumor, as well as sarcomas.[33,34]

Environmental Factors

Although many adult cancers are associated with exposure to environmental agents, few childhood tumors share a similar strong association. Because of the lengthy latency period required between

exposure and development of cancer, early exposure to carcinogens is presumed not to result in cancer until the child is an adult. To date, exposures to high-dose and high-dose-rate ionizing radiation have been established as risk factors for childhood leukemia.[35,36] Multiple other possible environmental risk factors for childhood cancer have been explored. Results of these studies have been mixed, and no definitive causal pathway for childhood cancer has been determined (Box 14.1).

Box 14.1

Factors That May Contribute to the Development of Childhood and Adolescent Cancers

- Genetic, genomic, and epigenetic factors
- Diet
- Immune function
- Occupational exposure
- Ionizing radiation
- Hormonal variations
- Viral illnesses
- Individual characteristics, such as the biologic, social, and physical environments

Prenatal Exposure

Prenatal exposure to some drugs and to ionizing radiation has been linked to childhood cancers. The most well-described drug is diethylstilbestrol (DES), which was prescribed by physicians to prevent recurrent spontaneous abortion. In 1971, DES

Emerging Science Box

Cancer Predisposition Genes and Pediatric Cancer

Recent studies using advanced genome sequencing techniques have provided additional insight into the prevalence of germline genetic

mutations that may predispose children and adolescents to cancer. In a US-based study, germline mutations have been identified in 565 genes associated with cancer development in 1120 children and adolescents with cancer and 966 individuals who did not have cancer.[1] The investigators found that 8.5% of individuals with cancer had a mutation associated with cancer development compared with only 1.1% of the individuals who did not have cancer. Mutations most frequently occurred in the TP53 gene, a gene involved in regulating cell division and preventing tumor formation. Other frequently affected genes were APC and BRCA2. The majority of children and adolescents with mutations in cancer predisposition genes did not have a family history of cancer. In a cohort study of 40 children and their parents in the Netherlands, investigators identified germline mutations that were the likely cause of cancer in 8 (20%) individuals.[2] They also identified additional genes that are likely associated with cancer predisposition.

Germline mutations in cancer-causing genes also have implications for survivors of childhood cancer. As survival rates increase, the number of individuals at risk for developing secondary cancers also increases. A recent US-based study identified mutations in 156 cancer predisposition genes among 11.8% of 2,450 childhood cancer survivors.[3] Variants in cancer predisposition genes were most prevalent among survivors of central nervous system tumors. The most frequently mutated genes included RB1, NF1, and BRCA2.

The results of these studies will guide additional epidemiologic studies, as well as studies investigating mechanisms of cancer development in children and adolescents across the cancer care continuum. Identifying the presence of these mutations also may help guide treatment, as well as genetic testing and counseling of other family members.

was identified as a transplacental chemical carcinogen because adenocarcinomas of the vagina and cervix occurred in a small percentage of

the daughters of women who took DES. No other studies have identified other drugs taken by pregnant women that may cause cancer in their children. Since then, other studies have attempted to identify drugs taken by pregnant women that may cause cancer in their offspring, but no other drugs have been found. In 2006, the Office of the US Surgeon General suggested evidence of a causal relationship among childhood leukemia, lymphoma, and brain tumors related to prenatal or postnatal environmental tobacco smoke exposure.

Current evidence suggests that an increased risk of childhood leukemia is associated with low levels of exposure to antenatal x-rays.[12,36] An association between antenatal x-ray exposure and childhood brain tumors has not been established. Other current areas of research include exploring epigenetic modifications resulting from prenatal exposures and their role in future cancer development.

Recent meta-analyses have suggested associations between parental exposure to pesticides and other potential environmental toxins before or during pregnancy and subsequent development of childhood cancer.[37,38] The strongest associations have been identified in relation to maternal exposure. Recent studies indicate that the risk of leukemia, lymphoma, and neuroblastoma is increased when the mother is exposed to pesticides in the prenatal period.[38–40] Maternal occupational benzene exposure has been associated with an increased risk of acute lymphoblastic leukemia.[41] Maternal exposure to hair dyes and occupational chemical exposure was associated with an increased risk of leukemia and neuroblastoma.[41–43]

The role of paternal exposure is less clearly defined. However, recent prospective analyses from the International Childhood Cancer Cohort Consortium indicated that paternal exposure to pesticides was associated with an increased risk of acute myelogenous leukemia but not acute lymphoblastic leukemia or central nervous system tumors.[44] In contrast, another study using more detailed exposure-related information identified an association between acute lymphoblastic leukemia and paternal, but not maternal, occupational exposure to pesticides.[45]

In contrast, however, a meta-analysis of 1426 cases of neuroblastoma failed to show an association between paternal occupational exposure to pesticides and the development of disease.[46]

Parental occupational exposure to livestock has also been a recent focus of investigation. A recent case control from Denmark spanning nearly 50 years

identified an association between paternal exposure and germ cell tumors as well as maternal exposure and subsequent astrocytomas.[47]

Childhood Exposure

Childhood exposures to ionizing radiation, drugs, electromagnetic fields, or viruses have been associated with the risk of cancer. Although high doses of ionizing radiation are established risk factors for the development of childhood cancer,[48] evidence is emerging about the role of lower doses as well as additional variables that may further convey an increased risk. Retrospective studies have shown a significant correlation between radiation-induced malignancies and either radiotherapy (cancer treatment) or radiation exposure from diagnostic imaging[49,50] (see Emerging Sciences Box: Risks from CT Imaging Scans and Pediatric Cancer). A case-control study of more than 1000 children in Finland with leukemia who were less than 15 years of age

Emerging Science Box

Risks from CT Imaging Scans and Pediatric Cancer

Computed tomography (CT) is the largest contributor to medical radiation exposure in the US population. CT exposures represent only about 12% of diagnostic radiologic procedures in large hospitals; however, it accounts for almost 49% of the US population's collective radiation dose from all medical x-ray examinations.

Concern about the risk of cancer in children associated with radiation exposure from CT is increasing. Epidemiologic studies have shown that children are more sensitive to radiation compared to adults. Because children have a longer life expectancy compared with adults, the window of opportunity to express radiation damage is increased. Children also may receive a higher radiation dose than necessary if the CT setting is not adjusted for their smaller size. The absolute cancer risks associated with CT, however, are very small. Lifetime risks of cancer because of CT exposures have been estimated by using projection models based on atomic bomb survivors. These risks are about 1 case of cancer for every 1000 people scanned, with a maximal incidence of about 1 case of cancer for every 500 people. A recent meta-analysis of seven studies that included 1,180,987 children identified a 1.32-fold greater risk of subsequent cancer development among children exposed to CT compared with those who were not exposed to CT.

The benefits of properly performed and clinically justified CT examinations should always outweigh the risks for an individual child. Key strategies to minimize radiation exposure include: (1) performing only necessary CT scans, (2) adjusting exposure parameters for children, and (3) using lower resolution scans when appropriate to the clinical decision to be made.

Future population-based studies should evaluate the changes in childhood cancers attributable to medical imaging scans as institutions adopt practices to reduce radiation from CT scans. Future studies should also include longer follow-up periods as well as provide additional detail regarding underlying genetic conditions that may provide insights into mechanisms by which CT exposure may contribute to increased cancer risk.

Data from Huang R, et al. Radiation exposure associated with computed tomography in childhood and the subsequent risk of cancer: A meta-analysis of cohort studies. *Dose Response*, 2020;18(2):1559325820923828; National Cancer Institute, National Institutes of Health. *NCI Radiation Risks and Pediatric Computed Tomography (CT): A Guide for Health Care Workers*. Bethesda, MD: National Cancer Institute; 2012. https://www.cancer.gov/about-cancer/causes-prevention/risk/radiation/pediatric-ct-scans. Accessed August 16, 2020.

did not demonstrate an overall association of childhood leukemia with background gamma radiation.[51] This study did, however, demonstrate an increased risk of leukemia in relation to increasing radiation dose among children between 2 and 7 years of age. Additionally, this study identified a positive association between leukemia with high hyperdiploid features and radiation dose. A similar increased risk was not identified for leukemia with other genetic features. Few studies have followed children for a long enough period of time to determine whether the risk of cancer remains increased in adulthood, although current studies with more rigorous methodology are assessing this risk.

In addition to the drug and environmental agents that are known to cause cancer in adults and therefore also are risks for exposure during childhood, a few drugs may particularly increase cancer risk during childhood (Table 14.4). Exposures during childhood to unspecified residential pesticides and insecticides have been associated with childhood leukemia.[52]

Table 14.4

Drugs That May Increase Risk of Childhood Cancer

Drug Class	Uses	Cancer Risk
Anabolic androgenic steroids	Stimulate bone growth and appetite; induce puberty; increase muscle mass and physical strength	Hepatocellular carcinoma Brain tumors
Epipodophyllotoxin and anthracycline chemotherapy agents	Cancer treatment	Leukemia
Immunosuppressive agents	Prevent organ rejection following transplantation surgery	Lymphoma

Drug Class	Uses	Cancer Risk
Anabolic androgenic steroids	Stimulate bone growth and appetite; induce puberty; increase muscle mass and physical strength	Hepatocellular carcinoma Brain tumors
Epipodophyllotoxin and anthracycline chemotherapy agents	Cancer treatment	Leukemia
Immunosuppressive agents	Prevent organ rejection following transplantation surgery	Lymphoma

In contrast, some exposures may be protective against childhood cancer. Current research suggests that early exposure to common infections may help "prime" the immune system, thereby protecting the child against acute lymphoblastic leukemia.[53]

Multiple other possible environmental risk factors for childhood cancer have been explored. The relationship between childhood cancer and exposure to radon[54–56] and electromagnetic fields has been the focus of many international epidemiologic studies, yet no conclusive evidence has been observed. A review of studies from 1997 to 2013 indicated that magnetic field exposure may be associated with an increased incidence of childhood leukemia[57]; however, the reported risk associated with exposure to magnetic fields and the development of childhood leukemia has been decreasing over the past 20 years.[58] In 2007, a task group of scientific experts convened by the World Health Organization (WHO) reported that it could

not confirm the existence of any health consequences from exposure to low-level magnetic fields[59] (see Emerging Sciences Box: Magnetic Fields and Development of Pediatric Cancer).

The strongest association between viruses and the development of cancer in children has been seen in cases of the Epstein-Barr virus (EBV) infection, which is linked to endemic Burkitt lymphoma, nasopharyngeal carcinoma, and Hodgkin disease. Children with acquired immunodeficiency syndrome (AIDS) have an increased risk of developing non-Hodgkin lymphoma and Kaposi sarcoma. The use of highly active antiretroviral therapy (HAART) in the developed world has dramatically reduced the incidence of AIDS-related malignancies.

Prognosis

Nearly 85% of children and adolescents diagnosed with cancer are cured. Mortality rates have declined from 6.5 per 100,000 in 1969 to 2.3 per 100,000 in 2015, largely because of advances in treatment and increased participation in clinical trials.[60]

Factors leading to these improved cure rates include the use of combination chemotherapy, multimodal treatment, advances in biotherapy, and improvements in nursing and supportive care. The development of research centers for comprehensive childhood cancer treatment, cooperation among treatment institutions, and the development of cooperative study groups facilitate refinements in treatment protocols and data sharing,

Emerging Science Box

Magnetic Fields and Development of Pediatric Cancer

The role of magnetic fields has been an ongoing area of concern as an environmental exposure that in relation to cancer development. Exposure to extremely low to mid-frequency magnetic fields is common, and common sources include electric power lines, computers, mobile phones, radio waves, and microwaves. These types of magnetic fields are non-ionizing and do not directly damage DNA.

The World Health Organization (WHO) identified a better understanding of health risks, including cancer, and exposure to low-frequency magnetic fields as a research priority in 2007. A recent meta-analysis evaluated nine case-control studies, representing eight different countries, conducted between 1997 and 2013 and involving 11,699 cases of

children with leukemia and 13,194 controls. This meta-analysis identified an increased risk of childhood leukemia associated with high levels of magnetic field exposure (≥0.4 μT). For additional perspective, <1% of the children in these studies experienced this level of exposure. The WHO has estimated that only about 1% to 4% of children worldwide live in conditions that exceed 0.4 μT.

Ongoing research is needed because any environmental factor may require many years of exposure to cause disease. Additionally, an association between a given factor and childhood cancer does not establish causality. Research is needed to better understand the relationships between exposures to extremely low- and low-frequency magnetic fields and other potential causative factors associated with childhood cancers. Research also is needed to identify potential mechanisms by which these types of magnetic fields, including the dose and duration of exposure, may contribute to the development of childhood cancer.

Data from National Cancer Institute. *Electromagnetic fields and cancer*; 2020. https://www.cancer.gov/about-cancer/causes-prevention/risk/radiation/electromagnetic-fields-fact-sheet. which further contribute to improved survival rates. Currently, clinical trials are being conducted by the Children's Oncology Group (COG) at more than 175 hospitals across the United States and are funded by the National Cancer Institute through CureSearch for Children's Cancer.

Although survival rates for adolescents have lagged behind those for children less than 15 years of age, recent data from the Centers for Disease Control and Prevention's National Center for Health Statistics are encouraging. These data indicate that, since 2000, 5-year survival rates for adolescents and young adults have aligned with those for younger children.[61]

Even with these improvements, adolescents remain vulnerable to poorer outcomes relative to younger children. A particular area of concern is lower rates of participation in clinical trials among adolescents relative to younger

children. Because many adolescents are transitioning to adult providers for primary care services, they may be referred to an adult cancer center rather than a pediatric center at the time of diagnosis. If adolescents are treated in adult cancer centers, a clinical trial may not be available. Some clinical trials that are available to adults may not be open to adolescents younger than 18 years of age even if their disease biology is similar to that of adult disease,[61] and fewer trials are available for young adolescents. The National Cancer Institute (NCI) and pediatric and adult cooperative groups sponsored by the NCI have launched a national initiative to increase the numbers of adolescents and young adults participating in clinical trials.

Childhood cancer survivors have a greater risk of developing a second cancer later in life. This risk may be associated with a variety of factors, including specific types of chemotherapy, as well as radiation to certain areas of the body. Genetic factors and the type of primary cancer also influence the risk of a second cancer. For example, children with a history of familial retinoblastoma are at increased risk of osteosarcoma developing later in life.

Because childhood cancer is viewed as a chronic disease instead of a fatal illness, treatment includes attention to the quality of life and symptom management. Even children whose cancers cannot be cured can experience improved quality of life with palliative care. Children and adolescents whose cancers are regarded as cured continue to face residual and late effects of their treatment. These late effects are more significant in children than in adults because children receive their treatment at a time when they are still physically immature and growing. Many late effects of cancer treatment need further study. Common late effects include physical impairments, reproductive dysfunction, soft tissue and bone atrophy, learning disabilities, secondary cancers, and psychological sequelae. Priorities for future research include learning about the genetic and genomic consequences of treatment, such as telomere shortening, and their associated consequences on survivor health and well-being.[62] A referral to genetic services is appropriate for families of children whose cancer is known to be transmitted genetically (e.g., retinoblastoma, LFS).

Summary Review

Incidence and Types of Childhood Cancers

1. Cancer in children and adolescents is rare, but it is still the leading cause of death from disease in this population.
2. Leukemia is the most common type of cancer among children less than 14 years of age. Tumors involving the brain or central nervous system are the second most common type of childhood cancer.
3. The most common cancers among adolescents (15 to 19 years of age) are Hodgkin and non-Hodgkin lymphoma, leukemia, germ cell tumors (particularly testicular), CNS tumors, thyroid cancer, and sarcomas.

Etiology

1. The interaction of many factors most likely produces cancer in children and adolescents, a concept referred to as multiple causation or multifactorial etiology.
2. Mutations in proto-oncogenes, tumor-suppressor genes, and mismatch repair genes have been associated with childhood and adolescent malignancies.
3. Risk factors associated with the development of childhood cancer include inherited and acquired genetic and genomic changes, nutrition and diet, immune function, occupational exposure, hormonal variations, and viral illnesses, as well as other individual characteristics, such as biologic, social, or physical environments.
4. Children with Down syndrome have an increased risk for the development of leukemia.
5. Childhood exposure to ionizing radiation, drugs, or viruses has been associated with the risk of developing cancer.

Prognosis

1. Nearly 85% of children and adolescents diagnosed with cancer are cured.
2. Childhood cancer survivors have a greater risk of developing a second cancer during their lifetime compared with the general population.
3. Reasons for improved survival among children and adolescents with cancer include research aimed at identifying less toxic treatments with fewer long-term side effects.

4. Young children are particularly prone to long-term sequelae of cancer therapy. The development of more effective, targeted therapies with fewer side effects is imperative.

The human nervous system is a remarkable structure responsible for decision-making, the body's ability to interact with the environment, and the regulation and control of activities involving our internal organs, muscles, and glands. It is a network composed of complex structures that transmit electrical and chemical signals between the brain and the body's many organs and tissues. This chapter provides a basic overview of the structure and function of the nervous system and supports the understanding of nervous system pathophysiology in the following chapters.

Overview and Organization of the Nervous System

Although the nervous system functions as a unified whole, structures and functions have been divided here to facilitate understanding. Structurally, the nervous system is divided into the central nervous system and the peripheral nervous system (Fig. 15.1). The **central nervous system (CNS)** consists of the brain and spinal cord, enclosed within the protective cranial vault and vertebrae, respectively. The **peripheral nervous system (PNS)** is composed of the cranial nerves, which project from the brain, and the spinal nerves, which project from the spinal cord. Cranial nerves can be viewed as modified spinal nerves. Cranial nerves control motor and sensory functions similarly to spinal nerves and have specialized sensory tasks, such as smell, taste, sight, and hearing (see section on Peripheral Nervous System). PNS pathways are differentiated into **afferent pathways (ascending pathways)**, which carry sensory impulses toward the CNS, and **efferent pathways (descending pathways)**, which innervate skeletal muscle or effector organs by transmitting motor impulses away from the CNS. Most peripheral nerves carry a combination of both afferent and efferent pathways.

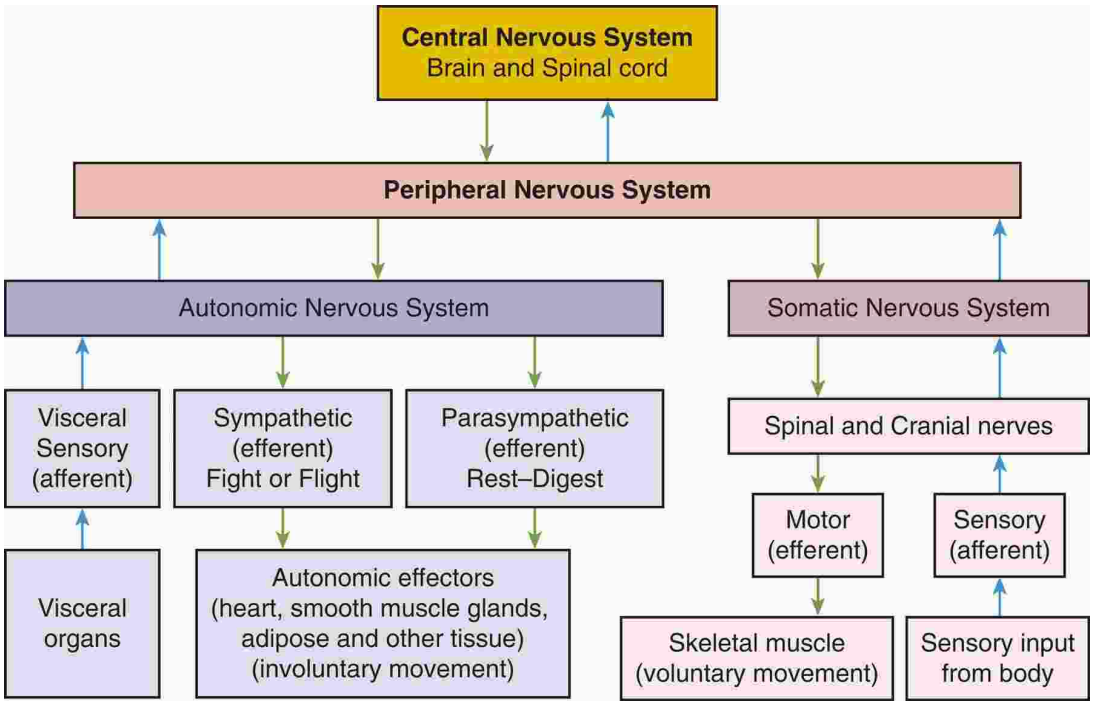

FIG. 15.1 **Organization of the Nervous System.**

A flowchart summarizes the organization of the nervous system through afferent and efferent pathways. The afferent (ascending) pathways in the organization are as follows. • Central nervous system (brain and spinal cord) and peripheral nervous system. • Peripheral nervous system and autonomic nervous system. • Autonomic nervous system and visceral sensory (afferent). • Visceral sensory (afferent) and visceral organs. • Peripheral nervous system and somatic nervous system. • Somatic nervous system and spinal and cranial nerves. • Sensory (afferent) and spinal and cranial nerves. • Sensory input from body and sensory (afferent). The efferent (descending) pathways in the organization are as follows. • Central nervous system (brain and spinal cord) and peripheral nervous system. • Peripheral nervous system and autonomic nervous system. • Autonomic nervous system and sympathetic (efferent) fight tot flight. • Sympathetic (efferent) fight or flight and autonomic effectors (heart, smooth muscle glands, adipose and other tissue) (involuntary movement). • Parasympathetic (efferent) rest-digest and autonomic effectors (heart, smooth muscle glands, adipose and other tissue)

(involuntary movement). • Peripheral nervous system and somatic nervous system. • Somatic nervous system and spinal and cranial nerves. • Spinal and cranial nerves and motor (efferent). • Motor (efferent) and skeletal muscle (voluntary movement).

Functionally, the PNS can be divided into the somatic nervous system and the autonomic nervous system. The **somatic nervous system** consists of pathways that regulate voluntary motor control (e.g., skeletal muscle). The **autonomic nervous system (ANS)** is involved in regulating the body's internal environment (viscera) through the involuntary control of organ systems. The ANS is further divided into sympathetic and parasympathetic divisions. Organs innervated by specific components of the nervous system are called **effector organs**.

Cells of the Nervous System

Two basic types of cells constitute nervous tissue: neurons and supporting nonneuronal neuroglial cells. The **neuron** is the primary cell of the nervous system. It is an electrically excitable cell, which transmits and receives information. **Neuroglial cells** provide structural support, protection, and nutrition for the neurons and facilitate neurotransmission. Neuroglial cells include astrocytes, microglia, and oligodendrocytes in the CNS; and Schwann (neurilemma) and satellite cells (a type of Schwann cell) in the PNS.

Neurons

Working alone or in units, neurons detect environmental changes and initiate body responses to maintain a dynamic steady state. Neuronal size and structure vary markedly, and each neuron is adapted to perform specialized functions. The cellular constituents of neurons include **microtubules** (transport substances within the cell), **neurofibrils** (very thin supportive fibers that extend throughout the neuron), **microfilaments** (proteins thought to be involved in the transport of cellular products), and **Nissl substances** (endoplasmic reticulum and ribosomes involved in protein synthesis). Although most neurons are nondividing cells, some neurons continue to divide after birth; for example, olfactory neurons in the nose continue to divide throughout life.

A neuron (Fig. 15.2) has three components: a cell body (soma), the dendrites (thin branching fibers of the cell), and the axons. Cell bodies for most neurons, even those extending axons into peripheral nerves, are located within the CNS. Dense collections of cell bodies in the CNS are called **nuclei**. Those in the PNS usually are found in groups called **ganglia** (or **plexuses**—a group of relay nerves). The **dendrites** are extensions that carry nerve impulses *toward* the cell body. The **dendritic zone** is the receptive portion of a neuron that receives a stimulus. **Axons** are long, conductive projections that carry nerve impulses *away* from the cell body. The **axon hillock** is the cone-shaped process

where the axon leaves the cell body. The first part of the axon hillock has the lowest threshold for stimulation, so action potentials begin there.

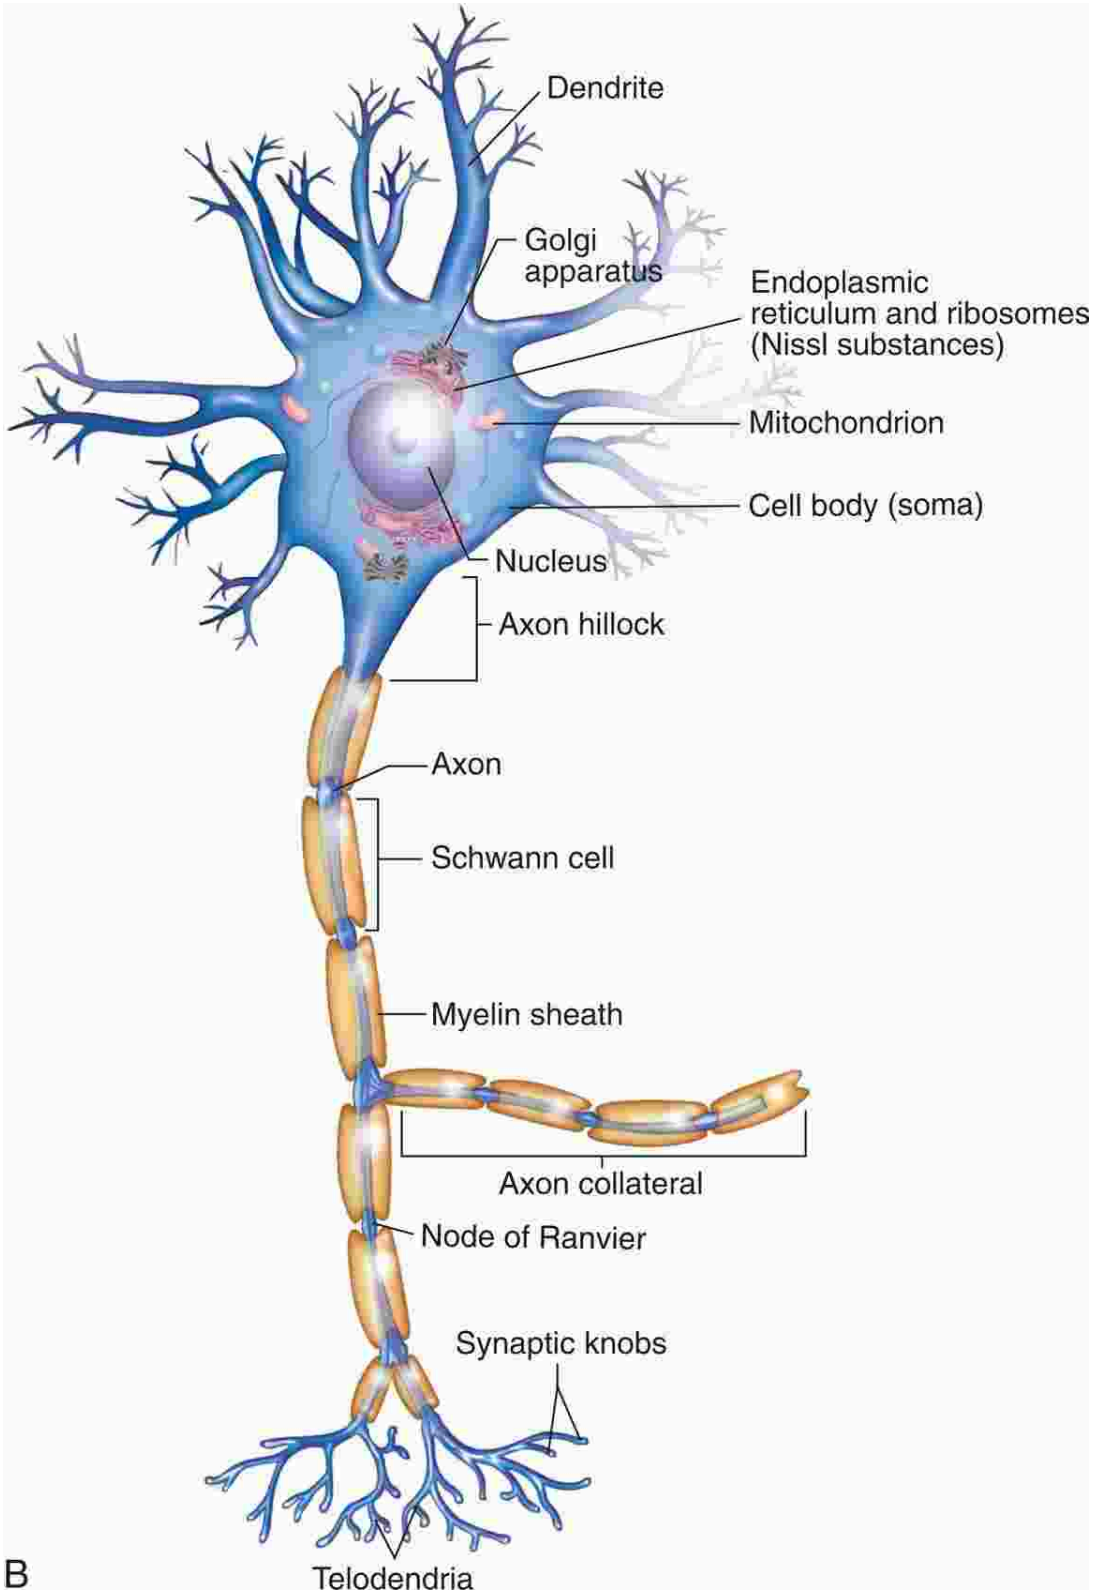

FIG. 15.2 Neuron Structure.
(A) Structural classifications of neurons based on the number of processes: unipolar, pseudopolar, bipolar, and multipolar. **(B)** Typical

multipolar neuron: Peripheral nervous system neuron with multiple extensions from the cell body. (A, From Watson C, Kirkcaldie M, Paxinos G. *The brain*. London: Academic Press; 2011. B, Modified from Patton KT, Thibodeau GA, Douglas MM. *Essentials of anatomy & physiology*. St. Louis: Mosby; 2012.)

A series of illustrations show neuron structures. Illustration A. There are four types of neurons. • Unipolar neuron. The illustration shows a nucleus inside a cell body with an axon and two synaptic knobs (nerve terminals). • Pseudounipolar neuron. The illustration shows a nucleus inside a cell body with a branch that splits into a dendrite on the right and an axon with synaptic knobs on the left. • Bipolar neuron. The illustration shows a nucleus inside a cell body with a branch on either side; dendrite on the right and axon with synaptic knobs on the left. • Multipolar neuron. The illustration shows a nucleus inside a cell body. The nucleus is surrounded by Nissl (in rough endoplasmic reticulum). The cell body has multiple branches of dendrites and one axon with synaptic knobs. Illustration B shows the structure of a typical multipolar neuron. The cell body has multiple dendrites and a nucleus at the center. Other structures inside the cell body (soma) are Golgi apparatus, endoplasmic reticulum and ribosomes (Nissl substances), and mitochondrion. An axon hillock extends into the axon with Schwann cell inside a myelin sheath. The axon branches into an axon collateral and a node of Ranvier that terminates with synaptic knobs on telodendrion.

A typical neuron has only one axon, which may be wrapped with a **myelin sheath**—a membrane made of a lipid material called **myelin**. In the CNS, myelin is produced by oligodendrocytes. Regions of the brain and spinal cord with a high level of myelination constitute the white matter, whereas regions lacking significant myelination (typically primarily composed of cell bodies) are gray matter. In the PNS, myelin is produced by Schwann cells. The myelin sheaths are interrupted at regular intervals by the **nodes of Ranvier**. Nutrient exchange is not possible through the myelin sheath, although it can occur at the nodes of Ranvier. Axons can branch at the nodes of Ranvier, forming axon collaterals. Axons end with telodendria, branches that terminate with synaptic knobs, which are used in neurotransmission.

Where there is myelin, the velocity of nerve impulses increases. Myelin acts as an insulator that allows an action potential to leap between segments rather than flowing along the entire length of the membrane, yielding the increased velocity. This

mechanism is referred to as **saltatory conduction**. Disorders of the myelin sheath (demyelinating diseases), such as multiple sclerosis, Guillain-Barré syndrome, and Charcot-Marie-Tooth disease, demonstrate the important role myelin plays in nerve conduction (see Chapter 17). Conduction velocities depend not only on the myelin coating but also on the diameter of the axon. Larger axons transmit impulses at a faster rate.

Neurons are structurally classified based on the number of processes (projections) extending from the cell body (see Fig. 15.2A). There are four basic types of cell configuration: (1) unipolar, (2) pseudounipolar, (3) bipolar, and (4) multipolar. **Unipolar neurons** have one process, an axon, which branches shortly after leaving the cell body. One example is found in the retina. **Pseudounipolar neurons** (*unipolar*) have one axon process and one dendrite process, but the dendrite and axon are fused near the cell body, and the axon then extends into the CNS. This configuration is typical of sensory neurons in both cranial and spinal nerves. **Bipolar neurons** have two distinct processes (one axon and one dendrite) arising directly from the cell body. This type of neuron connects the rod and cone cells of the retina. **Multipolar neurons** are the most common and have multiple processes capable of extensive branching. A motor neuron is typically multipolar.

Functionally, there are three types of neurons (their typical configuration is noted in parentheses): (1) sensory (mostly pseudounipolar), (2) associational (multipolar), and (3) motor (multipolar). **Sensory neurons** are afferent neurons, carrying impulses from peripheral sensory receptors to the CNS. **Associational neurons (interneurons)** transmit impulses from neuron to neuron, sensory to motor neurons. They are located solely within the CNS. **Motor neurons** are efferent neurons, transmitting impulses from the CNS to an effector (i.e., skeletal muscle or organs). In skeletal muscle, the end processes form a **neuromuscular (myoneural) junction** (see Fig. 15.14 and the Spinal Cord section later in the chapter).

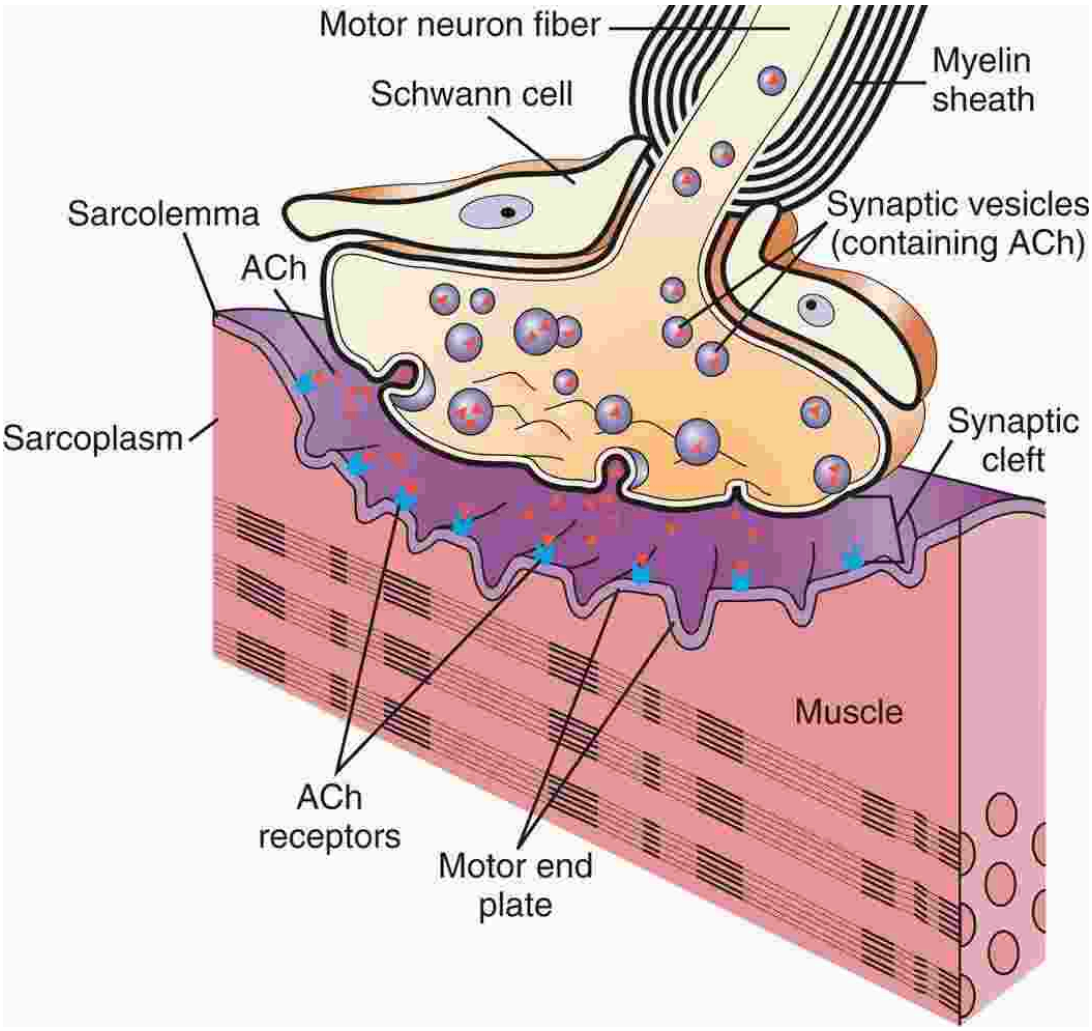

FIG. 15.14 Normal Neuromuscular Junction.
This figure shows how the distal end of a motor neuron fiber forms a synapse, or "chemical junction," with an adjacent muscle fiber. Neurotransmitters (specifically, acetylcholine *[ACh]*) are released from the neuron's synaptic vesicles and diffuse across the synaptic cleft. There they stimulate receptors in the motor end-plate region of the sarcolemma. (From Damjanov I. *Pathology for the health professions*, 4th edition. St. Louis: Saunders; 2012.)

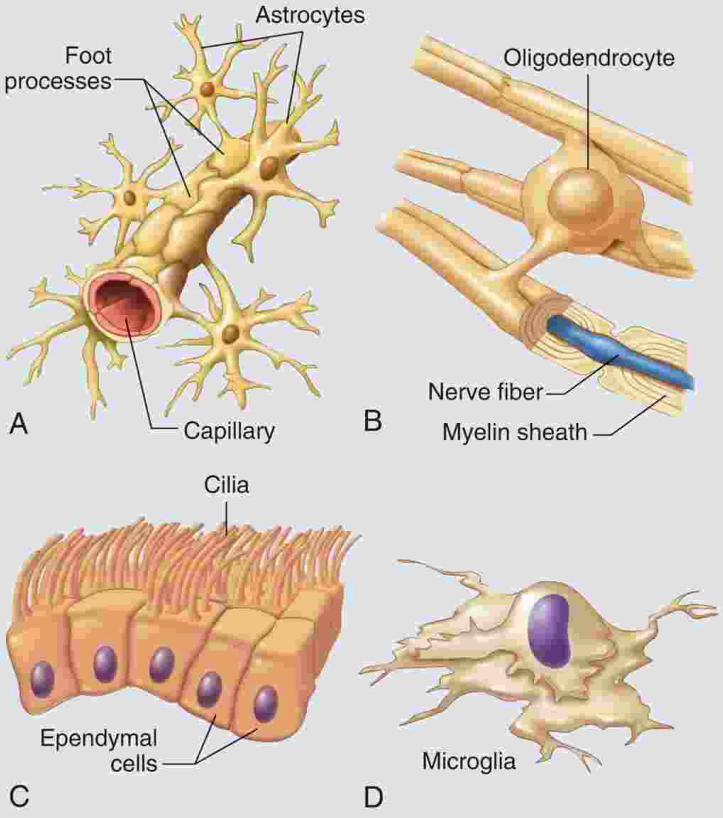
An illustration shows a cross-section of a normal neuromuscular junction. The following structures are labeled on the illustration: motor neuron fiber, myelin sheath, Schwann cell, synaptic vesicles (containing A C h), A C h, synaptic cleft, sarcolemma, A c h receptors, motor end plate, sarcoplasm, and muscle. Synaptic vesicles pass through the motor neuron fiber. The synaptic vesicles

release A C h into the synaptic cleft which bind to the A C h receptors on the motor end plate.

Neuroglia

Neuroglia (“nerve glue”) is the general classification of nonneuronal cells that support the nervous system's neurons. They comprise approximately 50% of the total brain and spinal cord volume. Neuroglia are present in both the CNS and PNS. **Astrocytes, oligodendroglia (oligodendrocytes), ependymal cells**, and **microglia** are found in the CNS; **Schwann cells**, **nonmyelinating Schwann cells**, and **satellite glial cell**s are found in the PNS (Fig. 15.3) (Emerging Science Box: Schwann Cells). The different types of neuroglia serve different functions (Table 15.1).

CENTRAL NERVOUS SYSTEM NEUROGLIA



PERIPHERAL NERVOUS SYSTEM NEUROGLIA

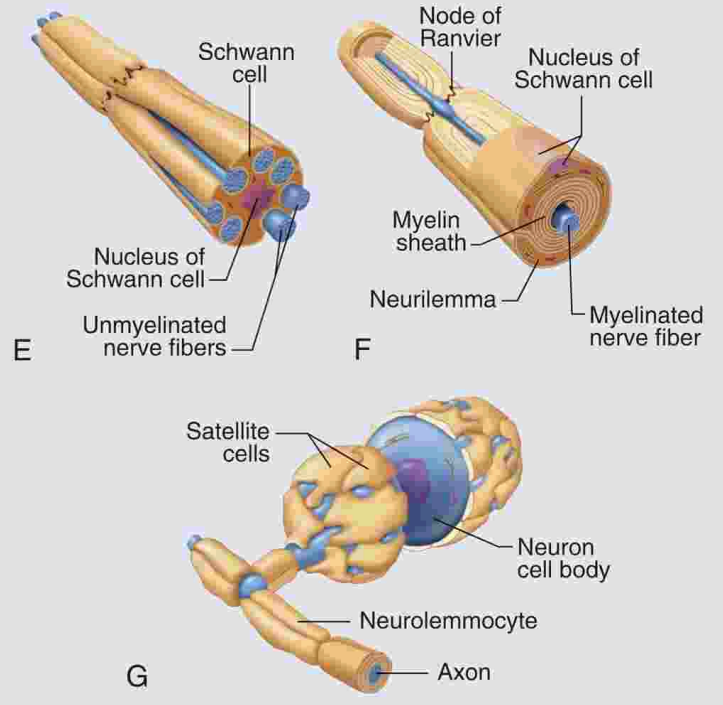


FIG. 15.3 Types of Neuroglial Cells.
Neuroglia of the central nervous system (CNS): **(A)** Astrocytes attached to the outside of a capillary blood vessel in the brain. **(B)** An oligodendrocyte with processes that wrap around nerve fibers in the CNS to form myelin sheaths. **(C)** Ciliated ependymal cells forming a sheet that usually lines fluid cavities in the brain. **(D)** A phagocytic microglial cell. Neuroglia of the peripheral nervous system (PNS): **(E)** A Schwann cell supporting a bundle of nerve fibers in the PNS. **(F)** Another type of Schwann cell encircling a peripheral nerve fiber to form a thick myelin sheath. **(G)** Satellite cells, another type of Schwann cell, surround and support cell bodies of neurons in the PNS. (From Patton KT, Thibodeau GA, Douglas MM. *Essentials of anatomy & physiology*. St. Louis: Mosby; 2012.)

A series of illustrations shows central nervous system neuroglia and peripheral nervous system neuroglia. The central nervous system neuroglia shows the following structures. • Illustration A. The structure shows the foot processes with multiple astrocytes around a single capillary. • Illustration B. The structure shows multiple nerve fibers, each covered in a myelin sheath and connected by oligodendrocyte. • Illustration C. The structure shows a layer of ependymal cells covered in cilia. • Illustration D. The structure shows microglia. The cells are distorted and shapeless. The peripheral nervous system neuroglia shows the following structures. • Illustration E. The structure shows a Schwann cell with a nucleus at the center. • Illustration F. The structure shows the node of Ranvier and labels the following structures beneath the nucleus of the Schwann cell, from the inside: myelinated nerve fiber, myelin sheath, neurilemma. • Illustration G. The structure shows a neuron cell body with satellite cells. The structure also labels the axon inside the neurolemmocyte.

Table 15.1

Support Cells of the Nervous System

Cell Type	Primary Functions
Central Nervous System	
Astrocytes	Form specialized contacts between neuronal surfaces and blood vessels
	Provide rapid transport for nutrients and metabolites
	Thought to form an essential component of blood-brain barrier
	Appear to be scar-forming cells of CNS, which may be foci for seizures
	Appear to work with neurons in processing information and memory storage
Oligodendroglia (oligodendrocytes)	Formation of myelin sheath in CNS
Microglia	Responsible for clearing cellular debris (phagocytic properties) and the key immune cell in the CNS
Ependymal cells	Serve as a lining for ventricles and choroid plexuses involved in production of cerebrospinal fluid
Peripheral Nervous System	
Schwann cells	Formation of myelin sheath in PNS
	Direct axonal regrowth and functional recovery in PNS
Nonmyelinating Schwann cells	Provide neuronal metabolic support and regeneration in PNS
Satellite glial cells	Surround sensory, sympathetic, and parasympathetic nerve cell bodies and ganglia to provide protection and promote cellular communication (similar to astrocytes in CNS)

CNS, Central nervous system; *PNS*, peripheral nervous system.

Nerve Injury and Regeneration

Mature nerve cells do not divide; therefore, injury can cause permanent loss of function. **Wallerian degeneration** occurs in the distal axon when an axon is severed, the portion cut off from the cell body, within hours of the injury. The morphologic and biochemical changes that occur in the distal axon include: (1) a characteristic swelling within the portion of the axon distal to the cut; (2) neurofilaments hypertrophy; (3) shrinkage and fragmentation of the myelin sheath; and (4) axon degeneration, and disappearance. The myelin sheaths reform into Schwann cells that align in a column between the severed part of the axon and the effector organ (Fig. 15.4B).

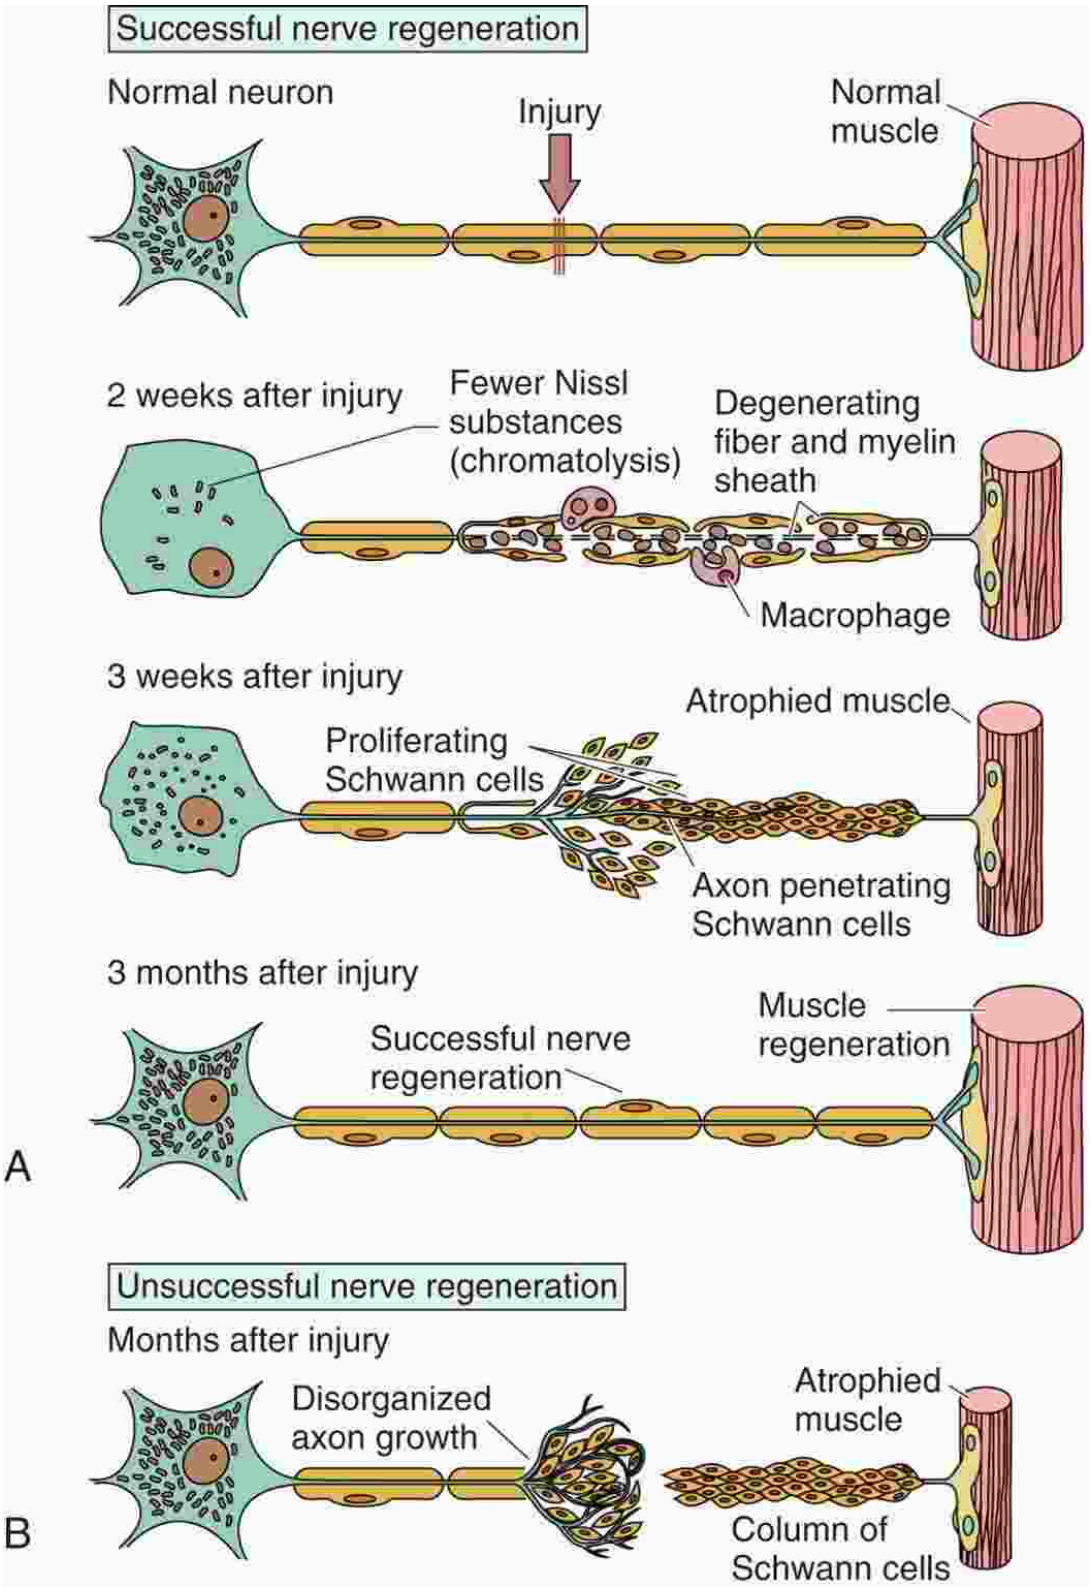

FIG. 15.4 Peripheral Nerve Regeneration Following Injury.
(A) In successful nerve regeneration, Schwann cells detach from the axons, proliferate, and, with recruited macrophages, help clear

cellular and myelin debris. A damaged motor axon can regrow to its distal connection only if the neurilemma remains intact (to form a guiding tunnel) and if scar tissue does not block its pathway. **(B)** Unsuccessful nerve regeneration results in the neuron remaining cut off from the effector organ. (From Gartner LP. *Textbook of histology*, 4th edition. Philadelphia: Elsevier; 2017.)

A series of illustrations show the peripheral nerve regeneration following injury. Illustration A. There are four stages of successful regeneration. Stage 1. The structure shows an injury along the axon of a normal neuron connected to a normal muscle. The cell body of the neuron comprises multiple Nissl substances. Stage 2, 2 weeks after injury. The structure shows fewer Nissl substances (chromatolysis) in the cell body. There are multiple macrophages along the degenerating fiber and myelin sheath. Stage 3, 3 weeks after injury. The structure shows an increase in Nissl substances in the cell body. Schwann cells proliferate around the axon penetrating the Schwann cells, connected to the atrophied muscle. Stage 4, 3 months after injury. The structure shows normal amount of Nissl substances in the cell body. The nerve has successfully regenerated and is connected to a regenerated muscle. Illustration B. An illustration shows the structure of a neuron in an unsuccessful nerve regeneration. The structure shows a cell body with Nissl substances. The site of disorganized axon growth along the axon is identified. A column of Schwann cells is connected to the atrophied muscle, but is disconnected from the axon.

At the proximal end of the injured axon, similar changes occur but only back to the next node of Ranvier. The cell body responds to trauma by swelling and dying by chromatolysis (dispersing the Nissl substance) or apoptosis. During the repair process, the cell increases protein synthesis and mitochondrial activity. Days to weeks after injury, new terminal sprouts project from the proximal segment and may enter the remaining Schwann cell pathway. (Fig. 15.4A contains a more detailed representation of these events.)

This process is very slow (about 1 mm/day) and is limited to myelinated fibers in the PNS. The regeneration of axonal constituents in the CNS is limited by an increased incidence of glial scar formation (gliosis) and the different nature of myelin formed by the oligodendrocyte.

Nerve regeneration depends on many factors, such as the location of the injury, the type of injury, the presence of inflammatory responses, and the process of scarring. The closer the injury is to the nerve's cell body, the greater chance that the nerve cell will die and not regenerate. A crushing injury allows for fuller recovery compared with a cut injury. Crushed nerves sometimes recover fully, whereas cut nerves often form connective tissue scars that block or slow regenerating axonal branches. Peripheral nerves injured close to the spinal cord recover poorly and slowly because of the long distance between the cell body and the peripheral termination of the axon.[1]

Nerve Impulse

Neurons generate and conduct electrical and chemical impulses by selectively changing the electrical potential of the plasma membrane and influencing other nearby neurons by releasing chemicals (neurotransmitters). An unexcited neuron maintains a resting membrane potential. When the membrane potential is sufficiently raised, an action potential is generated, and the nerve impulse then flows to all parts of the neuron. The action potential response occurs only when the stimulus is strong enough; the membrane remains unexcited if it is too weak. This property is termed the *all-or-none response* (see Chapter 1 for a discussion of electrical impulse conduction).

Synapses

Neurons are not physically contiguous with one another. The region between adjacent neurons is called a **synapse** (Fig. 15.5). The neurons that conduct a nerve impulse are named according to whether they relay impulses toward (**presynaptic neurons**) or away from (**postsynaptic neurons**) the synapse. The synapse is composed of a bulbous end of the presynaptic neuron (synaptic knob) that is separated from the postsynaptic neuron by a gap called the **synaptic cleft**. Four basic types of connections occur in regions of contact between the presynaptic and postsynaptic neurons. These are between axons (axo-axonic), from axon to cell body (axo-somatic), from axon to dendrite (axo-dendritic), and from dendrite to dendrite (dendro-dendritic).

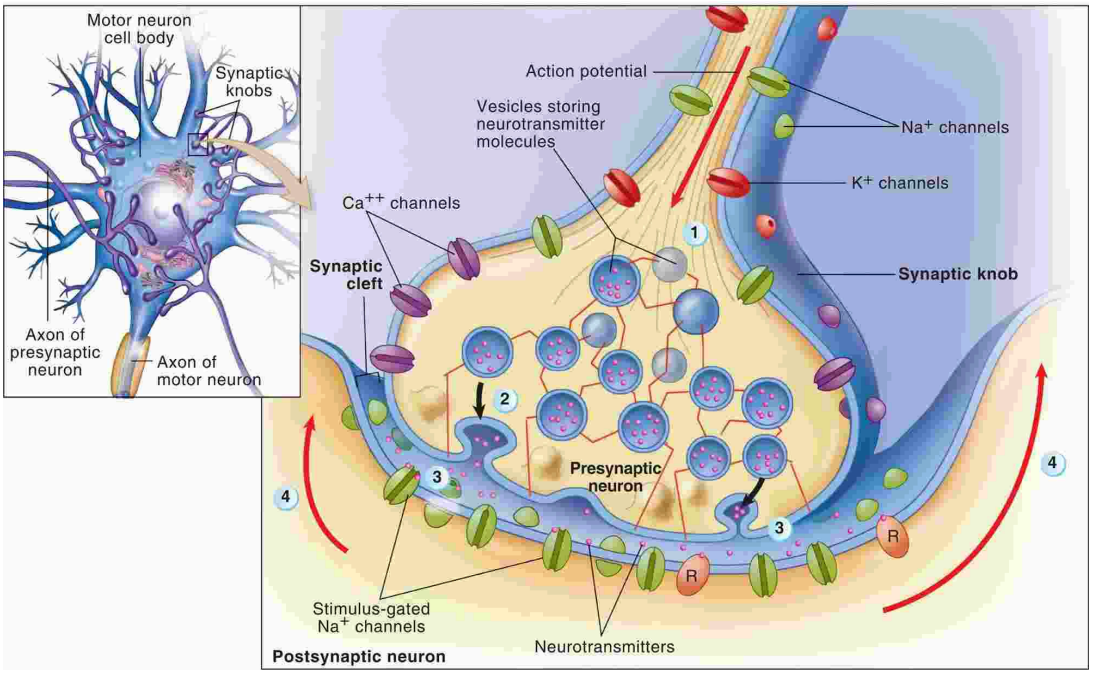

FIG. 15.5 **Neuronal Transmission and Synaptic Cleft.** Details illustrate the synaptic bouton (knob) of a presynaptic neuron, the plasma membrane of a postsynaptic neuron, and a synaptic cleft. At **step 1**, the action potential arrives at the synaptic bouton. At **step 2**, the rapid exocytosis of neurotransmitter molecules from vesicles in the knob occurs. At **step 3**, neurotransmitter diffuses into the synaptic cleft and binds to receptor molecules *(R)* in the plasma membrane of the postsynaptic neuron. The postsynaptic receptors directly or indirectly trigger the opening of stimulus gated ion channels, initiating a local potential in the postsynaptic neuron. At **step 4**, the local potential may move toward the axon, where an action potential may begin. (Adapted from Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Mosby; 2019.)

An illustration shows neuronal transmission and synaptic cleft. The structure of a motor neuron cell body with axon of presynaptic neuron, synaptic knobs, and axon of motor neuron. An accompanying illustration shows and labels the structures in the postsynaptic neuron. The structure identifies the action potential feeding into a synaptic knob. There are sodium ion channels, potassium ion channels, and calcium ion channels on the knob. A matrix of vesicles storing neurotransmitter molecules are identified at the base of the synaptic knob. Neurotransmitters are released into

the synaptic cleft that are attracted to the stimulus-gated sodium ion channels.

Impulses are transmitted across the synapse by chemical and electrical conduction (only chemical conduction is discussed here. Chapter 1 contains information on electrical conduction [see Fig.1.31].) When an impulse originates in a presynaptic neuron, the impulse reaches the vesicles, where chemicals (neurotransmitters) are stored in the **synaptic bouton**. Once released from the vesicles, the neurotransmitters diffuse across the synaptic cleft and bind to specific neurotransmitter (protein) receptor sites on the plasma membrane of the postsynaptic neuron, relaying the impulse (see Fig. 15.5). Brain synapses can change in strength and number throughout life, and this is known as synaptic plasticity or **neuroplasticity**.

Neurotransmitters

Neurotransmitters are chemicals synthesized in the neuron and localized in the presynaptic terminal (synaptic bouton). Neurotransmitters are released into the synaptic cleft in response to the arrival of an electrical impulse and bind to a receptor site (binding site) on the postsynaptic membrane of another neuron or effector, where they affect ion channels (see Fig. 15.5). Each neurotransmitter is removed by a specific mechanism from its site of action. Neurons can synthesize more than one neurotransmitter, and postsynaptic membranes can contain more than one type of transmitter-specific receptor. Many substances are neurotransmitters, including norepinephrine, acetylcholine, dopamine, histamine, and serotonin. Many of these transmitters have more than one function. **Neuromodulators** are chemical messengers released from a neuron in the CNS or the PNS, and this affects a group of neurons that have receptors for that messenger. They may have excitatory or inhibitory effects. Neurotransmitter and neuromodulator substances are summarized in Table 15.2.

Table 15.2

Substances That Are Neurotransmitters or Neuromodulators

Substance	Location	Effect	Clinical Example
Acetylcholine	Many parts of the brain, spinal cord, neuromuscular junction of skeletal muscle, and many ANS synapses	Excitatory or inhibitory	Alzheimer disease (a type of dementia) is associated with a decrease in the number of acetylcholine-secreting neurons. Muscle weakness caused by myasthenia gravis results from an autoimmune response to acetylcholine receptors on the postsynaptic terminal.
Monoamines			
Norepinephrine	Many areas of the brain and spinal cord; also in some ANS synapses	Excitatory or inhibitory	CNS: Sleep-wake cycles and mood. Cocaine and amphetamines[a] result in overstimulation of postsynaptic neurons. PNS: Sympathetic nerve transmission.
Serotonin	Many areas of the brain and spinal cord	Generally inhibitory	Is involved with mood, anxiety, and sleep induction. Levels of serotonin are elevated in schizophrenia (delusions, hallucinations, withdrawal).
Dopamine	Some areas of the brain and ANS synapses	Generally excitatory	Parkinson disease (depression of voluntary motor control) results from

Substance	Location	Effect	Clinical Example
			destruction of dopamine-secreting neurons. Drugs used to increase dopamine can induce vomiting and hallucinations.
Histamine	Posterior hypothalamus	Excitatory (H1 and H2 receptors) and inhibitory (H3 receptors)	There is no clear indication of histamine-associated pathologic conditions. Histamine is involved with arousal and attention and links to other brain transmitter systems.
Amino Acids			
Gamma-aminobutyric acid (GABA)	Most neurons of the CNS have GABA receptors	Majority of postsynaptic inhibition in the brain	Drugs that increase GABA function have been used to treat epilepsy by inhibiting excessive discharge of neurons.
Glycine	Spinal cord	Most postsynaptic inhibition in the spinal cord	Glycine receptors are inhibited by strychnine.
Glutamate and aspartate	Widespread in brain and spinal cord	Excitatory	Drugs that block glutamate or aspartate, such as riluzole, are used to treat amyotrophic lateral sclerosis. These drugs might prevent overexcitation from seizures and neural degeneration.
Neuropeptides			
Endorphins and enkephalins	Widely distributed in the CNS and	Generally inhibitory	Morphine and heroin bind to endorphin and

Substance	Location	Effect	Clinical Example
	PNS		enkephalin receptors on presynaptic neurons and reduce pain by blocking the release of neurotransmitters.
Substance P	Spinal cord, brain, and sensory neurons associated with pain, GI tract	Generally excitatory	Substance P is a neurotransmitter involved in pain transmission pathways. Blocking release of substance P by morphine reduces pain.
Vasoactive intestinal peptide	Gastrointestinal tract	Generally excitatory	Stimulates secretion, vasodilation, and smooth muscle relaxation (vasodilation, sphincter relaxation).

Substance	Location	Effect	Clinical Example
Acetylcholine	Many parts of the brain, spinal cord, neuromuscular junction of skeletal muscle, and many ANS synapses	Excitatory or inhibitory	Alzheimer disease (a type of dementia) is associated with a decrease in the number of acetylcholine-secreting neurons. Muscle weakness caused by myasthenia gravis results from an autoimmune response to acetylcholine receptors on the postsynaptic terminal.
Monoamines			
Norepinephrine	Many areas of the brain and spinal cord; also in some ANS synapses	Excitatory or inhibitory	CNS: Sleep-wake cycles and mood. Cocaine and amphetaminesa result in overstimulation of postsynaptic neurons. PNS: Sympathetic nerve transmission.
Serotonin	Many areas of the brain and spinal cord	Generally inhibitory	Is involved with mood, anxiety, and sleep induction. Levels of serotonin are elevated in schizophrenia (delusions, hallucinations, withdrawal).
Dopamine	Some areas of the brain and ANS synapses	Generally excitatory	Parkinson disease (depression of voluntary motor control) results from destruction of dopamine-secreting neurons. Drugs used to increase dopamine can induce vomiting and hallucinations.
Histamine	Posterior hypothalamus	Excitatory (H1 and H2 receptors) and inhibitory (H3 receptors)	There is no clear indication of histamine-associated pathologic conditions. Histamine is involved with arousal and attention and links to other brain transmitter systems.
Amino Acids			
Gamma-aminobutyric acid (GABA)	Most neurons of the CNS have GABA receptors	Majority of postsynaptic inhibition in the brain	Drugs that increase GABA function have been used to treat epilepsy by inhibiting excessive discharge of neurons.
Glycine	Spinal cord	Most postsynaptic inhibition in the spinal cord	Glycine receptors are inhibited by strychnine.
Glutamate and aspartate	Widespread in brain and spinal cord	Excitatory	Drugs that block glutamate or aspartate, such as riluzole, are used to treat amyotrophic lateral sclerosis. These drugs might prevent overexcitation from seizures and neural degeneration.
Neuropeptides			
Endorphins and enkephalins	Widely distributed in the CNS and PNS	Generally inhibitory	Morphine and heroin bind to endorphin and enkephalin receptors on presynaptic neurons and reduce pain by blocking the release of neurotransmitters.
Substance P	Spinal cord, brain, and sensory neurons associated with pain, GI tract	Generally excitatory	Substance P is a neurotransmitter involved in pain transmission pathways. Blocking release of substance P by morphine reduces pain.
Vasoactive intestinal peptide	Gastrointestinal tract	Generally excitatory	Stimulates secretion, vasodilation, and smooth muscle relaxation (vasodilation, sphincter relaxation).

ANS, Autonomic nervous system; *CNS*, central nervous system; *GI*, gastrointestinal; *PNS*, peripheral nervous system.

[a]Increase the release and block the reuptake of norepinephrine.

From Mtui E, Gruener G, Dockery P. *Fitzgerald's clinical neuroanatomy and neuroscience*, 7th edition. Philadelphia: Elsevier; 2016.

Because the neurotransmitter is normally stored on one side of the synaptic cleft, and the receptor sites are on the other side, chemical synapses operate in one direction.

Therefore, action potentials are transmitted along a multineuronal pathway in one direction. The binding of the neurotransmitter at the receptor site changes the permeability of the postsynaptic neuron and, consequently, its membrane potential. Two possible scenarios can occur:

1. The postsynaptic neuron may be excited (depolarized), called **excitatory postsynaptic potentials (EPSPs)**. If the EPSP reaches the threshold potential, an action potential is initiated.
2. The postsynaptic neuron's plasma membrane may be inhibited (hyperpolarized), called **inhibitory postsynaptic potentials (IPSPs)**. This makes the membrane less likely to reach the threshold potential, meaning the action potential is inhibited.

Chapter 1 reviews electrical impulses and membrane potentials.

Usually, a single EPSP cannot induce a neuron's action potential and the nerve impulse propagation. Whether this occurs, depends on the number and frequency of potentials the postsynaptic neuron receives—a concept known as **summation**. **Temporal summation** (time relationship) refers to the effects of successive, rapid impulses received from a single neuron at the same synapse. **Spatial summation** (spacing effect) is the combined effects of impulses from several neurons onto a single neuron simultaneously. **Facilitation** refers to the effect of EPSP on the plasma membrane potential. The plasma membrane is *facilitated* when summation brings the membrane closer to the threshold potential and decreases the stimulus required to induce an action potential. The effect that a chemical neurotransmitter has on the plasma membrane potential depends on the balance of these effects. The mechanisms of **convergence** (many neurons firing and converging on one neuron), **divergence** (one neuron firing and diverging on many neurons), summation, and facilitation allow for the integrative processes of the nervous system.

Central Nervous System

Brain

The **brain** is a functionally integrated circuit of millions of neurons with different genomes, structures, molecular composition, networks, and connections. It weighs approximately 3 pounds and receives 15% to 20% of the total cardiac output. The brain enables a person to reason, function intellectually, express personality and mood and perceive and interact with the environment.

The **cerebrum** is the largest part of the brain and contains both gray matter and white matter. The three primary embryonic vesicles (structural divisions) of the brain are (1) the forebrain (prosencephalon), (2) the midbrain (mesencephalon), and (3) the hindbrain (rhombencephalon). These three vesicles then develop further into the secondary vesicles and their structures, which are summarized in Table 15.3 and Fig. 15.6. The midbrain, medulla, and pons comprise the **brainstem**, which connects the brain's hemispheres, cerebellum, and spinal cord. A collection of nerve cell bodies (nuclei) within the brainstem makes up the **reticular formation**. The reticular formation

is a large network of diffuse nuclei that connect the brainstem to the cortex and control vital reflexes, such as cardiovascular function and respiration. It is essential for maintaining wakefulness and attention and is referred to as the **reticular activating system** (Fig. 15.7). Some nuclei within the reticular formation support specific motor movements, such as balance and posture.

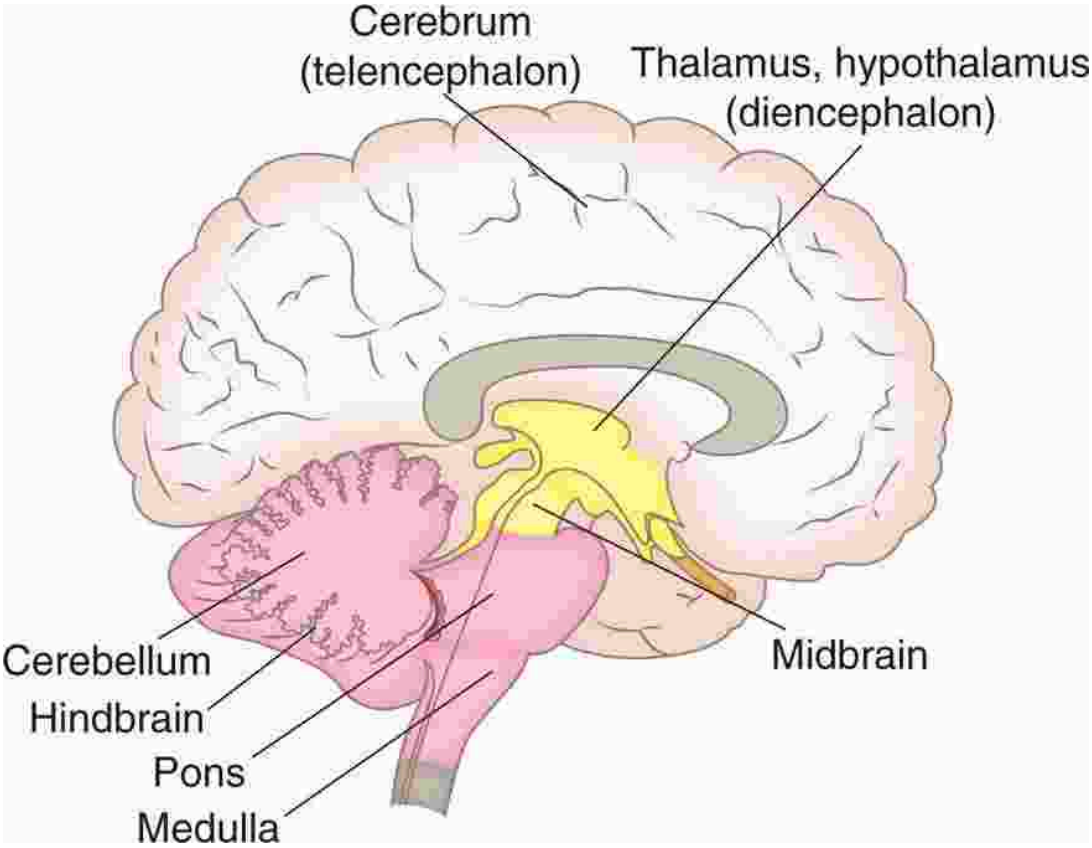

FIG. 15.6 Structural Divisions of the Brain. (From Standring S. *Gray's anatomy: The anatomical basis of clinical practice*, 40th edition. Philadelphia: Elsevier; 2008.)

An illustration shows the right lateral view of the brain and identifies the following structures, from the forebrain to the hindbrain: cerebrum (telencephalon), thalamus, hypothalamus (diencephalon), midbrain, cerebellum, hindbrain, pons, and medulla.

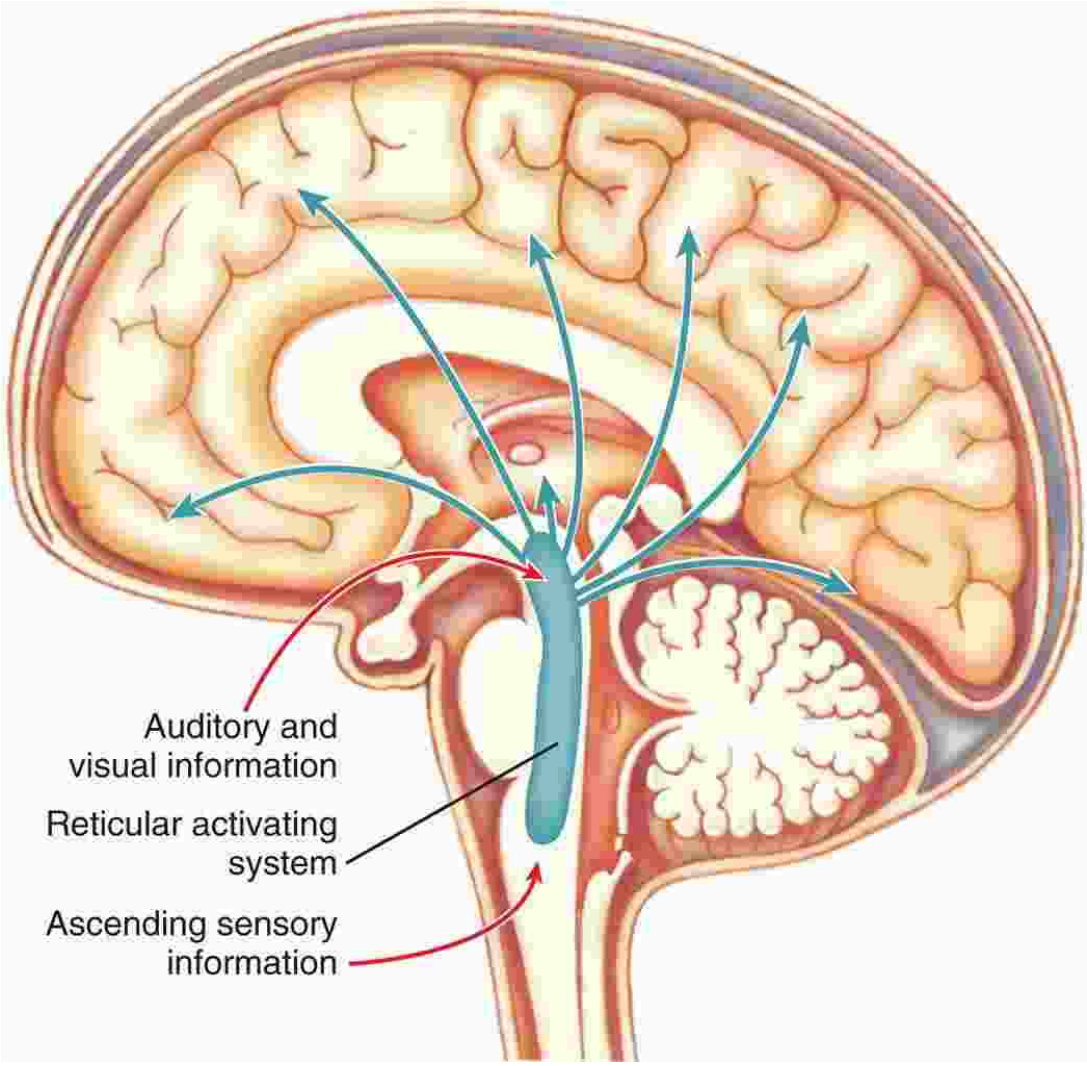

FIG. 15.7 Reticular Activating System.
The reticular activating system consists of nuclei in the brainstem reticular formation plus fibers that conduct sensory information to the nuclei and fibers that conduct from the nuclei to widespread areas of the cerebral cortex. Functioning of the reticular activating system is essential for consciousness.

An illustration shows the left lateral view of the human brain and traces the paths through reticular activating system. Auditory and visual information and ascending sensory information pass through the reticular activating system and spread inside the brain.

Divisions of the brain are associated with different functions but attributing specific functions to definite brain regions is not entirely accurate. However, functional specificity is very useful for localizing pathologic conditions in various nervous system

regions for clinical considerations. **Brodmann areas** are used to correlate functional activities to many regions of the cerebral cortex.[2]Fig. 15.8C illustrates these regions and describes some of the areas. The mapping of **brain networks** is also helpful in discovering how varying parts of the brain are interconnected when performing a specific function (see Emerging Science: Brain Networks).

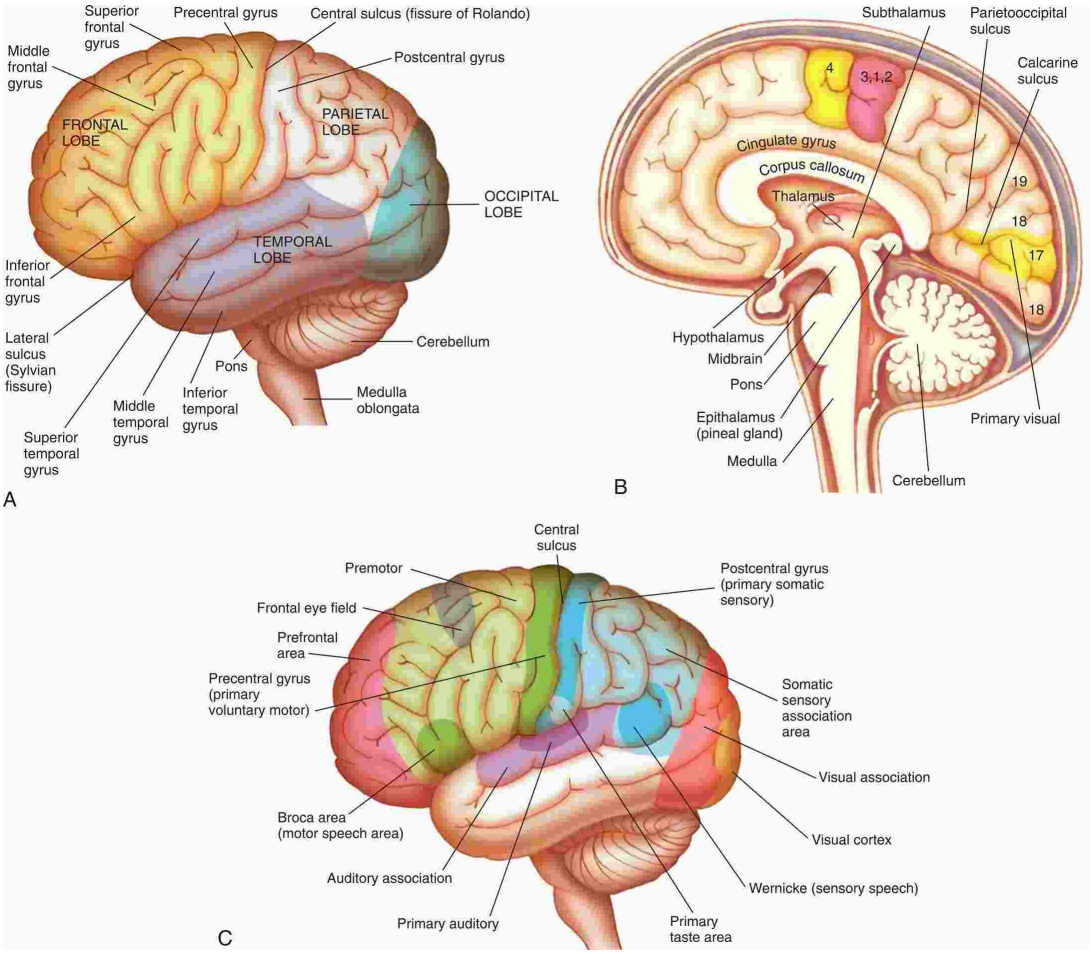

FIG. 15.8 The Cerebral Hemispheres.
(A) Left hemisphere of cerebrum, lateral view. **(B)** Functional areas of the cerebral cortex, midsagittal view. **(C)** Functional areas of the cerebral cortex, lateral view.

Three illustrations of the left lateral and midsagittal views of the human brain label the cerebral hemispheres. Illustration A. The following structures are identified in the frontal lobe: inferior frontal gyrus, middle frontal gyrus, superior frontal gyrus, and precentral gyrus. The central sulcus (fissure of Ronaldo) separates the frontal lobe from the parietal lobe. The postcentral gyrus in the parietal lobe is identified. The lateral sulcus (Sylvian fissure) separates the frontal lobe from the temporal lobe. The following structures are identified in the temporal lobe: inferior temporal gyrus, middle temporal gyrus, and superior temporal gyrus. The occipital lobe is identified at the back of the brain. The cerebellum is

labeled at the base of the brain, followed by the pons and the medulla oblongata. Illustration B. The following structures are labeled from above the midbrain to the hindbrain: thalamus, hypothalamus, subthalamus, corpus callosum, cingulate gyrus, parietooccipital sulcus, calcarine sulcus, and primary visual. The following structures are identified below the thalamus: epithalamus (pineal gland), midbrain, pons, cerebellum, and medulla. Illustration C. The following structures of the brain are labeled, clockwise from the frontal lobe: bronco area (motor speech area), prefrontal area, frontal eye field, premotor, precentral gyrus (primary voluntary motor), central sulcus, postcentral gyrus (primary somatic sensory), somatic sensory association area, visual association, visual cortex, Wernicke (sensory speech), primary taste area, primary auditory, auditory association, and Broca area (motor speech area).

Forebrain

Telencephalon

The **telencephalon (cerebral hemispheres)** consists of the cerebral cortex (the largest portion of the brain) and the basal ganglia (composed of several *nuclei*). The surface of the cerebral cortex is covered with convolutions called *gyri* (see Fig. 15.8A), which greatly increase the cortical surface area and the number of neurons. Grooves between adjacent gyrus are termed **sulci**; deeper grooves are fissures. The **cerebral cortex** contains an outer layer of cell bodies of neurons called **gray matter**, which is organized into columns perpendicular to the surface that receive, integrate, store, and transmit information. The cerebral cortex is located in the frontal, parietal, temporal, and occipital lobes. **White matter** lies beneath the cerebral cortex and is composed of myelinated nerve fibers (axons).

Lobes

The two cerebral hemispheres are separated by a deep groove known as the **longitudinal fissure** (see Fig. 15.10B). The surface of each hemisphere is divided into lobes named after the region of the skull under which each lobe lies: frontal, parietal, occipital, and temporal lobes.

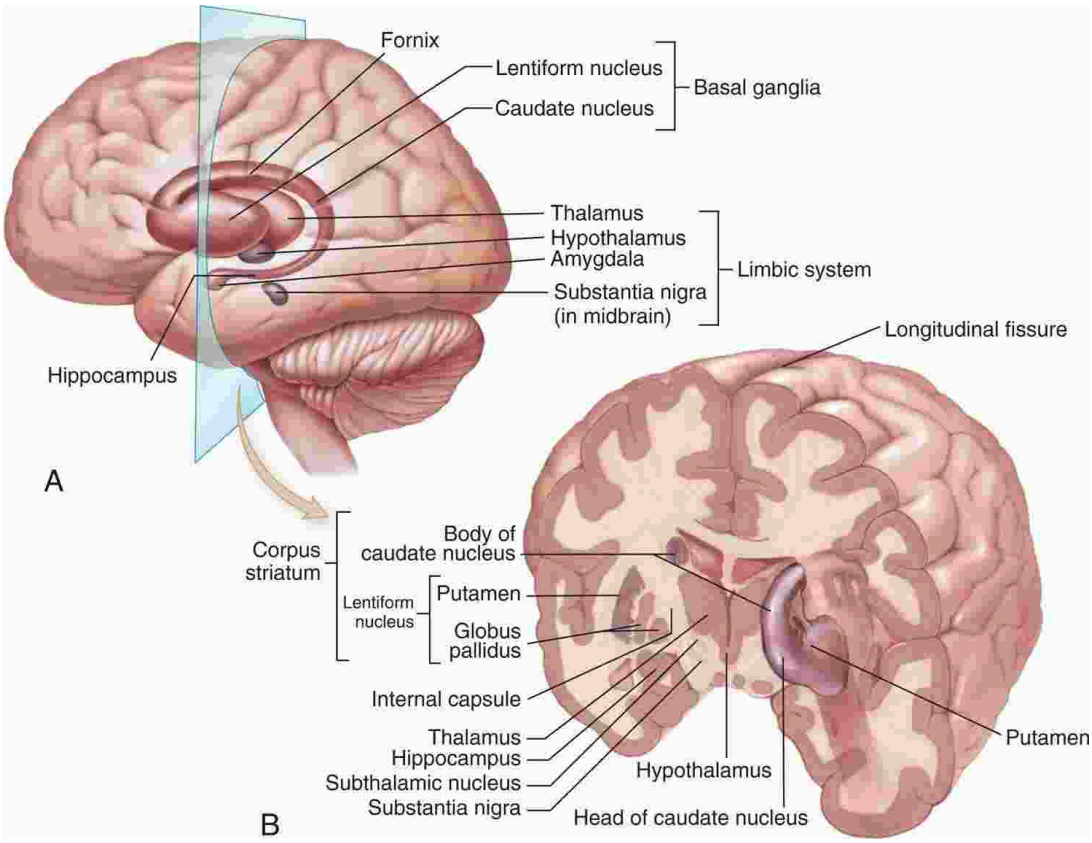

FIG. 15.10 **Basal Ganglia.**
(A) The basal ganglia seen through the cortex of the left cerebral hemisphere. **(B)** The basal ganglia seen in a frontal (coronal) section of the brain. The nucleus accumbens is not visible in this figure; it lies between the caudate nucleus and putamen. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th edition. St. Louis: Mosby; 2016.)

Illustration A shows the left cerebral hemisphere and labels the following structures: hippocampus, fornix, basal ganglia (lentiform nucleus, caudate nucleus), limbic system (thalamus, hypothalamus, amygdala, and substantia nigra in midbrain). Illustration B shows a cross-sectional view of the coronal section of the brain shows and labels the following structures: longitudinal fissure, putamen, head of caudate nucleus, hypothalamus, substantia nigra, subthalamic nucleus, hippocampus, thalamus, internal capsule, and corpus striatum. Corpus striatum is made of body of caudate nucleus and lentiform nucleus. The lentiform nucleus is made of putamen and globus pallidus.

The posterior margin of the **frontal lobe** is on the **central sulcus (fissure of Rolando)**, and it borders inferiorly on the **lateral sulcus (Sylvian fissure, lateral fissure)** (see Fig. 15.8A). The prefrontal area is responsible for goal-oriented behavior (e.g., ability to concentrate), short-term or recall memory, the elaboration of thought, and inhibition of the limbic areas of the CNS. The premotor area (Brodmann area 6) (see Fig. 15.8C) is involved in programming motor movements. This area contains the cell bodies that form part of the basal ganglia system. The frontal eye fields (the lower portion of Brodmann area 8), which control eye movements, are located on the middle frontal gyrus.

The primary motor area (Brodmann area 4) is located along the **precentral gyrus** forming the **primary voluntary motor area**. It has a specific correspondence between a body region and an area in the brain (somatotopic organization) that is often referred to as a *homunculus* (little man) (Fig. 15.9). Electrical stimulation of specific areas of this cortex causes specific muscles of the body to move. For example, stimulation of Brodmann area 4 in the medial longitudinal fissure affects the lower limb and foot, whereas stimulation of the superior lateral surface of the precentral gyrus affects the torso and arm, the middle third of the hand, and the lower third of the face and mouth/throat. The axons traveling from the cell bodies in and on either side of this gyrus project fibers (axons) that form the **pyramidal system**. This system includes the **corticobulbar tract** that synapses in the brainstem and provides voluntary control of muscles in the head and neck and the **corticospinal tracts** that descend into the spinal cord and provide voluntary control of muscles throughout the body. Cerebral impulses control function on the opposite side of the body, a phenomenon called *contralateral control* (see Fig. 15.15 later in the chapter). The Broca speech area is on the inferior frontal gyrus (Brodmann areas 44, 45). It is usually on the left hemisphere and is responsible for the motor aspects of speech. Damage to this area, commonly as a result of a cerebrovascular accident (stroke), results in the inability to form words or at least some difficulty in forming words (expressive aphasia) (see Chapter 17).

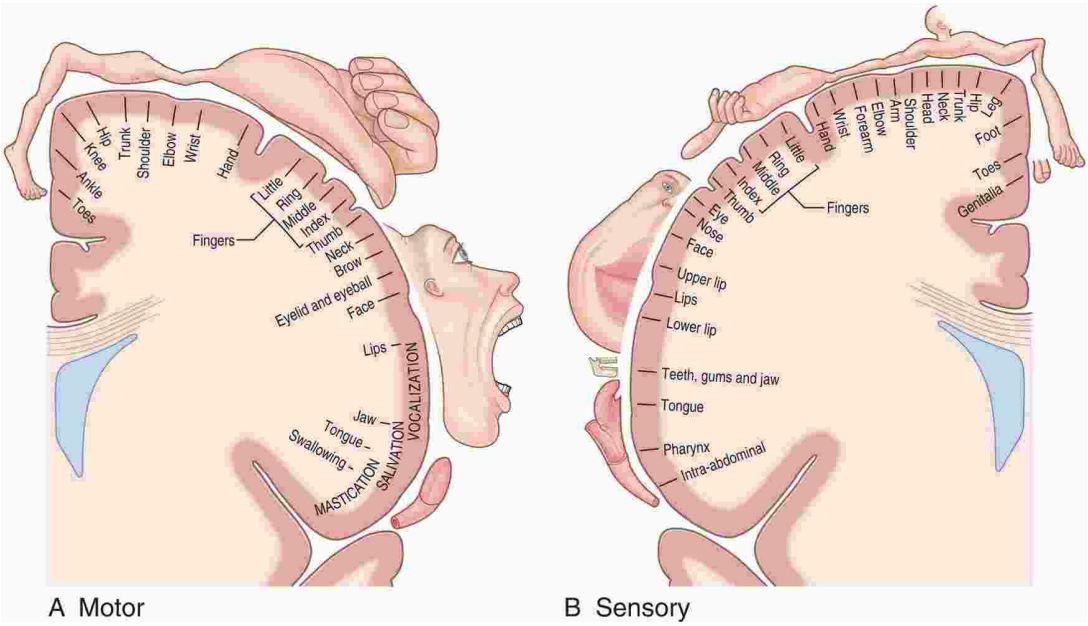

FIG. 15.9 Primary Somatic Sensory (A) and Motor (B) Areas of the Cortex.

(A) The motor homunculus shows proportional somatotopic representation in the main motor area. **(B)** The sensory homunculus shows proportional somatotopic representation in the somaesthetic cortex. (From Standring S. *Gray's Anatomy*. 40th edition. Edinburgh: Churchill Livingstone; 2008.)

Illustration A shows the representations in the main motor area, clockwise from the top: toes, ankle, knee, hip, trunk, shoulder, elbow, wrist, hand, fingers (little, ring, middle, index, thumb), neck, brow, eyelid and eyeball, face, lips (vocalization), jaw (salivation), tongue, and swallowing (mastication). Illustration B shows the representation in the somaesthetic cortex, counterclockwise from the top: genitalia, toes, foot, leg, hip, trunk, neck, head, shoulder, arm, elbow, forearm, hand, fingers (little, ring, middle, index, thumb), eye, nose, face, upper lip, lips, lower lip, teeth, gums, and jaw, tongue, pharynx, and intra-abdominal.

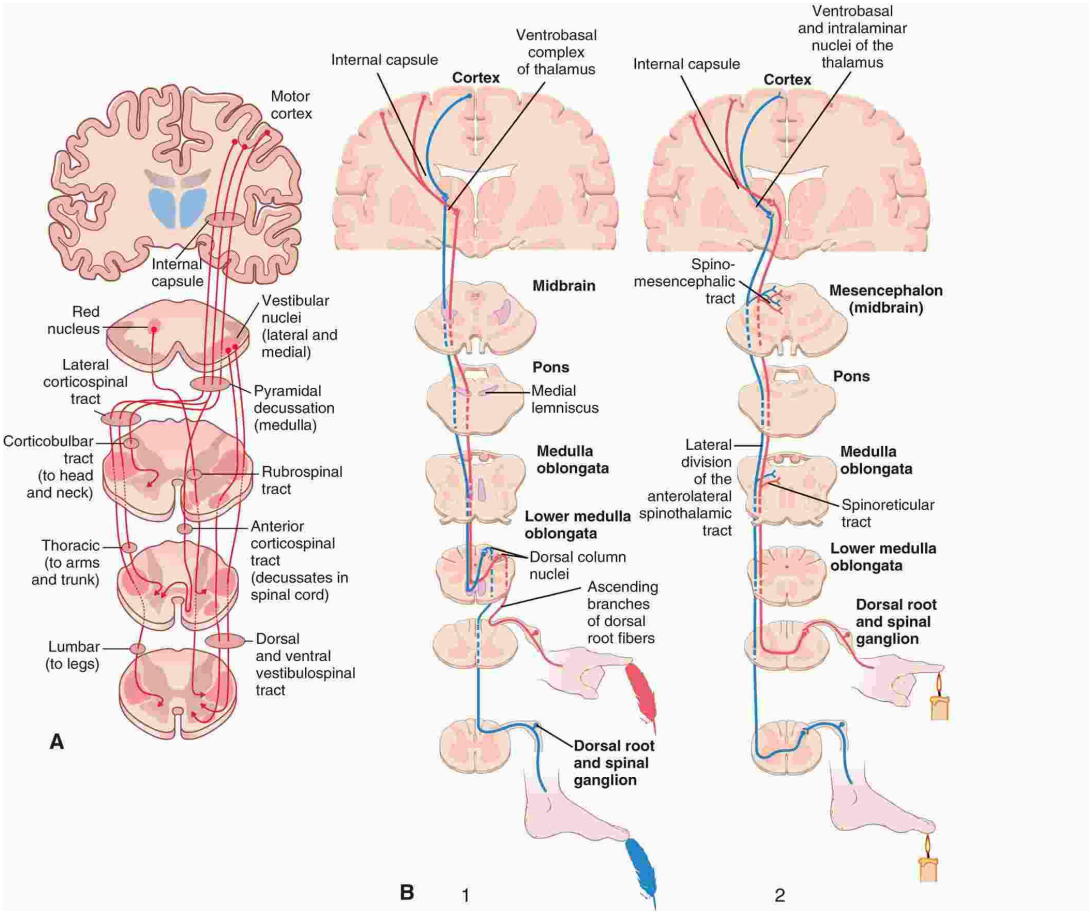

FIG. 15.15 Examples of Somatic Motor and Sensory Pathways. **(A)** Motor tracts. The pyramidal pathway through the lateral corticospinal tract and the extrapyramidal pathways through the rubrospinal, reticulospinal, and vestibulospinal tracts. Note that the pathways from the motor cortex cross over to the opposite side of the body, demonstrating contralateral control. **(B)** Sensory tracts. **1,** The dorsal column-medial lemniscal pathway for transmitting critical types of tactile signals: touch/proprioception. Note the lateral corticospinal tract decussation; the point where it crosses to the other side is in the lower medulla. **2,** Anterior and lateral divisions of the anterolateral spinothalamic sensory tract: pain/temperature. Note the decussation is in the spinal cord. (A, From Compston A, Lassmann H, McDonald I. *McAlpine's multiple sclerosis*, 4th edition. London: Churchill Livingstone; 2006. B, From Hall JE. *Guyton and Hall textbook of medical physiology*, 13th edition. Philadelphia: Saunders; 2016.)

Illustration A traces the somatic motor pathways from the motor cortex. Three pathways traced on the illustration are as follows • Motor cortex through internal capsule, vestibular nuclei (lateral and medial), pyramidal decussation (medulla), lateral corticospinal

tract, corticobulbar tract (to head and neck), and thoracic (to arms and trunk), to lumbar (to legs). • Vestibular nuclei (lateral and medial) through rubrospinal tract and anterior corticospinal tract (decussates in spinal cord), to dorsal and ventral vestibulospinal tract. • Red nucleus through rubrospinal tract and anterior corticospinal tract (decussates in spinal cord), to dorsal and ventral vestibulospinal tract. Illustration B traces two sensory pathways from the cortex. 1. The tip of the index finger touches a feather, activating the ascending branches of dorsal root fibers. The tip of the big toe touches a feather, activating the dorsal root and spinal ganglion. The pathways are then traced through the following structures: ascending branches of dorsal root fibers, dorsal column nuclei in lower medulla oblongata, medulla oblongata, pons (medial lemniscus), midbrain, spino-mesencephalic tract in mesencephalon (midbrain), and internal capsule (pathway from foot) or ventrobasal complex of thalamus (pathway from hand). 2. The tip of the index finger and the big toe touch a candle flame each, activating the dorsal root and spinal ganglion. The pathways are then traced through the following structures: dorsal root and spinal ganglion, lower medulla oblongata, spinoreticular tract, medulla oblongata, lateral division of the anterolateral spinothalamic tract, pons, and internal capsule (pathway from hand) or ventrobasal and intralaminar nuclei of the thalamus (pathway from foot).

The **parietal lobe** lies within the borders of the central, parietooccipital, and lateral sulci. This lobe contains the major area for somatic sensory input, located primarily along the **postcentral gyrus** (Brodmann areas 3, 1, 2) (see Fig. 15.8), which is adjacent to the primary motor area precentral gyrus. Communication between the motor and sensory areas (and among other regions in the cortex) is provided by **association fibers**. Much of this region is involved in sensory association (storage, analysis, and interpretation of stimuli). Fig. 15.9 shows the distribution of functions associated with both the primary motor area and the primary sensory area of the cerebral cortex.

The **occipital lobe** lies caudal to the parietooccipital sulcus and is superior to the cerebellum. The primary visual cortex (Brodmann area 17) is located in this region and receives input from the retinas. Much of the remainder of this lobe is involved in visual association (Brodmann areas 18, 19). The **temporal lobe** lies inferior to the lateral fissure and is composed of the superior, middle, and inferior temporal gyri. The primary

auditory cortex (Brodmann area 41) and related association area (Brodmann area 42) lie deep within the lateral sulcus on the superior temporal gyrus. The Wernicke area (posterior portion of Brodmann area 22) and adjacent portions of the parietal lobe constitute a *sensory speech area*. This area is responsible for reception and interpretation of speech, and dysfunction may result in receptive aphasia or dysphasia. The temporal lobe also is involved in memory consolidation and smell.

Another lobe, the **insula (insular lobe)**, lies hidden from view in the lateral sulci between each hemisphere's temporal and frontal lobes. The insula processes sensory and emotional information and routes the information to other areas of the brain. Lying directly beneath the longitudinal fissure is a mass of white matter pathways called the **corpus callosum (transverse or commissural fibers)**. This structure connects the two cerebral hemispheres through sensory and motor contralateral projection of axons and is essential in coordinating activities between hemispheres (see Fig. 15.8B).

Basal ganglia

Inside the cerebrum are numerous tracts (white matter) and nuclei (gray matter). The major **subcortical nuclei** are called the **basal ganglia (basal nuclei) system**. The basal ganglia system is a group of nuclei that includes the caudate nucleus, putamen, and globus pallidus (Fig. 15.10). The **putamen** and the **globus pallidus** together are called the **lentiform nucleus** (because they are shaped like a lentil). The caudate nucleus, putamen, and nucleus accumbens together are called the **striatum**. Functionally, the **substantia nigra** is a component of the basal ganglia. It synthesizes **dopamine**, a neurotransmitter and precursor of norepinephrine. The basal ganglia nuclei are important for voluntary movement and cognitive and emotional functions (i.e., the nucleus accumbens has pleasure and reward functions).

The **internal capsule** is a thick layer of white matter in which axons of afferent (sensory) and efferent (motor) pathways pass to and from the cerebral cortex through the center of the cerebral hemispheres and between the caudate and lentiform nuclei (see Fig. 15.10B). The basal ganglia, plus their direct and indirect interconnections with the thalamus, premotor cortex, red nucleus, reticular formation, and spinal cord, have been considered part of the extrapyramidal system. The **extrapyramidal system** is part of the motor control system that causes involuntary reflexes and coordinated movement and stabilizes motor control. Parkinson disease and Huntington disease are characterized by disruption of the extrapyramidal system and various involuntary or exaggerated motor movements (see Chapter 17).

Limbic system

The **limbic system** is a group of interconnected structures between the telencephalon and diencephalon and surrounding the corpus callosum. It comprises the amygdala, hippocampus, fornix, hypothalamus, and related autonomic nuclei (see Fig. 15.10A). It is an extension or modification of the olfactory system and influences the autonomic and endocrine systems. Its principal effects are involved in primitive behavioral responses, visceral reaction to emotion, motivation, mood, feeding behaviors, biologic rhythms, and the sense of smell. The limbic system mediates emotion and long-term memory through connections in the prefrontal cortex (limbic cortex).

Diencephalon

The **diencephalon (interbrain)** is surrounded by the cerebrum and sits on top of the brainstem. It controls vital functions and visceral activities and is closely associated with those of the limbic system. The diencephalon has four divisions: epithalamus, thalamus, hypothalamus, and subthalamus (see Table 15.3 and Fig. 15.8). The **epithalamus** forms the roof of the third ventricle (a brain cavity) and composes the most superior portion of the diencephalon.

The **thalamus** is the largest component of the diencephalon, and it borders and surrounds the third ventricle. It is a major integrating center for afferent impulses to the cerebral cortex. Various sensations are perceived at this level, but cortical processing is required for interpretation. The thalamus also serves as a relay center for information from the basal ganglia and cerebellum to the appropriate motor area.

The **hypothalamus** forms the base of the diencephalon. The hypothalamus functions to (1) maintain a constant internal environment and (2) implement behavioral patterns. Integrative centers control ANS function, regulate body temperature and endocrine function, and adjust emotional expression. The hypothalamus exerts its influence through the endocrine system and neural pathways (Box 15.1). The **subthalamus** flanks the hypothalamus laterally. It serves as an important basal ganglia center for motor activities.

Box 15.1

Functions of the Hypothalamus

- Visceral and somatic responses
- Affectual responses
- Hormone synthesis
- Sympathetic and parasympathetic activity
- Temperature regulation
- Fluid balance
- Appetite and feeding responses
- Physical expression of emotions
- Sexual behavior
- Pleasure-punishment centers
- Level of arousal or wakefulness

Midbrain

Mesencephalon

The **midbrain (mesencephalon)** is com-posed of the tectum (**corpora quadrigemina** [forms roof of the midbrain]), the tegmentum, and the cerebral peduncles. The tectum

includes two pairs of superior colliculi and two pairs of inferior colliculi. The **superior colliculi** are involved with voluntary and involuntary visual-motor movements (e.g., the ability of the eyes to track moving objects in the visual field). The **inferior colliculi** accomplish similar motor activities but involve movements affecting the auditory system (e.g., positioning the head to improve hearing). The **tegmentum** (the floor of the midbrain) is composed of the red nucleus and substantia nigra. The **red nucleus** receives ascending sensory information from the cerebellum and projects a minor motor pathway, the rubrospinal tract, to the cervical spinal cord. The **substantia nigra** synthesizes dopamine. The **cerebral peduncles** of the anterior midbrain are made up of efferent fibers of the corticospinal, corticobulbar, and corticopontocerebellar tracts (tracts that link the cortex to the brainstem).

Other notable structures of this region are the nuclei of the third and fourth cranial nerves. The **cerebral aqueduct (aqueduct of Sylvius)**, which carries cerebrospinal fluid (CSF), also traverses this structure. Obstruction of this aqueduct is often the cause of hydrocephalus.

Hindbrain

Metencephalon

The major structures of the **metencephalon** are the cerebellum and the pons. The **cerebellum** (seeFig. 15.8) is composed of two lobes of gray matter and white matter, and its cortical surface is convoluted, similar to the surface of the cerebrum. It also is divided by a central fissure into the right and left lobes connected by the **vermis**.

The cerebellum is responsible for reflexive, involuntary fine-tuning of motor control and maintaining balance and posture through extensive neural connections with the medulla (through the inferior cerebellar peduncle) and the midbrain (through the superior cerebellar peduncle). The two hemispheres are connected to the pons by the middle cerebellar peduncles. These connections allow extensive sampling of visual, vestibular, and proprioceptive data from other regions of the CNS and periphery. The cerebellum has *ipsilateral control* (same side) of the body, in contrast to the cerebral cortex, which has contralateral control of the body.

The **pons** (bridge) is easily recognized by its bulging appearance below the midbrain and above the medulla. Primarily it transmits information from the cerebellum to the brainstem and between the two cerebellar hemispheres. The nuclei of the fifth through eighth cranial nerves are located in this structure.

Myelencephalon

The **myelencephalon** usually is called the *medulla oblongata* and forms the lowest portion of the brainstem. Reflex activities, such as heart rate, respiration, blood pressure, coughing, sneezing, swallowing, and vomiting, are controlled in this area. The nuclei of cranial nerves IX through XII are located in this region.

A major portion of the descending motor pathways (i.e., corticospinal tracts) cross to the other side, or decussate, at the medulla (see Fig. 15.15 later in the chapter). These pathways, together with other areas of decussation in the CNS, are the basis for the phenomenon of **contralateral control** when cerebral impulses control function on the

opposite side of the body. Sleep–wake rhythms also are processed by neural influences from lower brain centers and are associated with a complex group of diffuse structures and functions (see Chapter 16), including the reticular activating system (cells that receive collateral signals from the afferent sensory pathways and project the signals to the higher brain centers, thus controlling CNS activity) (see Fig. 15.7).

Spinal Cord

The **spinal cord** is the portion of the CNS that lies within the vertebral canal and is surrounded and protected by the **vertebral column**. The spinal cord has many functions, including connecting the brain and the body through a long nerve cable, somatic and autonomic reflexes, motor pattern control, and sensory and motor modulation. The spinal cord originates in the medulla oblongata and ends at the first or second lumbar vertebra level in adults (Fig. 15.11A). The end of the spinal cord, the **conus medullaris**, is cone-shaped. Spinal nerves continue from the end of the spinal cord and form a nerve bundle called the **cauda equine**. The filament anchor from the conus medullaris to the coccyx is the **filum terminale**. The coverings of the spinal cord are illustrated in Fig. 15.11C.

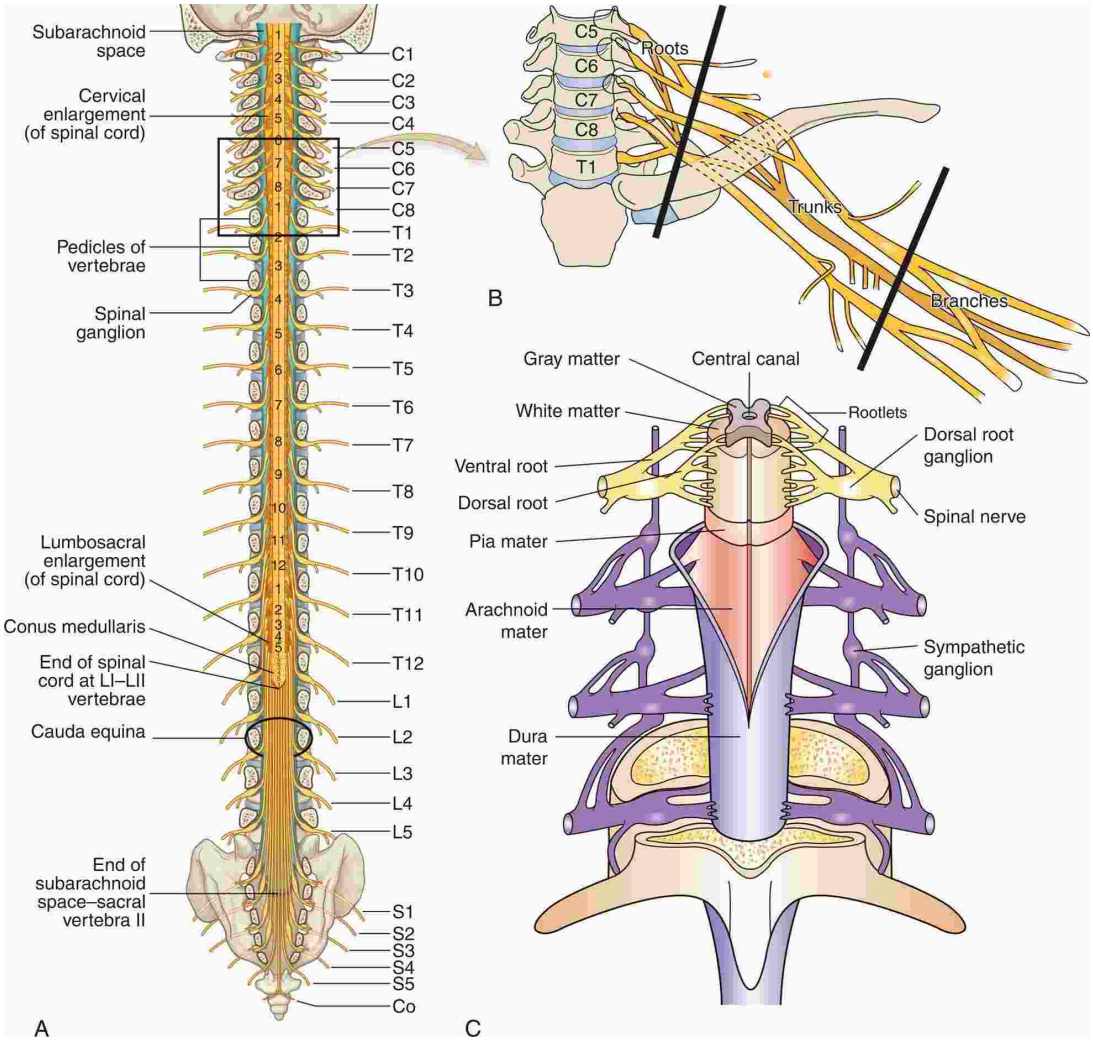

FIG. 15.11 Vertebral Canal, Spinal Cord, and Spinal Nerves. **(A)** Spinal cord and nerve root; cranial through sacral nerve distributions. **(B)** Enlarged schematic of the brachial plexus is shown. The general schematic of a spinal nerve can be compared to a tree with roots, trunks, and branches. **(C)** Coverings of the spinal cord. The dura mater is shown in purple. Note how it extends to cover the spinal nerve roots and nerves. The arachnoid mater is highlighted in pink and the pia mater in orange. (A, From Drake R, Gray H, Vogl W, et al. *Gray's anatomy for students*, 3rd edition. London: Churchill Livingstone; 2015. B, From Tu YK, Chung KC. *Practical management of pediatric and adult brachial plexus palsies*. London: Saunders; 2012. C, From Patton KT, Thibodeau GA. *Structure and function of the body*, 15th edition. St. Louis: Mosby; 2016.)

Illustration A shows the spinal cord and labels its different sections. From the top, the sections are as follows: subarachnoid space, cervical enlargement (of spinal cord), pedicles of vertebrae, spinal

ganglion, lumbosacral enlargement (of spinal cord), conus medullaris, end of spinal cord at L 1 and L 2 vertebrae, cauda equina, and end of subarachnoid space-sacral vertebra 2. The vertebrae are labeled from the top as follows: C 1 to C 8, T 1 to T 12, L 1 to L 5, S 1 to S 5, and C o. Illustration B shows a section of spinal cord, C 5 to T 1. The spinal nerves connected to the spinal cord comprise branches, trunks, and roots. Illustration C shows the coverings of the spinal cord. From the inside to the outside, the structures are as follows: central canal, gray matter, white matter, rootlets, ventral root, dorsal root, dorsal root ganglion, spinal nerve, pia mater, arachnoid mater, dura mater, and sympathetic ganglion.

Grossly, the spinal cord is divided into vertebral sections (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) that correspond to paired nerves (see Fig. 15.11A). A cross section of the spinal cord (Fig. 15.12) is characterized by a butterfly-shaped inner core of gray matter (containing nerve cell bodies). The **central canal** is filled with CSF, lies in the center of this region, and extends through the spinal cord from its origin in the fourth ventricle. The gray matter of the spinal cord is divided into three regions and displays specific functional characteristics. These regions include the posterior horn, the lateral horn, and the anterior horn. The **posterior horn**, or dorsal horn, is composed primarily of interneurons and axons from sensory neurons whose cell bodies lie in the **dorsal root ganglion**. At the tip of the posterior horn is the **substantia gelatinosa**, a structure involved in pain transmission (see Chapter 16). The **lateral horn** contains cell bodies involved with the ANS. The **anterior horn**, or ventral horn, contains the nerve cell bodies for efferent pathways that leave the spinal cord by way of spinal nerves.

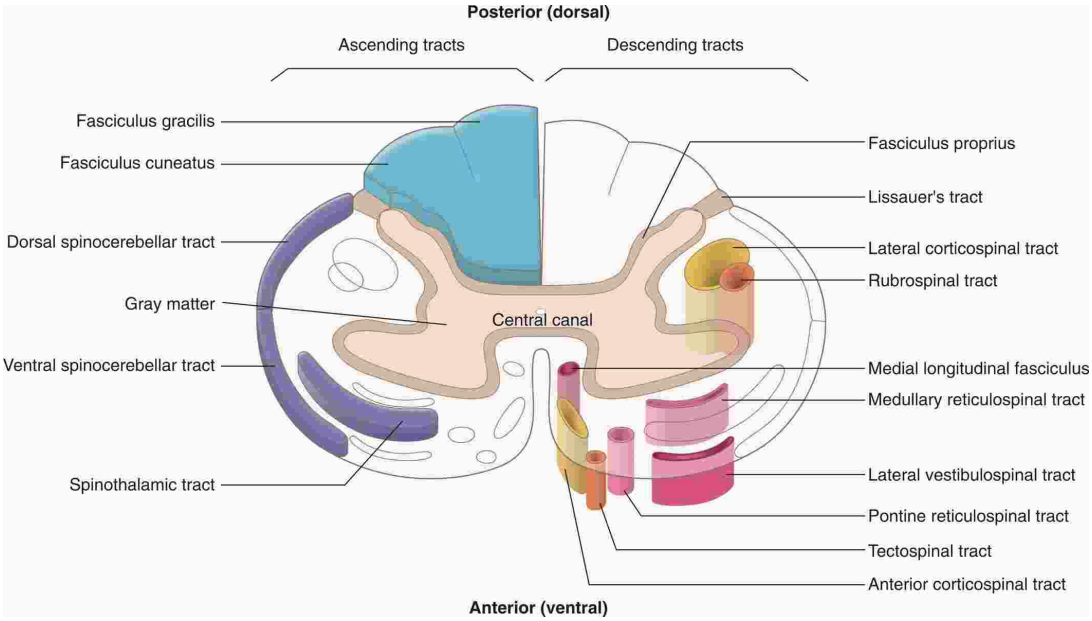

FIG. 15.12 The Spinal Cord. All ascending *(sensory)* and descending *(motor)* tracts are present bilaterally. In this figure, ascending tracts are emphasized on the left side, and descending tracts are emphasized on the right side. The location of the Lissauer tract and the fasciculus proprius (which contain both ascending and descending fibers) are also shown. (From Crossman AR, Neary D. *Neuroanatomy: An illustrated colour text*, 4th edition. London: Churchill Livingstone; 2015.)

An illustration of the central canal with the posterior (dorsal) side at the top and the anterior (ventral) side at the bottom identifies the ascending descending tracts in the spinal cord. The ascending tracts, from the top to the bottom, are as follows: fasciculus gracilis, fasciculus cuneatus, dorsal spinocerebellar tract, gray matter, ventral spinocerebellar tract, and spinothalamic tract. The descending tracts, from the top to the bottom, are as follows: fasciculus proprius, Lissauer's tract, lateral corticospinal tract, rubrospinal tract, medial longitudinal fasciculus, medullary reticulospinal tract, lateral vestibulospinal tract, pontine reticulospinal tract, tectospinal tract, and anterior corticospinal tract.

Surrounding the gray matter is white matter, which forms ascending and descending pathways called **spinal tracts**. Spinal tracts are named to denote their beginning and ending points. For example, the **spinothalamic tract** (see Fig. 15.12) carries sensory

nerve impulses from the spinal cord to the thalamus in the diencephalon. Numerous spinal tracts are grouped into columns according to their location within the white matter. These include the **anterior columns, lateral columns**, and **posterior columns** (see Fig. 15.12).

Neural circuits in the spinal cord, when activated, display specific sets of motor responses. **Reflex arcs** form basic units that respond to stimuli and provide protective circuitry for motor output. Structures needed for a reflex arc are a receptor, an **afferent (sensory) neuron**, an **efferent (motor) neuron**, and an effector muscle or gland. A simple reflex arc (e.g., knee-jerk reflex) may contain only two neurons (Fig. 15.13). Interneurons are usually present and provide a link between sensory and motor neurons. The motor effects of reflex arcs generally occur before the event is perceived in the brain's higher centers. Much internal environmental regulation is mediated by the ANS's reflex activity (e.g., cardiac muscle and smooth muscle contraction/relaxation and glandular responses).

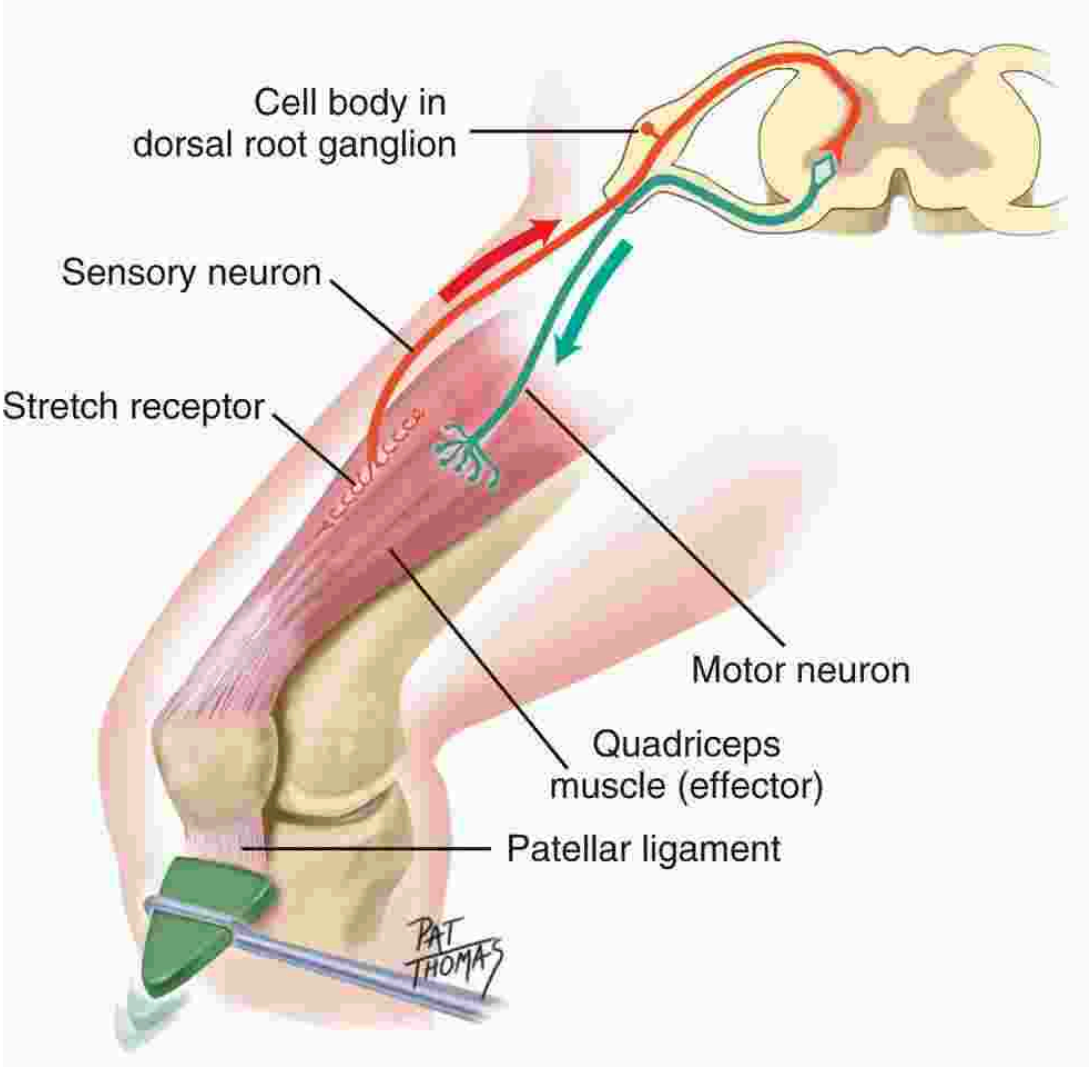

FIG. 15.13 Cross-Section of Spinal Cord Showing Simple Reflex Arc. (From Jarvis C. *Physical examination & health assessment*, 7th edition. St. Louis: Saunders; 2016.)

An illustration shows the cross-section of the spinal cord. The following structures are labeled along structure: cell body in dorsal root ganglion, sensory neuron, stretch receptor, motor neuron, quadriceps muscle (effector), and patellar ligament.

Afferent pathways transmit sensory information from peripheral receptors toward the cerebrum. The pathways terminate in the cerebral or cerebellar cortex or both. Efferent pathways primarily relay information away from the cerebrum to the brainstem or spinal cord. **Upper motor neurons** (i.e., corticospinal and corticobulbar tracts) are completely contained within the CNS. Their primary roles are controlling fine motor movement and influencing/modifying spinal reflex arcs and circuits. Generally,

upper motor neurons form synapses with interneurons, forming synapses with lower motor neurons that project into the periphery. **Lower motor neurons** directly influence muscles. Their cell bodies lie in the brainstem and spinal cord's gray matter, but their processes extend out of the CNS and into the PNS. Destruction of upper motor neurons usually results in initial paralysis followed within days or weeks by partial recovery, whereas destruction of the *lower motor neurons*leads to paralysis unless peripheral nerve damage is followed by nerve regeneration and recovery (see Fig. 15.4). Differences in injury to upper and lower motor neurons are presented in Chapter 17.

Nerve impulses regulate muscle activity (i.e., stimulation and contraction). Motor neurons innervate one or more muscle cells, forming **motor units**, consisting of a neuron and the skeletal muscles it stimulates. The junction between the axon of the motor neuron and the plasma membrane of the muscle cell is called the neuromuscular (myoneural) junction (Fig. 15.14). (Injury to motor neurons is discussed in Chapter 17.)

Motor Pathways

Clinically relevant motor pathways are the lateral corticospinal (connects motor cortex with anterior horn cells in the spinal cord) and pyramidal tracts (connects the motor cortex with the medullary pyramids and descend to synapse with lower motor neurons of several cranial nerves in the brain stem or spinal cord); and the extrapyramidal reticulospinal, vestibulospinal, and rubrospinal tracts. The corticospinal and corticobulbar pathways are essentially the same tract and consist of a two-neuron chain (Fig. 15.15). The cell bodies (upper motor neurons) originate in and around the precentral gyrus; pass through the corona radiata (connects motor and sensory pathways) of the cerebrum, the internal capsule, middle three-fifths of the cerebral pedunculus, pons, and pyramid; and decussate (cross contralaterally) in the medulla oblongata and form the lateral corticospinal tract of the spinal cord (see Figs. 15.12 and 15.15A) and thus control the opposite side of the body. The **corticobulbar tract axons** synapse on motor cranial nuclei within the brainstem that control the face, head, and neck muscles. The lateral corticospinal tract axons leave the tract to go to specific interneurons or motor neurons in the anterior horn. The **lateral corticospinal tract** has the same somatotopic organization as the body (see Figs. 15.9 and 15.15A). These lower motor neurons project through nerves to specific muscles.

The extrapyramidal tracts are involved in precise motor movements. The **reticulospinal tract** arises in the reticular formation of the medulla or pons (see Fig. 15.12) and modulates motor movement by inhibiting and exciting spinal activity. The **vestibulospinal tract** arises from a vestibular nucleus in the pons and causes the extensor muscles of the body to rapidly contract, most dramatically witnessed when a person starts to fall backward. The **rubrospinal tract** originates in the red nucleus, decussates, and terminates in the cervical spinal cord. It is important for muscle movement and fine muscle control in the upper extremities.

Sensory Pathways

The three clinically important spinal afferent pathways are the posterior column, **anterior spinothalamic tract**, and lateral spinothalamic tract (see Figs. 15.12 and

15.15B). The **posterior (dorsal) column (fasciculus gracilis** and **fasciculus cuneatus**) carries fine-touch sensation, two-point discrimination, and proprioceptive information (i.e., **epicritic information**). The posterior column is formed by a three-neuron chain. The first neuron of the chain is the primary afferent neuron. It also is the sensory neuron of the reflex arc. After entering the spinal cord, it sends its axon ipsilaterally (on the same side) up the spinal cord to a specific part of the posterior column and synapses in the three posterior column nuclei in the medulla oblongata. For example, a basketball player who is above 6 feet tall has primary afferent neurons that could be 6 feet long, running from the great toe up to the medulla oblongata. The axon of the second-order neuron crosses contralaterally in the medial lemniscus and ascends in the medulla and pons to synapse with a specific nucleus of the thalamus. The third-order neuron, originating in the thalamus, continues the tract into the internal capsule, corona radiata, and postcentral gyrus (Brodmann areas 3, 1, 2) (see Fig. 15.8, and 15.15B).

The **anterior** and **lateral spinothalamic tracts** are responsible for vague touch sensation and pain and temperature perception, respectively (see Figs. 15.12 and 15.15; see Chapter 16). These modalities are referred to as **protopathic**. These tracts also form a three-neuron chain. However, their primary afferent neurons synapse in the posterior horn of the spinal cord is not just at the level they enter the intervertebral foramen but in several spinal segments above and below their point of entry. This is an example of divergence. The axons of the second-order neurons in the posterior horn cross to the contralateral side in the spinal cord in the lateral column, ascend to the same thalamic nucleus as the posterior column pathway, and continue with the posterior column pathway to the postcentral gyrus.

Protective Structures

Cranium

The cranial vault encloses and protects the brain and its associated structures. The bony cranium comprises eight bones (frontal, two parietal, two temporal, ethmoid, sphenoid, and occipital). The **galea aponeurotica**, a thick, fibrous band of tissue overlying the cranium between the frontal and occipital muscles, affords added protection to the skull. The subgaleal space has venous connections with the dural sinuses. If there is increased intracranial pressure, blood can be shunted to the space, thus reducing pressure in the intracranial cavity. The subgaleal space is also a common site for wound drains after intracranial surgery.

The floor of the cranial vault is irregular and contains many foramina (openings) for cranial nerves, blood vessels, and the spinal cord to exit. The cranial floor is divided into three fossae (depressions). The frontal lobes lie in the **anterior fossa**, the temporal lobes and base of the diencephalon lie in the **middle fossa (temporal fossa)**, and the cerebellum lies in the **posterior fossa**. These terms are commonly used anatomic landmarks to describe the location of intracranial lesions.

Meninges

Surrounding the brain and spinal cord are three protective membranes: the dura mater, the arachnoid, and the pia mater. Collectively they are called the **meninges** (Fig.

15.16C). The **dura mater** (meaning literally "hard mother") is composed of two layers, with the venous sinuses formed between them. The outermost layer forms the **periosteum (endosteal layer)** of the skull. The **inner dura (meningeal layer)** is responsible for forming rigid membranes that support and separate various brain structures. One of these membranes, the **falx cerebri**, dips between the two cerebral hemispheres along the longitudinal fissure. The falx cerebri is anchored anteriorly to the base of the brain at the crista galli of the ethmoid bone. The **tentorium cerebelli**, a common landmark, is a membrane that separates the cerebellum below from the cerebral structures above. Internal to the dura mater is the location of the **arachnoid**, a spongy, web-like structure that loosely follows the contours of the cerebral structures.

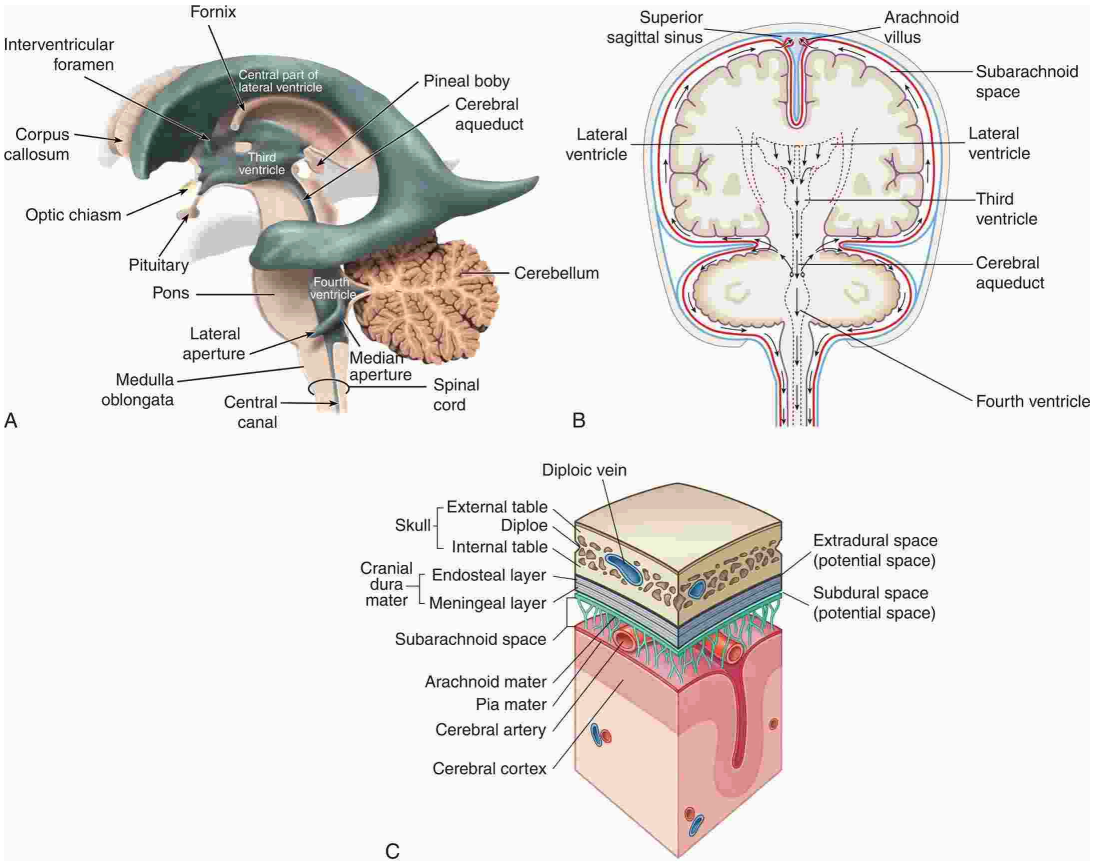

FIG. 15.16 Flow of Cerebrospinal Fluid and Meninges of the Brain.

(A) Ventricles highlighted in blue within a translucent brain in a left lateral view. **(B)** Flow of cerebral spinal fluid. The fluid produced by filtration of blood by the choroid plexus of each ventricle flows inferiorly through the lateral ventricles, interventricular foramen, third ventricle, cerebral aqueduct, fourth ventricle, and subarachnoid space to the blood. **(C)** Meninges of the brain in relation to cerebrospinal fluid and venous blood flow. (A and B, From Waugh A, Grant A. *Ross and Wilson anatomy and physiology in health and illness*, 12th edition. London: Churchill Livingstone; 2012. C, From Drake RL, Gray H, Vogl W, et al. *Gray's anatomy for students*, 3rd edition. London: Churchill Livingstone; 2015.)

Three illustrations, A, B, and C, show the flow of cerebrospinal fluid and meninges of the brain. Illustration A identifies the following structures with reference to the different ventricles. • Central part of lateral ventricle. Corpus callosum, interventricular foramen, and fornix. • Third ventricle. Pituitary, optic chiasm, pineal boby, cerebral aqueduct. • Fourth ventricle. Pons, lateral aperture,

medulla oblongata, cerebellum, median aperture, central canal, and spinal cord. Illustration B identifies the following structures on the posterior view of the brain, clockwise from the top: arachnoid villus, subarachnoid space, lateral ventricle, cerebral aqueduct, fourth ventricle, lateral ventricle, and superior sagittal sinus. Illustration shows a cross-sectional view of meninges of the brain. The following structures on the labeled on the illustration, from the top to the bottom: skull (external table, dipole, and internal table), diploic vein, extradural space (potential space), cranial dura mater (endosteal layer and meningeal layer, subdural space (potential space), subarachnoid space, arachnoid mater, cerebral artery, pia mater, and cerebral cortex.

The **subdural space** lies between the dura and arachnoid. Many small bridging veins that have little structural support traverse the subdural space. Their disruption results in a subdural hematoma (see Chapter 18). The **subarachnoid space** lies between the arachnoid and the pia mater and contains CSF (see Fig. 15.16C). Unlike the dura mater and the arachnoid, the delicate **pia mater** adheres to the brain and spinal cord contours. It provides support for blood vessels serving brain tissue. The **choroid plexuses**, which are structures that produce CSF, arise from the pia membrane.

The spinal cord is anchored to the vertebrae by extension of the meninges (see Fig. 15.11C). The meninges continue beyond the end of the spinal cord (at vertebrae levels L1 and L2) to the lower portion of the sacrum. CSF within the subarachnoid space also circulates down to the large **lumbar cistern**, extending from the second lumbar vertebra to the second sacral vertebra. Cisterns are expanded areas of the subarachnoid space. The **cerebellomedullary cistern (cisterna magna)** and the pontine cistern are two other important cisterns.

The meninges form potential and real spaces important to understanding functional and pathologic mechanisms. For example, between the dura mater and skull lies a potential space termed the **extradural space** (also called the **epidural space**) (see Fig. 15.16C). The arterial supply to the meninges consists of blood vessels that lie within grooves in the skull. A skull fracture can sever one of these vessels and produce an epidural hematoma.

Cerebrospinal Fluid and the Ventricular System

Cerebrospinal fluid (CSF) is a clear, colorless fluid similar to blood plasma and interstitial fluid. The intracranial and spinal cord structures float in CSF and are thereby partially protected from jolts and blows. The buoyant properties of the CSF also prevent the brain from tugging on meninges, nerve roots, and blood vessels. (Constituents of CSF are listed in Table 15.4.) Between 125 and 150 mL of CSF is circulating within the

ventricles (small cavities) and subarachnoid space at any given time. Approximately 600 mL of CSF is produced daily.

Table 15.4

Composition of Cerebrospinal Fluid

Constituent	Normal Value
Sodium (Na^+)	148 mM
Potassium (K^+)	2.9 mM
Chloride (Cl^-)	125 mM
Bicarbonate (HCO3−)	22.9 mM
Glucose (fasting)	50–75 mg/dL (60% of serum glucose)
pH	7.3
Protein	15–45 mg/dL
Albumin	80%
Globulin	6%–10%
Blood cells	
White (lymphocyte)	0–6/mm^3
Red	0

Ependymal cells in the choroid plexuses of the lateral, third, and fourth ventricles produce the major portion of CSF. (Ventricles are illustrated in Fig. 15.16A.) These plexuses are characterized by a rich network of blood vessels supplied by the pia mater and lie close to the ependymal cells of the ventricles. The tight junctions of the choroid blood vessel provide a limiting barrier between CSF and blood, which functions similarly to the blood-brain barrier (see the Blood-Brain Barrier section).

CSF exerts pressure within the brain and the spinal cord. When a person is supine, CSF pressure is about 80 to 180 mm of water pressure or approximately 5 to 14 mm of mercury pressure, but doubles when the person moves to the upright position. CSF flow results from the pressure gradient between the arterial system and the CSF-filled cavities. Beginning in the lateral ventricles, the CSF flows through the **interventricular foramen (foramen of Monro)** into the third ventricle and then passes through the cerebral aqueduct (aqueduct of Sylvius) into the fourth ventricle (see Fig. 15.16B). The CSF may pass through the fourth ventricle, through the paired **lateral apertures (foramen of Luschka),** or the **median aperture (foramen of Magendie)** before communicating with the subarachnoid spaces of the brain and spinal cord. CSF is produced continually but does not accumulate. Instead, it is reabsorbed into the venous circulation through the arachnoid villi. The **arachnoid villi** protrude from the arachnoid

space through the dura mater and lie within the blood flow of the venous sinuses (see Fig. 15.16B). CSF is reabsorbed through a pressure gradient between the arachnoid villi and the cerebral venous sinuses. The villi function as one-way valves directing CSF outflow into the blood but preventing blood flow into the subarachnoid space. Thus, CSF is formed from blood, and after circulating throughout the CNS, it returns to blood.

Vertebral Column

The vertebral column (Fig. 15.17) is composed of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal. Between each vertebra (except for the fused sacral and coccygeal vertebrae) is an **intervertebral disk** (Fig. 15.18). At the center of the intervertebral disk is the **nucleus pulposus**, a pulpy mass of elastic fibers. The intervertebral disk absorbs shocks, preventing damage to the vertebrae. The intervertebral disk is also a common source of back problems. If too much stress is applied to the vertebral column, the disk contents may rupture and protrude into the spinal canal, causing spinal cord compression or nerve roots. The disks can also degenerate.

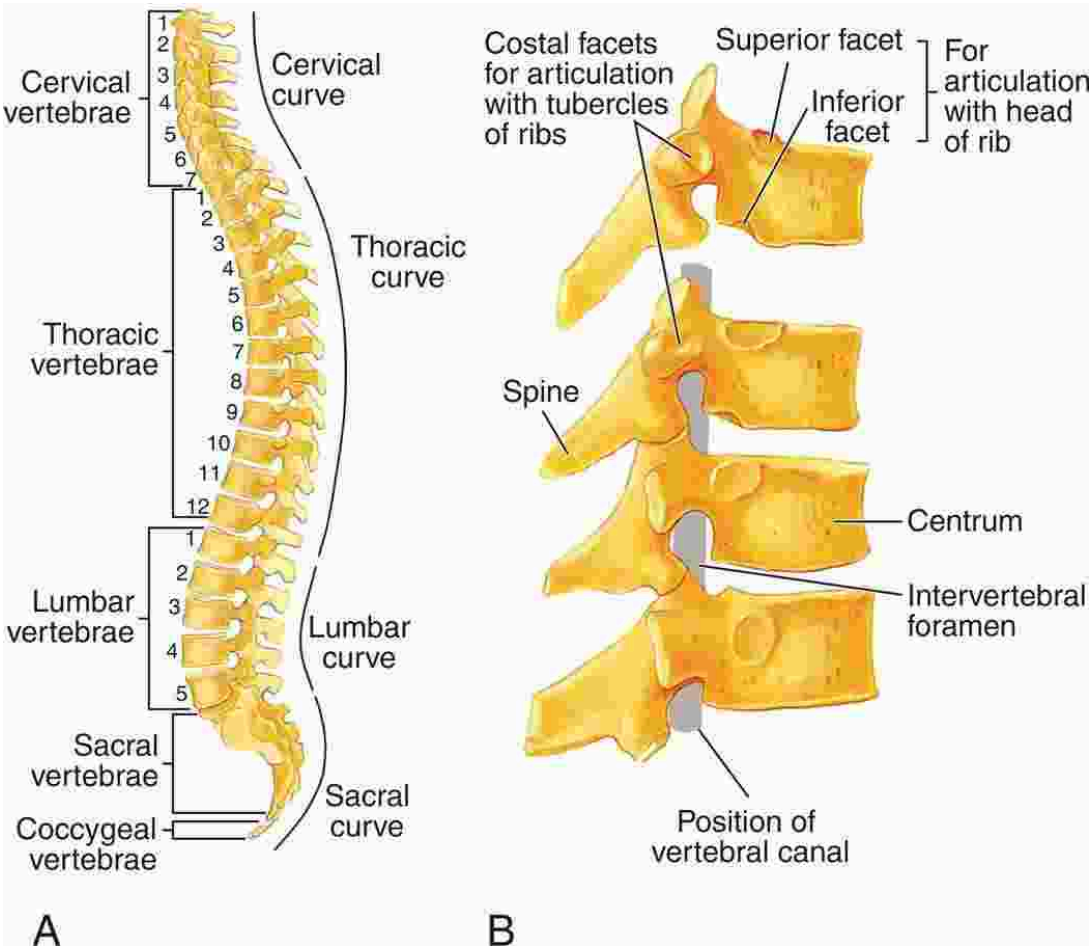

FIG. 15.17 **Vertebral Column.**
(A) The normal curves and regions of the vertebral column. The vertebrae in each region are numbered. **(B)** Lateral view of several vertebrae showing how they articulate. (From Solomon E. *Introduction to human anatomy and physiology*, 4th edition. St. Louis: Saunders; 2016.)

Illustration A is the right lateral view of the spinal cord, identifying the curves by location of the vertebrae. Cervical vertebrae (C 1 to C 7), cervical curve. Thoracic vertebrae (T 1 to T 12), thoracic curve. Lumbar vertebrae (L 1 to L 5), lumbar curve. Sacral vertebrae and coccygeal vertebrae, sacral curve. Illustration B shows a lateral view of the spine, identifying the following structures from the inside: position of vertebral canal, intervertebral foramen, centrum, and spine. An accompanying illustration shows the costal facets for articulation with tubercles of ribs and for articulation with head of

rib (superior facet and inferior facet for articulation with head of rib).

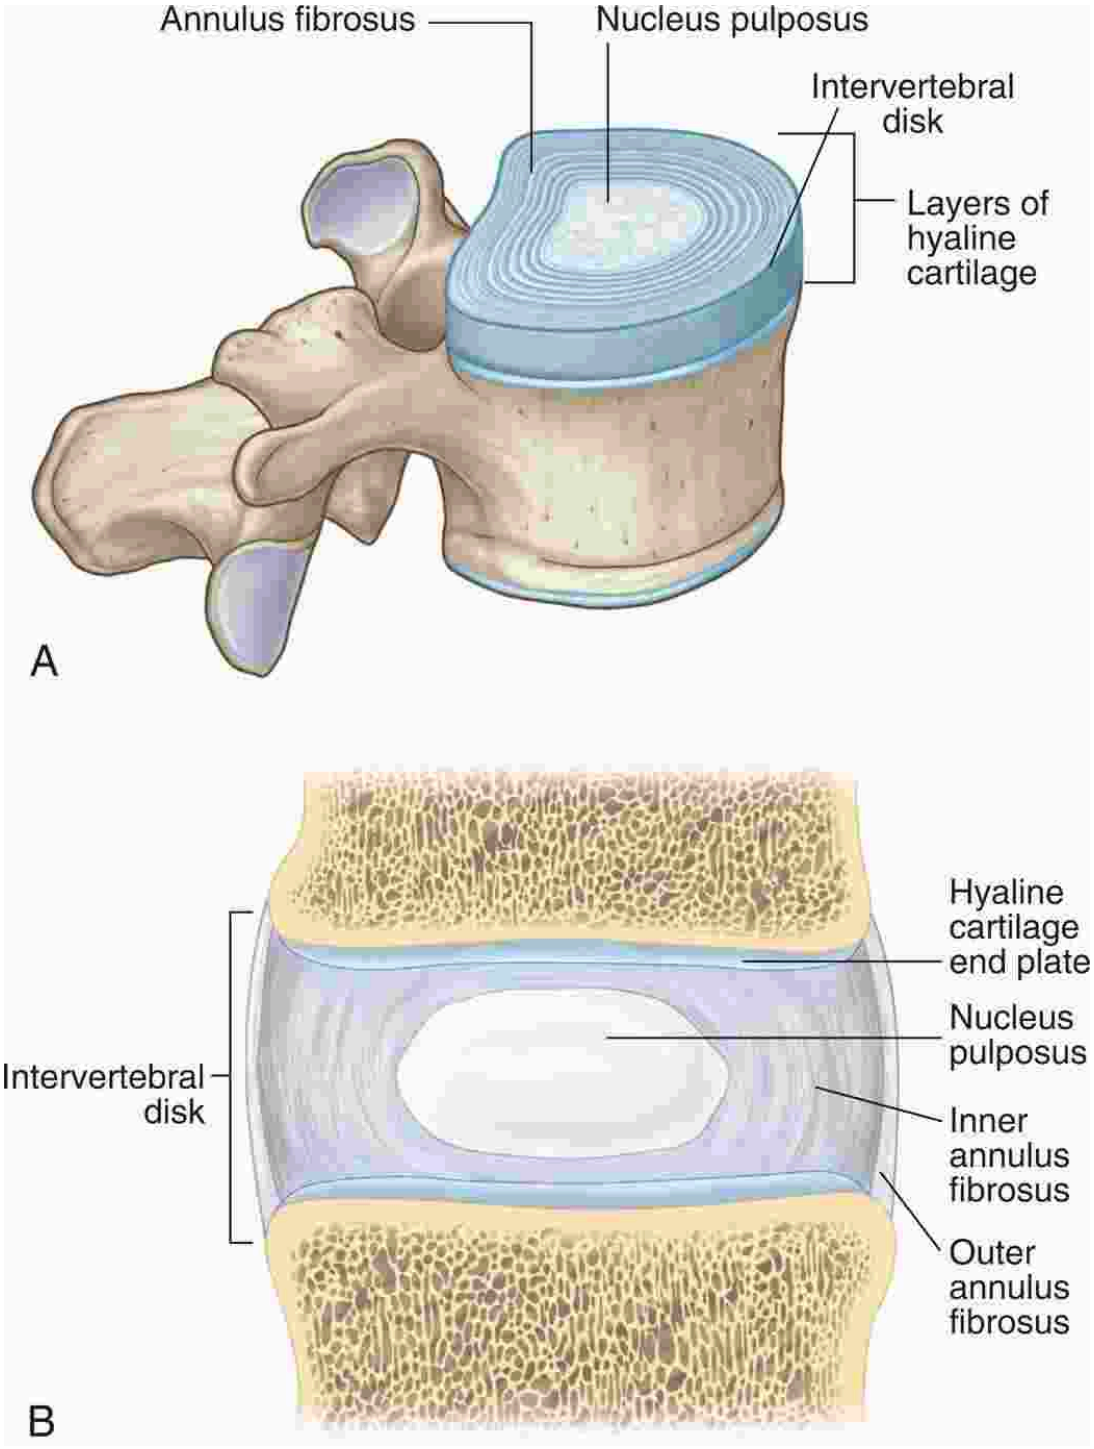

FIG. 15.18 **Intervertebral Disk.**
(A) Sagittal view of vertebra and intervertebral disk. **(B)** Lateral view of several vertebrae showing how they articulate. (A, From Drake R, Vogl AW, Mitchell AWM. *Gray's anatomy for students*, 3rd edition. London: Churchill Livingstone; 2015. B, From Lawry GV, Kreder HJ, Hawker G, Jerome, D. *Fam's musculoskeletal examination and joint injection techniques*, 2nd edition. Philadelphia: Mosby; 2010.)

Illustration A shows a sagittal view of a vertebra and identifies the following structures from the inside: nucleus pulposus, annulus fibrosus, and intervertebral disk followed by layers of hyaline cartilage. Illustration B shows a lateral view of a vertebra and identifies the following structures on the intervertebral disk, from the top to the bottom: hyaline cartilage end plate, nucleus pulposus, inner annulus fibrosus, and outer annulus fibrosus.

Blood Supply

Blood Supply to the Brain

The brain receives approximately 20% of the cardiac output or 800 to 1000 mL of blood flow per minute. Cerebral blood flow is autoregulated to maintain a stable flow during fluctuating perfusion pressures. Carbon dioxide is a primary regulator of blood flow within the CNS. It is a potent vasodilator, and its effects ensure an adequate blood supply.

The brain derives its arterial supply from the **internal carotid arteries** and the **vertebral arteries** (Fig. 15.19). The internal carotid arteries supply a proportionately greater amount of blood flow. They originate at the common carotid arteries, enter the cranium through the base of the skull, and pass through the **cavernous sinus**. After forming some small branches, these arteries divide into the anterior and middle cerebral arteries (Fig. 15.20). The vertebral arteries originate at the subclavian arteries and pass through the transverse foramina of the cervical vertebrae, entering the cranium through the foramen magnum. They join at the junction of the pons and medulla to form the **basilar artery** (see Fig. 15.20). The basilar artery divides at the level of the midbrain to form paired posterior cerebral arteries.

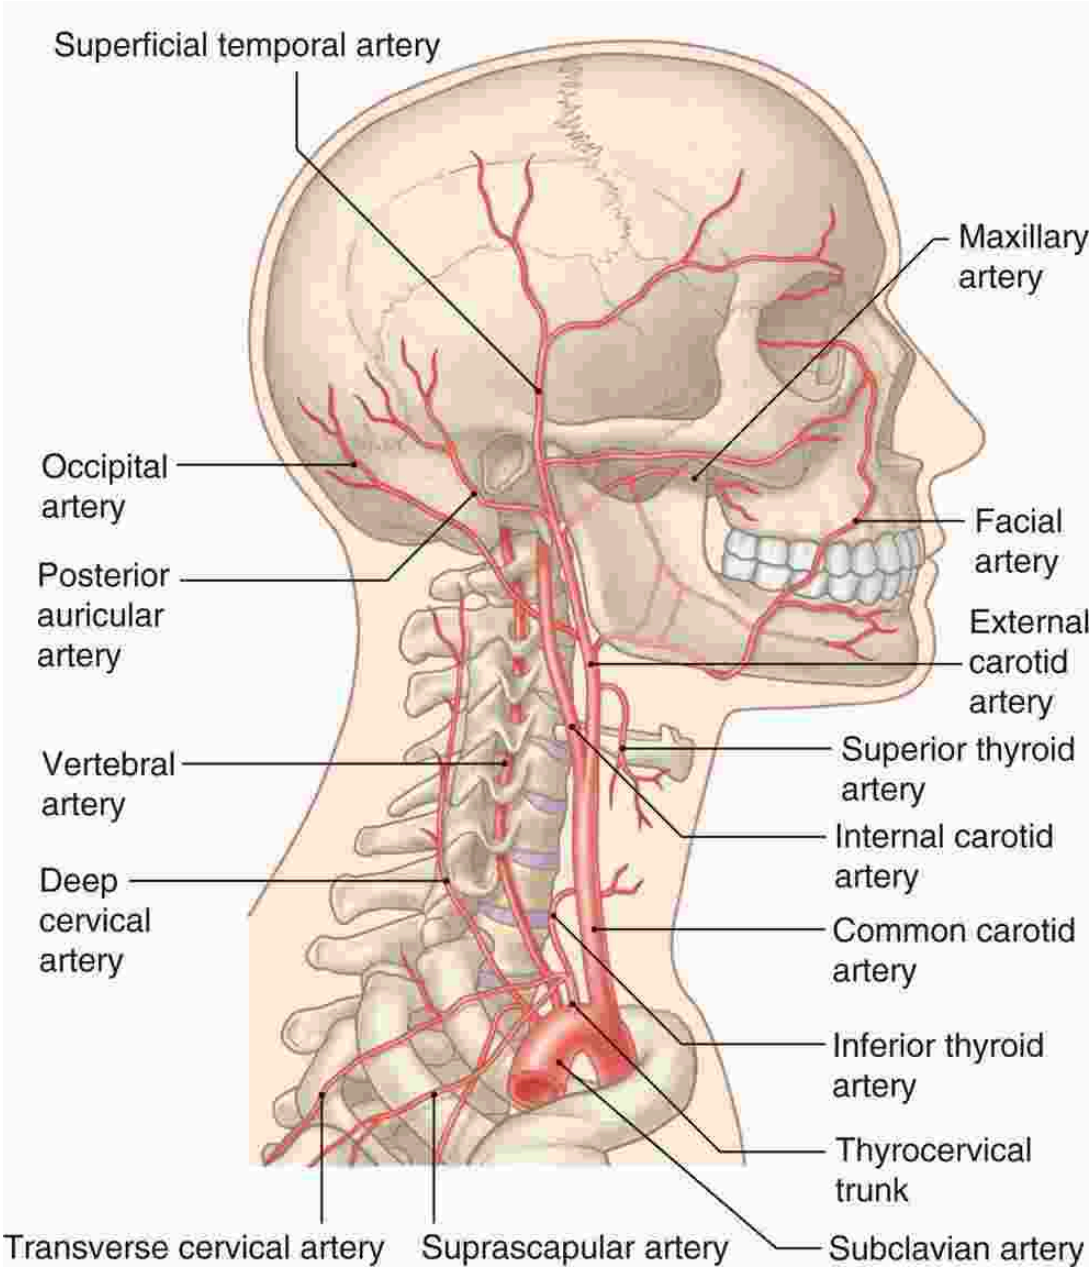

FIG. 15.19 **Major Arteries of the Head and Neck.** (From Moses KP. *Atlas of clinical gross anatomy*, 2nd edition. Philadelphia: Saunders; 2013.)

An illustration shows the right lateral view of the human skull and neck, highlighting the major arteries within the structure. The following arteries are identified from the top to the bottom along the anterior side: maxillary artery, facial artery, external carotid artery, superior thyroid artery, internal carotid artery, common carotid artery, inferior thyroid artery, thyrocervical trunk, and

subclavian artery. The following arteries are identified from the top to the bottom along the posterior side: superficial temporal artery, occipital artery, posterior auricular artery, vertebral artery, deep cervical artery, transverse cervical artery, and suprascapular artery.

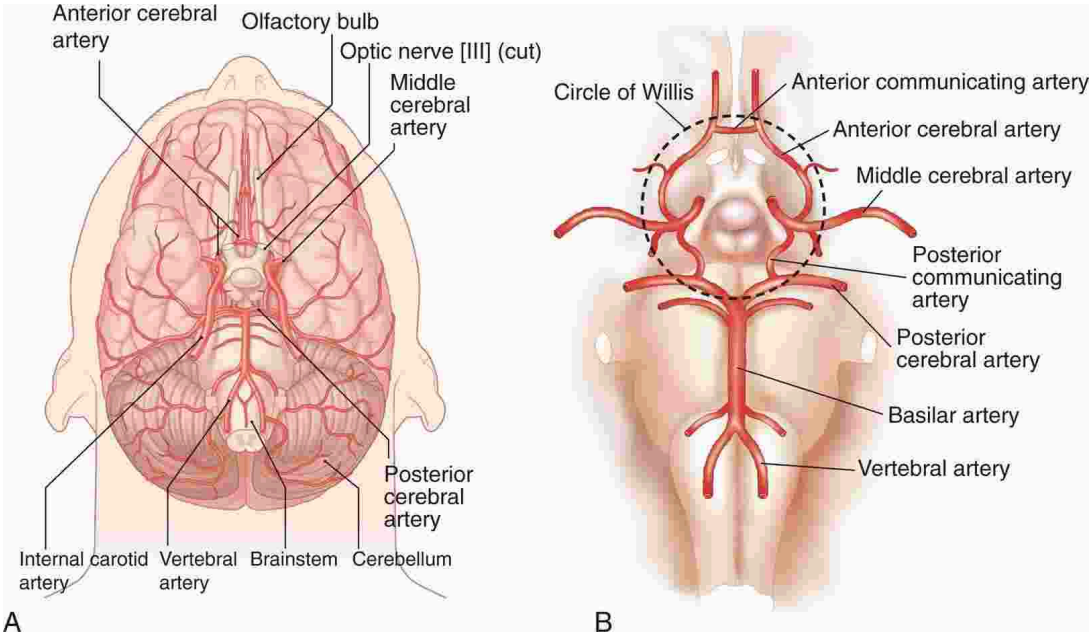

FIG. 15.20 **Arteries at the Base of the Brain.**
(A) View of the arteries at the base of the brain. **(B)** Circle of Willis. The arteries that compose the circle of Willis are the two anterior cerebral arteries, joined to each other by the anterior communicating artery and two short segments of the internal carotids, off of which the posterior communicating arteries connect to the posterior cerebral arteries. (A, From Moses KP. *Atlas of clinical gross anatomy*, 2nd edition. Philadelphia: Saunders; 2013. B, From Hagen-Ansert S. *Textbook of diagnostic sonography*, 7th edition. St. Louis: Mosby; 2012.)

Illustration A shows the inferior view of the human brain and identifies the following structures from the top to the bottom: olfactory bulb, anterior cerebral artery, optic nerve [3] (cut), middle cerebral artery, posterior cerebral artery, internal carotid artery, vertebral artery, brainstem, and cerebellum. Illustration B shows and labels the following arteries at the base of the brain, from the top to the bottom: circle of Willis, anterior communicating artery, anterior cerebral artery, middle cerebral artery, posterior communicating artery, posterior cerebral artery, basilar artery, and vertebral artery.

Three major paired arteries perfuse the cerebellum and brainstem: the posterior inferior cerebellar artery, the anterior inferior cerebellar artery, and the superior cerebellar arteries. They originate from the basilar artery. The basilar artery also gives rise to small pontine arteries. The large arteries on the surface of the brain and their

branches are called **superficial arteries (conducting arteries)**. Small branches that project into the brain are termed **projecting arteries (nutrient arteries)**.

The **circle of Willis** (see Fig. 15.20B) provides an alternative route for blood flow when one of the contributing arteries is obstructed (collateral blood flow). The circle of Willis is formed by the posterior cerebral arteries, posterior communicating arteries, internal carotid arteries, anterior cerebral arteries, and anterior communicating arteries. The anterior cerebral, middle cerebral, and posterior cerebral arteries leave the circle of Willis and extend to various brain structures, serving their associated brain territories. The border zone is the area between the major arterial territories. (Table 15.5 and Fig. 15.21 describe the structures served, the functional relationships, and the pathologic considerations related to occlusion of cerebral arteries.)

Table 15.5

Arterial Systems Supplying the Brain

Arterial Origin	Structures Served	Conditions Caused by Occlusion
Anterior cerebral artery	Basal ganglia; corpus callosum; medial surface of cerebral hemispheres; superior surface of frontal and parietal lobes	Hemiplegia on contralateral side of body, greater in lower than in upper extremities
Middle cerebral artery	Frontal lobe; parietal lobe; temporal lobe (primarily cortical surfaces)	Aphasia in dominant hemisphere and contralateral hemiplegia (see Chapter 17)
Posterior cerebral artery	Part of diencephalon (thalamus, hypothalamus) and temporal lobe; occipital lobe	Visual loss; sensory loss; contralateral hemiplegia if cerebral peduncle affected

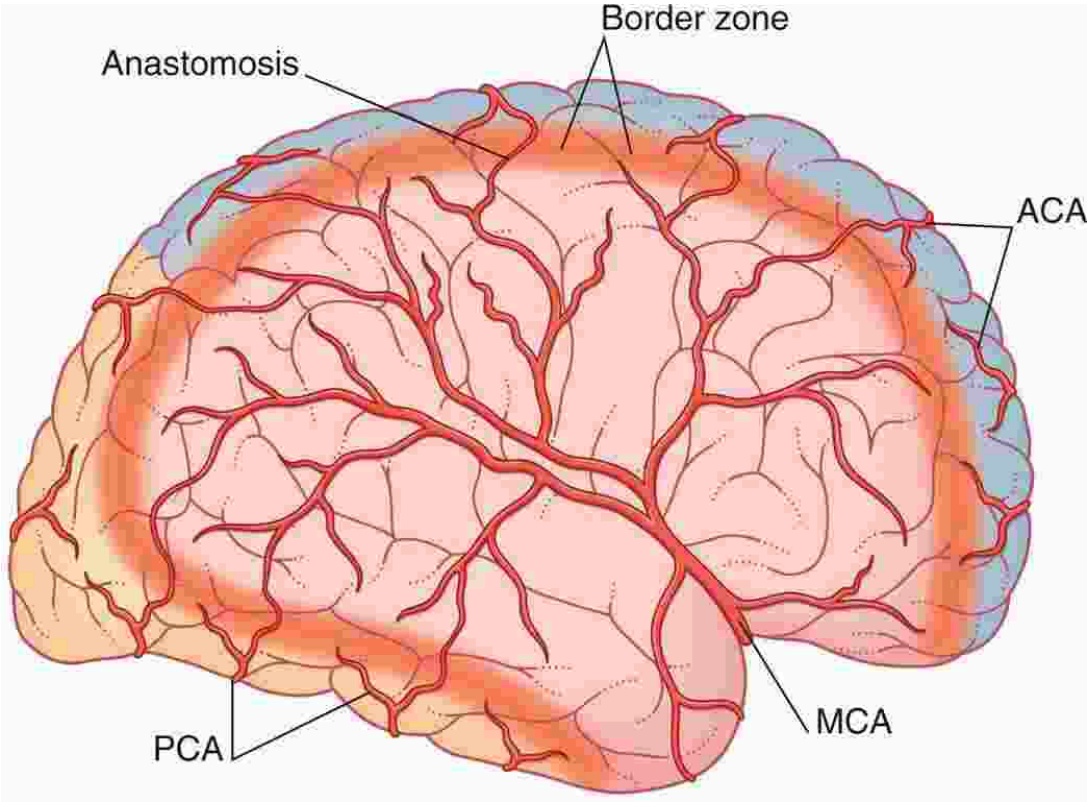

FIG. 15.21 Areas of the Brain Affected by Occlusion of the Anterior, Middle, and Posterior Cerebral Artery Branches. *ACA*, Gray area affected by occlusion of branches of anterior cerebral artery; *MCA*, pink area affected by occlusion of branches of middle cerebral artery; *PCA*, orange area affected by occlusion of branches of posterior cerebral artery. Occlusions can occur in the cortical or deep areas of the border zone. (From Mtui E, Gruener G, Fitzgerald MJT. *Clinical neuroanatomy and neuroscience*, 6th edition. Philadelphia: Saunders; 2012.)

Cerebral venous drainage does not parallel its arterial supply, whereas the venous drainage of the brainstem and cerebellum does parallel the arterial supply of these structures. The cerebral veins are classified as superficial and deep veins. The veins drain into venous plexuses and dural sinuses (formed between the dural layers) and eventually join the internal jugular veins at the skull base (Fig. 15.22). Adequacy of venous outflow can significantly affect intracranial pressure. For example, when individuals with a head injury turn or let their heads fall to the side, the action partially occludes venous return, and intracranial pressure can increase because of decreased flow through the jugular veins.

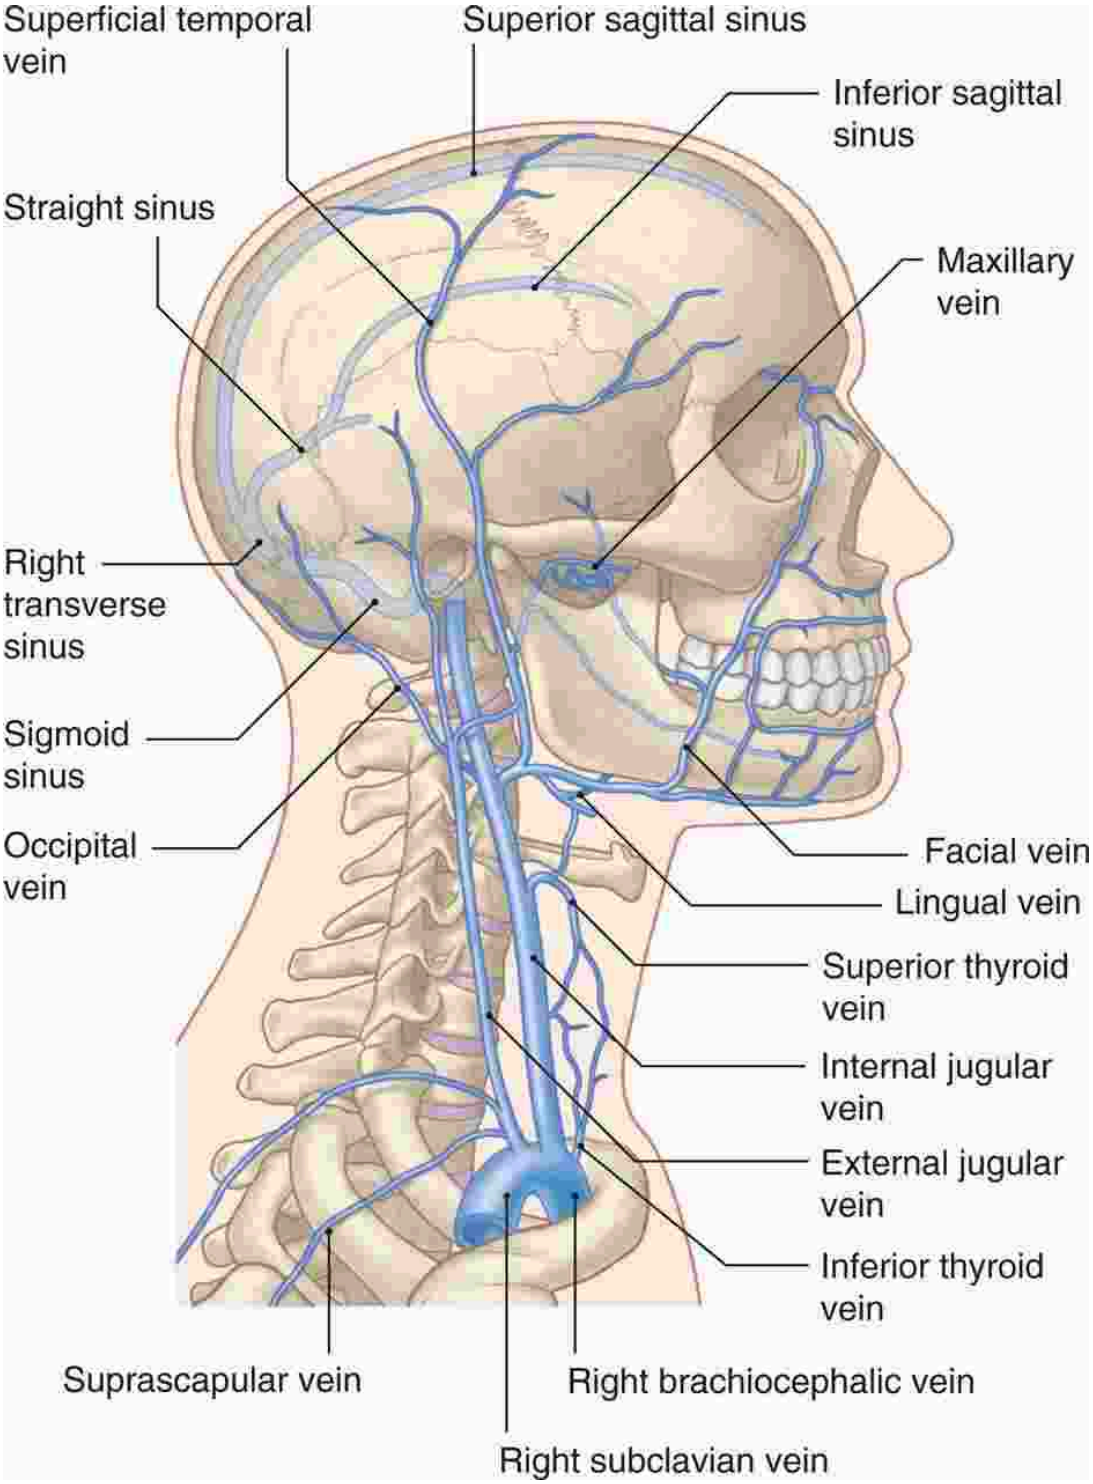

FIG. 15.22 Veins of the Head and Neck.
Deep veins and dural sinuses are projected on the skull. Note two superficial veins in the face are tributaries that send blood through emissary veins in the skull foramen into deep veins inside the skull, terminating in the internal jugular vein. (From Moses KP. *Atlas of clinical gross anatomy*, 2nd edition. Philadelphia: Saunders; 2013.)

An illustration shows the right lateral view of the human skull and neck, highlighting the major veins within the structure. The following veins are identified from the top to the bottom along the anterior side: maxillary vein, facial vein, lingual vein, superior thyroid vein, internal jugular vein, external jugular vein, inferior thyroid vein, right brachiocephalic vein, and right subclavian vein. The following veins are identified from the top to the bottom along the posterior side: superior sagittal sinus, superficial temporal vein, straight sinus, right transverse sinus, sigmoid sinus, occipital vein, and suprascapular vein.

Blood-Brain Barrier

The **blood-brain barrier (BBB)** describes cellular structures that selectively inhibit certain potentially harmful substances in the blood from entering the interstitial spaces of the brain or CSF, thus allowing neurons to function normally. Endothelial cells in brain capillaries with their intracellular tight junctions are the site of the BBB (Fig. 15.23). Supporting cells include astrocytes, pericytes, and microglia.[3] Some substances, including glucose, lipid-soluble molecules, electrolytes, and chemicals, can cross into and out of the brain facilitated by transport molecules. This has substantial implications for drug therapy because certain antibiotics and chemotherapeutic drugs show a greater propensity than others to cross this barrier. Breakdown of the BBB can contribute to brain invasion by toxic molecules or pathogens promoting neuroinflammation and neurodegeneration. The epithelium of the choroid plexus and the arachnoid membrane also provide barrier functions.[4]

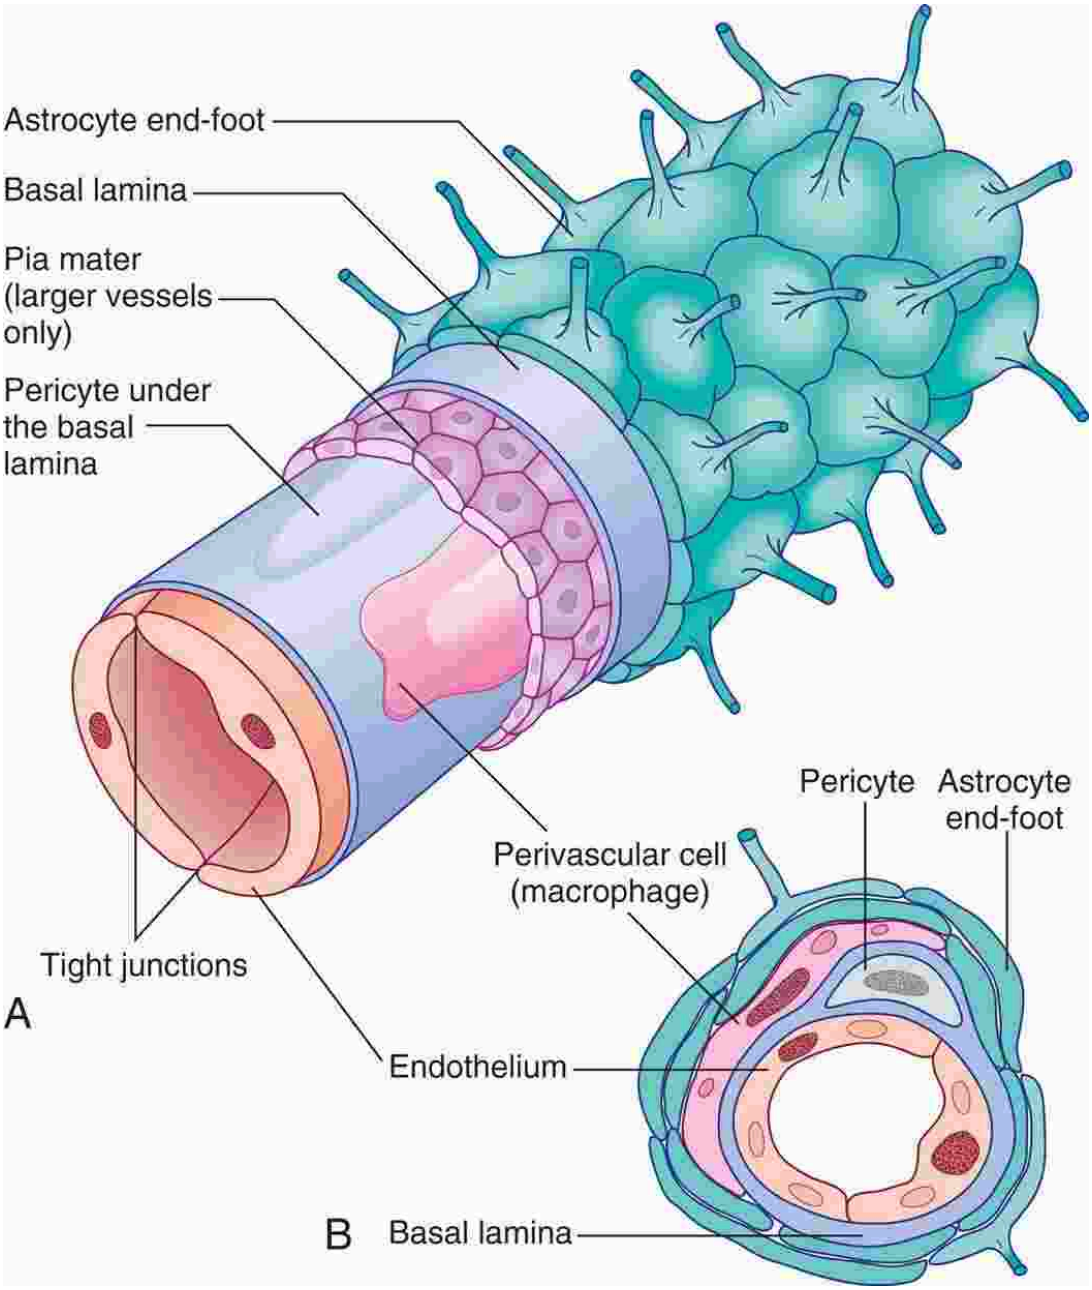

FIG. 15.23 Blood-Brain Barrier.
(A) Cellular structure of brain capillary. Endothelial cell membranes with tight junctions create a physical barrier between capillary blood and the brain, restricting movement of bacteria or neurotoxic substances. The pia mater is present only in larger vessels. **(B)** Cross-section. (From Standring S. *Gray's anatomy*, 41st edition. London: Elsevier; 2016.)

Illustration A is a lateral view of a brain capillary. The following structures are labeled, from the inside: tight junctions, endothelium,

pericyte under the basal lamina, perivascular cell (macrophage), pia mater (larger vessels only), basal lamina, and astrocyte end-foot. Illustration B is a cross-sectional view of a brain capillary. The following structures are labeled, from the inside: endothelium, basal lamina, pericyte, perivascular cell (macrophage), and astrocyte end-foot.

Blood Supply to the Spinal Cord

The spinal cord derives its blood supply from branches of the vertebral arteries and from branches from various regions of the aorta. The **anterior spinal artery** and the paired **posterior spinal arteries** branch from the vertebral artery at the base of the cranium and descend alongside the spinal cord. Arterial branches from vessels exterior to the spinal cord follow the spinal nerve through the intervertebral foramina, pass through the dura, and divide into the anterior and posterior radicular arteries (Fig. 15.24).

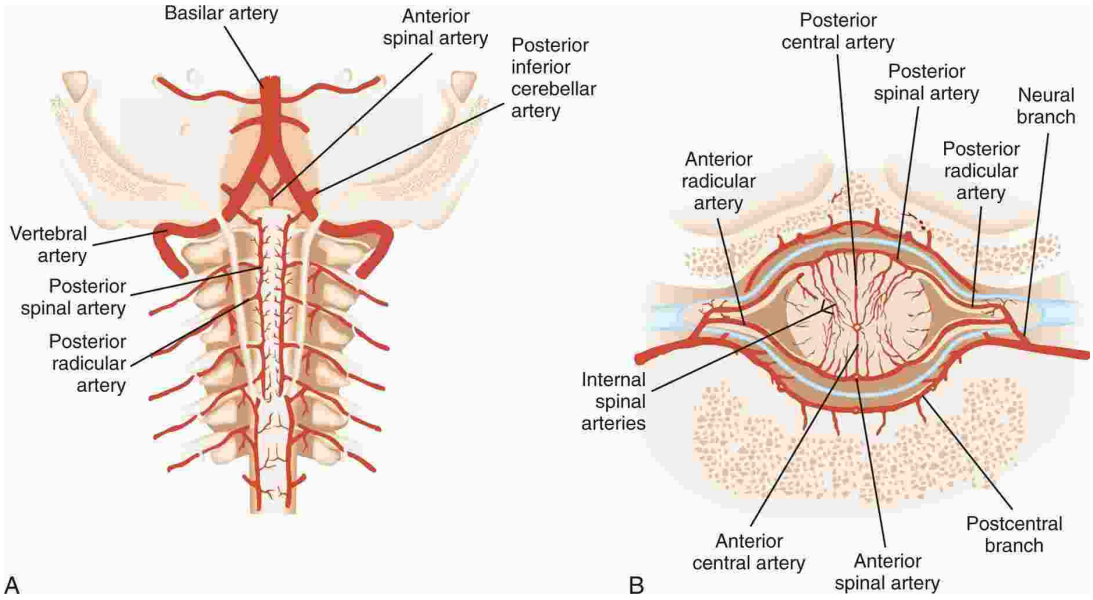

FIG. 15.24 Arteries of the Spinal Cord.
(A) Arteries of cervical cord exposed from the rear. **(B)** Arteries of spinal cord diagrammatically shown in horizontal section. (Redrawn from Rudy EB, eds. *Advanced neurological and neurosurgical nursing*. St. Louis: Mosby; 1984.)

Illustration A is a posterior view of the cervical cord, identifying the following arteries from the top to the bottom: basilar artery, anterior spinal artery, posterior inferior cerebellar artery, vertebral artery, posterior spinal artery, and posterior radicular artery. Illustration B is a cross-section view of the cervical cord, identifying the following arteries from the inside: anterior central artery, internal spinal arteries, posterior central artery, anterior spinal artery, posterior spinal artery, anterior radicular artery, posterior radicular artery, postcentral branch, and neural branch.

The radicular arteries eventually connect to the spinal arteries. Branches from the radicular and spinal arteries form plexuses whose branches penetrate the spinal cord, supplying the deeper tissues. Venous drainage parallels the arterial supply closely and drains into venous sinuses located between the dura and periosteum of the vertebrae.

Peripheral Nervous System

The **peripheral nervous system (PNS)** includes the nerves outside the CNS (see Fig. 15.1). The somatic nervous system is the part of the PNS that controls voluntary muscle movement (efferent nerves) and sensory information (afferent nerves). The cranial and

spinal nerves, including their branches and ganglia, constitute the PNS. The spinal nerves originate in the spinal cord. The cranial nerves originate in the brain and pass out of the skull. A peripheral nerve is composed of individual axons/dendrites, with most wrapped in a myelin sheath. These individual fibers are arranged in bundles called *fascicles* (Fig. 15.25B). The coverings provide structural support, a blood supply, and interstitial compartments necessary to deliver essential electrolytes to support nerve impulse conduction.

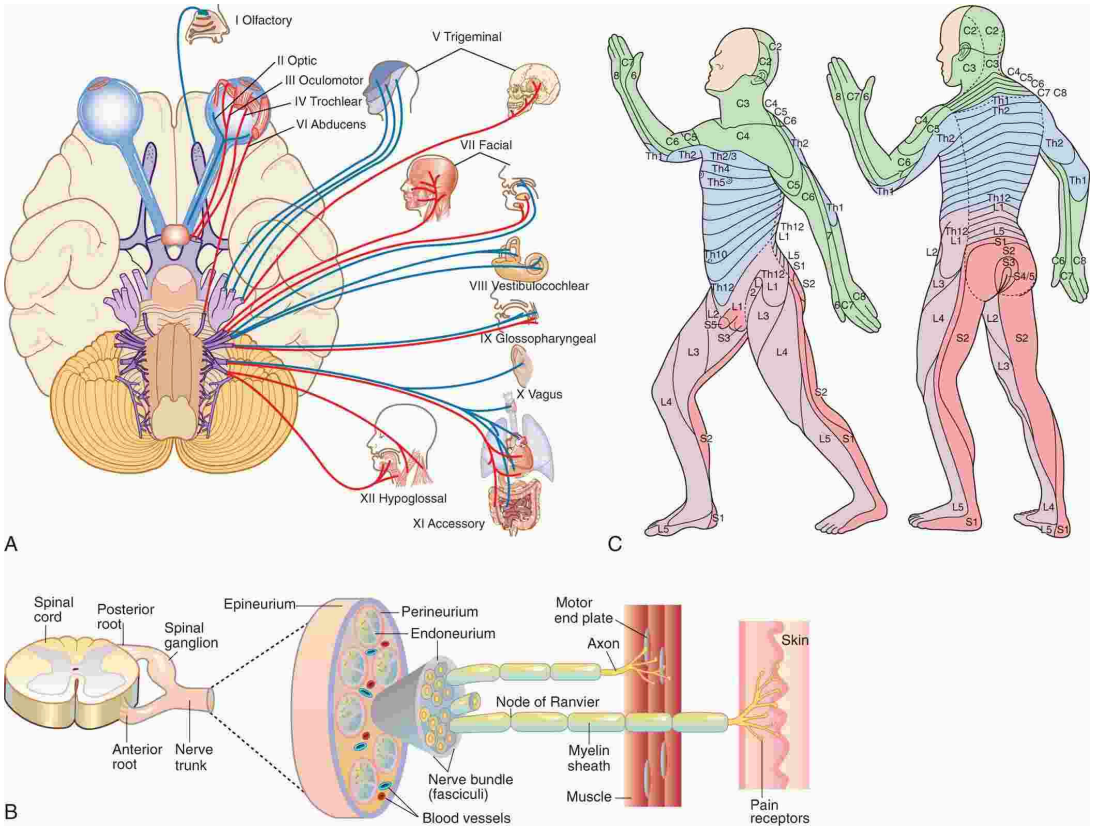

FIG. 15.25 Cranial and Peripheral Nerves and Skin Dermatomes. **(A)** Ventral surface of the brain showing attachment of the cranial nerves. The red lines indicate motor function, and the blue lines indicate sensory function. **(B)** Peripheral nerve trunk and coverings. **(C)** Dermatome map, anterolateral view *(left)*, and posterolateral view *(right)*. (A, From Applegate E. *The anatomy and physiology learning system*, 4th edition. St. Louis: Saunders; 2011. C, From Salvo SG. *Mosby's pathology for massage therapists*, 3rd edition. St. Louis: Mosby; 2014.)

Illustration A shows the ventral surface of the brain, identifying the motor and sensory functions linked to the cranial nerves. The motor functions are: 3 oculomotor, 4 trochlear, 6 abducens, 7 facial, 9 glossopharyngeal, and 12 hypoglossal. The sensory functions are: 1 olfactory, 2 optic, 5 trigeminal, 8 vestibulocochlear, 10 vagus, and 11 accessory. Here, facial 7, trigeminal 5, glossopharyngeal 9, and vagus 10 nerves are both sensory and motor. Illustration B shows a cross-sectional view of the spinal cord with posterior root, anterior root, spinal ganglion, and nerve trunk. An accompanying illustration shows the lateral view of the nerve trunk, identifying the following structures from the outside: epineurium,

perineurium, endoneurium, blood vessels, nerve bundle (fasciculi), node of Ranvier, myelin sheath, axon, muscle, motor end plate, pain receptors, skin. Illustration C shows the lateral and posterior view of a human figure and color-codes the different parts of the body by vertebrae connections. • C 1 to C 8: back of the head, neck, shoulders, front of the arms, and hands. • T h 1 to T h 12: back of the arms, chest, and upper back. • L 1 to L 5: front of the legs. • S 1 to S 5: back of the legs.

The 31 pairs of **spinal nerves** derive their names from the vertebral level from which they exit: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The first cervical nerve exits above the first cervical vertebra, and the rest of the spinal nerves exit below their corresponding vertebrae. From the thoracic region (and inferiorly), nerves correspond to the vertebral level above their exit (see Fig. 15.11).

Spinal nerves contain both sensory and motor neurons and are called **mixed nerves**. Their structure can be compared to that of a tree with roots, trunk, and branches (see Fig. 15.11B). They arise as rootlets that combine into *roots* lateral to anterior and posterior horns of the spinal cord. These two spinal nerve roots converge in the region of the intervertebral foramen to form the spinal nerve *trunk*. Shortly after converging, the spinal nerve divides into anterior and posterior rami *(branches)*. The anterior rami (except the thoracic) initially form **plexuses** (networks of nerve fibers), branching into the peripheral nerves. Instead of forming plexuses, the thoracic nerves pass through the thorax's intercostal spaces and innervate regions.

The main spinal nerve plexuses innervate the skin and the underlying muscles of the limbs. The **brachial plexus**, for example, is formed by the last four cervical nerves (C5 to C8) and the first thoracic nerve (T1) (see Fig. 15.11B). The brachial plexus innervates the nerves of the arm, wrist, and hand.

The posterior rami of each spinal nerve, with their many processes, are distributed to a specific area in the body. Sensory signals thus arise from specific sites associated with a specific spinal cord segment. Specific areas of cutaneous (skin) innervation at these spinal cord segments are called **dermatomes** (Fig. 15.25C). The dermatomes of various spinal nerves are distributed in a fairly regular pattern, although adjacent regions between dermatomes can be innervated by more than one spinal nerve.

Like spinal nerves, **cranial nerves** are categorized as peripheral nerves. Most of these are mixed nerves (like the spinal nerves), although some are purely sensory or purely motor. Cranial nerves connect to nuclei in the brain and brainstem (see Fig. 15.25A). Table 15.6 describes the cranial nerves and how to test them.

Table 15.6

The Cranial Nerves

Number and Name	Origin and Course	Function	How Tested
I. Olfactory	Fibers arise from nasal olfactory epithelium and form synapses with olfactory bulbs that transmit impulses to temporal lobe	Purely sensory; carries impulses for sense of smell	Person is asked to sniff aromatic substances, such as oil of cloves and vanilla, and to identify them
II. Optic	Fibers arise from retina of eye to form optic nerve, which passes through sphenoid bone; two optic nerves then form optic chiasma (with partial crossover of fibers) and eventually end in occipital cortex	Purely sensory; carries impulses for vision	Vision and visual field tested with an eye chart and by testing point at which person first sees an object (finger) moving into visual field; inside of eye is viewed with ophthalmoscope to observe blood vessels of eye interior
III. Oculomotor	Fibers emerge from	Contains motor fibers to inferior oblique	Pupils examined for size, shape, and

Number and Name	Origin and Course	Function	How Tested
	midbrain and exit from skull, and extend to eye	and to superior, inferior, and medial rectus extraocular muscles that direct eyeball; levator muscles of eyelid; smooth muscles of iris and ciliary body; and proprioception (sensory) to brain from extraocular muscles	equality; pupillary reflex tested with a penlight (pupils should constrict when illuminated); ability to follow moving objects
IV. Trochlear	Fibers emerge from posterior midbrain and exit from skull to run to eye	Proprioceptor and motor fibers for superior oblique muscle of eye (extraocular muscle)	Tested in common with cranial nerve III relative to ability to follow moving objects
V. Trigeminal	Fibers emerge from pons and form three divisions that exit from skull and run to face and cranial dura mater	Both motor and sensory for face; conducts sensory impulses from mouth, nose, surface of eye, and dura mater; also contains motor fibers that stimulate chewing muscles	Sensations of pain, touch, and temperature tested with safety pin and hot and cold objects; corneal reflex tested with a wisp of cotton; motor branch tested by asking subject to clench teeth, open mouth against resistance, and move jaw from side to side
VI. Abducens	Fibers leave inferior	Contains motor fibers to lateral rectus	Tested in common with cranial

Number and Name	Origin and Course	Function	How Tested
	pons and exit from skull, and extend to eye	muscle and proprioceptor fibers from same muscle to brain	nerve III relative to ability to move each eye laterally
VII. Facial	Fibers leave pons and travel through temporal bone and extend to face	Mixed: (1) supplies motor fibers to muscles of facial expression and to lacrimal and salivary glands, and (2) carries sensory fibers from taste buds of anterior part of tongue	Anterior two-thirds of tongue tested for ability to taste sweet (sugar), salty, sour (vinegar), and bitter (quinine) substances; symmetry of face checked; subject asked to close eyes, smile, whistle, and so on; tearing tested with ammonia fumes
VIII. Vestibulocochlear (acoustic)	Fibers run from inner ear (hearing and equilibrium receptors in temporal bone) to enter brainstem just below pons	Purely sensory; vestibular branch transmits impulses for sense of equilibrium; cochlear branch transmits impulses for sense of hearing	Hearing checked by air and bone conduction by use of a tuning fork; vestibular tests: Bárány and caloric tests
IX. Glossopharyngeal	Fibers emerge from midbrain and leave skull and extend to	Mixed: (1) motor fibers serve pharynx (throat) and salivary glands, and (2) sensory fibers carry impulses from	Gag and swallow reflexes checked; subject asked to speak and cough; posterior one-third of

Number and Name	Origin and Course	Function	How Tested
	pharynx, salivary glands, and tongue	pharynx, posterior tongue (taste buds), and pressure receptors of carotid artery	tongue may be tested for taste
X. Vagus	Fibers emerge from medulla, pass through skull, and descend through neck region into thorax and abdominal region	Fibers carry sensory and motor impulses for pharynx; a large part of this nerve is parasympathetic motor fibers, which supply smooth muscles of abdominal organs; receives sensory impulses from viscera	Same as for cranial nerve IX (IX and X are tested in common) because they both serve muscles of the throat
XI. Spinal accessory	Fibers arise from medulla and superior spinal cord and extend to muscles of neck and back	Provides sensory and motor fibers for sternocleidomastoid and trapezius muscles and muscles of soft palate, pharynx, and larynx	Sternocleidomastoid and trapezius muscles checked for strength by asking subject to rotate head and shrug shoulders against resistance
XII. Hypoglossal	Fibers arise from medulla and exit from skull, and extend to tongue	Carries motor fibers to muscles of tongue and sensory impulses from tongue to brain	Subject asked to stick out tongue, and any position abnormalities are noted

Number and Name	Origin and Course	Function	How Tested
I. Olfactory	Fibers arise from nasal olfactory epithelium and form synapses with olfactory bulbs that transmit impulses to temporal lobe	Purely sensory; carries impulses for sense of smell	Person is asked to sniff aromatic substances, such as oil of cloves and vanilla, and to identify them
II. Optic	Fibers arise from retina of eye to form optic nerve, which passes through sphenoid bone; two optic nerves then form optic chiasma (with partial crossover of fibers) and eventually end in occipital cortex	Purely sensory; carries impulses for vision	Vision and visual field tested with an eye chart and by testing point at which person first sees an object (finger) moving into visual field; inside of eye is viewed with ophthalmoscope to observe blood vessels of eye interior
III. Oculomotor	Fibers emerge from midbrain and exit from skull, and extend to eye	Contains motor fibers to inferior oblique and to superior, inferior, and medial rectus extraocular muscles that direct eyeball; levator muscles of eyelid; smooth muscles of iris and ciliary body; and proprioception (sensory) to brain from extraocular muscles	Pupils examined for size, shape, and equality; pupillary reflex tested with a penlight (pupils should constrict when illuminated); ability to follow moving objects
IV. Trochlear	Fibers emerge from posterior midbrain and exit from skull to run to eye	Proprioceptor and motor fibers for superior oblique muscle of eye (extraocular muscle)	Tested in common with cranial nerve III relative to ability to follow moving objects
V. Trigeminal	Fibers emerge from pons and form three divisions that exit from skull and run to face and cranial dura mater	Both motor and sensory for face; conducts sensory impulses from mouth, nose, surface of eye, and dura mater; also contains motor fibers that stimulate chewing muscles	Sensations of pain, touch, and temperature tested with safety pin and hot and cold objects; corneal reflex tested with a wisp of cotton; motor branch tested by asking subject to clench teeth, open mouth against resistance, and move jaw from side to side
VI. Abducens	Fibers leave inferior pons and exit from skull, and extend to eye	Contains motor fibers to lateral rectus muscle and proprioceptor fibers from same muscle to brain	Tested in common with cranial nerve III relative to ability to move each eye laterally
VII. Facial	Fibers leave pons and travel through temporal bone and extend to face	Mixed: (1) supplies motor fibers to muscles of facial expression and to lacrimal and salivary glands, and (2) carries sensory fibers from taste buds of anterior part of tongue	Anterior two-thirds of tongue tested for ability to taste sweet (sugar), salty, sour (vinegar), and bitter (quinine) substances; symmetry of face checked; subject asked to close eyes, smile, whistle, and so on; tearing tested with ammonia fumes
VIII. Vestibulocochlear (acoustic)	Fibers run from inner ear (hearing and equilibrium receptors in temporal bone) to enter brainstem just below pons	Purely sensory; vestibular branch transmits impulses for sense of equilibrium; cochlear branch transmits impulses for sense of hearing	Hearing checked by air and bone conduction by use of a tuning fork; vestibular tests: Bárány and caloric tests
IX. Glossopharyngeal	Fibers emerge from midbrain and leave skull and extend to pharynx, salivary glands, and tongue	Mixed: (1) motor fibers serve pharynx (throat) and salivary glands, and (2) sensory fibers carry impulses from pharynx, posterior tongue (taste buds), and pressure receptors of carotid artery	Gag and swallow reflexes checked; subject asked to speak and cough; posterior one-third of tongue may be tested for taste
X. Vagus	Fibers emerge from medulla, pass through skull, and descend through neck region into thorax and abdominal region	Fibers carry sensory and motor impulses for pharynx; a large part of this nerve is parasympathetic motor fibers, which supply smooth muscles of abdominal organs; receives sensory impulses from viscera	Same as for cranial nerve IX (IX and X are tested in common) because they both serve muscles of the throat
XI. Spinal accessory	Fibers arise from medulla and superior spinal cord and extend to muscles of neck and back	Provides sensory and motor fibers for sternocleidomastoid and trapezius muscles and muscles of soft palate, pharynx, and larynx	Sternocleidomastoid and trapezius muscles checked for strength by asking subject to rotate head and shrug shoulders against resistance
XII. Hypoglossal	Fibers arise from medulla and exit from skull, and extend to tongue	Carries motor fibers to muscles of tongue and sensory impulses from tongue to brain	Subject asked to stick out tongue, and any position abnormalities are noted

Autonomic Nervous System

The **autonomic nervous system (ANS)** coordinates and maintains a steady state among body organs and regulates cardiac muscle, smooth muscle, and the body's glands.[5] This system is considered an involuntary system because one generally cannot *will* these functions to happen. Components of the ANS are located in both the CNS and the PNS, but the ANS is considered to be part of the efferent division of the PNS. The ANS is separated both structurally and functionally into two divisions: (1) the sympathetic nervous system and (2) the parasympathetic nervous system (Fig. 15.26). The effects of these two divisions are usually antagonistic, which means one stimulates an effector and one inhibits an effector. In this way, an effector, such as the heart or the blood vessels, can be precisely controlled. Many neurons of the ANS travel in the spinal nerves and certain cranial nerves. The widespread activity of this system indicates that its components are distributed all over the body. The peripheral autonomic nerves carry mainly efferent fibers, and that will be the emphasis here. The *visceral* or *enteric autonomic nervous system* controls the gastrointestinal tract's sensory and motor function and operates independently of the brain and spinal cord.

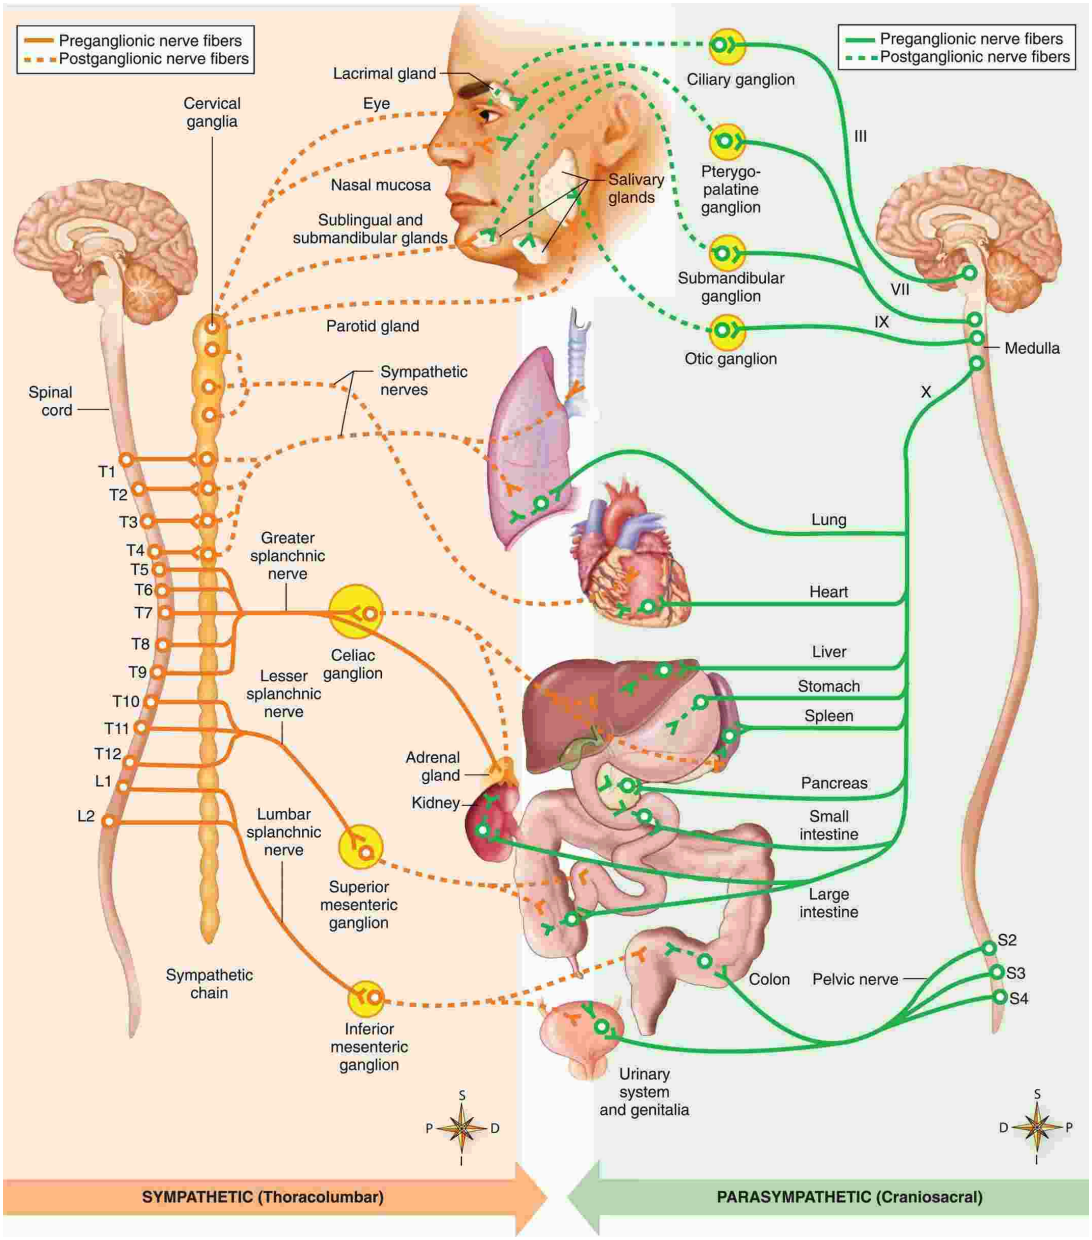

FIG. 15.26 Sympathetic and Parasympathetic Divisions of the Autonomic Nervous System.

Preganglionic neuron cell bodies are located in the brainstem and sacral cord segments (parasympathetic or “craniosacral” division) and thoracic and upper lumbar cord segments (sympathetic or “thoracolumbar” division). The axons of these neurons synapse with postganglionic neurons, which innervate smooth muscle, cardiac muscle, and glands of the body. The postganglionic neuron cell bodies may be located in distinct autonomic ganglia *(represented by circles)* or very near the wall of the innervated visceral organ. Note that sympathetic fibers provide the only innervation to peripheral effectors (sweat glands, arrector pili muscles, adipose tissue, and

blood vessels). (From Patton KA. *Anatomy & physiology*, 10th edition. St. Louis: Elsevier; 2019.)

An illustration maps the sympathetic and parasympathetic divisions of the autonomic nervous system. The sympathetic (thoracolumbar) divisions show the following preganglionic nerve fibers. • T 1 to T 4 from the spinal cord to the sympathetic nerves. • T 5 to T 9 from the spinal cord to the greater splanchnic nerve. • T 10 to T 12 from the spinal cord to the lesser splanchnic nerve. • L 1 and L 2 from the spinal cord to the lumbar splanchnic nerve. The sympathetic (thoracolumbar) divisions show the following postganglionic nerve fibers. • Cervical ganglia to the eye and nasal mucosa. • Cervical ganglia to the sublingual and submandibular glands. • Cervical ganglia to the parotid gland. • Cervical ganglia to the sympathetic nerves. • Greater splanchnic nerve to the liver, spleen, and adrenal gland. • Lumbar splanchnic nerve to the colon and urinary system and genitalia. The parasympathetic (craniosacral) divisions show the following preganglionic nerve fibers. • 3 to ciliary ganglion. • 6 to pterygo-palatine ganglion and submandibular ganglion. • 9 to otic ganglion. • 10 to lung, heart, liver, stomach, spleen, pancreas, small intestine, and large intestine. • S 2, S 3, and S 4 to pelvic nerve, colon, and urinary system and genitalia. The parasympathetic (craniosacral) divisions show the following postganglionic nerve fibers. • Ciliary ganglion to lacrimal gland. • Pterygo-palatine ganglion to eye and nasal mucosa. • Submandibular ganglion to sublingual and submandibular glands, including the salivary glands. • Otic ganglion to salivary glands.

The CNS has cardiovascular and respiratory centers in the reticular formation and the sympathetic and parasympathetic areas in the hypothalamus. CNS pathways interconnect all these areas and project to autonomic areas in the brain stem and spinal cord. Both divisions of the ANS are composed of autonomic nerves, ganglia, and plexuses. These structures, in turn, are made up of efferent (motor) autonomic neurons that conduct impulses away from the brainstem or spinal cord and down to the autonomic effectors. The efferent component of the ANS is a two-neuron system. **Preganglionic neurons** (myelinated) conduct impulses from the brainstem or spinal cord to an autonomic ganglion, where they synapse with a postganglionic neuron. **Postganglionic neurons** (unmyelinated) conduct impulses away from the ganglion to

the effector (Fig. 15.27). This arrangement contrasts with the efferent somatic nervous system, where a single motor neuron travels from the CNS to the innervated structure without passing through the ganglia (see Fig. 15.27D).

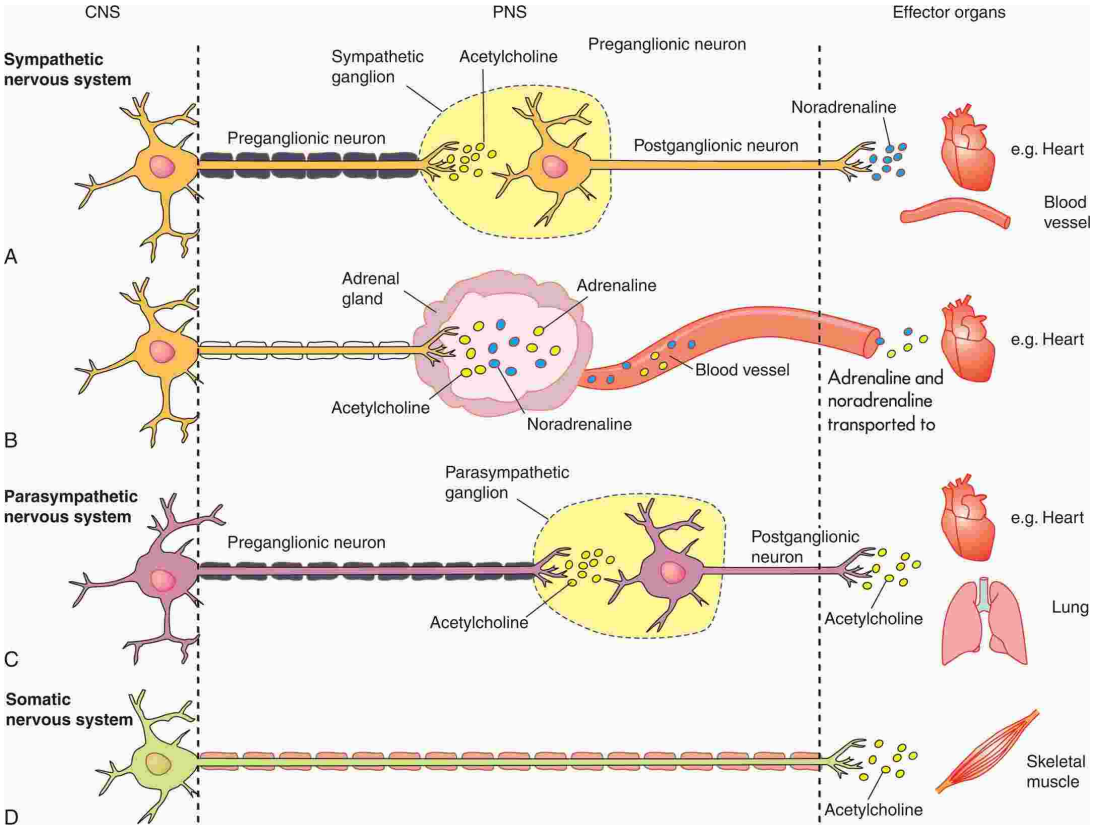

FIG. 15.27 Comparison of Neurotransmitters and Receptors Between the Sympathetic and Parasympathetic Nervous Systems.

Although not part of the autonomic nervous system, the somatic nervous system is included because of its similarity for comparison. In each case, the cell body of the first neuron is located in the central nervous system. (From Craft J, Gordon C, Huether SE, et al. *Understanding pathophysiology, Australian adaptation*, 2nd edition. Marrickville, Australia: Elsevier Australia; 2015.)

Four illustrations, A, B, C, and D, compare neurotransmitters and receptors between C N S, P N A, and the effector organs. Illustration A, sympathetic nervous system. The illustration shows a preganglionic neuron releasing acetylcholine in the sympathetic ganglion. The postganglionic neuron releases noradrenaline to heart or blood vessels. Illustration B, sympathetic nervous system. The illustration shows a neuron releasing acetylcholine into the adrenal gland. Adrenaline and noradrenaline pass through blood vessel to the heart. Illustration C, parasympathetic nervous system. The illustration shows a preganglionic neuron releasing acetylcholine

into the parasympathetic ganglion. The postganglionic neuron releases acetylcholine to the heart or the lungs. Illustration D, somatic nervous system. The illustration shows a neuron releasing acetylcholine to the skeletal muscle.

Anatomy of the Sympathetic Nervous System

The **sympathetic nervous system** mobilizes energy stores in times of need (e.g., in the "fight or flight" or stress response) (see Chapter 11 and Fig. 11.2). The sympathetic division is innervated by cell bodies located from the first thoracic (T1) through the second lumbar (L2) regions of the spinal cord and therefore is called the **thoracolumbar division** (see Fig. 15.26). The preganglionic axons of the sympathetic division form synapses shortly after leaving the spinal cord in the **sympathetic (paravertebral) ganglia** (see Fig. 15.27A). These preganglionic axons travel in several different ways: (1) directly synapsing with postganglionic neurons in the sympathetic chain ganglion at their level; (2) by traveling up the sympathetic chain ganglia; (3) by traveling down the sympathetic chain ganglion before forming synapses with a higher or lower postganglionic neuron; or (4) by traveling through the sympathetic chain ganglion to synapse with collateral ganglia (i.e., the **splanchnic nerves**, which lead to **collateral ganglia** on the front of the aorta). The collateral ganglia are named according to the branches of the aorta nearest them, namely the **celiac**, **superior mesenteric**, and **inferior mesenteric ganglia** (see Fig. 15.26). Postganglionic neurons leave the collateral ganglia and innervate the viscera below the diaphragm.

Preganglionic sympathetic neurons that innervate the adrenal medulla also travel in the splanchnic nerves and *do not* synapse before reaching the gland (see Figs. 15.26 and 15.27B). The secretory cells in the adrenal medulla are considered modified postganglionic neurons. Because preganglionic sympathetic fibers are all myelinated, travel to the adrenal medulla is quick, and innervation causes the rapid release of epinephrine and norepinephrine, which are mediators of the fight-or-flight response (see Chapter 11).

Anatomy of the Parasympathetic Nervous System

The **parasympathetic nervous system** conserves and restores energy when a person is at rest. The nerve cell bodies of this division are located in the cranial nerve nuclei and the sacral region of the spinal cord and therefore constitute the **craniosacral division**. Unlike the sympathetic branch, the preganglionic fibers in the parasympathetic division are longer and travel close to the organs they innervate before forming synapses with the relatively short postganglionic neurons (see Fig. 15.26). Parasympathetic nerves arising from nuclei in the brainstem travel to the viscera of the head, thorax, and abdomen within cranial nerves—including the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves.

Preganglionic parasympathetic nerves that originate from the sacral region of the spinal cord run either separately or together with some spinal nerves. The preganglionic axons unite to form the **pelvic splanchnic nerve**, which innervates the viscera of the pelvic cavity. These preganglionic axons synapse with postganglionic neurons in terminal ganglia located close to the organs they innervate.

Similar to the spinal nerves, the autonomic nerves also form plexuses. These are networks of nerves that have both parasympathetic and sympathetic neurons. They are usually located near the organs they innervate. Examples include the celiac (solar) plexus (contains the celiac ganglia and innervates many abdominal and pelvic organs), the cardiac plexus (innervates the heart), and Meissner and Auerbach plexuses (innervate the gastrointestinal tract).

Neurotransmitters and Neuroreceptors

Sympathetic preganglionic fibers and parasympathetic preganglionic and postganglionic fibers release **acetylcholine**—the same neurotransmitter released by somatic efferent neurons (see Fig. 15.27). These fibers are characterized by **cholinergic transmission**. Most postganglionic sympathetic fibers release **norepinephrine** (noradrenaline) and thus are considered to function by **adrenergic transmission**. A few postganglionic sympathetic fibers, such as those that innervate the sweat glands, release acetylcholine.

The action of catecholamines (adrenalin, noradrenaline, dopamine) varies with the type of neuroreceptor stimulated. Catecholamines are also released by the adrenal medulla gland, which physiologically and biochemically resembles the sympathetic nervous system. Two types of adrenergic receptors exist, α and β. Cells of the effector organs may have one or both types of adrenergic receptors. ***α*-Adrenergic receptors** have been further subdivided according to the action produced. α_1-Adrenergic activity is associated mostly with excitation or stimulation; α_2-adrenergic activity is associated with relaxation or inhibition. Most of the α-adrenergic receptors on effector organs belong to the α_1 class. **β-Adrenergic receptors** are classified as β_1-adrenergic receptors (which facilitate increased heart rate and contractility and cause the release of renin from the kidney) and β_2-adrenergic receptors (which facilitate all remaining effects attributed to β receptors).[6] Norepinephrine stimulates all α_1 and β_1 receptors and only certain β_2 receptors. The primary response from norepinephrine, however, is stimulation of α_1-adrenergic receptors that cause vasoconstriction. Epinephrine strongly stimulates all four types of receptors and induces general vasodilation because of the predominance of β receptors in muscle vasculatures. (Table 15.7 summarizes the effects of neuroreceptors on their effector organs.)

Table 15.7

Actions of Autonomic Nervous System Neuroreceptors

Effector Organ or Tissue	Adrenergic Receptors	Adrenergic Effects	Cholinergic Effects
Eye, iris			
Radial muscle	α_1	Dilation	—
Sphincter muscle	—	—	Constriction
Eye, ciliary muscle	β_2	Relaxation for far vision	Contraction for near vision
Lacrimal glands	α_1	Secretion	Secretion
Nasopharyngeal glands	—	—	Secretion
Salivary glands	α_1	Secretion of potassium and water	Secretion of potassium and water
	β	Secretion of amylase	—
Heart			
Sinoatrial (SA) node	β_1, β_2	Increase heart rate	Decrease heart rate; vagus arrest
Atrial	β_1, β_2	Increase contractility and conduction velocity	Decrease contractility; shorten action potential duration
Atrioventricular (AV) junction	β_1, β_2	Increase automaticity and propagation velocity	Decrease automaticity and propagation velocity
Purkinje system	β_1, β_2	Increase automaticity and propagation velocity	—
Ventricles	β_1, β_2	Increase contractility	Slight decrease in contraction
Arterioles			
Coronary	α_1, α_2, β_2	Constriction, dilation	Dilation
Skin and mucosa	α_1, α_2	Constriction	Dilation
Skeletal muscle	α, β_2	Dilation, constriction	Dilation

Effector Organ or Tissue	Adrenergic Receptors	Adrenergic Effects	Cholinergic Effects
Cerebral	α_1	Constriction (slight)	Dilation
Pulmonary	α_1, β_2	Constriction, dilation	Dilation
Mesenteric	α_1	Constriction	Dilation
Renal	α_1, β_1, β_2	Constriction, dilation	Dilation
Salivary glands	α_1, α_2	Constriction	Dilation
Veins, systemic	α_1, α_2, β_2	Constriction, dilation	—
Lung			
Bronchial muscle	α_2	Relaxation	Contraction
Bronchial glands	α_1, β_2	Decrease secretion; increase secretion	Stimulation
Stomach			
Motility	α_1, α_2, β_1, β_2	Decrease (usually)	Increase
Sphincters	α_1	Contraction (usually)	Relaxation (usually)
Secretion	α_2	Inhibition	Stimulation
Liver	α_1, β_2	Glycogenolysis and gluconeogenesis	—
Gallbladder and ducts	β_2	Relaxation	Contraction
Pancreas			
Acini	α	Decrease secretion	Secretion
Islet cells	α_2, β_2	Decrease secretion; increase secretion	—
Intestine			
Motility and tone	α_1, α_2, β_1, β_2	Decrease	Increase
Sphincters	α_1	Contraction	Relaxation (usually)
Secretion	α_2	Inhibition	Stimulation
Adrenal medulla	—	Secretion of epinephrine and norepinephrine	
Kidney			

Effector Organ or Tissue	Adrenergic Receptors	Adrenergic Effects	Cholinergic Effects
Renin secretion	α_1, β_1	Decrease; increase	—
Ureter			
Motility and tone	β_1	Increase	Increase (?)
Urinary bladder			
Detrusor	β_2	Relaxation	Contraction
Trigone and sphincter	α_1	Contraction	Relaxation
Sex organs, male	α_1	Ejaculation	Erection
Skin			
Pilomotor muscles	α_1	Contraction	—
Sweat glands	α_1	Localized secretion	—
Fat cells	α_2, β_1, β_2, β_3	Inhibition of lipolysis; stimulation of lipolysis	—
Pineal gland	β	Melatonin synthesis	—

Effector Organ or Tissue	Adrenergic Receptors	Adrenergic Effects	Cholinergic Effects
Eye, iris			
Radial muscle	α_1	Dilation	—
Sphincter muscle	—	—	Constriction
Eye, ciliary muscle	β_2	Relaxation for far vision	Contraction for near vision
Lacrimal glands	α_1	Secretion	Secretion
Nasopharyngeal glands	—	—	Secretion
Salivary glands	α_1	Secretion of potassium and water	Secretion of potassium and water
	β	Secretion of amylase	—
Heart			
Sinoatrial (SA) node	β_1, β_2	Increase heart rate	Decrease heart rate; vagus arrest
Atrial	β_1, β_2	Increase contractility and conduction velocity	Decrease contractility; shorten action potential duration
Atrioventricular (AV) junction	β_1, β_2	Increase automaticity and propagation velocity	Decrease automaticity and propagation velocity
Purkinje system	β_1, β_2	Increase automaticity and propagation velocity	—
Ventricles	β_1, β_2	Increase contractility	Slight decrease in contraction
Arterioles			
Coronary	$\alpha_1, \alpha_2, \beta_2$	Constriction, dilation	Dilation
Skin and mucosa	α_1, α_2	Constriction	Dilation
Skeletal muscle	α, β_2	Dilation, constriction	Dilation
Cerebral	α_1	Constriction (slight)	Dilation
Pulmonary	α_1, β_2	Constriction, dilation	Dilation
Mesenteric	α_1	Constriction	Dilation
Renal	$\alpha_1, \beta_1, \beta_2$	Constriction, dilation	Dilation
Salivary glands	α_1, α_2	Constriction	Dilation
Veins, systemic	$\alpha_1, \alpha_2, \beta_2$	Constriction, dilation	—
Lung			
Bronchial muscle	α_2	Relaxation	Contraction
Bronchial glands	α_1, β_2	Decrease secretion; increase secretion	Stimulation
Stomach			
Motility	$\alpha_1, \alpha_2, \beta_1, \beta_2$	Decrease (usually)	Increase
Sphincters	α_1	Contraction (usually)	Relaxation (usually)
Secretion	α_2	Inhibition	Stimulation
Liver	α_1, β_2	Glycogenolysis and gluconeogenesis	—
Gallbladder and ducts	β_2	Relaxation	Contraction
Pancreas			
Acini	α	Decrease secretion	Secretion

Modified from Brunton LL, Chabner B, Knollmann BC, eds. *Goodman & Gilman's pharmacological basis of therapeutics*, 12th edition. New York: McGraw-Hill; 2010; Dowd FJ, Yagiela JA, Johnson B, et al. *Pharmacology and therapeutics for dentistry*, 6th edition. St. Louis: Mosby; 2011.

Functions of the Autonomic Nervous System

Many body organs are innervated by both the sympathetic and parasympathetic nervous systems. The two divisions often cause opposite responses; for example, sympathetic stimulation of the stomach causes decreased peristalsis, whereas parasympathetic stimulation of the intestine increases peristalsis. In general, sympathetic stimulation promotes responses for the protection of the individual. For example, sympathetic activity increases blood glucose levels and temperature and increases heart rate and blood pressure. In emergency situations, a generalized and widespread discharge of the sympathetic system occurs and is known as the "fight or flight" reflex or acute stress response (see Chapter 11). This is accomplished by an increased firing frequency of sympathetic fibers and by activation of sympathetic fibers normally silent and at rest (fibers to the sweat glands, pilomotor muscles, and the adrenal medulla, as well as vasodilator fibers to muscle). Regulation of vasomotor tone is considered the single most important function of the sympathetic nervous system. (Fig. 15.28 illustrates some of the most important functions of the sympathetic nervous system.)

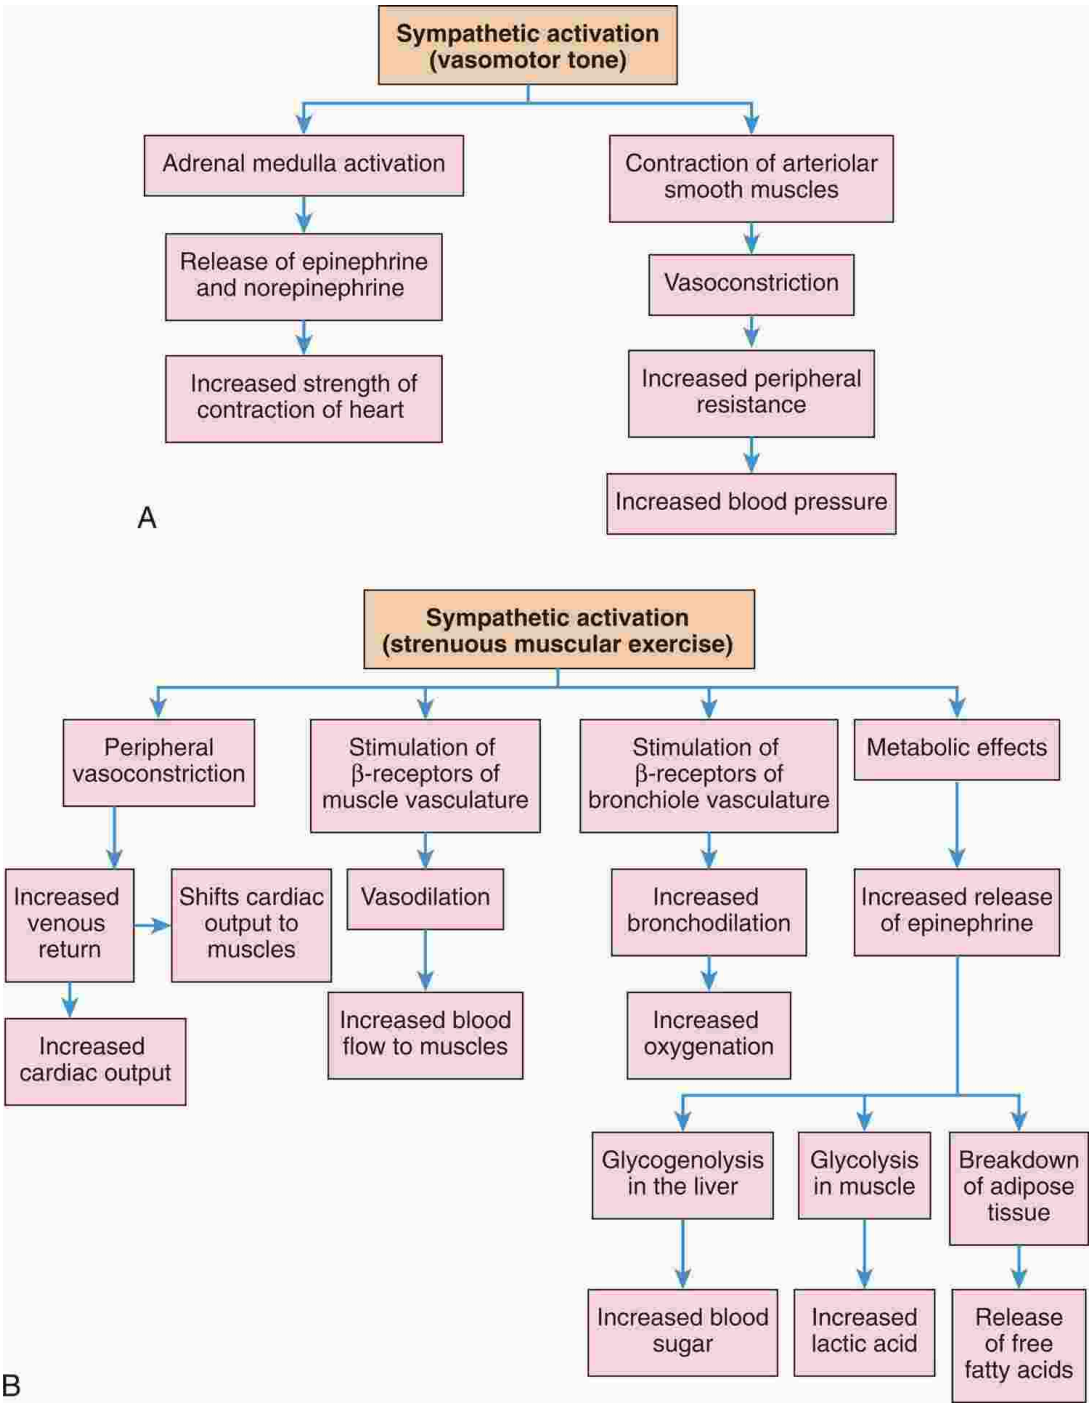

FIG. 15.28 Examples of Important Functions of the Sympathetic Nervous System.
(A) Regulation of vasomotor tone. **(B)** Regulation of strenuous muscular exercise ("fight-or-flight" or stress response). (See also Chapter 11 and Fig. 11.2 for more detail on the stress response.)

Flowchart A shows the functions of the sympathetic activation (vasomotor tone). • Adrenal medulla activation; release of epinephrine and norepinephrine; and increased strength of contraction of heart. • Contraction of arteriolar smooth muscles; vasoconstriction; increased peripheral resistance; and increased blood pressure. Flowchart B shows the functions of sympathetic activation (strenuous muscular exercise). • Peripheral vasoconstriction; and increased venous return leading to increased cardiac output or shifting of cardiac output to muscles. • Stimulation of beta-receptors of muscle vasculature; vasodilation; and increased blood flow to muscles. • Stimulation of beta-receptors of bronchiole vasculature; and increased bronchodilation; increased oxygenation. • Metabolic effects; and increased release of epinephrine. Increased release of epinephrine leads to the following three responses. • Glycogenolysis in the liver; and increased blood sugar. • Glycolysis in muscle; and increased lactic acid. • Breakdown of adipose tissue; and release of free fatty acids.

Increased parasympathetic activity promotes rest and tranquility and is characterized by reduced heart rate and enhanced visceral functions concerned with digestion. Stimulation of the vagus nerve (cranial nerve X) in the gastrointestinal tract increases peristalsis and secretion, as well as the relaxation of sphincters. Activation of parasympathetic fibers in the head, provided by cranial nerves III, VII, and IX, causes pupil constriction, tear secretion, and increased salivary secretion. Stimulation of the sacral division of the parasympathetic system contracts the urinary bladder and facilitates the process of penile erection.

The parasympathetic system lacks the generalized and widespread response of the sympathetic system. Specific parasympathetic fibers are activated to regulate particular functions. Although the actions of the parasympathetic and sympathetic systems are usually antagonistic, there are exceptions. Peripheral vascular resistance, for example, is increased dramatically by sympathetic activation but is not altered appreciably by activity of the parasympathetic system. Most blood vessels involved in the control of blood pressure are innervated by sympathetic nerves. To decrease blood pressure, therefore, it is more important to block or paralyze the continuous (tonic) discharge of the sympathetic system than to promote parasympathetic activity.

The CNS mechanisms involved in the aging process are extremely complex, and many questions have yet to be answered. *Geriatric Considerations: Aging & the Nervous System* summarizes the structural, cellular, cerebrovascular, and functional changes that occur in the nervous system with aging.

Geriatric Considerations

Aging and the Nervous System

Structural Changes with Aging

Decreased brain weight and size, particularly frontal regions
Increase in ventricular volume
Fibrosis and thickening of the meninges
Narrowing of gyri and widening of sulci
Increase in size of ventricles

Cellular Changes with Aging

Decrease in number of neurons not consistently related to changes in mental function
Decreased myelin
Lipofuscin deposition (a pigment resulting from cellular autodigestion)
Decreased number of dendritic processes and synaptic connections
Intracellular neurofibrillary tangles; significant accumulation in cortex associated with Alzheimer dementia
Imbalance in amount and distribution of neurotransmitters
Decrease in glucose metabolism

Cerebrovascular Changes with Aging

Arterial atherosclerosis (may cause infarcts and scars)
Increased permeability of blood-brain barrier
Decreased vascular density

Functional Changes with Aging

Decreased tendon reflexes
Progressive deficit in taste and smell
Decreased vibratory sense
Decrease in accommodation and color vision
Decrease in neuromuscular control with change in gait and posture
Sleep disturbances
Memory impairments
Cognitive alterations associated with chronic disease
Functional changes and nervous system aging have significant individual variation

Data from Chételat G, Landeau B, Salmon E, et al. Relationships between brain metabolism decrease in normal aging and changes in structural and functional

connectivity. *NeuroImage*, 2013;76:167–177; Fjell AM, Walhovd KB. Tests of Nervous System Structure and Function

Skull and Spine Roentgenograms

Roentgenograms (x-ray films) of the skull or spine from multiple angles (views) are used primarily to localize bony defects, bone density, erosion, or calcified structures. The pineal gland in older people becomes calcified and is useful as an internal brain landmark. Probably the most commonly used radiologic studies are x-ray films.

Computed Tomography

Computed tomography (CT) creates two-dimensional reconstructions from multiple radiologic images (x-rays) using computer-assisted analysis. It can demonstrate fine distinctions in shape, size, and densities of a variety of tissues based on differential absorption of x-rays. CT imaging is a noninvasive procedure used in evaluating cranial and spinal structures and hemorrhages, tumors, and distortions in the brain caused by pressure differences. A variety of contrast media are also commonly used in conjunction with this procedure to enhance the delineation of selected structures. **Spiral or helical CT** uses a multidetector scanner mounted on a rotating gantry to provide several axial images of a large continuous anatomic area in a matter of seconds. **Helical CT angiography** uses contrast media for the detection of aneurysms or ruptured aneurysms.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) uses a static magnetic field, instead of x-rays, to orient physiologic atomic particles. Disruption of this orientation by excitation of the particles using serial radiofrequency pulsations provides the image data. The specific tissue reaction is computer-analyzed to give an image with much better spatial resolution than that provided by CT. The MRI also reconstructs images in three angles at right angles (i.e., axial, sagittal, coronal). MRI is reported to have none of the adverse effects associated with radiation examinations. **Magnetic resonance spectroscopy (MRS)** can be completed simultaneously as a standard MRI by analyzing the chemical composition of proton (hydrogen) or phosphorous-based molecules and is useful for differentiating the chemical composition and function of various regions of the brain. **Functional MRI (fMRI)** detects changes in blood oxygenation and flow and can produce maps showing the parts of the brain that are functioning during a mental process. **Diffusion tensor imaging (DTI)** is an MRI technique that quantifies the size

and direction of white matter tracts by measuring asymmetries in the magnitude and direction of the diffusion of water molecules. Color coding and fiber tracking (tractography) add detail.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) uses special imaging techniques to visualize blood vessels in great detail. MRA can be used in conjunction with cerebral angiography to detect and localize pathologic lesions of the circulatory system of the brain, particularly the arterial system. In some cases, contrast agents are used.

Positron-Emission Tomography Scan

The **positron-emission tomography (PET) scan** uses CT imaging to detect the emission of positive electrons from trace amounts of radioactive substances injected into the bloodstream or administered as inhaled gases. With radioactive decay, radioactive substances emit a positron. As they are distributed in tissues, they display characteristic patterns that indicate physiologic and metabolic processes, for example, glucose and oxygen uptake, cerebral blood flow, neural and neurotransmitter function, and the effects of drugs. As a research tool, PET is being used to visualize the specific brain sites involved in the processing of information in the brain.

Single Photon Emission Computed Tomography

Single photon emission computed tomography (SPECT) uses radiotracers with longer half-lives than those used in PET scans. CT creates images after radionuclide substances (technetium [^{99m}Tc]) have been introduced into the bloodstream. For example, visualization of tissue uptake of the radioactive agent indicates blood-brain barrier integrity (increased uptake of the agent indicates disruption). This scanning technique also can identify abnormalities in blood-flow dynamics and cellular metabolic function. The brain scan is particularly helpful in detecting abnormal vascularity resulting from neoplasms, abscesses, and vascular lesions.

Cerebral Angiography

Cerebral angiography is a radiologic technique that demonstrates cerebrovascular blood flow. The introduction of a small catheter commonly performs this technique into the femoral artery. The catheter is then passed to the level of the cerebral circulation and through the aorta, and a contrast dye is injected. Serial x-ray films are then taken. These films demonstrate the flow of the dye through the cerebral vasculature and provide information on the patency, location, size, and flow pattern of the vessels. Another technique used in cerebral angiography is the retrograde (reverse flow) injection of the dye through catheterization of a brachial, axillary, subclavian, or femoral vein.

Echoencephalography (Ultrasound)

Echoencephalography, or **ultrasound**, is a safe, noninvasive procedure using sound waves deflected at differing rates, depending on the density of the tissue. Information is processed and displayed on an oscilloscope screen. It is useful primarily in detecting structural characteristics of intracranial space-occupying mass lesions and the determination of ventricular dimensions, especially in newborns where open fontanelles provide good acoustic windows.

Electroencephalography

The **electroencephalograph (EEG)** is a recording of electrical impulses arising from the brain's cortical surface that are detected by scalp electrodes. The recording of brain wave patterns is analyzed for alterations or localization (or both) of specific electrical activity. This test is especially useful in detecting and localizing foci that initiate seizure activity. It is also an important technique in the assessment of encephalopathy (altered mental status). Complete absence of electrical activity is seen in individuals who are legally "brain dead."

Magnetoencephalography

Magnetoencephalography (MEG) is a specialized imaging technique used to measure magnetic fields induced by electrical activity in the brain. Electrical activity in the brain, such as that detected by EEG, induces an orthogonally oriented magnetic field. MEG uses multiple sensors that allow vectoring and ultimately localization of the origin of the electrical activity that generated the field. The use of MEG has the advantage over EEG in that the induced magnetic field is not significantly dispersed by passing through the skull and soft tissues of the scalp. Co-registration of MEG and MRI data allow precise localization of the electrical focus for seizure onset.

Evoked Potentials

Evoked potentials (EPs) are a method of detecting electrical brain activity that results from a stimulus—primarily auditory, visual, or peripheral sensory. Electrical activity is computer-formatted to display changes in trends. The primary uses of EPs include perioperative detection of sensory pathway integrity and disease- or drug-related sensory dysfunction.

Cerebrospinal Fluid Analysis

CSF generally is obtained from the lumbar or cisternal subarachnoid space using a hollow needle that allows passive flow. The lumbar puncture is performed most often at the L3–L4 interspace (below the level of the spinal cord at L1–L2). Cisternal puncture is performed by inserting a needle into the cerebellomedullary cistern using an approach from the back of the neck in the region of the foramen magnum. CSF pressure is commonly measured during these procedures. The CSF can also be analyzed for gross characteristics and constituents (color, blood cells, electrolytes, and protein) and cultured for microorganisms.

Summary Review

Overview and Organization of the Nervous System

1. The nervous system divisions have been categorized as either structural (central nervous system [CNS] and peripheral nervous system [PNS]) or functional (somatic nervous system and autonomic nervous system [ANS]).
2. The CNS is contained within the brain and spinal cord.
3. The PNS is composed of cranial and spinal nerves, which carry impulses toward the CNS (afferent—sensory) and away from the CNS (efferent—motor) to and from target organs or skeletal muscle.
4. The somatic nervous system consists of pathways regulating voluntary motor control.

The ANS is involved in the involuntary control of organ systems. The ANS is divided into sympathetic and parasympathetic divisions.

Cells of the Nervous System

1. The neuron and neuroglial cells (nonnerve cells) make up nervous tissue. The neuron is specialized to transmit and receive electrical and chemical impulses, whereas the neuroglial cell provides supportive and maintenance functions.
2. The neuron is composed of a cell body, dendrite(s), and an axon. A myelin sheath around selected axons forms insulation that allows faster nerve impulse conduction, referred to as saltatory conduction.
3. The neuron is further divided into unipolar, pseudounipolar, bipolar, and multipolar categories, according to its structure and particular mechanics of impulse transmission. Functionally, the neuron can be sensory, associational, and motor.
4. Neuroglial cells ("nerve glue") support the CNS and comprise approximately half of the total brain and spinal cord volume.
5. Nerve injury usually leads to the degeneration of the portion cut off from the cell body, called Wallerian degeneration. The part of the axon connected to the cell body can undergo slow regeneration depending on the type and location of the injury.

The Nerve Impulse

1. The region between adjacent neurons is the synapse, and the region between the neuron and muscle is the neuromuscular junction.
2. Neurotransmitters are responsible for chemical conduction across the synapse, and the nerve impulse is regulated predominantly by a balance of inhibitory postsynaptic potentials (IPSPs) and excitatory postsynaptic potentials (EPSPs), temporal and spatial summation, and convergence and divergence.

The Central Nervous System

1. The cerebrum is the largest part of the brain and contains gray matter and white matter. The cerebral cortex is the brain's outer layer and contains only gray matter arranged in folds, composed mostly of cell bodies.
2. The brain is contained within the cranial vault and is divided into three distinct regions: (1) forebrain, (2) hindbrain, and (3) midbrain.
3. The forebrain includes the *telencephalon* (the two cerebral hemispheres) and allows conscious perception of internal and external stimuli, thought and memory processes, and voluntary control of skeletal muscles. The deep portion of the forebrain is termed the *diencephalon* and processes incoming sensory data. The center for the voluntary control of skeletal muscle movements is located along the precentral gyrus in the frontal lobe, whereas the center for perception is along the postcentral gyrus in the parietal lobe. The Broca area (inferior frontal gyrus—motor function) and the Wernicke area (superior temporal gyrus—sensory function) are major speech centers.
4. The midbrain is primarily a relay center for motor and sensory tracts and a center for auditory and visual reflexes.
5. The hindbrain allows sampling and comparison of sensory data received from the periphery and motor impulses of the cerebral hemispheres for coordination and refinement of skeletal muscle movement.
6. The spinal cord contains most of the nerve fibers that connect the brain with the periphery. The corticospinal tracts are descending pyramidal (motor) pathways from the motor cortex. The rubrospinal and reticulospinal tracts are descending extrapyramidal tracts that coordinate movement. The anterior, posterior, and lateral spinothalamic tracts carry sensory information to the brainstem and thalamus, where information is relayed to the sensory cortex. Reflex arcs are sensory and motor circuits completed in the spinal cord and influenced by the higher centers in the brain.
7. The CNS is protected by the bony cranium, meninges (dura mater, arachnoid, membrane, and pia mater), cerebrospinal fluid (CSF), and vertebral column. CSF is formed from blood components in the choroid plexuses of the ventricles and is reabsorbed in the arachnoid villi (located in the dural venous sinuses) after circulating through the brain and subarachnoid space.
8. The paired carotid and vertebral arteries supply blood to the brain and connect to form the circle of Willis. The major branches projecting from the circle of Willis are the anterior, middle, and posterior cerebral arteries. Drainage of blood from the brain is accomplished through the venous sinuses and jugular veins.
9. The blood-brain barrier is provided by tight junctions between the cells of brain capillary endothelial cells and surrounding supporting cells.
10. Blood supply to the spinal cord originates from the vertebral arteries and branches arising from the aorta.

The Peripheral Nervous System

1. The cranial and spinal nerves constitute the PNS. The PNS relays information from the CNS to muscle and effector organs through cranial and spinal nerve tracts arranged in fascicles (multiple fascicles bound together form the peripheral nerve).

The Autonomic Nervous System

1. The ANS is responsible for maintaining a steady state in the internal environment. Two opposing systems make up the ANS: (1) the sympathetic nervous system (thoracolumbar division) responds to stress by mobilizing energy stores and prepares the body to defend itself, and (2) the parasympathetic nervous system (craniosacral division) conserves energy and the body's resources. Both systems function, more or less, at the same time. The enteric autonomic nervous system controls the function of the gastrointestinal tract.

Tests of Nervous System Structure and Function

1. Tests of nervous system structure and function include x-ray films, CT, MRI and MRA, PET, SPECT, cerebral angiography, echoencephalography, electroencephalography, magnetoencephalography, EPs, and analysis of CSF.

Emerging Science Brain Networks

The architecture and integrated function of neural nodes, networks, and interconnected pathways within the brain are being mapped in the advancing field of human connectomics. Imaging techniques are combined with mathematical and computational models to produce visual representations of brain networks.

The figure below provides an illustration of brain connectivity showing interconnecting cortical pathways using diffusion tensor imaging tracking technology (the imaging of diffusion of water in tissue). Such mapping of the brain contributes to an understanding of the commonalities and individual differences of the normally functioning brain and changes associated with aging and disease (i.e., degenerative brain disease, epilepsy, schizophrenia, and brain tumors).

The Human Connectome Project (HCP) began in 2010 with funding from the National Institutes of Health and sought to collect high-quality images from a wide variety of subjects that would be shared openly. HCP processed images to minimize blurring that often occurs with scans due to head movements, which makes the images produced of exceptionally high quality. They have also provided numerous neuroimaging software and informatic tools for free use. The HCP data has been used in more than 140 studies thus far and will hopefully accelerate progress in understanding the healthy and diseased brain.

Data from Filippi M, et al. Assessment of system dysfunction in the brain through MRI-based connectomics, *Lancet Neurology*. 2013;12(12):1189–1199; Glasser MF, et al. The human connectome project's neuroimaging approach. *Nature Neuroscience*, 2016;19(9):1175–1187.

Emerging Science Box Schwann Cells

Schwann cells (SCs) are peripheral neuroglial cells derived from the neural crest. They are the most common cell type in the peripheral nervous system. There are several subtypes in addition to the myelin-forming cells. These include non–myelin-forming autonomic nervous system cells, perisynaptic cells, and perineuronal satellite cells of the dorsal root ganglia and of the autonomic ganglia. SCs are important for the maintenance of normal nervous system function, repair of neural injury, immune modulation, and upregulation of pain. Myelin-forming SCs form spirals of compact myelin lamellae in both small and large neurons. Increasing layers of lamellae increase the speed of salutatory conduction. These cells also can recognize antigen and be the target of autoimmune responses as occur with Guillain-Barré syndrome. Most neural cells in the peripheral nervous system are unmyelinated, and SCs in these nerves, as well as the dorsal root and sympathetic and parasympathetic ganglia, provide an axonal sheath but do not form myelin. With peripheral nerve injury, perineuronal satellite cells can up-regulate nerve growth factor and other molecules important to peripheral chronic pain syndromes. At the neuromuscular junction (NMJ), nonmyelinating SCs function to facilitate neurotransmission and repair damage. Transplant of SCs and use of exogenous neurotrophic factors are in the preclinical stage of evaluation.

The Special Senses 491
- Vision 491
- Hearing 498
- Olfaction and Taste 500

Somatosensory Function 502
- Touch 502
- Proprioception 502

Alterations in sensory function may involve dysfunctions of the general or the special senses. Dysfunctions of the general senses include chronic pain, abnormal temperature regulation, and tactile or proprioceptive dysfunction. Pain is a unique sensory experience that, although universally described as unpleasant, is nonetheless essential to an individual's survival. Pain provides protection by signaling the presence

of disease or injury. Like pain, variations in temperature can signal disease. Fever is a common manifestation of dysfunction and is often the first symptom observed in an infectious or inflammatory condition.

Sleep is a normal cyclic process that restores the body's energy and maintains normal function. Sleep is so essential to physiologic and psychologic function that sleep deprivation causes a wide range of clinical manifestations. Prolonged deprivation or disruption of sleep ultimately leads to serious dysfunction.

The special senses of vision, hearing, touch, smell, and taste are the means by which individuals perceive stimuli that are essential for interacting with the environment. Special sensory receptors are connected to specific areas of the brain through the afferent pathways of the peripheral and central nervous system (CNS). Each of the special senses thus involves a connected system of organs and tissues that receives stimuli and sends sensory messages to areas of the CNS, where they are processed and guide behavior. Dysfunctions of the special senses include visual, auditory, olfactory, and gustatory (taste).

Pain

Pain is one of the body's most important adaptive and protective mechanisms. It is a complex experience comprised of dynamic interactions among physical, cognitive, spiritual, emotional, and environmental factors and cannot be characterized as only a response to injury. McCaffery defined pain as "whatever the experiencing person says it is, existing whenever he says it does."[1] The International Association for the Study of Pain and the American Pain Society defined pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[2] A more recent proposal for the definition of pain is "pain is a mutually recognizable somatic experience that reflects a person's apprehension of threat to their bodily or existential integrity."[3] Acute pain is protective and promotes withdrawal from painful stimuli, allows the injured part to heal, and teaches avoidance of painful stimuli.

Neuroanatomy of Pain

Three parts of the nervous system are responsible for the sensation, perception, and response to pain:

1. The *afferent pathways*, which begin in the peripheral nervous system (PNS), travel to the spinal gate in the dorsal horn, and then ascend to areas in the diencephalon (thalamus, epithalamus, and hypothalamus) and cortex.
2. The *interpretive centers* located in the subcortical and cortical networks, brainstem, midbrain, diencephalon, and cerebral cortex.
3. The *efferent pathways* that descend from the central nervous system (CNS) back to the dorsal horn of the spinal cord.

The processing of potentially harmful (noxious) stimuli through a normally functioning nervous system is called **nociception**. **Nociceptors**, or pain receptors, are free nerve endings in the afferent peripheral nervous system. When they are stimulated, they cause **nociceptive pain**. The cell bodies of nociceptors are located in the dorsal root ganglia (DRG) for the body and in the trigeminal ganglion for the face. Nociceptors have a peripheral and central axonal branch that innervates their target organ and the spinal cord, respectively. Nociceptors are unevenly distributed throughout the body, so the relative sensitivity to pain differs according to their location (Table 16.1). Nociceptors respond to different types of noxious stimuli: mechanical (pressure or mechanical distortion), thermal (extreme temperatures), or chemical (acids or chemicals of inflammation, such as bradykinin, histamine, leukotrienes, or prostaglandins). Nociception involves four phases: transduction, transmission, perception, and modulation.[4]

Table 16.1

Stimuli That Activate Nociceptors (Pain Receptors)

Location of Receptor	Provoking Stimuli
Skin	Pricking, cutting, crushing, burning, freezing
Gastrointestinal tract	Engorged or inflamed mucosa, distention or spasm of smooth muscle, traction on mesenteric attachment
Skeletal muscle	Ischemia, injuries of connective tissue sheaths, necrosis, hemorrhage, prolonged contraction, injection of irritating solutions
Joints	Synovial membrane inflammation
Arteries	Piercing, inflammation
Head	Traction, inflammation, or displacement of arteries, meningeal structures, and sinuses; prolonged muscle contraction
Heart	Ischemia and inflammation
Bone	Periosteal injury: fractures, tumor, inflammation

Pain transduction is the process of converting a painful stimulus into an electrical signal that is transmitted to the CNS. Transduction begins when nociceptors are activated by a painful stimulus (physical, chemical, or thermal), causing ion channels (sodium, potassium, calcium) on nociceptors to open, creating electrical impulses that travel through axons of two primary types of nociceptors that are transmitted to the spinal cord, brainstem, thalamus, and cortex (see Fig. 15.15).[5] The two primary types of nociceptors are **A-delta (Aδ) fibers** and **C fibers**. Aδ fibers are larger myelinated fibers that rapidly transmit sharp, well-localized "fast" pain sensations, such as intense heat or a pinprick to the skin. Activation of these fibers causes a spinal reflex withdrawal of the affected body part from the stimulus, before a pain sensation is

perceived. C fibers are the most numerous, are smaller, unmyelinated, and are located in muscle, tendons, body organs, and the skin. They slowly transmit dull, aching, or burning sensations that are poorly localized and often constant.

Pain transmission is the conduction of pain impulses along the Aδ and C fibers (primary-order neurons) into the dorsal horn of the spinal cord (Fig. 16.1). Here they form synapses with excitatory or inhibitory interneurons (second-order neurons) in the substantia gelatinosa of the dorsal horn. The impulses then synapse with projection neurons (third-order neurons), cross the midline of the spinal cord, and ascend to the brain through two lateral spinothalamic tracts (Fig. 16.2). The anterior spinal thalamic tract carries fast impulses for acute sharp pain. The lateral spinothalamic tract carries slow impulses for dull or chronic pain. The fast, sharp pain is perceived first, followed by dull, throbbing pain. These tracts connect to the reticular formation, hypothalamus, thalamus (the major relay station of sensory information), and limbic system. The impulses are then projected to the somatosensory cortex for interpretation of the location and intensity of the pain (Fig. 16.3), and to other areas of the brain for an integrated response to pain.

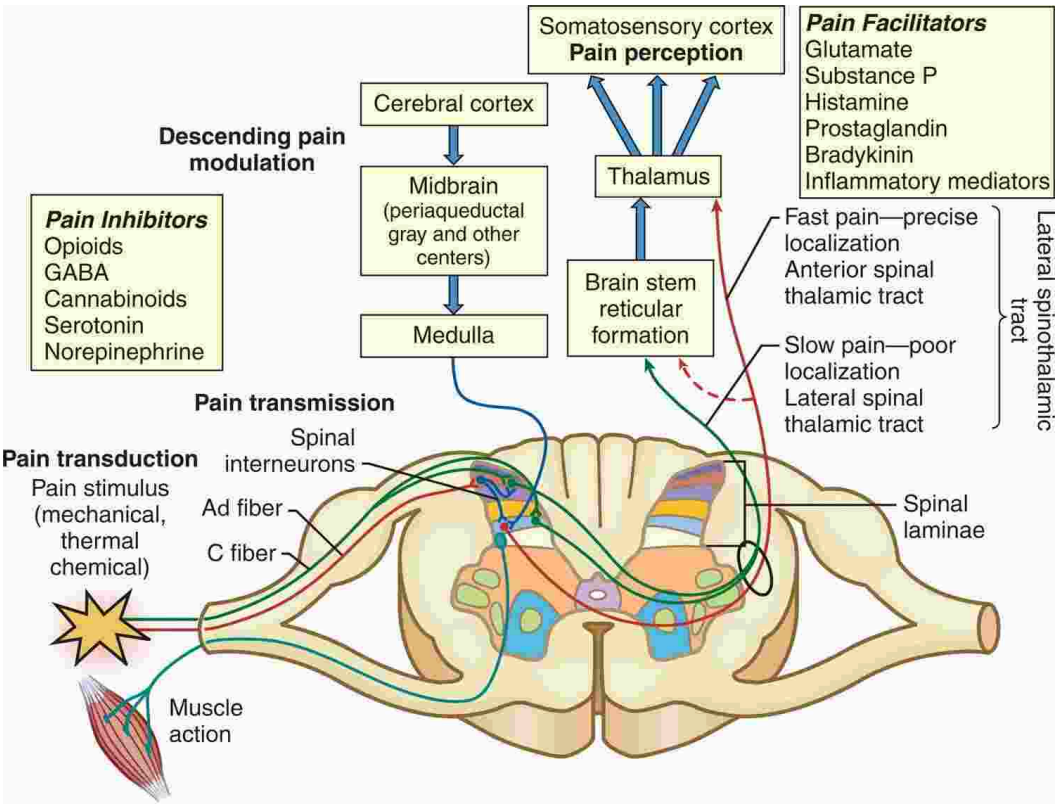

FIG. 16.1 Transmission of Pain Sensations.
The Aδ and C fibers synapse in the laminae of the dorsal horn, cross over to the contralateral spinothalamic tract, and then ascend to synapse in the midbrain through the neospinothalamic and paleospinothalamic tracts. Impulses are then conducted to the sensory cortex. Descending pain inhibition is initiated in the cerebral cortex or from the midbrain and medulla.

An illustration accompanied by a flow chart depicts the pain pathway involved in pain transduction, pain transmission, and descending pain modulation. The illustration shows the cross-section through the spinal cord with labels as follows. Pain transduction: Pain stimulus (mechanical, thermal chemical); pain transmission: Spinal interneurons, A fiber, C fiber;

spinal laminae. The pathway indicates the pain impulses along with the A fiber and C fibers into the dorsal horn by forming synapses with spinal interneurons. The flow chart represents impulse conducted to the somatosensory cortex through brain stem reticular formation and thalamus and the descending pain modulation in the cerebral cortex to form the midbrain (periaqueductal gray and other centers) and medulla. The anterior spinal thalamic tract carries fast pain through A fiber and the lateral spinal thalamic tract carries slow pain through C fiber. The pain inhibitors are opioids, G A B A, cannabinoids, serotonin, and norepinephrine. Pain facilitators are glutamate, substance P, histamine, prostaglandin, bradykinin, and inflammatory mediators.

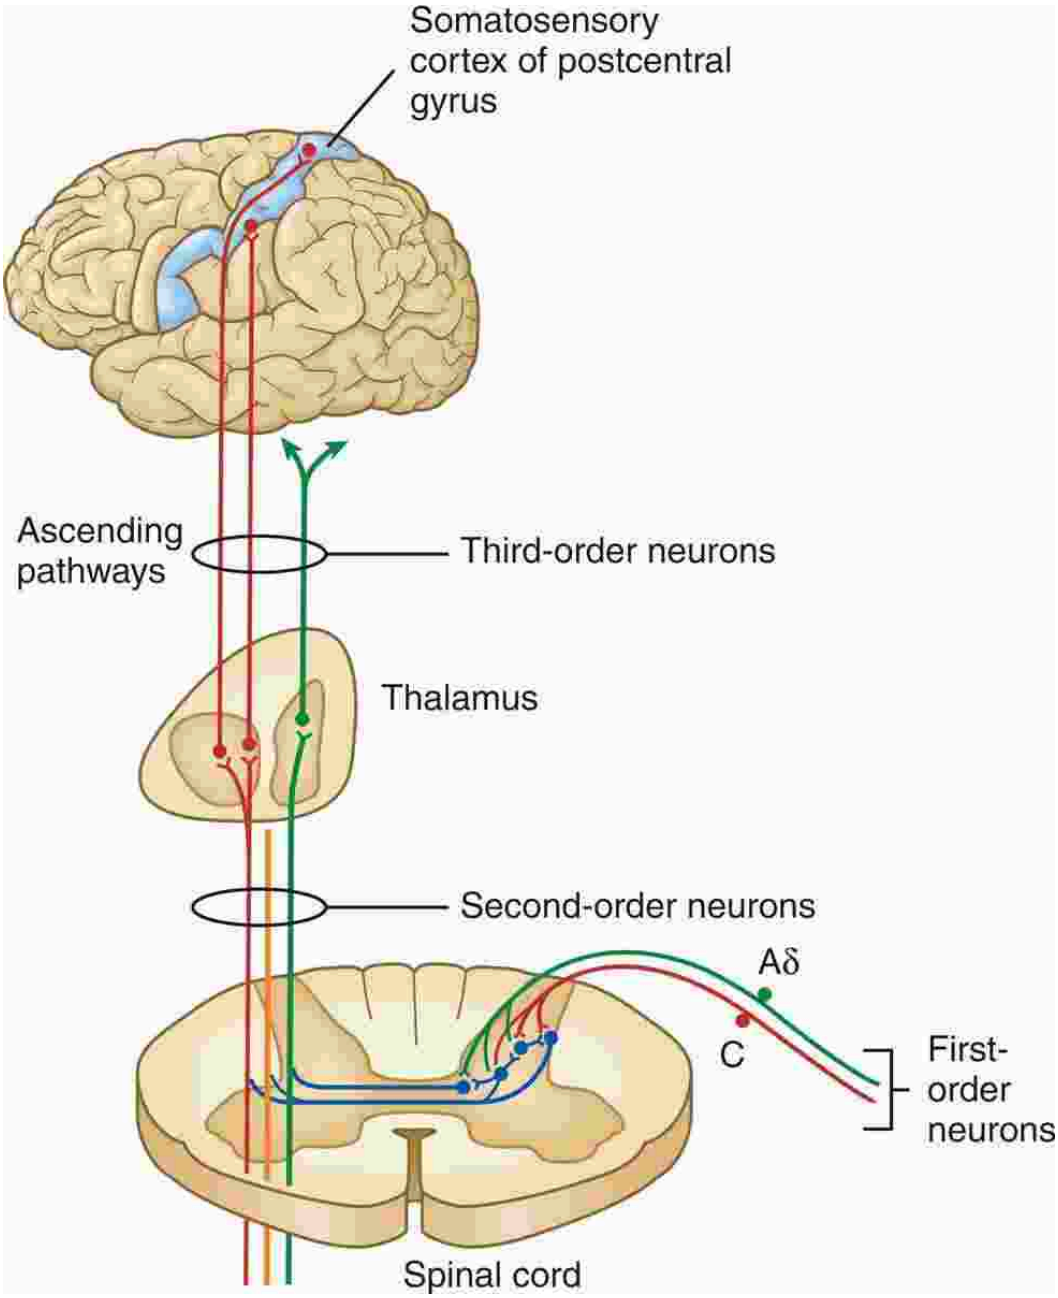

FIG. 16.2 Nociception Pathways.
Aδ and C fibers comprise the primary, first-order sensory afferents coming into the gate at the dorsal horn of the spinal cord. Second-order neurons cross the cord ("decussate") and ascend to the thalamus as part of the spinothalamic tract. Third-order afferents project to higher brain centers of the limbic system, the frontal cortex, and the primary sensory cortex of the postcentral gyrus of the parietal lobe.

An illustration demonstrates the pathways of nociception involving the first-order, second-order, and third-order neurons that carries action potential from the spinal cord to the somatosensory cortex of postcentral gyrus through the thalamus. The pathway indicates the impulses synapses with a projection of third-order neurons across the midline of the spinal cord, and ascend to the brain through two lateral spinothalamic tracts.

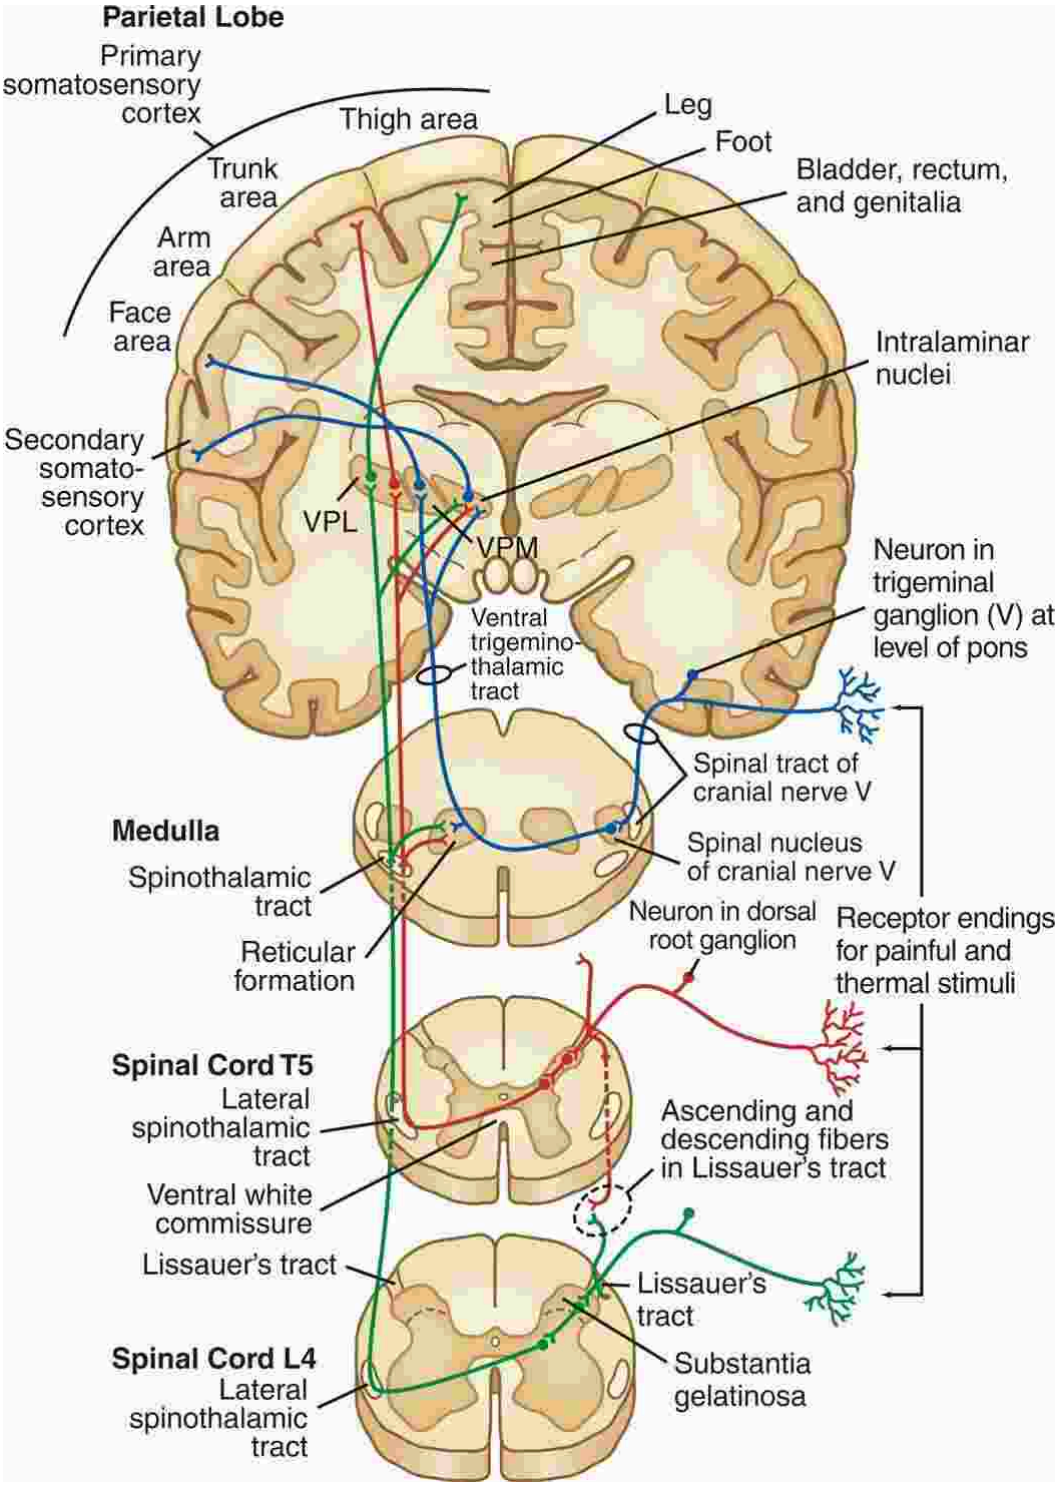

FIG. 16.3 Central Nervous System Pathways That Mediate the Sensations of Pain and Temperature. *VPL*, Ventral posterior lateral thalamic nuclei; *VPM*, ventral posterior medial thalamic nuclei.

Four series of illustrations depict the central nervous system pathways that mediate sensations of pain and temperature to the primary somatosensory cortex from the spinal cord L 4, spinal cord L 5, and medulla. The illustration of spinal cord L 4 depicts the coronal section of the spinal with labels: lateral spinothalamic tract, substantial gelatinosa, Lissauer's tract. The illustration of spinal cord T 5 depicts the coronal section of the spinal cord with labels: Lateral spinothalamic tract, ventral white commissure, Lissauer's tract, ascending and descending fibers in Lissauer's tract. The illustration of the medulla depicts the coronal section of the spinal cord with labels: Spinothalamic tract, reticular formation, a spinal tract of cranial nerve five, the spinal nucleus of cranial nerve five, a neuron in dorsal root ganglion. The illustration of the parietal lobe depicts the coronal section of the cortex with labels: Primary somatosensory cortex consisting of the face area, arm area, trunk area, thigh area, bladder, rectum and genitalia, leg, foot; secondary somatosensory cortex, ventral trigenmino-thalamic tract, a neuron in trigeminal ganglion five at the level of the pons, intralaminar nuclei. The tracts connect to the reticular formation, hypothalamus, thalamus and limbic system. The impulses are then projected to the somatosensory cortex for interpretation of the location and intensity of the pain and to other areas of the brain for an integrated response to pain.

Pain perception is the conscious awareness of pain, which occurs primarily in the reticular and limbic systems and the cerebral cortex. Interpretation of pain is influenced by many factors, including genetics, cultural preferences, sex roles, age, level of health, and past pain experiences. Three systems interact to produce the perception of pain.[6]

The **sensory-discriminative system** is mediated by the somatosensory cortex and is responsible for identifying the presence, character, location, and intensity of pain. The **affective-motivational system** determines an individual's conditioned avoidance behaviors and emotional responses to pain. It is mediated through the reticular formation, limbic system, and brainstem. The **cognitive-evaluative system** overlies the individual's learned behavior concerning the experience of pain and therefore can modulate perception of pain. It is mediated through the cerebral cortex. The integration of these three systems is referred to as the "pain matrix"[7] or networks of cerebral connectivity.

Pain threshold and tolerance are subjective phenomena that influence an individual's perception of pain. They can be influenced by genetics, sex, cultural perceptions, expectations, role socialization, physical and mental health, and age (Table 16.2A).

Table 16.2 A

Pain Perception in Infants, Children, and Older Adult Persons

Data from Anand KJS. Defining pain in newborns: need for a uniform taxonomy? *Acta Paediatr*. 2017;106(9):1438–1444; Lautenbacher S, et al. Age changes in pain perception: A systematic-review and meta-analysis of age effects on pain and tolerance thresholds. *Neurosci Biobehav Rev*. 2017;75:104–113; Tracy B, Sean Morrison R. Pain management in older

adults. *Clin Ther*. 2013;35(11):1659–1668; Walker SM. Neonatal pain. *Paediatr Anaesth*. 2014;24(1):39–48.

Pain threshold is defined as the lowest intensity of pain that a person can recognize.[2] Intense pain at one location may increase the threshold in another location. For example, a person with severe pain in one knee is more likely to experience less intense chronic back pain (this is called **perceptual dominance**). Because of perceptual dominance, pain at one site may mask other painful areas. Stress, excessive physical exertion, acupuncture, sexual activity, and other factors can increase the levels of circulating neuromodulators, thereby raising the pain threshold.

Pain tolerance is defined as the greatest intensity of pain that a person can endure.[2] It varies greatly among people and in the same person over time because of the body's ability to respond differently to noxious stimuli. Pain tolerance generally *decreases* with repeated exposure to pain, fatigue, anger, boredom, apprehension, and sleep deprivation and may *increase* with alcohol consumption, persistent use of opioid medications, hypnosis, distracting activities, and strong beliefs or faith.

Pediatric ConsiderationsPain Perception of Infants and Children

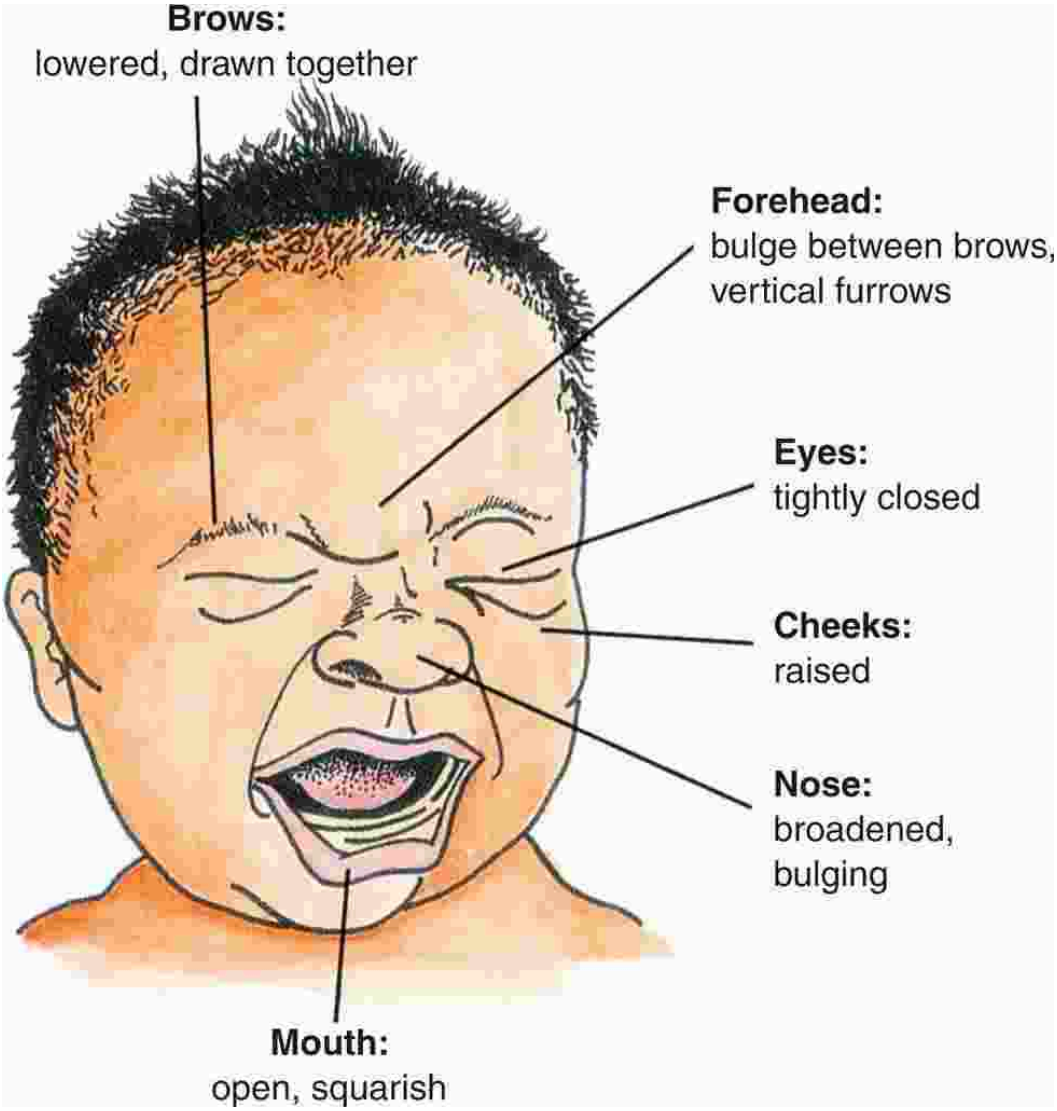
Infants and children have the anatomic and functional ability to perceive pain. However, in the pediatric population, pain is frequently under-recognized and inadequately treated.

Pain pathways and cortical and subcortical centers for pain perception, as well as neurochemicals associated with pain transmission and modulation, are functional in preterm and newborn infants. Alterations in biological factors (e.g., peripheral and central somatosensory function and modulation, brain structure and connectivity) and psychosocial factors (e.g., gender, coping style, mood, and parental response) that influence pain have been identified in children and young adults born very preterm or extremely preterm.[8]

Repetitive, painful experiences and prolonged exposure to analgesic drugs in preterm infants may permanently alter developing synaptic and neuronal pain-processing networks, causing irreversible hypersensitivity to pain with subsequent injury. Alterations occur in

both the excitatory and inhibitory pathways in the spinal cord and descending inhibitory processing from the brainstem. When children are not sufficiently treated for pain, stress hormones are released into their systems, resulting in increased catabolism, immunosuppression, and hemodynamic instability.[9]

Facial overexpression with furrowed eyebrows and exaggerated eye closure, body rigidity, loud crying, sleep disorders, resistance, and shifting the painful part of the body away from touch are the most consistent expressions of pain in infants.[9] There may be finger clenching, writhing, back arching, and head banging.



Painful Facial Expression of Infants. (From Hockenberry MJ. *Wong' s Nursing Care of Infants and Children*. 7th ed. St Louis: Mosby; 2003.)

An illustration of the anterior profile of a crying infant depicts the facial expression of pain labeled as follows. Brows: Lowered, drawn together. Forehead: bulge between brows, vertical furrows; eyes: Tightly closed; cheeks: raised; Nose: broadened bulging.

Toddlers in pain may exhibit verbal or physical aggression and crying, or may guard or defend the body part exposed to pain. Children, like adults, have highly individual responses to pain. Any behavioral and physiologic indicators of pain must be carefully and accurately assessed and adequately treated for children of all ages. Physiologic responses in all age groups may include increases in heart rate, blood pressure, and respiratory rate; flushing or pallor; sweating; and decreased oxygen saturation.

Assessment of pain includes a thorough pain history received from the child and/or parent, exploring the pain quality, characteristics, location, onset, duration, aggravating and alleviating factors, and impact on function. The measurement of pain severity should be done routinely using a developmentally appropriate validated tool. Commonly used tools are listed in Table 16.2B with specified age ranges for the tool.

Table 16.2B

Pediatric Pain Assessment Tools

Pain Assessment Tool	Age Range
Revised Premature Infant Pain Profile (PIPP-R)[1]	Less than 28 weeks to greater than 36 weeks gestational age
Revised Face Legs Activity Cry and Consolability (r-FLACC) scale[2]	2 months to 7 years of age
Faces Pain Scale—Revised (FPS-R)[3]	4 years of age and older
Children and Infants Postoperative Pain Scale (CHIPPS)[4] [*Paediatr Anaesth*. 2000;10(3): 303–318.]	Under 5 years of age
Numerical Rating Scale (NRS)[5]	8 years of age and older

therapy in children. *Adv Clin Exp Med*. 2020;29(3):365–374. doi:10.17219/acem/112600. PMID: 32129952.

There are biological and psychosocial factors that influence the perception and severity of pain. Alterations in biological factors, such as peripheral and central somatosensory function, pain modulation, brain structure, and connectivity, have been identified in children and young adults born very preterm or extremely preterm and play a role in pain. There are also psychosocial factors such as gender, coping style, mood, and parental response that influence pain.[8]

Geriatric Considerations Aging and Pain

Pain in the older adult population is highly prevalent and is a complex issue to both identify and treat. Some older adults have an increased pain threshold while others have a decreased pain tolerance; both factors play a role in the identification and treatment of pain.[10,11] It is important to assess the presence of pain in elderly persons with cognitive decline, as it is often neglected, underreported, underestimated, misdiagnosed, and not adequately treated.[12] Inadequate assessment of pain or lack of proper pain management is associated with adverse outcomes including depression, anxiety, sleep disturbances, and mood changes, which often lead to significant suffering, disability, and social isolation with greater costs and burden to the health care system.[10] Chronic and somatic pain have been shown to negatively affect the degree of frailty.[13] The most frequent pain conditions in older adults are chronic unspecified joint pain, chronic back pain, and chronic neck pain.[12] Pain must be accurately treated in relation to its effect on cognitive function, coexisting disease, drug interactions, other reactions to treatment, and an individual's ability to express pain and maintain safety. Treatment is often compounded by the high prevalence of polypharmacy within this population. Pharmacotherapies used for pain management in older adults are usually only partially effective and are often limited by side effects.[10] Older adults prescribed pharmacological treatment must be monitored

carefully for any alterations in cognition, liver and renal function, physiological changes, and possible drug interactions.[12]

Pain Modulation

Pain modulation involves many different facilitatory and inhibitory mechanisms that increase or decrease the transmission of pain signals throughout the nervous system. Mechanisms include neurotransmitters and central and spinal pathways. Depending on the mechanism, modulation can occur before, during, or after pain is perceived.[14] Analgesic drugs, anesthesia, and nonpharmacologic interventions such as transcutaneous nerve stimulation, acupuncture, hypnosis, and physical therapies are examples of strategies for enhancing pain modulation.

Neurotransmitters of Pain Modulation

A wide variety of neurotransmitters act to modulate control over transmission of pain impulses in the periphery, spinal cord, and brain. The peripheral triggering mechanisms that initiate release of **excitatory neurotransmitters** include tissue injury (prostaglandins, histamine, bradykinin) and chronic inflammatory lesions (lymphokines). Glutamate, aspartate, substance P, and calcitonin are common excitatory neurotransmitters in the brain and spinal cord. These substances sensitize nociceptors by reducing the activation threshold, leading to increased responsiveness of nociceptors.

Inhibitory neurotransmitters in the CNS include gamma-aminobutyric acid (GABA) and glycine. Norepinephrine and 5-hydroxytryptamine (serotonin) contribute to pain inhibition in the CNS but can excite peripheral nerves.

Endogenous opioids are a family of morphine-like neuropeptides that inhibit transmission of pain impulses in the periphery, spinal cord, and brain by binding with specific opioid receptors (mu [μ], kappa [κ], and delta [δ]) on neurons. They inhibit ion channels, preventing the release of excitatory neurotransmitters, such as substance P and glutamate, in the dorsal horn. In the midbrain they influence descending inhibitory pathways (Fig. 16.4).[15] In peripheral inflamed tissue, opioids are produced and released from immune cells and activate opioid receptors

on sensory nerve terminals.[16] Opioid receptors are widely distributed throughout the body and are responsible for general sensations of well-being and modulation of many physiologic processes, including control of respiratory and cardiovascular functions, stress and immune responses, gastrointestinal function, reproduction, and neuroendocrine control.[17,18]

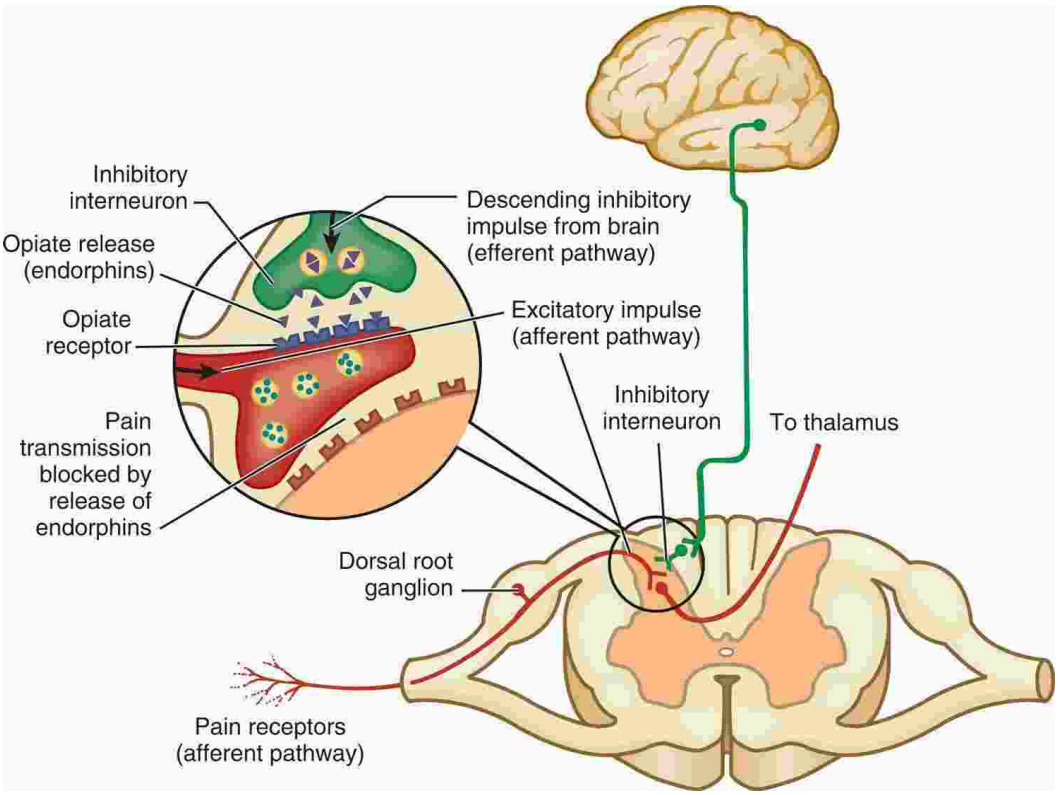

FIG. 16.4 Descending Pathway and Endorphin Response. In this figure, a descending inhibitory impulse is transmitted from the brain to an inhibitory interneuron in the dorsal horn, stimulating the release of endorphin. The endorphin activates a μ opioid receptor and results in inhibition of pain transmission to ascending pathways.

An illustration depicts the descending inhibitory impulse from the brain (efferent pathway) through the thalamus synapses at the inhibitory interneuron in the dorsal ganglion (afferent pathway) along with excitatory impulse (afferent pathway) and stimulates the opiate to release endorphins. The released endorphins activate the opioid receptor which inhibits pain transmission.

Enkephalins are the most prevalent of the natural opioids and bind to δ opioid receptors. **Endorphins** (endogenous morphine) are produced in the brain. The best-studied endorphin is β-endorphin, which binds to μ receptors and is purported to produce the greatest sense of exhilaration as well as substantial natural pain relief. **Dynorphins** are the most potent of the endogenous opioids, binding strongly with κ receptors to impede pain signals. Paradoxically, they play a role in neuropathic pain and in mood disorders and drug addiction. **Endomorphins** bind with μ receptors and have potent analgesic effects. **Nociceptin/orphanin FQ** is an opioid that *induces* pain or hyperalgesia but does not interact with opioid receptors. The nociceptin receptor is widely distributed throughout the PNS and CNS and is associated with numerous biological functions, including immune regulation, mood, feeding, muscle contractility, heart rate, and emotion.

Synthetic and natural opiates have pharmacologic actions similar to morphine and bind as direct agonists to the opioid receptors. Morphine has a 50 times higher affinity for μ receptors in comparison with other opioids. Naloxone is the only clinically used opioid receptor antagonist, with a higher affinity for the μ receptors than for the other receptors.

Endocannabinoids are synthesized from phospholipids and are classified as eicosanoids. They activate cannabinoid CB_1 (primarily in the CNS) and CB_2 receptors (primarily in immune tissue [e.g., the spleen]) to modulate pain and other functions, including memory, appetite, immune function, sleep, stress response, thermoregulation, and addiction. CB_1 receptors decrease pain transmission by inhibiting release of excitatory neurotransmitters in the spinal dorsal horn, periaqueductal gray (PAG; the gray matter surrounding the cerebral aqueduct), thalamus, rostral ventromedial medulla (RVM), and amygdala. **Cannabis** (marijuana) produces a resin containing cannabinoids. **Cannabinoids** are analgesic in humans, but their use is limited by their psychoactive and addictive properties. Work is in progress to develop cannabinoid receptor agonists that do not have addictive side effects.[19,20]

Pathways of Modulation

Descending inhibitory and **facilitatory pathways** inhibit or facilitate pain. Inhibitory pathways can activate opioid receptors and inhibit release of excitatory neurotransmitters, facilitate release of inhibitory

neurotransmitters, or stimulate inhibitory interneurons. Afferent stimulation of particularly the ventromedial medulla and PAG in the midbrain stimulates efferent pathways, which inhibit ascending pain signals at the dorsal horn. The RVM stimulates descending pathways that facilitate or inhibit pain in the dorsal horn.

Segmental pain inhibition occurs when **A-beta (Aβ) fibers** (large myelinated fibers that transmit touch and vibration sensations) are stimulated and the impulses arrive at the same spinal level or segment as impulses from Aδ or C fibers. They stimulate an inhibitory interneuron and decrease pain transmission. An example is rubbing an area that has been injured to relieve pain.

Diffuse noxious inhibitory control (DNIC) is an endogenous inhibitory pain system that involves a spinal-medullary-spinal pathway. Pain is relieved when two noxious or painful stimuli occur at the same time from different sites (pain inhibiting pain). The efficacy of DNIC is evaluated clinically by testing subjective responses to pain using **conditioned pain modulation (CPM)**. A CPM test uses a consistent protocol to deliver a measurable test pain stimulus at one site before and during or after the application of a measurable conditioning pain stimulus at a comparable site (e.g., the arms). A subjective pain intensity rating scale (i.e., 1 to 10) is used to measure intensity of pain at both sites. The conditioning pain stimulus is expected to affect the pain experience of the test stimulus. Use of CPM assessments can be helpful in determining an individual's endogenous pain inhibitory capacity and for managing acute or chronic pain.[21,22]**Expectancy-related cortical activation** (placebo effect [beneficial expectations] or nocebo effect [adverse expectations]) can exert control over analgesic systems to attenuate or intensify pain.[23] In other words, cognitive expectations can cause real, measurable physiologic effects that share some of the same descending pain pathways as the pain modulatory systems (see Emerging Science Box: Pain Management With Pharmacogenics).

Emerging Science BOX

Pain Management With Pharmacogenics

Pain management has been challenging in light of the United States public health crisis related to use of opioid drugs. Opiate misuse, abuse, and overdose has led to a forced reduction of opioid use for the treatment of pain. Pain is well known for its subjectivity and variability among individuals, creating challenges in development of successful treatment regimens. An emerging approach is the use of pharmacogenics, the study of genetic variants that influence the effects of a drug, to guide clinicians in the development of individualized pain management plans. Pharmacogenics focuses on individual genes, specifically CYP2D6. CYP2D6 is highly polymorphic and is involved in the metabolism of 25% of all drugs currently used in clinical practice. Many commonly used opioids are metabolized by CYP2D6 and their metabolic rate is dependent on the CYP2D6 polymorphism of the individual. Understanding specific gene alleles of individuals will identify ultra-rapid metabolizers, extensive metabolizers, intermediate metabolizers, and poor metabolizers, which would allow for person-specific dosing to limit the potential for opiate misuse, abuse, or overdose. DNA is obtained via buccal swab and analyzed in a pain-related gene panel. While this gene panel is not yet FDA approved, investigative studies have identified improved pain control with safe opioid administration when clinicians are able to tailor the pain management plan to the pharmacogenomics of each person. Pharmacogenomics can also identify potentially opioid-vulnerable individuals who can then be provided with opioid alternative treatments for their pain.

Clinical Descriptions of Pain

Pain can be described in a variety of ways. Due to the complex nature of pain, many terms overlap, and more than one description is often used. The broad categories of pain are summarized in Box 16.1. Some of the most common clinical pain presentations are summarized here.

Box 16.1

Categories of Pain

I Neurophysiologic Pain

A. Nociceptive pain
    1. Somatic (e.g., skin, muscle, bone)
    2. Visceral (e.g., intestine, liver, stomach)
    3. Referred
B. Neuropathic (non-nociceptive)
    1. Central pain (lesion in brain or spinal cord)
    2. Peripheral pain (lesion in peripheral nervous system)

II Neurogenic Pain

A. Neuralgia (pain in the distribution of a nerve)
B. Constant
    1. Sympathetically independent
    2. Sympathetically dependent

III Temporal Pain (Time Related, Duration)

A. Acute pain
    1. Somatic
    2. Visceral
    3. Referred
B. Chronic (pain lasting longer than 3 months)

IV Pain Location

A. Abdominal pain
B. Chest pain
C. Headache
D. Low back pain
E. Orofacial pain
F. Pelvic pain

V Etiologic Pain

A. Cancer pain
B. Dental pain
C. Inflammatory pain
D. Ischemic pain
E. Vascular pain

Adapted from Mersky H. Taxonomy and classification of chronic pain syndromes. In: Benzon HT, et al, eds. *Practical Management of Pain*. 5th ed. St Louis: Mosby; 2014:13–18.

Acute pain (nociceptive pain) is a normal protective mechanism that alerts the individual to a condition or experience that is immediately harmful to the body and mobilizes the individual to take prompt action to relieve it. Acute pain is transient, usually lasting seconds to days, sometimes up to 3 months. It begins suddenly and is relieved after the chemical mediators (usually related to inflammation) that stimulate pain receptors are removed. Stimulation of the autonomic nervous system results in physical manifestations, including increased heart rate, hypertension, diaphoresis, and dilated pupils. Anxiety related to the pain experience, including its cause, treatment, and prognosis, is common, as is the hope of recovery and expectation of limited duration.

Acute pain arises from cutaneous, deep somatic, or visceral structures and can be classified as (1) somatic, (2) visceral, or (3) referred. **Somatic pain** arises from the skin (i.e., from an abrasion or a laceration), joints (pain from arthritis or injured tendons), and muscles (strain from overuse or muscle injury). It is either sharp and well localized (especially fast pain carried by Aδ fibers) or dull, aching, throbbing, and poorly localized, as seen in polymodal unmyelinated C fiber transmissions. **Visceral pain** is transmitted by C fibers and refers to pain in internal organs and the lining of body cavities. It tends to be poorly localized with an aching, gnawing, throbbing, or intermittent cramping quality. It is carried by sympathetic fibers and is associated with nausea and vomiting, hypotension, and, in some cases, shock. Visceral pain often radiates (spreads away from the actual site of the pain) or is referred. Examples of conditions that cause visceral pain include gallstones,

pancreatitis, kidney stones, bowel obstruction, appendicitis, and bladder infection. **Referred pain** is felt in an area removed or distant from its point of origin—the area of referred pain is supplied by the same spinal segment as the actual site of pain. Referred pain can be acute or chronic. Impulses from many cutaneous and visceral neurons converge on the same ascending neuron, and the brain cannot distinguish between the different sources of pain. Because the skin has more receptors, the painful sensation is experienced at the referred site instead of at the site of origin. Referred pain can be acute or chronic. For example, the pain of pancreatitis may be felt in the right shoulder or scapula, or pain from the heart may be referred to the left shoulder or arm. Fig. 16.5 illustrates common areas of referred pain and their associated sites of origin.

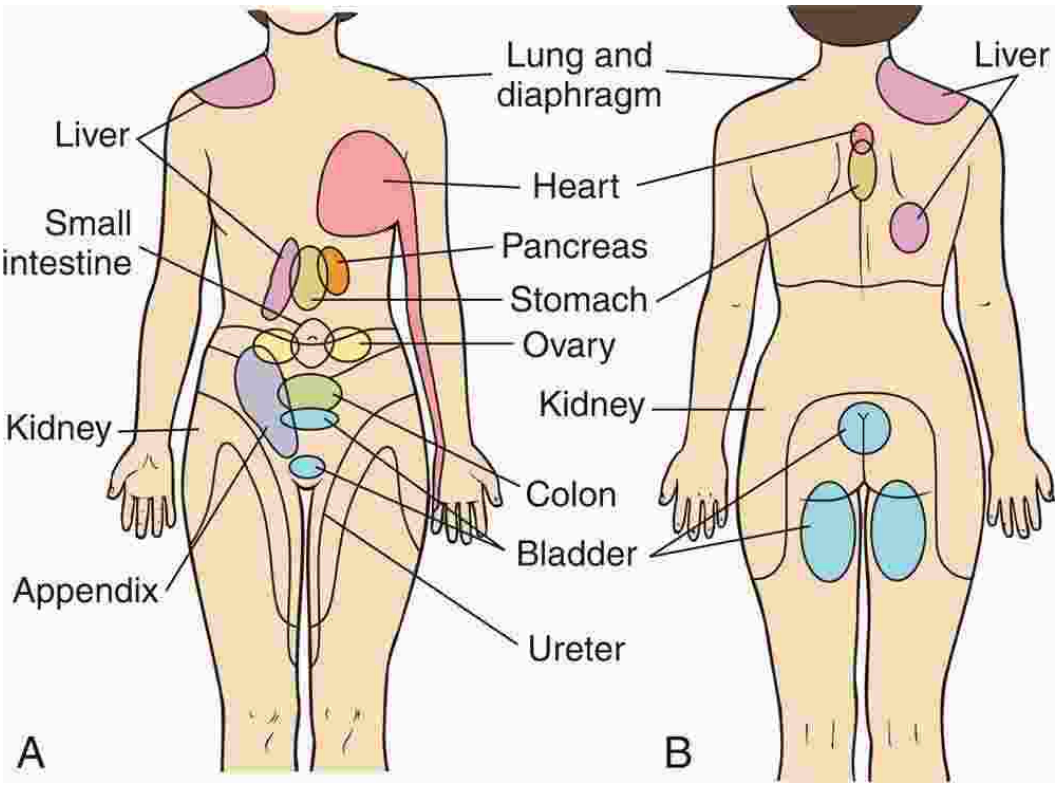

FIG. 16.5 **Sites of Referred Pain.**
(A) Anterior view. **(B)** Posterior view.

Two illustrations, A and B, depict the common areas of referred pain and their associated sites of origin labeled. Illustration A shows the anterior view of the human with the common areas of referred pain labeled as follows. Liver, small intestine, kidney, appendix, lung and diaphragm, heart, pancreas, stomach, ovary, colon, bladder, and ureter. Illustration B shows the posterior view of the human with common areas of referred pain labeled as follows. Lung and diaphragm, heart, stomach, kidney, bladder, and liver.

Chronic or **persistent pain** has been defined as lasting for more than 3 to 6 months in adults and is pain lasting well beyond the expected

normal healing time. It varies with the type of injury, is different among age groups, and produces varietal levels of disability.[24]

Chronic or persistent pain serves no purpose, is poorly understood, and causes suffering. It often appears to be out of proportion to any observable tissue injury. It may be ongoing (e.g., low back pain) or intermittent (e.g., migraine headaches). Changes in the PNS and CNS that cause dysregulation of nociception and pain modulation processes (peripheral and central sensitization) are thought to lead to chronic pain (see the discussion of neuropathic pain later in this section).

Neuroimaging studies have demonstrated brain changes in individuals with chronic pain, which may lead to cognitive deficits and decreased ability to cope with pain.[25,26] These negative manifestations of chronic pain are thought to be due, in part, to the stress of coping with continuous pain and may be reversible when pain is controlled. Because it is not yet possible to predict when acute pain will develop into chronic pain, early treatment of acute pain is encouraged. Comparison of acute and chronic pain is summarized in Table 16.3.

Table 16.3

Comparison of Acute and Chronic Pain

Characteristic	Acute Pain	Chronic Pain
Experience	An event	A situation; state of existence
Source	External agent or internal disease, injury, or inflammation	Unknown; if known, treatment is prolonged or ineffective
Onset	Usually sudden	May be sudden or develop insidiously
Duration	Transient (up to 3 months); usually of short durationResolves with treatment and healing	Prolonged (months to years); lasts beyond expected normal healing time
Pain identification	Painful and nonpainful areas generally well identified	Painful and nonpainful areas less easily differentiated; change in sensations becomes more difficult to evaluate
Clinical signs	Typical response pattern with more visible signs Anxiety and emotional distress common	Response patterns vary; fewer overt signs (adaptation) Can interfere with sleep, productivity, and quality of life

Characteristic	Acute Pain	Chronic Pain
Significance	Significant (informs person something is wrong); protective	Person looks for significance and meaning; serves no useful purpose
Pattern	Self-limiting or readily corrected	Continuous or intermittent; intensity may vary or remain constant
Course	Suffering usually decreases over time	Suffering usually increases over time
Actions	Leads to actions to relieve pain	Leads to actions to modify pain experience
Prognosis	Likelihood of eventual complete relief	Complete relief usually not possible

Characteristic	Acute Pain	Chronic Pain
Experience	An event	A situation; state of existence
Source	External agent or internal disease, injury, or inflammation	Unknown; if known, treatment is prolonged or ineffective
Onset	Usually sudden	May be sudden or develop insidiously
Duration	Transient (up to 3 months); usually of short durationResolves with treatment and healing	Prolonged (months to years); lasts beyond expected normal healing time
Pain identification	Painful and nonpainful areas generally well identified	Painful and nonpainful areas less easily differentiated; change in sensations becomes more difficult to evaluate
Clinical signs	Typical response pattern with more visible signs Anxiety and emotional distress common	Response patterns vary; fewer overt signs (adaptation) Can interfere with sleep, productivity, and quality of life
Significance	Significant (informs person something is wrong); protective	Person looks for significance and meaning; serves no useful purpose
Pattern	Self-limiting or readily corrected	Continuous or intermittent; intensity may vary or remain constant
Course	Suffering usually decreases over time	Suffering usually increases over time
Actions	Leads to actions to relieve pain	Leads to actions to modify pain experience
Prognosis	Likelihood of eventual complete relief	Complete relief usually not possible

Physiologic responses to intermittent chronic pain are similar to those for acute pain, whereas persistent pain allows for physiologic adaptation, producing a normal heart rate and blood pressure. This leads many to mistakenly conclude that people with chronic pain are

malingering because they do not appear to be in pain. As chronic pain progresses, certain behavioral and psychologic changes often emerge, including depression, difficulty eating and sleeping, preoccupation with the pain, and avoidance of pain-provoking stimuli.[27] The desire to relieve pain and the need to hide it become conflicting drives for those with chronic pain, who fear being labeled complainers.[28] Chronic pain is perceived as meaningless and is often associated with a sense of hopelessness as more time elapses; no relief seems possible. Some of the chronic pain syndromes are listed in Table 16.4. Chronic pain associated with specific organ systems is discussed in later chapters.

Table 16.4

Common Chronic Pain Syndromes

Condition	Description
Persistent low back pain	Most common chronic pain condition Results from poor muscle tone, inactivity, muscle strain, or sudden, vigorous exercise
Myofascial pain syndromes	Pain results from muscle spasm, tenderness, stiffness, or injury to muscle and fascia with peripheral and central sensitization Examples include myositis, fibrositis, myalgia, fibromyalgia, and muscle strain Trigger points—small hypersensitive regions in muscle or connective tissues that, when stimulated, produce pain in a specific area As disorder progresses, pain becomes increasingly generalized
Chronic postoperative pain	Persistent pain that can occur with disruption or cutting of sensory nerves; examples include post-thoracotomy, postmastectomy; risk factors may include preexisting pain and genetic susceptibility
Cancer pain	Attributed to advance of disease, treatment, or coexisting disease entities
Deafferentation pain	Pain because of alteration of sensory input into central nervous system is caused by damage

Condition	Description
	to peripheral nerves Common types include severe burning pain triggered by various stimuli, such as cold, light touch, or sound, and complex regional pain syndromes (occur after peripheral nerve injury and are characterized by continuous, severe, burning pain associated with vasomotor changes and muscle wasting)
Hyperalgesia	Increased sensitivity and decreased pain threshold to tactile and painful stimuli Pain is diffuse, modified by fatigue and emotion, and mixed with other sensations May result from chronic irritation of central nervous system areas
Hemiagnosia	Loss of ability to identify source of pain on one side of body Painful stimuli on that side produce discomfort, anxiety, moaning, agitation, and distress but no attempt to withdraw from stimulus Associated with stroke
Phantom limb pain	Pain experienced in amputated limb after stump has completely healed; may be immediate or occur months later; associated with preamputation pain, acute postoperative pain

Condition	Description
	Exact cause is unknown, thought to originate in brain; can be influenced by emotions/sympathetic stimulation
Complex regional pain syndrome	Chronic pain is usually associated with limb injury, surgery, or fractures Characterized by autonomic and neuroinflammatory features and pain out of proportion to expected pain

Condition	Description
Persistent low back pain	Most common chronic pain condition Results from poor muscle tone, inactivity, muscle strain, or sudden, vigorous exercise
Myofascial pain syndromes	Pain results from muscle spasm, tenderness, stiffness, or injury to muscle and fascia with peripheral and central sensitization Examples include myositis, fibrositis, myalgia, fibromyalgia, and muscle strain Trigger points—small hypersensitive regions in muscle or connective tissues that, when stimulated, produce pain in a specific area As disorder progresses, pain becomes increasingly generalized
Chronic postoperative pain	Persistent pain that can occur with disruption or cutting of sensory nerves; examples include post-thoracotomy, postmastectomy; risk factors may include preexisting pain and genetic susceptibility
Cancer pain	Attributed to advance of disease, treatment, or coexisting disease entities
Deafferentation pain	Pain because of alteration of sensory input into central nervous system is caused by damage to peripheral nerves Common types include severe burning pain triggered by various stimuli, such as cold, light touch, or sound, and complex regional pain syndromes (occur after peripheral nerve injury and are characterized by continuous, severe, burning pain associated with vasomotor changes and muscle wasting)
Hyperalgesia	Increased sensitivity and decreased pain threshold to tactile and painful stimuli Pain is diffuse, modified by fatigue and emotion, and mixed with other sensations May result from chronic irritation of central nervous system areas
Hemiagnosia	Loss of ability to identify source of pain on one side of body Painful stimuli on that side produce discomfort, anxiety, moaning, agitation, and distress but no attempt to withdraw from stimulus Associated with stroke
Phantom limb pain	Pain experienced in amputated limb after stump has completely healed; may be immediate or occur months later; associated with preamputation pain, acute postoperative pain Exact cause is unknown, thought to originate in brain; can be influenced by emotions/sympathetic stimulation
Complex regional pain syndrome	Chronic pain is usually associated with limb injury, surgery, or fractures Characterized by autonomic and neuroinflammatory features and pain out of proportion to expected pain

Neuropathic pain is chronic pain initiated or caused by a primary lesion or dysfunction in the somatosensory nervous system and leads to long-term changes in pain pathway structures (neuroplasticity) and abnormal processing of sensory information. There is amplification of pain without stimulation by injury or inflammation. Neuropathic pain is often described as burning, shooting, shock-like, or tingling. It is characterized by increased sensitivity to painful or nonpainful stimuli with hyperalgesia, **allodynia** (the induction of pain by normally nonpainful stimuli), and the development of spontaneous pain.[29] Neuropathic pain is classified as either peripheral or central and is associated with central and peripheral sensitization. **Peripheral neuropathic pain** is caused by peripheral nerve lesions. **Peripheral sensitization** is an increase in the sensitivity and excitability of primary sensory neurons and cells in the DRG. Examples include nerve entrapment, diabetic neuropathy, and chronic pancreatitis.

Central neuropathic pain is caused by a lesion or dysfunction in the brain or spinal cord. A progressive repeated stimulation of group C neurons (known as *wind-up*) in the dorsal horn leads to **central sensitization**, an increased sensitivity of central pain signaling neurons. This results in pathologic changes in the CNS that cause chronic pain. Examples include brain or spinal cord trauma, tumors, vascular lesions, multiple sclerosis, Parkinson disease, postherpetic neuralgia, and phantom limb pain.

The following mechanisms have been implicated in the cause of neuropathic pain[30]:

- Changes in sensitivity of neurons—lower threshold with peripheral and central sensitization
- Spontaneous impulses from regenerating peripheral nerves
- Alterations in the DRG and spinothalamic tract in response to peripheral nerve injury (i.e., deafferentation pain—loss of pain-related afferent information to the brain)
- Loss of pain inhibition and stimulation of pain facilitation by excitatory neurotransmitters in the dorsal horn (e.g., release of glutamate)
- Loss of descending inhibitory pain modulation

- Hyperexcitable spinal interneurons stimulated by Aβ fibers (nonpainful stimulation of pain)
- Release of nociceptive inflammatory cytokines, chemokines, and growth factors by activated glial cells
- Structural and functional alterations in brain processing neural networks

Because of the complexity of the causes of neuropathic pain syndromes, they are difficult to treat. Multimodal therapy is often needed, including nondrug treatment.[31]

An Overview of Chronic Pain Syndromes

Myofascial pain syndrome (MPS) is a regional pain syndrome associated with injury to muscle, fascia, and tendons and includes myositis, fibrositis, myofibrositis, myalgia, (see Chapter 44 for fibromyalgia), and muscle strain. MPS involves myofascial trigger points within a taut band of skeletal muscle ("muscle knots"). Compression of the trigger point causes a local twitch response (a small, quick contraction of muscle fibers) accompanied by referral of pain, motor dysfunction, and autonomic responses (e.g., flushing, diaphoresis, temperature changes). The symptoms often occur in association with poor muscle tone, inactivity, repeated muscle or tendon strain, sudden vigorous exercise, or muscle overuse. The pathophysiology is not clearly known. The pain may be the result of peripheral and central sensitization with low-threshold mechanosensitive afferents projecting to sensitized dorsal horn neurons. There may be neuroaxonal degeneration with alterations in neuromuscular transmission (e.g., extra leakage of acetylcholine at the neuromuscular junction induces persistent contraction) or muscle energy consumption that exceeds energy supply.[32] During the early stages of the disorder the pain is localized, but as the disorder progresses, it becomes deep, aching, and more generalized. **Chronic postoperative pain** is pain that persists for at least 3 months after surgery, after ruling out any other possible causes, such as infection, tumor recurrence, or pain arising from pre-existing conditions. The types of pain can include nerve injury, complex regional pain syndrome, phantom limb pain, chronic donor site pain, post-thoracotomy pain syndrome, post-mastectomy pain syndrome, joint arthroplasty pain, and postsurgical abdominal and pelvic pain. Nerve

injury and inflammation may induce plastic changes in the PNS and CNS contributing to peripheral and central nerve sensitization with allodynia and hypersensitivity. There may also be alterations in descending inhibitory pathways. Psychological factors, including anxiety and depression, also influence the occurrence of postoperative pain. Multimodal approaches to analgesia are needed for pain management including adequate management of preoperative pain and postoperative management of acute pain.[33–35]**Cancer pain** is often chronic, and the causes are multifactorial and related to site and type of cancer, extent of disease, treatment modalities, age, and access to care.[36] Cancers generate and secrete mediators that sensitize and activate primary afferent nociceptors in the area of the tumor, resulting in neurochemical reorganization of the spinal cord, which contributes to spontaneous activity and enhanced pain responsiveness. Increasing pressure of a growing tumor on nerve endings, tissue destruction, inflammatory mediators, distention of visceral surfaces, obstruction of ducts and intestine, pathologic fractures, chemotherapy, radiation therapy, surgical procedures, and opioid-induced hyperalgesia also promote pain. These processes lead to both nociceptive and neuropathic pain.[37] Therapeutic approaches to the management of cancer pain have advanced significantly in recent years, particularly in palliative care and hospice programs. Frequent assessment of pain, management of breakthrough pain, and implementation of individualized interdisciplinary therapeutic strategies (including pharmacotherapeutic, anesthetic, neurosurgical, psychologic, and rehabilitative techniques along with frequent evaluations) are essential to optimal cancer pain management. Research is in progress to evaluate the effects of different opioid receptors on tumor growth and suppression and will assist in selecting the optimum drugs for pain treatment.[38]**Post-stroke pain syndromes** can be acute but often occur up to 6 months after stroke and become chronic. Both nociceptive and neuropathic mechanisms of pain can be involved. Pain can include central poststroke pain or be secondary to spasticity, headache, shoulder pain, and complex region pain syndrome (see below). Central poststroke pain is pain and sensory abnormalities that manifest in the body parts that correspond to the area of the brain that have been injured by the cerebrovascular lesion.

Hyperalgesia, dysesthesias, allodynia, spontaneous pain, and other sensory deficits are common.

There may be hyperexcitation in the damaged sensory pathways, damage to the central inhibitory pathways, or a combination of the two, making it difficult to differentiate from other causes of pain.[39]

Phantom limb pain (PLP) is pain that an individual feels in the amputated limb, usually distally (hands and feet) after the stump has completely healed (1 to 3 months after amputation). PLP is differentiated from *residual limb pain*, which is pain originating from the actual site of the amputated limb and can be associated with infection and neuroma formation. Both types of pain can occur at the same time. PLP can be intermittent or severe and occasional or constant, throbbing, stabbing, burning, or cramping. Both peripheral and central mechanisms of pain contribute to phantom limb pain. There is injury to peripheral nerves with increased excitability. Changes in pain processing in both the brain and spinal cord are known to occur.[40] Nonpainful phantom limb sensations occur in almost all amputees, but the sensations usually fade with time. Chronic regional pain syndrome type II can also be a component of PLP.

Complex regional pain syndrome (CRPS) is chronic neuropathic pain usually associated with limb injury. Two forms are described: complex regional pain syndrome-I (CRPS-I) (previously termed reflex sympathetic dystrophy syndrome) associated with injury but no apparent nerve injury; and complex regional pain syndrome-II (CRPS-II) (previously termed causalgia) with evidence of nerve injury. The symptoms of both forms are similar. CRPS is distinguished from other chronic pain disorders by signs of autonomic and inflammatory changes in the pain region of the injured nerve. There are *autonomic symptoms*: changes in skin color, temperature, and sweating and alterations in hair and nail growth for the affected limb; *motor symptoms*: tremor or weakness may be present; and *sensory symptoms*: hypersensitivity, hyperalgesia, and allodynia. CRPS is further distinguished as "warm CRPS," associated with a warm, red, and edematous extremity; and "cold CRPS," associated with a cold, dusky, and sweaty extremity. Peripheral and central sensitization contribute to the pain syndrome, but the mechanisms are unknown. A combination of injury and the presence of inflammatory cytokines and neuropeptides may lead to peripheral

nociceptive sensitization and physiologic change in pain transmission and in autonomic and motor systems.[41]

Temperature Regulation

Human **thermoregulation** is achieved through precise balancing of heat production, heat conservation, and heat loss The normal range of body temperature is considered to be 36.2°C to 37.7°C (96.2°F to 99.4°F) overall, but a person's individual body parts will vary in temperature. Body temperature rarely exceeds 41°C (105.8°F). The extremities are generally cooler than the trunk, and the temperature at the core of the body (as measured by rectal temperature) is generally 0.5°C higher than the surface temperature (as measured by oral temperature). Internal temperature varies in response to activity, environmental temperature, and daily fluctuation (circadian rhythm). Oral temperatures fluctuate within 0.2°C to 0.5°C during a 24-hour period. Women tend to have wider fluctuations that follow the menstrual cycle, with a sharp rise in temperature just before ovulation. The daily fluctuating temperature in both sexes peaks around 6 p.m. and is at its lowest during sleep. Maintenance of body temperature within the normal range is necessary for life.

Control of Body Temperature

Temperature regulation (thermoregulation) is mediated primarily by the hypothalamus and endocrine system. Peripheral thermoreceptors in the skin, liver, and skeletal muscle (unmyelinated C fibers and thinly myelinatewd Aδ fibers) and central thermoreceptors in the hypothalamus, spinal cord, viscera, and great veins provide the hypothalamus with information about body temperatures. If these temperatures are low or high, the hypothalamus triggers heat production and heat conservation or heat loss mechanisms.[42]

Body heat is produced by the chemical reactions of metabolism and skeletal muscle tone and contraction. The heat-producing mechanism (chemical or non-shivering thermogenesis) begins with hypothalamic thyrotropin-releasing hormone (TRH); it stimulates the anterior pituitary to release thyroid-stimulating hormone (TSH), which acts on the thyroid gland and stimulates the release of thyroxine. Thyroxine

then acts on the adrenal medulla, causing the release of epinephrine into the bloodstream. Epinephrine causes cutaneous vasoconstriction, stimulates glycolysis, and increases metabolic rate, thus increasing body heat. Norepinephrine and thyroxine activate brown fat thermogenesis where energy is released as heat (non-shivering thermogenesis) instead of as adenosine triphosphate (ATP). Heat is distributed by the circulatory system.

The hypothalamus also triggers heat conservation by stimulating the sympathetic nervous system and results in increased skeletal muscle tone, initiating the shivering response and producing vasoconstriction. Sympathetic stimulation also constricts peripheral blood vessels and redistributes blood flow. Centrally warmed blood is shunted away from the periphery to the core of the body, where heat can be retained. This involuntary mechanism takes advantage of the insulating layers of the skin and subcutaneous fat to protect the core temperature. The hypothalamus relays information to the cerebral cortex about cold, and voluntary responses result. Individuals typically bundle up, keep moving, or curl up in a ball. These types of voluntary physical activities provide insulation, increase skeletal muscle activity, and decrease the amount of skin surface available for heat loss through radiation, convection, and conduction.

The hypothalamus responds to warmer core and peripheral temperatures by reversing the same mechanisms resulting in heat loss. Heat loss is achieved through (1) radiation, (2) conduction, (3) convection, (4) vasodilation, (5) evaporation (sweating), (6) decreased muscle tone, (7) increased respiration, (8) voluntary measures, and (9) adaptation to warmer climates (i.e., increasing or decreasing the volume of sweat). Table 16.5 summarizes further information about heat production and loss.

Table 16.5

Mechanisms of Heat Production and Heat Loss

Condition	Description
Heat Production	
Chemical reactions of metabolism	Occur during ingestion and metabolism of food and while maintaining body at rest (basal metabolism); occur in body core (e.g., liver)
Skeletal muscle contraction	Gradual increase in muscle tone or rapid muscle oscillations (shivering)
Nonshivering thermogenesis	Epinephrine is released and produces rapid, transient increase in heat production by raising basal metabolic rate; quick, brief effect that counters heat lost through conduction and convection; involves brown adipose tissue, which decreases markedly in older adults; thyroid hormone increases metabolism
Heat Loss	
Radiation	Heat loss through electromagnetic waves emanating from surfaces with temperature higher than surrounding air
Conduction	Heat loss by direct molecule-to-molecule transfer from one surface to another, so that warmer surface loses heat to cooler surface
Convection	Transfer of heat through currents of gases or liquids; exchanges warmer air at body's surface with cooler air in surrounding space
Vasodilation	Diverts core-warmed blood to surface of body, with heat transferred by conduction to skin surface and from there to surrounding

Condition	Description
	environment; occurs in response to autonomic stimulation under control of hypothalamus
Evaporation	Body water evaporates from surface of skin and linings of mucous membranes; major source of heat reduction connected with increased sweating in warmer surroundings
Decreased muscle tone	Exhausted feeling caused by moderately reduced muscle tone and curtailed voluntary muscle activity
Increased respiration	Air is exchanged with environment through normal process; minimal effect
Voluntary mechanisms	"Stretching out" and "slowing down" in response to high body temperatures; increasing body surface area available for heat loss; dressing in light-colored, loose-fitting garments
Adaptation to warmer climates	Gradual process beginning with lassitude, weakness, and faintness; proceeding through increased sweating, lowered sodium content, decreased heart rate, and increased stroke volume and extracellular fluid volume; and terminating in improved warm weather functioning and decreased symptoms of heat intolerance (work output, endurance, and coordination increase; subjective feelings of discomfort decrease)

Condition	Description

Temperature Regulation in Infants and Older Adult Persons

Infants (particularly low-birth-weight infants) and older adult persons require special attention to maintenance of body temperature. Term infants produce sufficient body heat, primarily through metabolism of brown fat, but cannot conserve heat produced because of their small body size, greater ratio of body surface to body weight, and inability to shiver. Infants also have little subcutaneous fat and thus are not as well insulated as adults. Children also have a greater ratio of body surface to body weight, lower sweating rate, higher peripheral blood flow in the heat, and a greater extent of vasoconstriction in the cold than adults. They can acclimatize to changes in environmental temperatures but do so at a lower rate than adults.

Older adult persons respond poorly to environmental temperature extremes because of their slowed blood circulation, structural and functional skin changes, overall decreased heat-producing activities, and the presence of disease (i.e., congestive heart failure, chronic lung disease, diabetes mellitus, or peripheral vascular disease). Cold stress in older adults also decreases coronary perfusion.[43] In addition, older adult persons have a decreased shivering response (delayed onset and decreased effectiveness), slowed metabolic rate, decreased vasoconstrictor response, diminished or absent ability to sweat, decreased peripheral sensation, desynchronized circadian rhythm, decreased perception of heat and cold, decreased thirst, decreased nutritional reserves, decreased brown adipose tissue, and decreased shivering response.[44,45]

Pathogenesis of Fever

Fever (febrile response) is a temporary resetting of the hypothalamic thermostat to a higher level in response to exogenous or endogenous pyrogens. **Exogenous pyrogens** (endotoxins produced by pathogens; see Chapter 10) stimulate the release of inflammatory **endogenous pyrogens** from phagocytic cells (primarily macrophages), including Prostaglandin E2 (PGE2), tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), interleukin-6 (IL-6), and interferon γ (IFNγ). These pyrogenic cytokines raise the thermal set point by acting on the hypothalamus to induce an integrated endocrine, autonomic nervous system, and behavioral response and also initiate the acute phase response (described below). The hypothalamic set point for temperature regulation is elevated, signaling an increase in heat production and conservation. Peripheral vasoconstriction shunts blood from the skin to the body core. Epinephrine release increases metabolic rate and muscle tone. Decreased release of vasopressin (anti-diuretic hormone) reduces the volume of body fluid to be heated. The individual feels colder, dresses more warmly, decreases body surface area by curling up, and may go to bed in an effort to get warm. Symptoms of lassitude and anorexia are common and may be related to energy conservation to support the increased metabolic demands of fever. Body temperature is maintained at the new level until the fever "breaks," when the set point

begins to return to normal with decreased heat production and increased heat reduction mechanisms. The individual feels very warm, dons cooler clothes, throws off the covers, and stretches out. Once the body has returned to a normal temperature, the individual feels more comfortable and the hypothalamus adjusts thermoregulatory mechanisms to maintain the new temperature (Fig. 16.6).

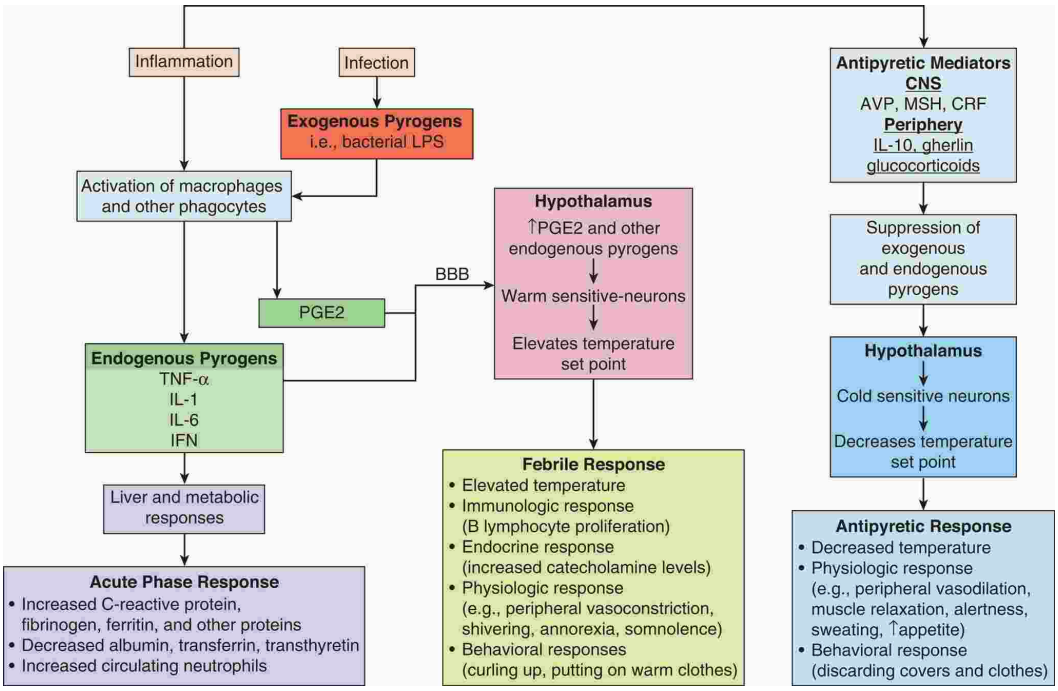

FIG. 16.6 Modulation of Fever and Acute Phase Response.
Infection and inflammation initiate the release of exogenous pyrogens from pathogens and endogenous pyrogens from macrophages and other immune cells. Endogenous pyrogens and PGE_2 act on the hypothalamus to elevate the temperature set point and initiate fever and the acute phase response. Fever is modulated by antipyretic mediators (cryogens) from both the CNS and periphery which suppress the febrile response and prevent damage from excessively high temperatures. *BBB*, Blood brain barrier; *AVP*, arginine vasopressin; *CRP*, C-reactive protein; *IFN*, interferon; *IL*, interleukin-1, interleukin-6; *MCH*, melanocortin; *PGE_2*, prostaglandin E_2; *TNF*-α, tumor necrosis factor-alpha.

A flow chart represents the pathogenesis of fever and the acute phase response. • The inflammation initiates the activation of macrophages and other phagocytes

from endogenous pyrogens such as T N F alpha, I L 1, I L 8, I F N and antipyretic mediators such as A V P, M S H, C R F in C NS and I L 10, ghrelin, glucocorticoids in the periphery leads to suppression of exogenous and endogenous pyrogens that acts on hypothalamus involves in cold-sensitive neurons and decreases temperature set point leading to an antipyretic response. • The inflammation that initiates endogenous pyrogens acts on liver and metabolic responses leads to acute phase response. • The infection initiates the exogenous pyrogens that are bacterial L P S from the activation of macrophages and other phagocytes and P G E 2 which acts on the hypothalamus and increases the P G E G and other endogenous pyrogens, warm-sensitive neurons and elevate temperature set point leading to a febrile response. • The acute phase response initiates an increase in C reactive protein, fibrinogen, ferritin, and other proteins; decreases albumin, transferrin, transthyretin; increases circulating neutrophils. • Febrile response initiates elevated temperature; immunologic response (B lymphocyte proliferation); endocrine response (increased catecholamine levels); physiologic response for example peripheral vasoconstriction, shivering, anorexia, somnolence; behavioral responses (curling up, putting on warm clothes). • Antipyretic responses initiate decreased temperature; physiologic responses for example peripheral vasodilation, muscle relaxation,

alertness, sweating, and increase appetite; behavioral response (discarding covers and clothes).

An **acute phase response** (see Chapter 7) is a defensive reaction to control pathogens that occurs when pyrogenic and other cytokines are released in response to infection and inflammation. Protective proteins such as C-reactive protein, fibrinogen, and ferritin are produced. Other proteins such as albumin, transferrin, and transthyretin are reduced. Neutrophils numbers are increased. In addition to fever, other symptoms occur, including anorexia, fatigue, malaise, somnolence, and loss of concentration. At the cellular level, inflammatory pyrogenic cytokines promote muscle catabolism and hyperglycemia (gluconeogenesis, glycogenolysis, and insulin resistance) by stimulating release of adrenocorticotropic hormone (ACTH) and glucocorticoids to support glucose-consuming cells.[46]

During inflammation and fever, **cryogens** modulate the duration and intensity of the febrile response. Antipyretic cytokines such as arginine vasopressin (AVP), melanocyte-stimulating hormone (MSH), and corticotropin-releasing factor (CRF) are released from the brain, and systemic anti-inflammatory mediators (e.g., IL-10, ghrelin, glucocorticoids) are released from the periphery. These mediators act as **endogenous cryogens** or **antipyretics** to decrease the thermal set point in the hypothalamus (see Fig. 16.6).[47] This antipyretic effect constitutes a negative-feedback loop for temperature control and prevents lethal effects of uncontrolled temperature elevation. When this antipyretic effect is ineffective or the physiologic response to fever is dangerous to organ system function, antipyretic medications (e.g., aspirin, acetaminophen, or ibuprofen) may be given to suppress PGE_2 and fever.

Febrile seizures may occur in children with temperatures greater than 38°C (100.4°F) without CNS infection, hypoglycemia, or electrolyte disorders. The seizures are caused by systemic infection with the release of inflammatory cytokines that cross the blood-brain barrier and stimulate neuronal hyperexcitability, triggering the seizure.[48] Febrile seizures are more predominant in boys before age 5 years, and genetic factors contribute to susceptibility. Simple febrile seizures are generally brief and self-limiting, lasting less than 5 minutes and without

recurrence. Complex febrile seizures last more than 15 minutes with focal neurologic signs (e.g., one side of body involved, stiff neck) and recur within 24 hours. Although in most instances there appear to be no long-term effects on the child, a small percentage of children may develop epilepsy.[49] Prolonged febrile seizures are associated with the development of temporal lobe epilepsy in children and are probably associated with functional changes in neurons and neural networks. Treatment includes antipyretic and/or antiepileptic drugs.[50]

Fever of unknown origin (FUO) is a body temperature of greater than 38.3°C (101°F) for longer than 3 weeks' duration that remains undiagnosed after 3 days of hospital investigation, three outpatient visits, or 1 week of ambulatory investigation. The clinical categories of FUO include infectious, rheumatic/inflammatory, neoplastic, HIV-associated, and miscellaneous and undiagnosed disorders.[51]

Benefits of Fever

Moderate fever helps the body respond to infectious processes through several mechanisms.[52,53]

1. Raising of body temperature kills many pathogens and adversely affects their growth and replication.
2. Higher body temperatures decrease serum levels of iron, zinc, and copper—minerals needed for bacterial replication.
3. Increased temperature causes lysosomal breakdown and autodestruction of cells, preventing viral replication in infected cells.
4. Heat increases lymphocytic transformation and motility of polymorphonuclear neutrophils, facilitating the immune response.
5. Phagocytosis is enhanced, and production of antiviral interferon is augmented.

Suppression of fever with antipyrogenic medications can be effective but should be used with caution.[54]

Infection and fever responses in older adult persons and children may vary from those in normal adults. Box 16.2 lists the principal features

associated with fever at these extremes of age.[45,55]

Box 16.2

Effects of Fever at the Extremes of Age

Older Adult Persons

Subtle or atypical responses to infectious fever are often accompanied by dehydration, and in severe systemic infection there may be no fever. Symptoms can include feeling cold or warm, having strange body sensations, headache, vivid dreams, and hallucinations.

Severe systemic infections may cause alternating hypothermia and high fever in a 24 h period.

Infants and Children

Infected babies may not develop infectious fever in the first few days of life.

Young infants (less than 60–90 days of age) often present with fever and no other symptoms, making differential diagnosis difficult.

Children develop higher temperatures than adults for relatively minor infections, and any skin vasoconstriction can lead to a rapid increase in body temperature.

Febrile seizures before age 5 years are more common and can be related to an autosomal dominant polygenic inheritance.

Severe systemic infections may cause alternating hypothermia and high fever in a 24 h period, the same as elderly adults.

Disorders of Temperature Regulation

Hyperthermia

Hyperthermia is elevation of the body temperature without an increase in the hypothalamic set point. Hyperthermia can produce nerve damage, coagulation of cell proteins, and death. At 41°C (105.8°F), nerve damage produces convulsions in the adult. Death results at 43°C (109.4°F). Hyperthermia may be therapeutic, accidental, or associated with stroke or head trauma. Prevention of hyperthermia in stroke and head trauma assists in limiting brain injury.[56]

Therapeutic hyperthermia is a form of local, regional, or whole-body hyperthermia used to destroy pathologic microorganisms or tumor cells by facilitating the host's natural immune process or tumor blood flow or activate drugs.[57,58]

The forms of **accidental hyperthermia** are summarized as follows.[59]

1. **Heat cramps**—severe, spasmodic cramps in the abdomen and extremities that follow prolonged sweating and associated sodium loss. Usually occur in those not accustomed to heat or those performing strenuous work in very warm climates. Fever, rapid pulse rate, and increased blood pressure accompany the cramps. Treatment includes administration of oral dilute salt solutions.
2. **Heat exhaustion**—results from prolonged high core or environmental temperatures that cause profound vasodilation and profuse sweating, leading to dehydration, decreased plasma volumes, hypotension, decreased cardiac output, and tachycardia. Symptoms include weakness, dizziness, confusion, nausea, and fainting. Treatment includes administration of oral or parenteral dilute salt solution.
3. **Heat stroke**—a potentially lethal condition associated with multiorgan failure. Heat stroke can be caused by exertion, by overexposure to environmental heat, or from impaired physiologic mechanisms for heat loss. With very high core temperatures (>40°C [104°F]), there is cell injury and loss of body heat regulation. Symptoms include high core temperature, absence of sweating, rapid pulse rate, confusion, agitation, and coma. The increase in skin blood flow requirements decreases intestinal blood flow and increases intestinal membrane permeability. Increased circulating endotoxin, release of inflammatory mediators, and hypovolemia promote coagulation with microvascular thrombosis leading to multiorgan system and neuronal dysfunction. Complications include cerebral edema, degeneration of the CNS, swollen dendrites, renal tubular necrosis, and hepatic failure with delirium, coma, and eventually death if treatment is not undertaken. There is

controversy about whether there is failure of the hypothalamic thermoregulatory center during the acute phase of recovery.[60,61]

4. **Malignant hyperthermia**—a potentially lethal hypermetabolic complication of a rare autosomal dominant inherited muscle disorder that may be triggered by inhaled halogenated anesthetics and depolarizing muscle relaxants.[62] The syndrome involves uncontrolled release of calcium from muscle cells with hypermetabolism, uncoordinated muscle contractions, increased muscle work, increased oxygen consumption, hypercarbia, and a raised level of lactic acid production. Acidosis develops, and body temperature rises, with resulting tachypnea, tachycardia, cardiac dysrhythmias, hypotension, decreased cardiac output, and cardiac arrest. Signs resemble those of coma—unconsciousness, absent reflexes, fixed pupils, apnea, and occasionally a flat electroencephalogram. Oliguria and anuria are common. It is most common in children and adolescents. Treatment includes withdrawal of the provoking agent, oxygen therapy, body cooling therapy, administration of drugs that inhibit calcium release from muscle (dantrolene), treatment of arrhythmias, and maintenance of urine output.

Hypothermia

Hypothermia (core body temperature less than 35°C [95°F]) produces depression of the CNS and respiratory system, vasoconstriction, alterations in microcirculation and coagulation, and ischemic tissue damage. Hypothermia may be accidental or therapeutic (Box 16.3). Most tissues can tolerate low temperatures in controlled situations, such as surgery. However, in severe hypothermia, ice crystals form on the inside of the cell, causing cells to rupture and die. Tissue hypothermia slows cell metabolism, increases the blood viscosity, slows microcirculatory blood flow, facilitates blood coagulation, and stimulates profound vasoconstriction (also see Frostbite, Chapter 46).

Box 16.3

Defining Characteristics of Hypothermia

Accidental Hypothermia

The unintentional decrease in core temperature to less than 35°C (95°F) results from sudden immersion in cold water, prolonged exposure to cold environments, diseases that diminish the ability to generate heat, or altered thermoregulatory mechanisms. It is most common among young and older adult persons.

Factors That Increase Risk

1. Hypothyroidism
2. Hypopituitarism
3. Malnutrition and muscle wasting
4. Parkinson disease
5. Rheumatoid arthritis
6. Chronic increased vasodilation
7. Failure of thermoregulatory control resulting from cerebral injury, ketoacidosis, uremia, sepsis, and drug overdose

Response Mechanisms

1. Peripheral vasoconstriction—shunts blood away from cooler skin to core to decrease heat loss and produces peripheral tissue ischemia
2. Intermittent reperfusion of extremities (Lewis phenomenon) helps preserve peripheral oxygenation until core temperature drops dramatically
3. Hypothalamic center induces shivering; thinking becomes sluggish, and coordination is depressed
4. Stupor; heart rate and respiratory rate decline; cardiac output diminishes; metabolic rate falls; acidosis; eventual ventricular fibrillation and asystole occur at 30°C (86°F) and lower

Treatment

1. Most changes are reversible with rewarming
2. Core temperature greater than 30°C (86°F)—active rewarming (external)

3. Core temperature less than 30°C (86°F) or with severe cardiovascular problems—active core rewarming (internal)

Targeted Temperature Management (Therapeutic Hypothermia)

Used to slow metabolism, prevent hypoxia and ischemic injury, and provide neuroprotection after cardiac arrest, during surgery (e.g., limb reimplantation), for treatment of neonatal encephalopathy, or to prevent fever or maintain normothermia. Studies are in progress to evaluate outcomes of hypothermia for management of neurologic injury.

Effects and Cautions

1. Stresses the heart, leading to ventricular fibrillation and cardiac arrest (may be desired outcome in open heart surgery when heart must be stopped)
2. Shivering increases metabolic rate, oxygen consumption, heart and respiratory rate, and exhausts liver glycogen stores.
3. Decreases insulin secretion, increases insulin resistance leading to hyperglycemia
4. Surface cooling may cause burns, frostbite, and fat necrosis
5. Immunosuppression with increased infection risk
6. Slows drug distribution, hepatic metabolism, and renal clearance of drug metabolites

Trauma and Temperature

Major body trauma can affect temperature regulation through various mechanisms. Damage to the CNS, release of inflammatory mediators, increased intracranial pressure, or intracranial bleeding typically

produces a body temperature of greater than 39°C (102.2°F), generally higher than infectious fever. This sustained noninfectious fever, often referred to as a **central fever or neurogenic fever**, appears with or without bradycardia. A central fever does not induce sweating and is very resistant to antipyretic therapy.[63] Other traumatic mechanisms that produce temperature alterations include accidental injuries, hemorrhagic shock, major surgery, and thermal burns. The severity and type of alteration (hyperthermia or hypothermia) vary with the severity of the cause and the body system affected.

Accidental Hypothermia Accidental hypothermia is generally the result of sudden immersion in cold water or prolonged exposure to cold environments. At particular risk for accidental hypothermia are infants and older adults, because thermoregulatory mechanisms are immature or altered in these two groups. Also at risk are individuals with conditions that diminish the ability to generate heat. Such conditions include hypothyroidism, hypopituitarism, decreased liver function, malnutrition, Parkinson disease, and rheumatoid arthritis. Other risk factors include chronic increased vasodilation and decreased thermoregulatory control caused by cerebral injuries, ketoacidosis, uremia, and drug overdoses. In acute hypothermia, peripheral vasoconstriction shunts blood away from the cooler skin to the core in an effort to decrease heat loss, which produces peripheral tissue ischemia. Intermittent reperfusion of the extremities (the Lewis phenomenon) helps preserve peripheral oxygenation. Intermittent peripheral perfusion continues until core temperatures drop dramatically.The hypothalamic center stimulates shivering in an effort to increase heat production. Severe shivering occurs at core temperatures of 35°C (95°F) and continues until core temperature (measure by esophageal probe) drops to about 30° to 32°C (86° to 89.6°F). Prolonged shivering can lead to exhaustion of liver glycogen stores. Thinking becomes sluggish and coordination is decreased at 34°C (93.2°F). As hypothermia deepens, paradoxical undressing may occur as hypothalamic control of vasoconstriction is lost and vasodilation occurs with loss of core heat to the periphery. The hypothermic individual therefore feels suddenly warm and begins to remove clothing.At 30°C (86°F), the individual becomes stuporous, heart rate and respiratory rate decline, and cardiac output is diminished. Cerebral blood flow is

decreased. Metabolic rate declines, further decreasing core temperature. Sinus node depression occurs with slowing of conduction through the atrioventricular node. In severe hypothermia (core temperature of 26° to 28°C [78.8° to 82.4°F]), pulse and respirations may be undetectable and require resuscitation. Acidosis is moderate to severe. Coagulopathy, ventricular fibrillation, and asystole are common.[117] Surface cooling may cause frostbite and fat necrosis.If hypothermia is mild, passive rewarming may be sufficient. If core temperature is greater than 30°C (86°F), active rewarming also may be required. Active rewarming uses warm-water baths, warm blankets, heating pads, and warm oral fluids when the individual is fully alert. Core rewarming may be accomplished through administration of warm intravenous (IV) solutions, warm gastric lavage, warm peritoneal lavage, inhalation of warmed gases, and, in extreme cases, exchange transfusions, warming blood in a pump oxygenator circuit, and mediastinal lavage.Rewarming generally should proceed no faster than a few degrees per hour. Short-term complications of rewarming include acidosis, rewarming shock, and dysrhythmias. Long-term complications include congestive heart failure, hepatic and renal failure, abnormal erythropoiesis, myocardial infarction, pancreatitis, and neurologic dysfunctions.

Therapeutic Hypothermia Therapeutic hypothermia is used to slow metabolism and preserve ischemic tissue after brain trauma or during brain surgery, after cardiac arrest, and in neonatal hypoxic encephalopathy. Hypothermia protects the brain by reduction in metabolic rate, ATP consumption, oxidative stress, and the critical threshold for oxygen delivery; modulation of excitotoxic neurotransmitters and calcium antagonism; preservation of protein synthesis and the blood-brain barrier; decreased edema formation; and modulation of the inflammatory response.

Sleep

Sleep is an active multiphase process that provides restorative functions and promotes memory consolidation. Complex neural circuits, interacting hormones, and neurotransmitters involving the hypothalamus, thalamus, brainstem, and cortex control the timing of the sleep-wake cycle and coordinate this cycle with circadian rhythms (24-

hour rhythm cycles).[64] Normal sleep has two primary phases that can be documented by electroencephalogram (EEG), a test that detects electrical activity in your brain: rapid eye movement (REM) sleep (20% to 25% of sleep time) and slow-wave (non-REM) sleep. Non-REM sleep is further divided into three stages (N1, N2, N3) from light to deep sleep. REM cycles do not typically start to occur until about 90 minutes into sleep. Four to six cycles of REM and non-REM sleep occur each night in an adult. Sleep duration and sleep architecture do not mature in children until after adolescence.[65] The hypothalamus is a major sleep center, and the hypocretins (orexins), acetylcholine, and glutamate are neuropeptides secreted by the hypothalamus that promote wakefulness. Prostaglandin D_2, adenosine, melatonin, serotonin, L-tryptophan, GABA, and growth factors promote sleep. The pontine reticular formation is primarily responsible for generating REM sleep, and projections from the thalamocortical network produce non-REM sleep.[66]

Rapid eye movement (REM) sleep is initiated by *REM-on* and *REM-off* neurons in the pons and mesencephalon. REM sleep occurs about every 90 minutes beginning 1 to 2 hours after non-REM sleep begins. This sleep is known as *paradoxical sleep* because the EEG pattern is similar to that of the normal awake pattern and the brain is very active with dreaming. REM and non-REM sleep alternate throughout the night, with lengthening intervals of REM sleep and fewer intervals of deeper stages of non-REM sleep toward morning. The changes associated with REM sleep include increased parasympathetic activity and variable sympathetic activity associated with rapid eye movement; muscle relaxation; loss of temperature regulation; altered heart rate, blood pressure, and respiration; penile erection in men and clitoral engorgement in women; release of steroids; and many memorable and often bizarre dreams. Respiratory control appears largely independent of metabolic requirements and oxygen variation. Loss of normal voluntary muscle control in the tongue and upper pharynx may produce respiratory obstruction which, in turn, can precipitate apneic events. Cerebral blood flow increases.

Non-REM sleep accounts for 75% to 80% of sleep time in adults and is initiated when inhibitory signals are released from the hypothalamus. Sympathetic tone is decreased and parasympathetic activity is increased during non-REM sleep, creating a state of reduced activity. The basal

metabolic rate falls by 10% to 15%; temperature decreases 0.5°C to 1°C (0.9°F to 1.8°F); heart rate, respiration, blood pressure, and muscle tone decrease; and knee jerk reflexes are absent. Pupils are constricted. During the various stages, cerebral blood flow to the brain decreases and growth hormone is released, with corticosteroid and catecholamine levels depressed. Non-REM sleep is associated with memory consolidation during slow wave sleep.[67] Box 16.4 summarizes sleep characteristics in infants, children, and older adult persons.

Box 16.4

Sleep Characteristics of Infants, Children, and Older Adult Persons

Infants

- Infants sleep 10–16 h/day: 50% REM (active) sleep, 25% non-REM (inactive) sleep.
- Infant sleep cycles are 50–60 min in length; 10–45 min of REM sleep accompanied by movement of the arms, legs, and facial muscles followed by about 20 min of non-REM sleep.
- At 1 year, REM and non-REM sleep cycles are about equal in length and infants sleep through the night with about two naps per day.

Children

- Children assume an adult sleep pattern between 3 and 5 years and sleep about 9–10 h per night.
- Inadequate sleep in adolescents is associated with obesity, depression, and poor academic performance.

Older Adult Persons

- Total sleep time is decreased with a longer time to fall asleep and poorer-quality sleep.

- Total time in slow-wave and final phase of non-REM sleep decreases by 15%–30%.
- Increases in stage 1 and 2 non-REM sleep, attributable to an increased number of spontaneous arousals.
- Older adult individuals tend to go to sleep earlier in the evening and wake earlier in the morning because of a phase advance in their normal circadian sleep cycle.
- Alterations in sleep patterns occur about 10 years later in women than in men.
- Sleep disorders are more likely in older adults and increase risks of morbidity, mortality, and changes in cognitive function.

non-REM, Non-rapid eye movement; *REM*, rapid eye movement.

Sleep Disorders

Because classification of sleep disorders is complex, a system has been established by the American Academy of Sleep Medicine and includes seven major categories: (1) insomnia, (2) sleep-related breathing disorders, (3) central disorders of hypersomnolence, (4) circadian rhythm sleep-wake disorders, (5) parasomnias, (6) sleep-related movement disorders, and (7) other sleep disorders.[68] The most common disorders are summarized here.

Common Dyssomnias

Insomnia is the inability to fall or stay asleep; it is accompanied by fatigue, malaise, and difficulty with performance during wakefulness and may be mild, moderate, or severe. It may be transient, lasting a few days or months (primary insomnia), and related to travel across time zones or caused by acute stress, or very commonly inadequate "sleep hygiene." Sleep hygiene simply refers to behavioral and environmental practices that are intended to promote better-quality sleep (e.g., avoiding all-nighters and caffeine late in the evening). Chronic insomnia lasts at

least 3 months and can be idiopathic, start at an early age, and be associated with drug or alcohol abuse, chronic pain disorders, chronic depression, the use of certain drugs, obesity, aging, genetics, and environmental factors that result in hyperarousal.[69]

Obstructive sleep apnea syndrome (OSAS) is the most commonly diagnosed sleep disorder and occurs in all age groups. However, the incidence of OSAS increases with age beyond 60 years. Major risk factors include obesity, male sex, older age, and postmenopausal status (not on hormone therapy) in women, craniofacial anomalies, and increased size of tonsillar and adenoid tissue.[70] OSAS results from partial or total upper airway obstruction to airflow recurring during sleep with continuous respiratory efforts made against a closed airway. It is often accompanied by excessive loud snoring, gasping, and multiple apneic episodes that last 10 seconds or longer. *Central sleep apnea* is the temporary absence or diminution of ventilatory effort during sleep with decreased sensitivity to carbon dioxide and oxygen tensions, and decreased airway dilator muscle activation. It may be associated with heart failure, neurologic disease, high altitude, or narcotic medications. *Obesity hypoventilation syndrome* is a combination of obesity (body mass index ≥ 30 $kg \cdot m^{-2}$), daytime hypercapnia (arterial carbon dioxide tension $\geq$ 45 mmHg), and sleep disordered breathing not caused by other disorders of hypoventilation. It may be related to leptin resistance because leptin also is a strong respiratory stimulant. The periodic breathing eventually produces arousal, which interrupts the sleep cycle, reducing total sleep time and producing sleep and REM deprivation. Sleep apnea produces hypercapnia and low oxygen saturation and if left untreated, eventually leads to polycythemia, pulmonary hypertension, systemic hypertension, stroke, right-sided congestive heart failure, dysrhythmias, liver congestion, cyanosis, and peripheral edema.

Hypersomnia (excessive daytime sleepiness) is associated with OSAS. Individuals may fall asleep while driving a car, working, or even while conversing, with significant safety concerns.[71] Sleep deprivation also can result in impaired mood and cognitive function characterized by impairments of attention, episodic memory, working memory, and executive functions (i.e., decision-making ability).

Polysomnography and home sleep testing are used to diagnose OSAS, in addition to the history and physical examination. Treatments include

use of continuous positive airway pressure (CPAP) and dental devices, surgery of the upper airway, hypoglossal nerve stimulation in selected individuals, and management of obesity.[72] Adenotonsillar hypertrophy is the major cause of obstructive sleep apnea in children, and obesity increases the risk. Tonsillectomy with or without adenoidectomy is the treatment of choice.[73]

Narcolepsy is a primary hypersomnia with disruption in REM sleep-wake cycles characterized by hallucinations, sleep paralysis, excessive daytime sleepiness, and, rarely, cataplexy (brief spells of muscle weakness). Narcolepsy is usually sporadic or can occur in families. Type I narcolepsy (narcolepsy with cataplexy) is associated with immune-mediated T-cell destruction of hypocretin (orexin)-secreting cells in the hypothalamus. Orexins stimulate wakefulness. Type II narcolepsy (narcolepsy without cataplexy) is less severe and associated with normal levels of orexins (hypocretins). The cause is unknown.[74]

Circadian rhythm sleep disorders are common disorders of the 24-hour sleep-wake schedule with disruption in the timing of sleep. They involve difficulty falling asleep, waking up during the sleep cycle, or waking up too early and being unable to fall back to sleep. These disorders can result from extrinsic causes, such as rapid time zone changes (or jet-lag syndrome), alternating the sleep schedule (rotating work shifts) involving 3 hours or more in sleep time, or changing the total sleep time from day to day. Common types of these disorders include **advanced sleep phase disorder** (early evening sleeping, e.g., 6:00 pm and early morning waking, e.g., 3:00 to 5:00 am), or **delayed sleep phase disorder** (late night sleeping, e.g., at 2:00 am and late morning or afternoon waking). A circadian rhythm sleep disorder known as **shift work sleep disorder** affects many shift workers who rotate or swing long shifts (such as nurses), particularly between the hours of 2200 (10 PM) and 0600 (6 AM). **Jet lag disorder** is a disturbance in the circadian rhythm from crossing time zones more rapidly than the circadian system can keep pace. Eastward travel is more difficult than westward travel because it is easier to delay sleep than to advance sleep.

The disruption of circadian rhythms may cause problems in the short term, such as cognitive deficits, poor vigilance, difficulty concentrating, and inadequate performance of psychomotor tasks. However, long-term health consequences of shift work sleep disorder may be quite serious

and include depression/anxiety, increased risk for cardiovascular disease, and increased all-cause mortality. Sleep cycle phenotype also has a genetic basis and influences the timing and cycles of sleep and can affect advances or delays in sleep-wake times (see Emerging Science Box: Shift Work Disorder).[75]

Emerging Science BOX

Shift Work Disorder

Shift work disorder coincides with a deviation between the light-dark cycle and the human activity-rest cycle. The circadian system works to ensure the body functions as a well-tuned clock. Within the hypothalamus, the suprachiasmatic nucleus (SCN) coordinates 24 h physiological rhythms. When aligned appropriately with the environment, the SCN promotes sleep and anabolic functions at night and wakefulness and catabolic functions during the day. The internal rhythm of the SCN becomes askew with shift work. There has already been strong evidence that links shift work with negative health outcomes, specifically cardiovascular disease and metabolic disorders. Emerging science has shown the biological consequences of shift work based on estimation of DNA methylation (DNAm), an epigenetic age estimator, which represents the aging process. Individuals with higher than usual DNAm compared with their chronological age have been termed "age-accelerated" which increases risk for age-related disease processes (i.e., stroke, cardiovascular disease, cancer, and death). Shift work and epigenetic age has most notably been associated with women who work more than 10 years, specifically involving night shifts. The estimated epigenetic age is 3 years older than those who have never worked shifts.

Data from Moreno CRC, et al. Working time society consensus statements: evidence-based effects of shift work on physical and mental health. *Ind Health*. 2019;57(2):139–157; White AJ, et al. Shift work, DNA methylation and epigenetic age. *Int J Epidemiol*. 2019;48(5):1536–1544.

Common Parasomnias

Parasomnias are unusual behaviors occurring during non-REM stage 3 (slow-wave) sleep (**disorders of arousal**) and REM-related sleep

behavior disorder.[76] Non-REM sleep behaviors are associated with an inability to maintain deep sleep and an increased number of arousals. Behaviors include sleepwalking, having night terrors, rearranging furniture, eating food, exhibiting sleep sex or violent behavior, and having restless leg syndrome. **REM sleep behavior disorder** (RBD) is manifested by loss of REM paralysis, leading to potentially injurious dream enactment. Nonmotor symptoms are nonspecific and include olfactory dysfunction, abnormal color vision, autonomic dysfunction, excessive daytime sleepiness, depression, and cognitive impairment. RBD is a common prodromal non-motor manifestation of Parkinson disease.[77]

Two dysfunctions of sleep (somnambulism and night terrors) are common in children and may be related to CNS immaturity. **Somnambulism (sleepwalking)** is a non-REM parasomnia disorder primarily of childhood and appears to resolve within a few years. Sleepwalking is therefore not associated with dreaming, and the child has no memory of the event on awakening. Sleepwalking in adults is often associated with sleep-disordered breathing. **Night terrors** are characterized by sudden apparent arousals in which the child expresses intense fear or emotion. However, the child is not awake and can be difficult to arouse. Once awakened, the child has no memory of the night terror event. Night terrors are not associated with dreams. Although this problem occurs most often in children, adults also may experience it with corresponding daytime anxiety.

Restless Leg Syndrome

Restless legs syndrome (RLS)/Willis Ekbom disease is a common sensorimotor disorder associated with unpleasant sensations (prickling, tingling, crawling) and nonvolitional periodic leg movements that occurs at rest and is worse in the evening or at night. There is a compelling urge to move the legs for relief, with a significant effect on sleep and quality of life. The disorder is more common in women, during pregnancy, in older adults, and in individuals with iron deficiency. RLS has a familial tendency, although no monogenetic cause has been found. RLS is associated with a circadian fluctuation of dopamine in the substantia nigra. Iron is a cofactor in dopamine production, and some individuals respond to iron administration as

well as low-dose dopamine agonists. Diagnostic and treatment guidelines have been established to assist with disease management.[78]

The Special Senses

Vision

The eyes are complex sense organs responsible for vision. Within a protective casing, each eye has receptors, a lens system for focusing light on the receptors, and a system of nerves for conducting impulses from the receptors to the brain. Visual dysfunction may be caused by abnormal ocular movements or alterations in visual acuity, refraction, color vision, or accommodation. Visual dysfunction also may be the secondary effect of another neurologic disorder.

The Eye

The wall of the eye consists of three layers: (1) sclera, (2) choroid, and (3) retina (Fig. 16.7). The **sclera** is the thick, white, outermost layer. It becomes transparent at the **cornea**—the portion of the sclera in the central anterior region that allows light to enter the eye. The **choroid** is the deeply pigmented middle layer that prevents light from scattering inside the eye. The **iris**, part of the choroid, has a round opening, the **pupil**, through which light passes. Smooth muscle fibers control the size of the pupil so that it adjusts to bright light or dim light and to close or distant vision.

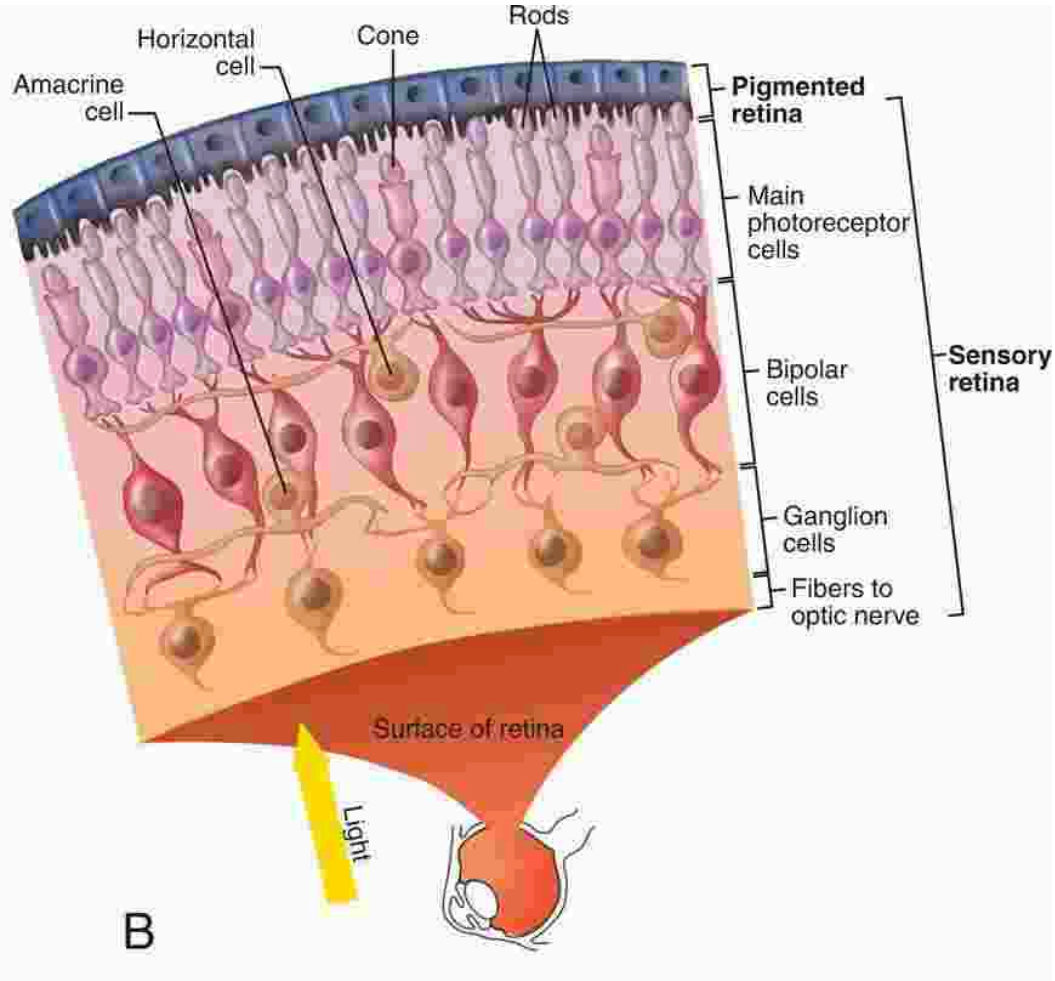

FIG. 16.7 **(A)** Internal anatomy of the eye. **(B)** The retina. (A, Adapted from Patton KT, Thibodeau GA. *Structure & function of the human body*. 13th ed. St Louis: Mosby; 2008. B, From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th ed, St Louis: Mosby; 2018.)

Illustration A depicts the cross-section of the eye with its internal structure labeled clockwise from the left: Visual axis, cornea, anterior chamber, suspensory ligament, lower lid, lateral canthus, ciliary body, retina, choroid, sclera, lateral rectus muscle, posterior cavity, fovea, central artery and vein, optic nerve, optic disc, medial rectus muscle, posterior chamber, the canal of

Schlemm, lacrimal duct, lacrimal caruncle, pupil, and lens. Illustration B depicts the enlarged view of the retina with its structure labeled: Pigmented retina consisting of rods and cone; sensory retina consisting of main photoreceptor cells, bipolar cells, ganglion cells, fibers to the optic nerve, amacrine cell, and horizontal cell main.

The **retina** is the innermost layer of the eye and contains millions of rods and cones—special photoreceptors that convert light energy into nerve impulses (see Fig. 16.7B). **Rods** mediate peripheral and dim light vision, do not mediate color, and are densest at the periphery. **Cones** are color and detail receptors, and densest in the center of the retina. There are no photoreceptors where the optic nerve leaves the eyeball; this creates the **optic disc**, or blind spot. Lateral to each optic disc is the **macula lutea**, the area of most distinct vision, and in the center is the **fovea centralis**, a tiny area that contains only cones and provides the greatest visual acuity (see Fig. 16.7).

Nerve impulses pass through the **optic nerves** (second cranial nerve) to the optic chiasm (Fig. 16.8). The nerves from the inner (nasal) halves of the retinas cross to the opposite side and join fibers from the outer (temporal) halves of the retinas to form the optic tracts (see Fig. 16.8). The fibers of the optic tracts synapse in the dorsal lateral geniculate nucleus and pass by way of the optic radiation (or geniculocalcarine tract) to the primary visual cortex in the occipital lobe of the brain. Some fibers terminate in the suprachiasmatic nucleus (SCN) of the hypothalamus (located above the optic chiasm) and are involved in circadian regulation of the sleep-wake cycle. Light entering the eye is focused on the retina by the **lens**—a flexible, biconvex, crystal-like structure. The flexibility of the lens allows a change in curvature with contraction of the ciliary muscles, called *accommodation*, and allows the eye to focus on objects at different distances. The eye has two segments divided by the lens: the anterior and posterior segments. The anterior segment has two chambers. The anterior chamber lies between the cornea and the iris; the posterior chamber lies between the iris and the

lens. **Aqueous humor** fills the anterior segment and helps maintain pressure inside the eye, as well as provide nutrients to the lens and cornea. Aqueous humor is secreted by the ciliary processes in the posterior chamber, flows through the pupil into the anterior chamber and drains though the trabecular meshwork, and is absorbed by endothelial cells in the canal of Schlemm. It then passes into the venous circulation. If drainage is blocked, intraocular pressure increases, causing glaucoma. The posterior segment extends from the back of the lens to the retinae and is filled with a gel-like substance called **vitreous humor** that cannot regenerate. Vitreous humor maintains intraocular pressure and prevents the eyeball from collapsing inward.

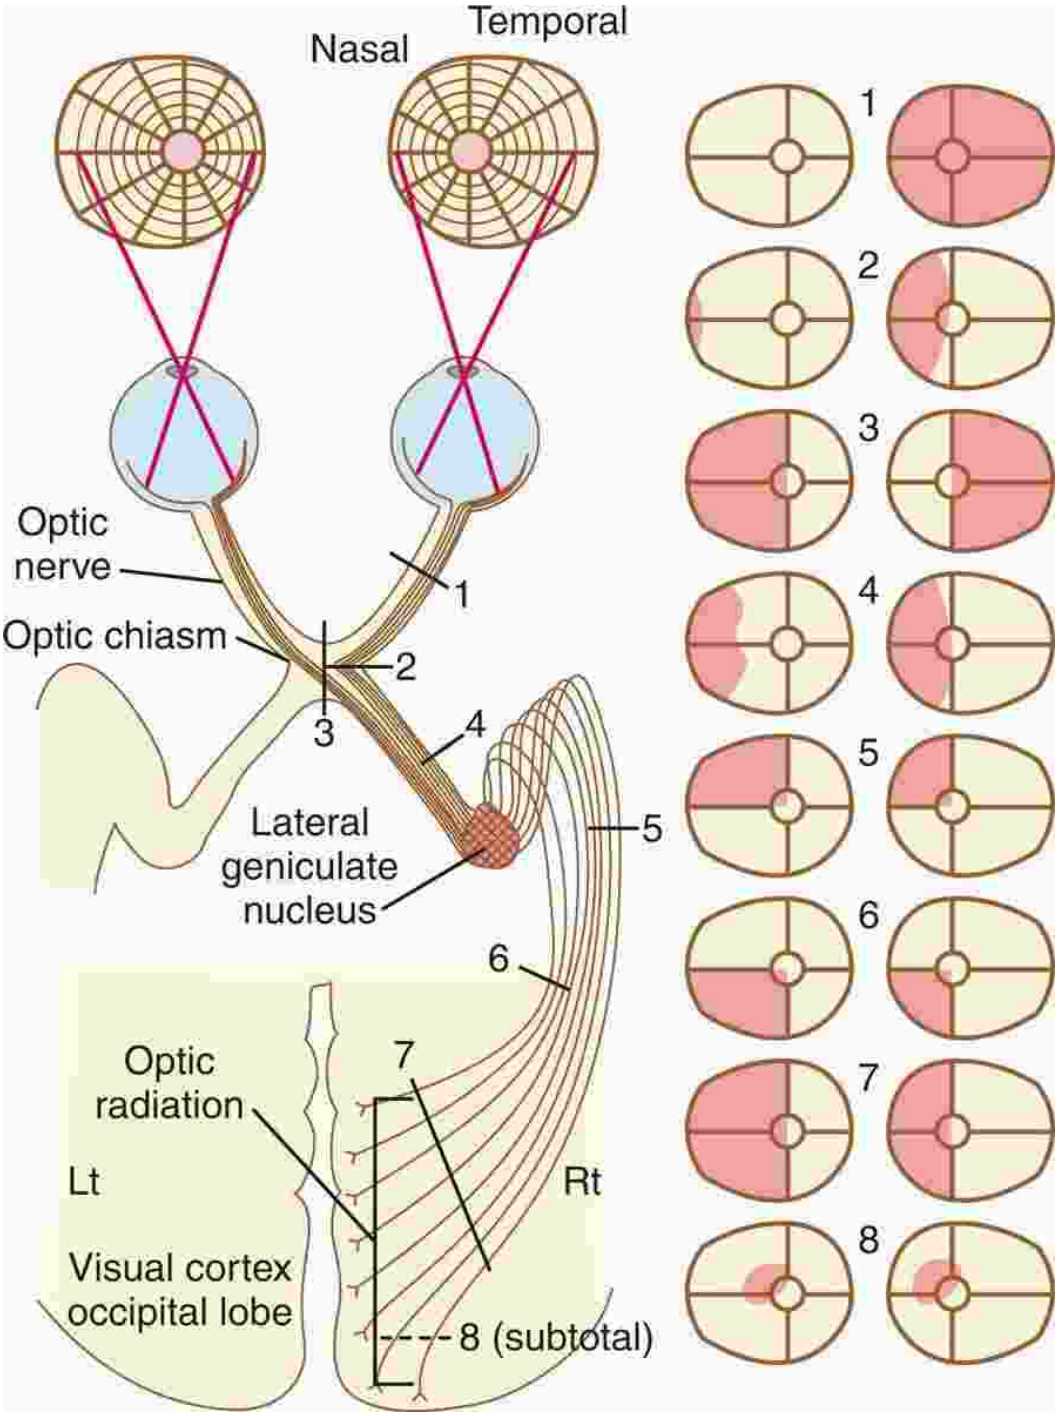

FIG. 16.8 **Visual Pathways and Defects.**
1, Optic nerve: blindness. *2*, Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopsia. *3*, Central optic chiasm: bitemporal hemianopsia. *4*, Optic tract: incongruous, incomplete homonymous hemianopsia. *5*, Temporal

loop of the optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. *6*, Parietal *(superior)* projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. *7*, Complete parieto-occipital interruption of the optic radiation: complete congruous homonymous hemianopsia with psychophysical shift of the foveal point, often sparing central vision and resulting in "macular sparing." *8*, Incomplete (subtotal) damage to the visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. (From Goldman C, ed. *Goldman's Cecil Medicine*. 24th ed. Vol 2. Philadelphia: Saunders; 2012.)

Two illustrations depict the visual field deficits produced by lesions at various points along the visual pathway. The illustration on the left depicts the visual pathway and the lesions at various points numbered from 1 through 8. The labels on the visual pathways are optic nerve, optic chiasm, lateral geniculate nucleus, optic radiation, and visual cortex occipital lobe. The illustration on the right depicts the eight visual pathway lesions.

Blood supply to the eye is provided by branches of the ophthalmic artery. The ciliary artery and its branches provide blood to the anterior eye and the layers of the eye wall. The central retinal artery provides blood to the inner retinal surface, and the choroid supplies nutrients to the outer surface of the retina. Six extrinsic eye muscles allow gross eye movements and permit eyes to follow a moving object (Fig. 16.9).

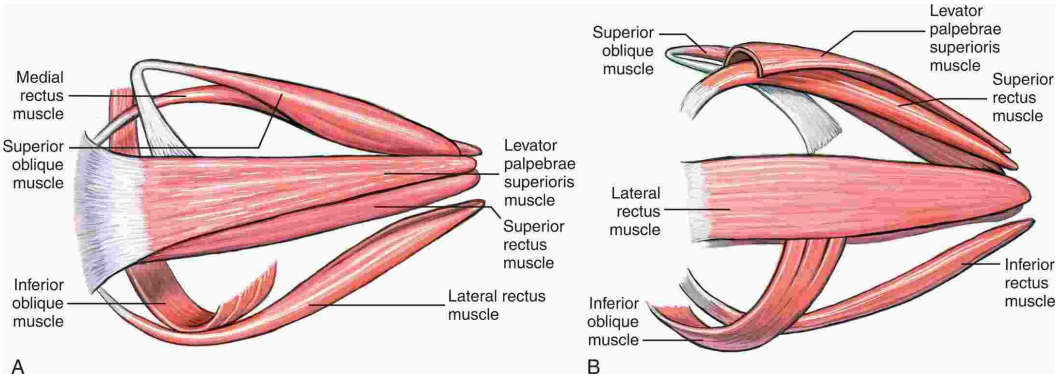

FIG. 16.9 Extrinsic Muscles of the Right Eye.
(A) Superior view. **(B)** Lateral view. (From Dutton JJ. *Atlas of Clinical and Surgical Orbital Anatomy*. 2nd ed. Philadelphia: Saunders; 2011.)

Illustration A depicts the superior view of the extrinsic muscle of the right eye with labels as follows. Medial rectus muscle, superior oblique muscle, inferior oblique muscle, levator palpebrae muscle, superior rectus muscle, and the lateral rectus muscle. Illustration B depicts the lateral view of the extrinsic muscle of the right eye with labels as follows. Superior oblique muscle, lateral rectus muscle, inferior oblique muscle, levator palpebrae superioris muscle, superior rectus muscle, and inferior rectus muscle.

Visual Dysfunction

Alterations in ocular movements

Abnormal ocular movements result from oculomotor, trochlear, or abducens cranial nerve dysfunction (see Table 15.6). The three types of eye movement disorders are (1) strabismus, (2) nystagmus, and (3) paralysis of individual extraocular muscles.

In **strabismus**, one eye deviates from the other when the person is looking at an object. This is caused by a weak or hypertonic muscle in

one eye. The deviation may be upward, downward, inward (esotropia), or outward (exotropia). Strabismus in children requires early intervention to prevent **amblyopia** (reduced vision in the affected eye caused by cerebral blockage of the visual stimuli). The primary symptom of strabismus is **diplopia** (double vision). Causes include neuromuscular disorders of the eye muscle, diseases involving the cerebral hemispheres, or thyroid disease.

Nystagmus is an involuntary unilateral or bilateral rapid, rhythmic oscillatory movement of the eyes. It may be present at rest or when the eye moves. **Pendular nystagmus** is characterized by a regular back and forth movement of the eyes with only slow phases. In **jerk nystagmus**, one phase of the eye movement is faster than the other. Nystagmus may be caused by imbalanced reflex activity of the inner ear, vestibular nuclei, cerebellum, medial longitudinal fascicle, or nuclei of the oculomotor, trochlear, and abducens cranial nerves (see Table 15.6 and Fig. 15.25). Drugs, retinal disease, diseases involving the cervical cord, stroke syndromes, brain tumors, and brain trauma also may produce nystagmus.[79]

Paralysis or loss of neuromuscular coordination of specific extraocular muscles may cause limited abduction, abnormal closure of the eyelid, ptosis (drooping of the eyelid), or diplopia (double vision) as a result of unopposed muscle activity. Trauma or pressure in the area of the cranial nerves or diseases such as diabetes mellitus and myasthenia gravis also paralyze specific extraocular muscles.

Alterations in visual acuity

Visual acuity is the ability to see objects in sharp detail. With advancing age, the lens of the eye becomes less flexible and adjusts slowly, and there is altered refraction of light by the cornea and lens. Thus visual acuity declines with age. Table 16.6 contains a summary of changes in the eye caused by aging. Specific causes of visual acuity changes are (1) amblyopia, (2) scotoma (blind spot in visual field), (3) cataracts, (4) papilledema, (5) dark adaptation, (6) glaucoma, (7) retinal detachment, and (8) macular degeneration (Table 16.7).

Table 16.6

Changes in the Eye Caused by Aging

Structure	Change	Consequence
Cornea	Thicker and less curved Formation of gray ring at edge of cornea (arcus senilis)	Increase in astigmatism Not detrimental to vision
Anterior chamber	Decrease in size and volume caused by thickening of lens	Occasionally exerts pressure on Schlemm canal and may lead to increased intraocular pressure and glaucoma
Lens	Increase in opacity	Decrease in refraction with increased light scattering (blurring) and decreased color vision (green and blue); can lead to cataracts
Ciliary muscles	Reduction in pupil diameter, atrophy of radial dilation muscles	Persistent constriction (senile miosis); decrease in critical flicker frequency[a]
Retina	Reduction in number of rods at periphery, loss of rods and associated nerve cells	Increase in minimum amount of light necessary to see an object
Macula	Atrophy (age-related macular degeneration)	Loss of vision

Structure	Change	Consequence
Vitreous	Liquefaction of vitreous and decrease in gel volume	Posterior vitreous detachment causing “floaters;” risk for retinal detachment

Structure	Change	Consequence

[a]The rate at which consecutive visual stimuli can be presented and still be perceived as separate.

Table 16.7

Causes of Visual Acuity Changes

Disorder	Description
Amblyopia	Reduced or dimmed vision; cause unknown Associated with strabismus Accompanies such diseases as diabetes mellitus, renal failure, and malaria and use of drugs such as alcohol and tobacco
Scotoma	Circumscribed defect of central field of vision Often associated with retrobulbar neuritis and multiple sclerosis, compression of optic nerve by tumor, inflammation of optic nerve, pernicious anemia, methyl alcohol poisoning, and use of tobacco
Cataract	Cloudy or opaque area in ocular lens—the leading cause of blindness Incidence increases with age because most commonly a result of degeneration; other causes are congenital
Papilledema	Edema and inflammation of optic nerve where it enters eyeball Caused by obstruction of venous return from retina by one of three main sources: increased

Disorder	Description
	intracranial pressure, retrobulbar neuritis, or changes in retinal blood vessels
Dark adaptation	With age, eye does not adapt as readily to dark Also, changes in quantity and quality of rhodopsin are causative; vitamin A deficiencies can produce this at any age
Glaucoma	Increased intraocular pressures (>12–20 mm Hg) Loss of acuity results from pressure on optic nerve, which blocks flow of nutrients to optic nerve fibers, leading to their death; second leading cause of blindness
Retinal detachment	Tear or break in retina with accumulation of fluid and separation from underlying tissue; seen as floaters, flashes of light, or a curtain over visual field; risks include extreme myopia, diabetic retinopathy, sickle cell disease

Disorder	Description
Amblyopia	Reduced or dimmed vision; cause unknown Associated with strabismus Accompanies such diseases as diabetes mellitus, renal failure, and malaria and use of drugs such as alcohol and tobacco
Scotoma	Circumscribed defect of central field of vision Often associated with retrobulbar neuritis and multiple sclerosis, compression of optic nerve by tumor, inflammation of optic nerve, pernicious anemia, methyl alcohol poisoning, and use of tobacco
Cataract	Cloudy or opaque area in ocular lens—the leading cause of blindness Incidence increases with age because most commonly a result of degeneration; other causes are congenital
Papilledema	Edema and inflammation of optic nerve where it enters eyeball Caused by obstruction of venous return from retina by one of three main sources: increased intracranial pressure, retrobulbar neuritis, or changes in retinal blood vessels
Dark adaptation	With age, eye does not adapt as readily to dark Also, changes in quantity and quality of rhodopsin are causative; vitamin A deficiencies can produce this at any age
Glaucoma	Increased intraocular pressures (>12–20 mm Hg) Loss of acuity results from pressure on optic nerve, which blocks flow of nutrients to optic nerve fibers, leading to their death; second leading cause of blindness
Retinal detachment	Tear or break in retina with accumulation of fluid and separation from underlying tissue; seen as floaters, flashes of light, or a curtain over visual field; risks include extreme myopia, diabetic retinopathy, sickle cell disease

A **cataract** is a cloudy or opaque area in the ocular lens and leads to visual loss when located on the visual axis (see Fig. 16.7). It is the leading cause of blindness in the world. The incidence of cataracts increases with age as lens proteins break down, leading to opacification. Cataracts develop because of alterations of metabolism and transport of nutrients within the lens. Although the most common form of cataract is degenerative, cataracts also may occur congenitally or as a result of infection, radiation, trauma, drugs, or diabetes mellitus. Cataracts cause decreased visual acuity, blurred vision, glare, and decreased color perception. Cataracts are treated by removal of the entire lens and replacement with an intraocular artificial lens.

Glaucomas are the second leading cause of blindness and are characterized by intraocular pressures greater than 12 to 20 mm Hg with death of retinal ganglion cells and their axons and irreversible loss of central and sometimes peripheral vision. There is a strong genetic tendency with higher prevalence among Black Americans. Chronic use of corticosteroids or drugs with anticholinergic properties can predispose to glaucoma. The two primary types of age-related glaucoma are differentiated by the configuration of the anterior chamber drainage angle and the location of where aqueous humor is obstructed from exiting the eye (Fig. 16.10).[80]

1. *Open angle*. This type of glaucoma is the most common and is characterized by outflow obstruction of aqueous humor at the trabecular meshwork or canal of Schlemm, even though there is adequate space for drainage. Often this is an inherited disease and is a leading cause of blindness with few preliminary symptoms. Obstruction results in high intraocular pressures with compression of the optic nerve head, which can cause blindness within hours or days. With *normal tension glaucoma* there may be neurodegeneration of the optic nerve head that leads to loss of vision without elevated intraocular pressures.
2. *Angle closure* or *narrow angle*. In this type of glaucoma there is displacement of the iris toward the cornea with obstruction of the trabecular meshwork and obstruction of outflow of aqueous humor from the anterior chamber; it may occur acutely with a sudden rise in intraocular pressure, causing pain and visual disturbances, and will need immediate treatment.

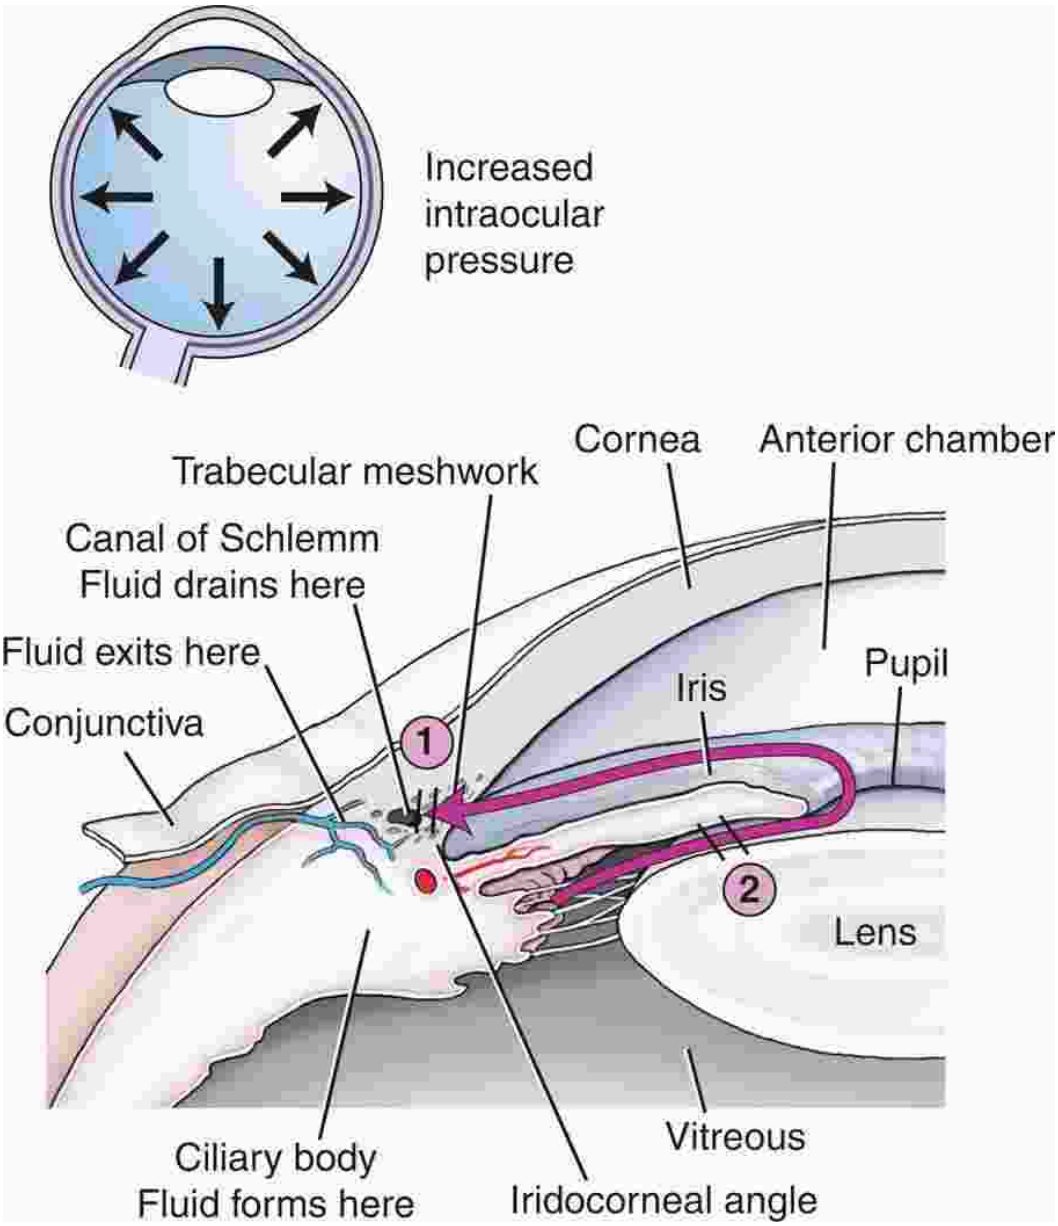

FIG. 16.10 Glaucoma.
1, Open-angle glaucoma. The obstruction to aqueous humor flow lies in the trabecular meshwork near canal of Schlemm, *2*, Closed-angle glaucoma. The iris presses against the lens, blocking aqueous flow into the anterior chamber.

The illustration on the top depicts the increased intraocular pressure. Illustration on the bottom depicts

the section of the outer eye with the structures labeled: conjunctiva where fluid exists here, the canal of Schlemm where fluid drains here, trabecular meshwork, cornea, anterior chamber, ciliary body where fluid forms, vitreous, iridocorneal angle, iris, pupils, and lens. An arrow mark at trabecular meshwork indicates open-angle glaucoma and at the iris indicates closed-angle glaucoma.

Congenital closure glaucoma is a rare disease associated with congenital malformations and other genetic anomalies. There is a defect in the development of the drainage angle formed by the cornea and iris. Aqueous humor cannot flow out normally. The intraocular pressure increases and leads to optic nerve damage. The disease is usually diagnosed by one year of age.

Glaucoma is often treated with pharmaceutical eyedrops to reduce secretion or increase absorption of aqueous humor. Angle closure glaucoma is a medical emergency. Surgical therapies are available to open the spaces of the trabeculae to control intraocular pressure.

Age-related macular degeneration (AMD) is a severe and irreversible loss of vision and a major cause of blindness in older individuals. Hypertension, cigarette smoking, diabetes mellitus, and a family history of AMD are risk factors. The degeneration usually occurs after the age of 60 years. The cause of AMD is unknown and complex because of the many components of eye structure, genetic diversity, and variable environmental factors. There are two forms: dry or non-neovascular (atrophic) and wet or exudative (neovascular). The *dry form* is more common and is slowly progressive with accumulation of drusen (waste products from photoreceptors) in the macula, choriocapillary loss, accumulation of lipofuscin (a lysosomal pigmented residue) in the retinae, and atrophy, leading to permanent central vision loss. Early symptoms include limited night vision and difficulty reading. The *wet form* includes abnormal choroidal blood vessel growth within the macula (neovascularization), leakage of blood or serum, retinal tears or detachment, fibrovascular scarring, loss of photoreceptors, and more

severe and rapid loss of central vision.[81] There are no approved treatments for dry AMD. Daily high doses of vitamins C and E, beta-carotene, and the minerals zinc and copper—called the AREDS formulation—can help slow the progression of dry AMD.[82] Treatment of wet AMD includes anti–vascular endothelial growth factor (anti-VEGF) intraocular injection to provide an anti-angiogenesis effect. New treatments are being evaluated including anti-VEGF antibodies, stem cell, and gene therapy.[81]

Retinal detachment is a common cause of visual impairment and blindness. Risk factors include retinal holes and vitreoretinal traction. Fluid (exudate, hemorrhage, or liquid vitreous) separates the retinal pigment epithelium from the photoreceptors in the neuroepithelium (see Fig. 16.7). The separation deprives the outer retina of oxygen and nutrients because the diffusion distance is increased. Communication is also disrupted between the pigment epithelium and photoreceptors. There is retinal degeneration and fibrosis with loss of vision. **Rhegmatogenous retinal detachment** (full-thickness retinal breaks caused by vitreoretinal traction) is the most common form of retinal detachment. Causes include intracapsular cataract extraction, severe myopia, age-related lattice degeneration, vitreoretinal traction, and trauma. Contraction of fibrous membranes can cause tractional separation of the retinal layers as occurs in proliferative diabetic retinopathy. Symptoms include dark floaters or squiggly lines in the field of vision; flashes of light; or a dark curtain or shadow on the sides or center of the visual field. Retinal detachment is a medical emergency. Treatment involves immediate surgical retinal reattachment.[83]

Alterations in accommodation

Accommodation refers to changes in the shape of the lens and allows for a change of focus from distant to near images. Accommodation is mediated through the oculomotor nerve. Pressure, inflammation, age, and disease of the oculomotor nerve may alter accommodation, causing diplopia, blurred vision, and headache.

Loss of accommodation with advancing age is termed **presbyopia**, a condition in which the ocular lens becomes larger, firmer, and less elastic. The major symptom is reduced near vision, causing the individual to hold reading material at arm's length. Treatment includes

corrective forward, contact, and intraocular lenses, corneal inlays, or laser refractive surgery for monovision.[84]

Alterations in refraction

Alterations in refraction are the most common visual problem. Causes include irregularities of the corneal curvature, the focusing power of the lens, and the length of the eye. The major symptoms of refraction alterations are blurred vision and headache. Three types of refraction alterations are as follows (Fig. 16.11):

Myopia—nearsightedness: The eyeball is lengthened, and light rays are focused in front of the retina when the person is looking at a distant object causing blurry vision. A concave lens is needed for correction. There is increased risk for retinal detachment, cataract formation, and glaucoma.

Hyperopia—farsightedness: the axis of the eyeball is too short and light rays are focused behind the retina when a person is looking at a near object and vision is blurry. A convex lens is needed for correction.

Astigmatism—unequal curvature of the cornea: Light rays enter the eye at two points and do not come to a single focus on the retina and cause blurry vision. Astigmatism may coexist with myopia, hyperopia, or presbyopia. Corrective lenses or laser surgery provide correction.

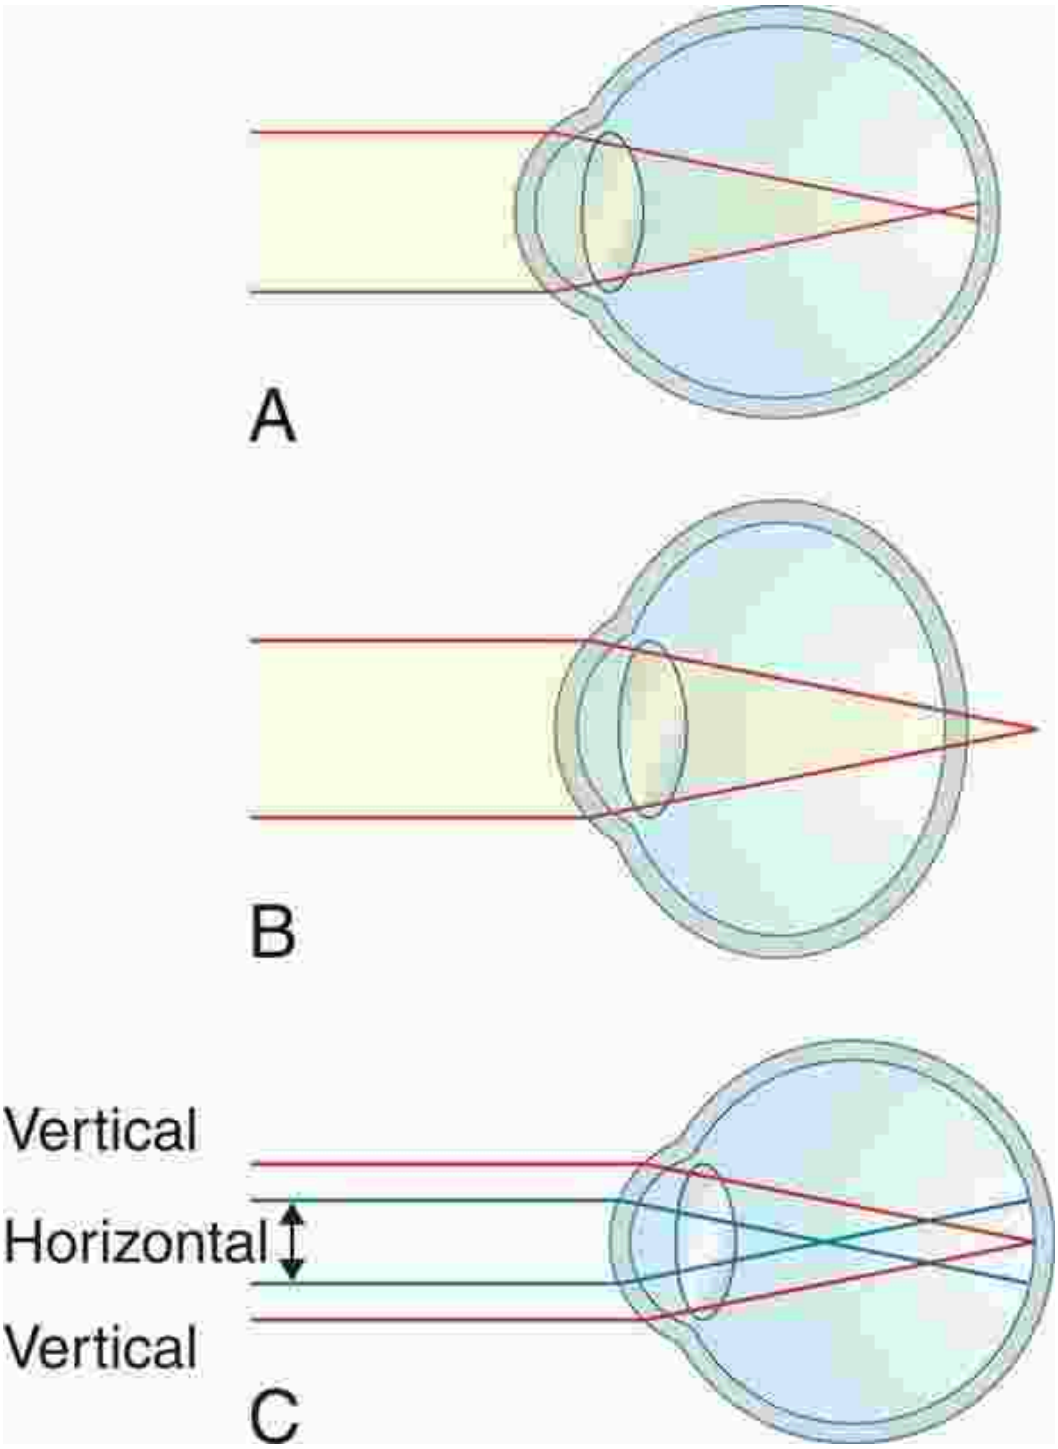

FIG. 16.11 Alterations in Refraction.
(A) Myopic eye. Parallel rays of light are brought to a focus in front of the retina. **(B)** Hyperopic eye. Parallel rays of light come to a focus behind the retina in the unaccommodative eye. (C) Simple

myopic astigmatism. The vertical bundle of rays is focused on the retina; the horizontal rays are focused in front of the retina. (From Stein HA, et al. *The Ophthalmic Assistant: A Text for Allied and Associated Ophthalmic Personnel*. 9th ed. Philadelphia: Saunders; 2013.)

Three illustrations A through C depict the three types of refraction alterations. Illustration A shows parallel rays of light from a distant object focused in front of the retina. Illustration B shows the parallel rays of light from a distant object focused behind the retina. Illustration C shows the horizontal and vertical rays focused in front and on the retina respectively.

Alterations in color vision

Normal sensitivity to color diminishes with age because of the progressive yellowing of the lens that occurs with aging. All colors become less intense, although color discrimination for blue and green is greatly affected. Color vision deteriorates more rapidly for individuals with diabetes mellitus than for the general population because diabetic neuropathy can also affect photoreceptors.

Abnormal color vision also may be caused by **color blindness** and is an X-linked genetic trait.[85] Congenital color blindness affects 6% to 8% of the male population and about 0.5% of the female population. Mutations in the genes coding for wavelength sensitivity of retinal cone photopigments leads to color blindness. Although many forms of color blindness exist, most commonly the affected individual cannot distinguish red from green rather than yellow from blue. In the most severe form (achromatopsia) individuals see only shades of gray, black, and white. Acquired color vision deficiency occurs with ocular, neurologic, or systemic disease.

Neurologic disorders causing visual dysfunction

Various neurologic disorders may cause visual dysfunction including stroke, traumatic brain injury, tumors, and neurodegenerative diseases. Vision may be disrupted at many points along the visual pathway, causing a variety of defects in fields of vision.[86] Visual changes do not always cause defects or blindness in the entire visual field; **hemianopia** is the term that describes defective vision in half of a visual field. Fig. 16.8 illustrates areas along the visual pathway that may be damaged and the associated visual changes. Because of the anatomy of the optic nerves, injury to the optic nerve causes ipsilateral (same side) blindness but a normal contralateral (opposite side) visual field. Injury to the **optic chiasm** (the X-shaped crossing of the optic nerves), often caused by atherosclerotic ischemia or external compression from trauma or aneurysm, can cause a variety of defects, depending on the location of injury. These defects vary because at the optic chiasm, nerve fibers from the medial half of each retina separate from the lateral half and enter the opposite optic tract.

Because of the normal structure of the visual pathways, destruction of one optic tract causes **homonymous hemianopsia** (complete loss of vision in the inner half of one eye and the outer half of the other). Thus, if an injury to the left optic tract occurs, the individual is blind in the right eye's medial (inner) field and the left eye's lateral (outer) field. If the compression of the optic tract is asymmetric, an incongruous (or uneven) homonymous defect results. Injury to one optic radiation (an ocular pathway in the internal capsule, temporal lobe, or occipital lobe) also causes a homonymous (same field) defect. A major injury in the optic radiation causes homonymous hemianopsia. A lesser injury may cause an upper quadrant homonymous defect. Generally the defects are the same size in both eyes. When the homonymous hemianopsia is caused by an occipital lobe lesion, the area of hemianopsia is split. Although visual acuity may remain unimpaired, reading is difficult because of the inability to group words.

Papilledema is edema of the optic nerve at its point of entrance into the eyeball. Papilledema is caused by increased intracranial pressure (e.g., brain tumors, intracranial hemorrhage, hydrocephalus, or cerebral edema). The subarachnoid space of the brain is continuous with the optic nerve sheath. As cerebrospinal fluid (CSF) pressure increases, the pressure is transmitted to the optic nerve and the optic nerve sheath

compresses the nerve and impedes axoplasmic transport. This leads to accumulation of axoplasmic substances at the level of the lamina cribrosa (a mesh-like structure in the sclera where the retinal nerves exit the eye and form the optic nerve), resulting in the characteristic swelling of the optic disc. Obliteration of the physiologic cup (a bright area normally located in the center of the optic disc) follows. Later the optic disc becomes raised above the level of the surrounding retina, and the margins become blurred and indistinct. With severe swelling, hemorrhage and patches of white exudate (caused by nerve infarcts) surround the disc margins. The edematous nerves compress the small retinal veins, causing venous stasis and engorgement. Headache is common and there may be no visual changes, blurred vision, or constriction of visual fields.[87]

External Eye Structure and Disorders

Protective external eye structures include the eyelids (palpebrae), conjunctivae, and lacrimal apparatus. The eyelids control the amount of light reaching the eyes, and the conjunctiva lines the eyelids. Tears released from the lacrimal apparatus bathe the surface of the eye and prevent friction, maintain hydration, and wash out foreign bodies and other irritants (Fig. 16.12).

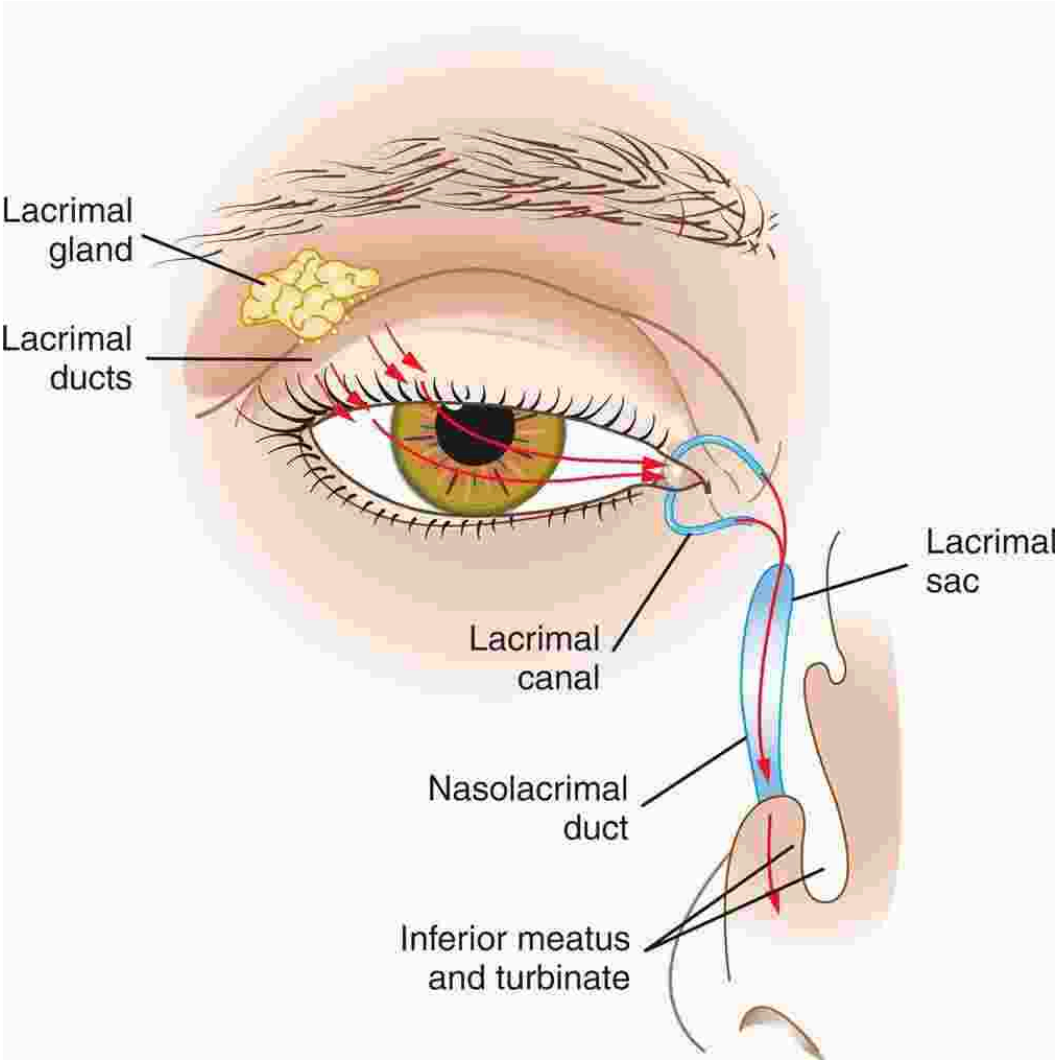

FIG. 16.12 Lacrimal Apparatus.
Fluid produced by lacrimal glands (tears) streams across the eye surface, enters the canals, and then passes through the nasolacrimal duct to enter the nose. (From Applegate E. *The Anatomy and Physiology Learning System*. 4th ed. St Louis: Saunders; 2011.)

An illustration of the anterior view of an eye depicts the structures labeled within the lacrimal apparatus. The labels are as follows. Lacrimal gland, lacrimal ducts, lacrimal canal, lacrimal sac, nasolacrimal duct, inferior meatus, and turbinate. The arrow marks indicate the

pathway of tears from streaming across the eye surface to the nose through the lacrimal canal and nasolacrimal duct.

Infection and inflammatory responses are the most common conditions affecting the supporting structures of the eyes. **Blepharitis** is an inflammation of the eyelids caused by *Staphylococcus* or seborrheic dermatitis. A **hordeolum (stye)** is an infection (usually staphylococcal) of the sebaceous glands of the eyelids, usually centered near an eyelash. A **chalazion** is a noninfectious lipogranuloma of the Meibomian (oil-secreting) gland that often occurs in association with a hordeolum and appears as a deep nodule within the eyelid. These conditions present with redness, swelling, and tenderness and are treated symptomatically. **Entropion** is a common eyelid malposition in which the lid margin turns inward against the eyeball. In ectropion, the eyelid turns outward away from the eye. Trichiasis is abnormally positioned eyelashes that grow back toward the eye. There are both surgical and nonsurgical treatments to reposition the lid margin. There are both surgical and nonsurgical treatments to reposition the lid margin.

Conjunctivitis is an inflammation of the conjunctiva (mucous membrane covering the front part of the eyeball) caused by viruses (most common), bacteria, allergies, or chemical irritants. Conjunctivitis can be acute, recurrent, or chronic and can be associated with systemic disease.[88]

Acute bacterial conjunctivitis (pinkeye) is highly contagious and often caused by *Staphylococcus, Haemophilus, Streptococcus pneumoniae*, and *Moraxella catarrhalis*, although other bacteria may be involved (Fig. 16.13). In children younger than 6 years, *Haemophilus* infection often leads to otitis media (conjunctivitis-otitis syndrome). Bilateral matting of the eyelids, gluing of eyelashes on awakening, lack of itching, and no previous history of conjunctivitis are predictors of bacterial conjunctivitis and differentiate it from viral conjunctivitis. Preventing the spread of the microorganism with meticulous hand washing and use of separate towels is important. The disease is also treated with topical antibiotics.

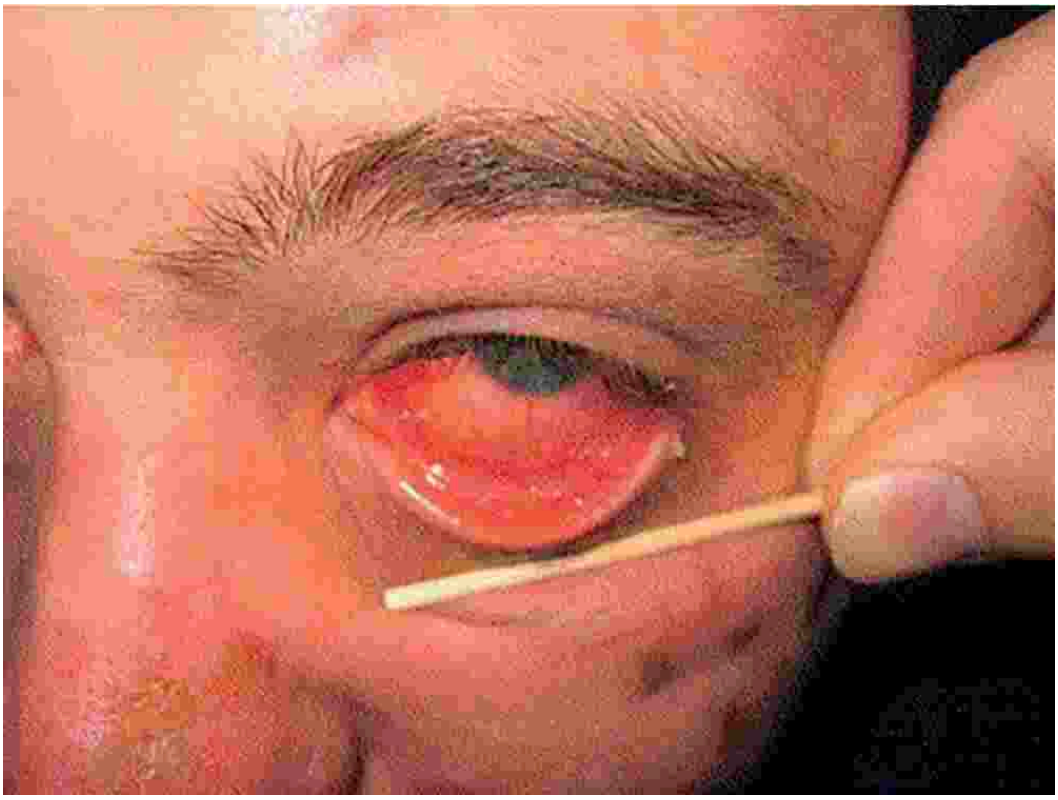

FIG. 16.13 Bacterial Conjunctivitis.
Staphylococcal conjunctivitis of the left eye with mild erythema and inflammatory edema of the eyelids. Purulent exudate can be seen at the lateral canthus.
(From Durkin SR, et al. Recurrent staphylococcal conjunctivitis associated with facial impetigo contagiosa. *Am J Ophthalmol*. 2006;141(1):189–190. https://doi.org/10.1016/j.ajo.2005.07.079.)

Viral conjunctivitis is caused by an adenovirus and is very contagious. Symptoms include edema, watering, redness, petechial hemorrhages of the conjunctiva, and photophobia. Treatment is usually symptomatic and can include antihistamines and cold compresses.

Allergic conjunctivitis is associated with a variety of antigens, including pollens. **Chronic conjunctivitis** results from any persistent conjunctivitis lasting more than 4 weeks. **Trachoma** (chlamydial conjunctivitis) is caused by *Chlamydia trachomatis* and often is associated with poor hygiene and leads to corneal scarring. It is the leading cause of preventable blindness in the world and is treated with azithromycin.[89] **Keratitis** is an infection of the cornea caused by bacteria,

viruses, fungus, or parasites. Bacterial infections can cause corneal ulceration, and type 1 herpes simplex virus can involve both the cornea and the conjunctiva. *Acanthamoeba* keratitis can occur from contact lens wear because of poor hygiene. Fungal infections are most common in tropical and subtropical climates. Severe ulcerations with residual scarring require corneal transplantation.[90]

Hearing

The Normal Ear

The ear is divided into three areas: (1) the external ear, involved only with hearing; (2) the middle ear, involved only with hearing; and (3) the inner ear, involved with both hearing and equilibrium.

The external ear is composed of the **pinna** (auricle), which is the visible portion of the ear, and the **external auditory canal**, a tube that leads to the middle ear (Fig. 16.14). The external auditory canal is surrounded by the bones of the cranium. The opening (meatus) of the canal is just above the **mastoid process**. The air-filled sinuses, called **mastoid air cells**, of the mastoid process promote conductivity of sound between the external and the middle ear. The **tympanic membrane** separates the external ear from the middle ear. Sound waves entering the external auditory canal hit the tympanic membrane (eardrum) and cause it to vibrate.

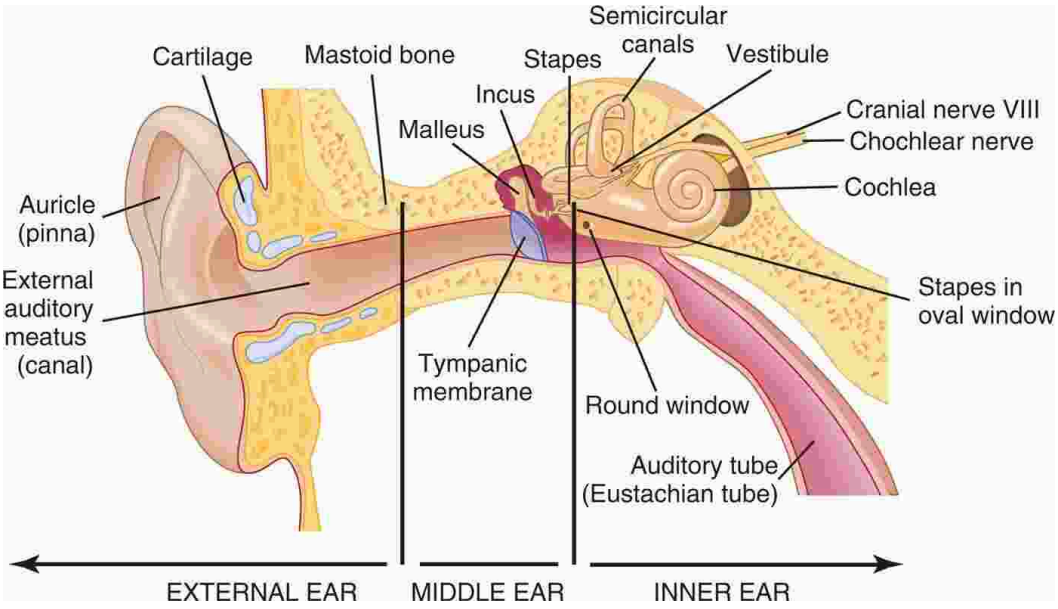

FIG. 16.14 External, Middle, and Inner Ears. (Anatomic structures are not drawn to scale.) (From Applegate E. *The Anatomy and Physiology Learning System*. 4th ed. St Louis: Saunders; 2011.)

An illustration depicts the cross-section of an ear with its parts labeled as follows. External ear: Mastoid bone, cartilage, auricle or pinna, and external auditory meatus or canal. Middle ear: Malleus, incus, stapes, and tympanic membrane; inner ear: Semicircular canals, vestibule, cranial nerve eight, cochlear nerve, cochlea, stapes in the oval window, round window, and auditory tube or eustachian tube.

The middle ear is composed of the **tympanic cavity**, a small chamber in the temporal bone. Three ossicles (small bones known as the **malleus [hammer]**, **incus [anvil]**, and **stapes [stirrup]**) transmit the vibration of the tympanic membrane to the inner ear. When the tympanic membrane moves, the malleus moves with it and transfers the vibration to the incus, which passes it on to the stapes. The stapes presses against the **oval window**, a small membrane of the inner ear. The movement of the

oval window promotes movement of the round window and sets the fluids of the inner ear in motion (Fig. 16.15).

FIG. 16.15 The Inner Ear.
(A) The bony labyrinth *(tan)* is the hard outer wall of the entire inner ear and includes the semicircular canals, vestibule, and cochlea. Within the bony labyrinth is the membranous labyrinth *(purple)*, which is surrounded by perilymph and filled with endolymph. Each ampulla in the vestibule contains a crista ampullaris that detects changes in head position and sends sensory impulses through the vestibular nerve to the brain. **(B)** Section of the membranous cochlea. Hair cells in the organ of Corti detect sound and send the information through the cochlear nerve. The vestibular and cochlear nerves join to form the eighth cranial nerve. (From Applegate E. *The Anatomy and Physiology Learning System*. 4th ed. St Louis: Saunders.)

Illustration A depicts the inner ear with its major structures labeled clockwise from the left: Bony labyrinth contains perilymph, membranous labyrinth containing endolymph, ampulla, vestibular nerve, cochlea, cochlear duct containing endolymph, round window, saccule, oval window, vestibule, utricle, and semicircular canals. Illustration B depicts the enlarged view of a section of the cochlea with its structure labeled: Scala vestibuli, vestibular membrane, cochlear duct or Scala media, tectorial membrane, organ of Corti or hairs cells and supporting cells, basilar membrane, Scala tympani, and cochlear nerve.

The **eustachian (pharyngotympanic) tube** connects the middle ear with the thorax. Normally flat and closed, the eustachian tube opens briefly when a person swallows or yawns, and it equalizes the pressure

in the middle ear with atmospheric pressure. Equalized pressure permits the tympanic membrane to vibrate freely. Through the eustachian tube the mucosa of the middle ear is continuous with the mucosal lining of the throat.

The inner ear is a system of osseous labyrinths (bony, maze-like chambers) filled with a fluid, the **perilymph**. The bony labyrinth is divided into the **cochlea**, the **vestibule**, and the **semicircular canals** (see Fig. 16.15). Suspended in the perilymph is the endolymph-filled membranous labyrinth that basically follows the shape of the bony labyrinth.

Within the cochlea is the **organ of Corti**, which contains **hair cells** (hearing receptors). Sound waves that reach the cochlea through vibrations of the tympanic membrane, ossicles, and oval window set the cochlear fluids into motion. Receptor cells on the basilar membrane are stimulated when their hairs are bent or pulled by fluid movement. Once stimulated, hair cells transmit impulses along the cochlear nerve (a division of the vestibulocochlear nerve) to the auditory cortex of the temporal lobe in the brain (see Fig. 16.15 and view an animation at www.youtube.com/watch?v=46aNGGNPm7s). This is where interpretation of the sound occurs.

The semicircular canals and vestibule of the inner ear contain **equilibrium receptors**. In the semicircular canals the dynamic equilibrium receptors respond to changes in direction of movement. Within each semicircular canal is the **crista ampullaris**, a receptor region composed of a tuft of hair cells covered by a gelatinous cupula. When the head is rotated, the endolymph in the canal lags behind and moves in the direction opposite to the head's movement. The hair cells are stimulated, and impulses are transmitted through the vestibular nerve (a division of the vestibulocochlear nerve) to the cerebellum.

The vestibule in the inner ear contains **maculae**—receptors essential to the body's sense of static equilibrium. As the head moves, **otoliths** (small pieces of calcium salts) move in a gel-like material in response to changes in the pull of gravity. The otoliths pull on the gel, which in turn pulls on the hair cells in the maculae. Nerve impulses in the hair cells are triggered and transmitted to the brain (see Fig. 16.15). Thus the ear not only permits the hearing of a large range of sounds but also assists with maintaining balance through the sensitive equilibrium receptors.

Auditory Dysfunction

Between 5% and 10% of the general population have impaired hearing, and it is the most common sensory defect. The major categories of auditory dysfunction are conductive hearing loss, sensorineural hearing loss, mixed hearing loss, and functional hearing loss. Hearing loss may range from mild to profound. Auditory changes caused by aging are common and incremental (see the box Geriatric Considerations: Aging and Changes in Hearing).

Geriatric ConsiderationsAging and Changes in Hearing[a]

Changes in Structure	Changes in Function
Cochlear hair cell degeneration	Inability to hear high-frequency sounds (presbycusis, sensorineural loss); interferes with understanding speech; hearing may be lost in both ears at different times
Loss of auditory neurons in spiral ganglia of organ of Corti	Inability to hear high-frequency sounds (presbycusis, sensorineural loss); interferes with understanding speech; hearing may be lost in both ears at different times
Degeneration of basilar (cochlear) conductive membrane of cochlea	Inability to hear at all frequencies but more pronounced at higher frequencies (cochlear conductive loss)
Decreased vascularity of cochlea	Equal loss of hearing at all frequencies (strial loss); inability to disseminate localization of sound
Loss of cortical auditory neurons	Equal loss of hearing at all frequencies (strial loss); inability to disseminate localization of sound

[a]Hearing loss affects about 50% of individuals older than 60 years and 80% of individuals 85 years or older. Hearing loss is associated with declining cognitive function; changes in perception, comprehension, and memory; impaired communication; and reduced quality of life. Causal mechanisms are not clearly known.

Data from Jayakody DMP, Friedland PL, Martins RN, et al. Impact of aging on the auditory system and related cognitive functions: a narrative review. *Front Neurosci*. 2018;12:125; Wu PZ, Liberman LD, Bennett K, et al. Primary neural degeneration in the human cochlea:

evidence for hidden hearing loss in the aging Ear. *Neuroscience*. 2019;407:8–20.

Conductive hearing loss

A **conductive hearing loss** occurs when physical anomalies in the outer or middle ear impair conduction of sound from the outer to the inner ear. Conditions that commonly cause a conductive hearing loss include impacted cerumen, foreign bodies lodged in the ear canal, benign tumors of the middle ear, carcinoma of the external auditory canal or middle ear, eustachian tube dysfunction, otitis media, acute viral otitis media, chronic suppurative otitis media, cholesteatoma (accumulation of keratinized epithelium), and otosclerosis.

Symptoms of conductive hearing loss include diminished hearing and a soft speaking voice. A soft speaking voice is often used because the individual hears his or her voice, conducted by bone, as loud.

Sensorineural hearing loss

A **sensorineural hearing loss** is caused by impairment of the organ of Corti or its central connections to the auditory cortex. The loss may occur gradually or suddenly. Conditions causing sensorineural loss include congenital and hereditary factors, noise exposure, aging, Ménière disease, ototoxicity, systemic disease (syphilis, Paget disease, collagen diseases, diabetes mellitus), neoplasms, and autoimmune processes. Congenital and neonatal sensorineural hearing loss may be caused by maternal rubella, ototoxic drugs, prematurity, traumatic delivery, erythroblastosis fetalis, bacterial meningitis, and congenital hereditary malfunction. Diagnosis is often made when delayed speech development is noted. Sudden-onset bilateral sensorineural hearing loss can be associated with stroke or trauma and is a medical emergency.[91]

Presbycusis is the most common form of sensorineural hearing loss in older adults and is usually bilateral and symmetric. Its cause may be atrophy of the basal end of the organ of Corti, loss of auditory receptors, changes in vascularity, or stiffening of the basilar membranes. Drug ototoxicities (drugs that cause destruction of auditory function) have been observed after exposure to various chemicals; for example,

antibiotics such as aminoglycosides (streptomycin, neomycin, gentamicin), and vancomycin; diuretics such as ethacrynic acid and furosemide; and chemicals such as salicylate, quinine, carbon monoxide, nitrogen mustard, arsenic, mercury, gold, tobacco, and alcohol. In most instances, the drugs and chemicals listed initially cause **tinnitus** (ringing in the ear) followed by a progressive high-tone sensorineural hearing loss that is permanent. With presbycusis there is loss of sound clarity related to cochlear impairment and hearing loss at high frequencies.[92]

Mixed and functional hearing loss

A **mixed hearing loss** is caused by a combination of conductive and sensorineural losses. With **functional hearing loss**, which is rare, the individual does not respond to voice and appears not to hear. It is thought to be caused by emotional or psychologic factors.

Ménière disease

Ménière disease (endolymphatic hydrops) is an episodic chronic disorder of the middle ear with an unknown etiology that can be unilateral or bilateral and with variable presentations. The most likely cause is excessive endolymph and pressure in the membranous labyrinth that disrupts both vestibular and hearing functions. There are four symptoms: recurring episodes of vertigo (often accompanied by severe nausea and vomiting), hearing loss, ringing in the ears (tinnitus), and a feeling of fullness in the ear. Treatment is symptomatic with medical management or surgical management when medications fail.[93]

Ear Infections

Otitis Externa

Otitis externa is the most common inflammation of the outer ear and may be acute or chronic, infectious or noninfectious. Risk factors include swimming with ear plugs, chronic dermatitis, and irritants such as hair spray or hair dyes. The most common origins of acute infections are bacterial microorganisms including *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and, less commonly, *Escherichia coli*. Fungal infections are less common. Infection usually follows prolonged exposure to moisture (swimmer's ear). The earliest symptoms are

inflammation with pruritus, swelling, and clear drainage, progressing to purulent drainage with obstruction of the canal. Tenderness and pain with earlobe retraction accompany inflammation. Acidifying solutions are used for early treatment and prevention. Topical antimicrobials and steroids usually provide effective treatment for later stages of disease. Chronic infections are more often related to allergy or skin disorders. **Malignant otitis externa** is a very rare serious complication of the spread of otitis externa into the mastoid and/or temporal bone causing osteomyelitis. It presents with headache and otalgia. Diagnosis requires advanced imaging, and treatment requires intravenous antibiotics.[94]

Otitis media

Otitis media (OM) is a common infection of infants and children. Most children have one episode by 3 years of age. The most common pathogens are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Moraxella catarrhalis*. Respiratory viruses have also been associated with OM.[95] Predisposing factors include allergy, sinusitis, submucosal cleft palate, adenoidal hypertrophy, eustachian tube dysfunction, and immune deficiency. Breast-feeding is a protective factor. Recurrent acute otitis media may be genetically determined.[96]

Acute otitis media (AOM) is associated with ear pain, fever, irritability, inflamed tympanic membrane, fluid in the middle ear, and holding or tugging at the ear. The appearance of the tympanic membrane progresses from erythema to opaqueness with bulging as fluid accumulates. There is an increasing prevalence of AOM caused by penicillin-resistant microorganisms. Otitis media with effusion (OME) is the presence of fluid in the middle ear without symptoms of acute infection (Fig. 16.16). Treatment includes symptom management, particularly of pain, with watchful waiting, antimicrobial therapy for severe illness, and placement of tympanostomy tubes when there is persistent bilateral effusion and significant hearing loss (chronic suppurative otitis media). Complications include mastoiditis, brain abscess, meningitis, and chronic otitis media with hearing loss. Persistent middle ear effusions may affect speech, language, and cognitive abilities. Multivalent vaccines for influenza result in modest prevention of acute otitis media.[97,98]

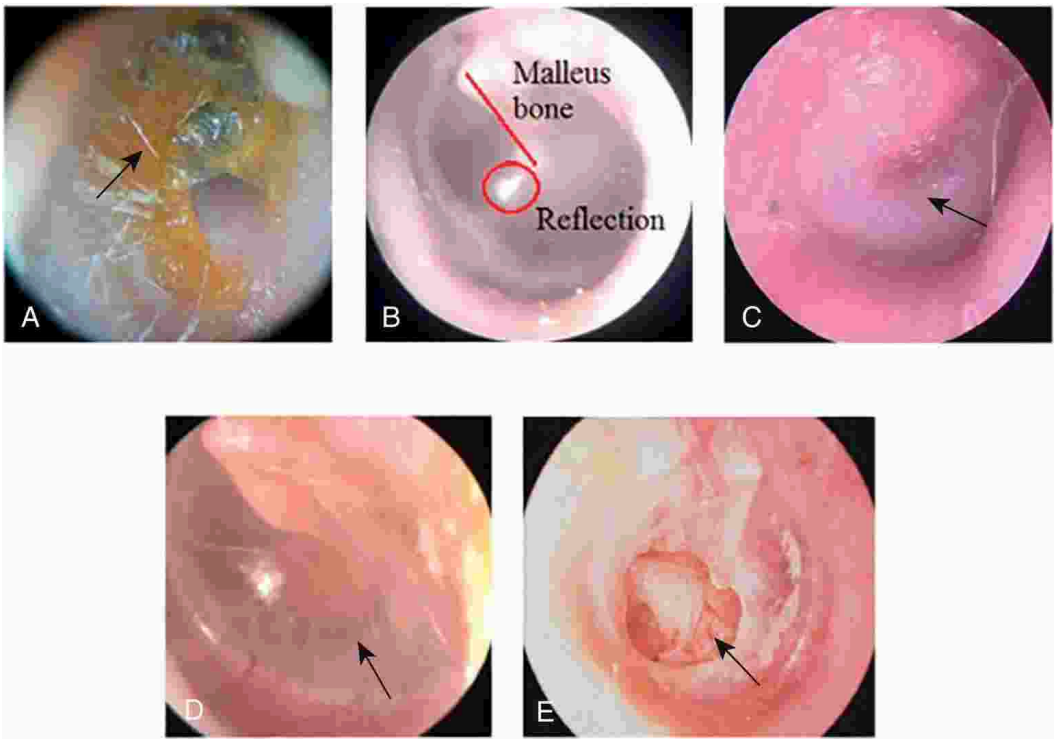

FIG. 16.16 Otitis Media. **(A)** Obstructing wax or foreign bodies in external ear canal *(see arrow)* precluding visualization of the TM to establish an OM diagnosis. **(B)** A normal TM *(n-TM)* showing a semitransparent pearly white TM, triangular-shaped light reflex, and malleus bone clearly visible (red ring and line, respectively). **(C)** Acute otitis media showing a bulging TM with red color *(see arrow)*. **(D)** Otitis media with effusion *(see arrow)* showing a retracted TM and fluid in the middle ear *(see arrow)*. **(E)** Chronic suppurative otitis media showing a TM perforation *(see arrow)*. *TM*, Tympanic membrane. (From Myburgh HC, et al. Otitis media diagnosis for developing countries using tympanic membrane image-analysis. *EBioMedicine*. 2016;5:156–160. https://www.sciencedirect.com/science/article/pii/S2352396416300500.)

Photomicrography A shows the external ear canal and an arrow indicates the presence of obstructing wax.

Photomicrography B shows the external ear canal with a light reflection indicated by a circle and a line indicating the malleus bone. Photomicrography C shows the external ear canal and an arrow mark indicates the bulged tympanic membrane. Photomicrography D shows the external ear canal and an arrow mark indicates the presence of fluid in the middle ear with a retracted tympanic membrane. Photomicrography E shows the external ear canal and an arrow mark indicates the perforated tympanic membrane.

Olfaction and Taste

Olfaction (smell) is a function of cranial nerve I and part of cranial nerve V. **Taste (gustation)** is a function of multiple nerves in the tongue, soft palate, uvula, pharynx, and upper esophagus innervated by cranial nerves VII and IX. Both cranial nerves are influenced by hormones within the sensory cells. Dysfunctions of smell and taste may occur separately or jointly. The strong relationship between smell and taste creates the sensation of flavor. If either sensation is impaired, the perception of flavor is altered. Olfactory structures are illustrated in Fig. 16.17.

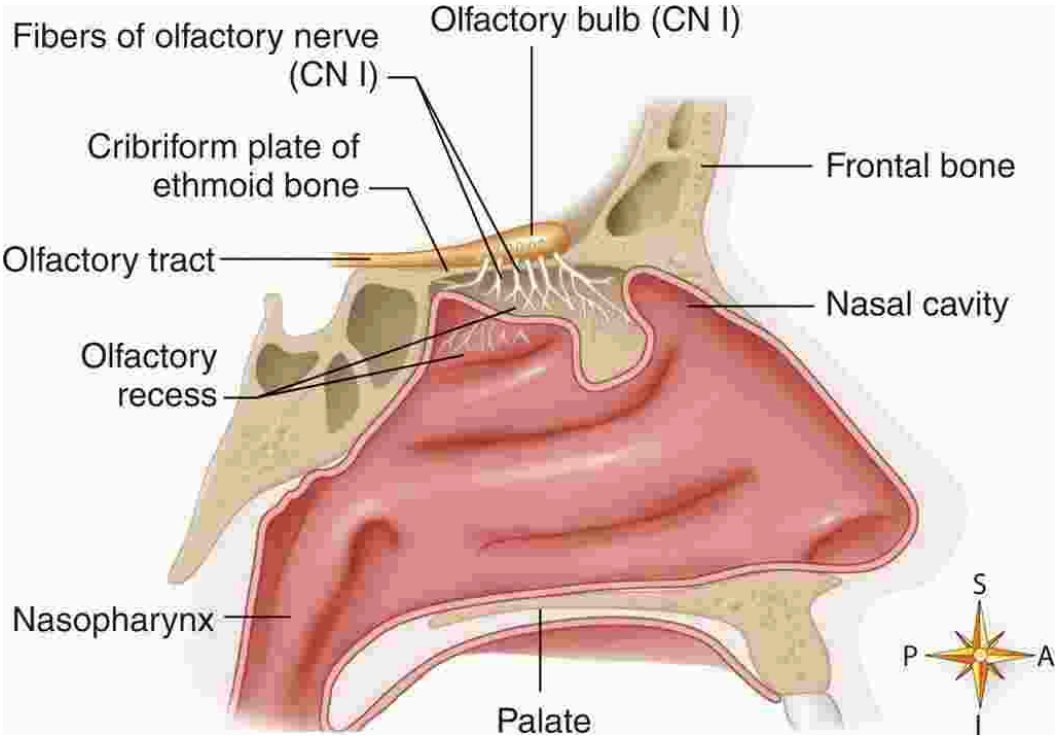

FIG. 16.17 Olfaction.
Midsagittal section of the nasal area shows the location of major olfactory sensory structures. (From Patton KT, Thibodeau GA, Douglas MM. *Essentials of Anatomy & Physiology*. St Louis: Mosby; 2012.)

An illustration depicts the midsagittal section of the nasal area with the major olfactory sensory structures labeled clockwise from the left: Olfactory bulb (CN 1), fibers of the olfactory nerve (C N 1), cribriform plate of the ethmoid bone, olfactory tract, olfactory recess, nasopharynx, palate, nasal cavity, and frontal bone.

Olfactory cells, located in the olfactory epithelium, are the receptor cells for smell. Seven different primary classes of olfactory stimulants have been identified: (1) camphoraceous, (2) musky, (3) floral, (4) peppermint, (5) ethereal, (6) pungent, and (7) putrid. Olfaction is important for detection of hazards in the environment, generating

feelings of pleasure, promoting adequate nutrition, influencing sexuality, and maintenance of mood.[99]

Olfactory dysfunctions include hyposmia, anosmia, hallucinations, and parosmia. **Hyposmia** is the impaired sense of smell, and **anosmia** is the complete loss of smell. Both conditions are associated with aging, neurodegenerative and nasal/sinus disorders, and head trauma. When hyposmia or anosmia occurs bilaterally, it is usually the result of rhinitis (inflammation of nasal mucosa), sinusitis, nasal polyps, or excessive smoking. Unilateral hyposmia or anosmia may indicate compression of one olfactory bulb (a bulb-like portion of the olfactory nerves) or nerve tract (olfactory nerve pathway), possibly by tumor or head trauma. **Olfactory hallucinations** arise from hyperactivity in cortical neurons and involve smelling odors that are not really present. They are associated with temporal lobe seizures and rarely with schizophrenia. **Parosmia**, an abnormal or perverted sense of smell, may occur with severe depression and in Parkinson and Alzheimer disease.[100] Sensitivity to odors declines steadily with aging. (See the box Geriatric Considerations: Aging and Changes in Olfaction and Taste for a summary of changes in olfaction and taste with aging.)

The primary sensations of taste are (1) sour, (2) salty, (3) sweet, (4) bitter, and (5) umami (savory taste of glutamate). Taste buds (fungiform, foliate, and circumvallate) sensitive to each of the primary sensations are located in specific areas of the tongue and are continuously renewing: sweet near the tip, salty on frontal sides, sour on the posterior sides, bitter on the very back, and umami overall surface of tongue. Taste receptors also are found on airway smooth muscle, bladder, breast cancer cells, ovarian cancer cells, and neuroblastoma (bitter) and in the gastrointestinal tract (bitter and sweet). Their function is not for taste. In the lung they stimulate bronchodilation and in the gastrointestinal tract they may participate in metabolic and digestive regulation. These receptors are being evaluated as targets for diagnosis and treatment.[101,102]

Geriatric Considerations

Aging and Changes in Olfaction and Taste

- Decline in sensitivity to odors, usually after age 80, occurs.
- Loss of olfaction may diminish appetite, taste, and food selection and may affect nutrition.
- Inability to smell toxic fumes or gases can pose a safety hazard.
- Decline in taste sensitivity is more gradual than decline in sense of smell. Sensitivity to sweetness is maintained and sensitivity to saltiness declines.
- Higher concentrations of flavors required to stimulate taste.
- Taste may be influenced by decreased salivary secretion.

Olfactory and Taste Dysfunctions

Olfactory dysfunctions include the following:

1. **Hyposmia**—impaired sense of smell
2. **Anosmia**—complete loss of sense of smell
3. **Olfactory hallucinations**—smelling odors that are not really present
4. **Parosmia**—abnormal or perverted sense of smell

The sense of taste can be impaired by injury, medications, oral infections, or aging. A change in taste may be attributed to impaired smell associated with injury near the hippocampus.

Hypogeusia is a decrease in taste sensation, whereas **ageusia** is an absence of the sense of taste. These disorders result from cranial nerve injuries and can be specific to the area of the tongue innervated. **Dysgeusia** is a perversion of taste in which substances possess an unpleasant flavor (i.e., metallic). Ageusia affecting the entire tongue may follow head injury. Hypogeusia and ageusia occur with viral respiratory and oral infections. Autoimmune disease (e.g., systemic lupus erythematosus) and cancer chemotherapy alter taste sensitivity. Damage to the glossopharyngeal nerve (cranial nerve IX, which innervates the posterior one-third of the tongue) causes the loss of the ability to detect bitterness. This loss occurs because the receptors for bitter are located on the base of the tongue. Damage to the facial nerve (cranial nerve VII, which innervates the anterior two-thirds of the tongue) causes loss of the

ability to detect sour, sweet, and salty tastes. Only bitter tastes can be detected. These losses occur because sour, sweet, and salt receptors are located on the anterior portion of the tongue.[103] Alterations in taste may compromise adequate nutrition or cause anorexia. Variations in taste and smell are important early manifestations of SARS-CoV-2 viral infection (see Emerging Science Box: Loss of Taste and Smell in SARS-CoV-2-Positive Persons).[104]

Emerging Science BOX

Loss of Taste and Smell in SARS-CoV-2-Positive Persons

The coronavirus SARS-CoV-2 or COVID-19 became a global viral pandemic in March 2020. Based on early research, a typical clinical presentation was known to include fever, cough and/or difficulty breathing, headache, and diarrhea. Early in the disease progression, an atypical presentation was identified in Europe including anosmia and ageusia. While many viral infections can lead to some degree of hyposmia, this symptom is concomitant with rhinorrhea. Similarly, ageusia is a common side effect of nasal obstruction often linked with viral infections. In those who are SARS-CoV-2-positive, anosmia has been present, but unassociated with rhinorrhea and ageusia has been present, but unassociated with nasal obstruction. Preliminary research also identified a predominantly slow resolution to anosmia and ageusia in SARS-CoV-2-positive individuals. The SARS-CoV-2 virus has been shown to infect the salivary glands and gingival mucosa and has been correlated with loss of taste. Additionally, the virus infects the supporting cells in the olfactory epithelium rather than the sensory neurons. Damage to these cells could affect the olfactory bulb and impair neuronal signaling for taste. Cells at these sites express angiotensin-converting enzyme 2 (ACE2) receptors and cell surface transmembrane serine protease 2 (TMPRSS2), both of which are critical for viral entry.

Data from Brann DH, et al. Non-neuronal expression of SARS-CoV-2 entry genes in the olfactory system suggests mechanisms underlying COVID-19-associated anosmia. *Sci. Adv*. 2020;6:eabc5801; Huang N, et al. SARS-CoV-2 infection of the oral cavity and saliva. *Nat Med*. 2021. Based on the emerging science of COVID-

19 studies, sudden loss of taste (ageusia) and loss of smell (anosmia) have been listed as important symptoms in the identification of active SARS-CoV-2 infection; Mastrangelo A, et al. Smell and taste disorders in COVID-19: from pathogenesis to clinical features and outcomes. *Neurosci Lett*. 2021;748:135694.

Somatosensory Function

Touch

The sensation of **touch** involves four afferent fiber types that mediate tactile sensation and there may be an additional sensory nerve that transmits pleasurable touch.[105] Receptors sensitive to touch are present in the skin with high densities in the fingers and lips. **Meissner** and **Pacinian corpuscles** sense movement across the skin and vibration, respectively. **Merkel disks** sense sustained light touch, and **Ruffini endings** respond to deep sustained pressure, stretch, and joint position. Specific sensory input is carried to the higher levels of the CNS by the dorsal column of the spinal cord and the anterior spinothalamic tract.

The cutaneous senses develop before birth, but structural growth continues into early adulthood. Then a gradual decline occurs, with loss in tactile discrimination with advancing age. Abnormal tactile perception may be caused by alterations at any level of the nervous system, from the receptor to the cerebral cortex. Factors that interrupt or impair reception, transmission, perception, or interpretation of touch—including trauma, tumor, infection, metabolic changes, vascular changes, and degenerative diseases—may cause tactile dysfunction. In addition, most tactile sensations evoke affective responses that determine whether the sensation is unpleasant, pleasant, or neutral. With aging, touch sensitivity declines and gentle touch becomes more pleasant. There is a decline in skin elasticity and tactile receptors and changes in central somatotropic organization.[106]

Proprioception

Proprioception is the awareness of the position of the body and its parts. It depends on impulses from the inner ear and from receptors in joints and ligaments. Sensory data are transmitted to higher centers, primarily through the dorsal columns and the spinocerebellar tracts, with some data passing through the medial lemnisci and thalamic radiations to the

cortex. These stimuli are necessary for the coordination of movements, the grading of muscular contraction, and the maintenance of equilibrium.

As with tactile dysfunction, any factor that interrupts or impairs the reception, transmission, perception, or interpretation of proprioceptive stimuli also alters proprioception and increases the risk for falls and injury. A progressive loss of proprioception has been reported in older adult persons with an increased risk for falls and injury.[107] Two common causes are vestibular dysfunction and neuropathy.

Specific vestibular dysfunctions are vestibular nystagmus and vertigo. **Vestibular nystagmus** is the constant, involuntary movement of the eyeball and develops when the semicircular canal system is overstimulated. **Vertigo** is the sensation of spinning that occurs with inflammation of the semicircular canals in the ear. The individual may feel either that he or she is moving in space or that the world is revolving. Vertigo often causes loss of balance, and nystagmus may occur. Ménière disease can cause loss of proprioception during an acute attack, so that standing or walking is impossible.

Peripheral neuropathies also can cause proprioceptive dysfunction. They may be caused by several conditions and commonly are associated with renal disease and diabetes mellitus. Although the exact sequence of events is unknown, neuropathies cause a diminished or absent sense of body position or position of body parts. Gait changes often occur.

Summary Review

Pain

1. Pain (nociception) is a complex, sensory experience involving emotion, cognition, and motivation. Acute pain is protective, promoting withdrawal from painful stimuli.
2. Three portions of the nervous system are responsible for the sensation, perception, and response to pain: (1) the afferent pathways, (2) the interpretive centers in the central nervous system, and (3) the efferent pathways.
3. Nociception involves four phases: transduction, transmission, perception, and modulation.

4. Pain transduction begins when nociceptors (pain receptors) are activated by noxious stimulants. There are two types of nociceptors: myelinated Aδ fibers transmit sharp, "fast" pain; smaller, unmyelinated C fibers more slowly transmit dull, less localized pain.
5. Pain transmission is the conduction of pain impulses along the nociceptors into the spinal cord and eventually to the brain.
6. Pain perception is the conscious awareness of pain. It occurs with the integration of three systems. The sensory-discriminative system (mediated by the somatosensory cortex) identifies the location and intensity of pain. The affective-motivational system (mediated by the reticular formation, limbic system, and brain stem) controls emotional and affective responses to pain. The cognitive-evaluative system (mediated by the cortex) coordinates the meaning and experience of pain.
7. Pain threshold is the lowest intensity of pain that a person can recognize. Pain tolerance is the greatest level of pain that an individual is prepared to tolerate. Both are subjective and influenced by many factors.
8. Pediatric pain considerations
9. Geriatric pain considerations
10. Pain modulation facilitates or inhibits the transmission of pain signals throughout the nervous system. Neuromodulators of pain include substances that (1) stimulate pain nociceptors (e.g., prostaglandins, bradykinins, lymphokines, substance P, glutamate) and (2) suppress pain (e.g., GABA, endogenous opioids, endocannabinoids). Some substances excite peripheral nerves but inhibit central nerves (e.g., serotonin, norepinephrine).
11. Endogenous opioids inhibit pain transmission and include enkephalins, endorphins, dynorphins, and endomorphins. They are produced in the central nervous system and by immune cells.
12. Descending inhibitory and facilitatory pathways and nuclei inhibit or facilitate pain. Efferent pathways from the ventromedial medulla and PAG inhibit pain impulses at the

dorsal horn. The RVM stimulates efferent pathways that facilitate or inhibit pain in the dorsal horn.

13. Segmental pain inhibition occurs when impulses from Aβ fibers (touch and vibration sensations) arrive at the same spinal level as impulses from Aδ or C fibers.
14. DNIC occurs when pain signals from two different sites are transmitted simultaneously and inhibit pain through a spinal-medullary-spinal pathway. Conditioned pain modulation uses a test pain stimulus and a conditioning pain stimulus with subjective measures of pain intensity to evaluate the efficacy of DNIC responses.
15. Because of the complex nature of pain, classifications of pain often overlap, and more than one description is often used.
16. Acute pain is a signal to the person of a harmful stimulus and may be (1) somatic (skin, joints, muscles), (2) visceral (inner organs, body cavities), or (3) referred (present in an area distant from its origin). The area of referred pain is supplied by the same spinal segment as the actual site of pain.
17. Chronic pain is pain lasting well beyond the expected normal healing time and may be ongoing (e.g., low back pain) or intermittent (e.g., migraine headaches). Psychologic, behavioral, and physiologic responses to chronic pain include depression, sleep disorders, preoccupation with pain, lifestyle changes, and physiologic adaptation.
18. Neuropathic pain is chronic pain with increased sensitivity to painful or nonpainful stimuli and results from abnormal processing of pain information in the peripheral or central nervous system.
19. Chronic pain syndromes include myofascial pain, chronic postoperative pain, cancer pain, post-stroke pain, phantom limb pain, and complex regional pain syndrome. These syndromes are complex, often involve both nociceptive and neuropathic pain mechanisms, and are difficult to treat.

Temperature Regulation

1. Temperature regulation (thermoregulation) is achieved through precise balancing of heat production, heat conservation, and heat loss. Body temperature is maintained in a range around 37°C (98.6°F).
2. Temperature regulation is mediated by the hypothalamus and endocrine system through peripheral thermoreceptors in the skin, liver, and skeletal muscle and central thermoreceptors in the hypothalamus, spinal cord, viscera, and great veins.
3. Heat is produced through chemical reactions of metabolism and skeletal muscle contraction. Heat is distributed by the circulatory system.
4. Heat is lost through radiation, conduction, convection, vasodilation, decreased muscle tone, evaporation of sweat, increased respiration, voluntary mechanisms, and adaptation to warmer climates.
5. Heat conservation is accomplished through vasoconstriction and voluntary mechanisms.
6. Infants do not conserve heat well because of their greater body surface/mass ratio and decreased amounts of subcutaneous fat. Older adult persons have poor responses to environmental temperature extremes as a result of slowed blood circulation, structural and functional changes in the skin, and overall decrease in heat-producing activities.
7. Fever involves the temporary "resetting of the hypothalamic thermostat" to a higher level. When the fever breaks, the set point returns to normal. Fever is triggered by the release of exogenous pyrogens from bacteria or the release of endogenous pyrogens (cytokines) from phagocytic cells.
8. Fever kills many pathogens and decreases serum levels of iron, zinc, and copper that are needed for bacterial replication.
9. The acute phase response is a defensive reaction to infection or injury that includes an inflammatory response, fever, and the production of immune cytokines and proteins that support the immune system in eliminating pathogens.
10. Endogenous cryogens are antipyretic substances that diminish fever and control the febrile response.

11. Febrile seizures occur in children with temperatures greater than 38°C (100.4°F) without CNS infection, hypoglycemia, or electrolyte disorders. They are usually brief and without recurrence.
12. Fever of unknown origin is a body temperature greater than 38.3°C (101°F) for longer than 3 weeks that remains undiagnosed after 3 days of investigation.
13. Fever production aids responses to infectious processes. Higher temperatures kill many microorganisms, promote immune responses, and decrease serum levels of iron, zinc, and copper, which are needed for bacterial replication.
14. Hyperthermia (marked warming of core temperature) can produce nerve damage, coagulation of cell proteins, and death. Therapeutic hyperthermia may be used to promote natural immune processes or promote tumor blood flow. Forms of accidental hyperthermia include heat cramps, heat exhaustion, heat stroke, and malignant hyperthermia. Heat stroke and malignant hyperthermia are potentially lethal.
15. Hypothermia (marked cooling of core temperature) slows the rate of cell metabolism, increases the viscosity of the blood, slows blood flow through the microcirculation, facilitates blood coagulation, and stimulates profound vasoconstriction. Hypothermia may be accidental or therapeutic.
16. Major body trauma can affect temperature regulation by damaging the CNS or causing inflammation, increased intracranial pressure, or intracranial bleeding. It results in a sustained, noninfectious fever called central fever.

Sleep

1. Sleep is an active process that provides restorative functions and promotes memory consolidation. Sleep is divided into REM and non-REM stages, each of which has its own series of stages. While asleep, an individual progresses through REM and non-REM (slow wave) sleep multiple times in a predictable cycle.
2. REM sleep is controlled by mechanisms in the pons and mesencephalon. It is known as paradoxical sleep because the

EEG pattern is similar to that of an awake person. The brain is very active with dreaming.

3. Non-REM sleep is controlled by release of inhibitory signals from the hypothalamus and accounts for 75% to 80% of sleep time. The body is in a state of reduced activity.
4. The sleep patterns of the newborn and young child vary from those of the adult in total sleep time, cycle length, and percentage of time spent in each sleep cycle. Older adult persons experience a total decrease in sleep time.
5. The restorative, reparative, and growth processes occur during slow-wave (non-REM) sleep. Sleep deprivation can cause profound changes in personality and functioning.
6. Sleep disorders include (1) dyssomnias, which are disorders of initiating or maintaining sleep (i.e., insomnia, obstructive sleep apnea syndrome, hypersomnia, or disorders of the sleep-wake schedule) and (2) parasomnias, which are unusual behaviors during sleep (i.e., sleepwalking or night terrors and restless leg syndrome).

The Special Senses

1. The special senses include vision, hearing, olfaction, and taste.
2. The eyes are responsible for vision. The wall of the eye has three layers: sclera, choroid, and retina. The retina contains millions of baroreceptors known as rods and cones that receive light through the lens and then convey signals to the optic nerve and subsequently to the visual cortex of the brain.
3. The eye is filled with vitreous and aqueous humor, which prevent it from collapsing.
4. The major alterations in ocular movement include strabismus, nystagmus, and paralysis of the extraocular muscles.
5. Alterations in visual acuity (the ability to see objects in sharp detail) can be caused by amblyopia, scotoma, cataracts, papilledema, dark adaptation, glaucoma, retinal detachment, and macular degeneration. Visual acuity decreases with age due to structural eye changes.

6. A cataract is a cloudy or opaque area in the ocular lens and leads to visual loss when located on the visual axis. Cataracts are the leading cause of blindness in the world.
7. Glaucoma is characterized by intraocular pressure with death of retinal ganglion cells and their axons. Open angle, angle closure or narrow angle, and congenital closure are the various forms, with angle closure glaucoma being a medical emergency.
8. Age-related macular degeneration is irreversible loss of vision with atrophic (dry) or neovascular (wet) forms.
9. Retinal detachment is a separation of the retinal pigment epithelium from the photoreceptors in the neuroepithelium with loss of vision.
10. Alterations in accommodation (changes in lens shape that changes focus from distant to near images) develop with increased intraocular pressure, inflammation, age, and disease of the oculomotor nerve. Presbyopia is loss of accommodation caused by loss of elasticity of the lens with aging.
11. Alterations in refraction, including myopia, hyperopia, and astigmatism, are the most common visual disorders.
12. Alterations in color vision can be related to yellowing of the lens with aging and color blindness, an inherited trait.
13. Trauma or disease of the optic nerve pathways can cause defects or blindness in the entire visual field or in half of the visual field (hemianopia).
14. The eyelids, conjunctivae, and lacrimal apparatus protect the eye externally. Infections are the most common disorders; they include blepharitis, conjunctivitis, chalazion, and hordeolum.
15. Blepharitis is an inflammation of the eyelid; a hordeolum (stye) is an infection of the eyelid's sebaceous gland; and a chalazion is an infection of the eyelid's Meibomian gland.
16. Conjunctivitis is an inflammation of the conjunctiva, and can be acute or chronic, bacterial, viral, or allergic. Redness, edema, pain, and lacrimation are common symptoms. Trachoma (chlamydial conjunctivitis) is the leading cause of preventable blindness in the world and is associated with poor hygiene.
17. Keratitis is a bacterial or viral infection of the cornea that can lead to corneal ulceration.

18. The ears are responsible for hearing. The ear is composed of external, middle, and inner structures.
19. The external ear structures are the pinna, auditory canal, and tympanic membrane. The external ear is only involved in hearing.
20. The middle ear is composed of the tympanic cavity (containing three bones: the malleus, the incus, and the stapes), oval window, eustachian tube, and fluid. These transmit sound vibrations to the inner ear. The middle ear is only involved in hearing.
21. The inner ear is involved in both hearing and equilibrium. It includes the bony and membranous labyrinths that transmit sound waves through the cochlea and to the cochlear nerve and ultimately to the brain. The semicircular canals and vestibule help maintain balance through the equilibrium receptors.
22. Impaired hearing is the most common sensory defect, occurring in 5% to 10% of the general population.
23. Hearing loss can be classified as conductive, sensorineural, mixed, or functional.
24. Conductive hearing loss occurs when sound waves cannot be conducted through the middle ear.
25. Sensorineural hearing loss develops with impairment of the organ of Corti or its central connections. Presbycusis is the most common form of sensorineural hearing loss in older adults.
26. A combination of conductive and sensorineural loss is mixed hearing loss. Loss of hearing with no known organic cause is functional hearing loss.
27. Ménière disease is a disorder of the middle ear that affects hearing and balance.
28. Otitis externa is an infection of the outer ear associated with prolonged exposure to moisture.
29. Otitis media is an infection of the middle ear that is common in children. Accumulation of fluid (effusion) behind the tympanic membrane is a common finding.
30. Olfaction (smell) is a function of cranial nerve I and part of cranial nerve V. Taste (gustation) is a function of multiple nerves

in the tongue, soft palate, uvula, pharynx, and upper esophagus innervated by cranial nerves VII and IX.

31. The perception of flavor is altered if olfaction or taste dysfunctions occur. Sensitivity to odor and taste decreases with aging.
32. Hyposmia is an impaired sense of smell, and anosmia is the complete loss of the sense of smell.
33. Hypogeusia is a decrease in taste sensation, and ageusia is the absence of the sense of taste.

Somatosensory Function

1. The sensation of touch is a function of receptors present in the skin, and the sensory response is conducted to the brain through the dorsal column and anterior spinothalamic tract.
2. Alterations in touch can result from alterations at any level of the nervous system.
3. Proprioception is the awareness of the position and location of the body and its parts. Proprioceptors are located in the inner ear, joints, and ligaments. Proprioceptive stimuli are necessary for balance, coordinated movement, and grading of muscular contraction.
4. Disorders of proprioception can occur at any level of the nervous system and result in impaired balance and lack of coordinated movement. Vestibular nystagmus is the constant, involuntary movement of the eyeball and develops when the semicircular canal system is overstimulated. Vertigo is the sensation of spinning that occurs with inflammation of the semicircular canals in the ear.

Alterations in Cognitive Systems, Cerebral Hemodynamics, and Motor Function

Kaveri Roy and Sue E. Huether

http://evolve.elsevier.com/Rogers/pathophysiology/

Chapter Outline

OUTLINE

Alterations in Cognitive Systems 509
- Alterations in Arousal 509
- Alterations in Awareness 516
- Data Processing Deficits 521

Alterations in Cerebral Hemodynamics 534
- Increased Intracranial Pressure 534
- Cerebral Edema 536
- Hydrocephalus 537

Alterations in Neuromotor Function 538
- Upper and Lower Motor Neuron Syndromes 538
- Extrapyramidal Motor Syndromes 541
- Alterations in Complex Motor Performance 543
- Alterations in Muscle Tone 544
- Alterations in Muscle Movement 546

Chronic Diseases and Disorders Involving Motor Function 547
- Chronic Progressive Motor Diseases of the Central Nervous System 547
- Demyelinating Disorders 557
- Neuromuscular Junction Disorders 560

Intellectual and behavioral functions are achieved by integrated processes of cognitive systems, sensory systems, and motor systems. The purpose of this chapter is to present the concepts and processes of these alterations as an approach to understanding the manifestation of neurologic dysfunction that can occur with disease or injury. Some specific diseases are also presented in this chapter (**Parkinson disease** [PD], **Huntington disease** [HD], and **amyotrophic lateral sclerosis** [ALS]) because they fit best here. The manifestations for specific central and peripheral nervous system disorders are presented in Chapter 18 (brain and spinal cord injury, stroke, seizure, and headache syndromes). Alterations in sensory function and sleep were presented in Chapter 16 (pain, temperature regulation, sleep, and the special senses—vision, hearing, touch, and proprioception).

The neural systems are structures that build, support, facilitate, and organize sensorimotor input and output.[1] The neural systems essential to cognitive function are (1) attentional systems that provide arousal and maintenance of attention over time, (2) memory and language systems by which information is communicated, and (3) affective or emotive systems that mediate mood, emotion, and intention. These core systems are fundamental to the processes of abstract thinking and reasoning. The products of abstraction and reasoning are organized and made operational through the executive attentional networks. The normal functioning of these systems manifests through the motor system in a behavioral array viewed by others as being appropriate to human activity and successful living.

Alterations in Cognitive Systems

Consciousness is a state of awareness both of oneself and of the environment and a set of responses to that environment. Consciousness has two distinct components: arousal (state of wakefulness or alertness) and awareness (content of thought). **Arousal** is mediated by the reticular activating system, which regulates aspects of attention and information processing and maintains consciousness (see Fig. 15.7). Cognitive cerebral functions require a functioning reticular activating system (RAS). Awareness

encompasses all cognitive functions and is mediated by attentional systems, memory systems, language systems, and executive systems.

Alterations in Arousal

Alterations in level of arousal may be caused by structural, metabolic, or psychogenic (functional) disorders.

Pathophysiology

Structural alterations in arousal are divided according to the original location of the pathologic condition: supratentorial (above the tentorium cerebelli—membrane), infratentorial (subtentorial, below the tentorium cerebelli—membrane) (see Figs. 15.17 and 17.17), extracerebral (outside the brain tissue), and intracerebral (within the brain tissue). Causes include infection, vascular alterations, neoplasms, traumatic injury, congenital alterations, degenerative changes, polygenic traits, and metabolic disorders.

Supratentorial disorders (above the tentorium cerebelli) produce changes in arousal by either diffuse or localized dysfunction. Diffuse dysfunction may be caused by disease processes affecting the cerebral cortex or the underlying subcortical white matter (e.g., encephalitis). Disorders outside the brain but within the cranial vault (extracerebral) also can produce diffuse dysfunction, including neoplasms, closed-head trauma with subsequent bleeding (i.e., subdural hematoma or subarachnoid hemorrhage), and subdural empyema (accumulation of pus). Disorders within the brain substance (intracerebral)—bleeding, infarcts, emboli, and tumors—function primarily as masses. Such localized destructive processes directly impair function of the thalamic or hypothalamic activating systems or secondarily compress these structures in a process of expansion or herniation.

Infratentorial disorders (below the tentorium cerebelli) produce a decline in arousal by (1) direct destruction or compression of the RAS and its pathways (e.g., accumulations of blood or pus, neoplasms, and demyelinating disorders), or (2) the brainstem (midbrain, pons, and medulla) may be destroyed either by direct invasion or by indirect impairment of its blood supply. The most common cause of direct destruction is cerebrovascular disease. Demyelinating diseases, neoplasms, granulomas, abscesses, and head injury also may cause brainstem destruction by tissue compression. This compression may occur because of (1) direct pressure on the pons and midbrain, producing ischemia and edema of the neurons of the RAS; (2) upward herniation of the cerebellum through the tentorial notch, thus compressing the upper midbrain and diencephalon; or (3) downward herniation of the cerebellum through the foramen magnum, compressing and displacing the medulla oblongata.

Metabolic alterations in arousal produce a decline in arousal by alterations in delivery of energy substrates as occurs with hypoxia, electrolyte disturbances, hypoglycemia, or hyperglycemia. Examples of systemic diseases that eventually produce nervous system disorders include liver or renal failure that cause alterations in neuronal excitability because of failure to metabolize or eliminate drugs and toxins. Hypothyroidism and adrenal insufficiency may be associated with alterations in arousal (e.g., myxedema coma and adrenal crisis) and are medical emergencies (see Chapter 22).

Psychogenic alterations in arousal (unresponsiveness), although uncommon, may signal general psychiatric disorders (see Chapter 19). Despite apparent unconsciousness, the person is physiologically awake, and the neurologic examination reflects normal responses.

Clinical Manifestations and Evaluation

Five patterns of neurologic function are critical to the evaluation process: (1) level of consciousness, (2) pattern of breathing, (3) pupillary reaction, (4) oculomotor responses, and (5) motor responses. Patterns of clinical manifestations help determine the extent of brain dysfunction and serve as indices for identifying increasing or decreasing central nervous system (CNS) function. Distinctions are made between metabolic and structurally induced manifestations (Table 17.1). The types of manifestations suggest the mechanisms of the altered arousal state (Table 17.2).

Table 17.1

Clinical Manifestations of Metabolic and Structural Causes of Altered Arousal

Manifestation	Metabolically Induced	Structurally Induced
Blink to threat (cranial nerves II, VII)	Equal	Asymmetric
Optic discs (cranial nerve II)	Flat, good pulsation	Papilledema
Extraocular movement (cranial nerves III, IV, VI)	Roving eye movements; normal doll's eyes and calorics	Gaze paresis, nerve III palsy, medial longitudinal fasciculus (MLF) syndrome (internuclear ophthalmoplegia)
Pupils (cranial nerves II, III)	Equal and reactive; may be large (e.g., atropine), pinpoint (e.g., opiates), or midposition and fixed (e.g., glutethimide [Doriden])	Asymmetric and/or nonreactive; may be midposition (midbrain injury), pinpoint (pons injury), large (tectal injury)
Corneal reflex (cranial nerves V, VII)	Symmetric response	Asymmetric response
Grimace to pain (cranial nerve VII)	Symmetric response	Asymmetric response
Motor function movement	Symmetric	Asymmetric
Muscle tone	Symmetric	Paratonic, spastic, flaccid, especially if asymmetric
Posture	Symmetric	Decorticate, especially if symmetric; decerebrate, especially if asymmetric
Deep tendon reflexes	Symmetric	Asymmetric
Babinski sign	Absent or symmetric response	Present
Sensation	Symmetric	Asymmetric

Table 17.2

Differential Characteristics of Disorders Causing Altered Arousal

Mechanism	Manifestations
Supratentorial mass lesions compressing or displacing diencephalons or brainstem	Initiating signs usually of focal cerebral dysfunction Signs of dysfunction progress rostral to caudal Neurologic signs at any given time point to one anatomic area (e.g., diencephalon, mesencephalon, medulla) Motor signs often asymmetric
Infratentorial mass or destruction, causing coma	History of preceding brainstem dysfunction or sudden onset of coma Localizing brainstem signs precede or accompany onset of coma and always include oculovestibular abnormality Cranial nerve palsies; usually manifest as "bizarre" respiratory patterns that appear at onset
Metabolic coma Exogenous toxins (e.g., drugs, carbon monoxide, heavy metals, pesticides) Endogenous toxins (organ system failure)	Confusion and stupor commonly precede motor signs Motor signs usually are symmetric Pupillary reactions usually are preserved Asterixis, myoclonus, tremor, and seizures are common Acid-base imbalance with hyperventilation or hypoventilation is common

Mechanism	Manifestations
Psychiatric unresponsiveness	Lids close actively Pupils reactive or dilated (cycloplegics) Oculocephalic reflexes are unpredictable; oculovestibular reflexes are physiologic (nystagmus is present) Motor tone is inconsistent or normal Eupnea or hyperventilation is usual No pathologic reflexes are present Electroencephalogram (EEG) is normal

Mechanism	Manifestations
Supratentorial mass lesions compressing or displacing diencephalons or brainstem	Initiating signs usually of focal cerebral dysfunction Signs of dysfunction progress rostral to caudal Neurologic signs at any given time point to one anatomic area (e.g., diencephalon, mesencephalon, medulla) Motor signs often asymmetric
Infratentorial mass or destruction, causing coma	History of preceding brainstem dysfunction or sudden onset of coma Localizing brainstem signs precede or accompany onset of coma and always include oculovestibular abnormality Cranial nerve palsies; usually manifest as "bizarre" respiratory patterns that appear at onset
Metabolic coma Exogenous toxins (e.g., drugs, carbon monoxide, heavy metals, pesticides) Endogenous toxins (organ system failure)	Confusion and stupor commonly precede motor signs Motor signs usually are symmetric Pupillary reactions usually are preserved Asterixis, myoclonus, tremor, and seizures are common Acid-base imbalance with hyperventilation or hypoventilation is common
Psychiatric unresponsiveness	Lids close actively Pupils reactive or dilated (cycloplegics) Oculocephalic reflexes are unpredictable; oculovestibular reflexes are physiologic (nystagmus is present) Motor tone is inconsistent or normal Eupnea or hyperventilation is usual No pathologic reflexes are present Electroencephalogram (EEG) is normal

Patterns of Neurologic Function

Level of consciousness is the most critical clinical index of nervous system function, with changes indicating either improvement or deterioration of the individual's condition. A person who is alert and oriented to self, others, place, and time is functioning at the highest level of consciousness, which implies full use of all the person's cognitive capacities. From this normal alert state, levels of

consciousness diminish in stages from confusion and disorientation (can occur simultaneously) to coma, each of which is clinically defined (Table 17.3). Guidelines are available to assist with the evaluation of prolonged disorders of consciousness.[2]

Table 17.3

Levels of Altered Consciousness

State	Definition
Confusion	Loss of ability to think rapidly and clearly; impaired judgment and decision making; difficulty following instructions
Disorientation	Beginning loss of consciousness; disorientation to time followed by disorientation to place and impaired memory; lost last is recognition of self
Lethargy	Limited spontaneous movement or speech; easy arousal with normal speech or touch; may not be oriented to time, place, or person
Obtundation	Mild to moderate reduction in arousal (awakeness) with limited response to the environment; falls asleep unless stimulated verbally or tactilely; answers questions with minimum response
Stupor	A condition of deep sleep or unresponsiveness from which the person may be aroused or caused to open eyes only by vigorous and repeated stimulation; response is often withdrawal or grabbing at stimulus
Light coma	Associated with purposeful movement on stimulation
Coma	No verbal response to the external environment or to any stimuli; noxious stimuli such as deep pain or suctioning yields motor movement
Deep coma	Associated with unresponsiveness or no response to any stimulus

Patterns of breathing help evaluate the level of brain dysfunction and coma. Rate, rhythm, and pattern should be evaluated. Breathing patterns can be categorized as hemispheric or brainstem (Table 17.4 and Fig. 17.1).

Table 17.4

Patterns of Breathing

Breathing Pattern	Description	Location of Injury
Hemispheric Breathing Patterns		
Normal	After a period of hyperventilation that lowers the arterial carbon dioxide pressure ($PaCO_2$), the individual continues to breathe regularly but with a reduced depth.	Response of the nervous system to an external stressor—not associated with injury to the central nervous system (CNS)
Posthyperventilation apnea	Respirations stop after hyperventilation has lowered the $PaCO_2$ level below normal. Rhythmic breathing returns when the $PaCO_2$ level returns to normal. (Usually, an intact cerebral cortex will trigger breathing within 10 s regardless of $PaCO_2$.)	Associated with diffuse bilateral metabolic or structural disease of the cerebrum
Cheyne-Stokes respirations	Breathing pattern has a smooth increase (crescendo) in the rate and depth of breathing (hyperpnea), which peaks and is followed by a gradual smooth decrease (decrescendo) in the rate and depth of breathing to the point of apnea when the cycle repeats itself. The hyperpneic phase lasts longer than the apneic phase (represents an amplitude change).	Bilateral dysfunction of the deep cerebral or diencephalic structures; seen with supratentorial injury and metabolically induced coma states unrelated to neurologic dysfunction; may see also in congestive heart failure (CHF)
Brainstem Breathing Patterns		
Central reflex hyperpnea (central neurogenic hyperventilation)	A sustained deep rapid but regular pattern (hyperpnea) occurs, with a decreased $PaCO_2$ and a corresponding increase in pH and increased PO_2.	May result from CNS damage or disease that involves the lower midbrain and upper pons; seen after increased intracranial pressure and blunt head trauma
Apneusis	A prolonged inspiratory cramp (a pause at full inspiration) occurs. A common variant of this is a brief end-inspiratory pause of 2 or 3 s, often alternating with an end-expiratory pause.	Indicates damage to the respiratory control mechanism located at the pontine level; most commonly associated with pontine infarction but documented with hypoglycemia, anoxia, and meningitis
Cluster (Biot) breathing	A cluster of breaths has a disordered sequence with irregular pauses between breaths.	Dysfunction in the lower pontine and high medullary areas

Breathing Pattern	Description	Location of Injury
Ataxic breathing	Completely irregular breathing occurs, with random shallow and deep breaths and irregular pauses. Often the rate is slow.	Originates from a primary dysfunction of the medulla
Gasping breathing pattern (agonal gasps)	A pattern of deep "all-or-none" breaths is accompanied by a slow respiratory rate.	Indicative of a failing medullary respiratory center

Breathing Pattern	Description	Location of Injury
Hemispheric Breathing Patterns		
Normal	After a period of hyperventilation that lowers the arterial carbon dioxide pressure ($PaCO_2$), the individual continues to breathe regularly but with a reduced depth.	Response of the nervous system to an external stressor—not associated with injury to the central nervous system (CNS)
Posthyperventilation apnea	Respirations stop after hyperventilation has lowered the $PaCO_2$ level below normal. Rhythmic breathing returns when the $PaCO_2$ level returns to normal. (Usually, an intact cerebral cortex will trigger breathing within 10 s regardless of $PaCO_2$.)	Associated with diffuse bilateral metabolic or structural disease of the cerebrum
Cheyne-Stokes respirations	Breathing pattern has a smooth increase (crescendo) in the rate and depth of breathing (hyperpnea), which peaks and is followed by a gradual smooth decrease (decrescendo) in the rate and depth of breathing to the point of apnea when the cycle repeats itself. The hyperpneic phase lasts longer than the apneic phase (represents an amplitude change).	Bilateral dysfunction of the deep cerebral or diencephalic structures; seen with supratentorial injury and metabolically induced coma states unrelated to neurologic dysfunction; may see also in congestive heart failure (CHF)
Brainstem Breathing Patterns		
Central reflex hyperpnea (central neurogenic hyperventilation)	A sustained deep rapid but regular pattern (hyperpnea) occurs, with a decreased $PaCO_2$ and a corresponding increase in pH and increased PO_2.	May result from CNS damage or disease that involves the lower midbrain and upper pons; seen after increased intracranial pressure and blunt head trauma
Apneusis	A prolonged inspiratory cramp (a pause at full inspiration) occurs. A common variant of this is a brief end-inspiratory pause of 2 or 3 s, often alternating with an end-expiratory pause.	Indicates damage to the respiratory control mechanism located at the pontine level; most commonly associated with pontine infarction but documented with hypoglycemia, anoxia, and meningitis
Cluster (Biot) breathing	A cluster of breaths has a disordered sequence with irregular pauses between breaths.	Dysfunction in the lower pontine and high medullary areas
Ataxic breathing	Completely irregular breathing occurs, with random shallow and deep breaths and irregular pauses. Often the rate is slow.	Originates from a primary dysfunction of the medulla
Gasping breathing pattern (agonal gasps)	A pattern of deep "all-or-none" breaths is accompanied by a slow respiratory rate.	Indicative of a failing medullary respiratory center

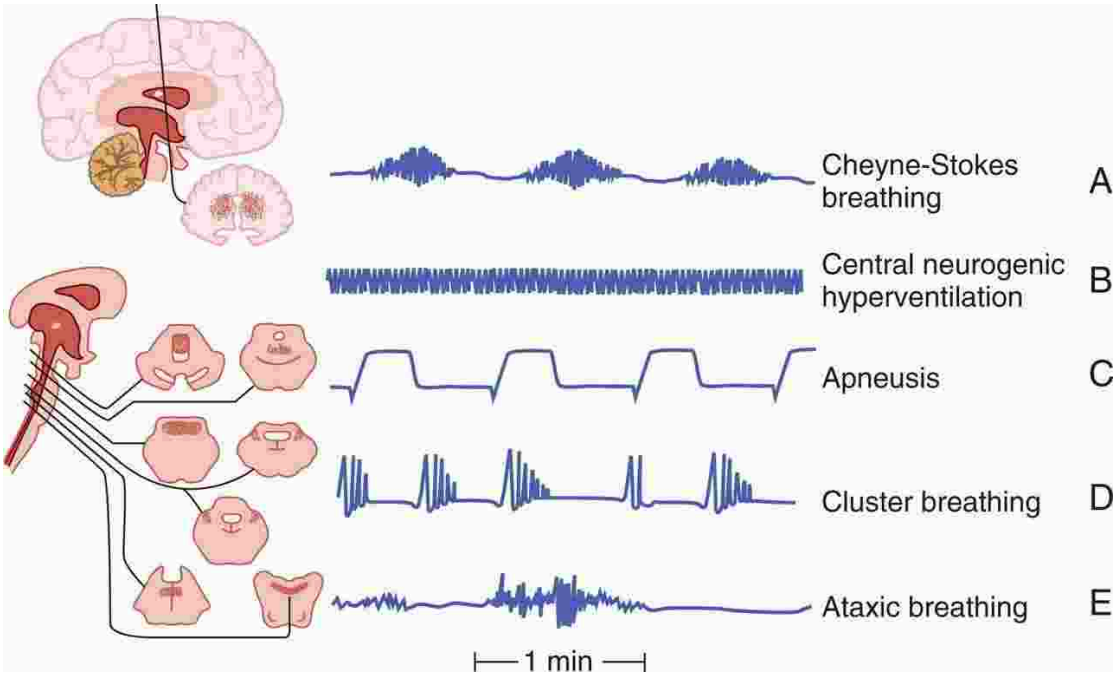

FIG. 17.1 Abnormal Respiratory Patterns With Corresponding Level of Central Nervous System Injuries.
(A) Cheyne-Stokes respiration is seen with metabolic injury and lesions in the forebrain and diencephalon. **(B)** Central neurogenic hyperventilation is most commonly seen with metabolic encephalopathies (lesion of midbrain, pons, or medulla). **(C)** Apneustic breathing (inspiratory pauses) is seen in persons with bilateral pontine lesions. **(D)** Cluster **(Biots)** breathing and ataxic breathing are seen in lesions at the pontine medullary junction. **(E)** Ataxic breathing occurs when the medullary ventral respiratory nuclei are injured. (From Urden LD, et al. *Critical care nursing: Diagnosis and management*, 6th edition. St. Louis: Mosby; 2010.)

An illustration depicts the abnormal respiratory patterns associated with pathologic lesions at various levels of the brain. Tracings by chest-abdomen pneumograph, inspiration reads up. A; Cheyne-stokes respiration. B; Central neurogenic hyperventilation. C; Apneusis. D; Cluster breathing. E; Ataxic breathing.

With normal breathing, a neural center in the forebrain (cerebrum) produces a rhythmic breathing pattern. When consciousness decreases, lower brainstem centers regulate the breathing pattern by responding only to changes in $PaCO_2$ levels. This pattern is called ***posthyperventilation apnea (PHVA)***.

Cheyne-Stokes respiration is an abnormal rhythm of ventilation (periodic breathing) with alternating periods of hyperventilation and apnea (crescendo-decrescendo pattern). In the damaged brain, higher levels of $PaCO_2$ are required to stimulate ventilation, and increases in $PaCO_2$ lead to tachypnea. The $PaCO_2$ level then decreases to below normal and breathing stops (apnea) until the carbon dioxide reaccumulates and again stimulates tachypnea (see Fig. 17.1). In cases of opiate or sedative drug overdose, the respiratory center is depressed, and the rate of breathing gradually decreases until respiratory failure occurs.

Central neurogenic hyperventilation is a respiratory pattern of sustained hyperventilation caused by a lesion that stimulates the respiratory center in the central pons. **Apneustic respirations** have prolonged inspiratory phase and a short expiratory phase caused by injury to the pons or upper medulla. ***Cluster***

(Biots) respirations are characterized by periods or clusters of rapid respirations of near equal depth resulting from trauma or compression to the medulla near the pontine junction or from chronic opioid abuse. ***Ataxic respirations*** are variable respirations with irregular prolonged periods of apnea associated with damage to the medulla (see Fig. 17.1).

Pupillary changes indicate the presence and level of brainstem dysfunction because brainstem areas that control arousal are adjacent to areas that control the pupils (Fig. 17.2). For example, severe ischemia and hypoxia usually produce dilated, fixed pupils. Hypothermia may cause fixed pupils. Some drugs affect pupils and must be considered in evaluating individuals in comatose states. Large doses of atropine and scopolamine (drugs that block parasympathetic stimulation) fully dilate and fix pupils. Doses of sedatives (e.g., glutethimide) in sufficient amounts to produce coma cause the pupils to become mid-position or moderately dilated, unequal, and commonly fixed to light. Opiates (which stimulate the parasympathetic nervous system) cause pinpoint pupils.

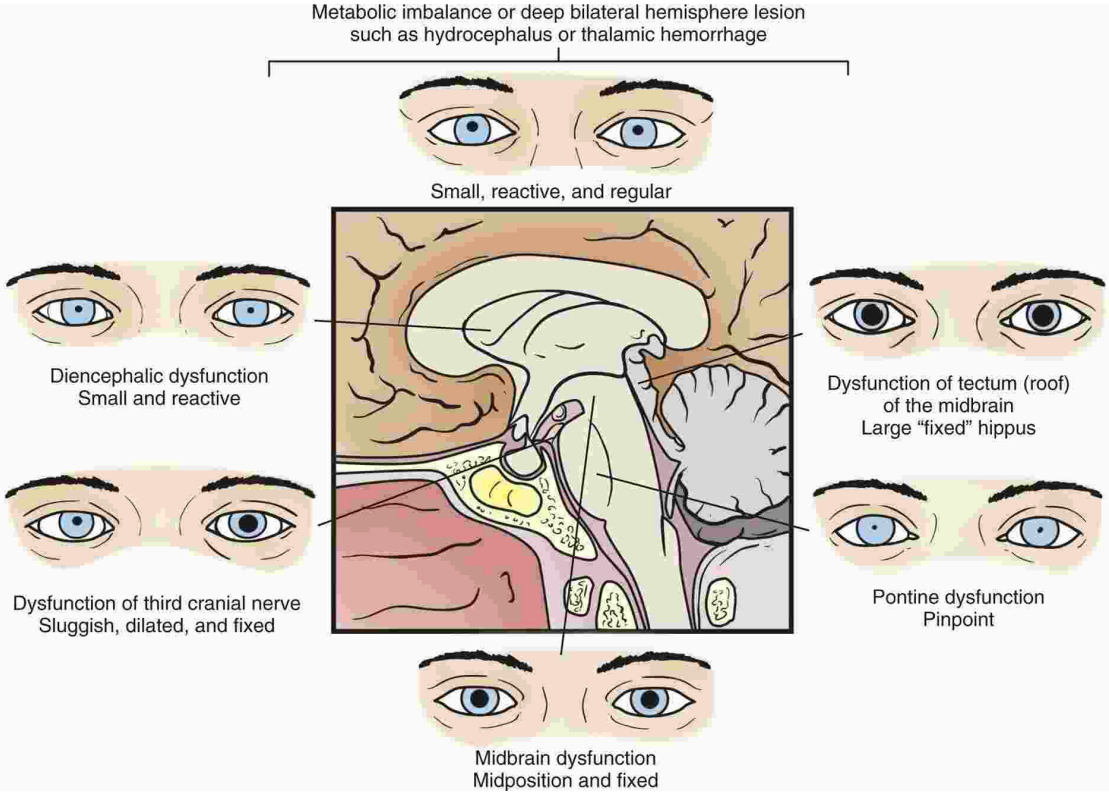

FIG. 17.2 Appearance of Pupils at Different Levels of Consciousness.

A series of illustrations shows the appearance of pupils at different levels of consciousness with reference to the brain stem. The six appearances are as follows. • Metabolic imbalance or deep bilateral hemisphere lesion such as hydrocephalus or thalamic hemorrhage. The pupils are small, receptive, and regular. • Dysfunction of tectum (roof) of the midbrain; large, fixed hippus. • Pontine dysfunction; pinpoint. • Midbrain dysfunctional; midposition and fixed. • Dysfunction of third cranial nerve sluggish, dilated, and fixed. • Diencephalic dysfunction; small and reactive.

Oculomotor responses are resting, spontaneous, and reflexive eye movements. They change at various levels of brain dysfunction in comatose individuals (Table 17.5). Persons with metabolically induced coma, except in cases of barbiturate-hypnotic and phenytoin (Dilantin) poisoning, generally retain ocular reflexes, even when other signs of brainstem damage, such as central neurogenic hyperventilation, are present.

Table 17.5

Changes in Oculomotor Responses

State	Resting and Spontaneous Eye Movements	Reflexive Eye Movements
Full consciousness	Eyes at rest, still (cortical gaze centers inhibit spontaneous roving eye movements)	Eyes move as the head turns Oculocephalic responses not elicited or inconsistently elicited (frontal gaze centers inhibit brainstem reflexes that fix gaze straight ahead) Oculovestibular (caloric) stimulation produces nystagmus
Cortical dysfunction or disruption of efferent pathways	Conjugate, horizontal, roving eye movements may well be present (cortical gaze centers no longer inhibit these brainstem-generated roving eye movements)	Gaze fixed straight ahead regardless of head position—positive doll's eyes reaction (normal oculocephalic reflexes are no longer inhibited by frontal gaze centers)
Diffuse anoxic damage to cortex	"Ocular dipping"—slow, dysrhythmic downward movement followed by faster, upward movement	Nystagmus is no longer induced by caloric stimulation (normally, a cold-water stimulus produces deviation of the eyes opposite the irrigated ear; a warm-water stimulus deviates the eyes to the same [ipsilateral] side) With an injury that depresses cortical gaze center function, the eyes (and often the entire head) deviate or appear to look toward the side of the injured hemisphere With an injury that irritates (stimulates) the neurons of the cortical gaze center, the eyes (and often the entire head) deviate away from the injured hemisphere (all fibers from the frontal gaze centers decussate and therefore control the function of the contralateral pontine gaze center, which moves the eyes in the ipsilateral direction)
Mesencephalon dysfunction	Roving eye movements cease, and the eyes become immobile and directed ahead (roving eye movements require an intact brainstem)	Oculovestibular reflexes become inconsistent and abnormal Loss of Bell phenomenon (upward deviation of eyes on stimulation) (requires intact eye

State	Resting and Spontaneous Eye Movements	Reflexive Eye Movements
	Eyes may turn down and inward	movement pathways from the mesencephalon to pons)
Pontine dysfunction	Loss of spontaneous blinking (requires an intact pons) "Ocular bobbing"—brisk, conjugate, downward movement of eyes with loss of horizontal eye movements	

State	Resting and Spontaneous Eye Movements	Reflexive Eye Movements
Full consciousness	Eyes at rest, still (cortical gaze centers inhibit spontaneous roving eye movements)	Eyes move as the head turns Oculocephalic responses not elicited or inconsistently elicited (frontal gaze centers inhibit brainstem reflexes that fix gaze straight ahead) Oculovestibular (caloric) stimulation produces nystagmus
Cortical dysfunction or disruption of efferent pathways	Conjugate, horizontal, roving eye movements may well be present (cortical gaze centers no longer inhibit these brainstem-generated roving eye movements)	Gaze fixed straight ahead regardless of head position—positive doll's eyes reaction (normal oculocephalic reflexes are no longer inhibited by frontal gaze centers)
Diffuse anoxic damage to cortex	"Ocular dipping"—slow, dysrhythmic downward movement followed by faster, upward movement	Nystagmus is no longer induced by caloric stimulation (normally, a cold-water stimulus produces deviation of the eyes opposite the irrigated ear; a warm-water stimulus deviates the eyes to the same [ipsilateral] side) With an injury that depresses cortical gaze center function, the eyes (and often the entire head) deviate or appear to look toward the side of the injured hemisphere With an injury that irritates (stimulates) the neurons of the cortical gaze center, the eyes (and often the entire head) deviate away from the injured hemisphere (all fibers from the frontal gaze centers decussate and therefore control the function of the contralateral pontine gaze center, which moves the eyes in the ipsilateral direction)
Mesencephalon dysfunction	Roving eye movements cease, and the eyes become immobile and directed ahead (roving eye movements require an intact brainstem) Eyes may turn down and inward	Oculovestibular reflexes become inconsistent and abnormal Loss of Bell phenomenon (upward deviation of eyes on stimulation) (requires intact eye movement pathways from the mesencephalon to pons)
Pontine dysfunction	Loss of spontaneous blinking (requires an intact pons) "Ocular bobbing"—brisk, conjugate, downward movement of eyes with loss of horizontal eye movements	

The presence of brisk oculocephalic reflexes and roving eye movements, as well as the failure to elicit nystagmus with instillation of cold or warm water into the external ear canal, indicates a decrease in consciousness (loss of cortical influence) but an intact brainstem (Figs. 17.3 and 17.4).

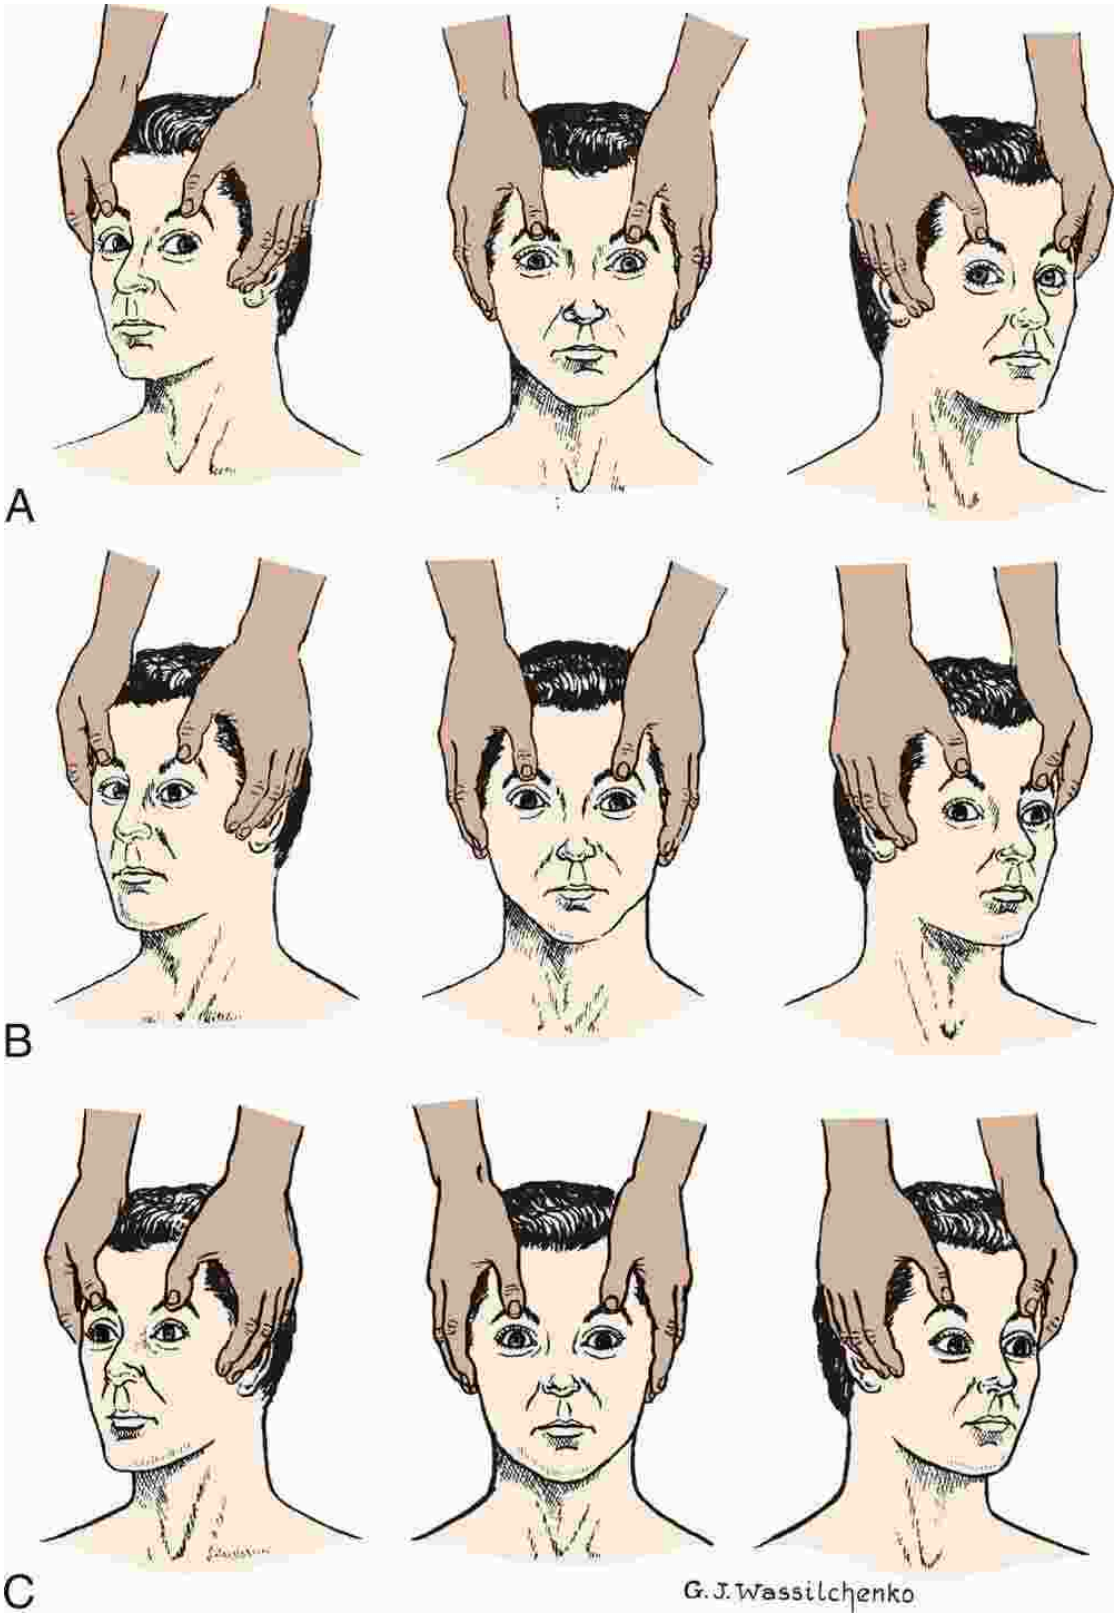

FIG. 17.3 Test for Oculocephalic Reflex Response (Doll's Eyes Phenomenon) **(A)** Normal response—eyes turn together to side opposite from turn of head. **(B)** Abnormal response—eyes do not turn in conjugate manner. **(C)** Absent response—

eyes do not turn as head position changes. (A and C, From Rudy EB. *Advanced neurological and neurosurgical nursing*. St. Louis: Mosby; 1984.)

Three sets of illustrations demonstrate the test for oculocephalic reflect response. Each set shows a pair of hands positioned on the sides of a person's face with the thumbs pulling upward on the eyebrows. In each set, the illustration on the left shows the head turned to the right, the illustration in the middle shows the head facing forward, and the illustration on the right shows the head turned toward the left. Top panel, A. The positions of the pupils are as follows. On the left, the pupils look to the left together. In the middle, the pupils look straight ahead together. On the right, the pupils look to the right together. Middle panel, B. The positions of the pupils are as follows. On the left, the pupils are converged toward the nose. In the middle, the pupils look straight ahead together. On the right, the right pupil looks to the right, while the pupil on the left look straight ahead. Bottom panel, C. The positions of the pupils are as follows. On the left, in the middle, and on the right, the pupils look absently straight ahead.

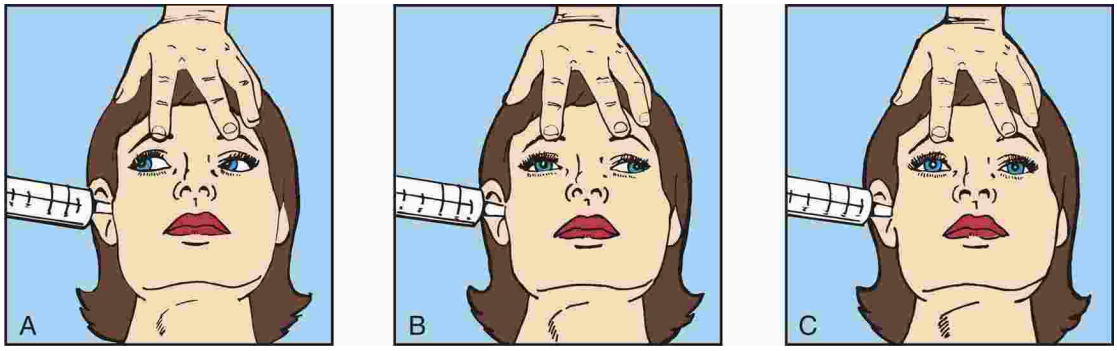

FIG. 17.4 Test for Oculovestibular Reflex (Caloric Ice-Water Test). **(A)** Normal response—conjugate eye movements. **(B)** Abnormal response—dysconjugate or asymmetric eye movements. **(C)** Absent response—no eye movements.

Three illustrations, A, B, and C, demonstrate the test of oculovestibular reflex. Each illustration shows a person's head in supine position, a hand pressing down on the head, and a syringe pressed into the right ear. Left panel, A. The pupils look together on the right, toward the syringe. Middle panel, B. The right pupil looks straight ahead, while the left pupil looks to the right. Right panel, C. Both pupils look straight ahead together.

Destructive or compressive injury to the brainstem causes specific abnormalities of the oculocephalic and oculovestibular reflexes. For example, a skewed deviation, in which one eye diverges downward and the other looks upward, indicates brainstem dysfunction. Destructive or compressive disease

processes that involve an oculomotor nucleus or nerve cause the involved eye to deviate outward, producing a resting dysconjugate lateral position of the eyes (each eye diverges laterally). Unilateral abducens paralysis (paralysis of cranial nerve VI) results in an upward deviation of the ipsilateral eye. With bilateral abducens paralysis, the eyes come together (converge). Reflexive eye movements may be suppressed by drugs, most commonly phenytoin, tricyclics, and barbiturates. Occasionally alcohol, phenothiazines, and diazepam may alter reflex eye movements.

Assessment of **motor responses** helps to evaluate the level of brain dysfunction and determine the side of the brain that is maximally damaged. The pattern of response noted may be (1) purposeful (a defensive or withdrawal movement of limbs to noxious stimuli); (2) inappropriate, or not purposeful (generalized motor movement, posturing, grimacing, or groaning); or (3) not present (unresponsive, no motor response). Purposeful movement requires an intact corticospinal system. Nonpurposeful movement is evidence of severe dysfunction of the corticospinal system.

Motor signs indicating loss of cortical inhibition are commonly associated with decreased consciousness and include primitive reflexes and rigidity (paratonia). Primitive reflexes include grasping, reflex sucking (tapping on lips stimulates sucking), snout reflex (tapping of closed lips at midlines causes pursing of lips), and palmomental reflex (stroking palm causes twitch of chin muscle), all of which are normal in the newborn but disappear in infancy (Fig. 17.5). Abnormal flexor and extensor responses in the upper and lower extremities are defined in Table 17.6 and illustrated in Fig. 17.6.

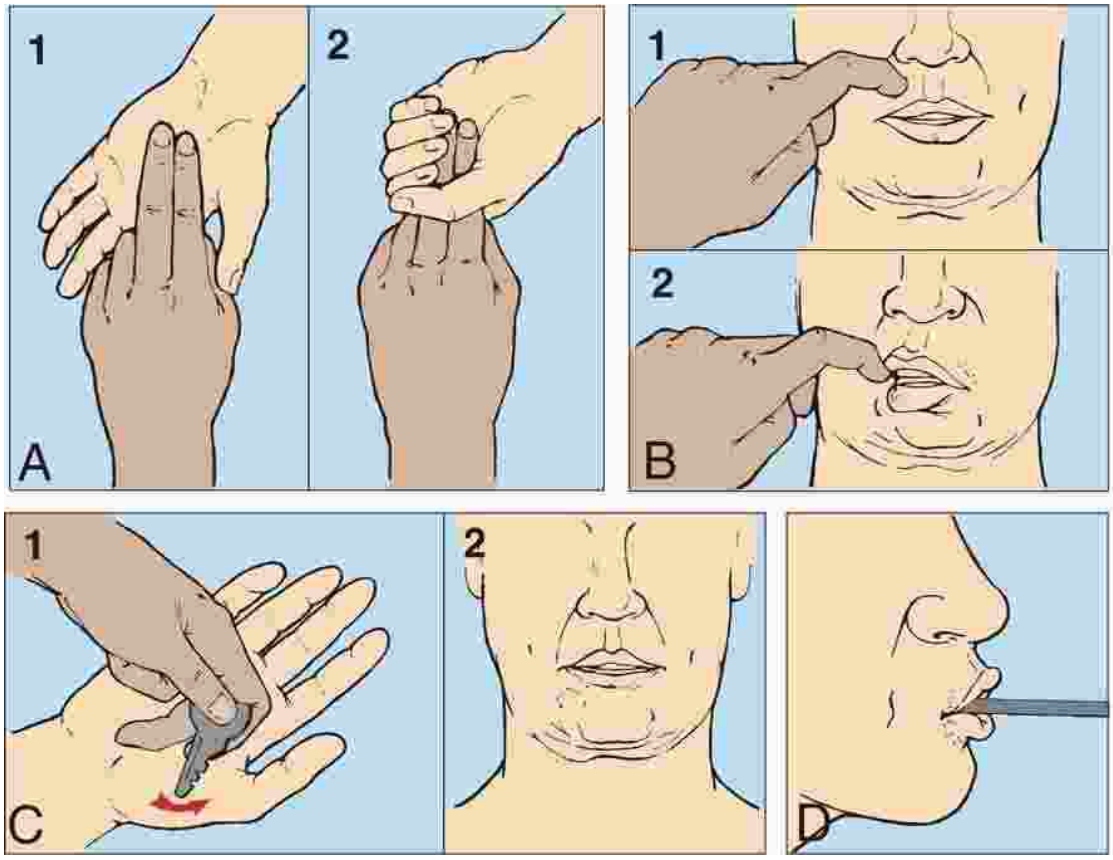

FIG. 17.5 Pathologic Reflexes.
(A) Primitive reflexes include grasping. (A1) Absent grasp; (A2) Grasp present. **(B)** Reflex sucking (tapping on lips stimulates sucking). (B1) Absent reflex. (B2) Reflex present. **(C)** Palmomental reflex. (C1) Stroking palm causes (C2) twitch of chin muscle. **(D)** Snout reflex (tapping of closed lips at midlines causes pursing of lips). (D1) Absent reflex. (D2) Reflex present.

Four pairs of illustrations, A, B, C, and D, demonstrate pathologic reflexes. Top-left panel, A. The illustration on the left, 1, shows two hands. The index and the middle fingers of one hand are placed on the open palm of the other hand. The illustration on the right, 2, shows the palm closed around the two fingers on the other hand. Top-right panel, B. The illustration on the left, 1, shows an index finger pressing above the upper lip. The illustration on the right, 2, shows the lips turned toward the finger, sucking. Bottom-left panel, C. The illustration on the left, 1, shows a hand holding a key and stroking near the thumb of an open palm. The illustration on the right, 2, shows the twitching chin of a person. Bottom-right panel, D. The illustration shows the right lateral profile of the lower jaw of a person. The lips are pursed around a pencil-like object.

Table 17.6

Abnormal Motor Responses With Decreased Responsiveness

Motor Response	Description of Motor Responses	Location of Injury
Decorticate posturing/rigidity: upper extremity flexion, lower extremity extension (see Fig. 17.6)	Slowly developing flexion of the arm, wrist, and fingers with abduction in the upper extremity and extension, internal rotation, and plantar flexion of the lower extremity	Hemispheric damage above midbrain releasing medullary and pontine reticulospinal systems
Decerebrate posturing/rigidity: upper and lower extremity extensor responses (see Fig. 17.)	Opisthotonos (hyperextension of the vertebral column) with clenching of the teeth; extension, abduction, and hyperpronation of the arms; and extension of the lower extremities	Associated with severe damage involving midbrain or upper pons
	In acute brain injury, shivering and hyperpnea may accompany unelicited recurrent decerebrate spasms	Acute brain injury may cause limb extension regardless of location
Extensor responses in the upper extremities accompanied by flexion in the lower extremities		Pons
Flaccid state with little or no motor response to stimuli		Lower pons and upper medulla

Motor Response	Description of Motor Responses	Location of Injury
Decorticate posturing/rigidity: upper extremity flexion, lower extremity extension (see Fig. 17.6)	Slowly developing flexion of the arm, wrist, and fingers with abduction in the upper extremity and extension, internal rotation, and plantar flexion of the lower extremity	Hemispheric damage above midbrain releasing medullary and pontine reticulospinal systems
Decerebrate posturing/rigidity: upper and lower extremity extensor responses (see Fig. 17.)	Opisthotonos (hyperextension of the vertebral column) with clenching of the teeth; extension, abduction, and hyperpronation of the arms; and extension of the lower extremities	Associated with severe damage involving midbrain or upper pons
	In acute brain injury, shivering and hyperpnea may accompany unelicited recurrent decerebrate spasms	Acute brain injury may cause limb extension regardless of location
Extensor responses in the upper extremities accompanied by flexion in the lower extremities		Pons
Flaccid state with little or no motor response to stimuli		Lower pons and upper medulla

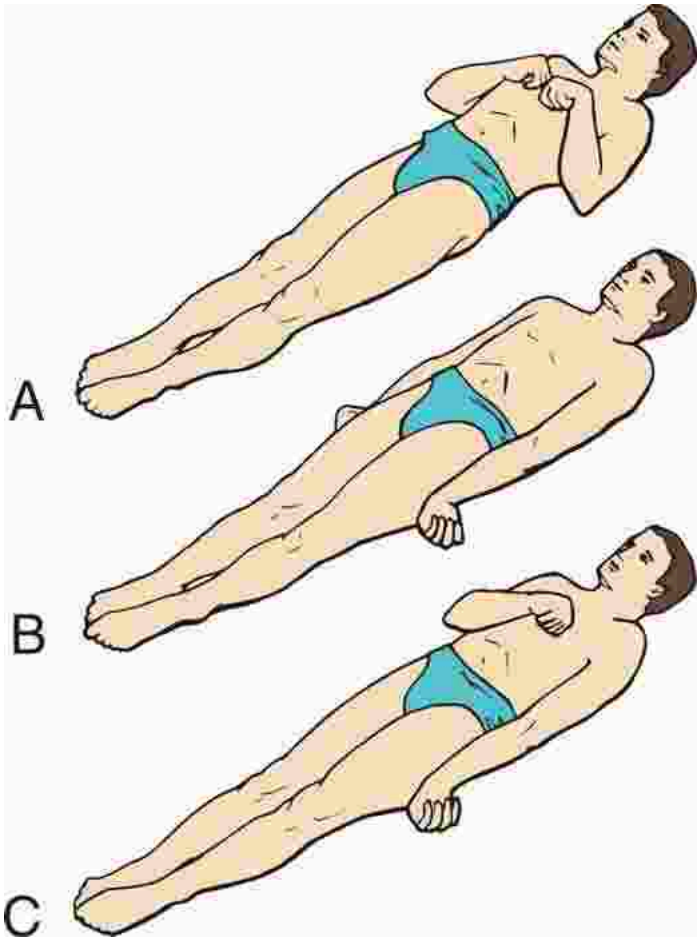

FIG. 17.6 Decorticate and Decerebrate Responses.
(A) *Decorticate response (flexor posturing):* bilateral flexion of elbows and wrists with shoulder adduction in upper extremities. Extension, internal rotation of lower extremities (lesions above the midbrain). **(B)** *Decerebrate response (extensor posturing):* all four extremities in rigid extension, internal rotation of shoulders with hyperpronation of forearms (midbrain lesions). **(C)** *Decorticate response on right side of body and decerebrate response on left side of body:* the most pronounced response differences are in the upper body. (From Rudy EB. *Advanced neurological and neurosurgical nursing*. St. Louis: Mosby; 1984.)

Three illustrations of a person in supine position demonstrate the decorticate and decerebrate responses. Top panel, A. The illustration shows the person's arms flexed with the hands together on the chest. The feet are pointed forward. Middle panel, B. The illustration shows the person's arms on their sides, the hands flexed outward, and the feet pointing forward. Bottom panel, C. The illustration shows one arm of the person on the side, the other arm flexed with the wrist on the chest, and the feet pointing forward.

Vomiting, yawning, and **hiccups** are complex reflex-like motor responses that are integrated by neural mechanisms in the lower brainstem. These responses may be produced by compression or diseases involving tissues of the medulla oblongata (e.g., infection, neoplasm, infarct, or other more

benign stimuli to the vagal nerve). Most CNS disorders produce nausea and vomiting. Vomiting without nausea indicates direct involvement of the central neural mechanism (or pyloric obstruction). Vomiting often accompanies CNS injuries that (1) involve the vestibular nuclei or its immediate projections, particularly when double vision (diplopia) also is present; (2) impinge directly on the floor of the fourth ventricle; or (3) produce brainstem compression secondary to **increased intracranial pressure** (**IICP**).

Complications of Alterations in Arousal

Complications of alterations in arousal fall into two categories: *extent of disability (morbidity)* and *mortality*. The outcomes depend on the cause and extent of brain damage and the duration of coma. Some individuals may recover consciousness and an original level of function, some may have permanent disability, and some may never regain consciousness and experience neurologic death. Two forms of neurologic death—brain death and cerebral death—result from severe pathologic conditions and are associated with irreversible coma. Other possible outcomes are a **vegetative state** (**VS**), a **minimally conscious state** (**MCS**), or locked-in syndrome. The extent of disability has four subcategories: recovery of consciousness, residual cognitive function, psychologic function, and vocational function. Technological advances in imaging, including functional magnetic resonance imaging (MRI) and positron emission tomography (PET), have provided new opportunities for assessing cognition and detecting consciousness for individuals in a prolonged coma.[3]

Brain death (total brain death) occurs when brain damage is so extensive that it can never recover (irreversible) and cannot maintain the body's internal homeostasis. State laws define brain death as irreversible cessation of function of the entire brain, including the brainstem and cerebellum. On postmortem examination, the brain is autolyzing (self-digesting) or already autolyzed. Brain death has occurred when there is no evidence of brain function for an extended period.[4] The abnormality of brain function must result from structural or known metabolic disease and must *not* be caused by a depressant drug, alcohol poisoning, or hypothermia. An isoelectric, or flat, electroencephalogram (EEG) (electrocerebral silence) for 6 to 12 hours in a person who is not hypothermic and has not ingested depressant drugs indicates brain death. The clinical criteria used to determine brain death are noted in Box 17.1. A task force for determination of brain death in children recommended the same criteria as for adults but with a longer observation period.[5,6]

Box 17.1

Criteria for Brain Death

1. Completion of all appropriate diagnostic and therapeutic procedures with no possibility of brain function recovery
2. Unresponsive coma (no motor or reflex movements)
3. No spontaneous respiration (apnea)
4. No brainstem functions (ocular responses to head turning or caloric stimulation; dilated, fixed pupils; no gag or corneal reflex [see Figs. 17.3 and 17.4])
5. Isoelectric (flat) EEG (electrocerebral silence)
6. Persistence of these signs for an appropriate observation period

EEG, Electroencephalogram.

Summarized from Wijdicks EF, Varelas PN, Gronseth GS, et al. Evidence-based guideline update: Determining brain death in adults: Report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*, 2010;74(23):1911–1918

Cerebral death or **irreversible coma** is death of the cerebral hemispheres exclusive of the brainstem and cerebellum. Brain damage is permanent, and the individual is unable to ever respond behaviorally in any significant way to the environment. The brainstem may continue to maintain internal

homeostasis (i.e., body temperature, cardiovascular functions, respirations, and metabolic functions). The survivor of cerebral death may remain in a coma or emerge into a persistent VS or a MCS. In coma, the eyes are usually closed with no eye opening. The person does not follow commands, speak, or have voluntary movement (Table 17.7).

Table 17.7

Comparative Clinical Features of Alterations in Levels of Arousal

Diagnosis	Arousal	Awareness	Communication
Coma	Eyes do not open spontaneously or in response to stimulation	No evidence of perception, communication ability, only reflexes and postural responses	None
Persistent vegetative state	Eyes open spontaneously; no visual tracking; sleep-wake cycle resumes or state of chronic wakefulness; arousal often sluggish	No evidence of cognitive function or purposeful motor activity	None
Akinetic mutism	Eyes open spontaneously; normal sleep-wake cycle; arousal level is normal	Visual tracking present; little or no following of commands	Little or no volitional speech or movement
Minimally conscious state	Eyes open spontaneously; normal to abnormal sleep-wake cycle; arousal level ranges from obtunded to normal	Inconsistent evidence of perception, communication ability, or purposeful motor activity; visual tracking often intact	Inconsistent verbalization and gesturing
Locked-in syndrome	Full arousal; sleep-wake cycle present; quadriplegic	Perceptions and emotions intact	Cannot speak or move muscles except vertical eye movement and blinking

Diagnosis	Arousal	Awareness	Communication
Coma	Eyes do not open spontaneously or in response to stimulation	No evidence of perception, communication ability, only reflexes and postural responses	None
Persistent vegetative state	Eyes open spontaneously; no visual tracking; sleep-wake cycle resumes or state of chronic wakefulness; arousal often sluggish	No evidence of cognitive function or purposeful motor activity	None
Akinetic mutism	Eyes open spontaneously; normal sleep-wake cycle; arousal level is normal	Visual tracking present; little or no following of commands	Little or no volitional speech or movement
Minimally conscious state	Eyes open spontaneously; normal to abnormal sleep-wake cycle; arousal level ranges from obtunded to normal	Inconsistent evidence of perception, communication ability, or purposeful motor activity; visual tracking often intact	Inconsistent verbalization and gesturing
Locked-in syndrome	Full arousal; sleep-wake cycle present; quadriplegic	Perceptions and emotions intact	Cannot speak or move muscles except vertical eye movement and blinking

Data from Giacino JT, Ashwal S, Childs N, et al. The minimally conscious state: Definition and diagnostic criteria. *Neurology*, 2002;58(3):349–353; Owen AM. Disorders of consciousness. *Annals of the New York Academy of Sciences*, 2008;1125:225–238.

A **persistent VS**, or **unresponsive wakefulness syndrome**, is complete unawareness of the self or surrounding environment and complete loss of cognitive function. The individual does not speak any comprehensible words or follow commands.[7] Sleep-wake cycles are present, eyes open spontaneously, and blood pressure and breathing are maintained without support. Brainstem reflexes (pupillary, oculocephalic, chewing, swallowing) are intact but cerebral function is lost. There may be random hand, extremity, or head movements. There is bowel and bladder incontinence. Recovery is unlikely if the state persists for 12 months.

In a MCS, individuals may follow simple commands; manipulate objects; gesture or give yes/no responses; have intelligible speech; and have movements, such as blinking or smiling, that occur in a meaningful relationship to the eliciting stimulus and are not attributable to reflexive activity.[8]

With **locked-in syndrome (ventral pontine syndrome)**, there is complete paralysis of voluntary muscles apart from vertical gaze and upper eyelid movement. Content of thought and level of arousal are intact, but the efferent pathways are disrupted (injury at the base of the pons with the reticular formation intact, often caused by basilar artery occlusion).[9] The individual cannot communicate either through speech or through body movement but is fully conscious with intact cognitive function. The upper cranial nerves (I to IV) often are preserved so that the person possesses vertical eye movement and blinking as a means of communication.

Akinetic mutism (AM) is a rare neurobehavioral state characterized by a severe loss of motivation to move or inability to voluntarily initiate goal-directed motor responses (akinetic), including speech (mutism), gestures, and facial expression. Generally, these individuals are alert, orient to external stimuli, and can follow the examiner with their eyes but do not initiate other voluntary activity or movement. This is not attributable to decreased wakefulness, motor weakness, or paralysis but rather a lack of "willfulness" to do so. The neuropathology is different when compared with the VS and locked-in syndrome and involves damage to frontal-subcortical structures involved in the translation of a motivational stimulus to a behavioral response. It may occur with cerebrovascular disease, obstructive hydrocephalus, or be associated with tumors. Combined deficits of vigilance, detection, and working memory accompanied by other deficits of the cognitive systems are common.[10]

Alterations in Awareness

Awareness (content of thought) encompasses all cognitive functions, including awareness of self, environment, affective states (i.e., moods), and memory. Awareness is mediated by all the core networks under the guidance of executive attention networks, including selective attention and memory. Executive attention networks involve abstract reasoning, planning, decision making, judgment, error correction, and self-control. Each attentional function is a network of interconnected brain circuits and not localized to a single brain area.

Selective attention (orienting) refers to the ability to select specific information to be processed from available, competing environmental and internal stimuli and to focus on that stimulus (i.e., to concentrate on a specific task without being distracted) to guide behavior. *Selective visual (spatial) attention* is the ability to select objects/events from multiple visual stimuli (location and movement in visual space) and process them to complete a task. *Selective auditory* or *hearing attention* is the ability to select or filter specific sounds and process them to complete a task. Multiple areas of the brain are involved in selective attention, including cortical areas, thalamic nuclei, and the limbic system. Frontal and parietal regions of the right hemisphere contribute to selective attention. The engagement component (identifying the target of attention) is mediated by the pulvinar nucleus of the thalamus and regulates cortical synchrony (Fig. 17.7).[11] The disengagement mechanism (shifting attention to a new target and re-engaging on the new target) is mediated by the right parietal lobe. The motor consequences of attention are mediated by the superior colliculus for visual orienting and spatial attention.[12]

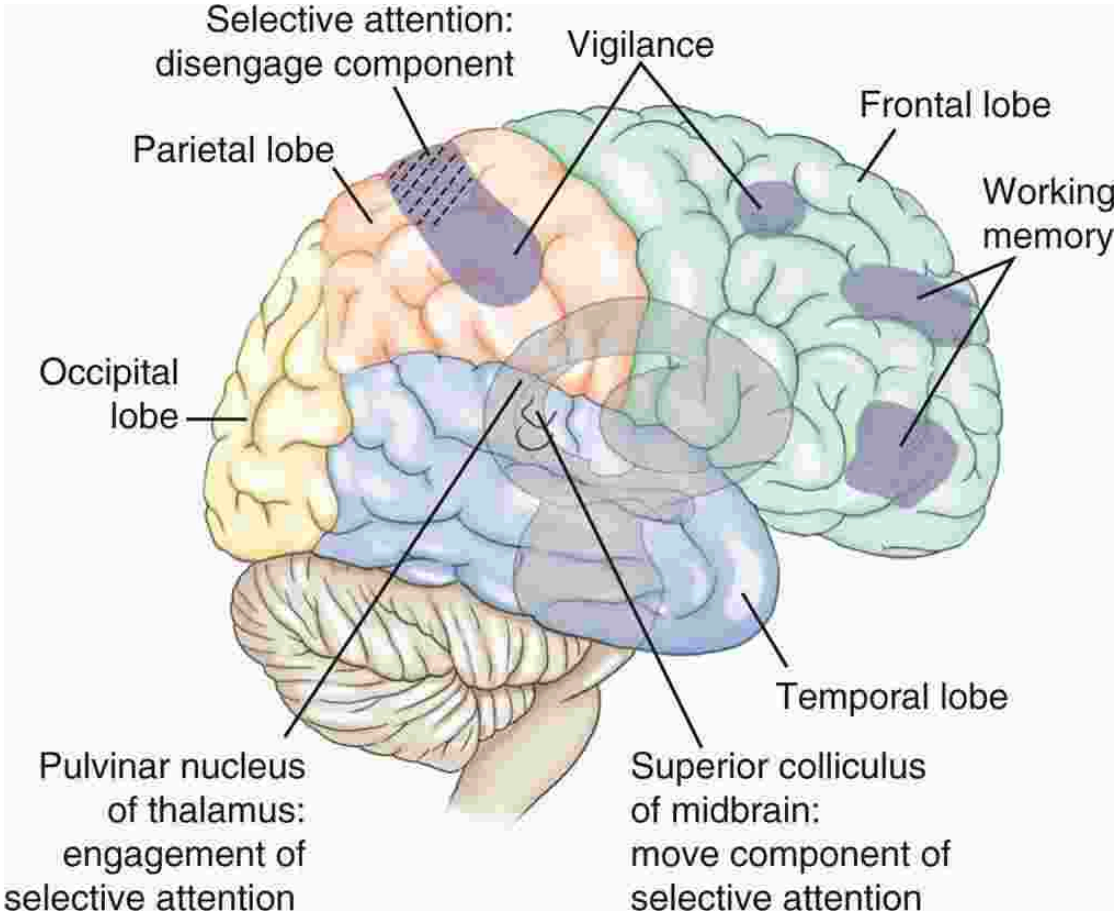

FIG. 17.7 Right cortical, subcortical, and brainstem areas of the brain—mediating cognitive functions. (From Boss BJ, Wilkerson R. Communication: Language and pragmatics. In: Hoeman SP, ed. *Rehabilitation nursing: Prevention, intervention, & outcomes*, 4th ed. St. Louis: Mosby; 2008:508.)

An illustration of the right lateral view of the brain shows and labels the following structures, clockwise from the top: vigilance, frontal lobe, working memory, temporal lobe, superior colliculus of midbrain (move component of selective attention), pulvinar nucleus of thalamus (engagement of selective attention), occipital lobe, parietal lobe, and selective attention (disengage component).

Selective attention deficits can be temporary, permanent, or progressive. Disorders associated with selective attention deficits include seizure activity, parietal lobe contusions, subdural hematomas, stroke, gliomas or metastatic tumor, late Alzheimer dementia, frontotemporal dementia (FTD), and psychotic disorders. Disorders of selective attention related to visual orienting behavior are produced by disease that involves portions of the midbrain. Disease affecting the superior colliculi manifests as a slowness in orienting attention. Parietal lobe disease may produce *unilateral neglect syndrome*, which is failure to report, respond, or orient to visual, auditory, or tactile stimuli that are presented contralateral to a brain lesion, provided this failure is not explained by primary sensory or motor disorders. For example, an individual with neglect following a right hemisphere lesion may fail to recognize a left limb, read from the left side of a book, ignore the food on the left side of the plate, remain unaware of

numerals on the left side of a clock, or have an abnormal rightward shift in head and eye position. The person can recognize individual sensory input from the ipsilateral side (the side with the hemispheric lesion) when asked but ignores (i.e., neglects, extinguishes) the sensory input from the contralateral side when stimulated from both sides. This phenomenon is called *extinction*.[13] The entire complex of sensory inattentiveness, loss of recognition of one's own body parts, and extinction, sometimes referred to as ***neglect syndrome***, is common after stroke, generally in the right hemisphere.[14]

Memory is the recording, retention, and retrieval of information. Two types of long-term memory exist: declarative and nondeclarative (Fig. 17.8).[168]

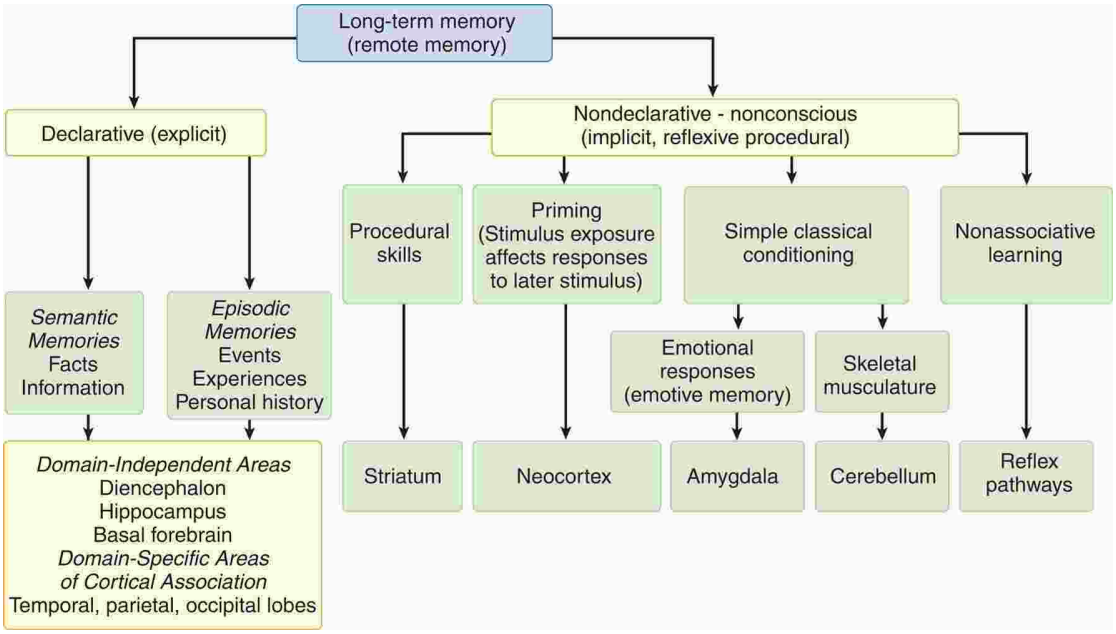

FIG. 17.8 Types of Memory and Associated Brain Systems (From Miller RD, et al. *Miller's anesthesia*, 7th edition. Philadelphia: Churchill Livingstone; 2010.)

A hierarchy diagram represents the types of memory and associated brain systems. Long-term memory (remote memory) is one of the following two types. • Declarative (explicit). • Nondeclarative - nonconscious (implicit, reflexive procedural). Declarative (explicit) memory stores the following two types of data. • Semantic, memories, facts, information. • Episodic, memories, events, experiences, personal history. The brain systems associated with both types of data are as follows: domain-independent areas, diencephalon, hippocampus, basal forebrain, domain-specific areas of cortical association, and temporal, parietal, and occipital lobes. Nondeclarative - nonconscious (implicit, reflexive procedural) memory stores the following types of data. • Procedural skills (associated with striatum). • Priming (stimulus exposure affects responses to later stimulus) (associated with neocortex). • Simple classical conditioning (emotional responses or emotive memory; skeletal musculature). • Nonassociative learning (associated with reflex pathways). Emotional responses are associated with the amygdala. Skeletal musculature is associated with cerebellum.

Declarative memory (conscious or explicit) involves the learning and remembrance of *episodic memories* (personal history and the where, what, and when of events and experiences) and *semantic memories* (facts and information). Declarative memory is mediated by domain-specific cortical areas of the association areas. This includes (1) areas of the temporal, parietal, and occipital lobes (Fig. 17.9), where long-term memories are thought to be stored; and (2) domain-independent areas of the medial temporal lobe (e.g., hippocampus), the diencephalon (thalamic structures and hypothalamus), and the basal forebrain (located ventral to the striatum and produces acetylcholine) (Fig. 17.10), where it is thought distinct, domain-specific features of an experience are related or bound.[168]

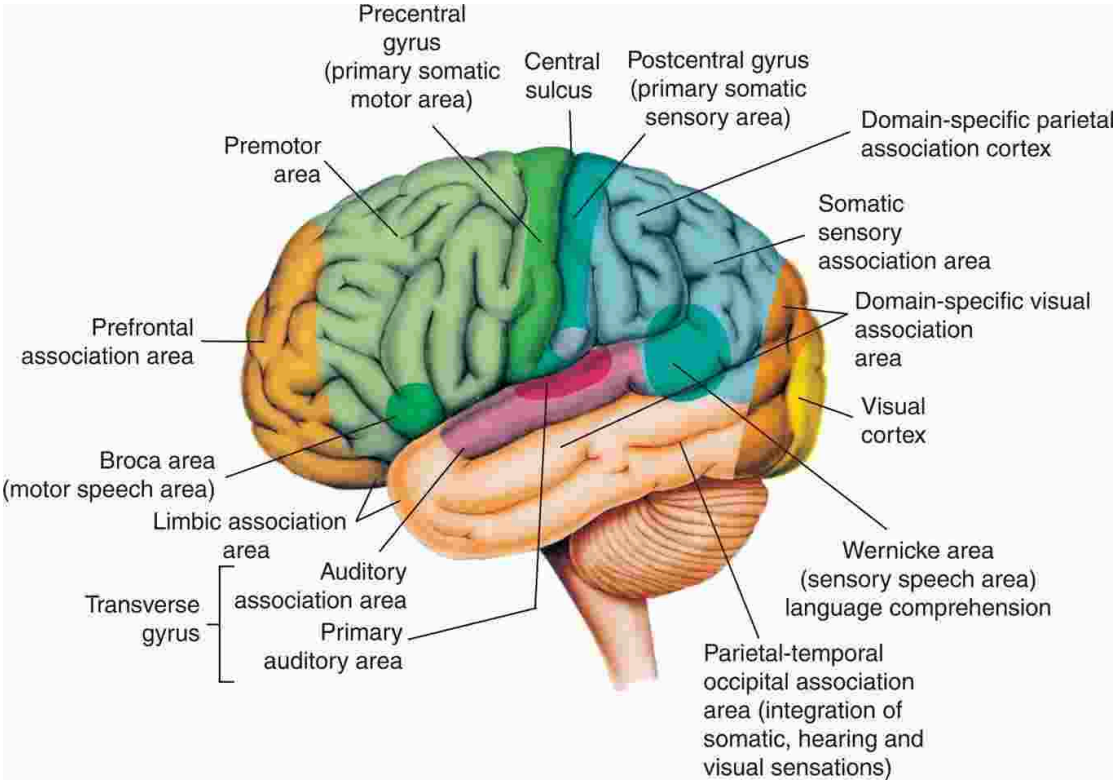

FIG. 17.9 Cortical Areas of the Left (Dominant) Hemisphere. (Adapted from Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Elsevier; 2018.)

An illustration of the left lateral view of the brain highlights the cortical areas of the left (dominant) hemisphere. The followings structures on the brain are labels, from the forebrain to the hindbrain: Broca area (motor speech area), prefrontal association area, premotor area, precentral gyrus (primary somatic motor area), central sulcus, postcentral gyrus (primary somatic sensory area), domain-specific parietal association cortex, somatic sensory association area, domain-specific visual association area, visual cortex, Wernicke area (sensory speech area) language comprehension, parietal-temporal occipital association area (integration of somatic, hearing, and visual sensations), transverse gyrus (auditory association area, primary auditory area), and limbic association area.

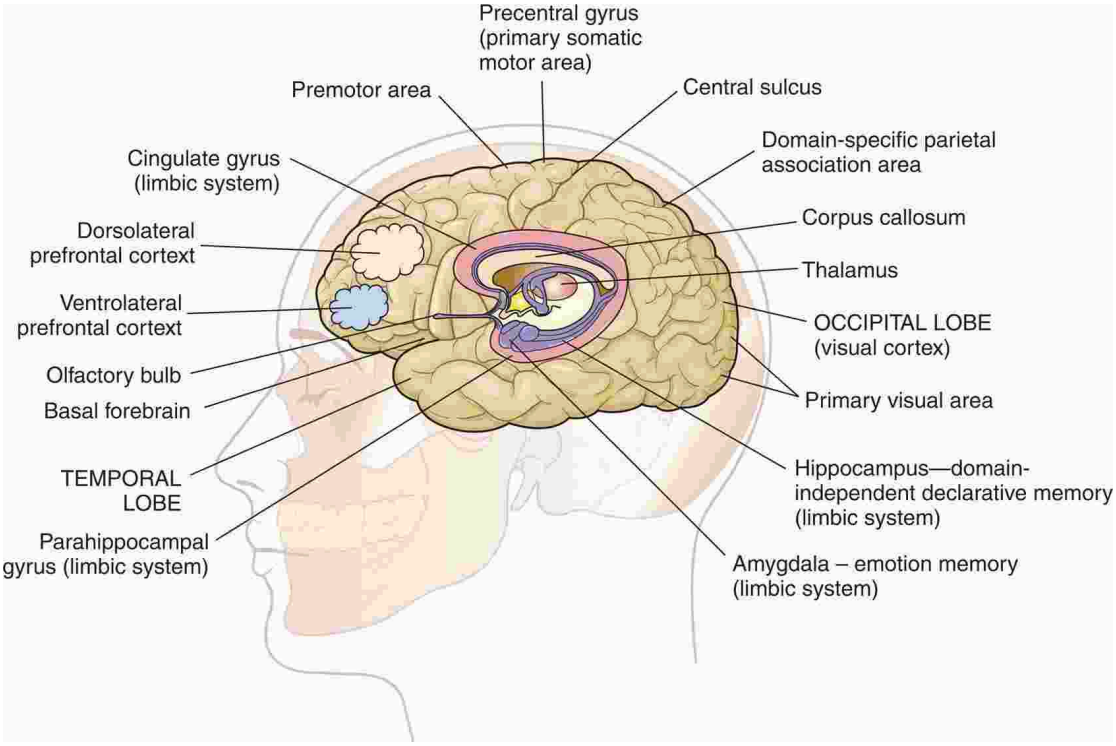

FIG. 17.10 **Midline Cortical and Deep Areas of the Cerebral Hemisphere.**

An illustration of the left lateral view of the brain in a person's head shows and labels the following structures, from the forebrain to the hindbrain: olfactory bulb, ventrolateral prefrontal cortex, dorsolateral prefrontal cortex, cingulate gyrus (limbic system), premotor area, precentral gyrus (primary somatic motor area), central sulcus, domain-specific parietal association area, corpus callosum, thalamus, occipital lobe (visual cortex), primary visual area, hippocampus-domain-independent declarative memory (limbic system), amygdala - emotion memory (limbic system), parahippocampal gyrus (limbic system), and temporal lobe.

Nondeclarative memory (nonconscious), also called *reflexive, procedural, or implicit memory*, is the memory for actions, behaviors (habits), skills, and outcomes.[168] It is not a language memory but a motor memory. Nondeclarative memory involves the construction of the motor pattern so that the action, behavior, or skill becomes increasingly automatic. The striatum of the basal ganglia supports this learning across trials (stimulus-response learning), as well as probabilistic classification learning, which supports outcome prediction. All skills and habits are stored in this memory network.[15] *Cerebellar memory* is involved in working memory (short term memory), in addition to motor coordination and nonmotor functions of cognition, emotion, and learning.[16] *Emotional memory* is mediated by the amygdala (located on the inner surface of the temporal lobe) (see Fig. 17.10) and other neural networks. The amygdala attaches positive (e.g., pleasure) or negative (e.g., fear) dispositions to stimuli in the absence of conscious recollection of the circumstances of the emotional experience.[17]

Amnesia is the loss of memory and can be mild or severe. Two types of amnesia are retrograde amnesia and anterograde amnesia. The person experiencing retrograde amnesia has difficulty retrieving past personal history memories or past factual memories. In anterograde amnesia, new personal or

factual memories cannot be formed, but memories of the distant past are retained and retrieved. These are disorders of domain-independent declarative memory networks, and the hippocampus and other temporal lobe structures often are involved. These memory disorders may be temporary (e.g., after a seizure) or permanent (e.g., after severe head injury or in Alzheimer disease [AD]). There may be only the memory disorder, or the memory disorder may be associated with other cognitive disorders. Global amnesia is a combination of anterograde and retrograde amnesia and involves the hippocampus. *Transient global amnesia* has a sudden onset, lasts less than 24 hours, and occurs in the absence of other neurological signs or symptoms. The causal mechanisms are not clear, but it can be associated with migraine headache, vagal stimulation, and cerebrovascular ischemia.[18] *Permanent global amnesia* is rare and associated with damage to the hippocampus.[19] *Domain–specific declarative memory loss* can manifest as agnosias (agnosias are in the section on Data Processing Deficits).

Image processing is a higher level of memory function and includes the ability to use sensory data and language to form concepts, assign meaning, and make abstractions. Alterations in image processing include an inability to form concepts and generalizations or to reason. Thinking is very concrete. These memory disorders may be temporary (e.g., after a seizure or postconcussive states) or permanent (e.g., after severe head injury, severe stroke, or in AD). There may be only the memory disorder, or the memory disorder may be associated with other cognitive disorders.

The prefrontal areas mediate several cognitive functions, called *executive attention functions* (planning, problem solving, goal setting). The *vigilance system* provides the person with the ability to maintain a sustained state of alertness or concentration for searching and scanning activities and involves the right frontal areas and the locus ceruleus (LC) (located in the rostral pons) (see Fig. 17.7). Through the neurotransmitter norepinephrine from the LC, the speed of the orienting (selective attention) network is increased, and the detection function of the anterior cingulate gyrus (see Fig. 17.10) is decreased.

Detection is the recognition of the object's identity and the realization that the object fulfills a desired goal (e.g., target selection among competing, complex contingencies). There is conscious execution of an instruction, ensuring that the instructions are followed. The anterior cingulate cortex inhibits automatic responses so that a less routine response can be given. The basal ganglia and cingulate, as well as other frontal areas, function in color, motion, and form detection.

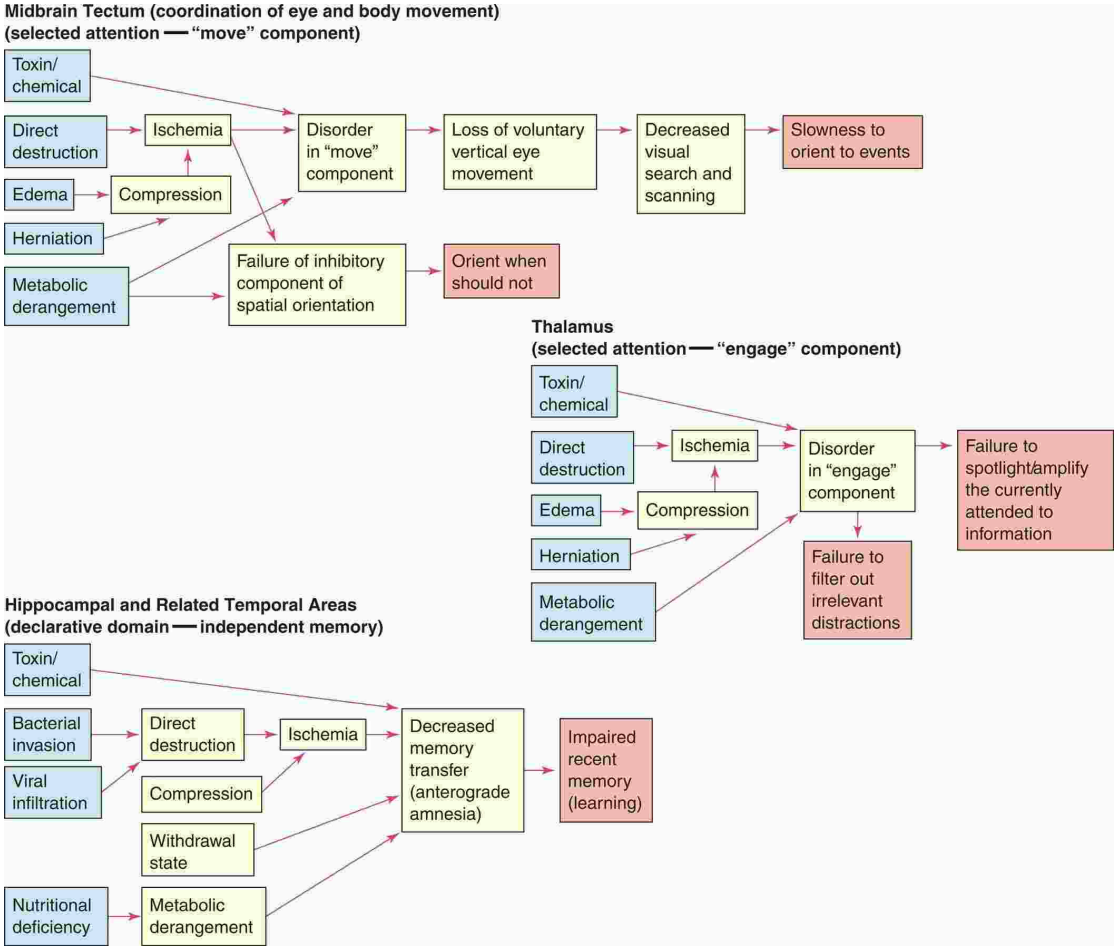
The anterior cingulate plus the ventrolateral and dorsolateral prefrontal cortex (see Fig. 17.10) are involved in the representations of information in the absence of a stimulus, such as spatial position of visual events in memory when the event is removed from view. Working memory (short-term or recent memory) gives the person control over information processing (see Fig. 17.7). These temporary storage areas permit the brain to maintain or discard a limited amount of information (e.g., to retrieve instructions, such as strings or patterns of words or colors) and other information (e.g., strings of digits) needed to maintain a current stream of thought, resist distraction, and perform an immediate task. When attention is diverted, long-term memory is required to complete the task.[168]

Isolated (pure) vigilance deficit, **detection deficit**, and **working memory deficits** are uncommon and involve focal lesions of the prefrontal cortex. Whether these losses are temporary or permanent depends on the cause and severity of injury.[20,21]

Executive attention deficits include the inability to maintain sustained attention and a working memory deficit. Sustained attention deficit is an inability to plan, set goals, and recognize when an object meets a goal. A working memory deficit is an inability to focus and remember instructions and information needed to guide behavior and complete a single task. Executive attention deficits may be temporary, progressive, or permanent.[22]

Pathophysiology

Very generally, the primary pathophysiologic mechanisms that operate in disorders of awareness are (1) direct destruction because of ischemia and hypoxia or indirect destruction because of compression and (2) the effects of toxins, inflammation, and chemicals, or metabolic derangement, including processes related to dementia. The pathophysiologic processes are summarized in Fig. 17.11.



Midbrain Tectum (coordination of eye and body movement)
(selected attention — "move" component)
Toxin/ chemical
Direct destruction
Ischemia
Disorder in "move" component
Loss of voluntary vertical eye movement
Decreased visual search and scanning
Slowness to orient to events
Edema
Compression
Herniation
Metabolic derangement
Failure of inhibitory component of spatial orientation
Orient when should not
Thalamus
(selected attention — "engage" component)
Toxin/ chemical
Direct destruction
Ischemia
Disorder in "engage" component
Failure to spotlight/amplify the currently attended to information
Edema
Compression
Herniation
Metabolic derangement
Failure to filter out irrelevant distractions
Hippocampal and Related Temporal Areas
(declarative domain — independent memory)
Toxin/ chemical
Bacterial invasion
Direct destruction
Ischemia
Decreased memory transfer (anterograde amnesia)
Impaired recent memory (learning)
Viral infiltration
Compression
Withdrawal state
Nutritional deficiency
Metabolic derangement

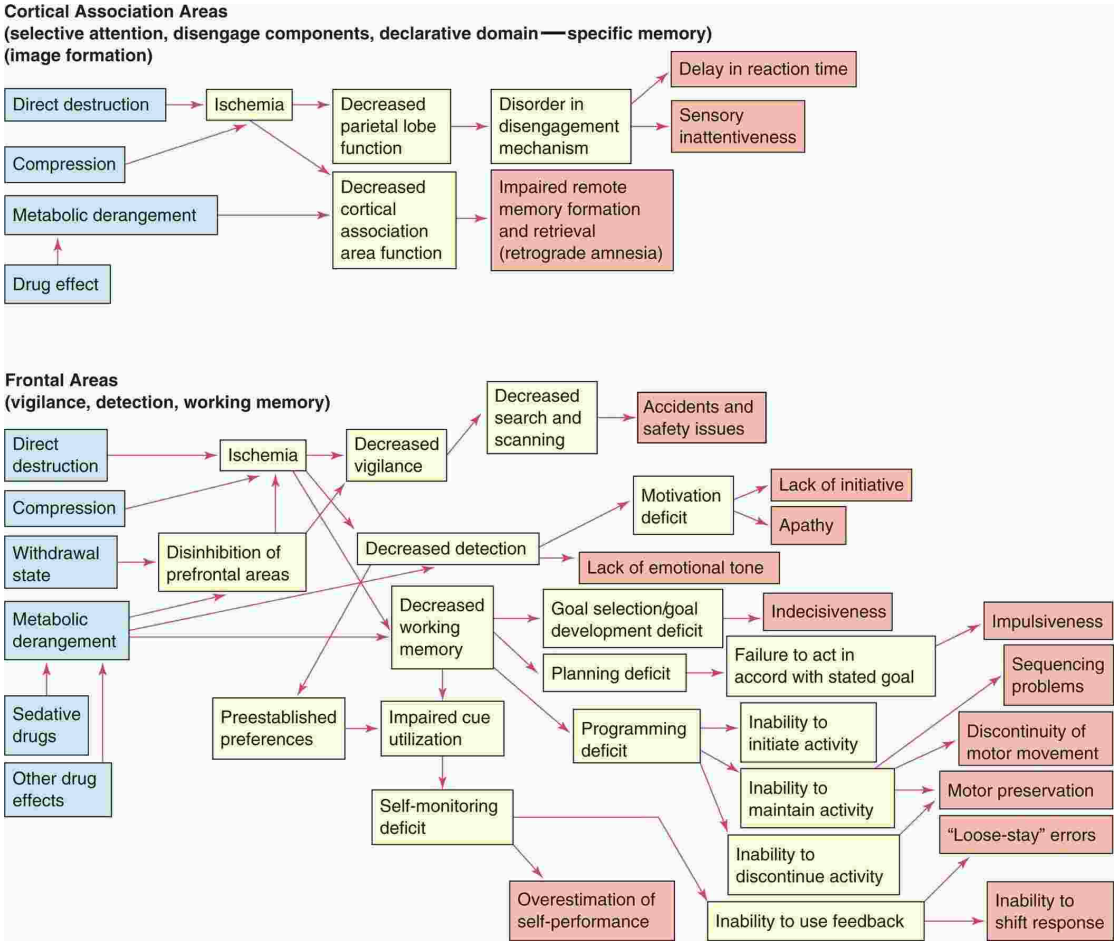


FIG. 17.11 **Cognitive Network Deficits** General pathophysiologic mechanisms underlying cognitive network deficits.

Three flowcharts show cognitive network deficits. Top panel, midbrain tectum (coordination of eye and body movement) (selected attention -move component). The pathways in the flowchart are as follows. 1. Toxin or chemical. Leads to 8. 2. Direct destruction. Leads to 6. 3. Edema. Leads to 7. 4. Herniation. Leads to 7. 5. Metabolic derangement. Leads to 8. 6. Ischemia. Leads to 8. 7. Compression. 8. Disorder in move component. Leads to 10. 9. Failure of inhibitory component of spatial orientation. Leads to 11. 10. Loss of voluntary vertical eye movement. Leads to 12. 11. Orient when should not. 12. Decreased visual search and scanning. Leads to 13. 13. Slowness to orient to events. Middle panel, thalamus (selected attention-engage component). The pathways in the flowchart are as follows. 1. Toxin or chemical. Leads to 8. 2. Direct destruction. Leads to 6. 3. Edema. Leads to 7. 4. Herniation. Leads to 7. 5. Metabolic derangement. Leads to 8. 6. Ischemia. Leads to 8. 7. Compression. 8. Disorder in engage component. Leads to 9 and 10. 9. Failure to spotlight or amplify the currently attended to information. 10. Failure to filter out irrelevant distractions. Bottom panel, hippocampal and related temporal areas (declarative domain-

independent memory). The pathways in the flowchart are as follows. 1. Toxin or chemical. Leads to 10. 2. Bacterial invasion. Leads to 5. 3. Viral infiltration. Leads to 5. 4. Nutritional deficiency. Leads to 8. 5. irect destruction. Leads to 9. 6. Compression. Leads to 9. 7. Withdrawal state. Leads to 10. 8. Metabolic derangement. Leads to 10. 9. Ischemia. Leads to 10. 10. Decreased memory transfer (anterograde amnesia). Leads to 11. 11. Impaired recent memory (learning). Two flowcharts show cognitive network deficits. Top panel, cortical association areas (selective attention, disengage components, declarative domain-specific memory). The pathways in the flowchart are as follows. 1. Direct destruction. Leads to 5. 2. Compression. Leads to 5. 3. Metabolic derangement. Leads to 7. 4. Drug effect. Leads to 3. 5. Ischemia. Leads to 6 and 7. 6. Decreased parietal lobe function. Leads to 8. 7. Decreased cortical association area function. Leads to 9. 8. Disorder disengagement mechanism. Leads to 10 and 11. 9. Impaired remote memory formation and retrieval (retrograde amnesia). 10. Delay in reaction time. 11. Sensory inattentiveness. Bottom panel, frontal areas (vigilance, detection, working memory). The pathways in the flowchart are as follows. 1. Direct destruction. Leads to 7. 2. Compression. Leads to 7. 3. Withdrawal state. Leads to 8. 4. Metabolic derangement. Leads to 8, 11, and 12. 5. Sedative drugs. Leads to 4. 6. Other drug effects. Leads to 4. 7. Ischemia. Leads to 10, 11, and 12. 8. Disinhibition of prefrontal areas. Leads to 10. 9. Preestablished preferences. Leads to 13. 10. Decreased vigilance. Leads to 15. 11. Decreased detection. Leads to 17 and 18. 12. Decreased working memory. Leads to 21, 22, and 23. 13. Impaired cue utilization. Leads to 14. 14. Self-monitoring deficit. Leads to 24. 15. Decreased search and scanning. Leads to 16. 16. Accidents and safety issues. 17. Motivation deficit. Lead to 18 and 19. 18. Lack of initiative. 19. Apathy. 20. Lack of emotional tone. 21. Goal selection or goal development deficit. Leads to 25. 22. Planning deficit. Leads to 26 and 30. 23. Programming deficit. Leads to 27, 28, and 29. 24. Overestimation of self-performance. 25. Indecisiveness. 26. Failure to act in accord with stated goal. Leads to 31. 27. Inability to initiate activity. 28. Inability to maintain activity. Leads to 32, 33, and 34. 29. Inability to discontinue activity. Leads to 34. 30. Inability to use feedback. Leads to 35 and 36. 31. Impulsiveness. 32. Sequencing problems. 33. Discontinuity of motor movement. 34. Motor preservation. 35. Loose-stay errors. 36. Inability to shift response.

Clinical Manifestations

Clinical manifestations of selective attention deficits, memory deficits, and executive attention function deficits are presented in Table 17.8.

Table 17.8

Clinical Manifestations of Cognitive Network Deficits

Deficit	Clinical Signs	Symptoms
Attention		
Selective attention (orienting)	Inability to focus attention; decreased eye, head, and body movements associated with focusing on the stimuli; decreased search and scanning; faulty orientation to stimuli causing safety problems	Person reports inability to focus attention, failure to perceive objects and other stimuli (history of injuries, falls, and safety problems)
Memory (Long Term, Remote)		
Domain-independent declarative	*Left hemisphere:* disorientation to time, situation, place, name, person (verbal identification); impaired language memory (e.g., names of objects); impaired semantic memory *Right hemisphere:* disorientation to self, person (visual), place (visual); impaired episodic memory (personal history); impaired emotional memory	Person reports disorientation, confusion, "not listening," "not remembering"; reports by others of person being disoriented, not able to remember, not able to learn new information
	Either or both hemispheres: confusion; behavioral change	
Domain-specific declarative	*Left hemisphere:* inability to retrieve personal history, past medical history; unaware of recent current events *Right hemisphere:* inability to recognize persons, places, objects, music, etc., from the past	Person reports remote memory problems; others report that person cannot recall formerly known information
Image processing (semantic processing)	Inability to categorize (identify similarities and differences), sort; inability to form concepts; inability to analyze relationships; misinterpretation; inability to interpret proverbs	Reports by others of frequent misinterpretation of data; failure to conceptualize or generalize information
	Inability to perform deductive reasoning (convergent reasoning); inability to perform inductive reasoning (divergent reasoning); inability to abstract; concrete reasoning demonstrated; delusions	Reports by others of predominantly concrete thinking; lack of understanding of everyday situations, healthcare regimens, delusional thinking

Deficit	Clinical Signs	Symptoms
Executive Attention Deficits		
Vigilance	Failure to search and scan environment	Person reports accidents, safety issues
Detection	Lack of initiative (anergy); lack of ambition; lack of motivation; flat affect; no awareness of feelings; appears depressed, apathetic, and emotionless; fails to appreciate deficit; disinterested in appearance; lacks concern about childish or crude behavior	Reports by others of laziness or apathy, flat affect or lack of emotional expression, failing to exhibit or be aware of feelings
Mild	Responds to immediate environment but no new ideas; grooming and social graces are lacking	Reports by others of lack of ambition, motivation, or initiative; failure to carry out adult tasks; lack of social graces and new ideas
Severe	Motionless, lack of responding to even internal cues; does not respond to physical needs; does not interact with surroundings	Reports by others of failure to groom or toilet self, unawareness of surroundings and own physical needs
	Inability to use feedback regarding behavior; failure to recognize omissions and errors in self-care, speech, writing, and arithmetic; impaired cue utilization; overestimation of performance	Reports by others of not changing behavior when requested; unawareness of limitations; does not recognize and correct errors in dressing, grooming, toileting, eating; fails to recognize speech and arithmetic errors; careless speech
	Failure to shift response set; failure to change behavior when conditions change; cue utilization may be impaired	Reports by others of failure to use feedback; inability to incorporate feedback (does not correct when feedback is given)
Working memory (recent memory, short-term memory)	Inability to set goals or form goals; indecisiveness	Reports by others of failure to set goals, indecisiveness
	Failure to make plans; inability to produce a complete line of reasoning; inability to make up a story; appears impulsive	Reports by others of failure to plan, impulsiveness, "does not think things through"
	Failure to initiate behavior; failure to maintain behavior; failure to discontinue behavior; slowness to alternate response for the next step; motor perseveration	Reports by others of not knowing where to begin, inability to carry out sequential acts (maintain a behavior), inability to cease a behavior

Deficit	Clinical Signs	Symptoms
Attention		
Selective attention (orienting)	Inability to focus attention; decreased eye, head, and body movements associated with focusing on the stimuli; decreased search and scanning; faulty orientation to stimuli causing safety problems	Person reports inability to focus attention, failure to perceive objects and other stimuli (history of injuries, falls, and safety problems)
Memory (Long Term, Remote)		
Domain-independent declarative	*Left hemisphere:* disorientation to time, situation, place, name, person (verbal identification); impaired language memory (e.g., names of objects); impaired semantic memory *Right hemisphere:* disorientation to self, person (visual), place (visual); impaired episodic memory (personal history); impaired emotional memory	Person reports disorientation, confusion, "not listening," "not remembering"; reports by others of person being disoriented, not able to remember, not able to learn new information
	Either or both hemispheres: confusion; behavioral change	
Domain-specific declarative	*Left hemisphere:* inability to retrieve personal history, past medical history; unaware of recent current events *Right hemisphere:* inability to recognize persons, places, objects, music, etc., from the past	Person reports remote memory problems; others report that person cannot recall formerly known information
Image processing (semantic processing)	Inability to categorize (identify similarities and differences), sort; inability to form concepts; inability to analyze relationships; misinterpretation; inability to interpret proverbs	Reports by others of frequent misinterpretation of data; failure to conceptualize or generalize information
	Inability to perform deductive reasoning (convergent reasoning); inability to perform inductive reasoning (divergent reasoning); inability to abstract; concrete reasoning demonstrated; delusions	Reports by others of predominantly concrete thinking; lack of understanding of everyday situations, healthcare regimens, delusional thinking
Executive Attention Deficits		
Vigilance	Failure to search and scan environment	Person reports accidents, safety issues
Detection	Lack of initiative (anergy); lack of ambition; lack of motivation; flat affect; no awareness of feelings; appears depressed, apathetic, and emotionless; fails to appreciate deficit; disinterested in appearance; lacks concern about childish or crude behavior	Reports by others of laziness or apathy, flat affect or lack of emotional expression, failing to exhibit or be aware of feelings
Mild	Responds to immediate environment but no new ideas; grooming and social graces are lacking	Reports by others of lack of ambition, motivation, or initiative; failure to carry out adult tasks; lack of social graces and new ideas
Severe	Motionless, lack of responding to even internal cues; does not respond to physical needs; does not interact with surroundings	Reports by others of failure to groom or toilet self, unawareness of surroundings and own physical needs
	Inability to use feedback regarding behavior; failure to recognize omissions and errors in self-care, speech, writing, and arithmetic; impaired cue utilization; overestimation of performance	Reports by others of not changing behavior when requested; unawareness of limitations; does not recognize and correct errors in dressing, grooming, toileting, eating; fails to recognize speech and arithmetic errors; careless speech
	Failure to shift response set; failure to change behavior when conditions change; cue utilization may be impaired	Reports by others of failure to use feedback; inability to incorporate feedback (does not correct when feedback is given)
Working memory (recent memory, short-term memory)	Inability to set goals or form goals; indecisiveness	Reports by others of failure to set goals, indecisiveness
	Failure to make plans; inability to produce a complete line of reasoning; inability to make up a story; appears impulsive	Reports by others of failure to plan, impulsiveness, "does not think things through"
	Failure to initiate behavior; failure to maintain behavior; failure to discontinue behavior; slowness to alternate response for the next step; motor perseveration	Reports by others of not knowing where to begin, inability to carry out sequential acts (maintain a behavior), inability to cease a behavior

Evaluation and Treatment

Immediate medical management is directed at diagnosing the cause and treating reversible factors. Rehabilitative measures for cognitive system deficits generally are either compensatory or restorative in

nature and have been greatly facilitated by computer technology and other electronic-assisted devices. Approaches based on behavioral techniques tend to be compensatory, whereas process-oriented approaches are restorative.

Selective attention and executive attention deficits masquerade as other cognitive deficits. Differential diagnosis of other cognitive deficits is blocked, and learning potential is largely obscured by the presence of an attention deficit. Therefore, diagnosis and treatment of attention deficits are fundamental.

Data Processing Deficits

Data processing deficits are problems associated with recognizing and processing sensory information and include agnosia, aphasia, and acute confusional states (ACSs).

Agnosia

Agnosia is a defect of pattern recognition—a failure to recognize the form and nature of objects by one or more of the senses. Agnosia can be tactile, visual, or auditory. For example, an individual may be unable to identify a safety pin by touching it with a hand but able to name it when looking at it. Agnosia may be as minimal as a finger agnosia (failure to identify by name the fingers of one's hand) or more extensive, such as a color agnosia.

Agnosia is produced by damage to the primary sensory area or in the interpretive areas of the cerebral cortex (parietal, temporo-occipital areas—Broca area and Wernicke area) (see Fig. 17.9). The symptoms of agnosia vary according to the location of the damage. The types of agnosia and the associated areas most involved with each are presented in Table 17.9. Although agnosia is commonly associated with cerebrovascular accidents, it may arise from any pathologic process that injures these specific areas of the brain (e.g., encephalitis, tumors, PD, trauma, or toxins).[23]

Table 17.9

Types of Agnosia (Concept Disorders)

Type of Agnosia	Definition	Location of Injury
Tactile agnosia (astereognosis)	Inability to recognize objects by touch	Parietal lobe
Spatial agnosia	Incapacity to find one's way around familiar places; disturbance of perception of space (disorders of [1] topographic [extrapersonal] orientation or [2] topographic and geographic memory [construction])	Parietal lobe
Gerstmann syndrome	Inability to write; loss of ability to do mathematics; inability to identify one's own or another's fingers; inability to make the distinction between the right and left side of the body.	Left angular gyrus (parietal lobe)
Finger agnosia (digital agnosia)	Inability to identify the names of one's fingers	
Right-left confusion	Inability to distinguish right from left	
Agraphia	Inability to write	
Acalculia	Inability to perform mathematic calculations	
Visual agnosia		
Object agnosia	Inability to recognize objects and pictures	Temporo-occipital area
Prosopagnosia	Inability to recognize faces	Temporo-occipital lobe, ventromedial region
Color agnosia	Inability to understand colors as qualities of objects; faulty color concepts and inability to evoke color images in the absence of color blindness; specific types: (1) "hue" problem, (2) color anomia (cannot name color)	Inferior occipital cortex in left hemisphere
Body image agnosias (may be spatial)		
Anosognosia	Ignorance or denial of existence of the disease	Right parietal lobe
Autotopagnosia	Loss of ability to identify the body, in whole or in part, or to recognize relationships among various parts	Right parietal lobe
Word blindness (alexia/dyslexia)	Inability to recognize written symbols	Left parietotemporal region
Auditory agnosia (pure word deafness)	Inability to recognize speech sounds	Superior temporal area
Amusia (music deafness)	Loss of capacity to recognize tones and melodies	Right superior temporal area

Aphasia

Aphasia is typically an acquired impairment of comprehension or production of language with impaired written or verbal communication. The terms aphasia and dysphasia are often used interchangeably; the term aphasia is used here.[24] Aphasia results from dysfunction in the left cerebral hemisphere (e.g., Broca area [inferior frontal gyrus] and Wernicke area [superior temporal gyrus]) and the subcortical and cortical connecting networks (see Fig. 15.8B and C). Aphasias are commonly associated with a cerebrovascular accident involving the middle cerebral artery or one of its many branches (see Fig. 15.21). Language disorders, however, may arise from a variety of injuries and diseases, including vascular, neoplastic, traumatic, degenerative, metabolic, or infectious causes. Most language disorders result from acute processes or a chronic residual deficit of the acute process.

Aphasias have been classified anatomically (e.g., Wernicke or Broca area aphasias) or functionally as disorders of fluency (quality and content of speech). Aphasia associated with the frontal lobe, also known as *Broca or motor aphasia*, involves loss of ability to produce spoken or written language with slow or difficult speech. The speech that is produced is dysfluent and agrammatic. Verbal comprehension is usually present. Aphasia is differentiated from *dysarthria*, in which words cannot be articulated clearly because of cranial nerve damage or muscle impairment. Aphasia that is known as *Wernicke or sensory* involves an inability to understand written or spoken language. Speech is fluent, flowing at a normal rate, but words and phrases have no meaning (fluent dysphasia). Language deficits can be comprehensive; motor language deficits can be accompanied by deficits in comprehension, and comprehension deficits can be accompanied by motor deficits in language. For this reason, it can be misleading to classify aphasia as being expressive or receptive.[25]

Anomic aphasia is a sensory aphasia distinguished by difficulty finding words and naming a person or object. It is the most common symptom of cerebrovascular-related aphasia. Circumlocution, or describing an object as a way of trying to name something, is common in anomic aphasia. Auditory comprehension is present in conductive aphasia, but there is impaired verbatim repetition. Naming also can be impaired. The person recognizes the errors and tries to correct them. Speech is fluent, but words and sounds may be transposed. Damage is typically in the left hemisphere to networks that connect Broca and Wernicke areas. Anomic aphasias can also result from AD and other neurodegenerative diseases. Transcortical aphasias are rare and can be motor, sensory, or mixed. They involve areas of the brain that connect to the language centers. Anomic aphasia resulting from right hemisphere damage is rare as well.

Global aphasia is the most severe aphasia and involves both motor and sensory aphasia. The individual is non-fluent or mute; cannot read or write; and has impaired comprehension, naming, reading, and writing. Global aphasia is usually associated with a cerebrovascular accident involving the middle cerebral artery. Table 17.10 compares types of aphasia, and Table 17.11 illustrates some of the language disturbances. Pure aphasias are rare and are often mixed, making diagnosis difficult. Most types of aphasia improve with speech rehabilitation; however, if the cause is progressive disease (e.g., AD), improvement is not expected. Maintenance and quality of life are typically the treatment goals for progressive disease.

Table 17.10

Major Types of Aphasia

Type	Expression	Verbal Comprehension	Repetition	Reading Comprehension	Writing	Loc
Expressive						
Broca, nonfluent or motor aphasia	Cannot find words, difficulty writing	Relatively intact	Impaired	Variable	Impaired	Lef
Transcortical motor, nonfluent aphasia	Halting speech	Intact	Intact	Impaired	Impaired	An
Receptive						
Wernicke, receptive fluent or sensory aphasia	Meaningless verbal language, inappropriate words or unable to monitor language for correctness so errors are not recognized Intonation, accent, cadence, rhythm, and articulation normal	Impaired; disturbance in understanding all language	Impaired	Impaired	Impaired	Lef
Conductive aphasia	Difficulty repeating words, phrases spoken to them;	Intact	Severely impaired	Variable	Variable	Inf

Type	Expression	Verbal Comprehension	Repetition	Reading Comprehension	Writing	Lo
	naming is impaired					
Anomic aphasia	Hesitancy, difficulty recalling names, objects, or numbers	Intact	Impaired	Variable	Intact except for anomia	Le
Transcortical sensory, fluent aphasia	Repeats words and phrases spoken to them	Poor	Intact	Impaired	Impaired	Po
Other						
Transcortical mixed motor and sensory, nonfluent	Repeats words and phrases spoken to them	Impaired	Intact	Impaired	Impaired	Le
Global or nonfluent; summation of motor and sensory aphasia	Mute	Impaired	Impaired	Impaired	Impaired	La

Type	Expression	Verbal Comprehension	Repetition	Reading Comprehension	Writing	Location of Lesion	Cause of Lesion
Expressive							
Broca, nonfluent or motor aphasia	Cannot find words, difficulty writing	Relatively intact	Impaired	Variable	Impaired	Left posteroinferior frontal lobe (Broca area)	Occlusion of one or several branches of left middle cerebral artery supplying inferior frontal gyrus
Transcortical motor, nonfluent aphasia	Halting speech	Intact	Intact	Impaired	Impaired	Anterior superior frontal lobe	Occlusion at the border zone between two arterial territories
Receptive							
Wernicke, receptive fluent or sensory aphasia	Meaningless verbal language, inappropriate words or unable to monitor language for correctness so errors are not recognized Intonation, accent, cadence, rhythm, and articulation normal	Impaired; disturbance in understanding all language	Impaired	Impaired	Impaired	Left posterosuperior temporal lobe (Wernicke area)	Occlusion of inferior division of left middle cerebral artery
Conductive aphasia	Difficulty repeating words, phrases spoken to them; naming is impaired	Intact	Severely impaired	Variable	Variable	Inferior and posterior temporal lobe; parietotemporal junction	Occlusion in distributions of left middle cerebral artery
Anomic aphasia	Hesitancy, difficulty recalling names, objects, or numbers	Intact	Impaired	Variable	Intact except for anomia	Left temporoparietal zones; arcuate fasciculus	Diffuse left hemisphere brain disease
Transcortical sensory, fluent aphasia	Repeats words and phrases spoken to them	Poor	Intact	Impaired	Impaired	Posterior temporal lobe	Occlusion at the border zone between two cerebral arterial territories
Other							
Transcortical mixed motor and sensory, nonfluent	Repeats words and phrases spoken to them	Impaired	Intact	Impaired	Impaired	Left cerebral hemisphere; spares the perisylvian cortex	Occlusion at the border zone between two cerebral arterial territories

Type	Expression	Verbal Comprehension	Repetition	Reading Comprehension	Writing	Location of Lesion	Cause of Lesion
Global or nonfluent; summation of motor and sensory aphasia	Mute	Impaired	Impaired	Impaired	Impaired	Large areas of the left cortex and subcortical regions	Occlusion of left middle cerebral artery of left internal carotid artery, tumors, other mass lesions, hemorrhage, embolic occlusion of ascending parietal or posterior temporal branch of middle cerebral artery

Table 17.11

Examples of Aphasia

Disorder	Example
Wernicke/Fluent/Sensory Aphasia	
Verbal paraphasia	*Question:* What did the car do?
	Person: The car would spit sweetly down the road. (The car sped swiftly down the road.)
Literal paraphasia	*Request:* Say "persistence is essential to success."
	Person: Mesastence is instans to success.
Neologism	*Question:* What do you call this? (Pointing to a plant.)
	Person: It's a logper.
Anomic aphasia (circumlocution example)	*Question:* What do you call this? (Pointing to a plant.) *Person:* Something that grows. *Person:* It's …
	Or
	Question: What did you do this morning?
	Person: Reading.
	Question: Were you reading a book or newspaper?
	Person: One of those.
Broca or Motor Aphasia	
Telegraphic style	*Question:* Where is your daughter?
	Person: New Orleans … home … Monday.

Acute Confusional States

Delirium (also known as acute confusional states or acute organic brain syndromes) are disorders of awareness, may be transient (acute) or persistent (chronic), and have either a sudden or a gradual onset. Delirium can be considered as a type of ACS, but for this discussion, ACSs, acute organic brain syndrome, and delirium are synonymous. Hospitalized older individuals are at greatest risk for delirium.[26,27]

Pathophysiology

Delirium or ACSs arise from disruption of a widely distributed neural network (see Figs. 17.7 and 17.10) and involve alterations in cognitive function, emotion, perception, and consciousness. **Delirium** symptoms typically develop over hours to days. The pathogenesis of delirium is not well understood. Many risk factors are associated with delirium; they are summarized in Table 17.12. There does not seem to be a single mechanism to explain the sensory and processing dysfunction of the brain during delirium. The etiological factors leading to delirium appear to be an alteration in neurotransmitter availability and function, as well as a failure in the function of neuronal networks that integrate and process sensory information and motor response. The System Integration Failure Hypothesis (SIFH) connects the pathology of the network dysconnectivity and dysfunction. The hypothesis integrates five pathological precipitants of delirium (neuronal aging, neuroinflammation, oxidative stress, neuroendocrine dysregulation, and circadian dysregulation) and proposes that all these factors are linked and have a role in causing delirium.[28]

Table 17.12

Risk Factors for Delirium

Premorbid Factors	Precipitating Factors	Hospital Factors
Advanced age Comorbidities—chronic disease Frailty Low educational level Visual/hearing impairment Alcohol/illicit drug use Poor nutrition Depression Dementia History of delirium	*Surgical stress:* cardiovascular, major abdominal, aortic, joint, brain, and emergency surgeries; anesthesia	Pain, infection, immobility, metabolic disorders, prolonged ileus, invasive devices, blood transfusion. Immobility, fall risk Sensory overload or deprivation Prolonged length of stay Lack of family communication
	Severe Medical Illness: Unplanned admission Dehydration Electrolyte imbalance Febrile illness Acute kidney injury Liver dysfunction Thyroid dysfunction Uncontrolled diabetes mellitus Heart failure Seizures Stroke Alcohol/drug withdrawal	*Treatment Related* Opioids, benzodiazepines, anticholinergics, polypharmacy Sleep deprivation Day-night disorientation Deep sedation Physical restraints Ventilation exceeding 96 h

Data from Wilson JE, Mart MF, Cunningham C, et al. Delirium. *Nature Reviews: Disease Primers*, 2020;6(1):90; Bellelli G, Brathwaite JS, Mazzola P. Delirium: A marker of vulnerability in older people. *Frontiers in Aging Neuroscience*, 2021;13:626127.

Neuronal aging causes increased astrocyte and microglial activity, resulting in brain inflammation and neurodegenerative disease. Proinflammatory cytokines and reactive oxygen species (ROS) are produced, causing chronic inflammation. As part of the inflammatory process, leukocytes cause increased permeability of the blood-brain barrier, increasing edema and promoting neuronal apoptosis. The consequences are a lack of perfusion and brain ischemia.

Chronic inflammatory processes go on to produce oxidative stress. Oxidative stress causes damage to the brain by the formation of ROS. ROS damages myelin sheaths and increases injury to cerebral tissues. This can lead to cognitive decline and potentially irreversible or persistent delirium. Oxidative stress can also cause a failure in oxidative metabolism, which leads to failure of ionic pumps and thus an alteration

in the release of neurotransmitters (e.g., glutamate, dopamine, acetylcholine, serotonin, and gamma-aminobutyric acid).

Physiological stress may result in neuroendocrine dysfunction. Continued stressors can cause high glucocorticoid levels. Chronic sleep deprivation, or circadian rhythm dysregulation, is considered a physiological stressor, which increases proinflammatory cytokines and cortisol levels, leading to cognitive alterations and delirium. With increased and prolonged exposure, glucocorticoids may affect neuronal function and cause neuronal injury and death.

Most metabolic disturbances (e.g., hypoglycemia, thyroid disorders, liver, or kidney disease) that produce delirium interfere with neuronal metabolism or synaptic transmission. Many drugs and toxins also interfere with neurotransmission function at the synapse.

Clinical Manifestations

There are four different types of delirium: hyperactive, hypoactive, mixed, and terminal. Delirium causes deficits in five different areas of brain function: cognitive deficits, attentional deficits, circadian rhythm dysfunction, emotional dysregulation, and psychomotor dysregulation. *Hyperactive delirium* manifests as restlessness, irritability, insomnia, tremulousness, hallucinations, or delusions. In a fully developed delirium state, the individual is completely inattentive, and perceptions are grossly altered, with extensive misperception and misinterpretation. The person appears distressed and often perplexed; conversation is incoherent. Frank tremor and high levels of restless movement are common. Violent behavior may be present. The individual cannot sleep, is flushed, and has dilated pupils, a rapid pulse rate (tachycardia), elevated temperature, and profuse sweating (diaphoresis).

Excited delirium syndrome (ExDS), also known as *agitated delirium*, is a type of hyperactive delirium that can lead to sudden death. Its symptoms include altered mental status, combativeness, aggressiveness, tolerance to significant pain, rapid breathing, sweating, severe agitation, elevated temperature, noncompliance, or poor awareness of direction from police or medical personnel, inability to become fatigued, unusual or superhuman strength, and inappropriate clothing for the current environment. Hypoglycemia, thyroid storm, certain kinds of seizures, cocaine, methamphetamine intoxication, and/or catecholamine-induced fatal arrhythmias are associated with ExDS.[29]

Hypoactive delirium is the most common form of delirium. It is associated with underactivity and may occur in individuals who have fevers or metabolic disorders (e.g., chronic liver or kidney failure), are under the influence of CNS depressants or are postoperative. The individual exhibits decreased mental function, specifically alertness, attention span, accurate perception, interpretation of the environment, and reaction to the environment. Forgetfulness, confusion, and apathy are prominent; speech may be slow, and the individual dozes frequently. Hypoactive delirium can be mistaken for depression or dementia, including AD (Table 17.13). It has the highest rate of mortality, as it is often undiagnosed, and treatment is delayed.[30]

Table 17.13

Comparison of Delirium and Dementia

Feature	Delirium	Dementia
Age	Usually older	Usually older
Onset	Acute—common during hospitalization	Usually insidious; acute in some cases of strokes/trauma
Associated conditions	Urinary tract infection, thyroid disorders, hypoxia, hypoglycemia, toxicity, fluid-electrolyte imbalance, renal insufficiency, trauma, multiple medications	May have no other conditions Brain trauma
Course	Fluctuating; remits with treatment	Chronic slow decline, usually starts with memory loss
Duration	Hours to weeks	Months to years
Attention	Impaired	Intact early; often impaired late
Sleep-wake cycle	Disrupted	Usually normal or fragmented
Alertness	Impaired	Normal
Orientation	Impaired	Intact early; impaired late
Behavior	Agitated, withdrawn/depressed	Intact early
Speech	Incoherent, rapid/slowed	Word-finding problems
Thoughts	Disorganized, delusions	Impoverished
Perceptions	Hallucinations/illusions	Usually intact early

Adapted from Caplan JP, Rabinowitz T. An approach to the patient with cognitive impairment: Delirium and dementia. *Medical Clinics of North America*, 2010;94(6):1103–1116, ix.

Mixed delirium is a combination of both hyperactive and hypoactive delirium, fluctuating from one to the other. Delirium resolves suddenly or gradually in 2 to 3 days, although delirium states occasionally persist for weeks.

Terminal delirium, also known as *terminal restlessness* or *terminal agitation*, is often seen in individuals during the final stages of dying. Metabolic dysfunction, common at the end of life as organs shut down, and neurotransmitter abnormalities are thought to be a major cause. Onset is often preceded by physical, emotional, or spiritual distress, anxiety, restlessness, and agitation. Hallucinations may also be seen (e.g., talking to someone who is not present). Terminal delirium is not reversible, but symptoms may come and go during the actively dying period. It is important to rule out all other causes of delirium prior to a diagnosis of terminal delirium.[31,32]

Evaluation and Treatment

An ACS is an acute medical problem. The initial goal is to establish that the individual's confusion arises from delirium and to identify the cause and contributing factors. Hypoactive delirium will need to be differentiated from depression or an underlying dementia. A complete history and physical examination, as well as laboratory tests including an electrocardiogram and bloodwork, urine, cerebral spinal fluid (CSF), and imaging studies are needed. Several assessment scales are available to guide evaluation.[33–35]

Once the cause is established, treatment is directed at addressing the underlying condition. Delirium can be preventable and reversible in some individuals with management of risk factors and early intervention. Assessing pain management, hydration, nutrition, sleep maintenance, hygiene, and toileting may prevent or treat the delirium. Drugs that may be contributing to or causing the condition are discontinued unless the problem is the result of drug withdrawal. Nonpharmacologic measures should be utilized initially to treat the delirium. Measures such as turning the lights low, minimizing noise, playing soothing music, and orientation to surroundings may reduce agitation and anxiety. If the individual is agitated, verbal de-escalation techniques and validating their reality instead of trying to reorient them may help to decrease their agitation and promote a feeling of calmness.

Pharmacologic (i.e., antipsychotics) interventions may be implemented once the underlying cause of delirium has been determined and all reversible causes have been ruled out. Typically, this route is only for individuals who display agitated forms of delirium. Though there is no approved medication for

delirium, drugs such as risperidone, olanzapine, quetiapine, and haloperidol can be used with caution. If these pharmacological measures are used, initial drug doses should be low and slowly titrated up.[36] If the individual has terminal delirium with severe refractory agitation, palliative sedation may be considered.[37]

Dementia

Dementia is an acquired deterioration and a progressive failure of many cerebral functions that includes impairment of intellectual processes with decreasing abilities in the areas of orientation, memory, language, judgment, and decision making. Because of declining intellectual ability, the individual may exhibit alterations in behavior, for example, agitation, wandering, and aggression.[38]

Dementias can be classified according to etiologic factors (e.g., genetics, trauma, tumors, vascular disorders, infections) and to associated clinical and laboratory signs. Dementing processes also have been grouped as cortical, subcortical, or both. Box 17.2 lists the potentially reversible and irreversible causes of dementia. AD is the most common cause followed by vascular dementia, then dementia with Lewy bodies (i.e., Parkinsonian dementia [see section on PD]), and FTD. Parkinsonian and Lewy body (intracellular inclusions with high concentrations and abnormal folding of alpha-synuclein and other proteins) dementia can be difficult to diagnose, and AD and vascular disease can appear concurrently. When different types of dementia occur concurrently, it is classified as a mixed dementia.[39] In people younger than 60 years, FTD rivals AD in terms of frequency.[40]

Box 17.2

Causes of Dementia

Potentially Reversible Causes of Dementia

Infection

- Encephalitis
- Meningitis
- Neurosyphilis

Normal Pressure Hydrocephalus

Chronic Subdural Hematoma

Nutritional Deficiencies

- Vitamin B_1 (thiamine) deficiency
- Vitamin B_{12} (cobalamin) deficiency
- Nicotinic acid deficiency (pellagra)

Side Effects of Medications

- Anticholinergics
- Antihypertensives
- Antihistamines

Chronic Intoxications

- Alcohol[a]
- Sedatives

Metabolic Disorders

Thyroid abnormalities
Addison disease
Cushing disease
Chronic hepatic encephalopathy
Renal failure with uremia

Central Nervous System Disorders

Frontal and temporal lobe tumors
Depression
Hydrocephalus
Cerebral vasculitis
Neurosarcoidosis
Pseudodementia

Irreversible Causes of Dementia

Neurodegenerative Disorders

Alzheimer disease[a]
Dementia with Lewy bodies
Frontotemporal dementia
Pick disease
Huntington disease
Parkinson disease

Vascular Disease

Vascular dementia[a]
Multi-infarct brain lesions
Focal infarct brain lesion
Binswanger disease (a rare diffuse white matter disease caused by arteriosclerosis and thromboembolism affecting the blood vessels that supply the white-matter, basal ganglia, and thalamus)
Amyloid angiopathy

Infection

Creutzfeldt-Jakob disease (CJD)
Postencephalitic dementia
HIV-associated dementia

Pathophysiology

Mechanisms leading to dementia include neuron degeneration, compression of brain tissue, atherosclerosis of cerebral vessels, and brain trauma. Genetic predisposition (Table 17.14) is associated with the neurodegenerative diseases, including AD, FTD, HD (see section on HD), and PDs (see section on PD) leading to abnormal protein accumulation within neurons and other vulnerable parts of the brain. CNS infections, including the human immunodeficiency virus (HIV) and prions in Creutzfeldt-Jakob disease (CJD) (see Table 17.14 and Box 17.3), also lead to nerve cell degeneration and brain atrophy. The neuropathology associated with HIV and HIV associated neurocognitive disorder (HAND) is presented in Chapter 18.

Table 17.14

The Most Common Molecular Mechanisms and Genes Associated With Degenerative Dementia

Dementia	Molecular Mechanism	Causal Genes (Chromosome)	Susceptibility Genes (Chromosome)	Pathology
Alzheimer disease (familial)	Amyloid beta protein Phosphorylated tau protein	*Early onset: autosomal dominant:* <2% carry these mutations APP (21), *PSEN1* (14), *PSEN2* (1) (most mutations are in *PSEN1*)	*Late onset: risk gene apoE4* (19) *CUGBP2* (10p)	Amyloid plaques, neurofibrillary tangles; neuronal and synaptic loss in the brain
Creutzfeldt-Jakob disease (hereditary form)	PrP^{SC} proteins type 1 and 2	Prion (20) (up to 15% of cases carry these dominant mutations)	*PRNP* codon 129 homozygosity for methionine or valine	Tau inclusions, spongiform changes, gliosis
Dementia with Lewy bodies	Alpha-synuclein	Very rare alpha-synuclein (4) (dominant)	Unknown	Alpha-synuclein inclusions (Lewy bodies)
Behavioral variant frontotemporal dementia	Microtubule-associated protein tau (MAPT) Progranulin (PGRN)	Tau exon and intron mutation (17) (about 10% of familial cases) *PGRN* (17) (10% of familial cases)	Tau haplotypes *(H1* and *H2)*	Tau inclusions, Pick bodies, neurofibrillary tangles
Huntington disease (autosomal dominant)	Huntingtin protein (polyglutamine)	*Autosomal dominant*: *HD-IT15* (4) (trinucleotide repeat expansion)	None known	Neuronal degeneration, astrogliosis
Parkinson disease	*Autosomal dominant:*	*Autosomal dominant:*	*GBA* (glucosidase beta acid)	Neuronal degeneration, alpha-synuclein

Dementia	**Molecular Mechanism**	**Causal Genes (Chromosome)**	**Susceptibility Genes (Chromosome)**	**Pathology**
Dementia	Alpha-synuclein Leucine-rich repeat kinase 2 *Autosomal recessive:* Parkin (juvenile onset) DJ-1 protein PTEN-induced putative kinase 1	*SNCA-PARK1* (4) *LRRK2-PARK8* (12) *Autosomal recessive:* *PARK2* (4) oncogene DJ-1 *(PARK7)* *PINK1 (PARK6)*	*SNCAIP* (alpha-synuclein interacting protein) *NR4A2* (orphan nuclear receptor) *UCH-L1 (PARK5)* ubiquitin C-terminal hydrolase Other low-risk genes	inclusions (Lewy bodies), gliosis; neuronal degeneration

Dementia	Molecular Mechanism	Causal Genes (Chromosome)	Susceptibility Genes (Chromosome)	Pathology
Alzheimer disease (familial)	Amyloid beta protein Phosphorylated tau protein	*Early onset: autosomal dominant:* <2% carry these mutations APP (21), *PSEN1* (14), *PSEN2* (1) (most mutations are in *PSEN1*)	*Late onset: risk gene apoE4* (19) *CUGBP2* (10p)	Amyloid plaques, neurofibrillary tangles; neuronal and synaptic loss in the brain
Creutzfeldt-Jakob disease (hereditary form)	PrP^{SC} proteins type 1 and 2	Prion (20) (up to 15% of cases carry these dominant mutations)	*PRNP* codon 129 homozygosity for methionine or valine	Tau inclusions, spongiform changes, gliosis
Dementia with Lewy bodies	Alpha-synuclein	Very rare alpha-synuclein (4) (dominant)	Unknown	Alpha-synuclein inclusions (Lewy bodies)
Behavioral variant frontotemporal dementia	Microtubule-associated protein tau (MAPT) Progranulin (PGRN)	Tau exon and intron mutation (17) (about 10% of familial cases) *PGRN* (17) (10% of familial cases)	Tau haplotypes *(H1* and *H2)*	Tau inclusions, Pick bodies, neurofibrillary tangles
Huntington disease (autosomal dominant)	Huntingtin protein (polyglutamine)	*Autosomal dominant*: *HD-IT15* (4) (trinucleotide repeat expansion)	None known	Neuronal degeneration, astrogliosis
Parkinson disease Dementia	*Autosomal dominant:* Alpha-synuclein Leucine-rich repeat kinase 2 *Autosomal recessive:* Parkin (juvenile onset) DJ-1 protein PTEN-induced putative kinase 1	*Autosomal dominant:* *SNCA-PARK1* (4) *LRRK2-PARK8* (12) *Autosomal recessive:* *PARK2* (4) oncogene DJ-1 *(PARK7)* *PINK1 (PARK6)*	*GBA* (glucosidase beta acid) *SNCAIP* (alpha-synuclein interacting protein) *NR4A2* (orphan nuclear receptor) *UCH-L1 (PARK5)* ubiquitin C-terminal hydrolase Other low-risk genes	Neuronal degeneration, alpha-synuclein inclusions (Lewy bodies), gliosis; neuronal degeneration

APP, Amyloid precursor protein; *PRNP*, pr ion protein; PrP^{SC}, prion protein scrapie form; *PSEN*, presenilin; *PTEN*, phosphatase and tensin homolog.

Box 17.3

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is a progressive, fatal, dementing neurologic illness caused by an infectious protein known as a *prion*. Prions are composed of misfolded prion proteins and can self-replicate and cause spongiform encephalopathy (numerous small vacuoles within the grey matter). The incidence is about 1 in 2 million population per year. Most cases are sporadic, and about 10% of cases are associated with mutations in the prion protein gene. Diagnosis is made by clinical evaluation, magnetic resonance imaging, and electroencephalography. Spinal fluid analysis shows the presence of 14-3-3 protein or human prion protein (PrP^{Sc}), and it also may be detected in olfactory epithelium, blood, and/or urine samples. Definitive diagnosis is made at autopsy. There may be years before onset of symptoms, which include rapidly progressive dementia and at least two of the four following features: myoclonus, visual disturbance or cerebellar ataxia, motor signs, and akinetic mutism. The disease is fatal in an average of 8 months from onset of symptoms, and there is no treatment. Tissue from persons with prion disease must not be transplanted. Animal forms of prion

disease include scrapie in sheep; chronic wasting disease in deer, elk, and moose; and bovine spongiform encephalopathy (BSE) in cows. BSE can be transmitted to humans by consumption of infected meat and is known as *new variant Creutzfeldt-Jakob disease*.

Clinical Manifestations

Clinical manifestations of the major dementias are presented in Table 17.15.

Table 17.15

Clinical Differentiation of the Major Degenerative Dementias

Disease	Mental Status	Neurobehavior	Neurologic Examination
Alzheimer disease	Memory loss, disorientation to place and time, loss of facial recognition	Initially normal; progressive cognitive, language, abstraction, and judgment impairment	Initially normal
Dementia with Lewy body (Lewy body dementia)	Initially affects concentration and attention, then memory or cognition loss but unpredictable levels of ability, attention, or alertness; delirium prone	Visual hallucinations, depression, sleep disorder, delusions, transient loss of consciousness	Parkinsonism Changes in walking or movement may present first
Frontotemporal disorders/degeneration/ dementia	*PPA variant* Language loss (difficulty with word finding and object knowledge), talking less and speech becoming hesitant, or loss of understanding of language, which may precede memory loss; spares drawing	*Behavioral variant FTD* Apathy, loss of empathy or sympathy, increased inappropriate social conduct, loss of judgment and reasoning, hyperorality, euphoria, depression	Caused by CBD and PSP variants
Huntington disease	Anxiety and depression	Apathy, loss of interest early; impaired cognition, judgment, and memory occur later	Chorea, bradykinesia, dystonia
Vascular dementia	Frontal/executive, cognitive slowing; memory can be intact	Often but not always sudden, usually within 3 months of a stroke; variable; apathy, falls, focal weakness, delusions, anxiety	Usually motor slowing, spasticity; can be normal or may have symptom improvement

Disease	Mental Status	Neurobehavior	Neurologic Examination
			with stroke recovery

Disease	Mental Status	Neurobehavior	Neurologic Examination

Evaluation and Treatment

Establishing the cause of dementia may be complicated, and individuals with clinical manifestations of dementia should be evaluated with laboratory and neuropsychologic testing to identify underlying conditions that may be treatable. Controlling associated risk factors such as head injury, diabetes, hypertension, hyperlipidemia, obesity, smoking, air pollution, and exposure to environmental toxins, as well as treating depression and avoiding excessive alcohol intake, may cause less neuronal damage and help to prevent dementia.

Increasing or maintaining cognitive reserve (brain resilience) is an important component of dementia prevention. Studies have found that individuals with untreated hearing loss, lower levels of education, and social isolation have a higher risk of dementia. Treating hearing loss, staying mentally active, and having a social network are also ways to reduce the risk of dementia. Individuals with dementia are known to go through an initial stage called mild cognitive impairment (MCI). MCI causes cognitive changes that can be noticed, but these changes are not serious enough to affect activities of daily living. Though individuals with MCI are at higher risk for dementia, not everyone with MCI progresses to dementia.[41–43] Unfortunately, no specific cure exists for most progressive dementias. Therapy is directed

at maintaining and maximizing use of the remaining capacities, restoring functions if possible, and accommodating to lost abilities. Educating the family and caregivers on the progressive nature of the disease process and ways to assist the individual physically and mentally is essential.

Alzheimer disease

AD also known as ***Alzheimer type dementia*** ***(ATD)*** is the leading cause of severe cognitive and behavioral dysfunction in older adults. An estimated 6.2 million Americans have AD, and two-thirds of these individuals are women.[44] However, the estimated number of Americans with dementia is thought to be much higher. Individuals with MCI are at a higher risk of developing AD. With better diagnostic tools, such as imaging and biomarkers, individuals with MCI related to AD will be included in the prevalence numbers. The greatest risk factors associated with AD are age and family history. Modifiable risk factors for dementia have been discussed previously (see previous section on Dementia). Fig. 17.12 summarizes the risk factors and pathogenesis of AD.

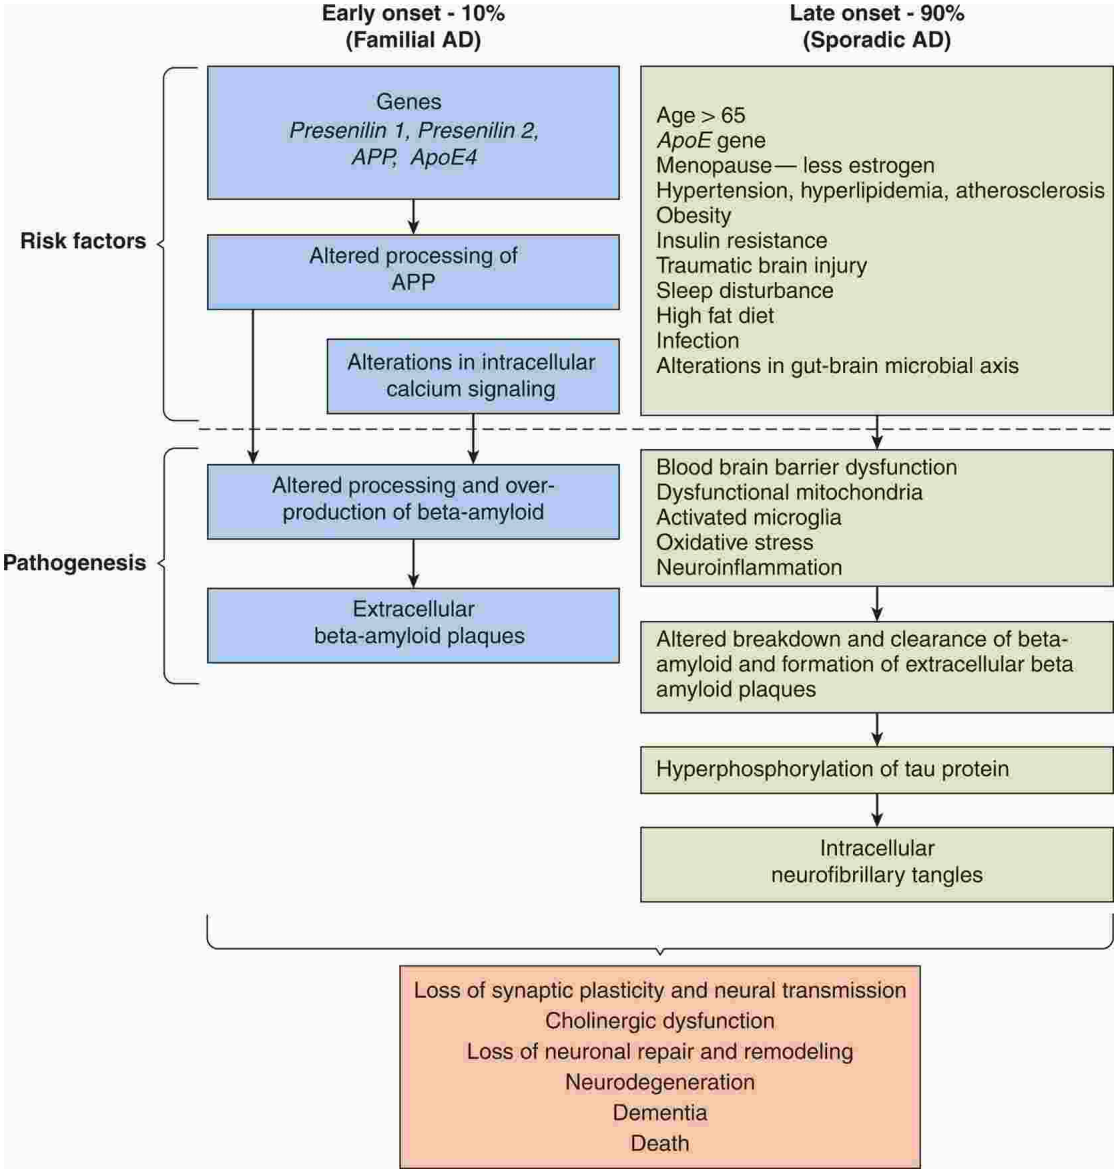

FIG. 17.12 Proposed Risk Factors and Pathogenesis of Alzheimer Disease
. *AD*, Alzheimer disease; *ApoE*, apolipoprotein E; *APP*, amyloid precursor protein.
(Data from Ganguly U, Kaur U, Chakrabarti SS et al. Oxidative stress, neuroinflammation, and nadph oxidase: Implications in the pathogenesis and treatment of Alzheimer's disease. *Oxidative Medicine and Cellular Longevity*, 2021;2021:7086512; Tini G, Scagliola R, Monacelli F et al. Modifiable risk factors for Alzheimer's disease. *Frontiers in Aging Neuroscience*, 2019;11:146.)

Two flowcharts show the proposed factors and pathogenesis of Alzheimer's disease. The flowchart on the left shows data for early onset, 10 percent (familial A D). 1. Risk factors: Genes, presenilin 1, presenilin 2, A P P, A p o E 4. 2. Risk

factors: Altered processing of A P P. 3. Risk factors: Alterations in intracellular calcium signaling. 4. Pathogenesis: Altered processing and over-production of beta-amyloid. 5. Pathogenesis: Extracellular beta-amyloid plaques. The flowchart on the right shows data for late onset, 90 percent (sporadic A D). 1. Risk factors: age greater than 65. A p E gene; menopause-less estrogen; hypertension, hyperlipidemia, atherosclerosis; obesity; insulin resistance; traumatic brain injury; sleep disturbance; high fat diet; infection; alterations in gut-brain microbial axis. 2. Pathogenesis: blood brain barrier dysfunction; dysfunctional mitochondria; activated microglia; oxidative stress; neuroinflammation. 3. Pathogenesis: altered breakdown and clearance of beta-amyloid and formation of extracellular beta amyloid plaques. 4. Hyperphosphorylation and tau protein. 5. Intracellular neurofibrillary tangles. Both types of onsets of the disease result in the following manifestations. • Loss of synaptic plasticity and neural transmission. • Cholinergic dysfunction. • Loss of neuronal repair and remodeling. • Neurodegeneration. • Dementia. • Death.

Pathophysiology

The exact cause of AD is unknown. However, studies are ongoing to classify the genetic variations. Genome-wide association studies have identified numerous single nucleotide variations for late-onset AD. Epigenetic mechanisms are associated with the pathology of AD, but the mechanisms are yet to be determined.

Early-onset AD (EOAD) accounts for 5% to 10% of cases of AD. Early-onset AD can be familial (FAD) or sporadic. The cause of sporadic EOAD is unknown. FAD represents about 10% to 15% of early-onset AD and is an autosomal dominant disease.[45] FAD has been linked to three causal genes with mutations on chromosome 21, although the mechanism of how they cause disease is not clear. The mutations result in the dysregulation of amyloid precursor protein (APP) processing and leads to alterations of folding and concentration of the derived amyloid beta protein. The consequence is the formation of amyloid plaque in the brain. The three gene mutations are:

1. *APP* gene mutation—abnormal APP. Normally APP is a transmembrane protein; processing of APP generates amyloid beta-protein, which is important for synapse formation, synaptic plasticity, increased release of acetylcholine, nicotinic acetylcholine receptor activation, and memory formation. Mutations change the structure and result in accumulation of beta-amyloid.[46,47]
2. *PSEN1* gene mutation (more common and found in more severe disease)—abnormal presenilin 1 protein (more than 200 mutations have been described)—PSEN 1 protein normally functions as a protease to cleave APP, generating amyloid-beta protein of varying lengths. Either loss or gain of function may alter amyloid beta production and accumulation and cause FAD.[48]
3. *PSEN2* gene—abnormal presenilin 2 protein (19 reported mutations)—PSEN2 protein is also a protease that cleaves APP, and mutation leads to alterations in amyloid-beta structure and aggregation.

Apolipoprotein E gene-allele 4 *(APOE4)* on chromosome 19 is also found. APOE4 protein helps to carry cholesterol and other lipids in the bloodstream, and the gene mutation is associated with alterations in lipid metabolism and interference with amyloid-beta protein clearance from the brain. The amyloid-beta protein is processed into neurotoxic fragments found in the plaques in the brain of people with AD.[49] Chromosome 21 is also involved in Down syndrome (Trisomy 21); as such, individuals with

Down syndrome have a high incidence of EOAD. Many individuals with Down syndrome develop AD by age 40 and have clinical manifestations of the disease before age 65. EOAD has an atypical clinical presentation (headaches, seizures, hyperreflexia), a faster rate of deterioration, delayed diagnosis, and a higher mortality rate. Traumatic brain injury is a common risk factor for those with EOAD; however, other associated risks, such as diabetes, cerebrovascular disease, and obesity, are not as common.[50]

Sporadic late-onset AD is the most common type of AD and does not have a specific genetic association; however, the cellular pathology is the same as that for gene-associated early- and late-onset AD. The main genetic risk for late-onset AD is related to age and *APO4E*.[51]

Pathologic alterations in the brain in both early- and late-onset AD include accumulation of extracellular neuritic plaques containing a core of abnormally folded beta amyloid proteins, intraneuronal neurofibrillary tangles consisting of hyper-phosphorylated tau proteins, and degeneration of basal forebrain cholinergic neurons with loss of acetylcholine. Failure to process and clear APP results in the accumulation of toxic fragments of amyloid-beta protein that leads to formation of diffuse neuritic plaques, disruption of nerve impulse transmission, and death of neurons. Amyloid-beta protein is also deposited in the smooth muscle of cerebral arteries, causing an amyloid angiopathy and chronic brain hypoperfusion, contributing to neurodegeneration. In some cases, differentiating AD from vascular dementia may be difficult (see next section) (Fig. 17.13).[52] However, the role of amyloid-beta protein in the diagnosis of AD is controversial as individuals without clinical manifestations of dementia have amyloid-beta plaques like individuals with dementia and individuals with other neurodegenerative diseases. There is also a hypothesis that amyloid-beta proteins may play a protective role in herpes-induced AD. There are different forms of amyloid-beta proteins and it is not yet clear which forms are the most pathological and by what mechanism they cause dementia.[53]

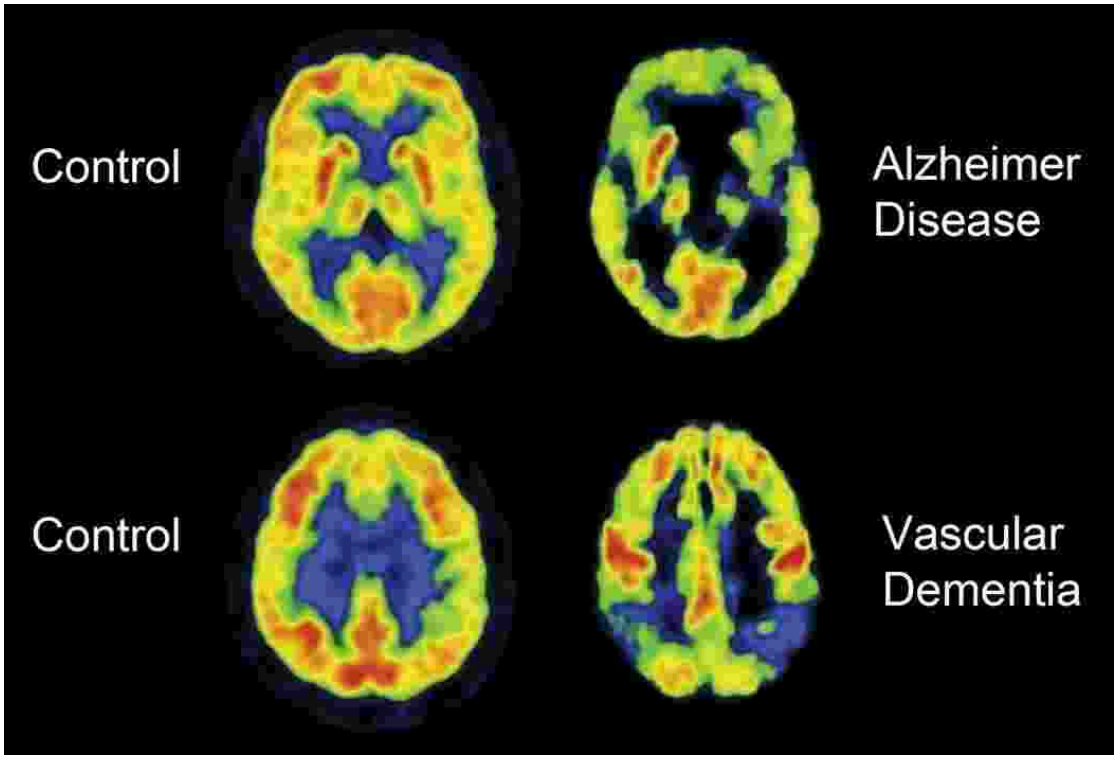

FIG. 17.13 PET scan comparison of Alzheimer disease (AD) and vascular dementia (VD; tracer added to glucose). Clinically, the severity of dementia was comparable. However, the pattern of pathologic changes differentiated these two diseases: in AD there is hypometabolism bilateral in the parieto-temporal cortex and to a lesser degree in the frontal association areas, whereas the primary cortical regions are spared; in VD there are patchy metabolic defects in the frontal lobe, basal ganglia, and thalamus. (From Heiss WD, Zimmermann-Meinzingen S. PET imaging in the differential diagnosis of vascular dementia. *Journal of Neurological Sciences*, 2012:322(1–2):268–273.)

The tau protein (a microtubule-binding protein) in neurons becomes hyperphosphorylated, detached from microtubules, and forms an insoluble intracellular filament called a **neurofibrillary tangle**. Tangles are flame-shaped (Fig. 17.14) and have been implicated in neuronal death by blocking transport of essential nutrients into the neuron. The spread of tau protein in the brain has four different distinct variants associated with AD symptoms (Box 17.4). Identifying tau variants within individuals with AD may lead to a better understanding of prognoses and clinical symptoms. Because different variants may respond differently to treatment, the goal is to have variant-specific interventions to reduce the accumulation of tau protein in the brain.[54]

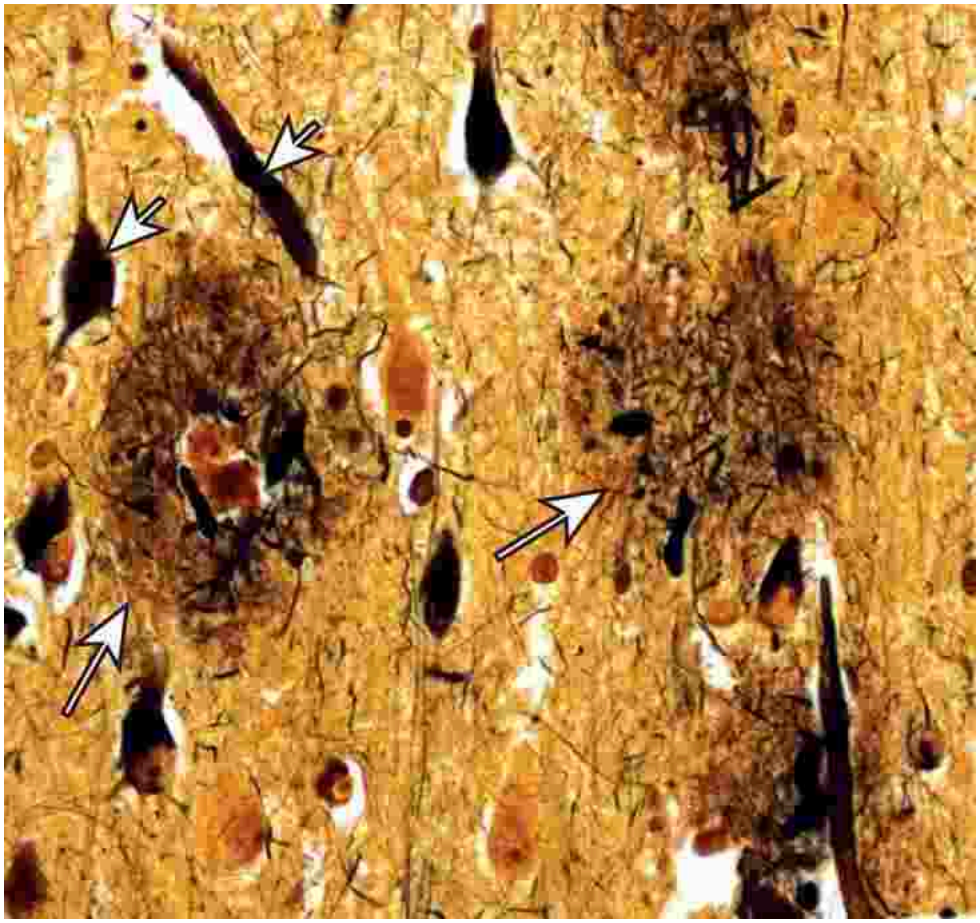

FIG. 17.14 Major Histopathologic Changes in Alzheimer Disease

Box 17.4

Variants of Tau Protein Distribution and Symptoms of Alzheimer Disease

Variant one (33%)—affects the temporal lobe and causes memory impairment.
Variant two (18%)—spreads in the cerebral cortex and causes problems with executive function but does not affect memory as much as variant one.
Variant three (30%)—causes the accumulation of tau protein in the visual cortex. Individuals with this variant have difficulties with orientation and distinguishing shapes, distance, location, and movement.
Variant four (19%)—spreads in an asymmetrical fashion in the left side of the brain and affects language abilities.

Data from: Vogel JW, Young AL, Oxtoby NP, et al. Four distinct trajectories of tau deposition identified in Alzheimer's disease. *Nature Medicine*, 2021;27(5):871–881.

Neuritic plaques and neurofibrillary tangles are more concentrated in the cerebral cortex and hippocampus (important for memory). The loss of neurons results in brain atrophy with decreases in weight and volume. The sulci widen, and the gyri thin, especially in the frontal and temporal lobes, and the ventricles enlarge to fill the space (Fig. 17.15). Loss of synapses, acetylcholine, and other neurotransmitters contributes to the decline of memory and attention and the loss of other cognitive functions associated with AD.

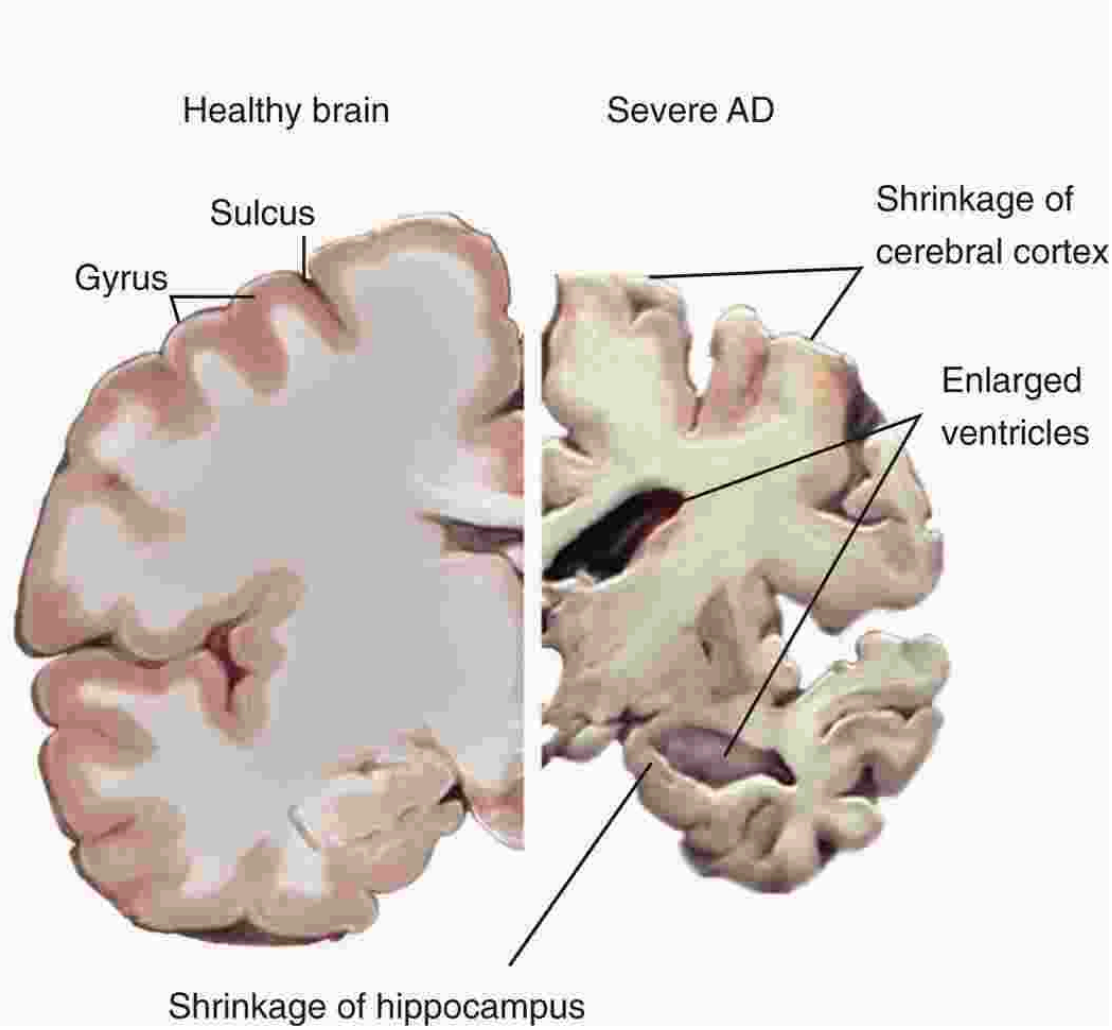

FIG. 17.15 Comparison of Normal and Alzheimer Brain
The brain decreases in volume and weight, the sulci widen, and the gyri thin, especially in the temporal and frontal lobes. The ventricles enlarge to fill the space. *AD*, Alzheimer disease. (From National Institute on Aging Scientific Images, Brain images. Available at https://www.nia.nih.gov/alzheimers/scientific-images.)

Two cross-sections of the brain compare the shape and size of a normal brain with that of a brain with Alzheimer disease. The gyrus and the sulcus in the healthy brain are identified. The shrinkage of cerebral cortex, enlarged ventricles, and shrinkage of hippocampus in a brain with severe Alzheimer's disease are identified.

Aging and injury may result in systemic changes and inflammation that contribute to the development and progression of AD. Misfolded and aggregated amyloid-beta and tau proteins trigger immune responses with activation of microglia and release of cytokines leading to neuroinflammation and oxidative stress, decreased oxygen and glucose transport, molecular changes in vascular smooth muscle and the blood-brain barrier, and mitochondrial defects that alter cell metabolism and processing of proteins that lead to neuronal cell death.[55–57]

Infectious factors have also been associated with increased rates of AD. Herpes simplex virus-1 (HSV-1) and its viral DNA has been found within the amyloid plaques of persons diagnosed with AD. As HSV-1 has an extremely high prevalence rate in all populations, the correlation between AD and HSV-1 is significant. In many individuals, the HSV-1 virus becomes latent within neuronal cells, and antibodies are produced against the virus; however, if an individual is immunocompromised, HSV-1 can become reactivated. This reactivated viral replication can cause inflammation and damage to neuronal cells, leading to AD. Human immunodeficiency viral infection (HIV) has also been associated with AD as the virus causes increased production of amyloid-beta proteins and decreased ability to clear these proteins. The Epstein-Barr virus, varicella zoster virus, spirochetes, and *Chlamydia pneumoniae* have also been linked to neuronal damage and cell death leading to AD.[58,59] In women, estrogen decline during the menopausal transition can promote a systemic inflammatory state contributing to neurodegenerative disease.[60] Sleep deprivation and sleep apnea can influence expression and development of AD.[61,62] Recently, it has been suggested that there is bidirectional neural, hormonal, and immunological signaling along the gut-brain microbial axis. Alterations in the gut microbiome (dysbiosis) have been hypothesized to lead to brain dysfunction and AD. These alterations can be caused by aging, dietary patterns, lifestyle, and infection.[63,64] (See Emerging Science Box: The Oral and Gut Microbiome and Alzheimer Disease.)

Clinical Manifestations

AD has a long preclinical and prodromal course, and pathophysiologic changes can occur decades before the appearance of the clinical dementia syndrome. The disease progresses from mild, short-term memory deficits to total loss of cognition and executive functions. Initial clinical manifestations are insidious and often attributed to forgetfulness, emotions, or other illness. The individual becomes progressively more forgetful over time, particularly in relation to recent events. Memory loss increases as the disorder advances, and the person becomes disoriented, confused, and loses the ability to concentrate. Abstraction, problem solving, and judgment gradually deteriorate with failure in mathematic calculation ability, language, and visuospatial orientation. Dyspraxia may appear.

Mental status changes induce behavioral changes, including irritability, agitation, and restlessness. Mood changes result from the deterioration in cognition. The person may become anxious, depressed, hostile, emotionally labile, and prone to mood swings. Motor changes may occur if the posterior frontal lobes are involved, causing rigidity and flexion posturing. Weight loss can be significant in the later stages of AD due to difficulty swallowing, aspiration, and decreased appetite. Skin breakdown and pressure ulcers are commonly seen in the later stages of AD as well. Great variability in age of onset, intensity and sequence of symptoms, and location and extent of brain abnormalities is common. Stages for the progression of AD are summarized in Table 17.16.

Table 17.16

Progression of Alzheimer Disease

Stage	Mild Cognitive Impairment	Early Stage	Middle Stage	Late Stage	End Stage
Cognitive	Mild memory loss, particularly for recent event (episodic memory) and new information (semantic memory)	Measurable short-term memory loss; difficulty planning; disorientation to location	Significant forgetfulness; easy to get lost; may dress inappropriately; may hallucinate	Little cognitive ability; language not clear; personality change; does not recognize family members; wandering; repetitive behavior	No significant c function; los speech
Functional	Possibly depression (vs. apathy); mild anxiety	Mild IADL problems	IADL-dependent; some ADL problems	ADL-dependent; incontinent; difficulty eating	Nonambulatory unable to eat

Stage	Mild Cognitive Impairment	Early Stage	Middle Stage	Late Stage	End Stage
Cognitive	Mild memory loss, particularly for recent event (episodic memory) and new information (semantic memory)	Measurable short-term memory loss; difficulty planning; disorientation to location	Significant forgetfulness; easy to get lost; may dress inappropriately; may hallucinate	Little cognitive ability; language not clear; personality change; does not recognize family members; wandering; repetitive behavior	No significant cognitive function; loss of word speech
Functional	Possibly depression (vs. apathy); mild anxiety	Mild IADL problems	IADL-dependent; some ADL problems	ADL-dependent; incontinent; difficulty eating	Nonambulatory/bedbound; unable to eat

ADL, Activities of daily living; *IADL*, instrumental activities of daily living.

Adapted from National Conference of Gerontological Nurse Practitioners and the National Gerontological Nursing Association. *Counseling Points* 2008;1(1):6.

Once an individual reaches end-stage dementia, they are often unable to ambulate or communicate and need assistance with all the activities of daily living. Death typically occurs from AD-related sequelae, such as aspiration pneumonia and sepsis.

Evaluation and Treatment

The clinical diagnosis of AD is made by ruling out other causes and utilizing the criteria that have been developed to assist in making a diagnosis.[65] A definitive diagnosis can only be made at autopsy. The clinical history, including mental status examinations (mini–mental status examination, clock drawing, and geriatric depression scale), cerebrospinal fluid analysis, brain imaging of structure, blood flow and

metabolism, and the course of the illness (which may span 5 years or more) is used to assess progression of the disease. Genetic susceptibility tests for *PSEN1*, *PSEN2*, and *APP* are used to screen for EOAD.[66]

Progress has been made in identifying imaging and biochemical markers to assist with risk assessment, early diagnosis, and evaluation of progression of Alzheimer-type and other neurodegenerative causes of dementia. A CT or MRI may show cortical and asymmetric hippocampal atrophy, both signs of AD. PET imaging can diagnose early-AD by showing accumulations of amyloid and hyperphosphorylated tau proteins. CSF biomarkers that indicate AD are low amyloid levels and high tau levels. Serum biomarker levels of amyloid protein can also indicate AD.[67] More recently, flotillin-1, a protein found in the plasma membrane of neurons within the amygdala, hippocampus, and isocortex of individuals with AD, has been identified as a promising serum and CSF biomarker. Low levels of flotillin-1 would indicate an AD diagnosis.[68]

AD currently has no cure. Therefore, treatment is directed at using devices to compensate for impaired cognitive function, such as memory aids, maintaining unimpaired cognitive functions, and maintaining or improving the general state of hygiene, nutrition, and health. Though healthy diet and exercise are recommended, randomized clinical trials have not shown that specific diets or supplements have a role in arresting the pathogenesis of dementia. Nonpharmacological interventions, such as providing specialized caregiver-patient dyad care plans and multidisciplinary care (social work, physical therapy, occupational therapy, speech and language therapy, caregiver support groups, and palliative and hospice care), have been effective in maintaining patient-caregiver quality of life.

Unfortunately, there are few pharmacotherapy options available to treat AD, and those available are largely ineffective at slowing the long-term progression of AD. Cholinesterase inhibitors (ChE-Is) are used in mild to moderate AD cases. Preserving acetylcholine in the brain is thought to delay neurofibrillary degeneration and death of neurons.[69] An *N*-methyl-D-aspartate (NMDA) receptor antagonist blocks glutamate activity and may provide symptom relief in moderate to severe AD. Excess glutamate is excitotoxic by allowing excess calcium to enter cells, causing cell death. NMDA receptor antagonists are thought to stabilize synaptic transmission and are neuroprotective.[70]

Currently, combination drug trials with disease-modifying and symptomatic therapies are being conducted. Add-on trials are being conducted with new medications that target amyloid proteins, tau proteins, or neuroinflammation while continuing standard treatment with ChE-Is or NMDA receptor antagonists. Combination therapies with symptomatic medications (targeting cognition, agitation, and seizures) include utilization of a 5-HT receptor antagonist, MAO-B inhibitor, anticonvulsants, melatonin, and glutamate modulators.[71] Anti-amyloid drugs targeting amyloid-beta and small molecules that can cross the blood-brain barrier as well as stem cell therapy are under investigation (see Emerging Science Box: Aducanumab for the Treatment of Alzheimer Disease).

Vascular cognitive impairment (vascular dementia)

Vascular cognitive impairment (vascular dementia) is a progressive disease and the second most common cause of dementia following AD (10% to 20% of cases). The specific pathogenesis of vascular dementia is not clearly known, but it is caused by reduced brain blood flow.[72] The pathology can be variable, including carotid artery stenosis, intracranial atherosclerotic small vessel disease, multiple ischemic infarcts, and hemorrhages that occur in different parts of the brain. The chronic hypoperfusion is associated with increased blood-brain barrier permeability, neuronal dysfunction and death, loss of white matter, and brain atrophy (see Fig. 17.13). Risk factors are the same as those for cerebrovascular disease: hypercholesterolemia, hypertension, diabetes, coronary artery disease, obesity, older age, physical inactivity, diet, and depression.[73,74]

There is no typical presentation for vascular dementia. The disease can be difficult to differentiate clinically from AD, and the symptoms can be much more variable. The diseases often coexist as a mixed dementia. Loss of executive function, decreased cognitive speed, and loss of information processing often occur first. Brain imaging provides the most definitive diagnosis. Prevention by reducing cardiovascular risk factors is a key strategy in stopping or slowing progression to vascular dementia. Treatment is mainly supportive and consists of multidisciplinary care.[75]

Frontotemporal dementia

FTD, previously known as ***Pick disease***, is a form of dementia and a degenerative disease of the frontal lobes. The specific mechanism of pathogenesis is unknown; however, there is a familial association with an age of onset less than 60 years and an estimated lifetime risk of 1 in 742. Most cases involve mutations of genes encoding tau protein, progranulin, and chromosome 9.[76] Three distinct clinical syndromes or variants have been described depending on the site of atrophy: frontal variant affecting behavior (loss of social function), personality progressive nonfluent aphasia, and semantic dementia (loss of meaning of words). Individuals with FTD may have a genetic predisposition to developing ALS or PD. MRI neuroimaging can identify grey matter atrophy and white matter abnormalities within the frontal and temporal lobes. Currently, there are no identified serum or CSF biomarkers or specific disease-modifying treatments. Supportive multidisciplinary care is recommended.[77,78]

Alterations in Cerebral Hemodynamics

An injured brain reacts with structural, chemical, and pathophysiologic changes. Primary brain injury is the original trauma, and secondary brain injury (see Chapter 18) is a consequence of alterations in cerebral blood flow, **intracranial pressure** (**ICP**), oxygen delivery, and inflammation. Several relevant features of cerebral hemodynamics relate to cerebral oxygenation (Box 17.5).

Box 17.5

Cerebral Hemodynamics

Cerebral blood flow (CBF) to the brain is normally maintained at a rate that matches local metabolic needs of the brain. CBF to gray matter is about 3 to 4 times greater than that to white matter because of the increased metabolic activity.
Cerebral perfusion pressure (CPP) (70–90 mm Hg) is the pressure required to perfuse the cells of the brain.
Cerebral blood volume (CBV) is the amount of blood in the intracranial vault at a given time.
Cerebral blood oxygenation is measured by oxygen saturation in the internal jugular vein.
Intracranial pressure (ICP) is normally 1–15 mm Hg, or 60–180 cm H_2O.

Alterations in cerebral blood flow may be related to three injury states: inadequate cerebral perfusion, normal cerebral perfusion but with an elevated ICP, and excessive **cerebral blood volume (CBV**—hyperemia). Treatments for these injury states are directed at improving or maintaining **cerebral perfusion pressure (CPP)** and controlling ICP. Target values for relevant cerebral blood flow parameters are presented in Table 17.17.

Table 17.17

Therapeutic Management Goals for Individuals With Altered Cerebral Hemodynamics

Clinical Parameter	Target Value
Central perfusion pressure	>70 mm Hg
Intracranial pressure	<20 mm Hg
Arterial CO_2 pressure ($PaCO_2$)	35 mm Hg
Mean arterial pressure	90 mm Hg
Temperature	34°C–36°C (93.2°F–96.8 °F)
Pulmonary capillary wedge pressure	10–15 mm Hg

Increased Intracranial Pressure

ICP normally is 5 to 15 mm Hg, or 60 to 180 mm H_2O. **IICP**, or intracranial hypertension, is generally defined as ICP greater than 20 to 25 mm Hg and may result from an increase in intracranial content (as occurs with tumor growth), edema, excess CSF, or hemorrhage. It necessitates an equal reduction in volume of the other cranial contents. The most readily displaced content is CSF. If ICP remains high after CSF displacement out of the cranial vault, CBV and blood flow are altered.

There are four progressive stages of IICP. In *stage 1 of intracranial hypertension*, vasoconstriction and external compression of the venous system occur to further decrease the ICP. Thus, during the first stage of IICP, the ICP may not change because of effective compensatory mechanisms, and there may be few symptoms (Fig. 17.16). Small increases in volume, however, cause an increase in pressure, and the pressure may take longer to return to baseline. This can be detected with ICP monitoring.

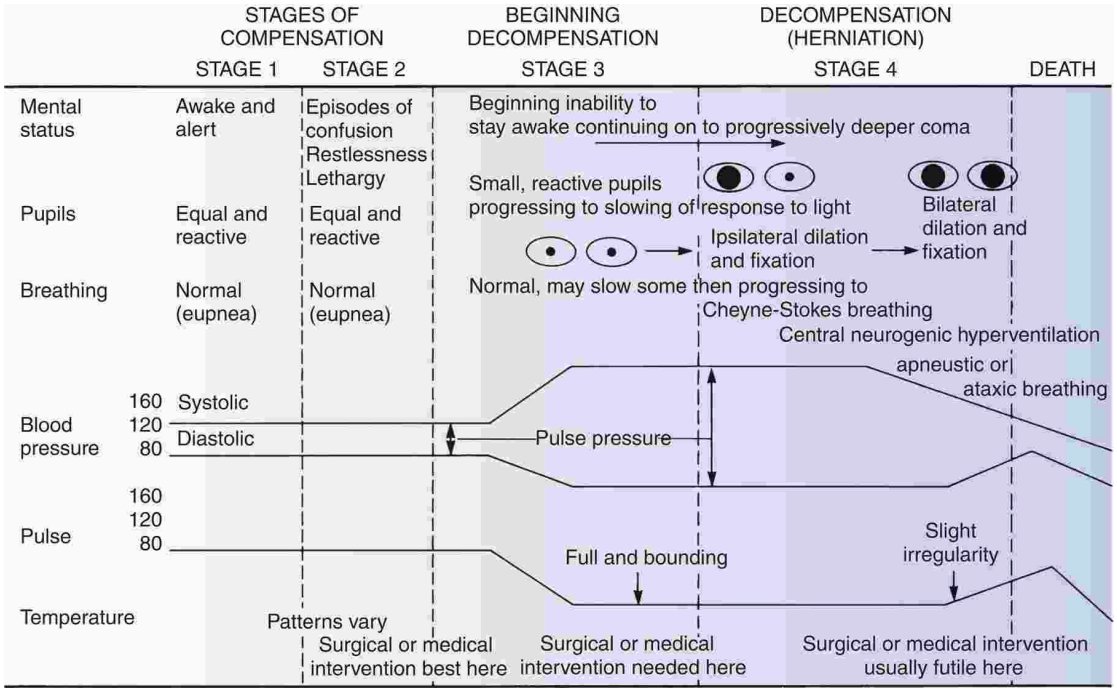

FIG. 17.16 Clinical Correlates of Compensated and Uncompensated Phases of Intracranial Hypertension. (From Beare PG, Myers JL. *Principles and practice of adult health nursing*, 3rd edition. St. Louis: Mosby; 1998.)

A table with illustrations shows the clinical correlations of compensated and uncompensated phases of intracranial hypertension. The stages in the table are as follows. 1. Stages of compensation: Stage 1 and Stage 2. 2. Beginning of decompensation: Stage 3. 3. Decompensation (herniation): Stage 4. 4. Death. The data from the table are as follows. • Mental status. Awake and alert at Stage 1. Episodes of confusion, restlessness, and lethargy at Stage 2. Beginning inability to stay awake at Stage 3. Progression to deeper coma at Stage 4. • Pupils. Equal and reactive at Stage 1 and Stage 2. Small, reactive pupils at Stage 3. Progression to slow response to light at Stage 3, including ipsilateral dilation and fixation at the beginning of Stage 4 and bilateral dilation and fixation at the end Stage 4. • Breathing. Normal (eupnea) at Stage 1 and Stage 2. Normal to slow at Stage 3. Progression to Cheyne-Stokes breathing at the beginning of Stage 4 and central neurogenic hyperventilation by the end of Stage 4. • Blood pressure. 160 to 120 systolic, 120 to 80 diastolic at Stage 1 and Stage 2. Increased systolic and decreased diastolic at Stage 3 and beginning of Stage 4. Decreasing systolic and decreasing diastolic at death. • Pulse. 160, 120, 80 at Stage 1 and Stage 2. Full and bounding at Stage 3. Slight irregularity at Stage 4. Decreasing diastolic at death. • Temperature. Patterns vary at Stage 1 and Stage 2. Surgical or medical intervention best at Stage 2. Surgical or medical interventional needed at Stage 3. Surgical or medical interventional is usually futile at the end of Stage 4.

In *stage 2 of intracranial hypertension*, there is continued expansion of intracranial contents. The resulting IICP may exceed the brain's compensatory capacity to adjust. The pressure begins to compromise neuronal oxygenation, and systemic arterial vasoconstriction occurs to elevate the systemic blood pressure sufficiently to overcome the IICP. Clinical manifestations at this stage are usually subtle and transient, including episodes of confusion, restlessness, drowsiness, and slight pupillary and breathing changes (see Fig. 17.16). Interventions at this stage reduce ICP and promote better clinical outcomes.

In *stage 3 of intracranial hypertension*, the ICP begins to approach arterial pressure, the brain tissues begin to experience hypoxia and hypercapnia, and the individual's condition rapidly deteriorates. Clinical manifestations include decreasing levels of arousal or central neurogenic hyperventilation, widened pulse pressure, bradycardia, and pupils that become small and sluggish (see Fig. 17.16).

Dramatic, sustained rises in ICP are not seen until all compensatory mechanisms have been exhausted. Then, dramatic rises in ICP occur over a very short period. **Autoregulation**, the compensatory alteration in the diameter of the intracranial blood vessels designed to maintain a constant blood flow during changes in CPP, is lost with progressively IICP. Accumulating carbon dioxide may still cause vasodilation locally, but without autoregulation, this vasodilation causes the hydrostatic (blood) pressure in the vessels to drop and blood volume to increase. The increasing pressure may exceed venous pressure and obstruct venous outflow. The brain volume is thus further enhanced, and ICP continues to rise. Small increases in volume cause dramatic increases in ICP, and the pressure takes much longer to return to baseline. As the ICP begins to approach systemic blood pressure, CPP falls, and cerebral perfusion slows dramatically. The brain tissues experience severe hypoxia, hypercapnia, and acidosis, all of which cause cerebrovascular vasodilation.

In *stage 4 of intracranial hypertension*, brain tissue shifts (herniates) from the compartment of greater pressure to a compartment of lesser pressure. IICP in one compartment of the cranial vault is not evenly distributed throughout the other vault compartments (see Figs. 17.16 and 17.17). With this shift in brain tissue, the herniating brain tissue's blood supply is compromised, causing further ischemia and hypoxia in the herniating tissues. The volume of content within the lower pressure compartment increases, exerting pressure on the brain tissue that normally occupies that compartment and impairing its blood supply. For example, herniation into the brainstem impairs the vital cardiovascular and respiratory regulatory centers and can cause death. Obstructive hydrocephalus, a blockage that prevents the flow of CSF in the brain, may develop. The herniation process markedly and rapidly increases ICP. Mean systolic arterial pressure soon equals ICP, and cerebral blood flow ceases at this point. The types of **herniation syndromes** are outlined in Box 17.6.

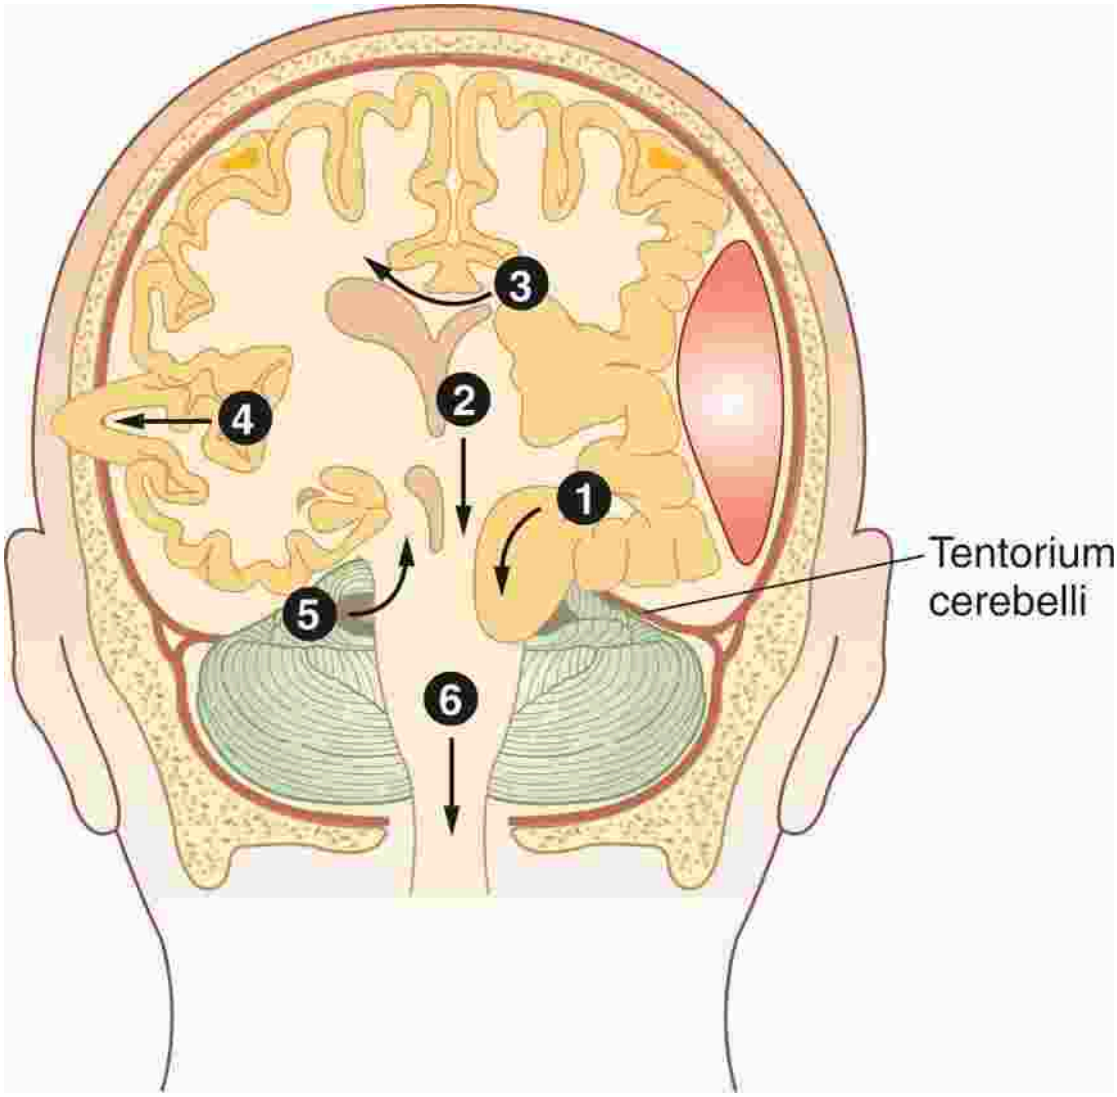

FIG. 17.17 Brain Herniation. Herniations can occur both above and below the tentorium cerebelli. *Supratentorial: 1*, uncal (transtentorial); *2*, central; *3*, cingulate; *4*, transcalvarial (external herniation through an opening in the skull). *Infratentorial: 5*, upward herniation of cerebellum; *6*, cerebellar tonsil moves down through foramen magnum.

Box 17.6

Brain Herniation Syndromes

Supratentorial Herniation

1. *Uncal herniation*. This occurs when the uncus or hippocampal gyrus, or both, shifts from the middle fossa through the tentorial notch into the posterior fossa, compressing the ipsilateral third cranial nerve, the contralateral third cranial nerve, and the mesencephalon. Uncal herniation generally is caused by an expanding mass in the lateral region of the middle fossa. The classic manifestations of uncal herniation are a decreasing level of consciousness, pupils that become sluggish before fixing and dilating (first the ipsilateral, then the contralateral pupil),

Cheyne-Stokes respirations (which later shift to central neurogenic hyperventilation), and the appearance of decorticate and then decerebrate posturing.

2. *Central herniation*. This is the straight downward shift of the diencephalon through the tentorial notch. It may be caused by injuries or masses located around the outer perimeter of the frontal, parietal, or occipital lobes; extracerebral injuries around the central apex (top) of the cranium; bilaterally positioned injuries or masses; and unilateral cingulate gyrus herniation. The individual rapidly becomes unconscious; moves from Cheyne-Stokes respirations to apnea; develops small, reactive pupils and then dilated, fixed pupils; and passes from decortication to decerebration.
3. *Cingulate gyrus herniation*. This occurs when the cingulate gyrus shifts under the falx cerebri. Little is known about its clinical manifestations.
4. *Transcalvarial herniation*. The brain shifts through a skull fracture or a surgical opening in the skull. This type of external herniation may occur during a craniectomy—surgery in which a flap of skull is removed, preventing the piece of skull from being replaced.

Infratentorial Herniation

The most common syndrome is *cerebellar tonsillar herniation*. The cerebellar tonsil shifts down through the foramen magnum because of increased pressure within the posterior fossa. The clinical manifestations are a stiff arched neck, paresthesias in the shoulder area, decreased consciousness, respiratory abnormalities, and pulse rate variations. Occasionally the force produces an *upward transtentorial* herniation of a cerebellar tonsil or the lower brainstem. There is increased intracranial pressure with compression of the ascending arousal system and loss of consciousness. If the cerebral aqueduct is compressed, there can be obstructive hydrocephalus. Cerebellar ischemia may occur from compression of the superior cerebellar artery (see Fig. 17.17).

Cerebral Edema

Cerebral edema is an increase in the fluid content of brain tissue (Fig. 17.18). The result is increased extracellular or intracellular tissue volume. It occurs after brain insult from trauma, inflammation, infection, toxicity, hemorrhage, tumor, ischemia, infarction, or hypoxia. The harmful effects of cerebral edema are caused by the distortion of blood vessels, the displacement of brain tissues, IICP, and the eventual herniation of brain tissue to a different brain compartment.

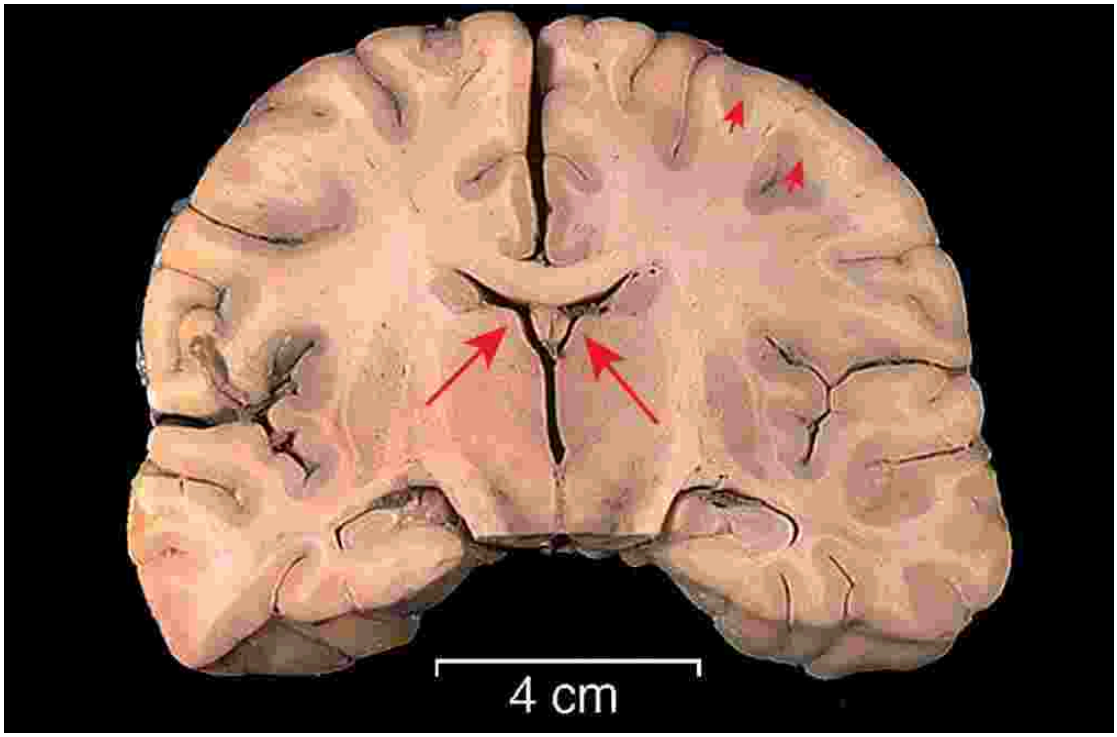

FIG. 17.18 Brain Edema
. This coronal section of cerebrum demonstrates marked compression in the lateral ventricles *(long arrows)* and flattening of gyri *(short arrows)* from extensive bilateral cerebral edema. Edema increases intracranial pressure, leading to herniation. (From Klatt EC. *Robbins and Cotran atlas of pathology*, 2nd edition. Philadelphia: Saunders; 2010.)

A closeup of a cross-section of a brain specimen with edema. The reference scale at the bottom measures the compression of the lateral ventricles at four centimeters. The flattening of the gyri is also identified at the edges of the cross-section.

There are three types of cerebral edema: (1) vasogenic edema, (2) cytotoxic (metabolic) edema, and (3) interstitial edema. **Vasogenic edema** is clinically the most common form. It is caused by the increased permeability of the capillaries (inflammatory response) that form the blood-brain barrier. Consequently, plasma proteins leak into the extracellular spaces, drawing water to them, and increasing the water content of brain parenchyma. Vasogenic edema begins in the area of injury and spreads with fluid accumulating in the white matter of the ipsilateral side because the parallel myelinated fibers separate more easily. Edema promotes formation of more edema because of ischemia from the IICP.

Clinical manifestations of vasogenic edema include focal neurologic deficits, disturbances of consciousness, and a severe increase in ICP. Vasogenic edema resolves by slow diffusion of fluid back into the blood stream.

In **cytotoxic (metabolic) edema**, toxic factors directly affect the cellular elements of the brain parenchyma (neuronal, glial, and endothelial cells), causing failure of the active transport systems. The most common cause is ischemia/hypoxia. The blood-brain barrier is not disrupted. The cells lose their potassium and gain larger amounts of sodium because of failure of cell membrane ion pumps. Water follows by osmosis into the cell so that the cells swell (intracellular edema). Cytotoxic edema occurs principally in the gray matter and may lead to increased vasogenic edema because of the loss of endothelial tight junctions.

Interstitial edema is seen most often with noncommunicating or obstructive hydrocephalus (see following section and Chapter 20). The edema is caused by increased CSF volume and transependymal movement of CSF from the ventricles into the extracellular spaces of the brain tissues. The brain fluid volume thus is increased predominantly around the ventricles. The hydrostatic pressure within the white matter increases, and the size of the white matter is reduced because of the rapid disappearance of myelin lipids.

Treatment of cerebral edema is directed at decreasing IICP. Treatment can include the use of oxygen, osmotherapy (e.g., mannitol), diuretics, the placement of a CSF drain tube, and maintenance of systemic blood pressure with fluid management. Steroids (dexamethasone) may be used to treat edema associated with brain tumors. Work is in progress to identify drug treatments that prevent cerebral edema before perfusion is compromised.[79]

Hydrocephalus

The term **hydrocephalus** refers to various conditions characterized by an excess of fluid within the cerebral ventricles, subarachnoid space, or both (see Fig. 20.8). Hydrocephalus occurs because of interference with CSF flow caused by increased fluid production, obstruction within the ventricular system, or defective reabsorption of the fluid. A tumor of the choroid plexus may, in rare instances, cause overproduction of CSF (Fig. 17.19). Hydrocephalus may develop from infancy through adulthood.

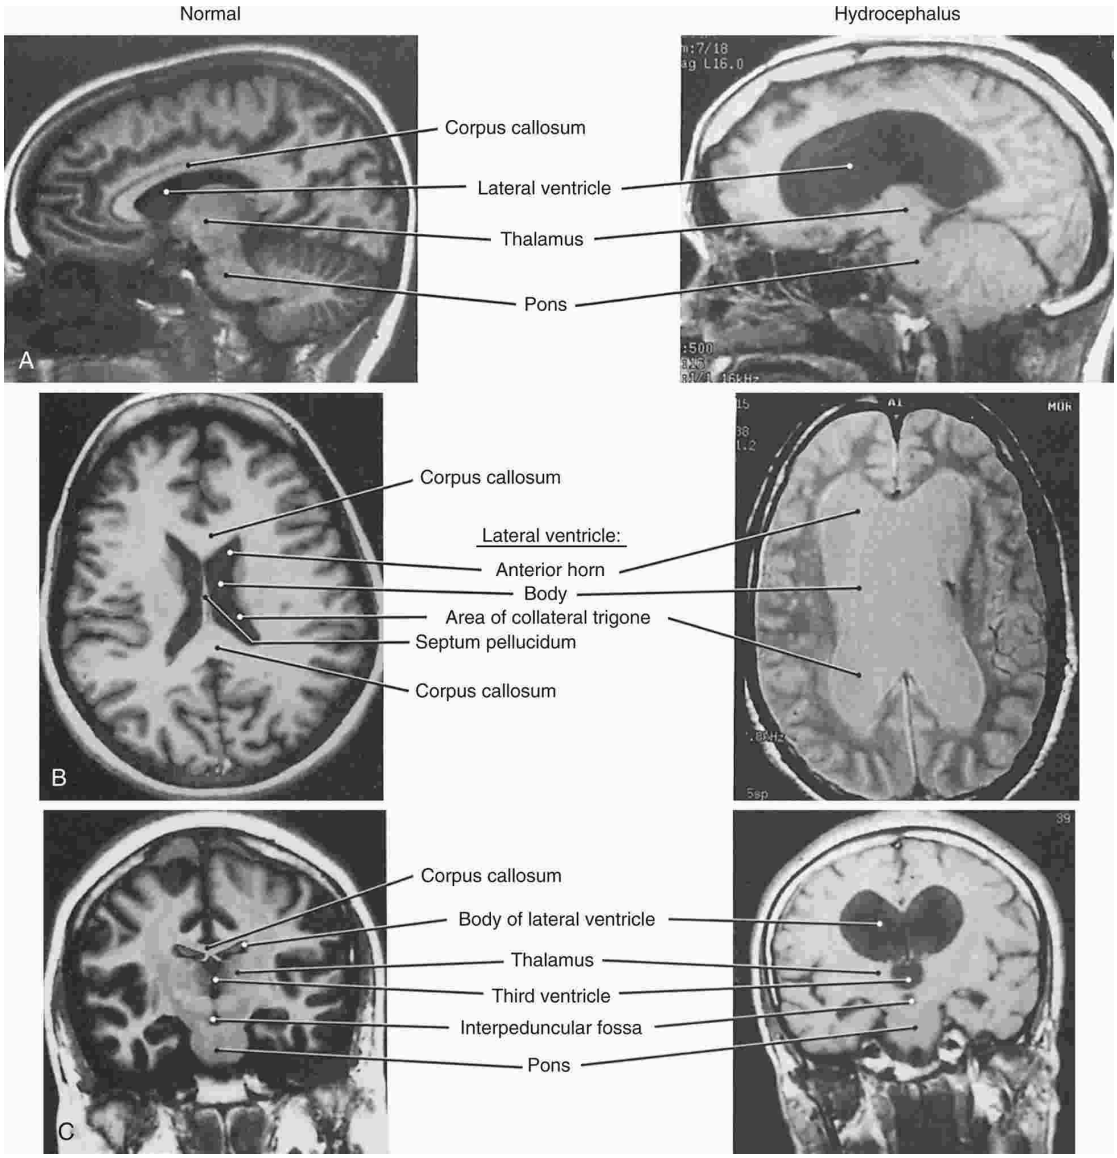

FIG. 17.19 Comparison of Normal and Hydrocephalic Brains
(A) Sagittal; **(B)** axial; and **(C)** coronal planes as seen in magnetic resonance imaging (MRI). (From Haines DE, ed. *Fundamental neuroscience for basic and clinical applications*, 4th edition. Philadelphia: Saunders; 2013.)

Three pairs of radiographs showing the lateral, superior, and posterior views of the brain compare the structures in a normal brain with those in a hydrocephalic brain. Top panel, A, lateral views of the brain. In the hydrocephalus brain, the corpus callosum is missing, the lateral ventricle is enlarged, the thalamus is smaller, and the pons is bigger. Middle panel, B, superior views of the brain. In the hydrocephalus brain, the corpus callosum and the septum pellucidum are missing, and the anterior horn, the body, and the area of collateral trigone are fused. Bottom panel, C, posterior views of the brain. In the hydrocephalus brain, the corpus callosum is missing, the body of lateral ventricle is enlarged, the

thalamus is smaller, the third ventricle is larger, the interpeduncular fossa is larger, and the pons is larger.

Types of Hydrocephalus

Noncommunicating hydrocephalus (obstructive)*(internal or intraventricular hydrocephalus)* is caused by obstruction within the ventricular system and occurs more often in children (see Chapter 20). Impaired absorption of CSF from the subarachnoid space occurs when an obstructive process disrupts the flow of CSF through the subarachnoid space. The fluid is prevented from reaching the convex portion of the cerebrum where the arachnoid granulations are located. There is dilation of the ventricular system proximal to the obstruction.

Communicating hydrocephalus (nonobstructive)*(extraventricular)* results from impaired reabsorption of CSF in the absence of obstruction between the ventricles and subarachnoid space. The most common causes of communicating hydrocephalus are subarachnoid hemorrhage, developmental malformation, head injury, neoplasm, inflammation (e.g., meningitis), scar tissue formation, high venous pressure in the sagittal sinus, and increased CSF secretion by the choroid plexus. It occurs more commonly in adults.

Normal-pressure hydrocephalus (NPH) is the dilation of the ventricles without increased pressure. It is a slowly developing form of communicating hydrocephalus that is often idiopathic and occurs mostly after age 65. Age-related impairment of meningeal lymphatic CSF drainage and glymphatic fluid exchange between CSF and interstitial fluid may contribute to the pathogenesis of idiopathic NPH.[80] The ventricles are enlarged, and the CSF pressure is minimally elevated. This form of hydrocephalus can also occur secondarily as a complication of head injury, subarachnoid hemorrhage, or can be associated with a benign external hydrocephalus (enlarged frontal subarachnoid spaces) in infancy.[81]**Acute hydrocephalus** may develop within several hours in persons who have sustained head injuries and is also known as traumatic hydrocephalus (see Subarachnoid Hemorrhage in Chapter 18). Acute hydrocephalus contributes significantly to IICP.

Pathophysiology

The obstruction of CSF flow associated with hydrocephalus produces increased pressure and dilation of the ventricles proximal to the obstruction. The increased pressure and dilation cause atrophy of the cerebral cortex and degeneration of the white matter tracts. Selective preservation of gray matter occurs. When excess CSF fills a defect caused by atrophy, a degenerative disorder, or a surgical excision, this fluid is not under pressure; therefore, atrophy and degenerative changes are not induced. This is known as **hydrocephalus ex vacuo**.

Clinical Manifestations

Most cases of hydrocephalus develop gradually and insidiously over time. Symptoms can include dizziness, headaches, nausea, vomiting, gait disturbances, change in personality, and seizures. Acute hydrocephalus presents with signs of rapidly developing IICP. The person rapidly deteriorates into a deep coma if not promptly treated. NPH has a long-term presentation and develops slowly over time. A triad of symptoms, including declining memory with loss of cognitive function; unsteady, broad-based gait; and urinary urgency and incontinence from detrusor overactivity, are common and make diagnosis difficult to differentiate from other causes of dementia. Additional clinical manifestations are apathy, inattentiveness, and indifference to self, family, and the environment.[82]

Evaluation and Treatment

A diagnosis of hydrocephalus is made based on clinical history, physical examination, CT scan, MRI, and evaluation of CSF dynamic parameters. A radioisotopic cisternogram may be performed to diagnose NPH. Hydrocephalus can be treated by surgery to resect cysts, neoplasms, or hematomas or by ventricular bypass into the normal intracranial channel or into an extracranial compartment using a shunting procedure, one of the three most common neurosurgical procedures. Excision or coagulation

of the choroid plexus is occasionally needed when a papilloma is present. In NPH, reduction in CSF is achieved through diuresis or placement of a ventriculoperitoneal shunt.[83]

Alterations in Neuromotor Function

Movements are complex patterns of activity controlled by the cerebral cortex, upper motor neurons of the pyramidal system, lower motor neurons (LMNs) (including the cranial and spinal nerves and gamma motor neurons) originating in the spinal cord and terminating at the myoneural junction (see section on Neuromuscular Junction), and the extrapyramidal system (EPS) (basal ganglia, thalamus, reticular formation, and cerebellum). Dysfunction in any of these areas can cause motor dysfunction. Alterations in motor function are associated with changes in muscle tone, muscle movement, and complex motor performance. Some types of diseases and disorders have concurrent alterations in cognitive, sensory, and autonomic nervous system function.

Upper and Lower Motor Neuron Syndromes

Upper Motor Neuron Syndromes

Upper motor neurons are nerves that travel in the pyramidal tract, divide into the corticobulbar and corticospinal tracts, and synapse on LMNs in the brainstem (cranial nerves) or lateral and anterior spinal cord (peripheral nerves). They carry the signals for voluntary motor movement. **Upper motor neuron syndromes** are the result of injury to pyramidal pathways that descend from the motor cortex (Figs. 17.20, 17.21, and 15.15). Upper motor neuron injury may be in the cerebral cortex, subcortical white matter, internal capsule, brainstem, or spinal cord but above the anterior horn cell. Injury may be caused by trauma, stroke, tumor, or infection (see Chapter 18). The injury causes the upper motor neuron signs and symptoms that are summarized in Table 17.18.

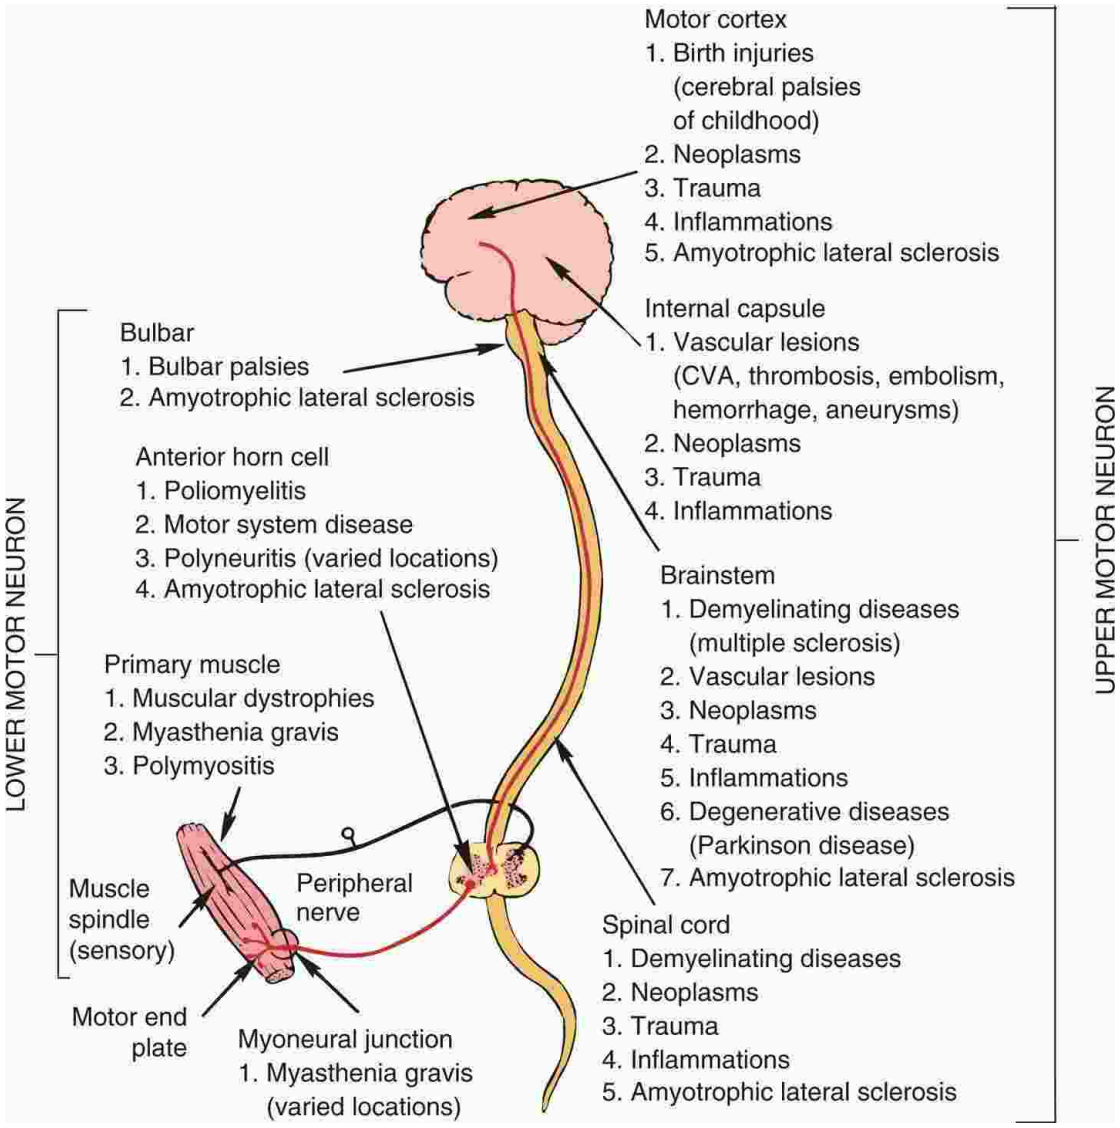

FIG. 17.20 Disturbances in Motor Function.
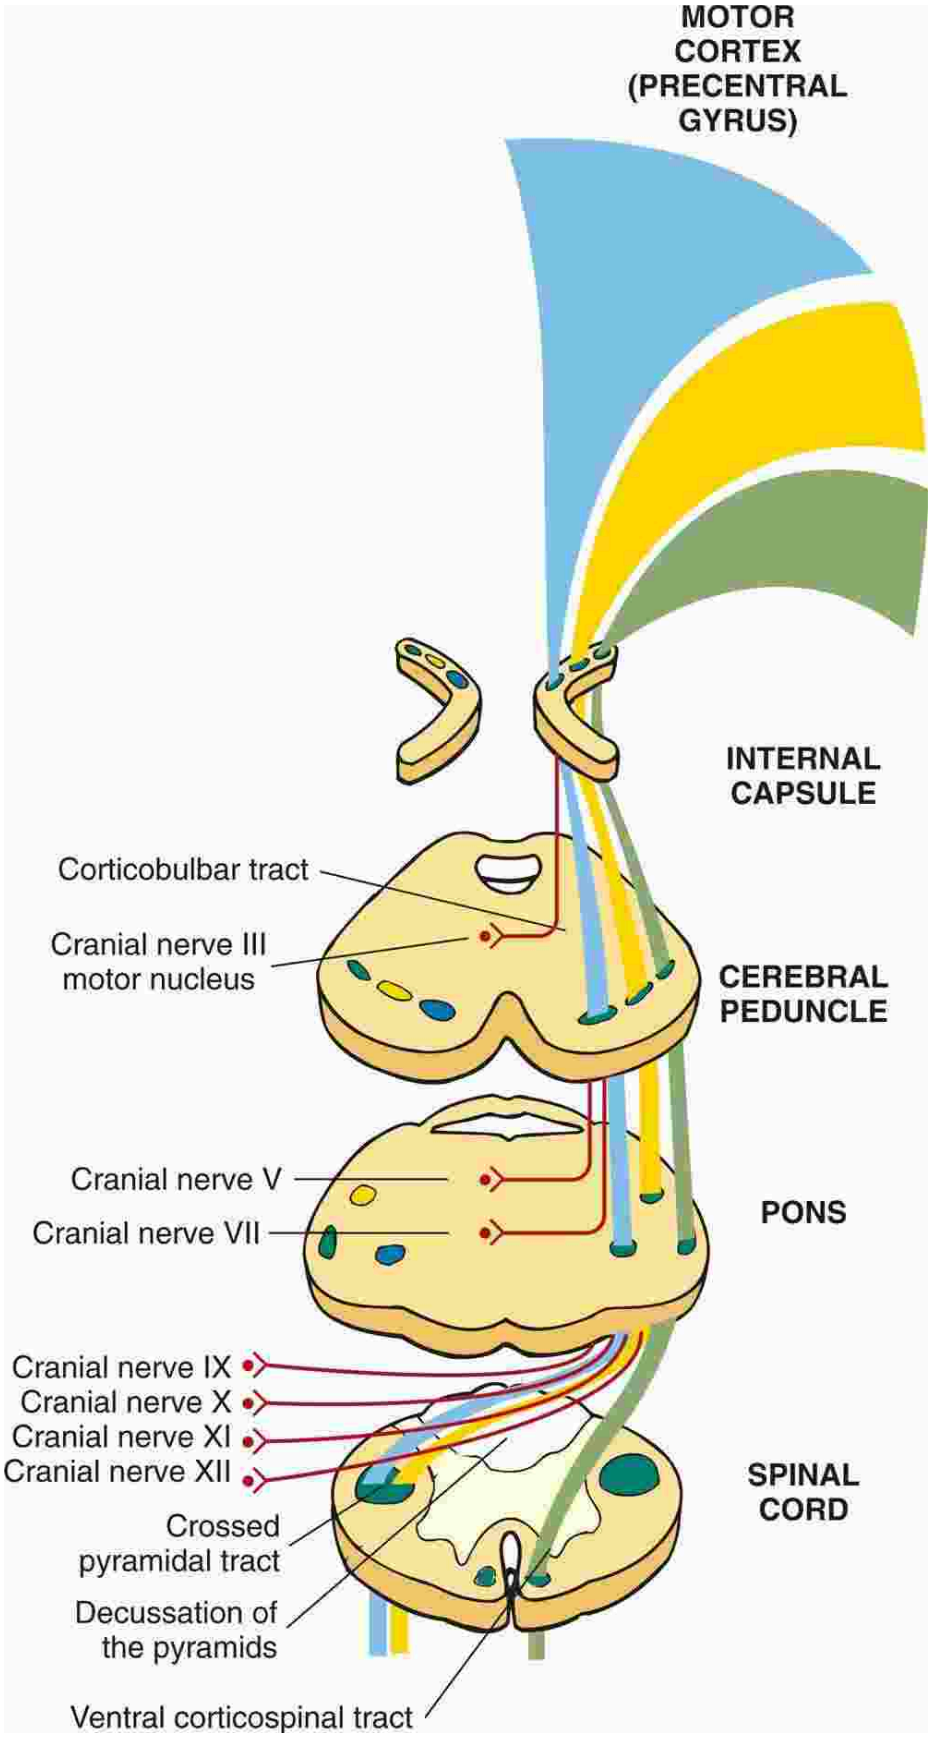
Disturbances in motor function are classified pathologically along upper and lower motor neuron structures. It should be noted that neoplasms occur at more than one site in an upper motor neuron *(above right)*. A few pathologic conditions, such as amyotrophic lateral sclerosis, involve upper and lower motor neuron structures. Other lesion sites include myoneural junctions and primary muscles, making it possible to classify conditions as neuromuscular and muscular, respectively. *CVA*, Cerebrovascular accident.

An illustration of the upper motor neuron (motor cortex, internal capsule, brainstem, and spinal cord) and the lower motor neuron (bulbar, anterior horn cell, primary muscle, and myoneural junction) lists the disturbances in motor function. The disturbances in the motor cortex are as follows. 1. Birth injuries (cerebral palsies of childhood). 2. Neoplasms. 3. Trauma. 4. Inflammations. 5. Amyotrophic lateral sclerosis. The disturbances in the internal capsule are as follows. 1. Vascular lesions (C V A, thrombosis, embolism, hemorrhage,

aneurysms). 2. Neoplasms. 3. Trauma. 4. Inflammations. The disturbances in the brainstem are as follows. 1. Demyelinating diseases (multiple sclerosis). 2. Vascular lesions. 3. Neoplasms. 4. Trauma. 5. Inflammations. 6. Degenerative diseases (Parkinson disease). 7. Amyotrophic lateral sclerosis. The disturbances in the spinal cord are as follows. 1. Demyelinating diseases. 2. Neoplasms. 3. Trauma. 4. Inflammations. 5. Amyotrophic lateral sclerosis. The disturbances in the bulbar are as follows. 1. Bulbar palsies. 2. Amyotrophic lateral sclerosis. The disturbances in the anterior horn cell are as follows. 1. Poliomyelitis. 2. Motor system disease. 3. Polyneuritis (varied locations). 4. Amyotrophic lateral sclerosis. The disturbances in the primary muscle are as follows. 1. Muscular dystrophies. 2. Myasthenia gravis. 3. Polymyositis. The disturbance in the myoneural junction is as follows. 1. Myasthenia gravis (varied locations). The muscle spindle (sensory), motor end plate, and peripheral nerve of the myoneural junction are identified.



MOTOR CORTEX (PRECENTRAL GYRUS)

Cranial nerve X
Cranial nerve XI
Cranial nerve XII
SPINAL CORD
Crossed pyramidal tract
Decussation of the pyramids
Ventral corticospinal tract

FIG. 17.21 Structures of the Upper Motor Neuron, or Pyramidal, System. Pyramidal system fibers are shown to originate primarily in the cells in the precentral gyrus of the motor cortex; to converge at the internal capsule; to descend to form the central third of the cerebral peduncle; to descend further through the pons, where small fibers supply cranial nerve motor nuclei along the way; to form pyramids at the medulla, where most of the fibers decussate; and then to continue to descend in the lateral column of the white matter of the spinal cord. A few fibers descend without crossing at the medulla level.

An illustration of the cross-sections of the internal capsule, the cerebral peduncle, the pons, and the spinal cord show the structures of the upper motor neuron. The structures identified on the cross-sectional illustrations are as follows. • Cerebral peduncle: corticobulbar tract, cranial nerve 3 motor nucleus. • Pons: cranial nerve 5, cranial nerve 7. • Spinal cord: cranial nerve 9, cranial nerve 10, cranial nerve 11, cranial nerve 12 exit before spinal cord; crossed pyramidal tract, decussation of the pyramids, and ventral corticospinal tract.

Table 17.18

Upper and Lower Motor Neuron Syndromes Signs and Symptoms

Upper Motor Neuron (Pyramidal Cells—Motor Cortex)	Lower Motor Neuron (Cranial Nerve Nuclei—Brainstem; Ventral Horn—Spinal Cord)
Muscle groups are affected	Individual muscles may be affected
Mild weakness (paresis)	Mild weakness (paresis)
Spastic paralysis	Flaccid paralysis
Minimal disuse muscle atrophy	Marked muscle atrophy
No fasciculations	Fasciculations
Hyperreflexia, increased muscle stretch reflexes (clasp-knife spasticity; resistance to passive flexion that releases abruptly to allow easy flexion)	Hyporeflexia, decreased muscle stretch reflexes
Clonus may be present	Clonus not present
Hypertonia, spasticity	Hypotonia, flaccidity
Pathologic reflexes (Babinski and Hoffmann signs, loss of abdominal reflexes)	No Babinski sign
Often initial impairment of only skilled movements	Asymmetric and may involve one limb only in beginning to become generalized as disease progresses

Upper motor neuron paresis is partial paralysis with incomplete loss of muscle power, whereas paralysis is complete loss of motor function. Different terms are used to describe the location of paralysis (Box 17.7). Upper motor neuron injury causes clinical manifestations that reflect muscle overactivity (spasticity and clonus) and loss of descending inhibitory control on LMNs. There is great

variation in symptomology, depending on extent of injury, the suddenness of onset, and the age of the individual.

Box 17.7

Upper Motor Neuron Paralysis

Hemiparesis/hemiplegia is paresis/paralysis of the upper and lower extremities on one side.
Diplegia is paralysis of corresponding parts of both sides of the body as a result of cerebral hemisphere injuries.
Paraparesis/paraplegia is weakness/paralysis of the lower extremities as a result of lower spinal cord injury.
Quadriparesis/quadriplegia is paresis/paralysis of all four extremities as a result of upper spinal cord injury (spinal cord injury is discussed in Chapter 18).

If the pyramidal system is interrupted above the level of the pons, the hand and arm muscles are significantly affected. Paralysis rarely involves all the muscles on one side of the body even when the hemiplegia results from complete damage to the internal capsule. Bilateral movements, such as those of the eye, jaw, and larynx, are affected only slightly, if at all. The antigravity muscles of the legs are predominately influenced. Because of their bilateral control, trunk muscles are much less affected. Spasticity is common, although rigidity occasionally occurs. Most often, passive range of motion causes the "clasp-knife" phenomenon or reflex (increased tone/resistance when rapidly flexing a limb joint with sudden relaxation) by activating stretch receptors in the muscle spindles and Golgi tendon organ. (Muscle function is discussed in Chapter 43.) The Babinski sign is present (an abnormal plantar reflex-stroking the sole of the foot causes extension of the big toe rather than the normal dorsiflexion and fanning of the other toes). The presence of the Babinski sign is normal in infants prior to maturation of the corticospinal tracts. Dysphagia and dysarthria are associated with damage to the corticobulbar tract. Interruption of the pyramidal tract below the pons results in spinal shock (see Chapter 18) with complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function.

Lower Motor Neuron Syndromes

Lower (primary, alpha) motor neurons are the large motor neurons that arise from nuclei in the anterior (ventral) horn of the spinal cord and the motor nuclei of the brainstem. They receive input from upper motor neurons, sensory neurons, and interneurons and extend as peripheral nerves to the myoneural junction. The axons from the nerve cell bodies directly innervate extrafusal fibers of skeletal muscles through the anterior spinal roots or cranial nerves (Fig. 17.22) and cause skeletal muscle contraction. Damage to alpha motor neurons (the cell body or the axon and surrounding myelin) results in symptoms called LMN syndromes.[84] The symptoms result from impairment of voluntary and involuntary movement, usually without sensory impairment (see Table 17.18). The symptoms include flaccid paresis or paralysis, hypotonia, hyporeflexia or areflexia, muscle atrophy, fasciculations, and fibrillations. The paresis and paralysis associated with anterior horn cell injury are segmental, but because each muscle is supplied by two or more spinal nerve roots, the segmental character of the weakness may be difficult to recognize. The cause of LMN syndromes can be sporadic or hereditary. Polio, facial (Bell) palsy (Box 17.8), and spinal muscular atrophy (rare inherited diseases of anterior horn cells) are examples of LMN diseases. The degree of paralysis or paresis is proportional to the number of LMNs affected. If only some of the motor units that supply a muscle are affected, only partial paralysis or paresis results. If all the motor units are affected, complete paralysis results. Other clinical manifestations also are proportional to the degree of dysfunction, but the precise manifestations depend on the location of the dysfunction in the motor unit and in the CNS.

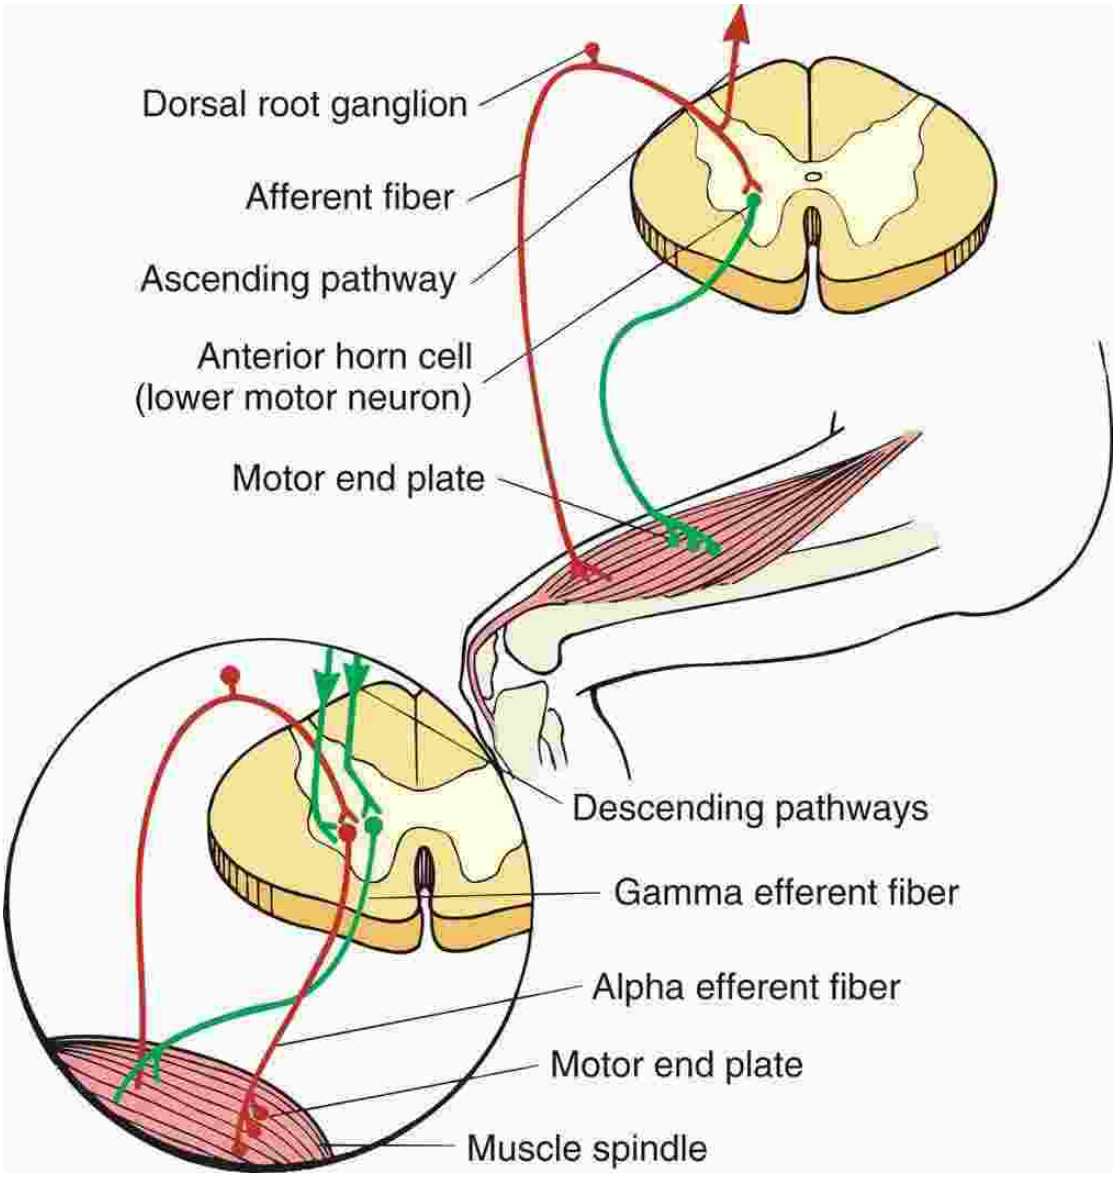

FIG. 17.22 Component Structure of a Lower Motor Neuron, Including Motor (Efferent) and Sensory (Afferent) Elements

. *Top*, Anterior horn cell (in anterior gray column of spinal cord and its axon), terminating in motor end plate as it innervates extrafusal muscle fibers in the quadriceps muscle. *Detailed enlargement:* Sensory and motor elements of the gamma loop system. The gamma efferent fiber is shown innervating the polar, or end, region of the muscle spindle (sensory receptor of skeletal muscle). Contraction of muscle spindle fibers stretches the central portion of the spindle and causes the afferent spindle fiber to transmit the impulse centrally to the cord. Muscle spindle afferent fibers in turn synapse on the anterior horn cell and are transmitted by way of gamma efferent fibers to skeletal (extrafusal) muscle, causing it to contract. Muscle spindle discharge is interrupted by active contraction of extrafusal muscle fibers.

An illustration of cross-section of the lower motor neuron identifies the following structures, from the top to the bottom: dorsal root ganglion, afferent fiber, ascending pathway (afferent), anterior horn cell (lower motor neuron),

motor end plate, descending pathways (efferent), gamma efferent fiber, alpha efferent fiber, motor end plate, and muscle spindle.

Box 17.8

Bell Palsy

Bell palsy is the most common paralysis of the seventh cranial (facial) nerve. The etiology of Bell palsy remains unknown, and diagnosis remains one of exclusion. There is usually an inflammatory reaction compressing the facial nerve in the fallopian (facial) canal of the middle ear, particularly in the narrowest labyrinthine segment, followed by demyelinating neural change. The most distressing symptoms are unilateral facial weakness and inability to smile or whistle. Bell palsy may be caused by reactivation of herpesviruses in cranial nerve VII (facial) geniculate ganglia or an autoimmune response. The signs usually have an acute onset (within 72 h). Herpes simplex type 1 has been detected in up to 78% of cases and herpes zoster in 30% of cases. Severe pain with facial palsy and a vesicular rash in the ear or mouth suggest herpes zoster infection. Ramsay Hunt syndrome (herpes zoster oticus) is rare, but complete recovery is less than 50%. Recovery from Bell palsy is usually complete within 4 months to 1 year and may not require treatment. Both disorders may be treated with antivirals, corticosteroids, or both, and physiotherapy. Facial nerve decompression is considered for complete facial nerve paralysis. Treatment should be individualized according to severity of symptoms.

Data from Zhang W, Xu L, Luo T, et al. The etiology of Bell's palsy: A review. *Journal of Neurology*, 2020;267(7):1896–1905; Lee SY, Seong J, Kim YH. Clinical implication of facial nerve decompression in complete bell's palsy: A systematic review and meta-analysis. *Clinical and Experimental Otorhinolaryngology*, 2019;12(4):348–359.

Gamma neurons (fusimotor neurons) are small and innervate muscle spindles (proprioceptors), the striated portions of intrafusal muscle fibers. The cell body is in the anterior gray column of the spinal cord and is dependent on input from the muscle spindle (arriving through an afferent limb rising to the cord). Gamma neurons maintain an appropriate level of tension on the muscle spindle receptor and maintain sensitivity of the muscle to the stretch reflex, maintain muscle tone, and protect the muscle from injury. They do not cause movement of a joint; dysfunction in this sensory-motor system (the gamma loop or alpha-gamma loop) (see Fig. 17.22) impairs tone and reduces the tendon reflexes, causing hyporeflexia. The muscles become susceptible to damage from hyperextensibility because the normal protective mechanisms that prevent muscle fiber injury are impaired, as seen in Ehler-Danlos syndrome. The degree of muscle tone loss and the loss of tendon reflexes are proportional to the dysfunction in these reflex motor units. Generally, the alpha and gamma motor neuron systems are equally affected. Therefore, the muscle is hypotonic or atonic and is accompanied by hyporeflexia or areflexia (loss of tendon reflexes) and flaccid paresis/paralysis.

Denervated muscles (i.e., muscles that have lost their nervous system input) atrophy over weeks to months, mostly from disuse, and demonstrate fasciculations (spontaneous action potentials that cause muscle rippling or quivering under the skin). Occasionally, denervated muscles will cramp. Fibrillation is an isolated contraction of a single muscle fiber because of metabolic changes in denervated muscle and is not clinically visible.

Several brainstem syndromes involve damage to one or more of the cranial nerve nuclei. These are called *cranial nerve palsies* (e.g., oculomotor nerve and facial nerve palsies) and may be caused by vascular occlusion, tumor, aneurysm, tuberculosis, or hemorrhage. Cranial nerve palsies may cause complete or partial paralysis of the areas innervated by the affected nerve.

The anterior horn cells and the motor nuclei of the cranial nerves may be affected secondarily in many severe pathologic processes that primarily involve the peripheral nerves. The condition may extend proximally to affect the nerve roots or rootlets and the motor neurons themselves, a process commonly seen, for example, in Guillain-Barré syndrome (GBS) (see Chapter 18). If enough motor neurons are

destroyed, permanent loss of motor function results because regeneration of the damaged axons requires a living neuronal cell body.

A group of degenerative disorders principally cause progressive motor cell atrophy.[85] One of these disorders is **progressive spinal muscular atrophy**, an LMN disease in which degenerated anterior horn cells of the spinal cord are the affected motor neurons. This disorder occurs in adults and closely resembles the familial progressive muscular atrophies that occur in infants and children and are considered inherited metabolic disorders (see Chapter 45). If the motor nuclei of the cranial nerves are affected instead of the anterior horn cells, the disorder is labeled **progressive bulbar palsy** (a variant of ALS), so named because the myelencephalon (medulla and upper cranial nerves) originally was called the *bulb*, and a degenerative process causes a progressively more serious condition. When any LMN syndrome involves the cranial nerves that arise from the bulb (i.e., cranial nerves IX, X, and XII), the dysfunction is called a **bulbar palsy**.

The clinical manifestations of bulbar palsy include paresis or paralysis of the jaw, face, pharynx, and tongue musculature. Articulation is affected, especially articulation of the lingual *(r, n, l)*, labial *(b, m, p, f)*, dental *(d, t)*, and palatal *(k, g)* consonants. Modulation is impaired, making the voice rasping or nasal. Pharyngeal reflexes are diminished or lost. Palate and vocal cord movement during phonation is impaired, and chewing and swallowing are affected. The facial muscles are weak, and the face appears to droop. The jaw jerk reflex is decreased. Atrophy eventually becomes apparent, as do fasciculations. All these manifestations become progressively worse, leading to aspiration, malnutrition, possible dehydration, and an inability to communicate verbally.

Extrapyramidal Motor Syndromes

The EPS encompasses all the motor pathways except the upper and LMNs. The EPS primarily controls fine motor and involuntary/automatic movement, complex coordinated movements, postural control, and locomotion. The EPS modulates voluntary motility through tonic inhibition or facilitation. Several regions of the brain are involved, including parts of the cerebral cortex, the cerebellum, thalamus, reticular formation, and nuclei of the basal ganglia. These regions project subcortical tracts and terminate in the spinal cord providing a complex motor control system. Symptoms of alterations of involuntary movement include tremors, spasms, inability to maintain posture, hypotonia, weakness, slowness of movement, and impairment of voluntary movements. There may also be impairment of cognitive functions, including memory and affective disorders such as depression. Alterations in EPS function are primarily related to neurodegenerative diseases (i.e., PD, ALS, and HD) and involve selective components of the system.

Two types of motor dysfunction comprise the **extrapyramidal motor syndromes:** (1) the basal ganglia motor syndromes and (2) the cerebellar motor syndromes. The cerebellum and basal ganglia are interconnected and communicate with the motor cortex, thalamus, and sensory pathways to control voluntary movement. Their pathways synapse on LMNs. Unlike pyramidal or upper motor syndromes, extrapyramidal motor syndromes result in movement or posture disturbance without significant paralysis, along with other distinctive symptoms (Table 17.19). These syndromes are associated with neurodegenerative diseases.[86]

Table 17.19

Pyramidal Versus Extrapyramidal Motor Syndromes

Manifestations	Pyramidal Motor Syndrome	Extrapyramidal Motor Syndrome
Unilateral movement	Paralysis of voluntary movement	Little or no paralysis of voluntary movement
Tendon reflexes	Increased tendon reflexes	Normal or slightly increased tendon reflexes
Babinski sign	Present	Absent
Involuntary movements	Absence of involuntary movements	Presence of tremor, chorea, athetosis, or dystonia
Muscle tone	Spasticity in muscles (e.g., clasp-knife phenomenon)	Plastic (equal throughout movement) rigidity, or intermittent (generalized but predominantly in flexors of limbs and trunk) rigidity (cogwheel rigidity); Bradykinesia
	Hypertonia present in flexors of arms and extensors of legs	Hypotonia, weakness, and gait disturbance in cerebellar disease

Basal ganglia motor syndromes are movement disorders that involve either a paucity or an excess of involuntary movements: hypotonic/hyperkinetic (e.g., chorea [irregular intervals of successive jerk-like contractions] associated with HD) or hypertonic/hypokinetic (e.g., bradykinesia/akinesia associated with PD) syndromes.[87] Stress and nervous tension typically worsen the symptoms, whereas relaxation improves motor performance. Akinesia may occur despite normal strength. Involuntary hyperkinetic movements include resting tremor, chorea, ballism (rhythmic writhing movements of the proximal limbs), athetosis (slow continuous involuntary rolling writhing movement often in the hand), and dystonia (a sudden sustained contraction). They can be associated with brain trauma, stroke, tumors, infection, metabolic disorders, multiple sclerosis (MS), progressive supranuclear palsy, HD, and medication side effects.

Basal ganglia motor syndromes also are characterized by hypotonia and alterations in posture. Rigidity, together with the cogwheel phenomenon, is present in all muscle groups but is most prominent in those that maintain flexed position (as seen in PD). Postural abnormalities result from the loss of normal postural reflexes. Dysfunctional equilibrium results from the loss of postural stability.

Cerebellar motor syndromes involve the cerebellum and may result in (1) acute loss of muscle tone; (2) difficulty with coordination of goal-directed voluntary movements such as gait (ataxia) or purposeful arm movements; (3) minor degrees of muscle weakness (slurred speech, difficulty swallowing, altered eye movements), tendency toward fatigue, and impairment of associated movements; (4) intention tremor (occurs at the end of a purposeful movement, such as pushing a button) and essential tremor (most common and occurs involuntarily and manifests as a rhythmic shaking of the body); and (5) disorders of equilibrium and posture. These syndromes are associated with hereditary ataxias, stroke, brain trauma, MS, or tumors; systemic disorders (toxin exposure, celiac disease, heat stroke); or are idiopathic. Cerebellar effects can be ipsilateral (primarily affecting the same side of the body), so damage to the right cerebellum generally causes symptoms on the right side of the body. Predominant symptoms depend on the area and extent of damage within the cerebellum (Table 17.20).[88]

Table 17.20

Cerebellar Motor Syndromes

Anatomic Location of Dysfunction	Characteristics
Rostral vermis (so-called *anterior lobe*)	Ataxia of stance and gait with varying degrees of instability of the trunk and ataxia of legs; anteroposterior body sway; presence of Romberg sign
Caudal vermis (including flocculonodular lobe)	Truncal, postural, and gait ataxia; omnidirectional body sway; Romberg negative; tendency to fall; saccadic slow pursuit, nystagmus; inability to suppress vestibulo-ocular reflex (doll's eyes)
Cerebellar hemisphere (neocerebellar syndrome)	Severe disturbance in ipsilateral limb movements; hypotonia in acute situation; dysmetria (extremity overshooting its target); decomposition of movement; kinetic tremor, past-pointing; deviation of gait; dysarthria
Pancerebellum (combines all other syndromes)	Ataxia of trunk and bilateral limbs; ataxia of gait and stance; dysarthria; oculomotor disturbance

Data from McGee S. *Evidence-based physical diagnosis*, 4th edition. St. Louis: Elsevier; 2018; Timmann D, Diener HC. Coordination and ataxia. In: Goetz GC, ed. *Textbook of clinical neurology*. St. Louis: Saunders; 2007.

Alterations in Complex Motor Performance

The alterations in complex motor performance include disorders of posture (stance), disorders of gait and balance, and disorders of expression. They primarily involve alterations of coordinating functions between the extrapyramidal and pyramidal motor systems.

Disorders of Posture (Stance)

An inequality of tone in muscle groups because of a loss of normal postural reflexes results in a posturing of limbs. Many reflex systems govern tone and posture, but the most important factor in posture control is the stretch reflex, in which extensor (antigravity) muscles stretching, causes increased extensor tone and inhibited flexor tone. Four types of postural disorders are described: (1) dystonic posture, (2) decerebrate posture, (3) basal ganglion posture, and (4) senile posture. Equilibrium and balance are disrupted when postural disorders are present.

Dystonia is the maintenance of an abnormal posture through excessive muscular contractions. Dystonia can affect any muscle and occur at any age. When muscular contractions are sustained for several seconds, they are called **dystonic movements**. When contractions last for longer periods, they are called **dystonic postures**, such as in torticollis. Dystonic postures may last for weeks, causing permanent fixed contractures. Dystonia has been associated with basal ganglia abnormality, but the exact pathophysiologic mechanisms are unknown. Botulinum toxin injection is an effective treatment for some types of dystonia (Box 17.9).

Box 17.9

Treatment of Dystonia

Treatment of dystonia is individually determined. Botulinum toxin injection, both A and B, is effective in relieving cervical dystonia (spasmodic torticollis) symptoms in adults and is an effective treatment for focal dystonia and pain. Other drugs (benzodiazepines, gamma-aminobutyric acid

[GABA] inhibitors, atypical anticonvulsants, dopaminergic agonists and antagonists), surgical interventions (deep brain stimulation and ablative therapies) or physical therapies can provide symptom relief.

Data from Jinnah HA. Medical and surgical treatments for dystonia. *Neurologic Clinics*, 2020;38(2):325–348. Lizarraga KJ, Al-Shorafat D, Fox S. Update on current and emerging therapies for dystonia. *Neurodegenerative Disease Management*, 2019;9(3):135–147.

One dystonic posture is decorticate posture (striatal posture or upper motor neuron dysfunction posture), which may be unilateral or bilateral in occurrence. **Decorticate posture** (also known as antigravity posture, hemiplegic posture, or flexor posturing) is characterized by upper extremities that are flexed at the elbows and held close to the body and by lower extremities that are externally rotated and extended (see Fig. 17.6). Decorticate posture/response is believed to occur with injury to the midbrain when the brainstem is not inhibited by the motor function of the cerebral cortex. Upper motor neuron posture is more commonly described as the arm flexed at the elbow with a wristdrop; the leg inadequately bent at the knee, the hip excessively circumducted, and the presence of a footdrop.

Decerebrate posture (decerebrate rigidity, extensor posturing) refers to increased tone in extensor muscles and trunk muscles with active tonic neck reflexes. When the head is in a neutral position, all four limbs are rigidly extended (see Fig. 17.6). The decerebrate posture is caused by severe injury to the brain and brainstem, resulting in overstimulation of the postural righting and vestibular reflexes. Decerebrate posturing is also caused by reversible metabolic disorders including electrolyte disorders (e.g., hyponatremia, hypocalcemia), hypoglycemia, and encephalitis.

Basal ganglion posture refers to a stooped, hyperflexed posture with a narrow-based, short-stepped gait. This postural abnormality results from the loss of normal postural reflexes and not from defects in proprioceptive, labyrinthine, or visual function. Dysfunctional equilibrium results when the individual loses stability and cannot make the appropriate postural adjustment to tilting or loss of balance, falling instead. Dysfunctional righting is the inability to right oneself when changing from a lying or crouching to a standing position or when rolling from the supine to the lateral or prone position. Dysfunctional postural fixation is the involuntary flexion of the head and neck, causing the person difficulty in maintaining an upright trunk position while standing or walking. Basal ganglion dysfunction, with loss of dopaminergic and cholinergic neurons, accounts for this posture and is commonly associated with PD (see PD section).

Disorders of Gait and Balance

Performance of gait and maintenance of balance are coordinated by vision, the vestibular system, the frontal lobes, basal ganglia, and cerebellum. Four predominant types of gait associated with neurologic disorders are (1) upper motor neuron dysfunction gait, (2) cerebellar (ataxic) gait, (3) basal ganglion gait, and (4) frontal lobe ataxic gait. As with posture, equilibrium and balance are affected with gait disturbances.[89] Several upper motor neuron gaits exist. With mild forms, the individual may have footdrop, fatigue, hip pain, and leg pain. A **spastic gait**, which is associated with unilateral injury, is manifested by a shuffling gait with the leg extended and held stiff, causing a scraping over the floor surface. The leg swings improperly around the body rather than being appropriately lifted and placed. The foot may drag on the ground, and the person tends to fall to the affected side. A **scissors gait** is associated with bilateral injury and spasticity. The legs are adducted, causing them to touch each other. As the person walks, the legs are still swung around the body but then cross in front of each other because of adduction. Injury to the pyramidal system accounts for these gaits (e.g., stroke, cerebral palsy, MS, and spinal cord tumor).

A **cerebellar gait** is wide based with the feet apart and often turned outward or inward for greater stability. The pelvis is held stiff, and the individual staggers and cannot walk a straight line. There is decreased walking speed and stride length and difficulty with balance. Cerebellar dysfunction with loss of coordination accounts for this particular gait.[90]

A **basal ganglion gait** is a wide-based gait in which the person walks with small steps and a decreased arm swing. The head and body are flexed, and the arms are semiflexed and abducted,

whereas the legs are flexed and rigid in more advanced states. Basal ganglion dysfunction accounts for this gait and is associated with PD.

A **frontal lobe ataxic gait** is wide based with increased body sway and falls, loss of control of truncal motion, gait ignition failure, start hesitation, shuffling, and freezing. The gait is associated with frontal lobe damage or dementia. The pattern may change as the frontal disease progresses. The slowness of walking, lack of heel-shin or upper limb ataxia, dysarthria, or nystagmus distinguishes the wide stance from cerebellar gait ataxia.

Gait disorders are often accompanied by balance, coordination, and sensory dysfunction that further alter mobility and increase risk for falls. Assessment and intervention strategies are important for prevention of injury.

Disorders of Expression

Disorders of expression involve motor aspects of communication and include (1) pseudobulbar affect (PBA), also known as pathological laughing or crying, (2) aprosody, and (3) dyspraxias and apraxias. PBA is a disinhibition phenomenon of inappropriate episodes of exaggerated uncontrollable laughter, crying, or both, without an apparent motivational stimulus and incongruent with mood or feeling. It occurs with various neurologic diseases including stroke, tumors, ALS, PD, traumatic brain injury, and epilepsy. The exact pathophysiology is not known, but it is associated with loss of descending control of brainstem centers (i.e., cortico-pontine-cerebellar pathway) that control emotional expression with decreases in serotonin and dopamine and increases in glutamate.[91,92]

Aprosody is the loss of voice modulation (pitch, speed, emphasis, emotion). Receptive aprosody involves an inability to *understand* emotion in speech and facial expression, whereas expressive aprosody involves the inability to *express* emotion in speech and facial expression. Work is in progress to identify the neural pathways linked to aprosody, including hemispheric lateralization and the amygdala.[93,94]

Dyspraxia is the partial inability and **apraxia** is the complete inability to perform purposeful or skilled motor acts in the absence of paralysis, sensory loss, abnormal posture and tone, abnormal involuntary movement, incoordination, or inattentiveness. There is a disconnect between movement and the purpose of the movement.[95] These are disorders of learned skilled movements (e.g., arm and hand movement [eating], standing and turning around, blowing out a candle, and using tools). Dyspraxias/apraxias may result from any pathologic process that disrupts the cortical areas necessary for the conceptualization and execution of a complex motor act, primarily in the motor-dominant left hemisphere.[96] Subtypes of dyspraxias/apraxias are associated with different locations of brain injury and include both dorsal and ventral pathways.[96] Numerous neurologic disorders can be associated with apraxia. including vascular disorders, particularly stroke, trauma, tumor, and degenerative disorders (PD and dementia), infections, and metabolic disorders. Both motor and sensory neural networks play a role in the planning and execution of skilled movements. True dyspraxias/apraxias occur when the connecting pathways between the left and right cortical areas are interrupted, causing language-motor and motor representation disconnections between the hemispheres.

Alterations in Muscle Tone

Normal muscle tone involves a slight resistance to passive movement. The resistance is smooth, constant, and even throughout the range of motion. The alterations of muscle tone and their characteristics and causes are presented in Table 17.21.

Table 17.21

Alterations in Muscle Tone

Alterations	Characteristics	Cause
Hypotonia	Passive movement of a muscle mass with little or no resistance	Thought to be caused by decreased muscle spindle activity as a result of decreased excitability of alpha motor neurons (e.g., muscular dystrophy, cerebral palsy)
	Muscles may be moved rapidly without resistance	
Flaccidity	Associated with limp, atrophied muscles, and paralysis	Occurs typically when nerve impulses necessary for muscle tone are lost
Hypertonia	Increased muscle resistance to passive movement May be associated with paralysis	Results when upper motor neuron damage results in loss of inhibitory control of lower motor neurons (e.g., stroke, brain tumors, multiple sclerosis)
	May be accompanied by muscle hypertrophy	
Spasticity	A gradual increase in tone, causing increased resistance until tone suddenly diminishes, which results in clasp-knife phenomenon; increased deep tendon reflexes (hyperreflexia); clonus (spread of reflexes)	Damage to upper motor neurons with excitability of alpha motor neurons to any input because of absence of descending inhibition of pyramidal systems (e.g., multiple sclerosis, brain trauma, cerebral palsy)
Paratonia (gegenhalten)	Resistance to passive movement, which varies in direct proportion to force applied	Exact mechanism unclear; associated with frontal lobe injury (e.g., progressive Alzheimer dementia)
Dystonia	Sustained involuntary muscle contraction with twisting movement	Produced by slow muscular contraction; lack of reciprocal inhibition of muscle (e.g., neuroleptic drug side effects, meningitis)
Rigidity	Muscle resistance to passive movement of a rigid limb that is uniform in both flexion and extension throughout the motion	Occurs as a result of constant, involuntary contraction of muscle—usually involves extrapyramidal tracts (e.g., Parkinson disease)
Plastic or lead-pipe rigidity	Increased muscular tone relatively independent of degree of force used in passive movement; does not vary throughout the passive movement	Associated with basal ganglion damage (e.g., Parkinson disease)
Cogwheel rigidity	Uniform resistance may be interrupted by a series of brief jerks, resulting in	Associated with basal ganglion damage

Alterations	Characteristics	Cause
	movements much like a ratchet, "cogwheel" phenomenon	
Gamma rigidity	Characterized by extensor posturing (decerebrate rigidity)	Loss of excitation of extensor inhibitory areas by cerebral cortex decreasing inhibition of alpha and gamma motor neurons
Alpha rigidity	Impaired relaxation characterized by extensor rigidity of skeletal muscle after contraction	Loss of cerebellum input to lateral vestibular nuclei

Alterations	Characteristics	Cause
Hypotonia	Passive movement of a muscle mass with little or no resistance	Thought to be caused by decreased muscle spindle activity as a result of decreased excitability of alpha motor neurons (e.g., muscular dystrophy, cerebral palsy)
	Muscles may be moved rapidly without resistance	
Flaccidity	Associated with limp, atrophied muscles, and paralysis	Occurs typically when nerve impulses necessary for muscle tone are lost
Hypertonia	Increased muscle resistance to passive movement May be associated with paralysis	Results when upper motor neuron damage results in loss of inhibitory control of lower motor neurons (e.g., stroke, brain tumors, multiple sclerosis)
	May be accompanied by muscle hypertrophy	
Spasticity	A gradual increase in tone, causing increased resistance until tone suddenly diminishes, which results in clasp-knife phenomenon; increased deep tendon reflexes (hyperreflexia); clonus (spread of reflexes)	Damage to upper motor neurons with excitability of alpha motor neurons to any input because of absence of descending inhibition of pyramidal systems (e.g., multiple sclerosis, brain trauma, cerebral palsy)
Paratonia (gegenhalten)	Resistance to passive movement, which varies in direct proportion to force applied	Exact mechanism unclear; associated with frontal lobe injury (e.g., progressive Alzheimer dementia)
Dystonia	Sustained involuntary muscle contraction with twisting movement	Produced by slow muscular contraction; lack of reciprocal inhibition of muscle (e.g., neuroleptic drug side effects, meningitis)
Rigidity	Muscle resistance to passive movement of a rigid limb that is uniform in both flexion and extension throughout the motion	Occurs as a result of constant, involuntary contraction of muscle—usually involves extrapyramidal tracts (e.g., Parkinson disease)
Plastic or lead-pipe rigidity	Increased muscular tone relatively independent of degree of force used in passive movement; does not vary throughout the passive movement	Associated with basal ganglion damage (e.g., Parkinson disease)
Cogwheel rigidity	Uniform resistance may be interrupted by a series of brief jerks, resulting in movements much like a ratchet, "cogwheel" phenomenon	Associated with basal ganglion damage
Gamma rigidity	Characterized by extensor posturing (decerebrate rigidity)	Loss of excitation of extensor inhibitory areas by cerebral cortex decreasing inhibition of alpha and gamma motor neurons
Alpha rigidity	Impaired relaxation characterized by extensor rigidity of skeletal muscle after contraction	Loss of cerebellum input to lateral vestibular nuclei

Hypotonia

In **hypotonia (decreased muscle tone)**, passive movement of a muscle occurs with little or no resistance. Hypotonia is commonly a symptom of LMN damage with loss of reflexes. It is thought to be caused by decreased muscle spindle activity secondary to decreased excitability of alpha motor neurons. Hypotonia contributes to ataxia and intention tremor in cerebellar damage and manifests with minimal weakness and normal or slightly exaggerated reflexes. A pure pyramidal tract injury (very rare) produces hypotonia and weakness. Hypotonia, often described as flaccidity (a state in which the muscle

may be moved rapidly without resistance), occurs when nerve impulses necessary for muscle tone are lost, such as in spinal cord injury or cerebrovascular accident.

Individuals with hypotonia report that they tire easily (asthenia) or are weak. They may have difficulty rising from a sitting position, sitting down without using arm support, or walking up and down stairs, as well as an inability to stand on their toes. Because of their weakness, accident proneness during locomotion and self-care activities is common. The joints become hyperflexible, so people with hypotonia may be able to assume positions that require extreme joint mobility. The joints may appear loose. The muscle mass atrophies because of decreased neural input entering the motor unit. Muscle cells are gradually replaced by connective tissue and fat. The muscles are flabby on palpation and are flat in appearance. Fasciculations may be present in some cases.

Hypertonia

Hypertonia is increased muscle tone. With passive movement of a muscle, there is resistance to stretch. Hypertonia is caused by upper motor neuron damage with loss of inhibitory control of LMNs (see the section on Upper Motor Neuron Syndromes). The four types of hypertonia are spasticity (usually corticospinal in origin with overactivation of alpha motor neurons), paratonia **(**gegenhalten**)**, dystonia, and rigidity (usually extrapyramidal in origin). Four types of rigidity are described: plastic or lead-pipe, cogwheel, gamma (independent of stretch reflex pathways), and alpha (dependent on stretch reflex pathways) (see Table 17.21).

Spasticity results from hyperexcitability of the stretch reflexes (overactivation of the alpha motor neurons) and is associated with damage to upper motor neurons (motor, premotor, and supplementary motor areas, as well as the lateral corticospinal tract) (Fig. 17.23). Spasticity is accompanied by increased deep tendon reflexes (hyperreflexia) and the spread of reflexes (clonus).

FIG. 17.23 Left-Sided Hemifacial Spasm. (From Perkin GD. *Mosby's color atlas and text of neurology*. London: Mosby-Wolfe; 1998.)

Paratonia (gegenhalten) is resistance to passive movement that increases with velocity of movement. **Dystonia** is increased involuntary muscle contractions, manifested as sustained, involuntary twisting movements. It is caused by slow muscle contraction and may be caused by a failure of reciprocal inhibition of muscles in close proximity (Figs. 17.24 and 17.25). Impairment of several levels of sensorimotor integration between the cortex, cerebellum, basal ganglia, and thalamus contribute to dystonia and hyperkinetic movement.[97]

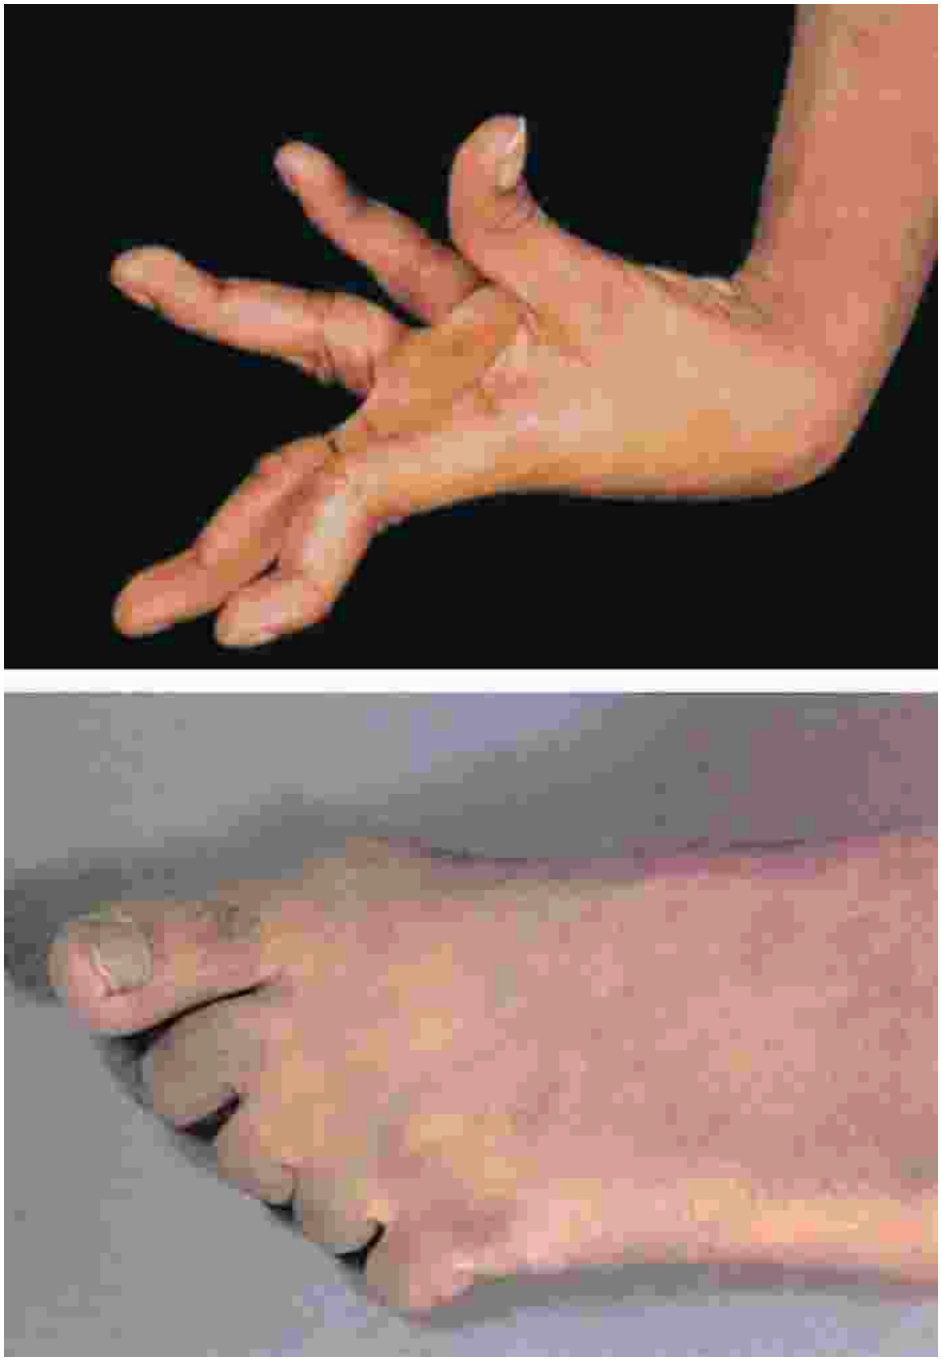

FIG. 17.24 Dystonic Posturing of the Hand and Foot. (From Perkin GD. *Mosby's color atlas and text of neurology*. London: Mosby-Wolfe; 1998.)

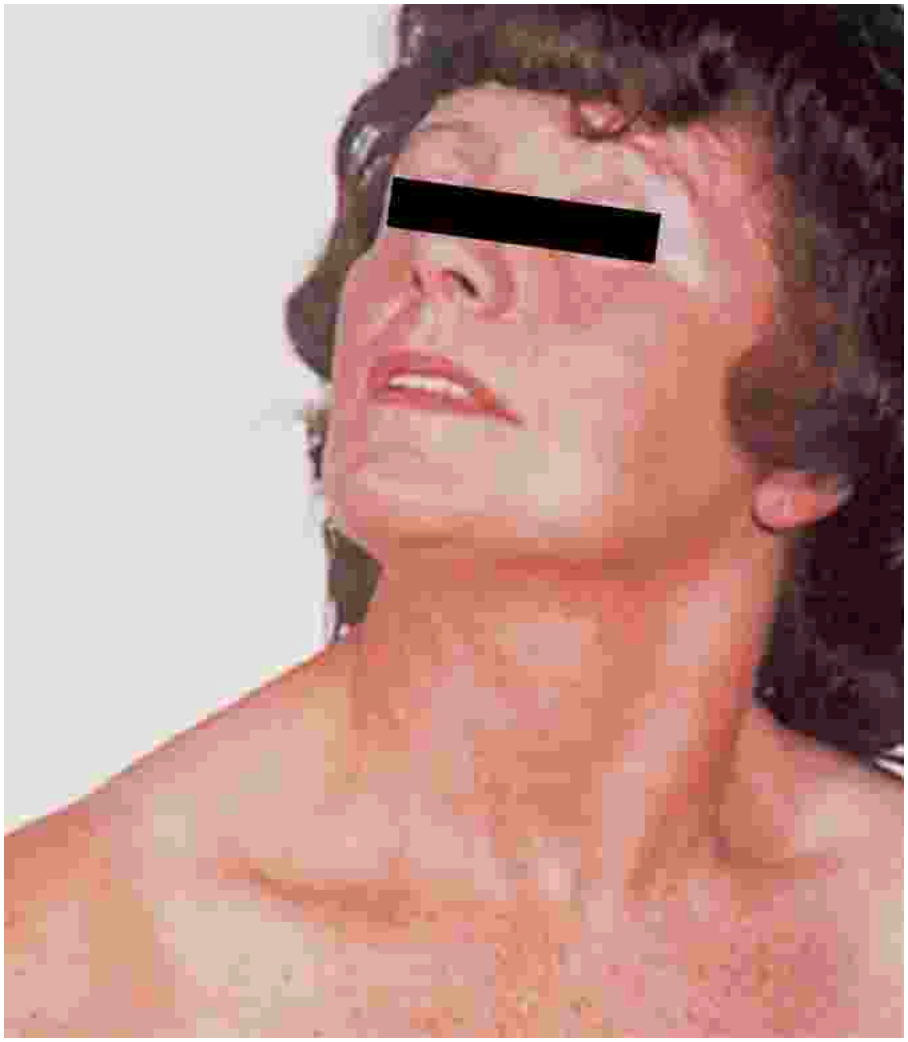

FIG. 17.25 Spasmodic Torticollis.
A characteristic head posture related to muscle spasticity, often involving the sternocleidomastoid muscle. (From Perkin GD, et al. *Atlas of clinical neurology*, 3rd edition. Philadelphia: Saunders; 2011.)

Rigidity produced by tonic reflex activity mediated by gamma motor neurons may be continuous or intermittent. The involved muscles are firm and tense; the increase in muscle movement is even and uniform throughout the range of passive movement. Four types of rigidity are described: plastic or lead pipe, cogwheel, gamma, and alpha (see Table 17.21).

Individuals with hypertonia may tire easily (asthenia) or are weak. Passive movement and active movement are equally affected, except in paratonia, in which more active than passive movement is possible. As a result of hypertonia and weakness, accident proneness during locomotion and self-care activities is common.

With these disorders, muscles may atrophy because of decreased use. However, hypertrophy occasionally occurs from overstimulation of muscle fibers. Overstimulation occurs when the motor unit reflex arc remains intact and functioning but is not inhibited by higher centers. The loss of inhibition and the constant state of excitation cause continual muscle contraction, resulting in enlargement of the muscle mass and the development of firm muscles (Fig. 17.26).

FIG. 17.26 Pseudohypertrophy of the Calf Muscles. (From Perkin GD, et al. *Atlas of clinical neurology*, 3rd edition. Philadelphia: Saunders, 2011.)

Alterations in Muscle Movement

Movement requires a change in the contractile state of muscles. Abnormal movements may occur when a variety of CNS dysfunctions alter muscular innervation. *Dopamine*, a neurotransmitter, has a role in several movement disorders. Some movement disorders (e.g., the akinesias) result from too little dopaminergic activity, whereas others (e.g., chorea, ballism, and tardive dyskinesia) result from too much dopaminergic activity. Still, others are not related primarily to dopamine function. Movement disorders are not associated necessarily with mass, strength, or tone but are neurologic dysfunctions with either an excess of movement or a lack of voluntary movement. Muscle strength is quantitatively evaluated on a scale of 0 to 4+ or 0 to 5, in which 4+ or 5 is normal, and 0 indicates an inability to move against gravity (Table 17.22).

Table 17.22

United Kingdom Medical Research Council Classification of Muscle Power

Grade	Definition
0	Total paralysis—no muscle contraction
1	Flicker of contraction—no joint movement
2	Movement with gravity eliminated
3	Movement against gravity but not resistance
4	Movement against resistance but incomplete
5	Normal power against resistance

Data from Vanhoutte EK, Faber CG, van Nes SI, et al. Modifying the Medical Research Council grading system through Rasch analyses. *Brain*, 2012;135(Pt 5):1639–1649.

Hypokinesia

Hypokinesia, bradykinesia, and akinesia are terms that represent a deficit of voluntary movement with loss of associated movement. PD symptoms are the hallmark of a lack of voluntary movement. **Hypokinesia (decreased movement)** is decreased amplitude of voluntary movement despite preserved consciousness and normal peripheral nerve and muscle function. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movement.

Akinesia is a decrease in voluntary and associated movements. It is related to dysfunction of the basal ganglia and substantia nigra (SN) and is caused by either a deficiency of dopamine or a defect of the postsynaptic dopamine receptors. **Bradykinesia** is slowness of voluntary movements. All voluntary movements become slow, labored, and deliberate with difficulty in (1) initiating movements, (2) continuing movements smoothly, and (3) performing synchronous (at the same time) and consecutive tasks. Both akinesia and bradykinesia involve a delay in the time it takes to start to perform a movement.

In hypokinesia there is loss of associated movement. The normal, habitually associated movements that provide skill, grace, and balance to voluntary movements are lost. Decreased associated movements accompanying emotional expression cause an expressionless face, a statue-like posture, absence of speech inflection, and absence of spontaneous gestures. Decreased associated movements accompanying locomotion cause reduction in arm and shoulder movements, hip swinging, and rotary motion of the cervical spine.

Hyperkinesia

Hyperkinesia is excessive, purposeless movement. Within this category are several specific dysfunctions, including tremors (Table 17.23). Also included under the general category of hyperkinesia are *dyskinesias* and abnormal involuntary movements. HD symptoms are the hallmark of hyperkinesia.

Table 17.23

Types of Hyperkinesia Syndromes

Type	Characteristics	Causes
Chorea[a]	Nonrepetitive muscular contractions, usually of the extremities of the face; random pattern of irregular, involuntary rapid contractions of groups of muscles; disappears with sleep, decreases with resting; increases with emotional stress and attempted voluntary movement	Associated with excess concentration of or a supersensitivity to dopamine within basal ganglia
Athetosis[a]	Disorder of distal-muscle postural fixation; slow, twisting, sinuous, irregular movements most obvious in the distal extremities, more rhythmic than choreiform movements and always much slower; movements accompany characteristic hand posture; slowly fluctuating grimaces	Occurs most commonly as a result of injury to the putamen of the basal ganglion; exact pathophysiologic mechanism is not known
Ballism	Disorder of proximal-muscle postural fixation with wild flinging movement of the limbs; movement is severe and stereotyped, usually lateral; does not lessen with sleep; ballism is most common on one side of the body, a condition termed *hemiballism*	Results from injury to the subthalamic nucleus (one of the nuclei that comprise the basal ganglia); thought to be caused by reduced inhibitory influence in the nucleus, a release phenomenon; hemiballism results from injury to the contralateral subthalamic nucleus
Hyperactivity	State of prolonged, generalized, increased activity that is largely involuntary but may be subject to some voluntary control; not highly stereotyped but rather manifests as continual changes in total body posture or in excessive performance of some simple activity, such as pacing under inappropriate circumstances	May be caused by frontal and reticular activating system injury
Wandering	Tendency to wander without regard for environment	"Release" phenomenon; associated with bilateral injury to globus pallidus or putamen
Akathisia	Special type of hyperactivity; mild compulsion to move (usually more localized to legs); severe frenzied motion possible; movements are partly voluntary and may be transiently suppressed; carrying	Dopaminergic transmission may be involved

Type	Characteristics	Causes
	out the movement brings a sense of relief; a frequent complication of antipsychotic drugs	
Tremor at rest	Rhythmic, oscillating movement affecting one or more body parts	Caused by regular contraction of opposing groups of muscles
Parkinsonian tremor	Regular, rhythmic, slow flexion-extension contraction; involves principally the metacarpophalangeal and wrist joints; alternating movements between thumb and index finger described as "pill rolling"; disappears during voluntary movement	Loss of inhibitory influence of dopamine in the basal ganglia, causing instability of basal ganglia feedback circuit within the cerebral cortex
Postural Tremor		
Asterixis (tremor of hepatic encephalopathy)	Irregular flapping movement of the hands accentuated by outstretching arms	Caused by transient inhibition of muscles that maintain posture; thought to be related to accumulation of products normally detoxified by the liver
Metabolic	Rapid, rhythmic tremor affecting fingers, lips, and tongue; accentuated by extending the body part; enhanced physiologic tremor	Occurs in conditions associated with disturbed metabolism or toxicity, as in thyrotoxicosis (hyperthyroidism), alcoholism, and chronic use of barbiturates, amphetamines, lithium, amitriptyline (Elavil); exact mechanism responsible unknown
Essential (familial)	Tremor of fingers, hands, and feet; absent at rest but accentuated by extension of body part, prolonged muscular activity, and stress	Not associated with any other neurologic abnormalities; cause unknown
Intentional Tremor		
Cerebellar	Tremor initiated by movement, maximal toward end of movement	Occurs in disease of the dentate nucleus (one of the deep cerebellar nuclei responsible for efferent output) and the superior cerebellar peduncle (a stalklike structure connected to the pons); caused by errors in feedback from the periphery and errors in preprogramming goal-directed movement
Rubral	Rhythmic tremor of limbs that originates proximally by movement	Results from lesions involving the dentatorubrothalamic tract (a spinothalamic tract connecting the red nucleus in the reticular

Type	Characteristics	Causes
		formation and the dentate nucleus in the cerebellum)
Myoclonus	Series of shocklike, nonpatterned contractions of a portion of a muscle, entire muscle, or group of muscles that cause throwing movements of a limb; usually appear at random but frequently triggered by sudden startle; do not disappear during sleep	Associated with an irritable nervous system and spontaneous discharge of neurons; structures associated with myoclonus include the cerebral cortex, cerebellum, reticular formation, and spinal cord

Type	Characteristics	Causes
Chorea[a]	Nonrepetitive muscular contractions, usually of the extremities of the face; random pattern of irregular, involuntary rapid contractions of groups of muscles; disappears with sleep, decreases with resting; increases with emotional stress and attempted voluntary movement	Associated with excess concentration of or a supersensitivity to dopamine within basal ganglia
Athetosis[a]	Disorder of distal-muscle postural fixation; slow, twisting, sinuous, irregular movements most obvious in the distal extremities, more rhythmic than choreiform movements and always much slower; movements accompany characteristic hand posture; slowly fluctuating grimaces	Occurs most commonly as a result of injury to the putamen of the basal ganglion; exact pathophysiologic mechanism is not known
Ballism	Disorder of proximal-muscle postural fixation with wild flinging movement of the limbs; movement is severe and stereotyped, usually lateral; does not lessen with sleep; ballism is most common on one side of the body, a condition termed *hemiballism*	Results from injury to the subthalamic nucleus (one of the nuclei that comprise the basal ganglia); thought to be caused by reduced inhibitory influence in the nucleus, a release phenomenon; hemiballism results from injury to the contralateral subthalamic nucleus
Hyperactivity	State of prolonged, generalized, increased activity that is largely involuntary but may be subject to some voluntary control; not highly stereotyped but rather manifests as continual changes in total body posture or in excessive performance of some simple activity, such as pacing under inappropriate circumstances	May be caused by frontal and reticular activating system injury
Wandering	Tendency to wander without regard for environment	"Release" phenomenon; associated with bilateral injury to globus pallidus or putamen
Akathisia	Special type of hyperactivity; mild compulsion to move (usually more localized to legs); severe frenzied motion possible; movements are partly voluntary and may be transiently suppressed; carrying out the movement brings a sense of relief; a frequent complication of antipsychotic drugs	Dopaminergic transmission may be involved
Tremor at rest	Rhythmic, oscillating movement affecting one or more body parts	Caused by regular contraction of opposing groups of muscles
Parkinsonian tremor	Regular, rhythmic, slow flexion-extension contraction; involves principally the metacarpophalangeal and wrist joints; alternating movements between thumb and index finger described as "pill rolling"; disappears during voluntary movement	Loss of inhibitory influence of dopamine in the basal ganglia, causing instability of basal ganglia feedback circuit within the cerebral cortex
Postural Tremor		
Asterixis (tremor of hepatic encephalopathy)	Irregular flapping movement of the hands accentuated by outstretching arms	Caused by transient inhibition of muscles that maintain posture; thought to be related to accumulation of products normally detoxified by the liver
Metabolic	Rapid, rhythmic tremor affecting fingers, lips, and tongue; accentuated by extending the body part; enhanced physiologic tremor	Occurs in conditions associated with disturbed metabolism or toxicity, as in thyrotoxicosis (hyperthyroidism), alcoholism, and chronic use of barbiturates, amphetamines, lithium, amitriptyline (Elavil); exact mechanism responsible unknown
Essential (familial)	Tremor of fingers, hands, and feet; absent at rest but accentuated by extension of body part, prolonged muscular activity, and stress	Not associated with any other neurologic abnormalities; cause unknown
Intentional Tremor		
Cerebellar	Tremor initiated by movement, maximal toward end of movement	Occurs in disease of the dentate nucleus (one of the deep cerebellar nuclei responsible for efferent output) and the superior cerebellar peduncle (a stalklike structure connected to the pons); caused by errors in feedback from the periphery and errors in preprogramming goal-directed movement
Rubral	Rhythmic tremor of limbs that originates proximally by movement	Results from lesions involving the dentatorubrothalamic tract (a spinothalamic tract connecting the red nucleus in the reticular formation and the dentate nucleus in the cerebellum)
Myoclonus	Series of shocklike, nonpatterned contractions of a portion of a muscle, entire muscle, or group of muscles that cause throwing movements of a limb; usually appear at random but frequently triggered by sudden startle; do not disappear during sleep	Associated with an irritable nervous system and spontaneous discharge of neurons; structures associated with myoclonus include the cerebral cortex, cerebellum, reticular formation, and spinal cord

[a]Choreoathetosis involves chorea and athetosis; precise pathophysiology unknown.

Dyskinesias

Paroxysmal dyskinesias are abnormal, involuntary movements that occur as spasms. The type of dyskinesia varies depending on the specific disorder. There is no loss of consciousness with this disorder.

Tardive dyskinesia (slow onset dyskinesia) is the involuntary movement of the face, trunk, and extremities. Although the condition occurs occasionally in individuals with PD, it usually occurs as a side effect of prolonged dopamine-receptor blocking agents, including antipsychotic drug therapy.[98] The antipsychotic drugs cause denervation hypersensitivity, thereby mimicking the effect of excessive dopamine. The most common symptom of tardive dyskinesia is rapid, repetitive, stereotypic movements, such as continual chewing with intermittent protrusions of the tongue, lip smacking, and facial grimacing.

Other movement disorders in this category are (1) complex repetitive movements, including automatism (unconscious behavior), stereotypy (ritualistic behavior such as rocking), complex tics, such as Tourette syndrome (see Emerging Science Box: Tourette Syndrome), compulsions, perseverations, and mannerisms; (2) excessive reactions to certain stimuli; and (3) paroxysmal excessive activity, including cataplexy and excessive startle reaction.

Chronic Diseases and Disorders Involving Motor Function

There are several chronic progressive diseases (PD, ALS, HD) in adults that primarily involve alterations in motor function with neurodegeneration. Additionally, there are diseases that primarily involve myelin degeneration (MS and Guillain Barré syndrome) or the myoneural junction (**myasthenia gravis** (MG). These diseases may involve the sensory and autonomic nervous systems with nonmotor symptoms, including decline of cognitive function. The pathogenesis varies, but they are commonly influenced by gene mutations, gene-to-environment interaction, or epigenetic expression. Most have a subtle onset, may progress rapidly or slowly, and/or with a pattern of remission and exacerbation of symptoms. The etiology may be unknown, and there is no cure. Early diagnosis, prevention of disease progression, and maintenance of function and quality of life are the aims of treatment and management. Table 17.24 summarizes the features of the most common of these diseases.

Table 17.24

Comparative Features of Progressive Diseases Involving Motor Function

Chronic Progressive Motor Diseases of the Central Nervous System

Parkinson Disease

PD is a complex motor disorder accompanied by systemic nonmotor and neurologic symptoms. Etiologic classification includes primary parkinsonism and secondary parkinsonism. The onset of primary PD usually begins after 40 years of age, with the incidence increasing after 60 years. It is estimated there will be 1,238,000 cases by 2030 compared to 930,000 cases in 2020 across North America.[99] Men are much more likely to have PD than women. The familial form represents about 3% to 5% of PD; most cases are sporadic or idiopathic. Secondary parkinsonism is caused by other neurodegenerative diseases and acquired disorders (head trauma, infection, neoplasm, atherosclerosis, toxins, and drug intoxication). Drug-induced parkinsonism, caused by neuroleptics, antiemetics, and antihypertensives, is the most common secondary form and is usually reversible. Box 17.10 summarizes the numerous diseases and contributing factors associated with parkinsonism.

Box 17.10

Primary and Secondary Causes of Parkinsonism

Primary Parkinsonism

Sporadic (idiopathic); most common form
Genetic: autosomal dominant; autosomal recessive
Phenotype may be influenced by gene-environment interactions

Secondary Parkinsonism

- Neurodegenerative disorders (sporadic or genetic)
  - Disorders associated with alpha-synuclein pathology
    - Multiple system atrophies (glial and neuronal inclusions)
      - Nigrostriatal degeneration
      - Olivopontocerebellar atrophy
      - Multiple system atrophy (Shy-Drager syndrome)
      - Motor neuron disease with Parkinson disease (PD) features
  - Dementia with Lewy bodies (cortical and brainstem neuronal inclusions)
- Disorders associated with primary tau pathology ("tauopathies")
  - Progressive supranuclear palsy
  - Corticobasal degeneration
  - Frontotemporal dementia
- Disorders associated with primary amyloid pathology ("amyloidopathies")
  - Alzheimer disease with parkinsonism
- Genetically mediated disorders with occasional parkinsonian features
  - Wilson disease
  - Hallervorden-Spatz disease
  - Chédiak-Higashi syndrome
  - SCA-3 spinocerebellar ataxia
  - X-linked dystonia-parkinsonism *(DYT3)*
  - Fragile X permutation associated with ataxia-tremor-parkinsonism syndrome
  - Huntington disease (Westphal variant)
  - Prion disease
  - Rett syndrome
- Miscellaneous acquired conditions
  - Vascular parkinsonism: atherosclerosis, amyloid angiopathy
  - Normal pressure hydrocephalus
  - Catatonia
  - Cerebral palsy
- Repeated head trauma ("dementia pugilistica" with parkinsonian features)
- Infectious and postinfectious diseases
  - Postencephalitic Parkinson disease
  - Creutzfeldt-Jakob disease
  - Neurosyphilis
- Metabolic conditions
  - Hypoparathyroidism or pseudohypoparathyroidism with basal ganglia calcifi-cations
  - Nonwilsonian hepatolenticular degeneration
- Multiple sclerosis
- Neoplastic disease
- Drugs
  - Neuroleptics (typical antipsychotics)
  - Selected atypical antipsychotics
  - Antiemetics (e.g., prochlorperazine, metoclopramide)
  - Dopamine-depleting agents (reserpine, tetrabenazine)
  - α-Methyldopa
  - Lithium carbonate
  - Valproic acid
  - Fluoxetine
- Toxins
  - 1-Methyl-1,2,4,6-tetrahydropyridine (MPTP)
  - Manganese
  - Cyanide
  - Methanol
  - Carbon monoxide

Carbon disulfide
Hexane
Pesticides (i.e., paraquat, rotenone)

Data from Checkoway H, Nielsen SS, Racette BA. Environmental exposures and risks for Parkinson's disease. In: Aschner M, ed. *Environmental factors in neurodevelopmental and neurodegenerative disorders*. Amsterdam: Academic Press; 2015:253–265; Fahn S, Jankovic J, Hallett M. Atypical parkinsonism, parkinsonism-plus syndromes, and secondary parkinsonian disorders. In: Fahn S, Jankovic J, Hallett M, eds. *Principles and practice of movement disorders*, 2nd edition. Philadelphia: Saunders; 2011:197–240; Singer HS, et al., eds. *Movement disorders in childhood*, 2nd edition. Amsterdam: Academic Press; 2016:301–316.

Pathophysiology

The pathogenesis of primary PD is unknown. Several gene mutations have been identified, including those associated with Lewy body (inclusions with high concentrations and abnormal folding of alpha-synuclein and other proteins) dementia. The most significant are listed in Table 17.14, and epigenetic interactions are probable causes of neurodegeneration in PD.[100] Potential environmental risk factors include exposure to pesticides, herbicides, chlorinated solvents, and heavy metals and head injury. The hallmark pathologic features of PD are loss of dopaminergic pigmented neurons in the SN pars compacta with dopaminergic deficiency in the putamen portion of the striatum (the striatum includes the putamen and caudate nucleus) (Fig. 17.27). Dopamine loss in other brain areas, including the brainstem, thalamus, and cortex, also occurs. The primary pathology is degeneration of the basal ganglia (corpus striatum, globus pallidus, subthalamic nucleus, and SN) (Fig. 17.28) with formation of Lewy bodies in the SN and dorsal striatum.

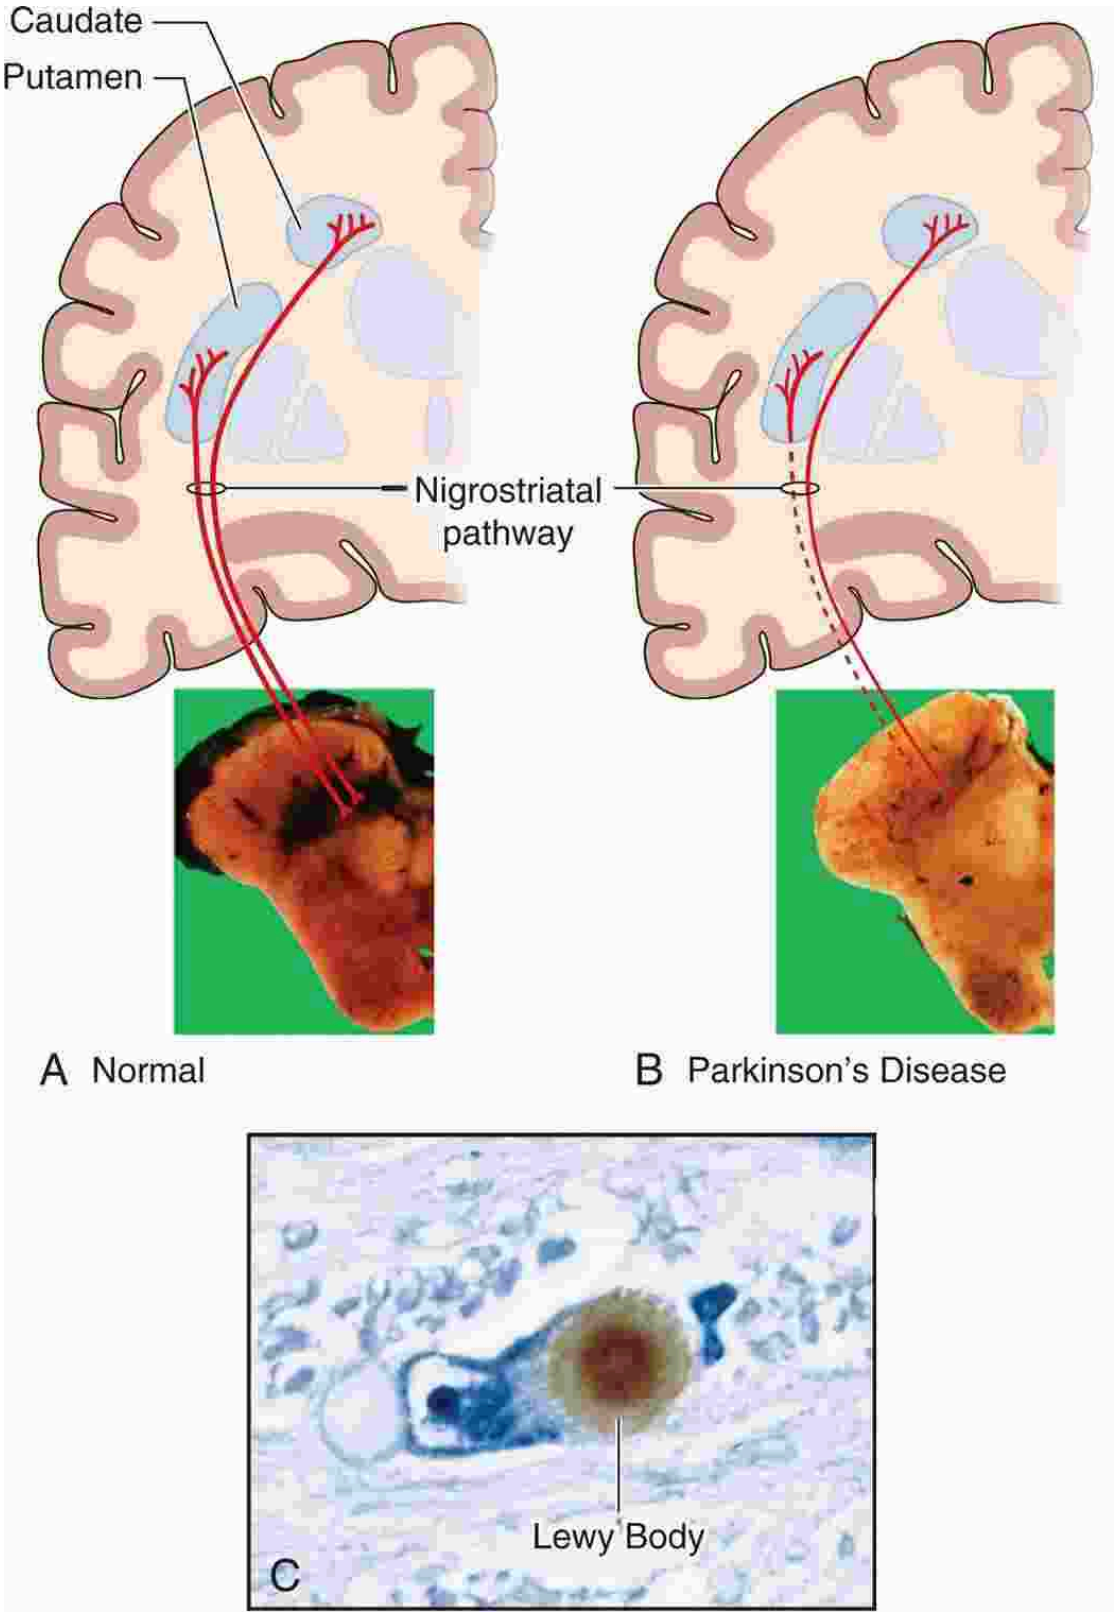

FIG. 17.27 Pathogenesis of Parkinson Disease.
(A) Diagram of the normal nigrostriatal pathway projecting from cell bodies in the substantia nigra pars compacta (SNpc) *(photo)*. These neurons project *(thick solid*

red lines) to the basal ganglia and synapse in the striatum to the putamen and caudate nucleus. **(B)** There is marked loss of pigmented dopaminergic neurons *(photo)* that project to the putamen *(thin dashed red line)* and a much more modest loss of those that project to the caudate *(thin red solid line)* in the diseased nigrostriatal pathway. Decreased neurotransmission to other neural centers, including the thalamus, primary motor cortex, sensory association areas, and other nerve centers occurs as the disease advances (not shown in this figure). **(C)** A Lewy body stained for alpha synuclein from a dopaminergic neuron in the SNpc. (Diagram from parts A and B and C (Lewy Body) are from Dauer W, Przedbprski S. Parkinson's disease: Mechanisms and models. *Neuron*, 2003;39(6);889–909, Figure. 1. The photos with the green background in Parts A and B are from Cross SS. *Underwood's pathology, a clinical approach*, 7th edition. Livingston: Churchill; 2019. ISBN 978-0-7020-7211-6 [main edition], Figure 26.29.)

Top panel, A and B. An illustration and an accompanying closeup of a brain specimen compare a normal brain with that of a brain with Parkinson's disease. In the brain with Parkinson's disease, the nigrostriatal pathway to the caudate is degenerating and that to the putamen is disconnected. Bottom panel, C. A photomicrograph shows a Lewy body or protein clumps in a brain specimen.

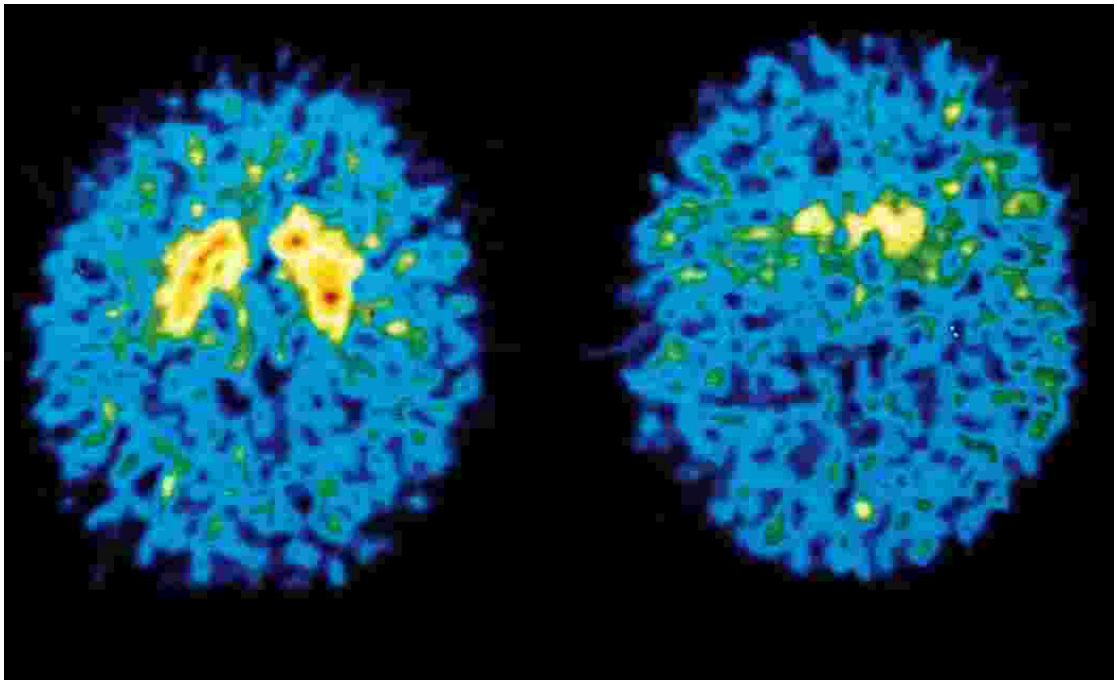

FIG. 17.28 Reduced Fluorodopa in Parkinson Disease.
Positron-emission tomography scan showing reduced fluorodopa (a radiotracer) uptake in the striatal basal ganglia consistent with neurodegeneration *(right)* compared with a normal control *(left)*. (From Perkin GD; Miller, DC; Lane, R; Patel, MC; Hochberg, FH. *Atlas of clinical neurology*, 3rd edition. Philadelphia: Saunders; 2011.)

It has been proposed that there is cell-to-cell pathogenic transmission of alpha synuclein through tunneling nanotubes, which induces the formation of Lewy bodies. This transmission is thought to move from the olfactory bulb and from gut axons traveling via the vagus nerve, to the upper brainstem,

and to the cortex.[101] Recent studies of the gut microbiome indicate that gut dysbiosis is a cause of synucleinopathies and neuroinflammation, contributing to early manifestations of subtle motor and gastrointestinal symptoms, such as constipation.[102]Degeneration of the locus coeruleus (LC), which contains noradrenergic neurons, also occurs in PD. Norepinephrine is thought to be neuroprotective, and loss of LC neurons may be associated with a worsening of disease progression and the behavioral symptoms of PD.[103] Other molecular events thought to be associated with the neurodegeneration of PD include neuroinflammation and mitochondrial oxidative stress.[104] The resulting depletion of dopamine (inhibitory) and relative excess of cholinergic (excitatory) activity in the feedback circuit are manifested by hypertonia (tremor and rigidity) and episodes of akinesia (freezing of movement), producing a syndrome of abnormal movements called **parkinsonism** (Parkinson syndrome, parkinsonian syndrome, paralysis agitans) (Fig. 17.29). Neuroimaging shows degeneration of dopaminergic neurons preceding the onset of motor symptoms by as long as 3 to 6 years. Dementia may develop over decades with infiltration of Lewy bodies and plaque formation, like AD. Loss of cholinergic subcortical input into the cortex is also associated with nonmotor symptoms of PD.

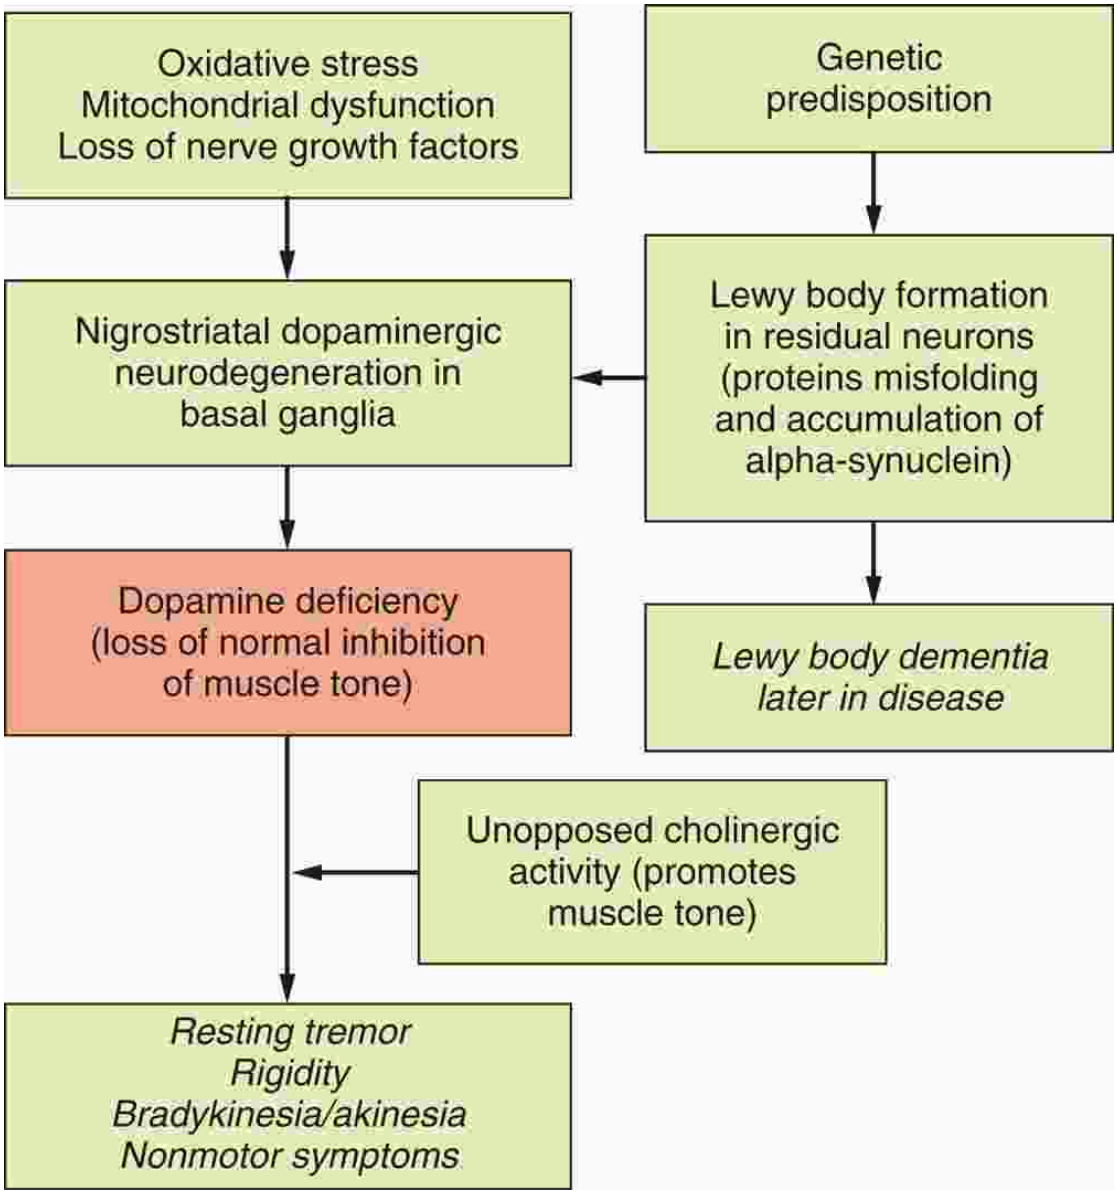

FIG. 17.29 **Pathophysiology of Parkinson Disease.**

A flowchart represents the pathophysiology of Parkinson disease. 1. Oxidative stress, mitochondrial dysfunction, and loss of nerve growth factors. Leads to 2. 2. Nigrostriatal dopaminergic neurodegeneration in basal ganglia. Leads to 3. 3. Dopamine deficiency (loss of normal inhibition of muscle tone). Leads to 4. 4. Resting tremor, rigidity, bradykinesia or akinesia, and nonmotor symptoms. 5. Generic predisposition. Leads to 6. 6. Lewy body formation in residual neurons (proteins misfolding and accumulation of alpha-synuclein). Leads to 2 and 7. 7. Lewy body dementia later in disease. 8. Unopposed cholinergic activity (promotes muscle tone). Leads to 7.

Clinical Manifestations

The classic manifestations of PD are resting tremor (decreases with voluntary movement), muscular rigidity, bradykinesia/akinesia (slowness of movement and freezing, postural instability and difficulty maintaining balance, dysarthria, and dysphagia). Nonmotor symptoms may precede motor symptoms by up to 20 years.[105] The symptoms may develop alone or in combination, but as the disease progresses, all are usually present. There is no true paralysis. Onset of symptoms is insidious, and symptoms appear after a significant loss of pigmented nigral neurons and striatal dopamine. The symptoms are always bilateral but usually involve one side early in the illness. Because the onset is insidious, the beginning of symptoms is difficult to document; symptoms may evolve and progress over a period of years. Reflex status, sensory status, and mental status usually are normal early in the disease.

Postural abnormalities (flexed, forward leaning), difficulty walking, and weakness develop (i.e., dragging one leg) as neurodegeneration progresses (Fig. 17.30). Disorders of equilibrium result from postural abnormalities. The person with PD is unable to make the appropriate postural adjustment to tilting or falling and falls like a post when starting to tilt. The short, accelerating steps of the person with PD are an attempt to maintain an upright position while walking. Individuals also are unable to right themselves when changing from a reclining or crouching position to a standing position. Speech may be slurred.

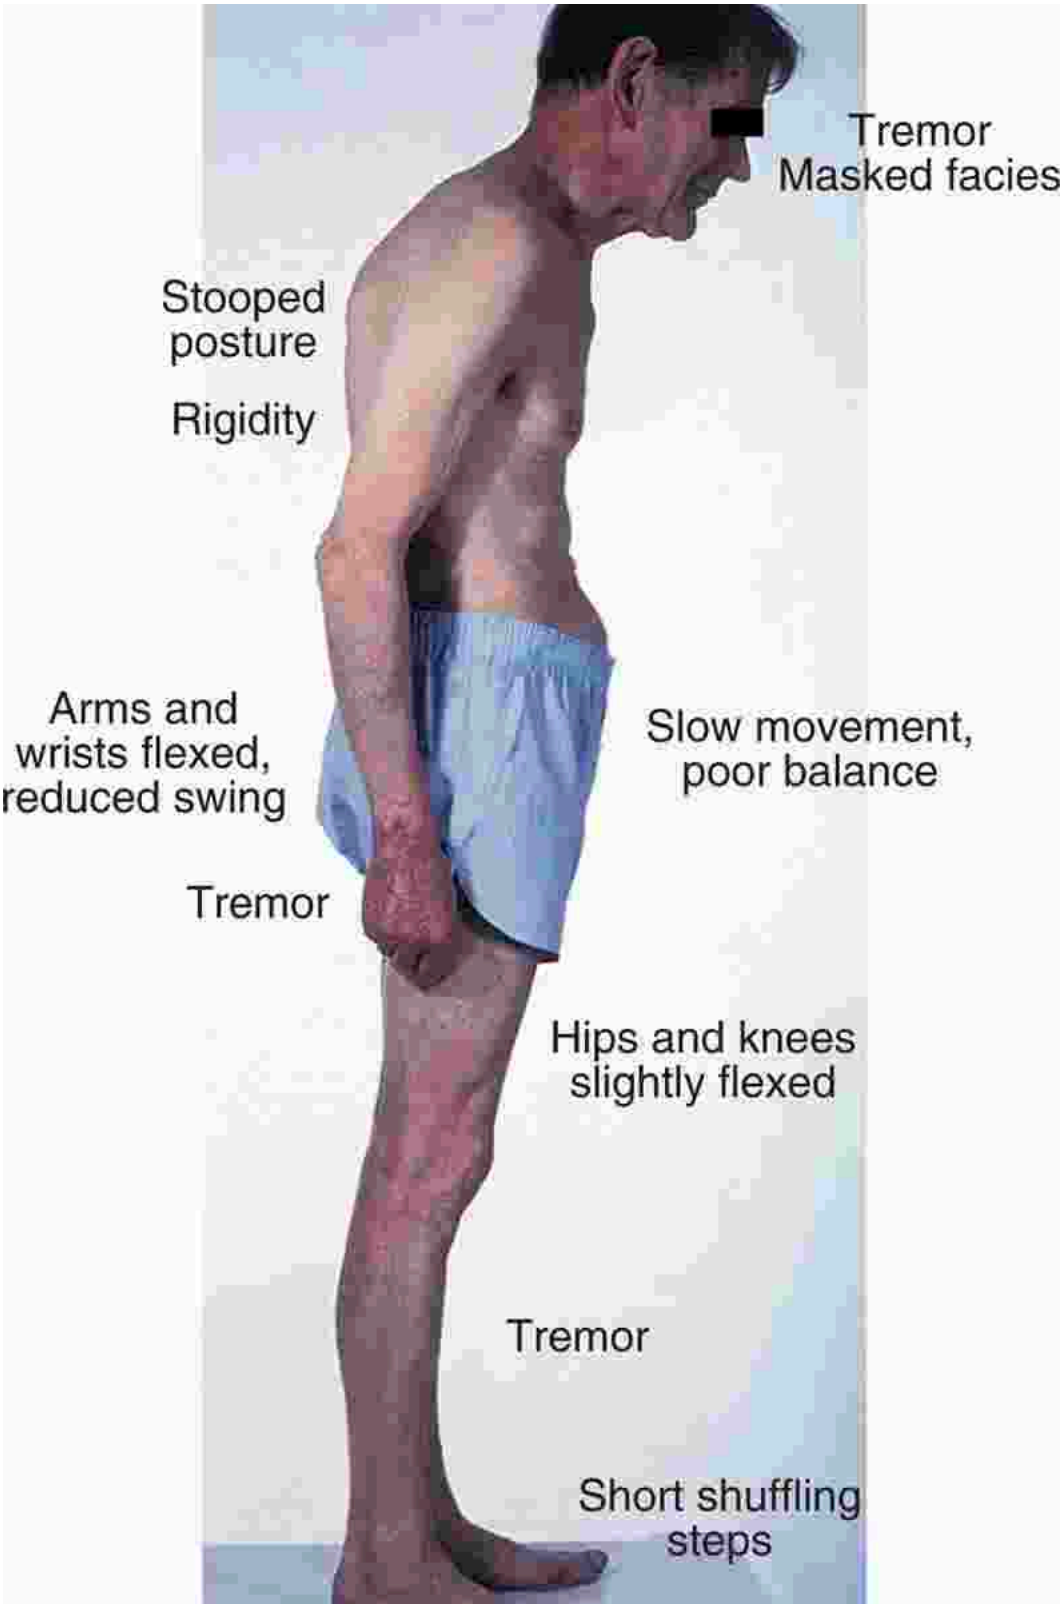

FIG. 17.30 Stooped Posture of Parkinson Disease. (From Perkin DG, et al. *Mosby's color atlas and text of neurology*, 2nd edition. London: Mosby; 2002.)

A right-lateral, full-body profile photo of a person with Parkinson's disease shows the following manifestations, from the top to the bottom. • Tremor, masked facies. • Stopped posture, rigidity. • Slow movement, poor balance. • Arms and wrists flexed, reduced swing. • Tremor (upper thighs). • Hips and knees slightly flexed. • Tremor (lower legs). • Short shuffling steps.

Nonmotor symptoms are common. Sleep disorders and excessive daytime sleepiness are commonly experienced. Sensory disturbances (pain and impaired smell and vision), urinary urgency, difficulty concentrating, depression, apathy, and hallucinations are some of the nonmotor symptoms of PD. Autonomic nervous system changes (i.e., alterations in blood pressure, heart rhythm, temperature control, digestion, bladder function, and sexual function) often begin early in the disease process and contribute to nonmotor symptoms. They are summarized in Table 17.25.

Table 17.25

Non-Motor Signs and Symptoms in Parkinson Disease

Function	Symptoms
Cardiovascular (>80%)	Orthostatic hypotension Supine hypertension Postprandial hypertension "Nondipping" blood pressure[a]
Gastrointestinal	Hypersalivation (>50%) Dysphagia (11%–81%) Gastroparesis (70%–100%) Constipation (20%–70%) Difficult defecation (77%) SIBO (20%–69%)
Thermoregulation	Hyperhidrosis (nocturnal sweating) hypohidrosis
Ocular	Pupillary supersensitivity Tear abnormality
Urinary (27%–85%)	Nocturia, frequency, incontinence
Sexual	Erectile dysfunction/ejaculation abnormality (>50%)

Function	Symptoms
Cardiovascular (>80%)	Orthostatic hypotension Supine hypertension Postprandial hypertension "Nondipping" blood pressure[a]
Gastrointestinal	Hypersalivation (>50%) Dysphagia (11%–81%) Gastroparesis (70%–100%) Constipation (20%–70%) Difficult defecation (77%) SIBO (20%–69%)
Thermoregulation	Hyperhidrosis (nocturnal sweating) hypohidrosis
Ocular	Pupillary supersensitivity Tear abnormality
Urinary (27%–85%)	Nocturia, frequency, incontinence
Sexual	Erectile dysfunction/ejaculation abnormality (>50%)

SIBO, Small intestine bacterial overgrowth.

[a]Absence of nocturnal decrease "dip" in blood pressure (compared to mean systolic BP).

Data from Chen Z, Li G, Liu J. Autonomic dysfunction in Parkinson's disease: Implications for pathophysiology, diagnosis, and treatment. *Neurobiology Disease*, 2020;134:104700.

Progressive cognitive impairment and dementia are more common in persons older than 70 years with alterations in executive function (concept formation, planning, abstraction, calculations, and judgment) and memory and visuospatial (complex perceptual discrimination and spatial orientation) deficits. Lewy bodies are distributed diffusely within many neurons, causing a Lewy body dementia.[106] Mental status may be further compromised by the side effects of the medication taken to control symptoms. A proposed progression of PD symptoms is summarized in Fig. 17.31.

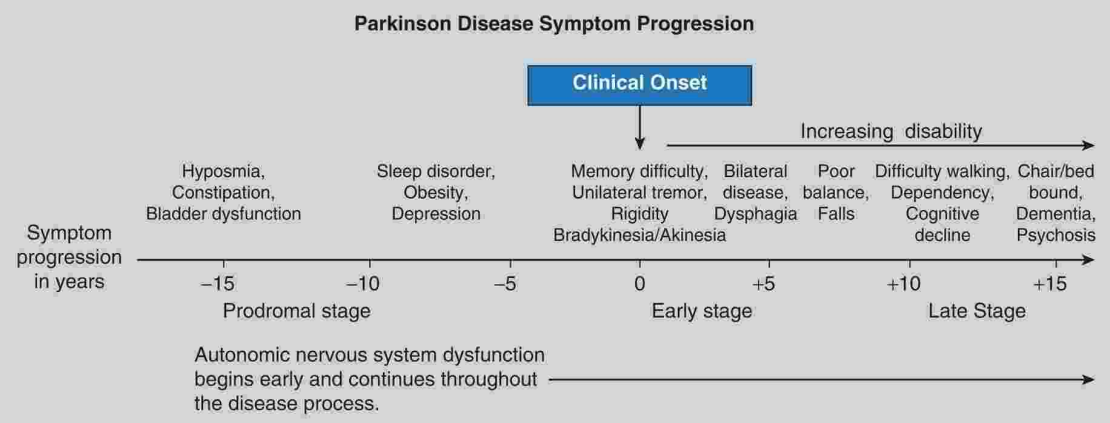

FIG. 17.31 Parkinson Disease Symptom Progression.
The progression of Parkinson disease symptoms from onset to death is shown as linear over a period of 30 years, but there is considerable individual variability and likely increasing disability in later years of the disease. Motor and non-motor symptoms are present. (Data from Hawkes CH, Del Tredici K, Braak H. A timeline for Parkinson's disease. *Parkinsonism and Related Disorders*, 2010;16(2):79–84; Tolosa E, Garrido A, Scholz SW, et al. Challenges in the diagnosis of Parkinson's disease. *Lancet Neurology*, 2021;20(5):385–397.)

A timeline shows the progression of Parkinson disease symptoms. • Autonomic nervous system dysfunction begins early and continues throughout the disease process. • 15 years before clinical onset: hyposmia, constipation, bladder dysfunction. • 10 years before clinical onset: sleep disorder, obesity, depression. • Clinical onset: memory difficulty, unilateral tremor, rigidity, bradykinesia or akinesia. • Early stage (up to 5 years): bilateral disease, dysphagia (increases over the years). • 5 to 10 years after clinical onset: poor balance, falls (increases over the years). • 10 years after clinical onset (late stage): difficulty walking, dependency, cognitive decline (increases over the years). • 15 years after clinical onset (late stage): chair or bed bound, dementia, psychosis (increases over the years).

Evaluation and Treatment

There is no diagnostic marker for sporadic PD, and definitive diagnosis is made by postmortem examination of neural tissue revealing the loss of nigrostriatal dopaminergic neurons and the presence of Lewy bodies within neurons. The clinical diagnosis of PD is based on the history and presenting features of the disease. Causes of secondary parkinsonism are first excluded. Specific gene panels and imaging studies are evolving for early diagnosis and for identifying early stages of structural and functional areas of brain changes.[107] Prodromal nonmotor symptoms of PD can precede motor symptoms (constipation, loss of smell, and sleep disorders), and their identification may assist early diagnosis and guide disease-modifying strategies. Biomarkers are being tested for early identification of prodromal disease.[108] Imaging techniques are being developed for identifying early stages of the disease and structural and functional areas of brain changes.[107]

Treatment of PD is symptomatic, with drug therapy to protect or restore striatal dopamine levels and decrease akinesia and manage nonmotor symptoms. Levodopa is first-line treatment and is generally well tolerated. ChE-Is may be helpful for MCI or dementia.[109] Deep brain stimulation (i.e., subthalamic

neurostimulation) is replacing surgery to treat persons unresponsive to drug therapy. Implants of stem cells and fetal cells, as well as gene therapy and immunotherapy, are strategies for future treatments.[110,111] Nonmotor symptoms and general immobility are special problems requiring interdisciplinary efforts to improve functional status.[112]

Huntington Disease

HD, also known as ***chorea***, is a relatively rare, hereditary, degenerative hyperkinetic movement disorder diffusely involving the basal ganglia and cerebral cortex. The onset of HD is usually between 25 and 45 years of age, when the trait may already have been passed to the person's children. The disease may progress for 10 to 25 years. The disorder has a prevalence rate of approximately 5 to 10 per 100,000 persons, occurs in all races, and rates vary in different regions across the world.[113]

Pathophysiology

HD is inherited from one or both parents who have the autosomal dominant trait with high penetrance. The genetic defect of HD is on the short arm of chromosome 4. There is an abnormally long polyglutamine tract in the huntingtin (HTT) protein with abnormal folding that is toxic to neurons caused by a cytosine-adenine-guanine (CAG) trinucleotide repeat expansion (40 to 70 repeats instead of 9 to 34). Age of symptom onset is related to the length of the repeat sequences and mechanisms of toxicity. Repeat lengths greater than 60 cause the juvenile form of the disease. Individuals with fewer CAG repeats develop disease symptoms when they are older and have a slower disease progression. Fathers, but not mothers, with high normal alleles do not develop HD but are at risk of transmitting potentially penetrant HD alleles (≥36) to their offspring, who can develop HD.[114]

The principal pathologic feature of HD is severe degeneration of the striatum. The degeneration of the basal ganglia leaves enlarged lateral ventricles (Fig. 17.32), and there is widespread degeneration in late stages of the disease. Expression of the *huntingtin* gene produces tangles of protein that collect in brain cells and chains of glutamine on the abnormal molecules that adhere to each other. The mechanism of neuronal death is unknown. The excitotoxic theory of striatal and cortical degeneration proposes that the mutated HTT protein produces excitotoxic pathways mediated by glutamate function that also induce concomitant dysregulation of dopaminergic function. Lysosomal autophagy is disrupted, resulting in accumulation of misfolded proteins. The HTT protein also alters cellular organelles, including mitochondrial function, axon transport, and synapses. Apoptotic pathways may be activated and cause neuronal death. Neurotrophic factors also may be depleted, and oxidative stress and inflammation likely contribute to loss of neurons and neurodegeneration.[115]

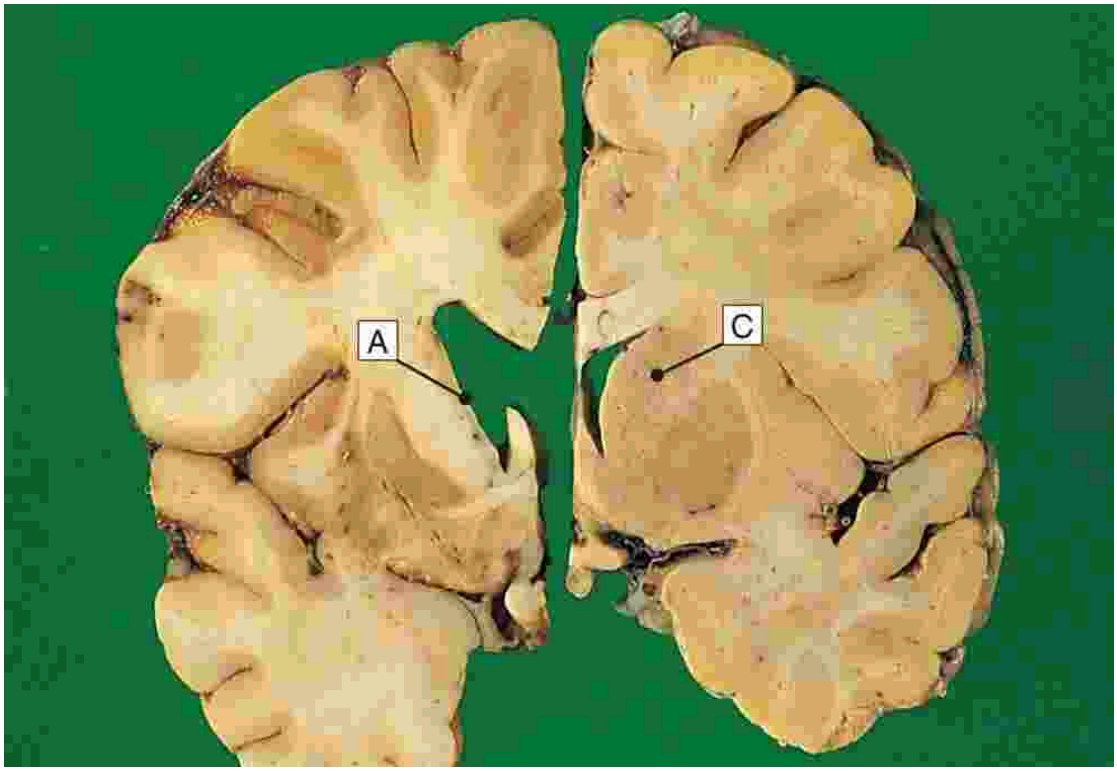

FIG. 17.32 Huntington Disease.
On the right is a normal brain with a normal caudate *(C);* on the left is a brain from an individual with Huntington disease showing severe atrophy of the caudate *(A)* and an enlarged lateral ventricle. (From Stevens A, Lowe J, Scott I. *Core pathology*, 3rd edition. London: Mosby; 2009.)

Clinical Manifestations

Symptoms of HD progress slowly through three stages. During the early stage, there are few symptoms, as there is adaptation to the slowly accumulating amounts of the HTT protein. During the middle stage, there are progressive motor symptoms, including involuntary fragmentary movements, such as chorea, athetosis, and ballism (see Table 17.23). Chorea, the most common type of abnormal movement, begins in the face and arms, eventually affecting the entire body. There is emotional lability and progressive dysfunction of intellectual and thought processes that may precede motor symptoms. Cognitive deficits include loss of working memory and reduced capacity to plan, organize, and sequence. Thinking is slow, and apathy is present. Any one of these features may mark the onset of the disease. Restlessness, disinhibition, and irritability are common. Euphoria or depression may be present. During late stages, chorea decreases and is replaced by rigidity, dystonia, and bradykinesia (Parkinsonian symptoms). The individual may be unable to talk, is bedridden, and requires help with all activities of daily living.[116]

Evaluation and Treatment

The diagnosis of HD is based on family history, clinical presentation of the disorder, and genetic testing. Neuroradiologic abnormalities can be demonstrated up to 15 years before clinical symptoms. No known treatment is effective in halting the degeneration or progression of symptoms, and the disease is fatal. Efforts are underway to identify biomarkers for early diagnosis and to monitor disease progression and treatment effectiveness. Symptomatic drug therapies are available, and HTT protein lowering therapies are being developed.[117]

Amyotrophic Lateral Sclerosis

ALS (also known as *motor neuron disease or* ***Lou Gehrig disease***) is a severe degenerative disorder with loss of lower and upper motor neurons resulting in progressive muscle weakness, paralysis, and death. *Amyotrophic* (without muscle nutrition and progressive muscle wasting) refers to the LMN component of the syndrome. *Lateral sclerosis*, scarring of the spinal cord, refers to the upper motor neuron component of the syndrome. Other brain systems become involved as the disease progresses, including cortical projections to subcortical structures leading to extra-motor deficits such as cognitive-behavioral disturbances, impaired ocular movements, and extrapyramidal alterations.[118] Thus, ALS is a multimodal systemic disorder, and currently, there are no biomarkers for predicting the onset and course of the disease.[119]

ALS may begin at any time from the fourth decade of life; its median age of onset is between 51 and 66 years of age, with about 5.2 cases per 100,000 persons in the United States. The prevalence is higher in individuals who are assigned male at birth. The prevalence of ALS is also much higher in individuals who are White compared to other ethnic groups.[120] Most cases of ALS are sporadic or simplex cases (an individual with ALS with no other familial occurrence of the disease). A subset (about 10% to 20%) has the familial form with four common genetic mutations in C9ORF72 (chromosome 9 open reading frame 72), superoxide dismutase *(SODI)*, and fused in sarcoma *(FUS)* that contribute to the neurotoxicity of proteins affecting motor neurons. Mutated TAR RNA-binding protein 43 (*TDP-43*-important for RNA processing and synthesis of cell proteins) is a major constituent of the toxic ubiquitinated protein inclusions found in motor neurons and glial cells. More than 30 ALS-associated genes have been identified, adding to the complexity of the disease. Onset is earlier in individuals with familial ALS.[121] Genetic testing is available for familial ALS.

Pathophysiology

The cause of ALS is unknown. Risk factors for ALS include age, male sex, and familial history. Environmental risk factors including smoking, BMI, and exercise; occupational and environmental exposures to toxins, head injuries, and viral infections are being examined. Nucleocytoplasmic transport defects, dysfunctional RNA metabolism, protein aggregation, impaired DNA repair, mitochondrial dysfunction and oxidative stress, impaired axonal transport, vesicular transport deficits, neuroinflammation, glutamate excitotoxicity, and oligodendrocyte dysfunction are some of the pathogenic mechanisms being investigated.[122] The principal pathologic feature of ALS is degeneration and death of upper and LMNs, including the neuromuscular junction (NMJ). Cortical hyperexcitability is an important early mechanism in the pathology of ALS, especially when evaluating neurodegeneration and disease progression. The mechanisms leading to enhanced neuronal intrinsic excitability and changes in excitatory and inhibitory synaptic activity are starting to be understood. Initially, ALS was thought to originate in the LMNs at the myoneuronal junction from pathologic activation of complement proteins and was erroneously classified as a neuromuscular disease. The disease then advanced from LMNs to the CNS. This process was called the dying back hypothesis. However, with advances in neuroimaging, the dying forward hypothesis is now widely accepted. The dying forward hypothesis states that ALS originates in the cortical motor neurons and mediate anterograde motor neuron degeneration due to glutamate excitotoxicity and accumulation of TDP-43, and advances to LMNs (Fig. 17.33). ALS is also now known to be a neurodegenerative disease, not a neuromuscular disease, that causes multisystem dysfunction.[123–125]

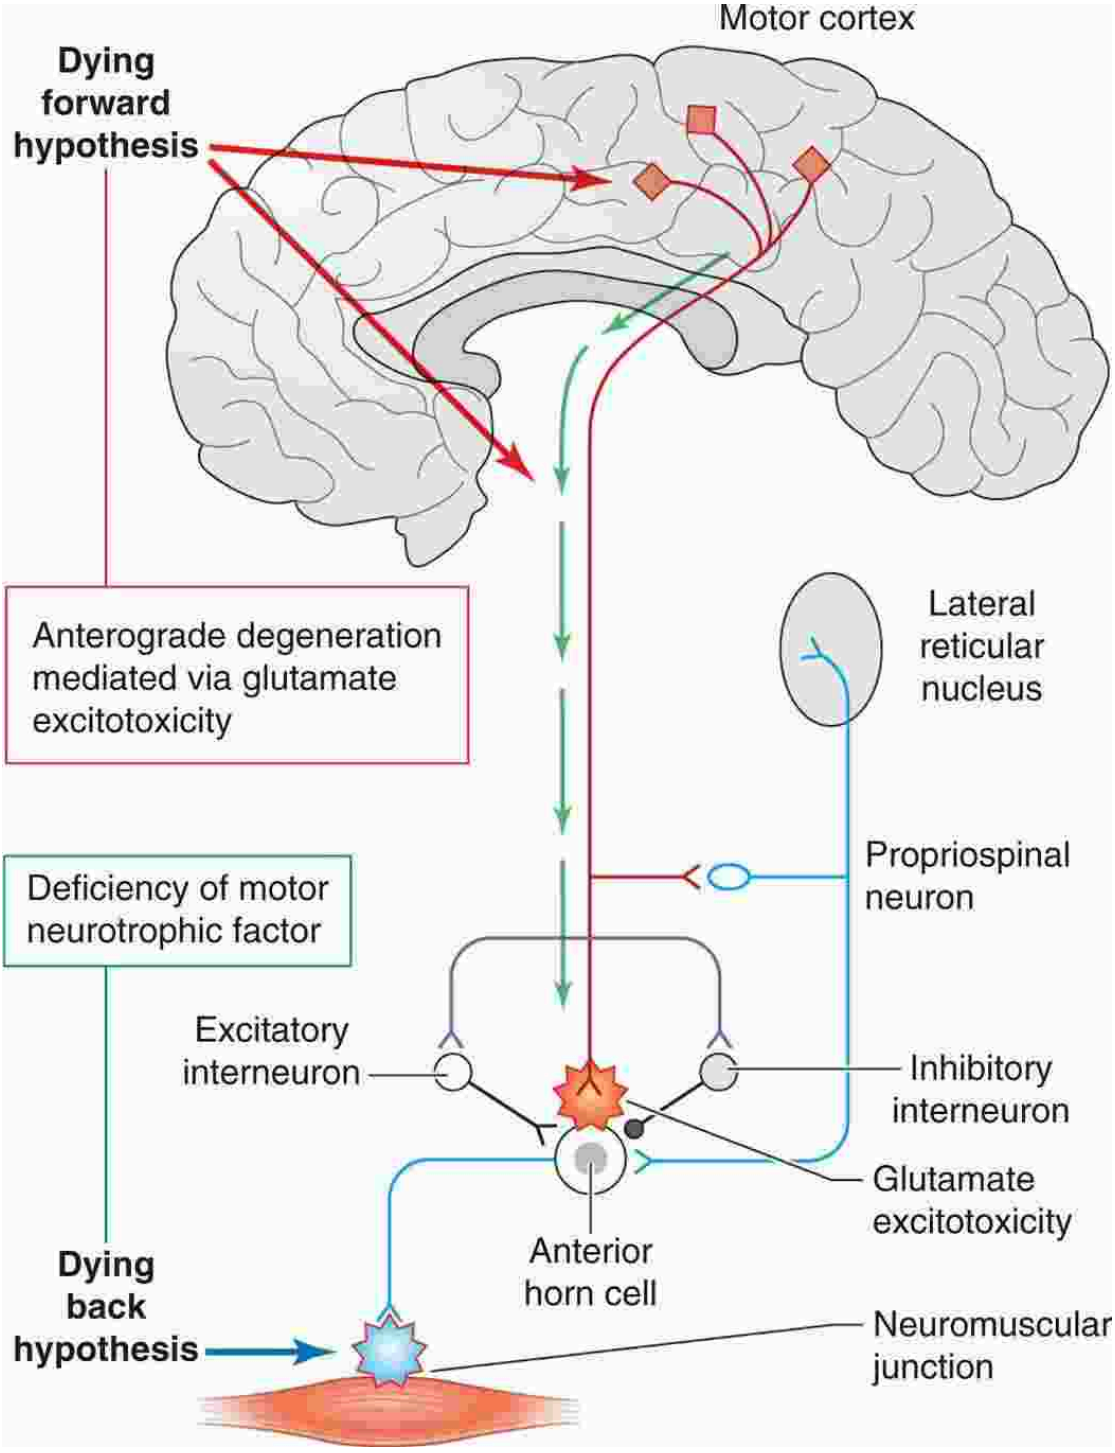

FIG. 17.33 The dying forward *(red arrows)* and dying back hypotheses *(blue arrow)* of amyotrophic lateral sclerosis pathogenesis. *NMJ*, Neuromuscular junction. (Reprinted with permission from Elsevier (From Kiernan MC, Vucic S, Cheah BC, et al. Amyotrophic lateral sclerosis. *The Lancet* 2011; 377(9769), 942–955. https://doi.org/10.1016/s0140-6736(10)61156-7.)

An illustration shows the pathogenesis of amyotrophic lateral sclerosis. The pathway of the dying forward hypothesis (anterograde degeneration mediated

via glutamate excitotoxicity) is from the motor cortex to the glutamate excitotoxicity to the anterior horn cell, with the excitatory interneuron and the inhibitory interneuron. The pathway of the dying back hypothesis (deficiency of motor neurotrophic factor) is from the neuromuscular junction to the anterior horn cell to the propriospinal neuron to the lateral reticular nucleus.

The accumulation of microscopic protein aggregates (e.g., *TDP-43* proteinopathy) in neurons and glia associated with degeneration of the primary motor cortex and motor cortex-spinal cord axis varies by cell pattern and genotype and may have implications for targeted therapy.[126] However, the source of neurotoxic molecules leading to neurodegeneration is still not clearly understood.[127] As the disease progresses, there is a decrease in large motor neurons in the spinal cord, brainstem, and cerebral cortex (premotor and motor areas) with ongoing degeneration in the remaining motor neurons. The nuclei of cranial nerves III, IV, and VI usually are not involved. Death of the motor neuron results in axonal degeneration and secondary demyelination with glial proliferation and sclerosis (scarring) along the corticospinal tract. However, there also is widespread neural degeneration of nonmotor neurons in the spinal cord and motor cortices, as well as in the premotor, sensory, and temporal cortices. Altered astrocyte function, activated microglia, and edema are seen to occur. Metabolic dysfunction is also common, causing weight loss, hypermetabolism, and hyperlipidemia, all of which suggest that ALS is a systemic disease. Hypermetabolism may also be associated with increased mitochondrial energy production, leading to large amounts of cytotoxic oxygen reactive species.[128] LMN degeneration denervates motor units. Adjacent, still-viable LMNs attempt to compensate by distal intramuscular sprouting, reinnervation, and enlargement of motor units.

Clinical Manifestations

Presentation of symptoms can be variable among individuals because of the numerous genes and multiple systems involved. The initial onset of ALS can be subtle, with cramping or weakness that affects a limb, incoordination, slurring of speech, and difficulty swallowing. About 70% to 75% of individuals have spinal ALS, with focal muscle weakness beginning in the arms and legs and progressing to muscle wasting and atrophy, spasticity, and loss of manual dexterity and gait (Fig. 17.34). The other 25% to 30% of individuals with ALS experience bulbar onset, with symptoms such as dysarthria, dysphagia, and dysphonia. Bulbar onset disease has a more rapid and progressive course. No associated sensory or autonomic symptoms are present. Muscle weakness in ALS exhibits the following characteristics:

1. Paresis usually begins in a single muscle group.
2. Corresponding muscle groups are asymmetrically affected in a mottled distribution.
3. Gradual involvement occurs in all striated muscles, except extraocular and heart muscles, and progresses to paralysis with no remissions.
4. Flaccid and spastic paresis may coexist in a single muscle group; flaccid paresis may mask spasticity, which is usually mild.
5. Urethral and anal sphincter weakness is uncommon.

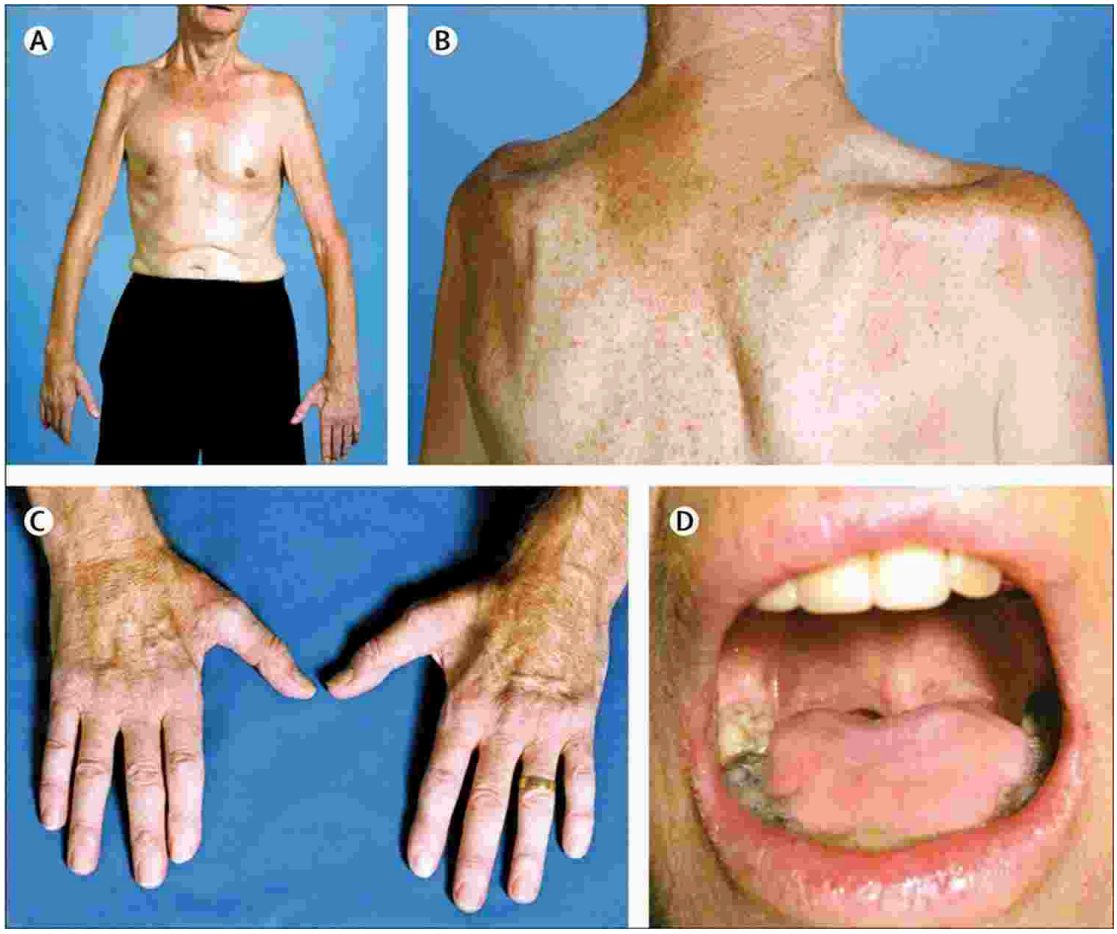

FIG. 17.34 Muscle Wasting and Amyotrophic Lateral Sclerosis. **(A)** Symmetrical upper limb wasting results in an inability to lift arms against gravity ("man-in-the-barrel" or flail-arm variant amyotrophic lateral sclerosis [ALS]). **(B)** Wasting of supraspinatus and infraspinatus muscles, as well as substantial loss of deltoid muscle. The glenohumeral joint becomes prominent, and prone to subluxation. **(C)** Disproportionate wasting of the thenar muscles combined with the first dorsal interossei, the so-called "split-hand," is a typical feature in ALS. **(D)** Substantial wasting of the tongue muscles in bulbar-onset ALS. Note the absence of palatal elevation present on vocalization. Difficulty with mouth opening and dysphagia might require supplementary feeding through a percutaneous endoscopic gastrostomy. (Reprinted with permission from Elsevier (From Kiernan MC, Vucic S, Cheah BC, et al. Amyotrophic lateral sclerosis. *The Lancet* 2011; 377(9769), 942–955. https://doi.org/10.1016/s0140-6736(10)61156-7.)

Four photos illustrate muscle wasting and amyotrophic lateral sclerosis. Top-left panel, A. The photo shows a person's atrophied arms. Top-right panel, B. The photo shows the back and shoulders of a person. The left shoulder is atrophied when compared to the right shoulder. Bottom-left panel, C. The photo shows the hands of a person on a flat surface. The muscles on the side of the thumbs in both hands are disproportionately atrophied. Bottom-right panel, D. The closeup of a person's open mouth shows an atrophied tongue.

The LMN syndrome of flaccid paresis consists of weakness of individual muscles, progressing to paralysis, associated with hypotonia and primary muscle atrophy (i.e., atrophy caused by denervation). Hypotonia is manifested by (1) decreased resistance to passive movement, (2) hypoactive or absent deep tendon reflexes, (3) absent abdominal and cremasteric reflexes, and (4) absent Babinski sign. Primary atrophy is manifested by (1) severe, irreversible muscular wasting; (2) fasciculations and fibrillation; (3) metabolically related changes in the skin and appendages; and (4) specific electromyographic (EMG) findings. Metabolic changes include: (1) thinning of the skin, (2) thickening of the nails, (3) loss of body hair, and (4) decreased perspiration.

The upper motor neuron syndrome of spastic paresis consists of weakness of movement patterns, progressing to paralysis, associated with spasticity, and, in some cases, atrophy secondary to disuse. Spasticity is manifested by (1) clasp-knife phenomenon, evident with passive movement; (2) hyperactive deep tendon reflexes and clonus with severe spasticity; (3) absent abdominal and cremasteric reflexes; and (4) presence of Babinski sign. A subset of individuals also demonstrates extrapyramidal symptoms with difficulty initiating gait and postural instability.[129]

The coexistence of FTD dementia and ALS has been demonstrated and has been found to be related to common gene mutations. Cognitive impairment due to FTD occurs in around 50% of ALS (spinal and bulbar onset) individuals and can cause executive dysfunction, behavior changes, and language deficits.[130,131] A summary of upper and lower motor and extra-motor signs and symptoms is presented in Table 17.26.

Table 17.26

Clinical Signs and Symptoms of Amyotrophic Lateral Sclerosis

Spinal Onset	Bulbar Onset
Upper Motor Neuron	*Upper Motor Neuron*
Weakness and slow movement	Slow speech
Spasticity and loss of dexterity	Hyperactive reflexes
Babinski sign	Palmomental reflex
Hoffman sign	Jaw jerk reflex

Lower Motor Neuron	*Lower Motor Neuron*
Weakness	Facial weakness
Muscle atrophy	Low palatal elevation
Fasciculations	Dysarthria
	Tongue fasciculations
	Tongue atrophy
EXTRAPYRAMIDAL SIGNS	
Tremors, akinesia	
Postural disturbances	
Gait difficulty	
Rigidity	
EXTRA-MOTOR SIGNS	
Pain	
Fatigue	
Paresthesias	
Depression	
FRONTO-TEMPORAL DEMENTIA	
Personality change	
Behavioral abnormalities	
Language dysfunction	
Memory impairment	

Evaluation and Treatment

The diagnosis of ALS is based predominantly on medical history and physical examination with no evidence of other neuromuscular disorders. Transcranial magnetic stimulation, electromyography, and muscle biopsy results can verify cortical hyperexcitability, LMN degeneration, and denervation. Imaging studies and cerebrospinal fluid biomarkers can assist in making the diagnosis. Neurofilament light chains, found in the cerebrospinal fluid after motor neuron damage, may be a promising biomarker and prognostic tool as it correlates with disease severity.[132]

Riluzole (Rilutek), an antiglutamate, was the first drug approved by the Food and Drug Administration (FDA) for treatment of ALS. It is an oral medication and prolongs life for about 3 months. The mechanism of action is a decreased uptake of glutamate and neuromuscular excitation. In 2017, the FDA approved a second treatment, Edaravone (Radicava), to treat ALS. Edaravone is an antioxidant and free radical scavenger thought to reduce oxidative stress and neuronal death. It is administered intravenously and delays progression of the disease. Dextromethorphan-Quinidine (Neudexta) is an FDA-approved symptom management drug that helps bulbar symptoms, such as swallowing, hypersalivation, and speaking. Clinical trials are in progress for evaluation of gene therapy, immunotherapy, and targeted drug therapy.[133–135] Supportive and rehabilitation management is directed at relief of symptoms, prevention of complications, maintenance of maximal function, and maintenance of optimal quality of life. Special problems requiring preventive and symptomatic management are communication difficulties caused by dysmasesis and dysphonia, salivation problems with either thick saliva or excessively thin saliva (sialorrhea), and dyspnea caused by diaphragmatic and intercostal weakness. Ventilatory issues become prominent. Mobility and safety needs related to ambulation and activities of daily living must also be addressed. Psychologic support of the affected individual and the family is extremely important in this disorder. ALS is fatal from respiratory failure, usually within 2 to 5 years of diagnosis. A small percentage of individuals live 5 years or longer.[136]

Demyelinating Disorders

Demyelinating disorders are the result of damage to the myelin nerve sheath and affect neural transmission. They can occur in either the central (i.e., MS) or the peripheral (i.e., GBS) nervous system. Contributing factors include genetics, infections, autoimmune reactions, environmental toxins, and unknown factors.

Multiple Sclerosis

MS is a chronic immune-mediated inflammatory disease involving degeneration of CNS myelin, scarring (sclerosis or plaque formation), and loss of axons. MS is caused by an autoimmune response to self or microbial antigens in genetically susceptible individuals. The etiology of MS is unknown. The onset of MS is usually between 20 and 40 years of age and is more common in women. Men may have a more severe progressive course. The prevalence rate is higher in northern latitudes and areas with lack of sun exposure. Inconclusive risk factors that may be involved include a gene-environment interaction including factors such as smoking, vitamin D deficiency, obesity, and Epstein-Barr virus infection.[137,138] Life expectancy is not greatly altered by MS, and the disease course often extends over 30 years.

Pathophysiology

MS is a diffuse and progressive CNS autoimmune inflammatory disease that affects white and gray matter throughout the brain and spinal cord. There are multiple focal areas of myelin loss within the CNS called *plaques*. The plaques form when autoreactive T cells and B cells cross the blood–brain barrier into the brain and spinal cord. T cells recognize myelin as autoantigens and attack it. B cells produce myelin-specific antibodies, which are recognized by glial cells (macrophages). Activated glial cells engulf the antibodies, damaging the myelin. These attacks on myelin leave patches disrupting neurotransmission. With resolution of inflammation (a period of remission), the injury leaves a glial scar or sclerosis, the classic lesion of MS (Fig. 17.35). During early stages oligodendrocytes (myelin-producing cells) repair myelin. With progressive attacks, oligodendrocytes are also injured and lost. The loss of oligodendrocytes prevents remyelination, and over time the injury is irreversible with loss of axons (Fig. 17.36). Loss of myelin disrupts nerve conduction, leading to symptom presentation. There is at least partial myelin repair during relapse of symptoms. Ultimately there is death of neurons and brain atrophy in the most progressive forms of the disease. *Spinal MS* can occur concurrently with or independently of brain lesions. The multifocal, multistage features of MS lesions produce symptoms that are multiple and variable. Thus, inflammation, demyelination, myelin repair, loss of oligodendrocytes, and scar formation distinguish MS from other demyelinating disorders of the CNS.[139]

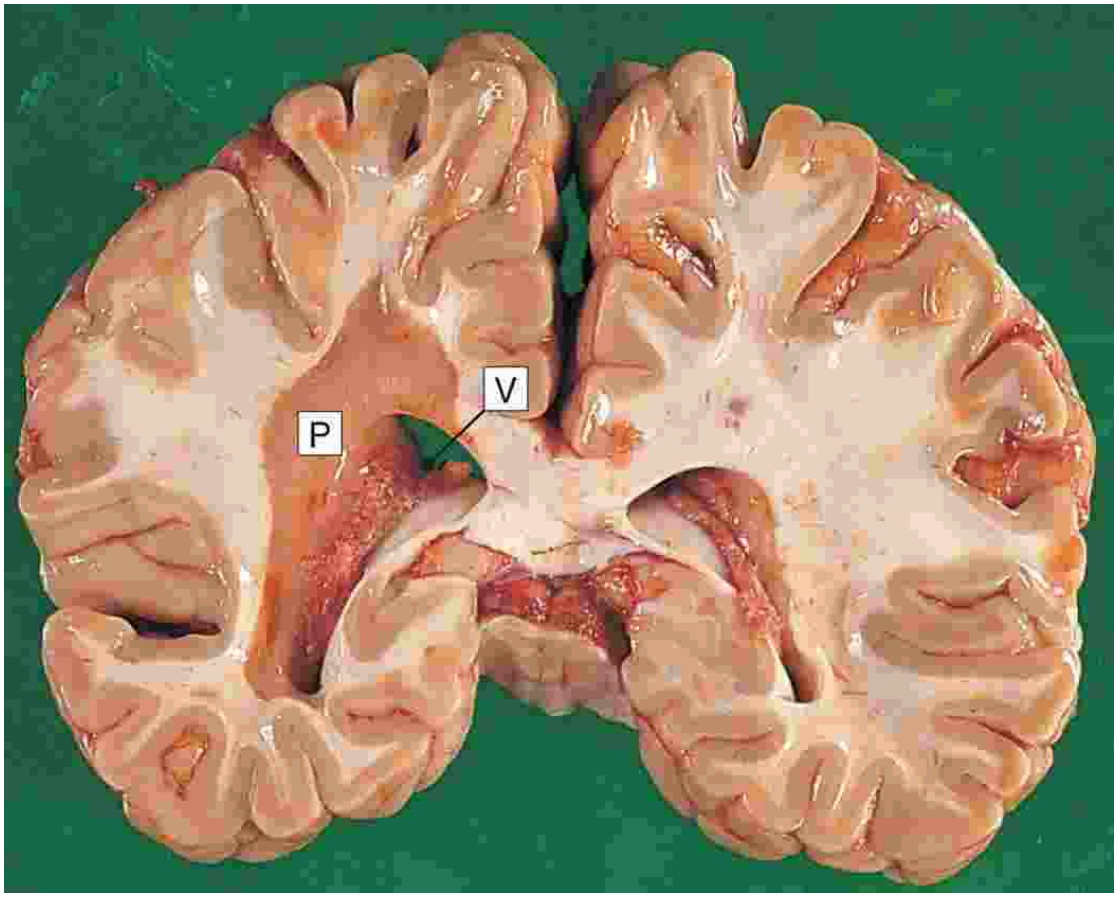

FIG. 17.35 Multiple Sclerosis (Gross). Seen here in periventricular white matter is a large “plaque” *(P)* of demyelination that has a sharp border with adjacent normal white matter. Such plaques have a gray-tan appearance and are typically associated with the clinical appearance of transient or progressive loss of neurologic function in multiple sclerosis (MS). Because MS is often multifocal, and the lesions appear in various white matter locations in the central nervous system over time, the clinical course and findings can be quite varied. *V*, ventricle. FIG. 17.36 Pathogenesis of Multiple Sclerosis

An illustration shows the pathogenesis of multiple sclerosis. The following parts of a neuron are labeled: nucleus, dendrites, myelin sheath, call body, nodes of Ranvier, and synapses. An oligodendrocyte is attached to a normal nerve on the left and a damaged nerve on the right. The nucleus, myelin, and axon of the normal nerve are identified. The damaged myelin and exposed axon are of the damaged nerve are identified. A magnified view of the damaged nerve shows, damaged myelin, macrophages (microglia), activated T cells, and exposed axon.

Clinical Manifestations

The onset, duration, and severity of symptoms are different for each person and depend on the location and extent of disease. A *clinically isolated syndrome* of neurologic symptoms that lasts 24 hours or less may initially occur. It can be related to inflammation and demyelination but may never progress to develop into MS. There is no evidence of previous episodes of demyelination. Work is in progress to identify the prodromal symptoms of MS more specifically.[140]

MS develops when symptoms last more than 24 hours; occur in the absence of fever, infection, or encephalopathy; and are caused by inflammation and demyelination in the CNS. The subtypes of MS are based on the clinical course and are summarized in Table 17.27. The most common initial symptoms of MS are paresthesia of the face, trunk, or limbs; weakness; impaired gait; or urinary incontinence, indicating diffuse CNS involvement. Monofocal symptoms are caused by a single lesion and include optic neuritis, spinal cord syndrome, and brainstem and cerebellar syndromes. *Optic neuritis* is a common presentation in one eye with progressive blurring of vision and pain with eye movement. *Spinal cord syndrome* is common and can involve both sensory and motor tracks starting on one side and progressing to the other. *Brainstem syndromes* can involve facial sensory loss or weakness, vertigo, or double vision. *Cerebellar syndromes* demonstrate lack of coordination, intention tremor, gait instability, ataxia, and nystagmus.

Table 17.27

Types of Multiple Sclerosis

Type	Clinical features	Disability over time
Relapsing-remitting (most common 80%–90%)	Long periods of remission with few exacerbations; stable between exacerbations; minimal disability or progression of disease	
Primary progressive (least common)	Gradual progression of symptoms without periods of remission from the start of disease. Disease more common in spinal cord with less cognitive decline.	
Secondary progressive	Initial relapsing-remitting disease with gradual neurologic deterioration with or without exacerbations. May have more severe symptoms between relapses. 	

Type	Clinical features	Disability over time
Progressive relapsing	Gradual progression of symptoms with exacerbations and fewer remissions	

Type	Clinical features	Disability over time
Relapsing-remitting (most common 80%–90%)	Long periods of remission with few exacerbations; stable between exacerbations; minimal disability or progression of disease	
Primary progressive (least common)	Gradual progression of symptoms without periods of remission from the start of disease. Disease more common in spinal cord with less cognitive decline. 	
Secondary progressive	Initial relapsing-remitting disease with gradual neurologic deterioration with or without exacerbations. May have more severe symptoms between relapses. 	
Progressive relapsing	Gradual progression of symptoms with exacerbations and fewer remissions	

Lesions in the cerebrum present as hemifacial weakness, pain, and motor impairments. Cognitive deficits, including memory and attention problems, are common later in the disease, as well as emotional liability psychiatric disorders, depression, and dementia. Most persons present with a remitting-relapsing course and without treatment transition to the progressive types with insidious neurologic decline that occurs over years. After years of disease, 50% of individuals appear to have established syndromes of multifocal involvement.

Disease exacerbations (also known as *relapses* or *flares*) are the temporary occurrence or worsening of symptoms. The symptoms may be mild or serious, may last for several days or weeks, and may be followed by progressive symptoms, including paresthesia, difficulty speaking, ataxia, or visual changes. The mechanism of these exacerbations is related to delayed or blocked conduction caused by inflammation and demyelination. Various events can occur immediately before the exacerbation of symptoms and are regarded as precipitating factors or triggers, including trauma, emotional stress, and pregnancy. Painful sensory events, spastic paralysis, and bowel and bladder incontinence are common with spinal involvement.

Recovery from symptoms during remissions is caused by down-regulation of inflammation and the restoration of axonal function, either by remyelination, the resolution of inflammation, or the restoration of conduction to demyelinated axons. Pregnancy does not appear to alter the course of MS. Symptoms improve in some cases and may be related to the immune tolerance that develops during pregnancy.[141] There are no specific markers for early detection of disease or disability progression.[142] Disability progression is evaluated by the Expanded Disability Status Scale and components of the MS Functional Composite (timed 25-foot walk, 9-hole peg test, low-contrast visual acuity, symbol digit modalities test).[143,144]

Evaluation and Treatment

There is no single test available to diagnose or rule out MS. Diagnostic criteria include history, clinical examination, CSF findings, and evoked potentials in combination with MRI (most sensitive test for detecting demyelinated plaque, disease progression [new lesions], and treatment response).[145,146] Clinical symptoms include neurologic findings not attributable to another diagnosis with two or more episodes lasting at least 24 hours and occurring at least 1 month apart. Persistently elevated levels of CSF immunoglobulin G (IgG) are found in about two-thirds of individuals with MS, and oligoclonal IgG bands on electrophoresis are found in more than 90% of individuals with MS. Evoked potential studies aid diagnosis by detecting decreased conduction velocity in visual, auditory, and somatosensory pathways. The 2017 revisions of the McDonald criteria are used to guide diagnosis.[145]

The treatment goal in MS is prevention of exacerbations, prevention of permanent neurologic damage, and control of symptoms. Disease-modifying drugs are initiated with diagnosis and include corticosteroids, immunosuppressants, and immune system modulators.[147] Continuous monitoring is important because of the increased risk for infection when taking these drugs. Plasma exchange may be used in persons who do not respond to steroids. Drugs are also available for symptom control. Supportive care includes participation in a regular exercise program, cessation of smoking, and avoidance of overwork, extreme fatigue, and heat exposure. The administration of vitamin D to prevent disease progression has found no therapeutic effect, and further clinical trials are needed.[148] New treatments are becoming available, including stem cell transplantation and monoclonal antibodies.[149,150]

Guillain-Barré Syndrome

GBS is a rare demyelinating disorder caused by a humoral (antibody) and cell-mediated immunologic reaction directed at the peripheral nerves. There is a demyelinating subtype known as acute inflammatory demyelinating polyneuropathy ADIP and an axonal subtype known as acute motor axonal neuropathy (AMAN—absence of sensory involvement). GBS usually occurs within 4 weeks after a respiratory tract or gastrointestinal infection and has been associated with surgery, immunization, immune check point inhibitors, and infections, including *Campylobacter jejuni*, the Zika virus, and the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).[151] In axonal forms of GBS, it is

proposed that molecular mimicry of pathogen-borne antigens (i.e., *C. jejuni*) leads to the generation of cross-reactive antibodies that target axonal gangliosides at nodes of Ranvier, activate complement, and disrupt nerve conduction in peripheral motor nerves.[152] Supportive diagnostic studies include evaluation of blood serum, cerebrospinal fluid, and electromyography.[153]

The clinical manifestations can vary from tingling and weakness to ascending flaccid paralysis starting in the legs and progressing to complete quadriplegia, respiratory insufficiency, and autonomic nervous system instability (low blood pressure and arrhythmias). Diagnostic criteria include progressive weakness of more than two limbs, areflexia, and progression for no more than 4 weeks. Intravenous immunoglobulin or plasmapheresis is used during the acute phase with respiratory support as needed, followed by aggressive rehabilitation. Targeted immunotherapy to human complement is under investigation. Recovery occurs within weeks to months or up to 2 years. Approximately 20% of individuals have residual weakness.[153]

Neuromuscular Junction Disorders

Motor function requires the transmission of the nerve impulse at the NMJ with the release of adequate amounts of neurotransmitter from the presynaptic terminals of the axon and effective binding of the released transmitter to the receptors on the membranes of muscle cells (see Fig. 15.14). Alterations in the amount or function of the neurotransmitter or the receptors affects motor function.

Neuromuscular junction disorders (NMJDs), whose pathogenesis is caused by autoantibodies, include MG and the rare pre-synaptic Lambert-Eaton myasthenic syndrome. In addition, there are rare inherited (congenital) myasthenic syndromes that result from mutations in different key proteins for the postsynaptic nicotinic acetylcholine receptor, ion channels, and motor end plates at the NMJ. Details related to those disorders are not included here.

Myasthenia Gravis

MG is an acquired chronic autoimmune disease mediated by antibodies against the acetylcholine receptor (AChR) at the postsynaptic membrane of the NMJ. About 14 to 40 per 100,000 people in the United States have the disease. It is more common in women at ages 20 to 30 years and more common in men over 60 years.[154]

MG is associated with an increased incidence of thymomas and other autoimmune diseases, including systemic lupus erythematosus, rheumatoid arthritis, polymyositis, and thyrotoxicosis. (Autoimmune mechanisms are discussed in Chapter 9.) About 27% of family members have autoimmune diseases. The etiology of MG is unknown, and the disease is usually sporadic. Some persons have genetic susceptibility related to variants in AchR genes, as well as the major histocompatibility genes, and they can present with varying clinical phenotypes.[155]

Presynaptic autoimmune diseases are rare and include **Lambert-Eaton myasthenic syndrome**. There are autoantibodies to calcium channels on presynaptic nerve terminals, which presents with more leg and arm weakness and is commonly associated with small-cell lung carcinoma (Fig. 17.37).[156]

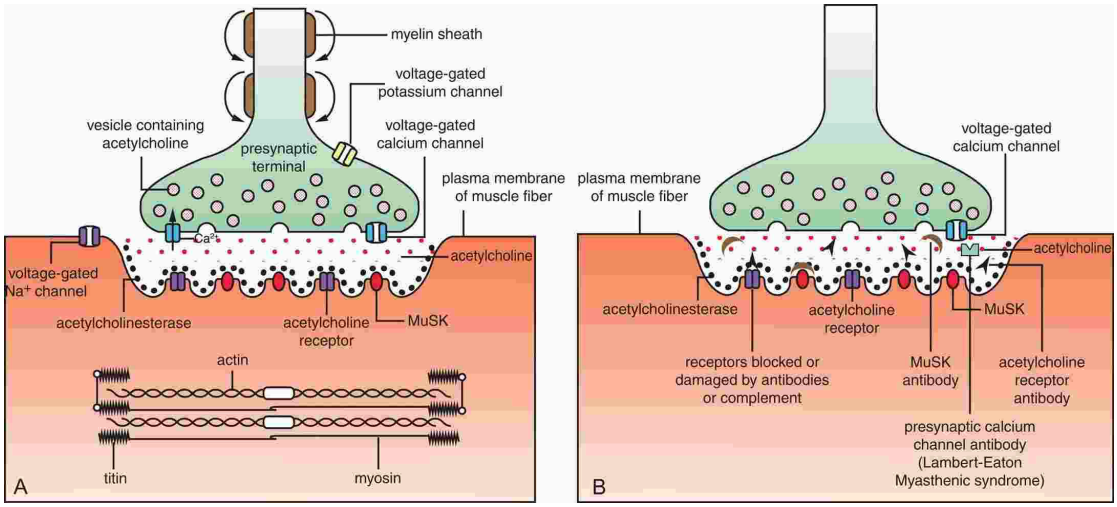

FIG. 17.37 Antibodies and Myasthenia Gravis.
Schematic diagrams of **(A)** a normal neuromuscular junction illustrating locations of the presynaptic vesicles, acetylcholine within the synapse, and the postsynaptic acetylcholine receptors, as well as **(B)** a neuromuscular junction affected by myasthenia gravis, with antibodies that interfere with the binding or structure, or both, of the acetylcholine receptors and muscle-specific kinase (MuSK). (Note that antibodies to both proteins are not typically present in the same individual, though this phenomenon has been reported on occasion.) Presynaptic calcium channel antibodies occur with Lambert-Eaton myasthenic syndrome. (From Darras BT, et al. *Neuromuscular disorders of infancy, childhood, and adolescence*, 2nd edition. London: Academic Press; 2015.)

Two illustrations of neuromuscular junctions show antibodies and myasthenia gravis. Left panel, A. The following structures on the illustration are labeled. • Myelin sheath. • Voltage-gated potassium channel. • Presynaptic terminal. • Vesicle containing acetylcholine. • Plasma membrane of muscle fiber. • Actin, titin, myosin, and voltage-gated calcium channel. • Acetylcholine. • Acetylcholine receptor. • Mu S K. • Acetylcholinesterase. • Voltage-gated sodium ion channel. • Plasma membrane of fiber. Right panel, B. The following structures on the illustration are labeled. • There is no myelin sheath, voltage-gated potassium channel, or voltage-gated sodium channel. • Voltage-gated calcium channel. • Acetylcholine. • Acetylcholine receptor antibody. • Mu S K. • Mu S K antibody. • Presynaptic calcium channel antibody (Lambert-Eaton Myasthenic syndrome). • Acetylcholine receptor. • Receptors blocked or damaged by antibodies or complement. • Acetylcholinesterase. • Plasma membrane of fiber.

Pathophysiology

MG is a T cell-dependent, B-cell mediated autoimmune disease (type II hypersensitivity) caused by IgG antibodies against nicotinic acetylcholine receptors (AchR) (80%–90% of cases) in the postsynaptic membrane at the NMJ. The autoantibodies destroy the AchR receptor sites through antibody-mediated complement activation and formation of membrane attack complex or block Ach attachment to the

membrane receptor. The consequence is diminished transmission of nerve impulses across the NMJ (see Fig. 17.37). Muscle depolarization is incomplete or unsuccessful and leads to muscle weakness. The cause of this autosensitization is unknown. Thymic abnormalities are common with hyperplasia of germinal centers, where T cells interact with B cells to produce antibodies. There is breakdown in self-tolerance leading to immune-mediated destruction of the AChR. This is more common in women with early-onset disease. About 10% to 20% of individuals with MG develop thymoma, and about 30% of individuals with thymoma develop MG.[157,158]

In some types of MG, antibodies are directed against other components of the NMJ. About 10% to 15% of individuals with MG do not have AchR antibodies on testing but have MuSK antibodies (an IgG4 subtype). This is now subtyped as MuSK antibody–associated MG, which is not complement-mediated. It is more common in females in their 40 s and affects individuals of equatorial nations and African descent. Other subgroups of antibodies include lipoprotein-related protein 4 (LRP4), or agrin, a component of MuSK receptor function.[159]

Clinical Manifestations

The onset of *generalized AchR myasthenia* is insidious and may develop over several years. Early-onset MG is more common in women at ages 20 to 40 years of age. Late-onset MG is more common in men older than 60 years. The hallmark clinical manifestation is fatigable muscle weakness, which may involve ocular, bulbar (muscles of the eyes, face, mouth, throat, and neck), respiratory, and limb muscles. The variable distribution of ACh receptor sites, number of and different isoforms of antibodies, or the presence of thymoma determine when and which muscle groups are affected first. The extraocular eye muscles and the levator muscles of the eyelid are most affected as they have a small number of AchR.

Manifestations include diplopia, ptosis, and ocular palsies. The muscles of facial expression, mastication, swallowing, and speech are the next most involved. The results are facial droop and an expressionless face; difficulty chewing and swallowing, which are associated with dietary changes and weight loss; drooling; episodes of choking and aspiration; and a nasal, low volume but high-pitched monotonous speech pattern. The muscles of the neck, shoulder girdle, and hip flexors are less frequently affected, but muscle fatigue is common after exercise, and there can be progressive weakness. The respiratory muscles of the diaphragm and chest wall become weak, with impaired ventilation. Impairment in deep breathing and coughing predisposes the individual to atelectasis and congestion. Clinical manifestations may also appear during pregnancy, during the postpartum period, or in conjunction with the administration of certain anesthetic agents.

The progression of MG varies. The clinical manifestations of MG involve remissions and exacerbation of different types: relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing. It usually appears first as a mild case that spontaneously remits, with a series of relapses and symptom-free intervals ranging from weeks to months. Over time, the disease can progress slowly or rapidly or take a fulminating course.[160]

Ocular myasthenia is a subtype of MG that may occur with milder forms of MG. Ocular myasthenia is more common in males and with a late onset. Weakness of the eye muscles and eyelids is characteristic and may include swallowing difficulties and slurred speech as well.[161] *Juvenile MG* is very rare and occurs in children younger than 18 years of age. The disease is similar to generalized AchR myasthenia, usually less severe, and is treated aggressively to prevent long-term progression and disability.[162] In *transient neonatal myasthenia*, transitory signs of MG are present in about 10% to 15% of infants born to mothers with MG. Myasthenia immunoglobulin is transferred from the mother to the neonate through the placenta. There is generalized hypotonia, respiratory distress, and poor sucking in addition to extraocular muscle weakness. The signs appear 1 to 3 days after birth and persist for a few days to a few weeks.[163]

MuSK antibody type MG often involves severe swallowing and breathing (bulbar) problems. Clinical manifestations may first appear during pregnancy, during the postpartum period, or in conjunction with the administration of certain anesthetic agents. The progression of MG varies, appearing first as a

mild case that spontaneously remits with a series of relapses and symptom-free intervals ranging from weeks to months. Over time, the disease can progress, and all muscles are weak.[164]

Myasthenic crisis occurs when severe muscle weakness causes extreme quadriparesis or quadriplegia, respiratory insufficiency with shortness of breath and a markedly decreased tidal volume and vital capacity, and extreme difficulty in swallowing. The individual in myasthenic crisis is in danger of respiratory arrest. **Cholinergic crisis** is a result of overstimulation of nicotinic and muscarinic receptors at neuromuscular junctions, usually seondary to the inhibition of acetylcholinesterase. A cholinergic crisis may result from cholinergic drug toxicity, with increased intestinal motility, episodes of diarrhea, and complaints of intestinal cramping, bradycardia, pupillary constriction, increased salivation, and diaphoresis. The clinical picture resembles that of myasthenic crisis, but the weakness occurs 30 to 60 minutes after taking anticholinergic medication. The clinical manifestations are caused by the smooth muscle hyperactivity secondary to excessive accumulation of Ach at the NMJs and excessive parasympathetic-like activity. As in myasthenic crisis, the individual is in danger of respiratory arrest.

Drugs that worsen symptoms include chloroquine, quinine, quinidine, procainamide, and botulinum toxin; aminoglycoside, fluoroquinolones, erythromycin antibiotics, neuromuscular blocking agents (pancuronium, D-tubocurarine), and immune checkpoint inhibitors.[156]

Evaluation and Treatment

The diagnosis of MG is made based on history and physical findings of weakness and muscle fatigability. Detection of AchR, MuSK, and the LRP4 antibodies is diagnostic of MG and defines MG subtypes. Results of EMG studies (rapid nerve stimulation and single-fiber electromyography) can aid diagnosis in seronegative individuals. Mediastinal CT and MRI help determine whether a thymoma is present.[165]

Treatment of MG is individualized and based on the MG subgroup symptoms. Acetylcholinesterase inhibitors (pyridostigmine—prevents degradation of Ach), corticosteroids and other immunosuppressant drugs (e.g., rituximab, chimeric monoclonal antibody against the protein CD20 primarily found on the surface of B cells, azathioprine, cyclosporine, mycophenolate mofetil) are used to treat MG and myasthenic crisis. Intravenous immunoglobulin and plasmapheresis may be lifesaving during myasthenic crisis, before and after thymectomy, and at the start of immunosuppressant therapy. For individuals with cholinergic crisis, treatment is to withhold anticholinesterase drugs (i.e., acetylcholinesterase inhibitors and cholinesterase inhibitors), then initiate treatment with anticholinergic drugs. However, anticholinergic medications do not block the severe muscle weakness effects associated with a severe cholinergic crisis, possibly requiring ventilatory support. At which time, the anticholinergic drugs are generally discontinued until the individual improves.

Thymectomy is the treatment of choice for a thymoma and those with anti-AChR antibodies because this terminates the production of self-reactive T cells and B cells that produce the antibodies. Current treatments for MG have improved prognosis, including in those individuals who have ocular myasthenia. Guidelines are available to guide the management of MG.[166] Several clinical trials are in progress to identify predictive biomarkers, evaluate targeted therapies, including complement and antigen specific T and B cells inhibitors, and vaccines to protect the AchR.[167]

Botulism

Botulism poisoning results from the botulinum neurotoxin released from *Clostridium botulinum*. The toxin inhibits the release of ACh at the myoneural junction and causes flaccid paralysis, including respiratory paralysis and death. Other forms include *C. botulinum*—contaminated wounds, infant and adult intestinal botulism released from spores that grow in the intestine after eating contaminated food, and iatrogenic botulism from accidental overdose of botulinum toxin. The endospores are resilient and resistant to heat. All forms are life-threatening and require emergency treatment. Treatments include supportive care with mechanical ventilation and antitoxin.

Summary Review

Alterations in Cognitive Systems

1. Three systems support cognitive function: attentional systems, memory and language systems, and affective or emotive systems.
2. Full consciousness is an awareness of oneself and the environment and includes an ability to respond to external stimuli with a wide variety of responses.
3. Consciousness has two components: arousal (state of awakeness) and awareness (content of thought).
4. Alterations in level of arousal may be caused by structural, metabolic, or psychogenic disorders.
5. Levels of consciousness can diminish in stages from alert and oriented to confusion and coma.
6. An alteration in breathing pattern and level of coma reflects the level of hemispheric and brainstem dysfunction.
7. Pupillary changes reflect changes in level of brainstem function, drug action, and response to hypoxia and ischemia.
8. Abnormal eye movements, including nystagmus and divergent gaze, reflect alterations in brainstem function.
9. Level of brain dysfunction manifests by changes in generalized motor responses or the presence of no responses.
10. Loss of cortical inhibition associated with decreased consciousness includes abnormal flexor and extensor movements.
11. Brain death represents irreversible total brain damage, including an inability to maintain cardiac, respiratory, and other vital functions. Cerebral death or irreversible coma is death of the cerebral hemispheres exclusive of the brainstem and cerebellum.
12. Arousal returns in the vegetative state and minimally conscious state, but content of thought is absent or markedly reduced, respectively.
13. With locked-in syndrome (ventral pontine syndrome) content of thought and level of arousal are intact, but the efferent pathways are disrupted with complete paralysis.
14. Akinetic mutism is a neurobehavioral state characterized by a severe loss of motivation to move or inability to voluntarily initiate motor responses, or both.
15. Alterations in awareness encompass all cognitive functions, including awareness, selective attention, and memory.
16. With a deficit in selective attention, mediated by the brainstem, the parietal lobe structures, and the pulvinar nucleus of the thalamus, the individual cannot focus on selective stimuli (visual and/or auditory or tactile) and thus neglects those stimuli, causing a neglect syndrome.
17. Memory is the recording, retention, and retrieval of information. Declarative memory is remembrance of personal history, events, experiences, facts, and information. Nondeclarative memory is a motor memory for actions, behaviors, skills, and outcomes. Emotional memory attaches positive or negative qualities to a memory.
18. Amnesia can be retrograde (loss of past memories) or anterograde (retention of old memories but an inability to form new ones). Global amnesia is a combination of both.
19. Frontal areas mediate vigilance, detection, and working memory (temporary storage of information). With a vigilance deficit, the person cannot maintain search and scanning activities. With a detection deficit, the person is unmotivated and unable to use feedback. With executive attention deficits there is working memory deficit and an inability to plan, remember instructions, and complete a task.
20. Data processing deficits are problems associated with recognizing and processing sensory information and include agnosias, aphasia, and acute confusional states.
21. Agnosias are a defect of recognition and may be tactile, visual, or auditory. They are caused by dysfunction in the primary sensory area or the interpretive areas of the cerebral cortex.
22. Aphasia is an impairment of comprehension or production of language. Aphasia may be motor (speaking or writing) or sensory (understanding spoken or written language).
23. Anomic sensory aphasia is an inability to name objects, people, or qualities.
24. Transcortical aphasias can be motor, sensory, or mixed, and are rare.

25. Global aphasia involves anterior and posterior speech areas, with both motor and sensory aphasia.
26. Delirium or acute confusional states are characterized chiefly by alterations in cognitive function, perception, and consciousness, and are associated with neuronal aging, neuroinflammation, oxidative stress, neuroendocrine dysregulation, and circadian dysregulation.
27. There are four types of delirium: hyperactive, hypoactive, mixed, and terminal.
28. Dementia is an acquired impairment of intellectual function, memory, and language with alteration in behavior and can be caused by genetic predisposition, trauma, vascular disease, infection, and progressive neurodegeneration.
29. Alzheimer disease is the most common chronic, irreversible dementia with accumulations of amyloid-beta and tau protein neurofibrillary tangles in the brain. Less common forms include vascular and frontotemporal dementia.

Alterations in Cerebral Hemodynamics

1. Cerebral perfusion pressure is a determinant for cerebral blood flow and oxygenation.
2. An injured brain may experience cerebral hypoperfusion, normal cerebral blood flow but with increased intracranial pressure or cerebral hyperemia.
3. Increased intracranial pressure may result from edema, excess cerebral spinal fluid, hemorrhage, or tumor growth. When intracranial pressure approaches arterial pressure, hypoxia and hypercapnia produce brain damage.
4. Cerebral edema is an increase in the fluid content of the brain resulting from infection, inflammation, hemorrhage, tumor, ischemia, infarct, or hypoxia.
5. The shifting or herniation of brain tissue from one compartment to another disrupts the blood flow of both compartments and damages brain tissue.
6. Supratentorial herniation involves temporal lobe and hippocampal gyrus shifting from the middle fossa to the posterior fossa; transtentorial herniation with a downward shift of the diencephalon through the tentorial notch; and shifting of the cingulate gyrus herniation under the falx.
7. The most common infratentorial herniation is a shift of the cerebellar tonsils through the foramen magnum.
8. Hydrocephalus comprises a variety of disorders characterized by an excess of fluid within the cranial ventricles, subarachnoid space, or both. Hydrocephalus occurs because of interference with cerebral spinal fluid flow caused by increased fluid production or obstruction within the ventricular system or by defective reabsorption of the fluid.

Alterations in Neuromotor Function

1. Motor neuron diseases result from progressive degeneration of upper or lower motor neurons in the cortex, brainstem, or spinal cord.
2. Motor movements are controlled by the pyramidal system (upper motor neurons), lower motor neurons, the extrapyramidal system, and the myoneural junction.
3. An upper motor neuron syndrome is characterized by spastic paresis or paralysis, hypertonia, hyperreflexia, and spasticity from interruption of the pyramidal system.
4. Interruption of the pyramidal tract below the pons results in spinal shock with complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function.
5. Lower motor neuron syndromes manifest with impaired voluntary and involuntary movements, usually without sensory impairment and flaccid paralysis, muscle atrophy, fasciculations, and fibrillations.
6. Partial paralysis occurs with only partial loss of alpha motor neurons, and total paralysis is complete loss of alpha motor neurons. Loss of gamma motor neurons impairs muscle tone and decreases deep tendon reflexes.

7. Nuclear palsies involve damage to the cranial nerve nuclei.
8. Bulbar palsies involve cranial nerves IX, X, and XII.
9. Extrapyramidal motor syndromes include basal ganglia and cerebellar motor syndromes and result in alterations of fine motor control with disturbances in posture, balance, and loss of smooth, coordinated movement. They are commonly associated with degenerative diseases of the central nervous system.
10. Basal ganglia disorders manifest with alterations in muscle tone and posture, including rigidity, involuntary movements, and loss of postural reflexes.
11. Cerebellar motor syndromes result in loss of muscle tone, difficulty with coordination, and disorders of equilibrium and gait.
12. Alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.
13. Disorders of posture include dystonic posture, decerebrate posture, basal ganglion posture, and senile posture.
14. Disorders of gait include upper motor neuron gaits (spastic and scissors), cerebellar gait, basal ganglion gait, and frontal lobe ataxic gait.
15. Disorders of expression include hypermimesis and hypomimesis.
16. Dyspraxia is the partial inability and apraxia is the complete inability to perform purposeful or skilled motor acts.
17. Hypotonia and hypertonia are the main categories of altered muscle tone.
18. Hypotonia is decreased muscle tone with flaccidity and loss of reflexes and commonly is a symptom of lower motor neuron damage.
19. Hypertonia is increased muscle tone, and there are four types: spasticity, paratonia (gegenhalten), dystonia, and rigidity.
20. Alteration in muscle movement includes hypokinesia (slow movement), hyperkinesia (excessive movement), and dyskinesias (abnormal voluntary movement including Tourette syndrome).
21. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movements.
22. Hyperkinesias include chorea, athetosis, ballism, akathisia, tremor, and myoclonus.

Chronic Diseases and Disorders Involving Motor Function

1. Parkinson disease is a common degenerative disorder of the basal ganglia (corpus striatum) involving degeneration of the dopamine-secreting nigrostriatal pathway resulting in overactivity by the subthalamic nucleus, causing tremor, rigidity, and bradykinesia. Involvement of the limbic system causes emotional lability. Progressive dementia may be associated with Lewy body formation and advanced stages of the disease. Most cases are sporadic and associated with head trauma, infection, neoplasm, atherosclerosis, toxins, or drug intoxication. Less than 5% have a familial or genetic cause.
2. Parkinson disease nonmotor symptoms are commonly associated with disruption of the autonomic nervous system and include unstable blood pressure, arrhythmias, and alteration in temperature control, digestion, bladder function, and sexual function.
3. Huntington disease (chorea) is a rare hereditary irreversible disease involving the basal ganglia and frontal cerebral cortex. The *huntingtin* gene produces tangles of protein that collect in brain cells and chains of glutamine on the abnormal molecules that adhere to each other. There is a depletion of neurons that secrete gamma-aminobutyric acid (an inhibitory neurotransmitter) that causes involuntary, fragmentary movements accompanied by emotional lability and progressive dementia.
4. Amyotrophic lateral sclerosis is a disease of upper and lower motor neurons. The pathogenesis of amyotrophic lateral sclerosis is not fully known; however, motor neuron degeneration occurs as well as degeneration of the nonmotor neurons in the cortices and spinal cord. *Lateral sclerosis*, or scarring of the spinal cord, refers to the upper motor neuron component of the syndrome. Most cases are sporadic, and 10% to 20% are familial. Clinical manifestations of amyotrophic lateral sclerosis may include weakness in all muscles that may begin in a single muscle group, slurring

of speech, and difficulty swallowing. Flaccid paresis progressing to paralysis is characteristic of the lower motor neuron syndrome.

5. The demyelinating disorders include multiple sclerosis and Guillain Barré syndrome.
6. Multiple sclerosis is a chronic inflammatory disease involving degeneration of central nervous system myelin in genetically susceptible individuals and is more common in women. The cause is unknown. Autoreactive T and B cells recognize myelin autoantigens and produce myelin-specific antibodies, triggering inflammatory demyelination with loss of oligodendrocytes, and plaque formation, leading to disruption of nerve conduction throughout the brain and spinal cord and, over time, loss of neurons.
7. The clinical manifestations of multiple sclerosis involve remissions and exacerbation of different types: relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing. Optico-spinal multiple sclerosis involves the optic nerve and cranial nerves III through XII. Spinal multiple sclerosis primarily involves the spinal tracts and dorsal column with spastic paresis and bowel and bladder dysfunction. Cerebellar multiple sclerosis manifests with motor ataxia and weakness.
8. Guillain-Barré syndrome is a rare demyelinating disorder caused by an antibody and cell-mediated immunologic reaction directed against peripheral nerves that causes weakness or paralysis and can have irreversible effects. It usually occurs 4 weeks after a respiratory or gastrointestinal infection (e.g., *Campylobacter jejuni* and Zika virus), and molecury mimicry of pathogen-borne antigens has been proposed as a theory of pathogenesis. Different subtypes have been identified, and clinical manifestations depend on the subtype.
9. Disorders of the myoneural junction include myasthenia gravis, Lambert-Eaton syndrome, and botulism.
10. Myasthenia gravis results from a defect in nerve impulse transmission at the neuromuscular junction with generalized, ocular, or neonatal subtypes. Autoantibodies, complement deposits, and membrane attack complex destroy the acetylcholine receptor sites, causing decreased transmission of nerve impulses, leading to muscle weakness, including ocular and systemic muscles. There can be childhood and adult onset.
11. Lambert-Eaton myasthenic syndrome is related to autoantibodies to calcium channels on presynaptic nerve terminals and presents with leg and arm weakness.
12. Botulism is poisoning by botulinum toxin released by *Clostridium botulinum* that acts by inhibiting release of Ach at the myoneural junction, causing life-threatening flaccid paralysis.

Emerging Science Box

The Oral and Gut Microbiome and Alzheimer Disease

Chronic periodontitis is thought to be one of the major factors linking the gut microbiome to Alzheimer disease (AD) as individuals with periodontitis have greater memory decline among individuals with mild cognitive impairment. It is thought that toxic substances released by *Porphyromonas gingivalis*, and other gram-negative bacteria associated with periodontal disease, damage the blood-brain barrier, and promote neuroinflammation, amyloid deposition, and Tau protein phosphorylation, contributing to cognitive decline. Bacteria may also enter the bloodstream via dental procedures, including root canals and extractions, cross the damaged blood-brain barrier (BBB) and directly injure nerve tissue. With periodontal disease, large quantities of bacteria are swallowed. These pathogens initiate an inflammatory response within the gut, releasing proinflammatory cytokines. The inflammatory response increases intestinal permeability, releasing pathogens and proinflammatory mediators into the bloodstream. Systemic inflammation then occurs, which causes the BBB to leak, allowing pathogens, inflammatory mediators, and leukocytes to enter the brain, leading to neuroinflammation, neurodegeneration, and cell death. Probiotics, fecal transplantation, antibiotic use. and diet are being explored as ways to restore a healthy intestinal flora and slow down AD progression.

Aducanumab for the Treatment of Alzheimer Disease

In June 2021, the first anti-amyloid medication produced by Biogen and called aducanumab (Aduhelm) was granted Fast Track designation by the Food and Drug Administration (FDA). Aducanumab is a monoclonal antibody that reduces aggregated beta amyloid in the brain and is used specifically for the treatment of Alzheimer disease (AD). It is the first new medication in a decade to be approved for individuals with AD and the only medication that is purported to reverse the damage of beta amyloid and cognitive decline of affected individuals. Results of the drug have been mixed, and the FDA decision to approve it also came with the recommendation to continue Phase III clinical trials to verify the efficacy of this medication. US Food and Drug Administration. FDA news release: FDA Grants Accelerated Approval for Alzheimer's Drug, June 7, 2021. Available at https://www.fda.gov/news-events/press-announcements/fda-grants-accelerated-approval-alzheimers-drug.

Emerging Science Box

Tourette Syndrome

There is growing evidence that Tourette syndrome (TS, also known as Tourette Disorder) occurs worldwide and has common features across all races and cultures. The hallmark features of TS are the presence of involuntary motor tics (sudden, rapid, repetitive, nonrhythmic movements) and vocal–phonic tics (unintentional uttering of sounds). The tics may be either simple, involving only an individual muscle group (e.g., eye blinking or grunting), or complex, requiring coordinated movement of muscle groups (e.g., head banging or repeating of another person's words) and may be preceded by an aura. Sensory tics involve unpleasant sensations in the face, head, and neck areas. Probably underdiagnosed, the onset of TS is typically between the ages of 2 and 15 years, with the tics lessening in adulthood. The syndrome has a complex multifactorial etiology with undetermined genetic, environmental, immune, and hormonal factors. The pathophysiology of TS is unclear and currently under study. There is evidence of cortico-striato-thalamocortical dysfunction and, in some cases, altered dopaminergic neurotransmission and abnormalities in brain gamma-aminobutyric acid (loss of inhibition). The criteria for diagnosis include the occurrence of two or more motor tics *and* at least 1 vocal tic (usually every day), have been present for at least a year, started before age 18 years, and not due to taking medicine or other drugs or due to having another medical condition that can cause tics. TS is often diagnosed in association with anxiety, depression, attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder. Habit reversal therapy addressing the urge to move is the most common behavioral therapy. However, the efficacy of all behavioral therapies needs further investigation. Pharmacologic treatments target symptoms and can have significant side effects. Deep brain stimulation has also been used to treat refractory symptoms of TS in selected individuals with some success. Alterations of the Brain, Spinal Cord, and Peripheral Nerves

Jan Powers and Kathleen E. Hubner

http://evolve.elsevier.com/Rogers/pathophysiology/

Chapter Outline

OUTLINE

Central Nervous System Disorders, 570
- Traumatic Brain and Spinal Cord Injury, 570
- Degenerative Disorders of the Spine, 584
- Seizure Disorders and Epilepsy, 588
- Cerebrovascular Disorders, 591
- Primary Headache Syndromes, 597

Infection and Inflammation of the Central Nervous System, 599
- Meningitis, 600
- Encephalitis, 602
- West Nile Virus, 603
- Brain or Spinal Cord Abscess, 604
- Neurologic Complications of Human Immunodeficiency Virus, 604

Peripheral Nervous System Disorders, 605
- Peripheral Neuropathies, 605

Tumors of the Central Nervous System, 606
- Brain Tumors, 606
- Spinal Cord Tumors, 610

Alterations in central nervous system (CNS) function are caused by traumatic injury, vascular disorders, tumor growth, infectious and inflammatory processes, and metabolic derangements, including nutritional deficiencies and drugs or chemicals. Alterations in peripheral nervous system function involve the nerve roots, nerve plexus, the peripheral nerves, or the neuromuscular junction. Disorders related to demyelinating diseases and the neuromuscular junction were presented in Chapter 17.

Central Nervous System Disorders

Traumatic Brain and Spinal Cord Injury

Traumatic Brain Injury

Traumatic brain injury (TBI) is an alteration in brain function or other evidence of brain pathology caused by an external force. Approximately 1.7 million cases of TBI occur in the United States each year. An estimated 13.5 million individuals live with a disability due to TBI in the United States alone, with nearly 61,000 deaths related to TBI in 2019.[1] Those who survive a TBI may have long-term effects with cognitive function, motor function, and behavior changes.[2] The leading causes of TBI-related deaths are due to suicide, unintentional falls, and motor vehicle crashes. The leading causes of nonfatal TBI in the United States arise from falls, motor vehicle–related injuries, and strikes or blows to the head from or against an object (17%), such as sports injuries. The most common causes of TBI for children and older adults are unintentional falls. Males have the highest incidence in all age groups.

In recent years, individuals with TBI have shown improved survival. This is attributed to advancements in safety measures (e.g., passive seat restraints, air bags, protective head gear), reduced transport time to hospitals or trauma centers, improved on-scene medical management, imaging of brain injury, prevention and management of secondary brain injury, and a better understanding of all degrees of brain injury severity.

TBI can be classified as primary or secondary injuries. Primary brain injury is caused by a direct impact. The injury can be a focal brain injury, affecting only one area of the brain, or a diffuse brain injury, involving more than one area of the brain. Both types of injury can be associated with the same initiating event. Blunt trauma may result in both focal and diffuse brain injuries, and they usually occur at the same time (Table 18.1). Focal brain injury and diffuse brain injuries each account for approximately half of all injuries. However, focal brain injury accounts for more than two-thirds of head injury deaths. Secondary injury is an indirect consequence of the primary injury. It includes systemic and brain tissue responses with a cascade of cellular and molecular cerebral events involving the inflammatory response to injury (Fig. 18.1 and see Table 18.1). TBI can be mild, moderate, or severe (Table 18.2). The Glasgow

Coma Scale (GCS) is commonly used to grade severity of injury (Table 18.3). Most TBIs are mild.

Table 18.1

Classification of Brain Injuries

Type of Injury	
Primary Brain Injury	
Focal Brain Injury	Localized injury from impact
Closed injury	Blunt trauma
• Coup	Injury is directly below site of forceful impact
• Contrecoup	Injury is on opposite side of brain from site of forceful impact
• Epidural (extradural) hematoma	Vehicular accidents, minor falls, sporting accidents
• Subdural hematoma	Forceful impact: vehicular accidents or falls, especially in elderly persons or persons with chronic alcohol abuse
• Contusions	Bleeding caused by forceful impact, usually vehicular accidents or long-distance falls
Open injury	Penetrating trauma: missiles (bullets) or sharp projectiles (knives, ice picks, axes, screwdrivers)
• Compound fracture	Objects strike head with great force or head strikes object forcefully; temporal blows, occipital blows, upward impact of cervical vertebrae (basilar skull fracture)
Diffuse Brain Injury	

Type of Injury	
Concussion	May or may not have loss of consciousness with no visible changes on brain imaging
Diffuse axonal injury (can occur with focal injury)	Traumatic shearing forces; tearing of axons from twisting and rotational forces with injury over widespread brain areas; moving head strikes hard, unyielding surface or moving object strikes stationary head; torsional head motion without impact
Subarachnoid hemorrhage	Shearing forces tear small bridging blood vessels with bleeding into the subarachnoid space
Secondary Brain Injury	
Systemic processes	Hypotension, hypoxia, ischemia, anemia, hypercapnia, and hypocapnia
Intracerebral processes	Inflammation, cerebral edema, increased intracranial pressure (IICP), brain herniation, decreased cerebral perfusion pressure, ischemia
Cellular processes	Release of excitatory neurotransmitters (glutamate); failure of cell ion pumps, mitochondrial failure; disruption of blood brain barrier, cell death

Type of Injury	
Primary Brain Injury	
Focal Brain Injury	Localized injury from impact
Closed injury	Blunt trauma
• Coup	Injury is directly below site of forceful impact
• Contrecoup	Injury is on opposite side of brain from site of forceful impact
• Epidural (extradural) hematoma	Vehicular accidents, minor falls, sporting accidents
• Subdural hematoma	Forceful impact: vehicular accidents or falls, especially in elderly persons or persons with chronic alcohol abuse
• Contusions	Bleeding caused by forceful impact, usually vehicular accidents or long-distance falls
Open injury	Penetrating trauma: missiles (bullets) or sharp projectiles (knives, ice picks, axes, screwdrivers)
• Compound fracture	Objects strike head with great force or head strikes object forcefully; temporal blows, occipital blows, upward impact of cervical vertebrae (basilar skull fracture)
Diffuse Brain Injury	
Concussion	May or may not have loss of consciousness with no visible changes on brain imaging
Diffuse axonal injury (can occur with focal injury)	Traumatic shearing forces; tearing of axons from twisting and rotational forces with injury over widespread brain areas; moving head strikes hard, unyielding surface or moving object strikes stationary head; torsional head motion without impact
Subarachnoid hemorrhage	Shearing forces tear small bridging blood vessels with bleeding into the subarachnoid space
Secondary Brain Injury	
Systemic processes	Hypotension, hypoxia, ischemia, anemia, hypercapnia, and hypocapnia
Intracerebral processes	Inflammation, cerebral edema, increased intracranial pressure (IICP), brain herniation, decreased cerebral perfusion pressure, ischemia
Cellular processes	Release of excitatory neurotransmitters (glutamate); failure of cell ion pumps, mitochondrial failure; disruption of blood brain barrier, cell death

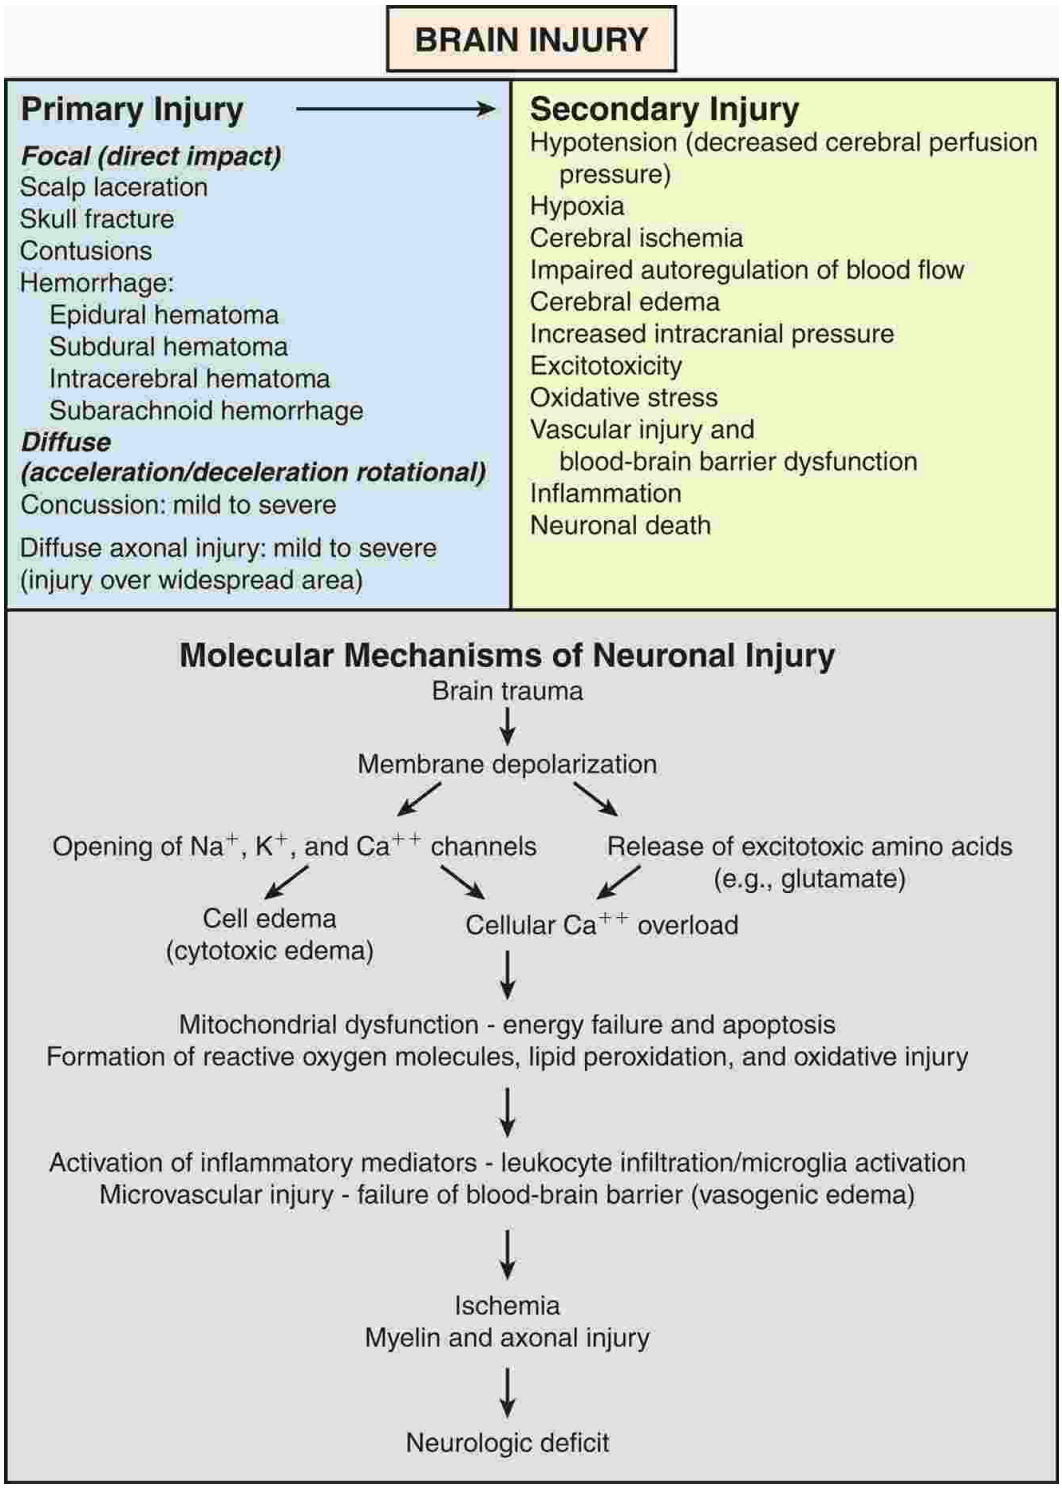

FIG. 18.1 Pathophysiology of Brain Injury Use.

Two textboxes and a flowchart represent the pathophysiology of brain injury use. Top-left panel. The

textbox lists the manifestations of primary injury. Focal (direct impact) injury includes scalp laceration, skull fracture, contusions, hemorrhage (epidural hematoma, subdural hematoma, intracerebral hematoma, and subarachnoid hemorrhage). Diffuse (acceleration or deceleration rotational) injury includes concussion (milt to severe) and diffuse axonal injury (mild to severe; injury over widespread area). Primary injury leads to secondary injury (top-right panel). Top-right panel. The textbox lists the manifestations of secondary injury. These injuries include hypotension (decreased cerebral perfusion pressure), hypoxia, cerebral ischemia, impaired autoregulation of blood flow, cerebral edema, increased intracranial pressure, excitotoxicity, oxidative stress, vascular injury and blood-brain barrier dysfunction, inflammation, and neuronal death. Bottom panel. The flowchart shows the molecular mechanisms of neuronal injury. The sequence of the mechanisms is as follows. 1. Brain trauma. Leads to 2. 2. Membrane depolarization. Leads to 3 and 4. 3. Opening of sodium ion, potassium ion, and calcium ion channels. Leads to 5 and 6. 4. Release of excitotoxic amino acids (example, glutamate). Leads to 6. 5. Cell edema (cytotoxic edema). 6. Cellular calcium ion overload. Leads to 7. 7. Mitochondrial dysfunction–energy failure and apoptosis; Formation of reactive oxygen molecules, lipid peroxidation, and oxidative injury. Leads to 8. 8. Activation of inflammation mediators–leukocyte infiltration or microglia activation; Microvascular injury-

failure of blood-barrier (vasogenic edema). Leads to 9. 9. Ischemia; myelin and axonal injury. Leads to 10. 10. Neurologic deficit.

Table 18.2

Comparison of Mild Traumatic Brain Injury With Moderate and Severe Traumatic Brain Injury

Variable	Mild TBI (Concussion)	Moderate and Severe TBI
Clinical definition	Loss of consciousness lasting <30 minutes, any alteration of consciousness, or post-traumatic amnesia lasting <24 h; some definitions include Glasgow Coma Scale score of 13–15	Loss of consciousness lasting ≥30 min to prolonged coma, posttraumatic amnesia lasting ≥24 h up to permanently, or Glasgow Coma score as low as 3
Focal neurologic signs	Usually none or transient	Frequently present
Neuroimaging with CT or MRI	Usually negative	Diagnostic
Natural History	Full recovery is usual; there is lack of consensus on the natural history of concussion and postconcussive symptoms	Natural history and recovery are directly related to the severity of the injury and functional neuroanatomy
Predictors of persistent symptoms or disability	Psychological factors (e.g., depression, anxiety, or PTSD), compensation and litigation, and negative expectations and beliefs are the strongest risk factors	Directly related to injury characteristics

Variable	Mild TBI (Concussion)	Moderate and Severe TBI
Neurocognitive testing	Often inconclusive beyond the period of acute injury	Essential and valuable component of ongoing clinical care
Neuronal-cell damage	Metabolic and ionic processes caused by axonal twisting or stretching; these can lead to secondary disconnection	Combination of cellular disruption directly related to injury and metabolic, vascular, and ionic processes

CT, Computed tomography; *MRI*, magnetic resonance imaging; *PTSD*, posttraumatic stress disorder; *TBI*, traumatic brain injury.

Table 18.3

Glasgow Coma Scale[a]

Score[b]	Best Eye Response Score (4)	Best Verbal Response Score (5)	Best Motor Response Score (6)
1	No eye opening	No verbal response	No motor response
2	Eye opening to pain	Incomprehensible sounds	Extension to pain
3	Eye opening to verbal command	Inappropriate words	Flexion to pain
4	Eyes open spontaneously	Confused	Withdrawal from pain
5	NA	Oriented	Localizing pain
6	NA	NA	Obeys commands

Score[b]	Best Eye Response Score (4)	Best Verbal Response Score (5)	Best Motor Response Score (6)
1	No eye opening	No verbal response	No motor response
2	Eye opening to pain	Incomprehensible sounds	Extension to pain
3	Eye opening to verbal command	Inappropriate words	Flexion to pain
4	Eyes open spontaneously	Confused	Withdrawal from pain
5	NA	Oriented	Localizing pain
6	NA	NA	Obeys commands

[a]The GCS is scored between 3 and 15, with 3 being the worst and 15 the best. It is composed of the sum of three parameters: Best Eye Response (E), Best Verbal Response (V), and Best Motor Response (M). Mild Brain Injury = 13 or higher; Moderate Brain Injury = 9 to 12; Severe Brain Injury = 8 or lower.

[b]It is important to break the scoring report into its components (e.g., E3V3M5 = GCS 11). A total score is meaningless without this information. Age affects the GCS. Elderly individuals with a traumatic brain injury (TBI) have higher (better) GCS scores than younger individuals with a TBI of similar anatomic severity.

Scale score in patients with traumatic brain injury. *Journal of the American Medical Association Surgery*, 2014;149(7):727–734.

Primary brain injury

Focal brain injury

Focal brain injury can be caused by closed (blunt) trauma or open (penetrating) trauma. Closed trauma or injury is more common and involves either the head striking a hard surface (e.g., motor vehicle accidents or falls), a rapidly moving object striking the head (e.g., a baseball or a falling object), or by blast waves (e.g., an explosion or a tornado). A linear skull fracture or simple break or "crack" in the skull may occur. The dura remains intact, and brain tissues are not exposed to the environment. Open head trauma or injury involves a skull fracture, and a break in the dura results in exposure of the cranial contents to the environment. Skull fractures include compound fracture or perforated fracture and linear, comminuted, and basilar skull fracture (BSF; in the cranial vault or at the base of the skull). Focal brain injuries include contusions and hematomas. Types of hematomas include subdural hematomas (SDHs), epidural hematomas (EDHs), and intracerebral hemorrhage (ICH).

Closed head injuries are specific, grossly observable skull and brain lesions that occur in a precise location. Of blunt trauma injuries, 75% to 90% are mild. Injury to the cranial vault, vessels, and supporting structures can produce more severe damage, including contusions and epidural, subdural, subarachnoid, and ICHs. The dura mater remains intact, and brain tissues are not exposed to the environment. The smaller the area of impact, the more severe the injury because of the concentration of force. The injury may be a **coup injury** (injury at site of impact) or a **contrecoup injury** (injury from brain rebounding and hitting the opposite side of skull or forces being transmitted through the cerebrospinal fluid [CSF]) (Fig. 18.2). Compression of the skull at the point of impact produces **contusions** or brain bruising from blood leaking from an injured vessel (Fig. 18.3). The severity of contusion varies with the amount of energy transmitted by the skull to underlying brain tissue. Contusions occur most commonly in the frontal lobes, the temporal lobes, and at the frontotemporal junction. Injuries in these areas cause changes in attention,

memory, intellectual function, affect, emotion, and behavior. Less commonly, contusions occur in the parietal and occipital lobes. Focal cerebral contusions are usually superficial, involving just the brain gyri. Hemorrhagic contusions may coalesce into a large confluent intracranial hematoma.

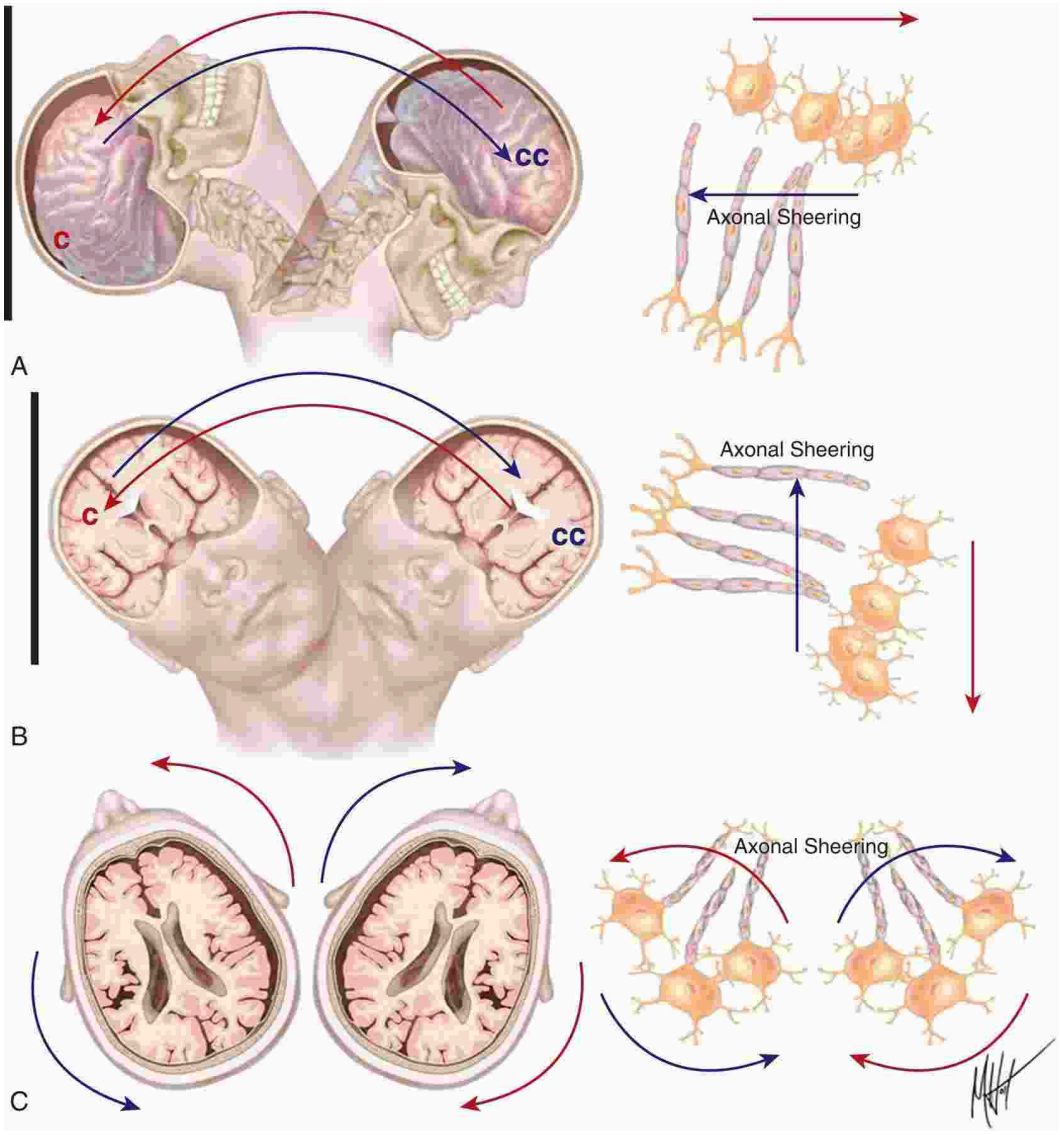

FIG. 18.2 Coup and Contrecoup Focal Injury With Acceleration/Deceleration Axonal Shearing. **(A)** Sagittal force causing coup *(c)* the site of impact, and contrecoup injury *(cc)*. **(B)** Lateral force causing coup *(c)* and contrecoup *(cc)* injury. **(C)** Axial or rotational injury with shearing of axons, particularly at base of brain. Acceleration/deceleration axonal shearing injury occurs throughout the brain (*red and blue directional arrows* in all three images). (Borrowed from Pascual JM, Preito R. Surgical management of severe closed head injury in adults. In: Quinones-Hinojosa A, eds. *Schmidek and Sweet operative neurosurgical techniques*, 6th ed,

vol 2. Philadelphia: Saunders; 2012:1513–1538. Originally redrawn from Adams JH. Brain damage in fatal non-missile head injury in man. In: Braakman R, eds. *Handbook of clinical neurology, head injury*, Vol 13. Gennarelli TA, Thibault LE, Adams JH, et al. Diffuse axonal injury and traumatic coma in the primate. *Annals of Neurology*, 1982;12:564–574.)

Three sets of illustrations show the coup and contrecoup focal injury with acceleration or deceleration axonal shearing. Top panel, A. The illustration shows the right lateral view of a personâ€™s head, highlighting the brain inside the skull. The head rocks back (toward the occipital bone) and forth (toward the frontal bone). The backward motion is labeled C, and the forward motion is labeled C C. An accompanying illustration shows an arrow pointing rightward above a series of horizontally connected neurons and an arrow pointing leftward over a some vertically positioned axons, labeled axonal sheering. Middle panel, B. The illustration shows the anterior view of a personâ€™s head, highlighting the brain inside the skull. The head rocks left and right. The leftward motion is labeled C, and the rightward motion is labeled C C. An accompanying illustration shows an arrow pointing upward over some horizontally placed axons, labeled axonal sheering, and an arrow pointing downward over some vertically connected neurons. Bottom panel, C. The illustration shows the superior view of a personâ€™s head, highlighting the brain inside the skull. The head turns clockwise and counterclockwise. The counterclockwise motion is labeled C. An accompanying illustration shows a set of

neurons with axons. Axonal sheering is identified for both clockwise and counterclockwise motions.

FIG. 18.3 Cerebral Contusion.
Close-up view of a contused brain region with characteristic streak-like, densely arranged hemorrhages in the cortex (cut surface here). Such lesions represent “bruises” on the surface of the brain caused by violent contact between the delicate brain parenchyma and the hard inner surface of the skull.
(From Pollak S, Saukko P. Blunt Injury, Forensic Medicine/Causes of Death, Encyclopedia of Forensic Sciences. London: Academic Press; 2013.)

A contusion may be evidenced by immediate loss of consciousness (generally no longer than 5 minutes), loss of reflexes, transient cessation of respiration, brief period of bradycardia, and decrease in blood pressure (lasting 30 seconds to a few minutes). Vital signs may stabilize to normal values in a few seconds; reflexes then return, and the person regains

consciousness over minutes to days. With more severe injury, residual deficits may persist, and some persons never regain a full level of consciousness.

Evaluation is based on the results of the health history, level of consciousness according to the GCS (see Table 18.3), outcomes of imaging studies, and assessment of vital parameters (e.g., intracranial pressure [ICP] and electroencephalogram [EEG]). Large contusions and lacerations with hemorrhage may be surgically excised. Treatment is otherwise directed at controlling ICP, neuroprotection, and managing symptoms.

Brain edema forms around and in damaged neural tissues, contributing to increasing ICP (see Chapter 17). Increased ICP (IICP) occurs when one or more of the contents of the cranial vault—brain tissue, CSF, and blood —increases in volume, because the cranial vault itself is a rigid, fixed compartment. Multiple hemorrhages, edema, infarction, and necrosis can occur within the contused areas. The maximal effects of these injuries peak 18 to 36 hours after severe head injury.

A hematoma is a blood clot within the brain or on its surface. Hematomas include epidural, subdural, and intracerebral locations (Fig. 18.4). An epidural (extradural) hematoma(EDH) is bleeding between the dura mater and the skull. This is often the result of an arterial bleed. The most common site of injury is the temporal fossa as a result of injury to the middle meningeal artery and less commonly to the meningeal vein or dural sinus (Fig.18.5). It represents 1% to 2% of major head injuries and occurs in all age groups but most commonly in those 20 to 40 years old. An EDH can result in brain herniation (see Fig. 18.5).

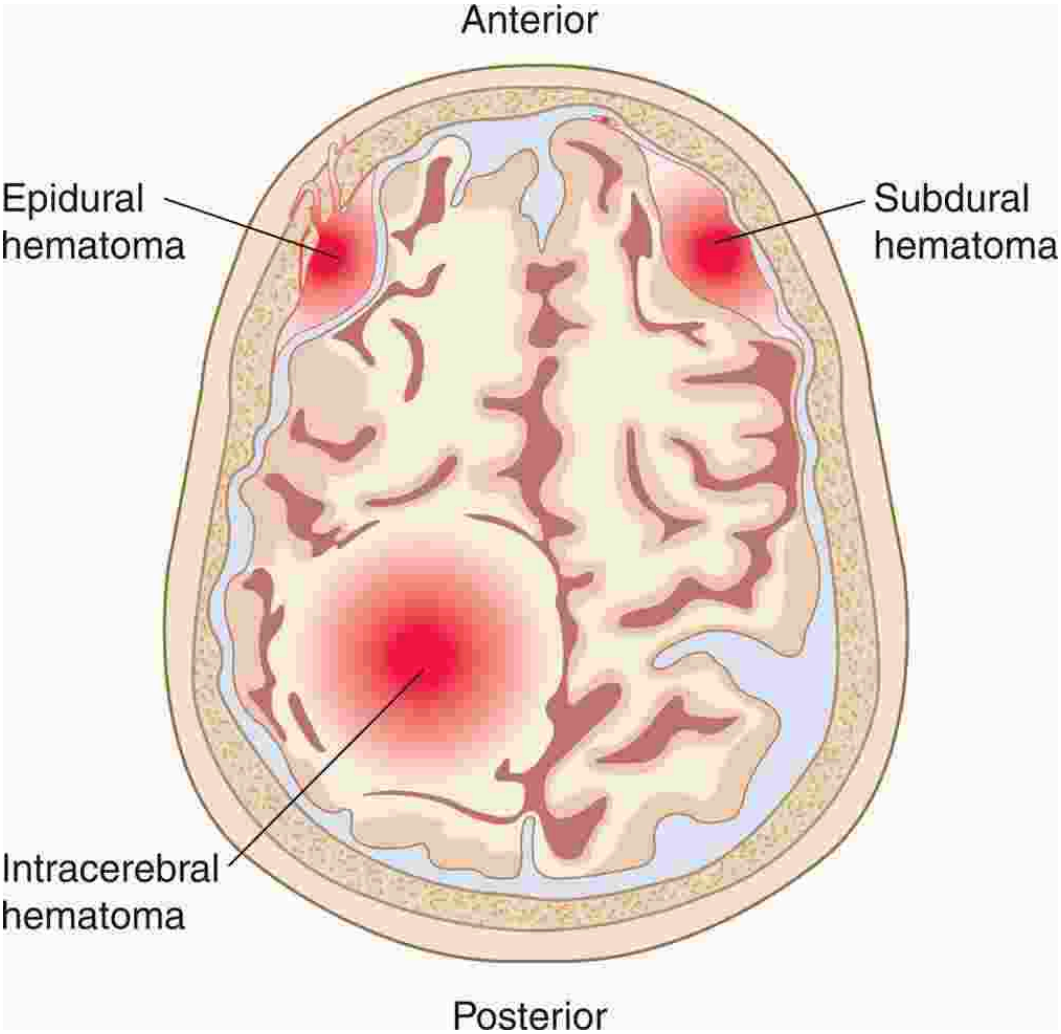

FIG. 18.4 Brain Hematomas.

An illustration of the superior view of the brain shows the anterior side at the top and the posterior side at the bottom. The following areas of the brain with hematomas are labeled. â€¢ Top-left, epidural hematoma. â€¢ Top-right, subdural hematoma. â€¢ Bottom-left, intracerebral hematoma.

FIG. 18.5 Epidural Hematoma, CT Image.
Note the large right epidural hematoma with a lens-shaped outline as the smooth dura becomes indented against the underlying cortex on the right lateral aspect of the cerebrum. The epidural hematoma is confined within an area bounded by cranial sutures where the dura is firmly adherent to the skull. Note the mass effect with effacement of the lateral ventricles and the shift of midline to the left *(arrows)*. In this case the individual fell from a height and struck the right side of his head, severing the middle meningeal artery. This epidural hematoma collected within hours. *CT*, Computed tomography. (From Klatt EC. *Robbins and Cotran atlas of pathology*, 3rd edition. Philadelphia: Saunders, 2015.)

Classic presentation of individuals with temporal EDHs involves loss of consciousness at initial injury, a period of lucidity, and then loss of

consciousness again. If a vein is bleeding (a slower bleed), one-third of those affected then become lucid for a few minutes to a few days. As the hematoma accumulates, a headache of increasing severity, vomiting, drowsiness, confusion, and seizure occur. The expanding hematoma causes temporal lobe herniation, and the level of consciousness is rapidly lost, with ipsilateral pupillary dilation and contralateral hemiparesis. Imaging usually is needed to diagnose EDH. The prognosis is good if intervention is initiated before bilateral dilation of the pupils occurs. EDHs are medical emergencies requiring evaluation, monitoring, and surgical evacuation of the hematoma.[3]

A **subdural hematoma (SDH)** is bleeding between the dura mater and the arachnoid membrane covering the brain and is caused by tearing of veins (Fig. 18.6). It is the most common cause of a traumatic intracranial mass lesion, occurring in approximately 10% to 20% of individuals. Nontraumatic SDH can rarely develop in association with anticoagulant therapy or vascular malformations. *Acute SDHs* develop rapidly, commonly within hours. *Subacute SDHs* develop more slowly, often over 48 hours to 2 weeks. *Chronic SDHs* develop over weeks to months. These SDHs act like expanding masses, increasing ICP that eventually compresses the bleeding vessels. If untreated, brain herniation can result. With a chronic SDH, the existing subdural space gradually fills with blood. A vascular membrane forms around the hematoma in approximately 2 weeks (Fig. 18.7). Further enlargement may take place.

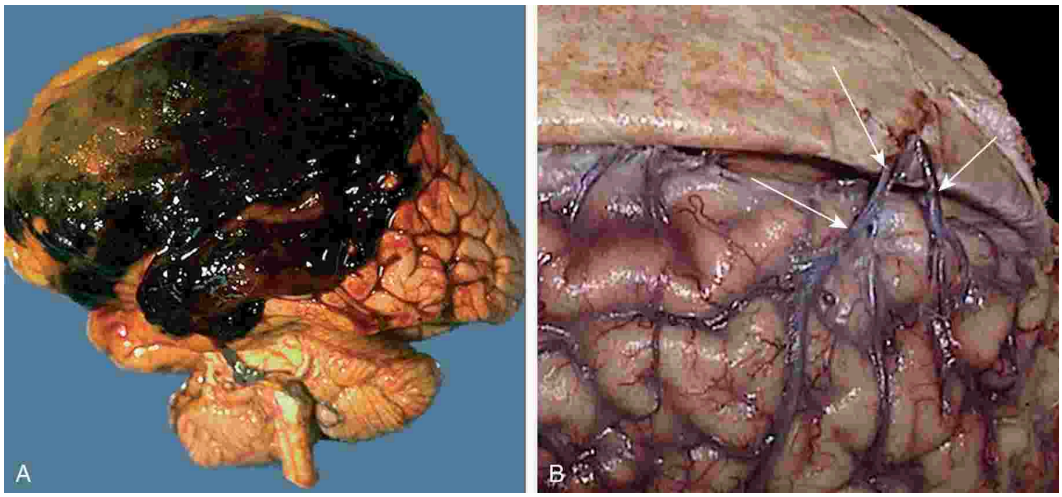

FIG. 18.6 Subdural Hematoma and Bridging Veins. A large subdural hematoma **(A)** is seen in the frontoparietal region. A subdural hematoma forms after head trauma that severs the bridging veins from dura to brain, shown in the right panel **(B)**, where the dura has been folded back to reveal the normal appearance of the bridging veins that extend across to the superior aspect of the cerebral hemispheres. Older adults and the very young are at greater risk because their cerebral veins are more vulnerable to injury. Because the bleeding is venous, blood collects over hours to weeks, with variable onset of symptoms. Because the blood collects beneath the dura, a subdural hematoma can be seen to cross the region of cranial sutures. (From Klatt EC. *Robbins and Cotran atlas of pathology*, 3rd edition. Philadelphia: Saunders, 2015.)

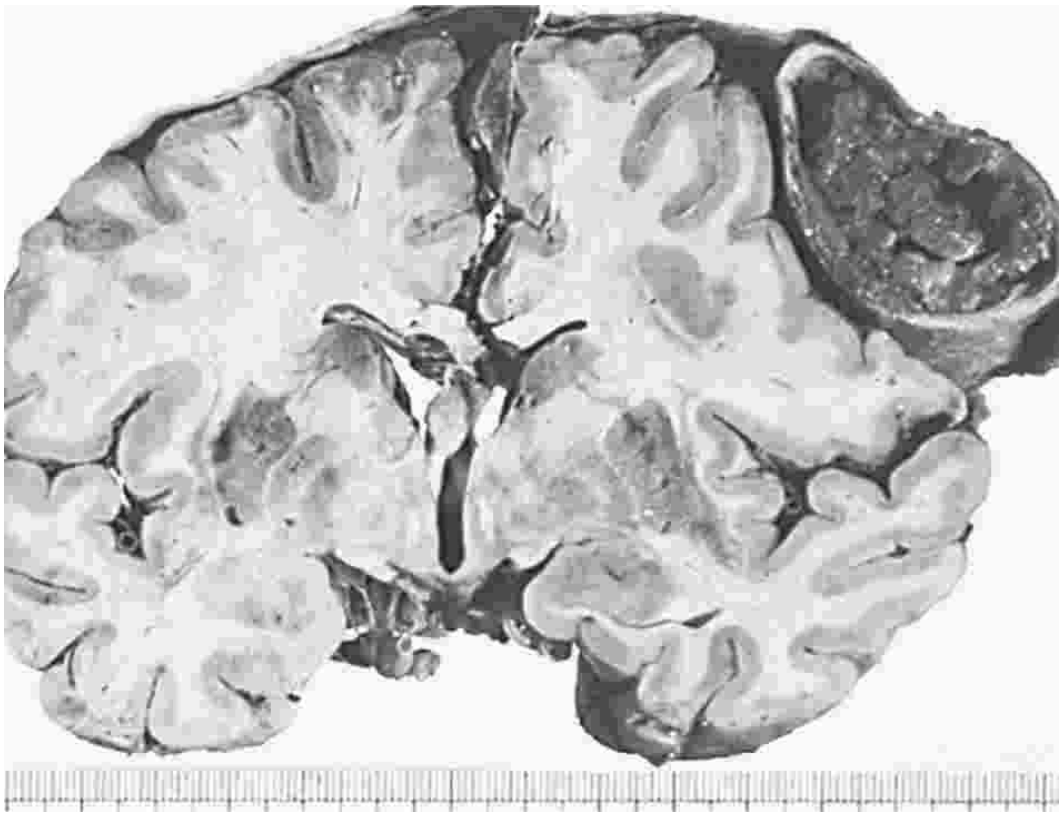

FIG. 18.7 Chronic Subdural Hematoma.
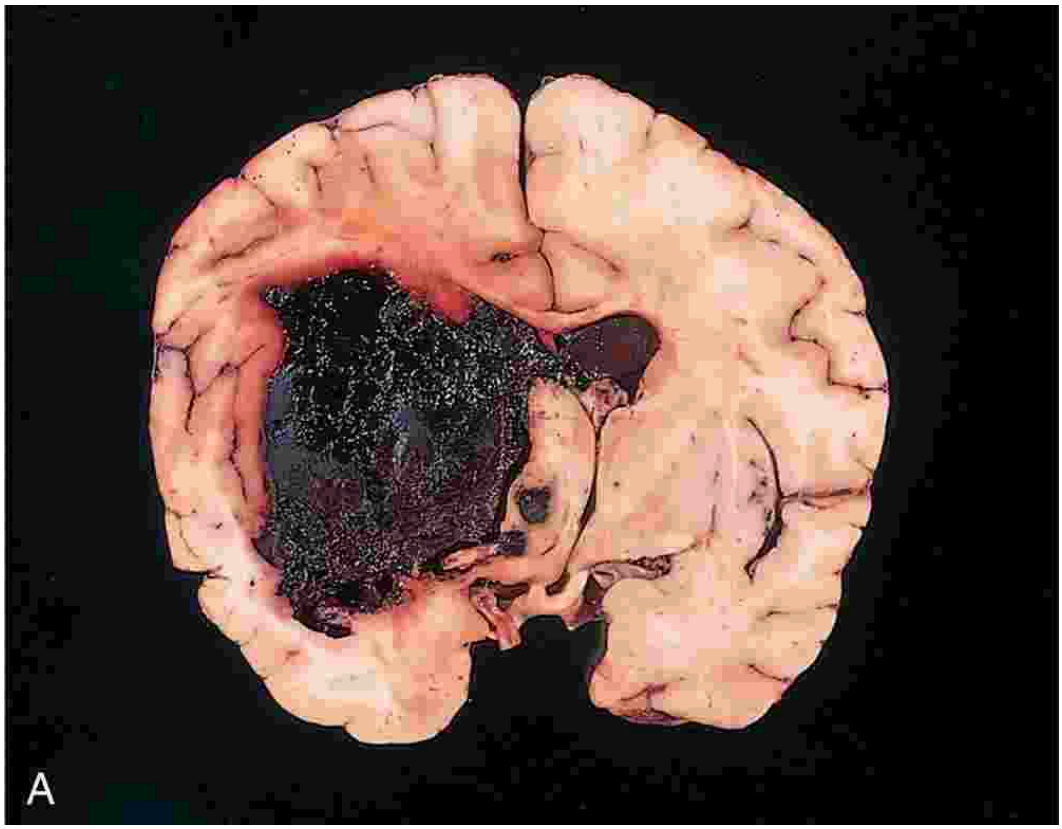
Compression of underlying brain and lateral ventricle. Note the capsule around the hematoma. (From Kissane JM, eds. *Anderson's pathology*, 9th edition. St. Louis: Mosby; 1993.)

In acute, rapidly developing SDHs, the expanding clots directly compress the brain. As the ICP rises, bleeding veins are compressed, thus bleeding can be self-limiting. Cerebral compression and displacement of brain tissue can cause temporal lobe herniation.

An acute SDH classically begins with headache, drowsiness, restlessness, or agitation, slowed cognition, and confusion. These symptoms are related to brain shifting or distortion, followed by IICP and low cerebral perfusion pressure. The symptoms worsen over time and progress to loss of consciousness, respiratory pattern changes, and pupillary dilation (i.e., the symptoms of temporal lobe herniation). Homonymous hemianopia (loss of vision in either the right or the left field [see Fig. 16.8]), dysconjugate gaze, and gaze palsies also may occur. Severity of injury is measured using the GCS, ICP monitoring, and brain imaging. In general, clinical deterioration, a clot thickness greater than

10 mm, a midline shift greater than 5 mm, GCS score decreased by 2 or more points from injury to hospital admission, or individuals presenting with pupillary abnormalities are suggested as critical parameters for surgery to remove the clot.[4,5] Of those individuals affected by chronic SDHs, 80% have chronic headaches and tenderness over the hematoma on palpation. Most persons appear to have a progressive dementia with generalized rigidity (paratonia). Chronic SDHs are more common in the elderly, resulting from a slow bleed caused by the decrease in brain size (atrophy), which pulls veins from the dura. With brain atrophy, the bleeding may not be recognized right away because there is room within the cranial vault for blood to accumulate before causing IICP. Chronic SDHs require clot evacuation.[6]

Intracerebral (hemorrhage) hematomas (ICHs) (bleeding within the brain tissue) occur in 2% to 3% of persons with head injuries. The hematomas may be single or multiple and are associated with contusions. Most hematomas are located in the frontal and temporal lobes but may occur in the hemispheric deep white matter. Penetrating injury or shearing forces traumatize small blood vessels. The ICH then acts as an expanding mass, increasing the ICP, compressing brain tissues, and causing edema (Fig. 18.8). Delayed ICHs may appear 3 to 10 days after the head injury. ICHs also can occur with non-TBI, such as hemorrhagic stroke.



A

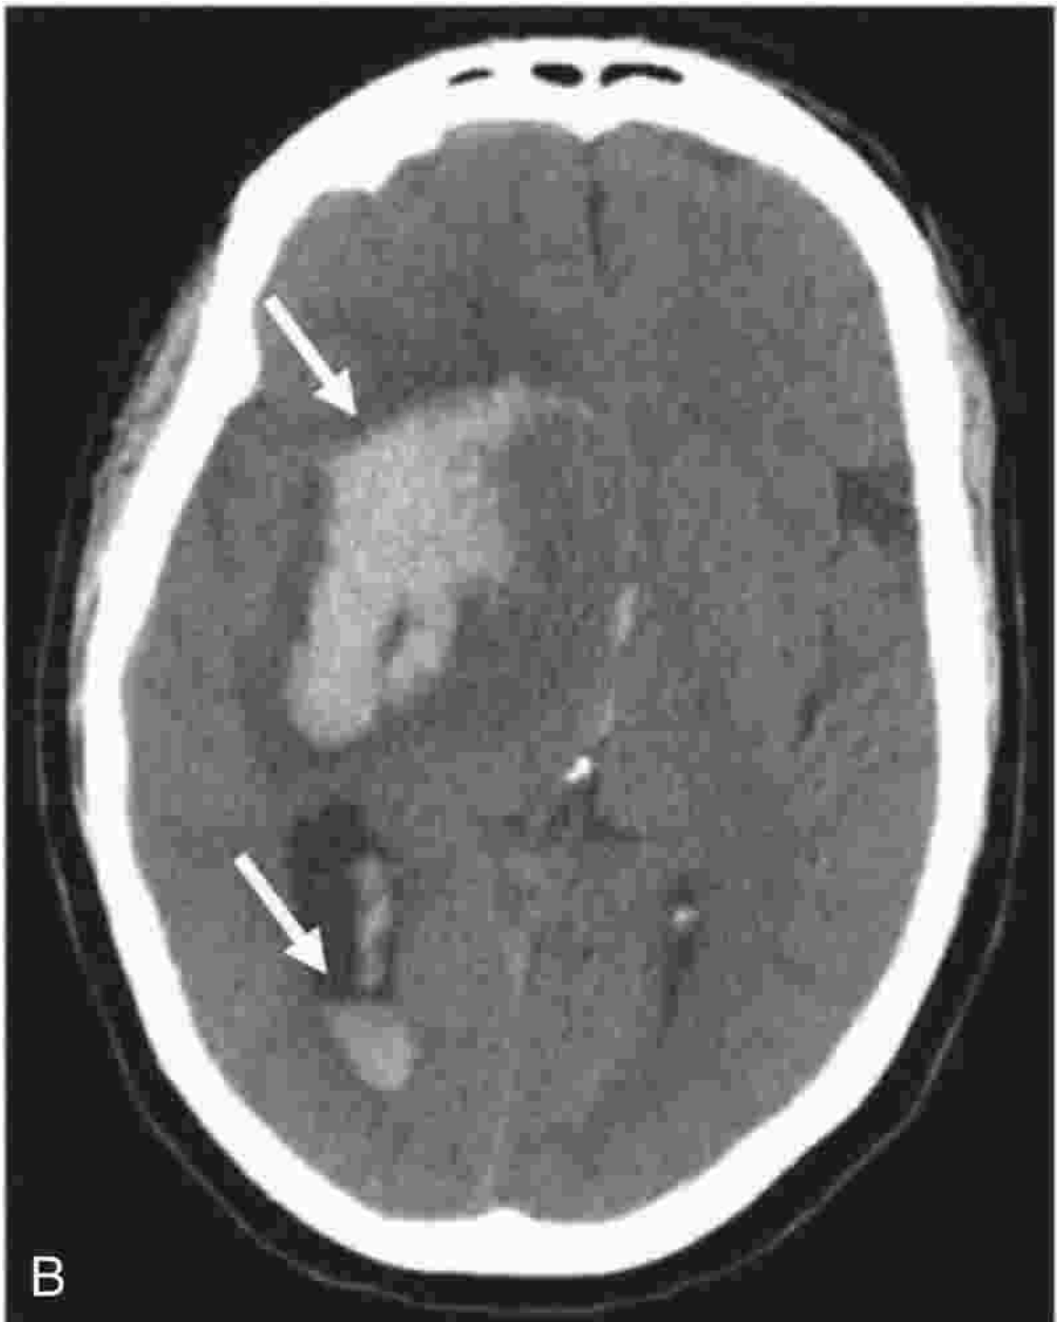


FIG. 18.8 **(A)** Acute intracerebral hemorrhage. A fresh hematoma has disrupted and expanded the left cerebral hemisphere, causing the midline structures to shift to the right. Uncontrolled hypertension is an important cause of this catastrophic lesion. **(B)** Head computed tomography (CT) scan of intracerebral hemorrhage. Note that the acute hemorrhage appears hyperdense *(white)* on the CT scan. (From Kumar V,

Cotran RS, *Robbins SL. Robbins basic pathology*, 7th edition. Philadelphia: Saunders; 2003.)

Closeup A shows a cross-sectional brain specimen with a large, bloody mass of hematoma in the left cerebral hemisphere. Radiograph B shows a superior view of the brain with the anterior side at the top. Two regions of hemorrhage, larger at the top and smaller at the bottom, are identified on the left cerebral hemisphere.

ICHs cause a decreasing level of consciousness. However, in the case of coma or a confusion state from other injuries, the cause of this increasing unresponsiveness can be difficult to detect. Contralateral hemiplegia also may develop, and, as the ICP rises, temporal lobe herniation may occur. In delayed ICH, the presentation is similar to that of a hypertensive brain hemorrhage—sudden, rapidly progressive decreased level of consciousness with pupillary dilation, breathing pattern changes, hemiplegia, and bilateral positive Babinski reflexes (stroking the lateral side of the sole of the foot causes extension of the big toe—moves up—with fanning of the other toes).

The history and physical examination help to establish the diagnosis, and imaging confirms it. Surgical evacuation of a hematoma is performed, considering clinical signs and symptoms, size, and location of the hematoma, and associated comorbid conditions. Otherwise, treatment is directed at reducing the ICP and allowing the hematoma to reabsorb slowly.[7,8]

Skull Fractures: Linear skull fractures or simple breaks or "cracks" in the skull may accompany TBIs. The dura mater remains intact. **Open brain injury** (trauma that penetrates the dura mater) occurs with penetrating trauma or skull fracture. A break in the dura results in exposure of the cranial contents to the environment. Penetration of the dura mater produces both focal and diffuse injuries. An open brain injury can originate from compound skull fractures and missile injuries (e.g., bullets, rocks, shell fragments, knives, and blunt instruments). An open **compound skull fracture** involves a communication between the cranial contents and the environment and should be investigated whenever

lacerations of the scalp, tympanic membrane, sinuses, eye, or mucous membranes are present. Depressed skull fractures will cause pressure on the brain tissue. These injuries can be associated with environmental debris and are prone to infection. They require prompt débridement and cleaning to prevent infection.[9]

Fractures may involve the cranial vault or the base of the skull. BSFs are problematic because they can cause injury to nerves, arteries, or other structures. If the fracture extends into the sinuses or involves the cribriform plate (BSF), cranial nerve damage and leakage of CSF from the nose or ears may occur.[10] The mechanisms of open brain trauma are crush injury, penetrating injuries, lacerations, and stretch injury (blood vessels and nerves damaged without direct contact as a result of stretching). The tangential injury is to the coverings and the brain (scalp and brain lacerations) and may also include skull fractures as well as meningeal or cerebral lacerations from projectiles and debris driven into the brain.

Most persons lose consciousness with open brain injury. The depth and duration of the coma are related to the location of injury, extent of damage, and amount of bleeding. Open brain injury often requires débridement of the traumatized tissues to prevent infection and to remove blood clots, thereby reducing ICP. The ICP also is managed with dehydrating agents, osmotic diuretics, or a combination of these drugs. Broad-spectrum antibiotics are administered to prevent infection.

A compound fracture may be diagnosed through physical examination, skull x-ray films, or both. BSF is determined based on clinical findings, such as spinal fluid leaking from the ear or nose. Classic signs of periorbital ecchymosis (raccoon eyes) or ecchymosis over the mastoid bone (battle sign) are often noted on assessment for individuals with BSF (Fig. 18.9). Skull x-rays often do not display the fracture, although intracranial air (pneumocephalus) or air in the sinuses on imaging is indirect evidence of a BSF. Bed rest and close observation for meningitis and other complications are prescribed for a BSF.

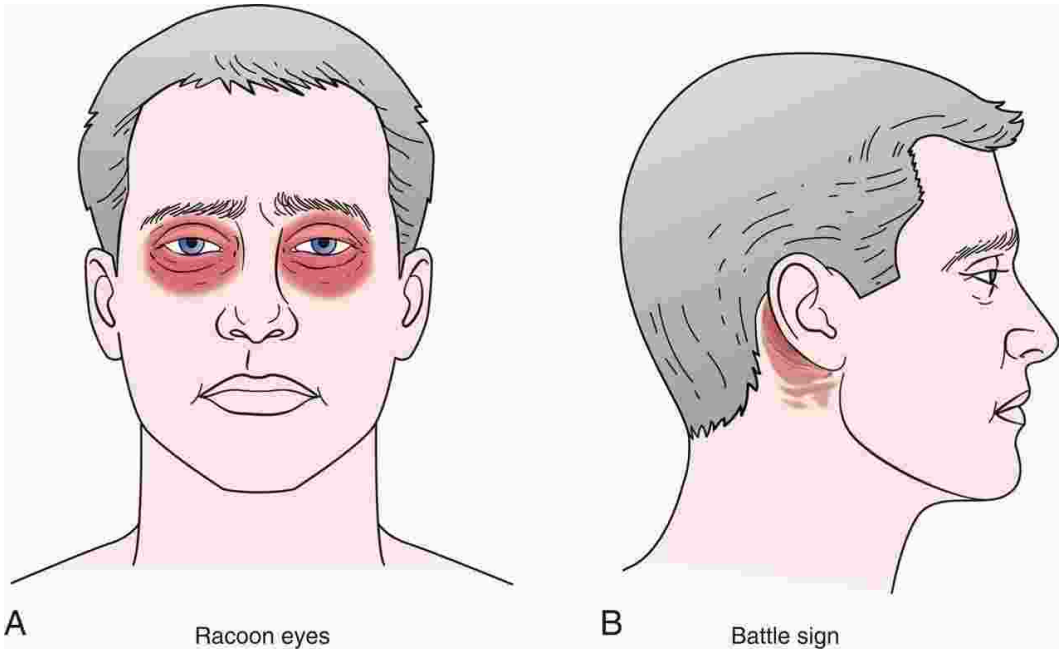

FIG. 18.9 Signs of Basilar Skull Fracture.
(A) Raccoon eyes: from leakage of blood from anterior fossa into periorbital tissues. **(B)** Battle Sign: from postauricular hematoma. (From Magee DJ, Manske RC: *Orthopedic physical assessment*, 7th ed. St. Louis, 2021, Elsevier.)

Diffuse brain injury

TBIs can produce microscopic changes that do not appear on computed tomography (CT) scans and are scattered throughout the brain. This category of injuries, called diffuse brain injury, may occur with or without an associated mass lesion. The most common diffuse brain injury is diffuse axonal injury (DAI) caused by shearing forces (see section later) (Fig. 18.10). Another diffuse injury with TBI is subarachnoid hemorrhage (SAH). SAH is bleeding into the subarachnoid space; this is often caused by aneurysm rupture (see section on Hemorrhagic Stroke). However, SAH can also occur after TBI when shearing forces tear small bridging blood vessels with bleeding into the subarachnoid space. The bleeding appears as diffuse blood spread thinly over the brain. Most cases of SAH associated with head trauma are mild. Severe traumatic SAH can result in hydrocephalus from damage to arachnoid granulations and mechanical blockage to the flow of CSF.[11]

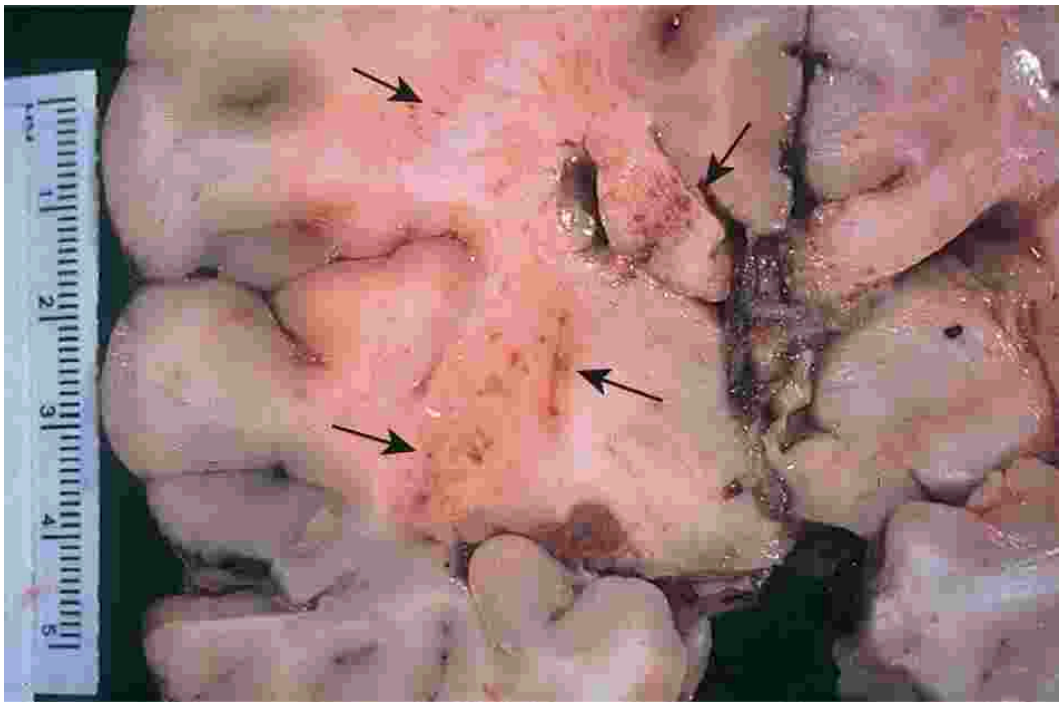

FIG. 18.10 Diffuse Axonal Injury.
Gross photograph demonstrating characteristic hemorrhage lesions within the corpus callosum.
(Courtesy Walter Kemp, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas. From Kumar V, Cotran RS, Robbins SL. *Robbins basic pathology*, 7th edition. Philadelphia: Saunders; 2003.)

Diffuse axonal injury (DAI), also known as **traumatic axonal injury or multifocal axonal injury**, involves widespread areas of the brain and occurs with all severities of brain injury. DAI results from mechanical effects of high levels of acceleration and deceleration injury, such as whiplash, or rotational forces that cause shearing and stretch of delicate axonal fibers and white matter tracts that project to or from the cerebral cortex (see Fig. 18.2). The most severe axonal injuries are more peripheral to the brainstem.[12] If enough axons are harmed in this way, the ability of nerve cells to communicate with each other may be lost or greatly impaired, possibly leaving an individual with behavioral, cognitive, and physical changes and severe disabilities. Pathophysiologically, axonal damage can be seen only with an electron microscope at postmortem examination and involves numerous axons, either alone or in conjunction with actual tissue tears. Advanced imaging techniques assist in defining

areas of injury. DAI is often not visible on CT imaging but may be seen as diffuse punctate hemorrhages in areas where axons and small blood vessels are torn. More damaged axons are visible 12 hours to several days after the initial injury. The severity of diffuse injury correlates with how much shearing force was applied to the brainstem.

DAI is not associated with intracranial hypertension immediately after injury; however, acute brain swelling, caused by vasodilation, increased intravascular blood flow within the brain, and increased cerebral blood volume, is seen often and can result in hypoxic-ischemic injury and death. DAI may induce long-term neurodegenerative processes. These changes may continue for years after injury, with the development of chronic traumatic encephalopathy (CTE) and Alzheimer disease–like pathologic changes.[13]

Secondary brain injury

Secondary brain injury is an indirect result of primary brain injury, including trauma and stroke syndromes. It occurs as a consequence of primary injury, a cascade of cerebral and molecular events initiated at the time of trauma and lasts for hours to days. Both systemic and cerebral processes are contributing factors. Systemic processes include hypotension, hypoxia, anemia, ischemia, hypercapnia, and hypocapnia. Cerebral contributions include inflammation, cerebral edema, IICP, microthrombosis, decreased cerebral perfusion pressure, cerebral ischemia, and brain herniation. Molecular mechanisms include excitotoxicity (excessive stimulation by excitatory neurotransmitters, such as glutamate), potassium efflux, calcium influx, spreading waves of depolarization, mitochondrial dysfunction, oxidative stress, the secretion of inflammatory cytokines and chemokines, apoptosis, blood brain barrier disruption, and neuronal death.

Cerebrovascular autoregulation (constriction or dilation in response to increases or decreases in cerebral perfusion pressure) is also impaired after brain injury and may be transient or persistent with alterations in CO_2 reactivity (e.g., CO_2 vasodilation). Vasospasm commonly occurs, contributing to brain hypoperfusion and ischemia. The vasospasm is caused by chronic depolarization of vascular smooth muscle, release of endothelin (vasoconstrictor), and decreased availability of nitric oxide (vasodilator). The molecular mechanisms of secondary brain injury are summarized in Fig. 18.1.[14,15]

The management of secondary brain injury is related to prevention of hypoxia and maintenance of cerebral perfusion pressure. Management includes removal of hematomas and treatment of hypotension, hypoxemia, anemia, cerebral edema, ICP, fluid and electrolyte balance, body temperature, ventilation, and nutrition. The development of neuroprotective agents, particularly antiinflammatory agents, is in progress but challenging to develop because of the complexity of multiple interacting secondary injury cascades.[16] Supportive treatments also are important. Nutrition management has emerged as critically important in the care of individuals with severe brain injury and should be initiated within the first 24 hours after injury.[17] Long-term recovery and mortality can be influenced by systemic complications, such as pneumonia, fever, infections, and immobility, that contribute to further brain injury and delays in repair and recovery

Categories of traumatic brain injury

Several categories of TBI exist and are presented here as mild, moderate, and severe. Concussion is the mildest form of TBI and occurs when a head injury causes a sudden change in mental status. More than 50% of the US population participates in sports, and there are approximately 3.8 million concussions each year.[18] The severity of TBI commonly considers the duration of loss of consciousness, the GCS score, posttraumatic amnesia, and brain imaging results.[14]

Mild traumatic brain injury is characterized by immediate but transitory clinical manifestations. There may be no loss of consciousness, or loss of consciousness may last less than 30 minutes. Most blunt trauma injuries cause mild concussion. The GCS score is 13 to 15. The initial confusional state lasts for 1 to several minutes, possibly with amnesia for events preceding the trauma (retrograde amnesia). Persons may experience headache, nausea, vomiting, impaired ability to concentrate, and difficulty sleeping for up to a few days.

Moderate traumatic brain injury is any loss of consciousness lasting more than 30 minutes and up to 6 hours. The GCS score is 9 to 12. A BSF may be present, but there is no brainstem injury; however, there may be transitory decerebration or decortication (see Fig. 17.6). The person is often confused and experiences posttraumatic amnesia that lasts for more than 24 hours. There may be permanent deficits in selective attention,

vigilance, detection, working memory, data processing, vision or perception, and language, as well as mood and affect changes ranging from mild to severe. Brain imaging is abnormal.

Severe traumatic brain injury is loss of consciousness lasting more than 6 hours. The GCS is 3 to 8. Frequently there are associated signs of brainstem damage, including changes in pupillary reaction, cardiac and respiratory symptoms, decorticate or decerebrate posturing (see Fig. 17.6), and abnormal reflexes. Brain imaging is abnormal. IICP appears 4 to 6 days after injury. Pulmonary complications occur frequently, with profound sensorimotor and cognitive system deficits. Severely compromised coordinated movements and verbal and written communication, inability to learn and reason, and inability to modulate behavior also are evident. Individuals will require intensive care unit (ICU) care, intubation/mechanical ventilation, and vigilant care to prevent IICP. Severe injury causes permanent neurologic deficits, and some individuals remain in a vegetative state or die as a result of brain injury or secondary complications.

The goal of treating TBI is to maintain cerebral perfusion and oxygenation and promote neuroprotection. Implementation of management guidelines for TBI decreases death and improves neurologic outcome. Corticosteroids increase mortality with acute TBI and, consequently, should not be used.[19]

Complications of Traumatic Brain Injury

Many complications are associated with TBI and are related to the severity of injury and the parts of the brain that are affected. Altered states of consciousness can range from confusion to deep coma (see Table 17.3). Cognitive deficits, hydrocephalus, sensory-motor disorders (including pain, paresis, and paralysis), and loss of coordination may be present. Three of the most common posttraumatic brain syndromes are summarized as follows.

Postconcussion syndrome occurs with mild TBI. Symptoms are nonspecific and include headache (most common), dizziness, fatigue, nervousness or anxiety, irritability, insomnia, depression, inability to concentrate, and forgetfulness; they may last for weeks to months after a mild concussion. Treatment entails reassurance and symptomatic relief in addition to 24 hours of close observation after the concussion in the event bleeding or swelling in the brain occurs. Symptoms requiring further

evaluation and treatment include drowsiness or confusion, nausea or vomiting, severe headache, memory deficit, seizures, drainage of cerebrospinal fluid from the ear or nose, weakness, or loss of feeling in the extremities, asymmetry of the pupils, and double vision. Guidelines for the management of pediatric and adult concussion are available.[20–23] Guidelines have been published for the management of sports-related concussion.[24]

Posttraumatic seizures (epilepsy) occur in approximately 10% to 20% of TBIs, with the highest risk among open brain injuries. Seizures can occur early, within days, and up to 2 to 5 years or longer after the trauma. Causal mechanisms are poorly understood, but they are associated with both focal and diffuse brain injury that creates epileptogenic foci with seizures and epilepsy. Seizure prevention using drugs, such as phenytoin, is initiated for moderate to severe TBI at the time of injury and continued for the first week. Continued antiseizure treatments are used only if seizures occur.[25]

Chronic traumatic encephalopathy (CTE) (previously called *dementia pugilistica*) is a progressive dementing disease that develops with repeated brain injury associated with sporting events, blast injuries in soldiers, or work-related head trauma. Tau neurofibrillary tangles are present in the brain. CTE is associated with violent behaviors, loss of control, depression, suicide, memory loss, and cognitive change that lasts at least 12 months. Research is in progress to discover the mechanistic link between neurotrauma and CTE. It is diagnosed from history, clinical evaluation, and at autopsy.[26]

Spinal Cord and Vertebral Injury

A spinal cord injury (SCI) is damage to the nerves within the bony protection of the spinal canal. The nerves can be severed, bruised, stretched, or crushed. The most common cause is trauma from vehicular accidents, falls, diving, violence, and sports injuries. SCI results in the loss of the ability to send and receive messages from the brain to the body's system that controls sensory, motor, and autonomic function. Each year 17,900 persons experience serious SCI, and 78% of new SCI cases are male. The average age at injury is 43 years. Motor vehicle crashes are the leading cause of injury, followed by falls and then violence, other events, and sports activities.[27]

Elderly people are particularly at risk for trauma that results in serious SCI because of preexisting degenerative vertebral disorders.

Pathophysiology

Primary spinal cord injury occurs with the initial mechanical trauma and immediate tissue destruction. Injuries to the cord are summarized in Table 18.4. Primary SCI may be complete or incomplete. With complete transection, there is loss of movement and sensation below the site of injury. Spinal injury can also occur if an injured spine is not adequately immobilized immediately following injury. Primary spinal cord injury can occur in the absence of vertebral fracture or dislocation and is related to longitudinal stretching of the cord with or without flexion or extension of the vertebral column, or both. The stretching causes altered axon transport, edema, myelin degeneration, and retrograde or wallerian neural degeneration (see Chapter 15).

Table 18.4

Spinal Cord Injuries

Injury	Description
Cord concussion	Results in temporary disruption of cord-mediated functions
Cord contusion	Bruising of neural tissue causes swelling and temporary loss of cord-mediated functions
Cord compression	Pressure on cord causes ischemia to tissues; must be relieved (decompressed) to prevent permanent damage to spinal cord
Laceration and shearing	Tearing of neural tissues of spinal cord; may be reversible if only slight damage sustained by neural tissues; may result in permanent loss of cord-mediated functions if spinal tracts are disrupted
Transection	Severing of spinal cord causes permanent loss of function
• Complete	All tracts in spinal cord are completely disrupted; all cord-mediated functions below transection are completely and permanently lost
• Incomplete	Some tracts in spinal cord remain intact, together with functions mediated by these tracts; has potential for recovery, although function is temporarily lost
• Preserved sensation only	Some demonstrable sensation below level of injury

Injury	Description
• Preserved motor nonfunctional	Preserved motor function without useful purpose; sensory function may or may not be preserved
• Preserved motor functional	Preserved voluntary motor function that is functionally useful
Hemorrhage	Bleeding into neural tissue as a result of blood vessel damage; usually no major loss of function
Damage or obstruction of spinal blood supply	Causes local ischemia

Injury	Description
Cord concussion	Results in temporary disruption of cord-mediated functions
Cord contusion	Bruising of neural tissue causes swelling and temporary loss of cord-mediated functions
Cord compression	Pressure on cord causes ischemia to tissues; must be relieved (decompressed) to prevent permanent damage to spinal cord
Laceration and shearing	Tearing of neural tissues of spinal cord; may be reversible if only slight damage sustained by neural tissues; may result in permanent loss of cord-mediated functions if spinal tracts are disrupted
Transection	Severing of spinal cord causes permanent loss of function
• Complete	All tracts in spinal cord are completely disrupted; all cord-mediated functions below transection are completely and permanently lost
• Incomplete	Some tracts in spinal cord remain intact, together with functions mediated by these tracts; has potential for recovery, although function is temporarily lost
• Preserved sensation only	Some demonstrable sensation below level of injury
• Preserved motor nonfunctional	Preserved motor function without useful purpose; sensory function may or may not be preserved
• Preserved motor functional	Preserved voluntary motor function that is functionally useful
Hemorrhage	Bleeding into neural tissue as a result of blood vessel damage; usually no major loss of function
Damage or obstruction of spinal blood supply	Causes local ischemia

Secondary spinal cord injury is a complex pathophysiologic cascade of vascular, cellular, and biochemical events that begins within a few minutes after injury and continues for weeks. Secondary injury includes hemorrhages, inflammation, edema, ischemia, free radical formation, and

apoptosis/necrosis. Hemorrhages develop in the central gray matter, and edema develops in the white matter, impairing the microcirculation of the cord. The hemorrhages and edema are followed by loss of vascular autoregulation, vasospasm and vascular occlusion, reduced perfusion, and development of ischemic areas, which are maximal at the level of injury and two cord segments above and below it. Cord swelling increases the individual's degree of dysfunction, making it difficult to distinguish functions permanently lost from those temporarily impaired. In the cervical region at C1 to C4, cord swelling may be life threatening because cardiovascular and respiratory control functions can be lost. Diaphragm function may be impaired because phrenic nerves exit at C3 to C5. Excitotoxicity (excessive stimulation by excitatory neurotransmitters, such as glutamate), intracellular calcium overload, oxidative damage, and cell death occur similarly to those previously described for TBI. Spared neurons continue to be chronically injured, with death of oligodendrocytes and myelin degeneration, axonal disruption, glial scarring, cystic cavitation, and release of inhibitory mediators. The process presents a physical and chemical barrier to regeneration.[28]

Vertebral injuries result from acceleration, deceleration, or deformation forces occurring at impact. These forces cause vertebral fractures, dislocations, and penetration of bone fragments that can cause compression to the tissues, pull or exert traction (tension) on the tissues, or cause shearing of tissues so they slide into one another (Figs. 18.11–18.14). Vertebral injuries can be classified as (1) simple fracture—a single break usually affecting transverse or spinous processes; (2) compressed (wedged) vertebral fracture—vertebral body compressed anteriorly; (3) comminuted (burst) fracture—vertebral body shattered into several fragments; and (4) dislocation.

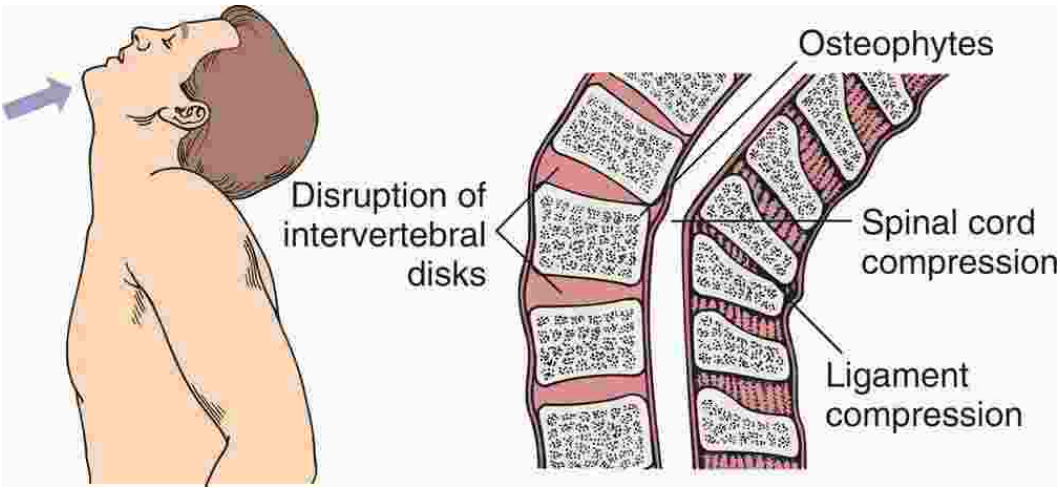

FIG. 18.11 Hyperextension Injuries of the Spine. Hyperexten-sion injuries of the spine can result in fracture or nonfracture injuries with spinal cord damage.

Two illustrations show hyperextension injuries of the spine. Left panel. The illustration shows the left lateral view of the upper body of a person with his head bent backward. Right panel. The illustration shows and identifies the disruption of intervertebral disks, osteophytes, spinal cord compression, and ligament compression in the vertebral column.

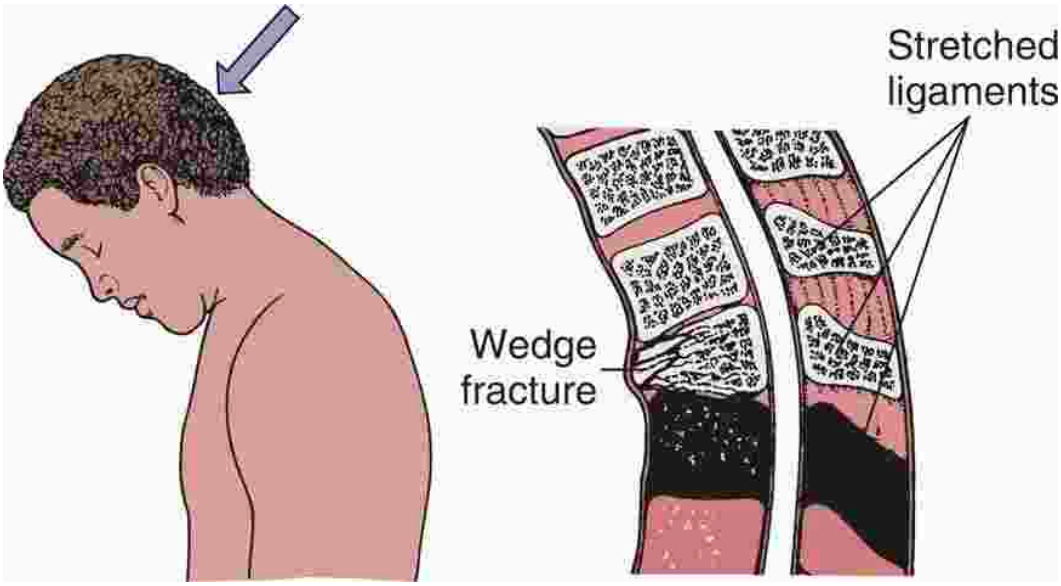

FIG. 18.12 Flexion Injury of the Spine.
Hyperflexion produces translation (subluxation) of vertebrae that compromises the central canal and compresses spinal cord parenchyma or vascular structures.

Two illustrations show flexion injuries of the spine. Left panel. The illustration shows the left lateral view of the upper body of a person with his head bent forward. Right panel. The illustration shows and identifies the wedge fracture and the stretched ligaments in the vertebral column.

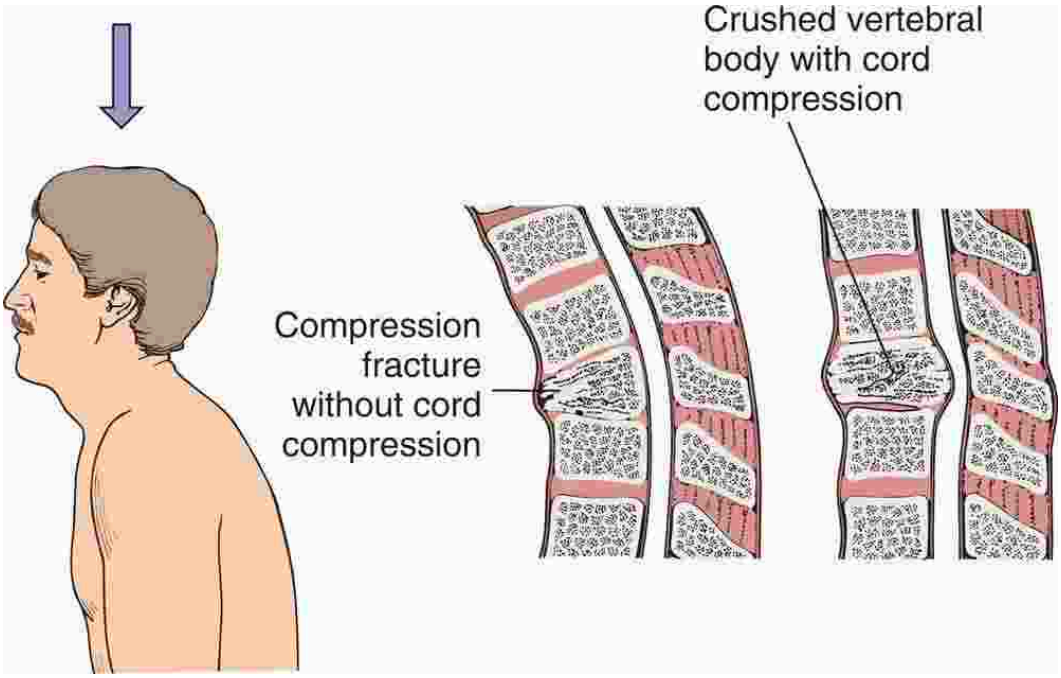

FIG. 18.13 Axial Compression Injuries of the Spine. In axial compression injuries of the spine, the spinal cord is contused directly by retropulsion of bone or disk material into the spinal canal.

Two illustrations show flexion injuries of the spine. Left panel. The illustration shows the left lateral view of the upper body of a person with a compressed neck. Right panel. The illustration shows and identifies the compression fracture without cord compression and the crushed vertebral body with cord compression.

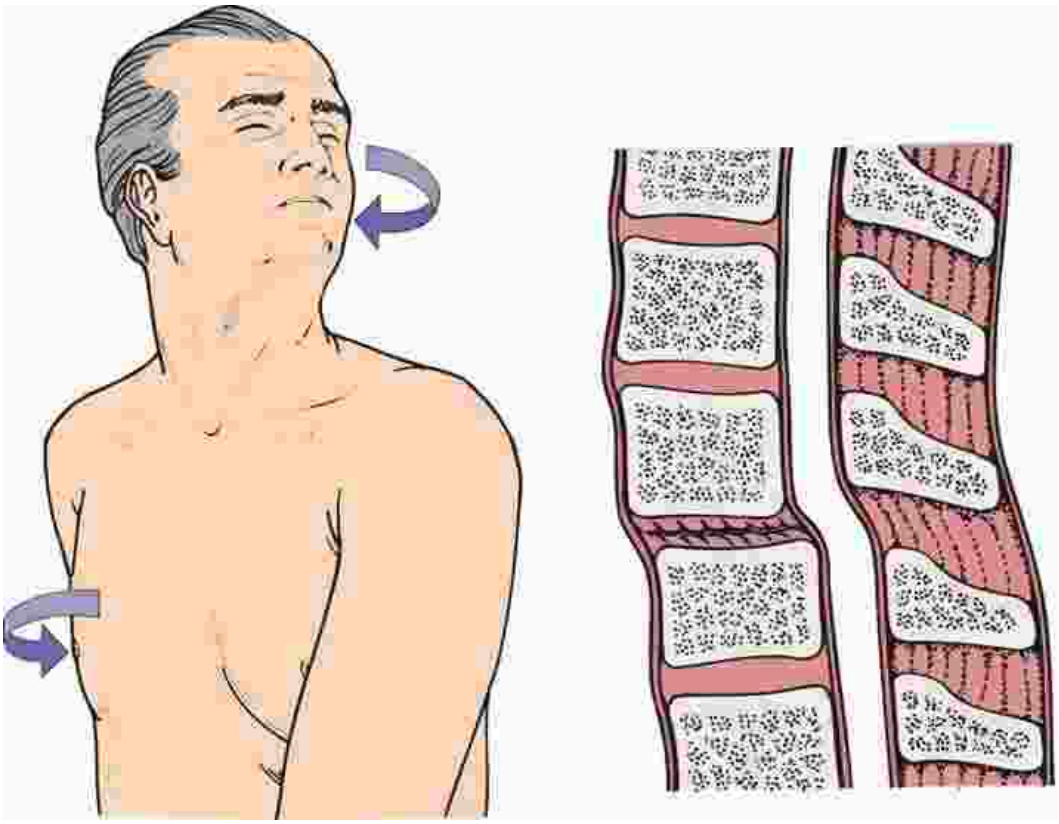

FIG. 18.14 Flexion-Rotation Injuries of the Spine.

Two illustrations show flexion-rotation injuries of the spine. Left panel. The illustration shows the left lateral view of the upper body of a person twisted to the left. Right panel. The illustration shows the dislocation of intervertebral disks and the ligaments in the spinal cord.

The vertebrae fracture readily with both direct and indirect trauma. When the supporting ligaments are torn, the vertebrae move out of alignment, and dislocations occur. A horizontal force moves the vertebrae straight forward; if the individual is in a flexed position at the time of injury, the vertebrae are then angulated. Flexion and extension injuries may result in dislocations and subluxation of the vertebrae. (Bone, ligament, and joint injuries are presented in Table 18.5).

Table 18.5

Mechanisms of Vertebral Injury Involving Bone, Ligaments, and Joints

Mechanism of Injury	Location of Vertebral Injury	Forces of Injury	Location of Injury
Hyperextension	Fracture and dislocation of posterior elements, such as spinous processes, transverse processes, laminae, pedicles, or posterior ligaments	Results from forces of acceleration/deceleration and sudden reduction in anteroposterior diameter of spinal cord	Cervical area
Hyperflexion	Fracture or dislocation of vertebral bodies, disks, or ligaments	Results from sudden and excessive force that propels neck forward or causes an exaggerated lateral movement of neck to one side	Cervical area
Vertical compression (axial loading)	Shattering fractures	Results from a force applied along an axis from top of cranium through vertebral bodies	T12 to L2
Rotational forces	Rupture support	Add shearing force to acceleration forces	Cervical area

Mechanism of Injury	Location of Vertebral Injury	Forces of Injury	Location of Injury
(flexion-rotation)	ligaments in addition to producing fractures		

Mechanism of Injury	Location of Vertebral Injury	Forces of Injury	Location of Injury
Hyperextension	Fracture and dislocation of posterior elements, such as spinous processes, transverse processes, laminae, pedicles, or posterior ligaments	Results from forces of acceleration/deceleration and sudden reduction in anteroposterior diameter of spinal cord	Cervical area
Hyperflexion	Fracture or dislocation of vertebral bodies, disks, or ligaments	Results from sudden and excessive force that propels neck forward or causes an exaggerated lateral movement of neck to one side	Cervical area
Vertical compression (axial loading)	Shattering fractures	Results from a force applied along an axis from top of cranium through vertebral bodies	T12 to L2
Rotational forces (flexion-rotation)	Rupture support ligaments in addition to producing fractures	Add shearing force to acceleration forces	Cervical area

Vertebral body fractures may not involve cord damage. Vertebral injuries in adults occur most often at vertebrae C1 to C2 (cervical), C4 to C7 (cervical), and T10 (thoracic) to L2 (lumbar) (see Fig. 15.11), the most mobile portions of the vertebral column. The spinal cord also occupies most of the vertebral canal in the cervical and lumbar regions, so it can be easily injured in these locations. Functioning after SCI depends on type and level of injury (Tables 18.6 and 18.7).

Table 18.6

Level of Injury: American Spinal Injury Association Scale

A = no motor control, no sensation

B = no motor control, some sensation

C = some motor function

D = motor function incomplete with more function below lesion area

E = normal

B = no motor control, some sensation

C = some motor function

D = motor function incomplete with more function below lesion area

E = normal

Table 18.7

Level of Injury Outcomes

C1–C3	Limited movement of head and neck.
C3–C4	Usually has head and neck control. Individuals at C4 level may shrug their shoulders.
C5	Typically has head and neck control, can shrug shoulder, and has shoulder control. Can bend his/her elbows and turn palms face up.
C6	Has movement in head, neck, shoulders, arms, and wrists. Can shrug shoulders, bend elbows, turn palms up and down, and extend wrists.
C7	Has similar movement as an individual with C6, with added ability to straighten his/her elbows.
T1	Has added strength and precision of fingers that result in limited or natural hand function.
T2–T6	Has normal motor function in head, neck, shoulders, arms, hands, and fingers. Has increased use of rib and chest muscles, or trunk control.
T7–T12	Has added motor function from increased abdominal control.
L1–L5	Has additional return of motor movement in the hips and knees.
S1–S5	Depending on level of injury, there are various degrees of return of voluntary bladder, bowel, and sexual functions.

Clinical Manifestations/Complications

Spinal shock is the temporary loss of spinal cord functions below the lesion. Spinal shock develops immediately after injury because of loss of continuous tonic discharge from the brain or brainstem and inhibition of central descending impulses that control and modulate spinal cord neurons. It is caused by cord hemorrhage, edema, or anatomic transection. Normal activity of spinal cord cells at and below the level of injury ceases, with complete loss of reflex function, flaccid paralysis, absence of sensation, loss of bladder and rectal control, transient drop in blood pressure, bradycardia, and poor venous circulation. The condition also results in disturbed thermal control because the sympathetic nervous system is damaged. The hypothalamus cannot regulate body heat through vasoconstriction and increased metabolism; therefore the individual assumes the temperature of the air (poikilothermia). Spinal shock can progress for several hours but generally lasts 2 to 3 days. It terminates with the reappearance of bulbocavernosus reflex activity, hyperreflexia, spasticity, and reflex emptying of the bladder, all of which may take weeks to months. Table 18.8 summarizes the clinical manifestations of SCI.

Table 18.8

Clinical Manifestations of Spinal Cord Injury

Stage	Manifestations
Spinal Shock Stage	
Complete spinal cord transection	Loss of motor function 1. Quadriplegia with injuries of cervical spinal cord 2. Paraplegia with injuries of thoracic spinal cord Muscle flaccidity Loss of all reflexes below level of injury Loss of pain, temperature, touch, pressure, and proprioception below level of injury Pain at site of injury caused by zone of hyperesthesia above injury Atonic bladder and bowel Paralytic ileus with abdominal distention Loss of vasomotor tone in lower body parts; low and unstable blood pressure Loss of perspiration below level of injury Loss or extreme depression of genital reflexes, such as penile erection and bulbocavernosus reflex Dry and pale skin; possible ulceration over bony prominences Respiratory impairment

Stage	Manifestations
Spinal Shock Stage	
Partial spinal cord transection	Asymmetric flaccid motor paralysis below level of injury Asymmetric reflex loss Preservation of some sensation below level of injury Vasomotor instability less severe than that seen with complete cord transection Bowel and bladder impairment less severe than that seen with complete cord transection Preservation of ability to perspire in some portions of body below level of injury *Brown-Séquard syndrome* (associated with penetrating injuries, hyperextension and flexion, locked facets, and compression fractures) 1. Ipsilateral paralysis or paresis below level of injury 2. Ipsilateral loss of touch, pressure, vibration, and position sense below level of injury 3. Contralateral loss of pain and temperature sensations below level of injury *Cauda equina syndrome* (compression of nerve roots below L1 caused by fracture and dislocation of spine or large posterocentral intervertebral disk herniation) 1. Lower extremity motor deficits

Stage	Manifestations
Spinal Shock Stage	
	2. Variable sensorimotor dysfunction (i.e., saddle anesthesia) 3. Variable reflex dysfunction in lower extremities 4. Neurogenic bladder or bowel, and sexual dysfunction
Heightened Reflex Activity Stage	
	Emergence of Babinski reflexes Hyperactive ankle and knee reflexes Reflex urinary incontinence and defecation Episodes of hypertension Defective heat-induced sweating Development of extensor reflexes, first in muscles of hip and thigh, later in leg

Stage	Manifestations
Spinal Shock Stage	
Complete spinal cord transection	Loss of motor function 1. Quadriplegia with injuries of cervical spinal cord 2. Paraplegia with injuries of thoracic spinal cord Muscle flaccidity Loss of all reflexes below level of injury Loss of pain, temperature, touch, pressure, and proprioception below level of injury Pain at site of injury caused by zone of hyperesthesia above injury Atonic bladder and bowel Paralytic ileus with abdominal distention Loss of vasomotor tone in lower body parts; low and unstable blood pressure Loss of perspiration below level of injury Loss or extreme depression of genital reflexes, such as penile erection and bulbocavernosus reflex Dry and pale skin; possible ulceration over bony prominences Respiratory impairment

Ipsilateral paralysis or paresis below level of injury 2. Ipsilateral loss of touch, pressure, vibration, and position sense below level of injury 3. Contralateral loss of pain and temperature sensations below level of injury *Cauda equina syndrome* (compression of nerve roots below L1 caused by fracture and dislocation of spine or large posterocentral intervertebral disk herniation) 1. Lower extremity motor deficits 2. Variable sensorimotor dysfunction (i.e., saddle anesthesia) 3. Variable reflex dysfunction in lower extremities 4. Neurogenic bladder or bowel, and sexual dysfunction
Heightened Reflex Activity Stage	
	Emergence of Babinski reflexes Hyperactive ankle and knee reflexes Reflex urinary incontinence and defecation Episodes of hypertension Defective heat-induced sweating Development of extensor reflexes, first in muscles of hip and thigh, later in leg

Neurogenic shock, also called *vasogenic shock*, occurs with cervical or upper thoracic cord injury above T6 and may be seen in addition to spinal shock. Neurogenic shock is a serious, life-threatening condition. It occurs as a result of loss of sympathetic tone, through loss of supraspinal control and unopposed parasympathetic tone mediated by the intact vagus nerve. Neurogenic shock causes widespread dilation of blood vessels with severe hypotension, bradycardia, and failure of body temperature regulation with hypothermia (see Chapter 48).

Neurogenic shock may be complicated by hypovolemic or cardiogenic shock if there is concurrent blood loss or heart failure (see Chapters 32 and 48). Loss of motor and sensory function depends on the extent and level of injury. Paralysis of the lower half of the body with both legs involved is termed *paraplegia*. Paralysis involving all four extremities is termed *quadriplegia* (tetraplegia). In complete quadriplegia, the level of injury is above C6 and all upper extremity function is lost. In incomplete quadriplegia, function at or above C6 is preserved, leaving the shoulder, upper arm, and some forearm muscle control intact. The initial clinical manifestations associated with acute SCI are related to the spinal shock described earlier and include (1) rapid development of flaccid paralysis below the level of injury, (2) loss of sensations in the lower extremities and possibly lower trunk (depending on the level of injury), and (3) loss of spinal and autonomic reflexes below the level of injury. The duration of this areflexic state is highly variable. In most persons, reflex activity returns in approximately a week. Return of spinal neuron excitability occurs slowly. First to return is the bulbocavernosus reflex (indicative of intact S2 to S4 spinal reflex arcs).[29] Depending on the degree of damage, either of the following can occur: (1) motor, sensory, reflex, and autonomic functions return to normal, or (2) autonomic neural activity in the isolated segment develops. Spasticity is common, with hyperreflexia, clonus, and painful muscle spasms. Sometimes after several months, episodes of autonomic hyperreflexia occur.

Autonomic hyperreflexia (dysreflexia) is a severe, life-threatening complication associated with a SCI at level T6 or above, where descending inhibition is blocked resulting in autonomic nervous system dysregulation. Autonomic hyperreflexia occurs because descending inhibition is blocked (Fig. 18.15). It may occur after spinal shock resolves and be a recurrent complication. Characteristics include paroxysmal hypertension (up to 300 mm Hg, systolic), a pounding headache, blurred

vision, sweating above the level of the lesion, with flushing of the skin, nasal congestion, nausea, piloerection caused by pilomotor spasm, and bradycardia (30 to 40 beats/min). The symptoms may develop singly or in combination. The condition can cause serious complications (stroke, seizures, myocardial ischemia, and death) and requires immediate treatment.

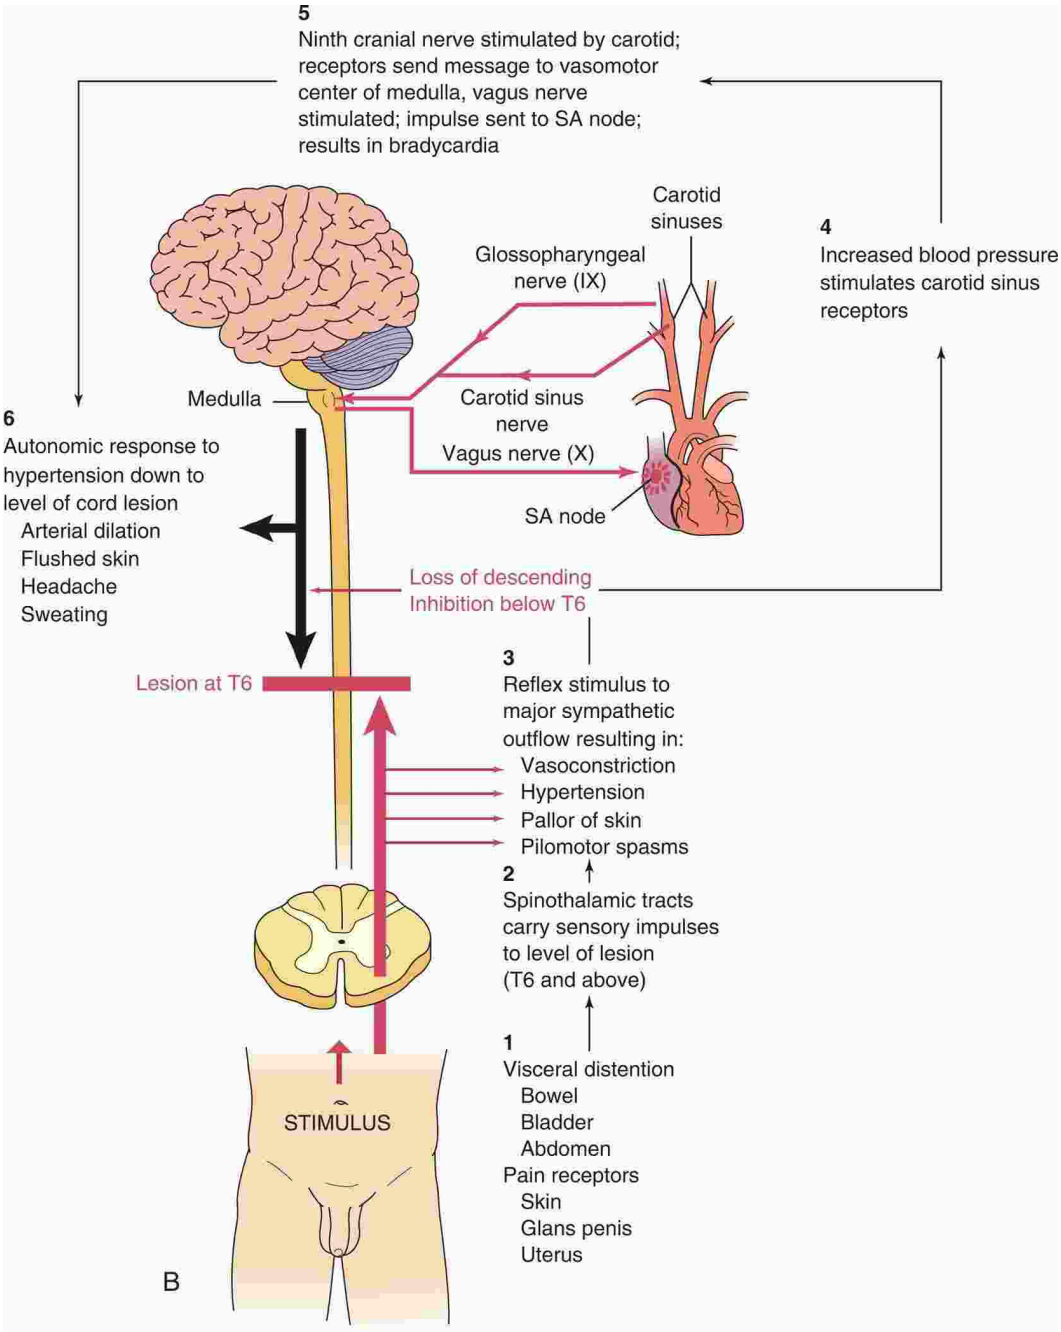

FIG. 18.15 Autonomic Hyperreflexia.
(A) Normal response pathway. **(B)** Autonomic hyperreflexia pathway. *SA*, Sinoatrial. (Modified from Rudy EB. *Advanced neurological and neurosurgical nursing*. St. Louis: Mosby; 1984.)

An illustrated flowchart represents the normal response pathway in an autonomic hyperreflexia. 1. The

illustration shows the male pelvic region. The text reads, visceral distention (bowel, bladder, and abdomen) and pain receptors (skin, glans penis, and uterus). 2. The illustration shows the superior view of the spinal cartilage. The text reads, spinothalamic tracts carry the impulses to brain. 3. The illustration shows the left lateral view of the brain. The text reads, brain interprets sensory inputs; course of action determined (empty bladder; remove painful stimulus, etcetera). 4. The text reads, corticospinal tracts carry motor impulses to appropriate muscles. 5. The illustration shows and identifies the spinal ganglion, gray ramus, splanchnic nerve, and vagus nerve, connecting the spinal cartilage and the kidney. The text reads, motor output (empty bladder; remove painful stimulus, et cetera); eliminates stimulus to sensory nerve.

In autonomic hyperreflexia, sensory receptors below the level of the cord lesion are stimulated. The intact autonomic nervous system reflexively responds with an arteriolar spasm that increases blood pressure. Baroreceptors in the cerebral vessels, the carotid sinus, and the aorta sense the hypertension and stimulate the parasympathetic system. The heart rate decreases, but the visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the cord, and there is loss of blood pressure regulation.

The most common trigger is a distended bladder or rectum (constipation); however, any sensory stimulation (i.e., skin or pain receptors) can elicit autonomic hyperreflexia (tight clothing or shoes). The primary intervention is to locate and remediate the source causing the autonomic dysreflexia. (e.g., emptying of the bladder or bowel and elevating the head of the bed). Drug therapy may be required to lower blood pressure and reduce complications. Bladder, bowel, and skin care management are important preventive strategies. Education of the

individual and family regarding triggers and acute management is important, as is wearing a medic alert tag.[30]

Evaluation and Treatment

Diagnosis of SCI is based on physical examination and imaging studies. Initial treatment should be focused on determination of the extent of the injury. For a suspected or confirmed vertebral fracture or dislocation, regardless of the presence or absence of SCI, the immediate intervention is immobilization of the spine to prevent further injury. Decompression and surgical fixation may be necessary. Neurogenic shock must be differentiated from other kinds of shock (e.g., hypovolemic shock). Blood pressure control, lung function, nutrition, skin integrity, prevention of pressure ulcers, pain management, and bladder and bowel management must be addressed because all systems and organs are affected below the level of neurologic injury. Early intervention and rehabilitation provide the most hope to preserve the cord, prevent irreversible damage, and prevent long term complications The American Spinal Injury International standards for neurologic classification of SCI is a starting evaluation for predicting outcomes after SCI.[31,32] Neuroprotective, neuroregenerative, and neuroplastic strategies are under clinical investigation.[33–37]

Degenerative Disorders of the Spine

Low Back Pain

Low back pain (LBP) affects the area between the lower rib cage and gluteal muscles and often radiates into the thighs. Approximately 80% of the population experiences LBP at some time during their lives, and approximately 25% of the adult population in the United States has experienced LBP in the past 3 months.[38] LBP is the leading global cause of years lived with disability.[39]

The burdens of disability include psychological, financial, occupational, and social effects on the person and family members. Risk factors include occupations that require repetitive lifting in the forward bent-and-twisted position, exposure to vibrations caused by vehicles or industrial machinery, obesity, osteoporosis, and cigarette smoking.

Pathophysiology

Most cases of LBP are idiopathic or nonspecific, and no precise diagnosis is possible. Acute LBP (lasting less than 4 weeks) is often associated with muscle or ligament strain and is more common in individuals younger than 50 years of age without a history of cancer. The interspinous bursae can be a source of pain, particularly in the lumbar vertebrae. The ligaments of the spine are supplied with pain receptors, and all these ligaments are vulnerable to traumatic tears (sprains) and fracture. Chronic LBP is also related to inflammation and the development of peripheral and central neuropathic pain (Fig. 18.16A).[40]

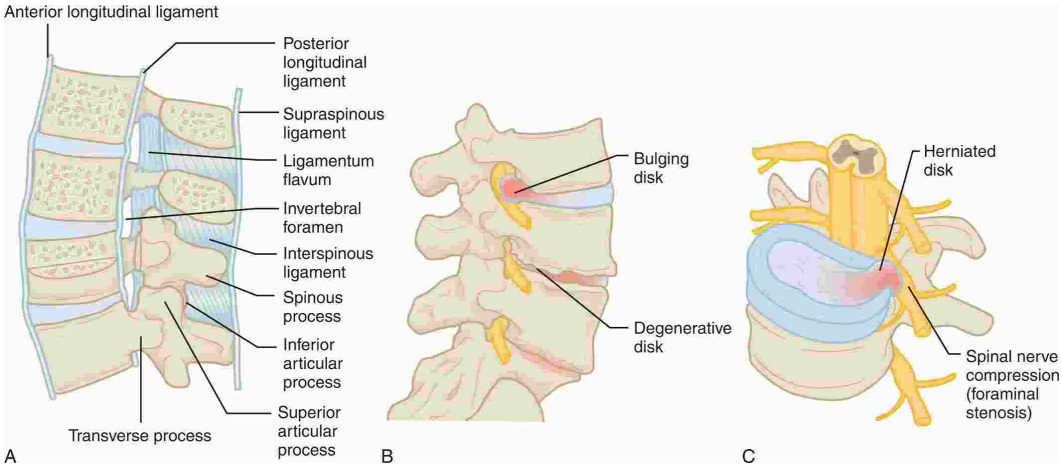

FIG. 18.16 Spinal Ligaments, Degenerating Disk, and Herniated Disk.
(A) Ligaments of the spine. **(B)** Bulging disk with spinal nerve compression and degenerative disk showing collapse of vertebral body. **(C)** Herniated disk with spinal nerve compression.

Left panel, A. The illustration shows the lateral view of the spine and identifies the following ligaments, from the top to the bottom: anterior longitudinal ligament, posterior longitudinal ligament, supraspinous ligament, ligamentum flavum, invertebral foramen, interspinous ligament, spinous process, inferior articular process, superior articular process, and transverse process. Middle panel, B. The illustration shows the lateral view of a section of the spinal cord, identifying a building disk at the top and a degenerative disk at the bottom. Right panel, C. The illustration shows the superior view of a herniated disk and identifies the spinal compression (foraminal stenosis).

Common causes of chronic LBP (greater than 3 months duration) include spondylolysis (vertebral stress fracture), spondylolisthesis

(vertebra slides forward or slips in relation to a vertebra below), spinal osteochondrosis (abnormal bone growth), spinal stenosis, degenerative disk disease (DDD), and lumbar disk herniation (see Fig. 18.16). Other causes include tension caused by tumors or disk prolapse, bursitis, synovitis, spinal immobility, inflammation caused by infection (as in osteomyelitis), and pain referred from viscera or the posterior peritoneum. Systemic causes of LBP include bone diseases, such as osteoporosis or osteomalacia, and hyperparathyroidism. Anatomically, LBP must originate from innervated structures, but deep pain is widely referred and varies. The nucleus pulposus has no intrinsic innervation, but when extruded or herniated through a prolapsed disk, it irritates the spinal nerve and associated structures and causes pain referred to the segmental area (see Fig. 18.16C).

Clinical Manifestations

Some individuals with acute LBP have pain along the distribution of a lumbar nerve root (radicular pain), most commonly involving the sciatic nerve (sciatica). **Sciatica** is often accompanied by neurosensory and motor deficits, such as tingling, numbness, and weakness in various parts of the leg and foot. Chronic LBP may be associated with progressive motor or sensory deficits, **cauda equina syndrome** (new-onset bowel or bladder incontinence or urinary retention, loss of anal sphincter tone, and saddle anesthesia), a history of cancer metastasis to bone, and suspected spinal infection.

Evaluation and Treatment

Diagnosis of LBP is based on the history and physical examination. Imaging and nerve conduction studies are obtained with severe neurologic deficit or serious underlying disease ("red flags"), including progressive or rapid motor or sensory loss (e.g., saddle anesthesia), new urinary retention or overflow incontinence, history of cancer, recent invasive spinal procedure, and significant trauma relative to age.[41] The straight leg raise test (Lasegue test) assesses sciatic pain (radiating pain from the buttocks to the leg) due to lumbosacral nerve root irritation. Diagnosis and treatment guidelines are available to plan therapy.[42] Most individuals with acute LBP benefit from a nonspecific short-term treatment regimen with return to normal activities, avoiding bed rest, nonsteroidal antiinflammatory drugs, muscle relaxants, exercises,

physical therapy, and education.[43] Surgical treatments, specifically discectomy and spinal fusions, are used for individuals not responding to medical management or for emergency management of cauda equina syndrome. Individuals with chronic LBP may benefit from antiinflammatory and muscle relaxant medications, exercise programs, massage, topical heat, spinal manipulation, acupuncture, cognitive-behavioral therapies, and interdisciplinary care. There is scant evidence for efficacy of opioids for chronic LBP but a high risk for addiction. The complexity of causes contributes to the difficulty in defining pathogenesis and clearly defining the most effective therapies.[44,45]

Degenerative Joint Disease

Spondylolysis

Spondylolysis is a structural defect (degeneration, fracture, or developmental defect) in the pars interarticularis of the vertebral arch (the joining of the vertebral body to the posterior structures). The lumbar spine at L5 is affected most often. Mechanical pressure may cause an anterior or posterior displacement of the deficient vertebra (spondylolisthesis). Heredity plays a significant role, and spondylolysis is associated with an increased incidence of other congenital spinal defects. As a result of torsional and rotational stress, "microfractures" can occur at the affected site and eventually cause dissolution of the pars interarticularis. Segmental instability causes tension on the facet joint capsules and ligaments. There is compensatory muscle spasm related to the instability, and there may be central or foraminal stenosis that generates radicular pain and recurrent LBP.[46]

Cervical spondylolysis is facet hypertrophy and disk degeneration with narrowing in the cervical spine predominantly at C5 to C6 and C6 to C7.[47] It may present as a cervical radiculopathy or a cervical myelopathy. Clinical manifestations of cervical radiculopathy include neck or occipital pain as well as pain in the medial aspects of the scapula, shoulder, or arm. Sensory symptoms, such as tingling or numbness, follow a dermatomal pattern; weakness follows the pattern of innervation of the affected nerve root. Occipital or suboccipital headache is another symptom. Cervical myelopathy can also cause difficulty walking, altered sensation in the feet, and sphincter disturbances (occurs late).

Spondylolisthesis

Spondylolisthesis is an osseous defect of the pars interarticularis and allows a vertebra to slide anteriorly in relation to the vertebra below. The problem is prevalent among athletes related to repetitive stress.[48] Degenerative lumbar spondylolisthesis is a common cause of LBP. Commonly there is involvement of L5 to S1. Spondylolisthesis is graded from 1 to 4 based on the percentage of slip that occurs. Grades 1 and 2 have symptoms of pain in the lower back and buttocks, muscle spasms in the lower back and legs, and tightened hamstrings. Conservative management includes exercise, back bracing, pain medications, epidural steroid injections, transforaminal injections, and physical therapy. Vertebral slippage in grades 3 and 4 usually requires surgical intervention.[49]

Spinal stenosis

Spinal stenosis is a narrowing of the spinal canal that causes pressure on the spinal nerves or cord. It can be congenital or acquired (more common) and is associated with trauma or arthritis. Spinal stenosis is categorized by the area of the spine affected: cervical, thoracic (less common), or lumbar. Acquired conditions include a bulging disk, facet hypertrophy, or a thick, ossified posterior longitudinal ligament (more common in the cervical spins). Symptoms are related to the area of the spine affected and can produce pain; numbness; and tingling in the neck, hands, arms, or legs, with weakness and difficulty walking. Surgical decompression is recommended for those with chronic symptoms and those who do not respond to medical management.[50]

Degenerative Spine Disease

Degenerative disk disease

Degenerative disk disease (DDD) is common in individuals 30 years of age and older. It is, in part, a process of normal aging as a response to continuous vertical compression of the spine (axial loading). DDD includes a genetic component, involving genes that code for spinal cartilage. The combination of environmental interactions and genetic predisposition increases susceptibility to lumbar disk disease by disrupting normal building and maintenance of proteoglycans with inflammation and physical compression of the intervertebral disk

matrix.[51] The annulus (outer fibrous ring) can tear, and the disk can herniate, pinching nerves or placing strain on the spine. Fibrocartilage replaces the gelatinous proteoglycans of the nucleus pulposus as the disk changes with age. There may be shrinkage of the nucleus pulposus that produces prolapse or folding of the annulus with secondary osteophyte formation at the margins of the adjacent vertebral body. The pathologic findings in DDD include disk protrusion, spondylolysis and/or subluxation (spondylolisthesis), degeneration of vertebrae, spinal stenosis, and compression of nerves. Lumbar disk disease commonly affects adults at some point in their lives. However, only a small percentage of people with DDD have any functional incapacity because of pain.

Herniated Intervertebral Disk

Herniation of an intervertebral disk is a displacement of the nucleus pulposus or annulus fibrosus beyond the intervertebral disk space (see Fig. 18.16C). Rupture of an intervertebral disk usually is caused by trauma, DDD, or both. Risk factors are weight-bearing sports, light weightlifting, and certain work activities, such as repeated lifting. Men are affected more often than women, with the highest incidence in the 30- to 50-year age group. Most commonly affected are the lumbosacral disks L4 to L5 and L5 to S1 (Fig. 18.17). Disk herniation occasionally occurs in the cervical area, usually at C5 to C6 and C6 to C7. Herniations at the thoracic level are extremely rare. The herniation may occur immediately, within a few hours, or months to years after injury.

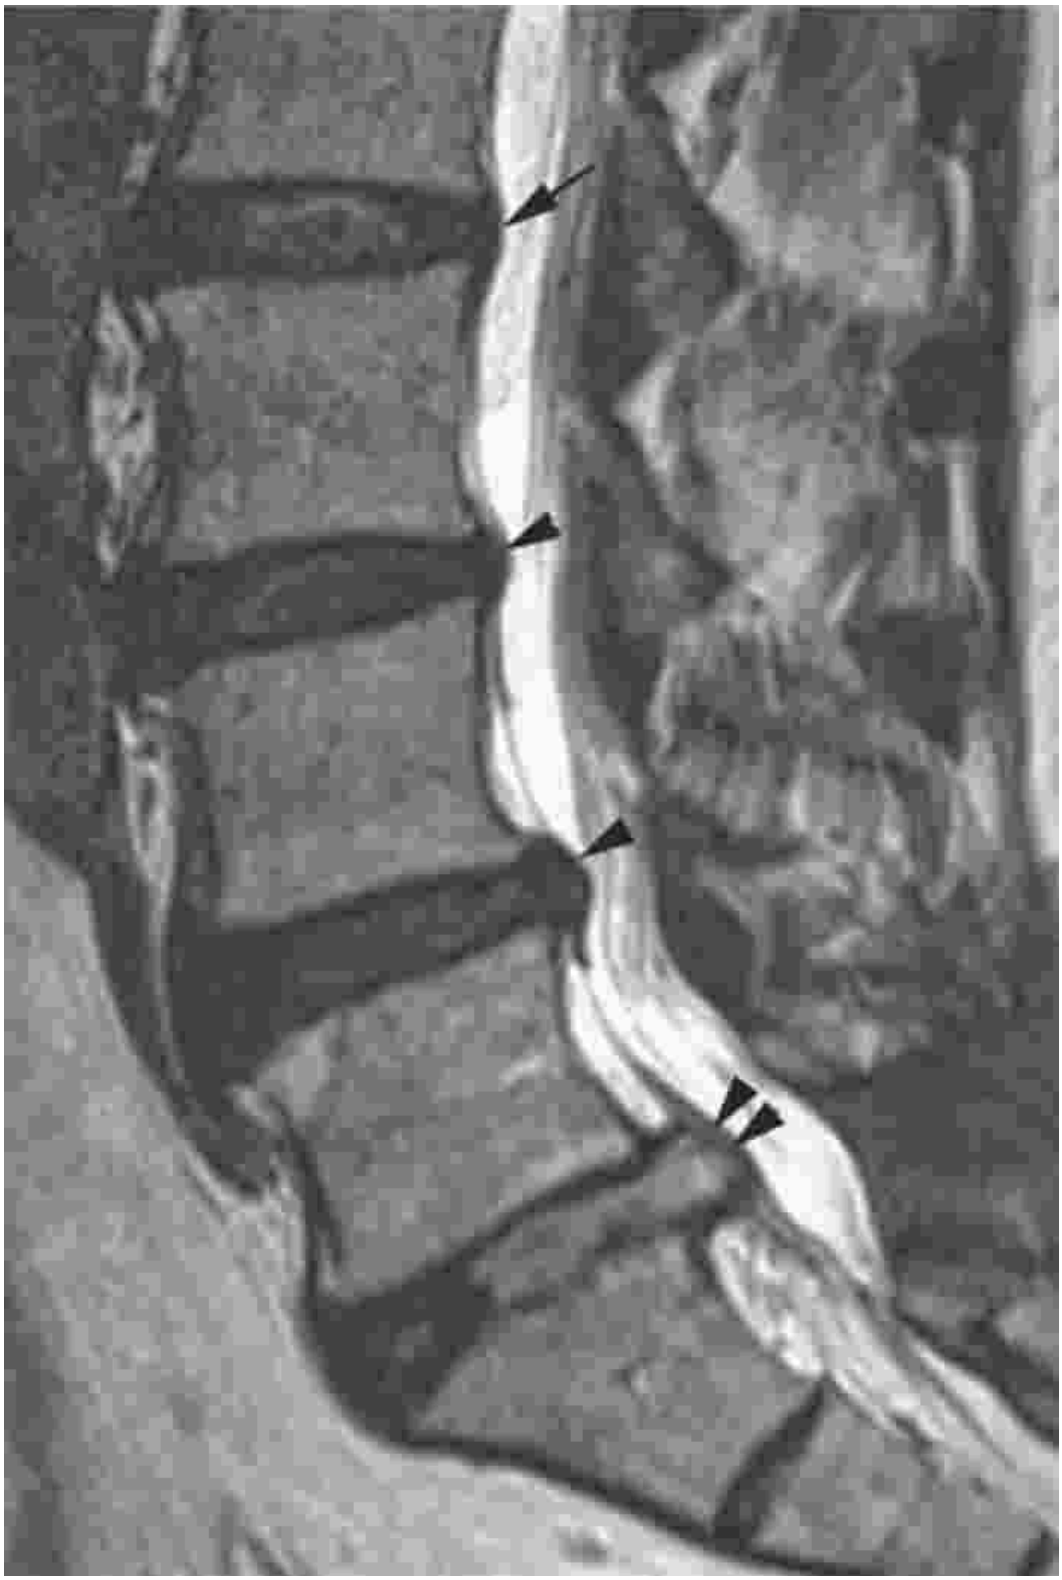

FIG. 18.17 Disc Bulge, Protrusion, and Herniation. Magnetic resonance imaging of lumbar spine. Sagittal T2-weighted image demonstrates examples for all

stages of disk pathology. Viewing from rostral to caudal, a disk bulge *(arrow)*, a small and more prominent protrusion *(arrowheads)*, and a herniation *(double arrowhead)* are seen. (From Daroff RB, et al. *Bradley's neurology in clinical practice*. Philadelphia: Saunders; 2012.)

Pathophysiology

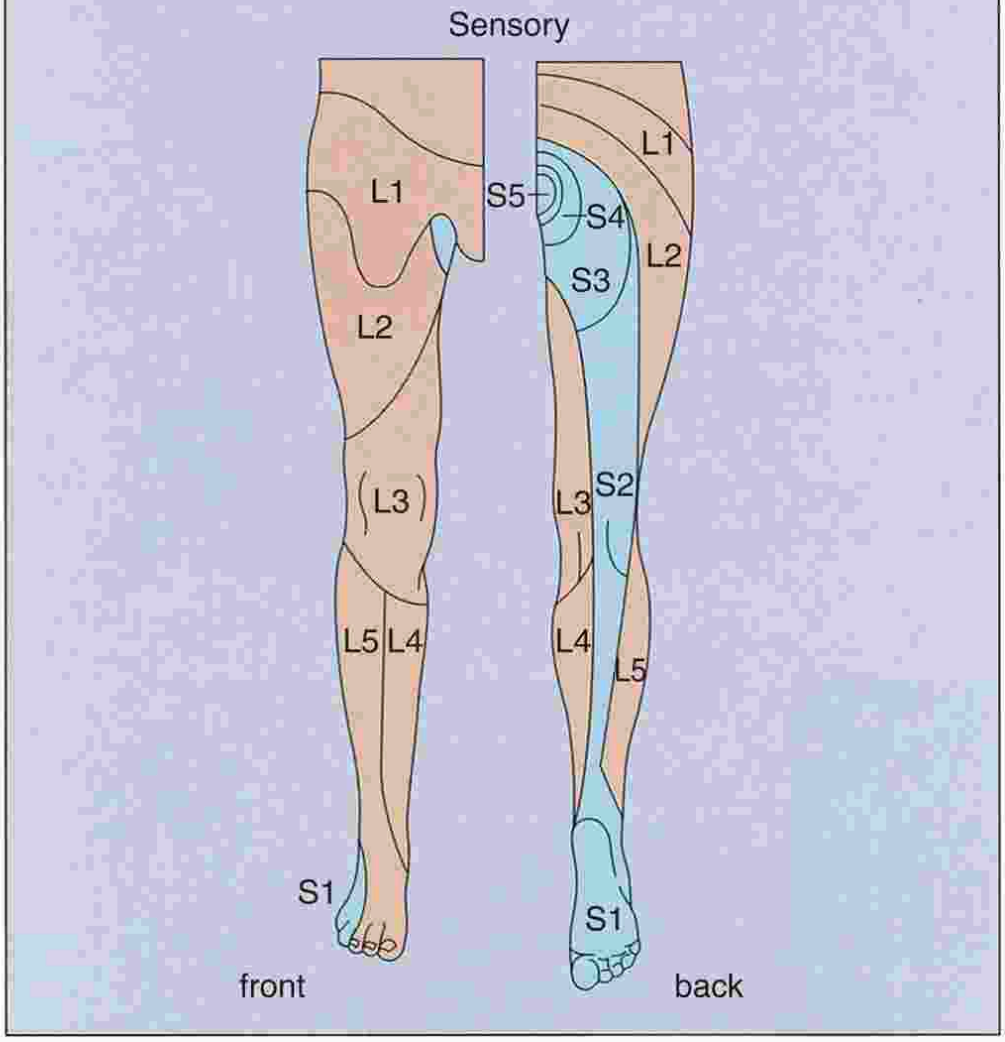
In a herniated disk, the ligament and posterior capsule of the disk are usually torn, allowing the nucleus pulposus to extrude and compress the nerve root. The vascular supply may be compromised and cause inflammatory changes in the nerve root (radiculitis). Occasionally, the injury tears the entire disk loose, causing the disk capsule and nucleus pulposus to protrude onto the nerve root or compress the spinal cord.

Clinical Manifestations

The location and size of the herniation into the spinal canal, together with the amount of space in the canal, determine the clinical manifestations associated with the injury (Fig. 18.18A). Compression or inflammation, or both, of a spinal nerve resulting from disk herniation follows a dermatomal distribution called **radiculopathy** (see Fig. 18.18B). A herniated disk in the lumbosacral area is associated with pain that radiates along the sciatic nerve course over the buttock and into the calf or ankle. The pain occurs with straining, including coughing and sneezing, and usually on straight leg raising. Other clinical manifestations include limited range of motion of the lumbar spine; tenderness on palpation in the sciatic notch and along the sciatic nerve; impaired pain, temperature, and touch sensations in the L4 to L5 or L5 to S1 dermatomes of the leg and foot; decreased or absent ankle jerk reflex; and mild weakness of the foot. More rarely, there is development of cauda equina syndrome (see Table 18.8).

Motor, reflex, and sensory changes

Muscle	Reflex
L4, L5 — tibialis anterior, extensor hallucis longus L4, L5, S1 — gastrocnemius, soleus	L4 knee (+L2,3) L5 no reflex S1 ankle



A

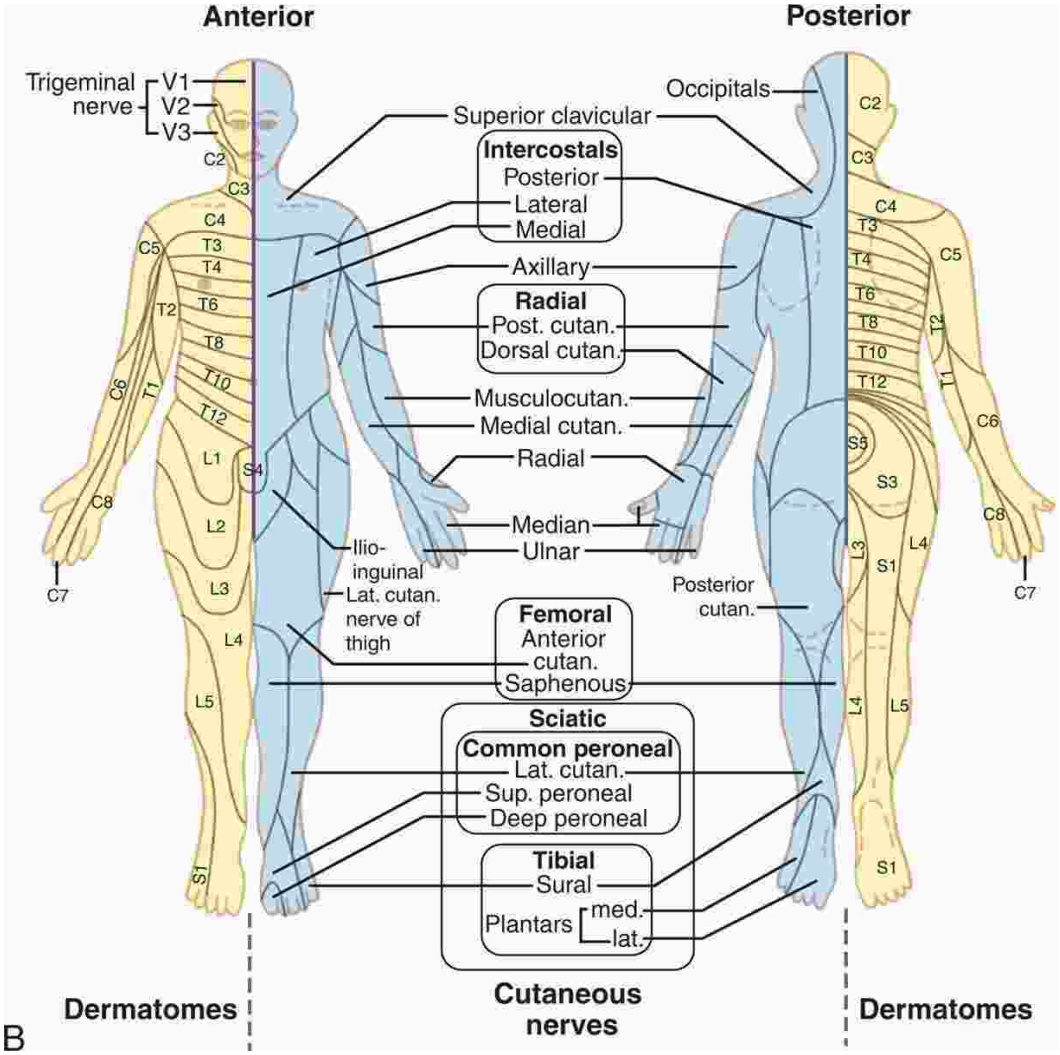


FIG. 18.18 Dermatomes Associated With Muscle, Reflex, and Sensory Changes. **(A)** Clinical features of herniated nucleus pulposus. **(B)** Sites of radicular pain associated with sensory nerve distribution of skin dermatomes. (Redrawn from Patton HD, et al, eds. *Introduction to basic neurology*. Philadelphia: WB Saunders; 1976. Borrowed from Canale ST, Beaty JH. *Campbell's operative orthopaedics*, 12th edition. St. Louis: Mosby; 2013.)

Left panel, A. The illustration shows the front and back of a leg, sectioning the sensory muscles and reflexes. The illustration on the left, showing the anterior view of a leg, identifies the following sensory regions from the top

to the bottom: L 1 (near the pelvis), L 2 (upper thigh), L 2 (lower thigh and knee), L 4 (medial side of the leg), L 5 (lateral side of the leg), and S 1 (outer toes). The illustration on the right, showing the posterior view of the leg, identifies the following sensory regions from the top to the bottom: L 1 (upper thigh), L 2 (lateral side of the thigh), S 4 and S 3 (inner thigh), L 3 (medial side of the lower thigh and knee), S 2 (lateral side of the lower thigh, knee, and central calf), L 4 (medial side of the leg), L 5 (lateral side of the leg), S 1 (foot), tibialis anterior extensor, hallucis longus, gastrocnemius, soleus, L4 knee (positive L 2,3), L5 no reflex, and S1 ankle. Right panel, B. The illustration shows the anterior and posterior view of the human body, sectioning the sites of radicular pain associated with sensory nerve distribution of skin dermatomes. The illustration on the left, representing the anterior view of the body, shows the following dermatomes labels on the left, from the top to the bottom: trigeminal nerve (V 1, V 2, V 3), C 2, C 3, C 4, T 3 to T 12, L 1 to L 5, and S 1. C 5 to C 8 and T 1 and T 2 are identified along the arm. The illustration on the right, representing the posterior view of the body, shows the following dermatomes labels on the right, from the top to the bottom: C 2, C 3, C 4, T 3 to T 12, S 5, S 3, S 1, L 3, L 4, and L 5. C 5 to C 8 and T 1 and T 2 are identified along the arm. The right side of the anterior view and the left side of the posterior view identify the following cutaneous nerves, from the top to the bottom: occipitals, superior clavicular, intercostals (posterior, lateral,

medial), axillary, radial (posterior cutaneous, dorsal cutaneous), musculocutaneous, medial cutaneous, radial, median, ulnar, ilioinguinal, lateral cutaneous nerve of thigh, posterior cutaneous, femoral (anterior cutaneous, saphenous), sciatic (common peroneal, tibial). Common peroneal include lateral cutaneous, superior cutaneous, and deep peroneal. Tibial include sural and plantars (medial and lateral).

With the herniation of a lower cervical disk, paresthesia (sensation of tingling, numbness, or burning) and pain are present in the upper arm, forearm, and hand along the affected nerve root distribution. Neck motion and straining, including coughing and sneezing, may increase neck and nerve root pain. Neck range of motion is diminished. Slight weakness and atrophy of biceps or triceps muscles may occur; the biceps or triceps reflex may decrease. Occasionally, signs of both corticospinal and sensory tract impairments appear, including motor weakness of the lower extremities, sensory disturbances in the lower extremities, and presence of a Babinski reflex.

Evaluation and Treatment

Diagnosis of a herniated intervertebral disk is made through the history and physical examination, imaging, electromyography, and nerve conduction studies. Evidence-based practice guidelines have been published to guide treatment options.[52,53] Most herniated disks heal spontaneously over time and do not require surgery. Physical therapy, interventional modalities such as intradiscal therapies, and epidural injections can relieve pain. Discectomy, fusion, or artificial disc replacement are surgical options if there is evidence of severe compression (weakness or decreased deep tendon, bladder, or bowel reflexes) or if a conservative approach is unsuccessful. Cauda equina syndrome rarely develops and requires emergency surgical evaluation and long-term follow-up.[54]

Seizure Disorders and Epilepsy

Seizure disorders represent a manifestation of disease and not a specific disease entity. A **seizure** is a sudden, transient disruption in brain electrical function caused by abnormal excessive discharges of cortical neurons. **Epilepsy** is a cause of seizures and a disease of the brain. Epilepsy is defined using the following criteria: (1) at least two unprovoked seizures occurring more than 24 hours apart; (2) one unprovoked (or reflex) seizure that has at least a 60% risk of recurrence after two unprovoked seizures, occurring over the next 10 years; and (3) diagnosis of an epilepsy syndrome.[55]

An **epilepsy syndrome** is defined as a characteristic seizure associated with abnormal findings on EEG and magnetic resonance imaging (MRI), that occur together in a recognizable pattern (considerations would be age, time of day, triggers, and type of seizures). There are many of these syndromes; they are rare and often occur in children (e.g., childhood absence epilepsy and juvenile myoclonic epilepsy) (see Chapter 20).[56] Epilepsy was estimated to have affected approximately 3 million adults and 470,000 children in the United States in 2015.[57]

Conditions Associated With Seizure Disorders

Any disorder that alters the neuronal environment may cause seizure activity. Conditions that may produce a seizure are metabolic disorders, congenital malformations, genetic predisposition, perinatal injury, postnatal trauma, myoclonic syndromes, infection, brain tumor, vascular disease, drug or alcohol abuse, and toxins. The mechanisms resulting in seizure activity can include stimulation of CNS excitatory pathways, inhibition of inhibitory pathways within the CNS, or withdrawal of long-term CNS depressants.[58] The onset of seizures also may indicate the presence of an ongoing primary neurologic disease. Metabolic and structural causes of recurrent seizures in adults are summarized in Table 18.9. The cause of seizures is often unknown.

Table 18.9

Structural/Metabolic Causes of Recurrent Seizures in Adults

Age at Onset	Probable Cause
Young adults (18–35 years)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines) Brain tumor Idiopathic Illicit drug use (e.g., cocaine, amphetamines) Posttraumatic brain injury Perinatal insults
Older adults (>35 years)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines) Brain tumor Cerebrovascular disease (e.g., stroke, aneurysm, arteriovenous malformations) CNS degenerative diseases (e.g., Alzheimer disease, multiple sclerosis) Major depression Idiopathic Metabolic disorders (e.g., uremia, hepatic failure, electrolyte abnormalities, hypoglycemia) Posttraumatic brain injury

Age at Onset	Probable Cause
Young adults (18–35 years)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines)
	Brain tumor
	Idiopathic
	Illicit drug use (e.g., cocaine, amphetamines)
	Posttraumatic brain injury
	Perinatal insults
Older adults (>35 years)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines)
	Brain tumor
	Cerebrovascular disease (e.g., stroke, aneurysm, arteriovenous malformations)
	CNS degenerative diseases (e.g., Alzheimer disease, multiple sclerosis)
	Major depression
	Idiopathic
	Metabolic disorders (e.g., uremia, hepatic failure, electrolyte abnormalities, hypoglycemia)
	Posttraumatic brain injury

CNS, Central nervous system.

Data from Daroff RB, et al. *Bradley's neurology in clinical practice*, 7th edition. Philadelphia: Elsevier.

The threshold for seizures may be lowered by hypoglycemia; fatigue or lack of sleep; emotional or physical stress; fever; large amounts of water ingestion (hyponatremia); constipation; use of antipsychotic drugs (i.e., chlorpromazine and clozapine), especially when combined with alcohol; or hyperventilation (respiratory alkalosis). Some environmental stimuli, such as blinking lights, a poorly adjusted television screen, loud noises, certain music, certain odors, or merely being startled, have been known to initiate a seizure. Women with epilepsy may have increased seizure activity associated with menses. The patterns include perimenstrual (C1 pattern), at ovulation (C2 pattern), and during the luteal phase (C3 pattern). Patterns C1 and C3 are associated with low progesterone levels with reduced sensitivity to inhibitor neurotransmitters. Pattern C2 is associated with a surge in estrogen, but the mechanism is unknown.[59]

Types of Seizures and Epilepsies

Seizures and epilepsies can be classified in different ways, and the International League Against Epilepsy (ILAE) 2017 classification is commonly used to assist with diagnosis and treatment.[56] The

classification of seizures considers: (1) the origin of the seizure in the brain (focal or generalized onset); (2) degree of awareness during the seizure (awareness of self and environment); and (3) level of body movement (motor or nonmotor). The classification of epilepsies considers the type of seizures occurring with epilepsy and epilepsy syndromes. Details of the classification are summarized in Table 18.10.

Table 18.10

Classification of Seizures and Epilepsies

Seizure Type	Description of Seizure Event
Focal seizures (previously partial seizures)	Seizures originating in one area of the brain; an aura is common

Motor

Tonic: stiffening of body muscles with falling; loss of consciousness; can occur in sleep; more common in infants and children

Atonic: sudden, brief loss of muscle tone with falling (drop attacks); usually no loss of consciousness

Myoclonic: sudden brief shock-like jerks or twitches of the arms and/or legs; may drop things; no impairment of consciousness; frequently occurs shortly after awakening

Tonic-clonic: Abrupt loss of consciousness, body stiffening (tonic) and then shaking (clonic); may begin with sudden cry, sometimes loss of bladder control, or biting of tongue; usually lasts ~2 min, followed by a period of confusion, agitation, and fatigue; headaches and soreness are common afterward

Hyperkinetic: bimanual or bipedal motor activity such as kicking and thrashing, clapping and rubbing of both hands, hugging, sometimes with sexual automatisms and autonomic changes with or without preserved awareness

Nonmotor

Sensory: numbness, tingling or burning sensation, flashing lights, auditory experiences

Cognitive: aphasia, hallucination, memory or attention impairment

Emotional or affective: fear, agitation, anger, crying, laughing, paranoia Autonomic: blushing, pallor, increased or decreased heart rate, hyperventilation or hypoventilation, nausea	
Without loss of awareness	Recall, responsiveness, and consciousness are intact
Impaired awareness (also known as *complex focal seizure*)	Loss of consciousness or awareness; vague or dream-like state
Unknown	Unable to determine awareness or onset
Focal to bilateral tonic-clonic seizure	Begins in one part of brain (focal seizure) and spreads to both sides of brain followed by generalized tonic-clonic seizure; loss of consciousness
Generalized seizures	Seizures originating in both sides of the brain simultaneously with loss of consciousness: *Motor:* tonic-clonic, tonic, atonic, clonic, myoclonic, myoclonic-atonic, clonic-tonic-clonic (see above descriptions); *Nonmotor* (absence seizures): typical, atypical myoclonic, eyelid myoclonia
Epileptic spasms (formerly known as *infantile spasms*)	Episodes of sudden flexion or extension involving neck, trunk, and extremities; clinical manifestations range from subtle head nods to violent body contractions (jackknife seizures); onset between 3 and 12 months of age; may occur after infancy, may be idiopathic, genetic, result of metabolic disease, or in response to CNS insult; spasms occur in clusters of 5–150 times per day; EEG shows large-amplitude, chaotic, and disorganized pattern called "hypsarrhythmia"
EPILEPSY SEIZURE TYPES	Focal, generalized, combined focal and generalized, unknown
Epilepsy Syndromes (examples)	
Childhood absence epilepsy syndrome	Wide variety of abnormal activity occurring many times a day, including rhythmic eye movements, a blank stare with lack of awareness, rhythmic chewing, swimming movements; episodes last 10–20 s and end suddenly followed by normal activity. Child

	may not be aware seizure activity occurred. Seizures develop between 4 and 8 years of age and may disappear during adolescence.
Lennox-Gastaut syndrome	Epileptic syndrome with onset in early childhood, 1–5 years of age; includes various generalized seizures (tonic-clonic, atonic [drop attacks], akinetic, absence, and myoclonic); EEG has characteristic "slow spike and wave" pattern; results in intellectual disability and delayed psychomotor developments
Juvenile myoclonic epilepsy	Generalized epilepsy syndrome with onset in adolescence; multifocal myoclonus; seizures often occur early in morning, aggravated by lack of sleep or after excessive alcohol intake; occasional generalized convulsions; requires long-term medication treatment
Unclassified epileptic seizures	Etiology remains unknown; seizures do not have distinct clinical and EEG features
Pseudoseizures	Nonepileptic phenomena that look like epileptic seizures; diagnosis often requires video-EEG monitoring to capture spells, and determine that EEG is normal during clinical events; frequently occurs in setting of child abuse
Status Epilepticus	A condition resulting either from the failure of the mechanisms responsible for seizure termination or from the initiation of mechanisms which lead to abnormally prolonged seizures (more than 5 min). It is a condition that can have long-term consequences including neuronal death, neuronal injury, and alteration of neuronal networks, depending on the type and duration of seizures.

Seizure Type	Description of Seizure Event
Focal seizures (previously partial seizures)	Seizures originating in one area of the brain; an aura is common Motor Tonic: stiffening of body muscles with falling; loss of consciousness; can occur in sleep; more common in infants and children Atonic: sudden, brief loss of muscle tone with falling (drop attacks); usually no loss of consciousness Myoclonic: sudden brief shock-like jerks or twitches of the arms and/or legs; may drop things; no impairment of consciousness; frequently occurs shortly after awakening Tonic-clonic: Abrupt loss of consciousness, body stiffening (tonic) and then shaking (clonic); may begin with sudden cry, sometimes loss of bladder control, or biting of tongue; usually lasts ~2 min, followed by a period of confusion, agitation, and fatigue; headaches and soreness are common afterward Hyperkinetic: bimanual or bipedal motor activity such as kicking and thrashing, clapping and rubbing of both hands, hugging, sometimes with sexual automatisms and autonomic changes with or without preserved awareness Nonmotor Sensory: numbness, tingling or burning sensation, flashing lights, auditory experiences Cognitive: aphasia, hallucination, memory or attention impairment Emotional or affective: fear, agitation, anger, crying, laughing, paranoia Autonomic: blushing, pallor, increased or decreased heart rate, hyperventilation or hypoventilation, nausea
Without loss of awareness	Recall, responsiveness, and consciousness are intact

Data from Sarmast ST, Abdullahi AM, Jahan N. Current classification of seizures and epilepsies: Scope, limitations and recommendations for future action. *Cureus*, 2020;12(9):e10549.

Pathophysiology

Epilepsy is the result of the interaction of complex genetic mutations with environmental effects that cause abnormalities in synaptic transmission, an imbalance in the brain's excitatory and inhibitory neurotransmitters, alterations of receptors and ion channels activated by neurotransmitters,[60] or the development of abnormal nerve connections or loss of nerves after injury. The ILAE has proposed six groups for categorizing etiology of epilepsy: genetic, structural, metabolic, immune, infectious, and unknown. These categories may be interrelated and continue to be revised (Fig. 18.19).

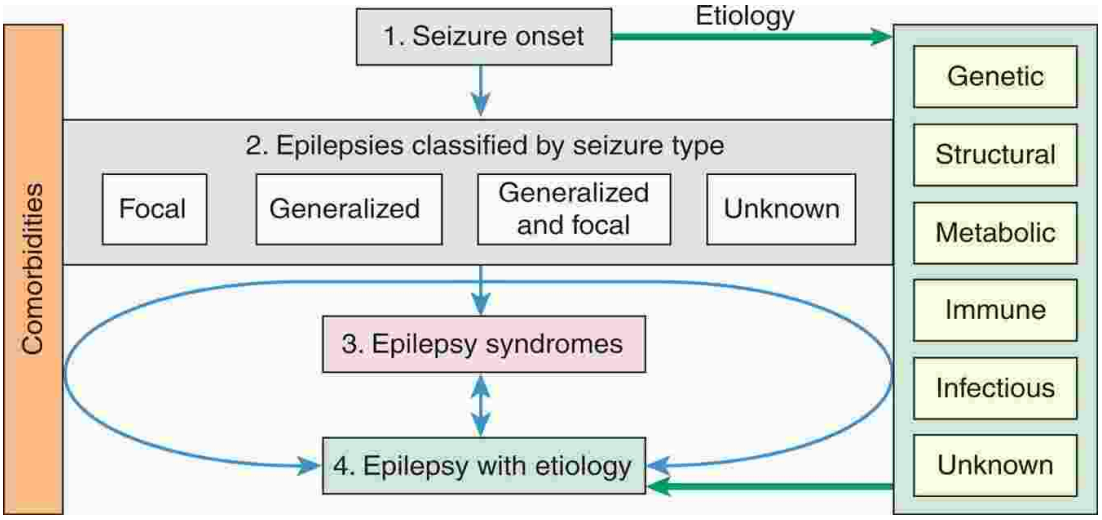

FIG. 18.19 Framework for Classification of Epilepsy. (From Scheffer IE, French J, Hirsch E, et al. Classification of the epilepsies: New concepts for discussion and debate—Special report of the ILAE Classification Task Force of the Commission for Classification and Terminology. *Epilepsia Open*, 2016;1(1–2):37–44.)

An illustration shows the framework for classification of epilepsy. The comorbidities of epilepsy are as follows. 1. Seizure onset; etiology (genetic; structural; metabolic; immune; infectious; and unknown). Leads to 2. 2. Epilepsies classified by seizure type: focal; generalized; generalized and focal; and unknown. Leads to 3 and 4. 3. Epilepsy syndromes. Leads to 4. 4. Epilepsy with etiology. Leads to 3.

A group of neurons may exhibit a paroxysmal depolarization shift and function as an **epileptogenic focus**. These neurons are hyperexcitable and are more easily activated by hyperthermia, hypoxia, hypoglycemia, hypernatremia and hyponatremia (more common), hypocalcemia, hypomagnesemia, repeated sensory stimulation, and certain sleep phases. Epileptogenic neurons fire more frequently and with greater amplitude. When the intensity reaches a threshold point, cortical excitation spreads. Excitation of the subcortical, thalamic, and brainstem areas corresponds to the **tonic phase** (muscle contraction with increased muscle tone) and is associated with loss of consciousness. The **clonic phase** (alternating contraction and relaxation of muscles) begins when inhibitory neurons in the cortex, anterior thalamus, and basal ganglia react to the cortical excitation. The seizure discharge is interrupted, producing intermittent muscle contractions that gradually decrease and finally cease. The epileptogenic neurons are exhausted.

During seizure activity, oxygen is consumed at a high rate—approximately 60% greater than normal. Although cerebral blood flow also increases, oxygen is rapidly depleted along with glucose, and lactate accumulates in brain tissue. Continued, severe seizure activity has the potential for progressive hypoxic brain injury and irreversible damage. In addition, if a seizure focus in the brain is active for a prolonged period, a **mirror focus** may develop in contralateral normal tissue and cause seizure activity, particularly with focal (i.e., temporal or frontal lobe) epilepsy.

With status epilepticus, the individual may still be in a postictal state (a state that follows an epileptic seizure and returns to baseline) when the next seizure begins. Status epilepticus most often results from abrupt discontinuation of antiseizure medications but also may occur in untreated or inadequately treated persons with seizure disorders. The situation is a medical emergency because of the resulting cerebral hypoxia. Intellectual disability, dementia, other brain damage, and even death are serious threats. There is also a high risk for aspiration to occur.

Clinical Manifestations

The phases associated with a seizure are summarized in Table 18.11. Two types of symptoms signal the **preictal phase** of a generalized tonic-clonic seizure: prodroma, early manifestations occurring hours to days before a seizure that may include anxiety, depression, or inability to think clearly; and a focal seizure or **aura** that immediately precedes the onset of a generalized tonic-clonic seizure. Both may become familiar warning signs to the person experiencing recurrent generalized seizures that may enable the person to prevent injuries during the seizure. The **ictus** is the episode of the epileptic seizure with tonic-clonic activity. Relaxation of urinary and bowel sphincters may occur, leading to bladder and bowel incontinence. Airway maintenance needs to be ensured.

Table 18.11

Terminology Used to Describe Phases of a Seizure

Term	Definition
Prodroma	Early clinical manifestations, such as malaise, headache, or a sense of depression, that may occur hours to a few days before the onset of a seizure
Aura	A focal seizure experienced as a peculiar sensation preceding the onset of a generalized seizure or complex partial seizure that may take the form of gustatory, visual, or auditory experience; a feeling of dizziness or numbness; or just "a funny feeling"
Ictus	The episode of the seizure
• Tonic phase	A state of muscle contraction in which there is excessive muscle tone
• Clonic phase	A state of alternating contraction and relaxation of muscles
Postictal state	The period immediately following the cessation of seizure activity

Term	Definition
Prodroma	Early clinical manifestations, such as malaise, headache, or a sense of depression, that may occur hours to a few days before the onset of a seizure
Aura	A focal seizure experienced as a peculiar sensation preceding the onset of a generalized seizure or complex partial seizure that may take the form of gustatory, visual, or auditory experience; a feeling of dizziness or numbness; or just "a funny feeling"
Ictus	The episode of the seizure
• Tonic phase	A state of muscle contraction in which there is excessive muscle tone
• Clonic phase	A state of alternating contraction and relaxation of muscles
Postictal state	The period immediately following the cessation of seizure activity

Status epilepticus in adults is defined as: (1) a state of continuous tonic-clonic seizures lasting more than 5 minutes, (2) rapidly recurring seizures before the person has fully regained consciousness from the preceding seizure, or (3) a single seizure lasting more than 30 minutes. It is a condition requiring prompt diagnosis and treatment because of the resulting cerebral hypoxia. Long-term consequences can include neuronal death, neuronal injury, and alteration of neuronal networks.

The **postictal state** follows an epileptic seizure and can include signs of headache, confusion, aphasia, memory loss, and paralysis that may last hours or a day or two. Deep sleep also is common. Sudden unexpected death during the postictal state is uncommon and is more prevalent with nocturnal, generalized tonic-clonic seizures and treatment failure.[61,62]

Evaluation and Treatment

A thorough health history is a critical aspect of diagnosing a seizure disorder and establishing the cause and onset. Details include subjective sensations, altered consciousness, motor signs, behavioral changes, and the environmental setting.[63] The health history is supplemented by the physical examination and laboratory tests of blood and urine (blood glucose, serum calcium, blood urea nitrogen, urine sodium, and creatinine clearance) to identify any systemic diseases known to have seizures as a clinical manifestation. Brain imaging and CSF examination are useful for identifying any neurologic diseases associated with seizures. The EEG is useful in assessing the type of seizure and may help to determine its focus. Combined EEG and functional MRI (fMRI) can be used to identify neural networks involved in epileptic activity. Differentiating a generalized epilepsy from a focal epilepsy is vital to treatment and prognosis.[64,65]

Treatment for a seizure disorder is first to correct or control its cause, if possible. If this is not possible, the primary means of management is the judicious administration of antiseizure medications to reduce neuron firing. Antiseizure drugs (e.g., diazepam, gabapentin, phenytoin) can enhance gamma-aminobutyric acid (GABA), which mediates inhibitory activity or inhibit glutamate activity by inhibiting glutamate synthesis, by blocking voltage-gated sodium channels at glutamatergic nerve terminals, or by reducing calcium conduction. The therapeutic goal is complete suppression of seizure activity without intolerable side effects of the drug or drug resistance. Dietary treatments (e.g., ketogenic diet or caloric restriction) are effective for some individuals.[66] Surgical interventions (e.g., laser ablation therapy) requires mapping of the seizure onset zone and can improve seizure control and quality of life in people with drug-resistant epilepsy.[67] Neuromodulation (e.g., vagus nerve, trigeminal nerve, or deep brain stimulation) can reduce seizure frequency in some persons with drug-resistant or surgery-resistant seizures.[68]

See Emerging Science Box: Ketogenic Diet and Seizure Management in Chapter 20.

Cerebrovascular Disorders

Cerebrovascular disease (CVD) is any abnormality of the brain caused by a pathologic process in the blood vessels. CVD is the most frequently occurring neurologic disorder and frequently requires hospitalization. Included in this category are lesions of the vessel wall (e.g., aneurysm or malformations), occlusion of the vessel lumen by thrombus or embolus, rupture of the vessel, and alteration in blood quality, such as increased blood viscosity.

The brain abnormalities induced by CVD are either (1) ischemia with or without infarction (death of brain tissues) or (2) hemorrhage. The common clinical manifestation of CVD is a cerebrovascular accident (CVA) or stroke. The symptoms occur suddenly and are focal (i.e., slurred speech, difficulty swallowing, limb weakness, or paralysis). In its mildest form, a CVA is so minimal that it is almost unnoticed. In its most severe form, hemiplegia, coma, and death result.

Cerebrovascular Accidents (Stroke Syndromes)

Cerebrovascular accidents (CVAs; stroke syndromes) are the leading cause of disability; they are the third leading cause of death in women and the fifth leading cause of death in men in the United States. Of all strokes, 87% are ischemic and 13% are hemorrhagic (intracerebral 10% and subarachnoid 3%). Approximately 25% of strokes are recurrent strokes. Although hemorrhagic strokes are less common, they account for approximately 40%

of stroke-related deaths. Approximately 75% of CVAs occur among those older than 65 years. The incidence is approximately twice as high in Black Americans than in White Americans. Smoking, hypertension, diabetes mellitus, atrial fibrillation, and prior stroke increase the risk for recurrent stroke.[69] Transient ischemic attacks (TIAs) may precede a stroke. CVAs are classified pathophysiologically as ischemic or hemorrhagic strokes. If there is no identifiable cause of an ischemic stroke, it is classified as *undetermined* or *cryptogenic*. Risk factors for stroke are summarized in Box 18.1.

Box 18.1

Risk Factors for Stroke

- Poorly controlled or uncontrolled arterial hypertension
- Smoking, which increases the risk of stroke by 2–4 times
- Insulin resistance and diabetes mellitus
- Atrial fibrillation
- Polycythemia (excess red blood cells) and thrombocythemia (excess platelets)
- High total cholesterol or low high-density lipoprotein (HDL) cholesterol, elevated lipoprotein-a

Carotid Artery Disease

- Congestive heart disease, valvular disease, peripheral vascular disease

Chronic Kidney Disease

- Hyperhomocysteinemia
- Sickle cell disease
- Postmenopausal hormone therapy
- High sodium intake >2300 mg; low potassium intake <4700 mg
- Obesity
- Obstructive sleep apnea
- Depression
- *Chlamydia pneumoniae* infection
- Physical inactivity
- Family history of ischemic stroke
- Black American
- Female

Data from: Forouzanfar MH, Alexander L, Anderson HR, et al. Global, regional, and national comparative risk assessment of 79 behavioural, environmental and occupational, and metabolic risks or clusters of risks in 188 countries, 1990–2013: A systematic analysis for the global burden of disease study 2013. *Lancet*, 2015;386:2287–2323. American Stroke Association: Stroke Risk Factors. https://www.stroke.org/en/about-stroke/stroke-risk-factors. Accessed March 4, 2022.

Transient ischemic attacks (TIAs) are episodes of neurologic dysfunction resulting from temporary arterial obstruction of brain blood flow. These episodes last less than 24 hours and do not show evidence of acute infarction on brain imaging.[70] The clinical manifestations of a TIA can include hemiparesis, numbness, sudden confusion, loss of balance, loss of vision, speech disturbances, or a sudden severe headache. Approximately 9% to 17% of individuals experiencing a TIA will have a stroke within 3 months.[71]

Acute Ischemic stroke

Acute ischemic stroke (AIS) occurs when there is sudden neurologic dysfunction caused by focal brain ischemia lasting more than 24 hours or with evidence of acute infarction on brain imaging, irrespective of symptom duration. AIS can be further divided into disabling (major) AIS and nondisabling (minor) AIS, based on the severity of presenting neurologic deficits.[70]

Thrombotic strokes (cerebral thrombosis) arise from arterial obstruction caused by thrombus formation in arteries supplying the brain or intracranial vessels. Conditions causing increased coagulation (e.g., dehydration) or inadequate cerebral perfusion (e.g., hypotension or prolonged vasoconstriction from malignant hypertension) increase the risk of thrombosis. Cerebral thrombosis develops most often from atherosclerosis and inflammatory disease processes that damage arterial walls. It may take as long as 20 to 30 years for obstruction to develop at the branches and curvatures found in the cerebral circulation (see Chapter 32 for a discussion of atherogenesis). The smooth stenotic area can degenerate, forming an ulcerated area of the vessel wall. Platelets and fibrin adhere to the damaged wall, and a clot forms, gradually occluding the artery. Thrombotic strokes also occur when parts of the clot detach, travel upstream, and obstruct blood flow, causing acute ischemia.

Embolic stroke involves fragments that break from a thrombus formed outside the brain, usually in the heart, aorta, or common carotid artery. Other sources of embolism include fat, air, tumor, bacterial clumps, and foreign bodies. The embolus usually involves small brain vessels and obstructs at a bifurcation or other point of narrowing, thus causing ischemia. An embolus may plug the lumen entirely and remain in place or shatter into fragments and become part of the vessel's blood flow. Risk factors for an embolic stroke include atrial fibrillation, left ventricular aneurysm or thrombus, left atrial thrombus, recent myocardial infarction, bacterial endocarditis, rheumatic valve disease, mechanical valvular prosthesis, atrial septal defects, patent foramen ovale, and primary intracardiac tumors. In persons who experience an embolic stroke, a recurrent stroke usually follows because the source of emboli continues to exist. Embolization is usually in the distribution of the middle cerebral artery (see Fig. 15.20). Ischemic strokes in children are associated with congenital heart disease, cerebral arteriovenous malformations (AVMs), and sickle cell disease (see Chapter 20).

Lacunar strokes (lacunar infarcts or small vessel disease) are usually caused by occlusion of a single, deep perforating artery that supplies a small penetrating subcortical vessel, causing ischemic lesions (0.5 to 15 mm) or lacunes deep in the brain (i.e., thalamus or basal ganglia) but not in the cortex. They account for approximately 25% of ischemic strokes, with a 20% recurrence rate, and are associated with cerebral small vessel disease and untreated hypertension. The small area of brain infarction is called a *lacune*. Because of the location and small area of infarction, they may manifest as pure motor or sensory deficits. They may also be silent and are found in approximately 20% to50% of older adults.[72]

Hypoperfusion, or **hemodynamic stroke**, is associated with *systemic* hypoperfusion caused by cardiac failure, pulmonary embolism, or bleeding that results in inadequate blood supply

to the brain. Stroke may occur more readily if there is carotid artery occlusion. Symptoms are usually bilateral and diffuse.

Pathophysiology

Cerebral infarction results when an area of the brain loses its blood supply because of vascular occlusion. Causes include (1) acute vascular occlusion (e.g., embolus or thrombi), (2) gradual vessel occlusion (e.g., atheroma), and (3) partial occlusion of stenotic vessels. Cerebral thrombi and cerebral emboli most commonly produce occlusion, but atherosclerosis and hypertension are the dominant underlying processes.

There is a central core of irreversible ischemia and necrosis within a cerebral infarction. The central core is surrounded by a zone or rim of borderline hypoxic tissue known as the **penumbra** or **ischemic penumbra**. Hypoxia in the penumbra is not severe enough to result in structural damage. Prompt restoration of perfusion in the penumbra by injection of thrombolytic agents promotes perfusion and may prevent necrosis and loss of neurologic function. The window of opportunity for protecting the penumbra is approximately 3 hours.

Cerebral infarctions are ischemic or hemorrhagic. In *ischemic infarcts*, the affected area becomes pale and softens 6 to 12 hours after the occlusion. Necrosis, swelling around the insult, and mushy disintegration appear by 48 to 72 hours after infarction. There is infiltration of macrophages and phagocytosis of necrotic tissue. The necrosis resolves by approximately the second week, ultimately leaving a cavity surrounded by glial scarring.

Hemorrhagic transformation of an ischemic stroke is bleeding that occurs into the infarcted area through leaking vessels. Hemorrhagic transformation may be exacerbated by thrombolytic therapy and occurs more commonly with massive ischemic infarction. Unfortunately, reperfusion can compromise recovery by accelerating the sequence of secondary metabolically damaging events, including release of calcium, neuroexcitation (release of glutamate), inflammation, and oxidative stress (reperfusion injury) (see Chapter 2).

Clinical Manifestations

Clinical manifestations of thrombotic and embolic stroke vary, depending on the artery obstructed. Different sites of obstruction create different occlusion syndromes and are summarized in Table 18.12. Contralateral sensory and motor manifestations occur on the opposite side of the body from the location of the brain lesion because motor tracts originate in the cortex and most cross over in the medulla. Sensory tracts originate in the periphery and cross over in the spinal cord. Ipsilateral manifestations occur on the same side as the brain lesion but are rare in stroke syndromes.

Table 18.12

Signs and Symptoms of Stroke Involving Major Cerebral Vessels

Cerebral Vessel	Signs and Symptoms
Anterior cerebral artery (ACA)	Contralateral leg more than arm weakness (hemiparesis) and minimal numbness; akinetic mutism (inability to move or speak) and incontinence if bilateral vessel involvement; acute confusional state if nondominant hemisphere
Middle cerebral artery (MCA)	Contralateral upper limb more than leg weakness (hemiparesis) and numbness, ipsilateral hemianopsia and aphasia if stroke in dominant hemisphere
Posterior cerebral artery (PCA)	Contralateral weakness and dizziness, hemianopsia and ataxia, alexia without agraphia (can write but not read), altered memory, visual agnosia, cortical blindness with bilateral hemisphere involvement.
Basilar artery	Difficulty breathing, ataxia (impaired balance and coordination), tremor, diplopia, nystagmus (involuntary, rapid eye movement), dysphagia, dysarthria, vomiting, amnesia, coma
Cerebellar artery	Ataxia, vertigo, headache, nausea and vomiting, slurred speech.

Data from Micieli A, Joundi R, Khosravani H, et al. Stroke syndromes: The code Stroke Handbook. In Micieli A, Joundi R, Gladstone DF, eds. *Approach to the acute stroke patient*. London: Academic Press; 2020.

Evaluation and Treatment

Diagnosis and treatment should be done as soon as possible. Time of the initiating event and medical and medication history, particularly anticoagulants, can guide therapy. Imaging is critical to diagnose stroke, to exclude hemorrhage or large established infarcts, and to identify potentially treatable large vessel occlusion. Treatment of ischemic stroke is focused on (1) restoring brain perfusion in a time frame that does not contribute to reperfusion injury, (2) counteracting ischemic pathways, (3) lowering cerebral metabolic demand so that the susceptible brain tissue is protected against impaired perfusion, (4) preventing recurrent ischemic events, and (5) promoting tissue restoration. Intravenous reperfusion therapy using tissue-type plasminogen activator (tPA) is given within 3 and up to 4.5 hours of onset of symptoms. Other strategies include endovascular intra-arterial thrombolysis, thrombectomy, and placement of removable stents. Guidelines are available for the early management of AIS.[73,74]

Supportive management is given to control cerebral edema and IICP and to provide neuroprotection. Arresting the disease process and preventing recurrent stroke by control of risk factors is critical, and antiplatelet therapy may be instituted. Guidelines are available for the prevention of stroke risk in women.[75] Rehabilitation is indicated for ischemic strokes, and recovery of function is often possible. Neuroprotective and neuroregenerative strategies are under investigation.[76–79]

Hemorrhagic stroke occurs within the brain tissue. Spontaneous hemorrhages can occur in intracerebral locations or in the subarachnoid or subdural spaces.

The primary cause of intracerebral hemorrhagic stroke is chronic hypertension. Other causes include amyloid angiopathy (accumulation of β amyloid in walls of leptomeningeal vessels and cortical capillaries in the brain), tumors, coagulation disorders, trauma, or illicit drug use, particularly cocaine. Hypertensive causes of hemorrhagic stroke involve primarily smaller arteries and arterioles that have been damaged by chronic hypertension. Microaneurysms in these smaller vessels may precipitate the bleeding. Prevention or control of hypertension reduces the incidence of hemorrhagic stroke.

Subarachnoid hemorrhage (hematoma) (SAH) is associated with ruptured aneurysms, AVMs, or brain trauma. *Subdural hemorrhage* (hematoma) is usually associated with brain trauma (see the Traumatic Brain Injury section).

Pathophysiology

Brain damage occurring with hemorrhagic stroke is categorized into primary and secondary brain injury. Primary injury is the result of blood vessel rupture and the mass effect of bleeding into the brain tissue and hematoma formation. The most common sites for hypertensive hemorrhages are in the deeper parts of the brain: the basal ganglia, thalamus, pons, and caudate nucleus. Adjacent brain tissue is deformed, compressed, and displaced. This causes ischemia, edema, IICP, and necrosis. The expanding mass effect can cause brain stem herniation. Rupture or seepage of blood into the ventricular system often occurs, and hydrocephalus can develop due to microscopic blood obstruction of the CSF outflow tracts at the arachnoid granulations and adhesion formation within the ventricles.[80] Maximal cerebral edema develops in approximately 72 hours and takes approximately 2 weeks to subside. Secondary injury is the cascade of cellular and molecular changes initiated by the primary injury. Complement releases membrane attack complex, promoting edema and red blood cell lysis. Activation of microglia/macrophages and leukocyte infiltration stimulates release of inflammatory cytokines and an inflammatory reaction in surrounding brain tissue that appears rapidly and peaks in several days. Oxidative stress and excitotoxicity contribute to cell injury and death. Blood components including thrombin and iron from hemoglobin breakdown products also promote secondary injury (Fig. 18.20).[81] Most persons survive an initial ischemic stroke unless there is massive cerebral edema, which is nearly always fatal. The cerebral hemorrhage resolves through reabsorption. Macrophages and astrocytes clear blood from the area and a cavity forms, surrounded by a dense scar after reabsorption of the blood.

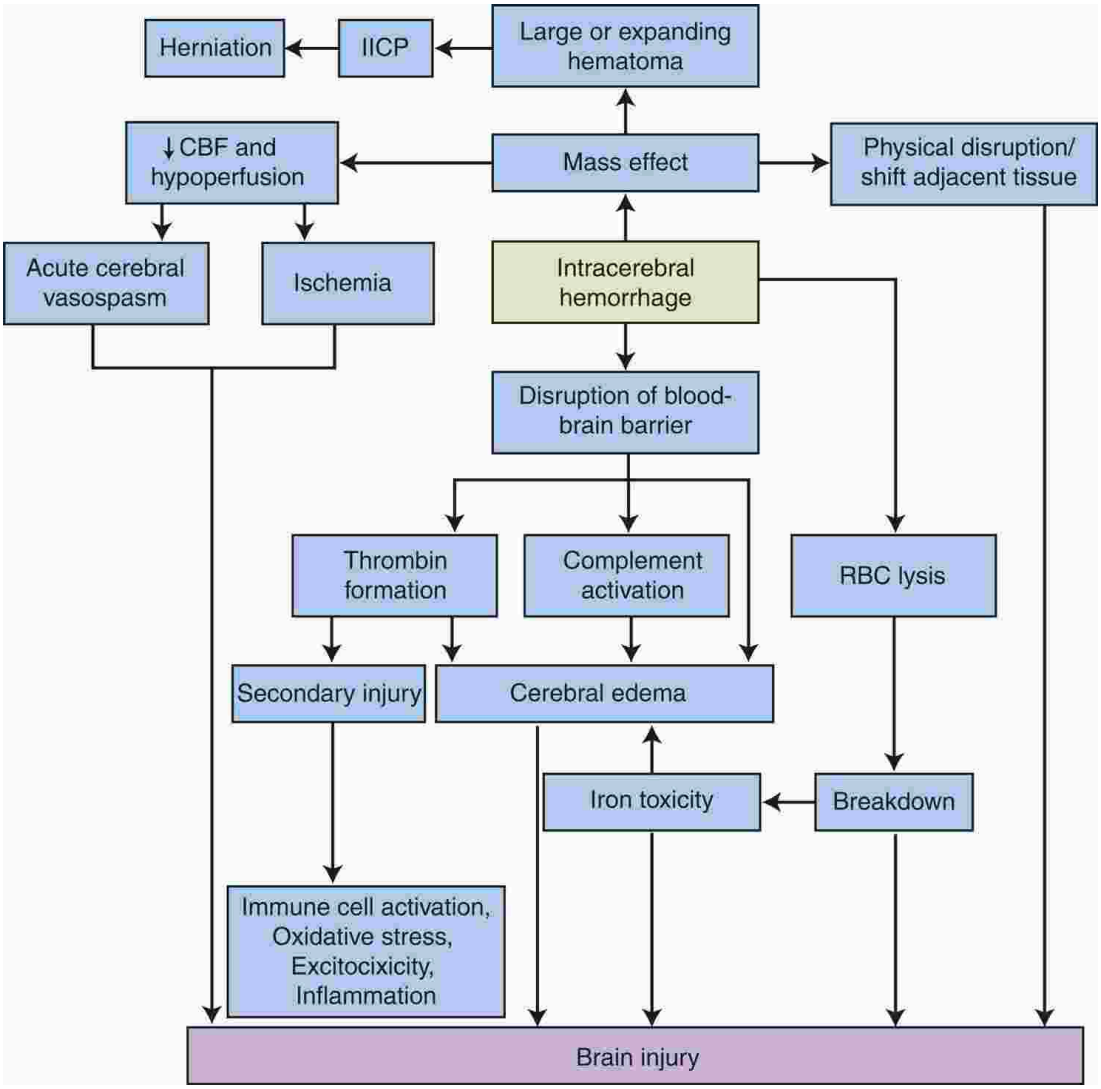

FIG. 18.20 Injury Mechanisms Promoted by Intracerebral Hemorrhage. Hemorrhages can induce neuronal injury through mass effect, particularly in large hematomas that can cause increased intracranial pressure and herniation. Hemorrhages may also cause tissue damage through cerebral edema and secondary "neurotoxic" mechanisms caused by activation of the coagulation cascade, complement, microglia, oxidative stress, neurotoxicity, and inflammation. Not all potential interactions are shown (e.g., thrombin may potentiate iron-induced injury; the complement and inflammatory systems overlap; and several factors contribute to cerebral edema). *CBF*, Cerebral blood flow; *IICP*, increased intracranial pressure; *RBC*, red blood cell. (Data from Dasari R, Bonsack F, Sukumari-Ramesh S. Brain injury and repair after intracerebral hemorrhage: The role of microglia and brain-infiltrating macrophages. *Neurochemistry International*, 2021;142:104923; O'Carroll CB, Brown BL, Freeman WD. Intracerebral hemorrhage: A common yet disproportionately deadly stroke subtype. *Mayo Clinic Proceedings*, 2021;96(6):1639–1654.)

An illustration of the superior view of the brain with the anterior side at the top identifies the locations of intracranial hemorrhages, clockwise from the top: subarachnoid hemorrhage, subdural hemorrhage, deep intracerebral hemorrhage, extradural hemorrhage, intraventricular hemorrhage, and lobar intracerebral hemorrhage.

Clinical Manifestations

The clinical manifestations of hemorrhagic stroke are similar to those for ischemic stroke and depend on the location and size of the bleeding. Symptoms can occur suddenly and with activity. Once a deep unresponsive state occurs, the person rarely survives. The immediate prognosis is grave; however, if the person survives, recovery of function is often possible.

It is difficult to differentiate ischemic from hemorrhagic stroke based on symptoms. Individuals experiencing intracranial hemorrhage from a ruptured or leaking aneurysm have one of three sets of symptoms: (1) onset of an excruciating generalized headache with an almost immediate lapse into an unresponsive state; (2) headache but with consciousness maintained and there may be seizures, nausea, and vomiting; and (3) sudden lapse into unconsciousness. If the hemorrhage is confined to the subarachnoid space, there may be no local signs. If bleeding spreads into the brain tissue, hemiparesis/paralysis, dysphasia, or homonymous hemianopia (visual field loss on the same side of both eyes) may be present. Warning signs of an impending aneurysm rupture include headache, transient unilateral weakness, transient numbness and tingling, and transient speech disturbance. However, such warning signs are often absent.

Evaluation and Treatment

Diagnosis of hemorrhagic stroke considers the health history, clinical presentation, laboratory tests, and neuroimaging procedures (CT and MRI). Treatment needs to be initiated within 3 to 4 hours of symptom onset for reversibility of brain ischemia. Treatment of intracranial bleeding, regardless of the cause, focuses on stopping or reducing the bleeding; controlling blood pressure, edema, and IICP; preventing rebleeding; and preventing vasospasm. Surgical treatments, including endovascular approaches, are options for ruptured aneurysms, vascular malformations, and SAH. New minimally invasive surgical techniques for intracranial hematoma evacuation have been developed.[82] Clinical guidelines for the management of spontaneous ICH have been published by the American Heart Association/American Stroke Association.[83] Efforts are in progress to control the mass effects of the hematoma and to suppress secondary cell injury.[84] Care in multidisciplinary stroke rehabilitation units with effective interprofessional communication appears to be most effective at reducing disability, dependency, and length of hospital stay for all stroke syndromes.[85–87]

Intracranial aneurysm

An **intracranial aneurysm** is a dilation or ballooning of an arterial vessel from a weakness in the vessel wall. Risk factors include arteriosclerosis, congenital abnormality, cocaine use, trauma, cigarette smoking, or family history. The size may vary from 2 mm to 2 or 3 cm. Most aneurysms are located at bifurcations in or near the circle of Willis, in the vertebrobasilar

arteries, or within the carotid system, where there is higher wall shear stress (frictional force of blood against the endothelium of a blood vessel) and flow turbulence (see Fig. 18.20). Aneurysms may be single, but, in some instances, more than one is present. In these instances, the aneurysms may be unilateral or bilateral. The peak incidence of rupture occurs in persons 50 to 59 years of age, with the incidence in postmenopausal women slightly higher than that in men.

Pathophysiology

No single pathologic mechanism exists. Aneurysm development is attributed to hemodynamic and wall shear stress and flow turbulence, particularly at bifurcations, such as in or near the circle of Willis, in the vertebrobasilar arteries, or within the carotid artery system (see Fig. 18.20). They are a symptom of underlying hemodynamic stress, and inflammation leads to loss of vessel wall integrity. Hypertension and certain connective tissue disorders in which there are abnormalities in the extracellular matrix exacerbate aneurysm formation.[88] Aneurysms rupture through thin areas of blood vessels, often at bifurcation sites. There is hemorrhage into the subarachnoid space that spreads rapidly, producing localized changes in the cerebral cortex and focal irritation of nerves and arteries. Bleeding ceases when a fibrin-platelet plug forms at the point of rupture and as a result of compression. Blood undergoes reabsorption through arachnoid villi, usually within 3 weeks.

Aneurysms may be classified on the basis of their shape. *Saccular aneurysms (berry aneurysms)* are the most common (in approximately 2% of the population) and can result from congenital abnormalities in the tunica media (middle layer) of the arterial wall and wall weakening related to atherosclerosis and hypertension. The sac gradually grows over time. A saccular aneurysm may be (1) round with a narrow stalk connecting it to the parent artery, (2) broad-based without a stalk, or (3) cylindrical (Figs. 18.21 and 18.22). The highest incidence of rupturing or bleeding (SAH) is among persons 20 to 50 years of age.

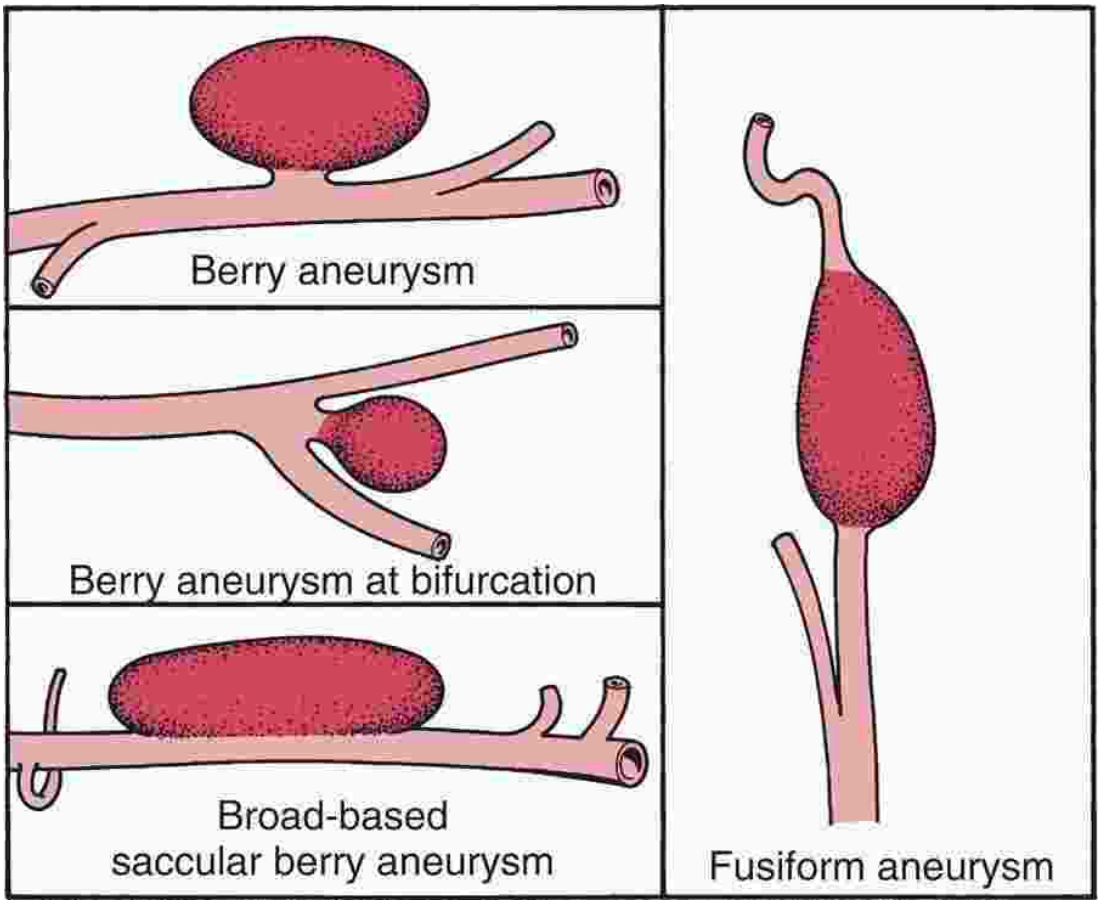

FIG. 18.21 Types of Aneurysms.

A flowchart shows the injury mechanisms promoted by intracerebral hemorrhage. 1. Intracerebral hemorrhage. Leads to 2, 5, and 6. 2. Disruption of blood-brain barrier. Leads to 3, 4, and 8. 3. Thrombin formation. Leads to 7 and 8. 4. Complement activation. Leads to 8. 5. R B C lysis. Leads to 11. 6. Mass effect. Leads to 12, 15, and 16. 7. Secondary injury. Leads to 9. 8. Cerebral edema. Leads to 19. 9. Immune cell activation; oxidative stress; excitotoxicity; and inflammation. 10. Iron toxicity. Leads to 8 and 19. 11. Breakdown. Leads to 10 and 19. 12. Decreased C B F and hypoperfusion. Leads to 13 and 14. 13. Acute cerebral vasospasm. Leads to 19. 14. Ischemia. Leads to 19. 15. Physical disruption or shift adjacent tissue. Leads to 19. 16. Large or expanding hematoma. Leads to 17. 17. I I C P. Leads to 18. 18. Herniation. 19. Brain injury.

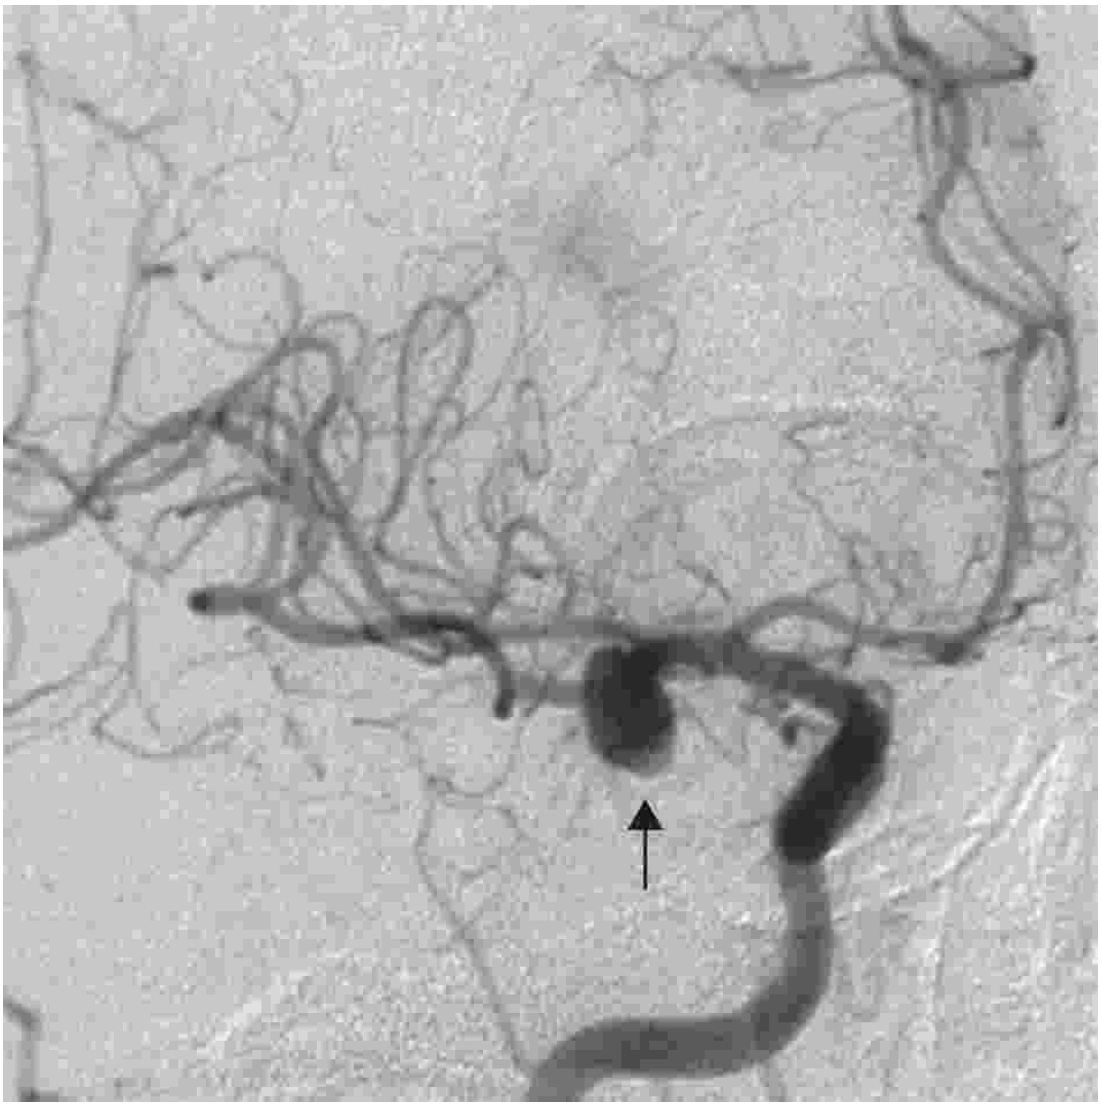

FIG. 18.22 Angiogram of a Berry Aneurysm. In this contrast-enhanced lateral view, a portion of the cerebral arterial circulation can be seen as a berry aneurysm *(arrow)* involving the middle cerebral artery of the circle of Willis at the base of the brain. (From Klatt EC. *Robbins and Cotran atlas of pathology*, 3rd edition. Philadelphia: Saunders, 2015.)

Four illustrations show different types of aneurysms. Top-left panel, berry aneurysm. The illustration shows a large bulge on the main blood vessel. Middle-left panel, berry aneurysm at bifurcation. The illustration shows a large bulge at the junction of the branching blood vessel. Bottom-left panel, broad-based saccular beery aneurysm. The illustration shows a wide bulge on the main blood vessel. Right panel,

fusiform aneurysm. The illustration shows a long bulge along the length of the main blood vessel.

Fusiform aneurysms (giant aneurysms) are less common, occur as a result of diffuse arteriosclerotic changes, and are found most commonly in the basilar arteries or terminal portions of the internal carotid arteries (see Fig. 18.21). They act as space-occupying lesions.

Clinical Manifestations

Aneurysms often are asymptomatic, and their presence is unknown until discovered incidentally or at autopsy. Clinical manifestations include sudden severe headache or dizziness and cranial nerve compression, but the signs vary, depending on the location and size of the aneurysm. Cranial nerves III, IV, V, and VI (see Table 15.6) are affected most often. Unfortunately, the most common first indication of the presence of an aneurysm is an acute SAH, ICH, or combined SAH-ICH.

Evaluation and Treatment

Diagnosis before a bleeding episode is made through arteriography. Intracranial aneurysms may be found incidentally during CT or MRI imaging for other conditions. After a subarachnoid or ICH, a tentative diagnosis of an aneurysm is based on clinical manifestations, history, and imaging. Treatments for intracranial aneurysm are individualized, and there are both medical (e.g., control of hypertension and vasospasm) and surgical (e.g., placement of endovascular coils) options. Modifiable risk factors include smoking, alcohol use, and hypertension.[88,89]

Subarachnoid hemorrhage

Subarachnoid hemorrhage (SAH) is the escape of blood from a defective or injured vessel into the subarachnoid space (Fig. 18.23). Individuals at risk for an SAH are those with intracranial aneurysm, intracranial AVM (see the next section), hypertension, and a family history of SAH and those who have sustained head injuries. SAHs often recur, especially from a ruptured intracranial aneurysm. SAH is associated with approximately 2% to 7% of all strokes and 85% of ruptured intracranial aneurysms.[90]

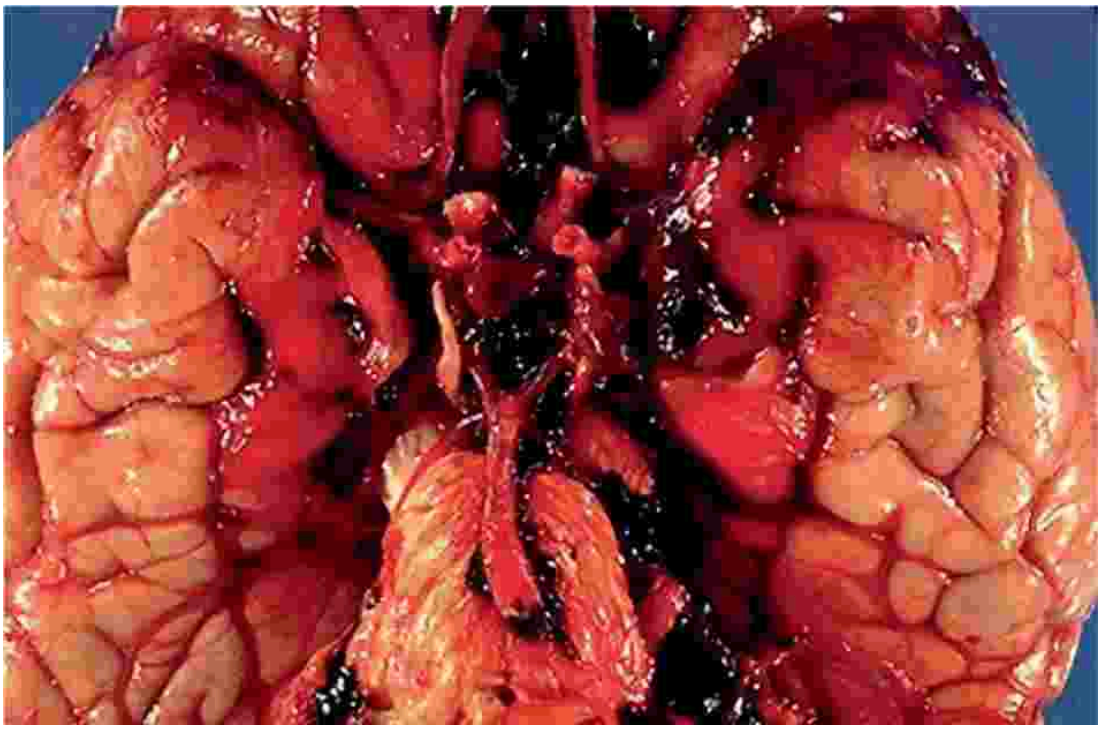

FIG. 18.23 Subarachnoid Hemorrhage, Gross.
Subarachnoid hemorrhage resulting from rupture of a berry aneurysm.
(From Klatt EC. *Robbins and Cotran atlas of pathology*, 3rd edition. Philadelphia: Saunders; 2015.)

Pathophysiology

When a vessel is leaking, blood oozes into the subarachnoid space. When a vessel tears, blood under pressure is pumped into the subarachnoid space. Autoregulation of blood flow is impaired, and there is a compensatory increase in systolic blood pressure. The expanding hematoma acts like a space-occupying lesion and expands intracranial volume. There is compression and displacement of brain tissue with IICP, decreased perfusion pressure and cerebral blood flow, blood-brain barrier breakdown, brain edema, inflammation, and cell death. Secondary brain injury can occur as described for TBI and hemorrhagic stroke. In addition, the escaped blood coats nerve roots, clogs arachnoid granulations impairing CSF reabsorption, and obstructs foramina (passages) within the ventricular system impairing CSF circulation. Ultimately, granulation tissue is formed. There may be meningeal scarring with impairment of CSF reabsorption and secondary hydrocephalus. Mortality in SAH is approximately 50% at 1 month.

Delayed cerebral ischemia is a syndrome of progressive neurologic deterioration (i.e., development of hemiparesis or aphasia) associated with cerebral artery vasospasm and decreased perfusion. It occurs in 3 to 14 days after an SAH in approximately 50% of cases and is a significant cause of morbidity and mortality. The mechanism of vasospasm is not completely understood. Proposed mechanism includes microthrombi formation from endothelial damage, the loss of autoregulation of blood flow, cortical spreading depolarization, nitric oxide (a vasodilator) deficiency, increased endothelin-1 (a vasoconstrictor), inflammation-mediated oxidative stress with damage to smooth muscle,

and upregulation of apoptotic pathways. Vasospasm with microthrombosis causes decreased cerebral perfusion with extension of ischemic injury and increased risk of death. It is difficult to manage, and there are serious side effects of various preventive and treatment options. New diagnostic and treatment strategies are emerging.[88,91]

Clinical Manifestations

Early manifestations associated with leaking vessels are episodic and include headache, changes in mental status or level of consciousness, nausea or vomiting, and focal neurologic defects (weakness or paralysis, loss of sensation, aphasia). A ruptured vessel causes a sudden, throbbing, "explosive" headache that develops in seconds, accompanied by nausea and vomiting, visual disturbances, motor deficits, and loss of consciousness related to a dramatic rise in ICP. Meningeal irritation and inflammation often occur, causing neck stiffness (nuchal rigidity), photophobia, blurred vision, irritability, restlessness, and low-grade fever.[92] A positive **Kernig sign** (straightening the knee with the hip and knee in a flexed position produces pain in the back and neck regions) and a positive **Brudzinski sign** (passive flexion of the neck produces neck pain and increased rigidity) may appear. No localizing signs are present if the bleeding is confined completely to the subarachnoid space. However, they may develop if there is delayed cerebral ischemia.

The Hunt and Hess SAH grading system is commonly used and is based on the description of the clinical manifestations (Table 18.13).[93] Rebleeding is a significant risk with a high mortality (up to 70%). The period of greatest risk is during the first 72 hours and up to 2 weeks after the initial episode of bleeding. Rebleeding is manifested by a sudden increase in blood pressure and ICP, along with a deteriorating neurologic status.

Table 18.13

Subarachnoid Hemorrhage Classification Scale

Category	Description
Grade I	Neurologic status intact; mild headache, slight nuchal rigidity
Grade II	Neurologic deficit evidenced by cranial nerve involvement; moderate to severe headache with more pronounced meningeal signs (e.g., photophobia, nuchal rigidity)
Grade III	Drowsiness and confusion with or without focal neurologic deficits; pronounced meningeal signs
Grade IV	Stuporous with pronounced neurologic deficits (e.g., hemiparesis, dysphasia); nuchal rigidity
Grade V	Deep coma state with decerebrate posturing and other brainstem functioning

From Tateshima S, Duckwiler G. Vascular diseases of the nervous system. In Daroff RB, et al, eds. *Bradley's neurology in clinical practice*. Philadelphia: Saunders; 2012.

Seizures occur in 25% of persons with an SAH, and hydrocephalus after a bleeding episode occurs in 20% of cases. Hypothalamic dysfunction, manifested by salt wasting, hyponatremia, and electrocardiograph (ECG) changes, is common.

Evaluation and Treatment

Aneurysmal SAH is a neurologic emergency. The diagnosis of an SAH is based on the clinical presentation, imaging, and cerebrospinal fluid evaluation. Treatment is directed at controlling systemic blood pressure, ICP, vasospasm, fluid volume; improving cerebral perfusion pressure; preventing ischemia and hypoxia of neural tissues; and avoiding rebleeding episodes. Surgical intervention is common.[88]

Vascular malformation

Vascular malformations are rare congenital vascular lesions. An **arteriovenous malformation (AVM)** is a mass of dilated vessels between the arterial and venous systems (arteriovenous fistula) that lacks a muscularis layer and an intervening capillary bed. AVMs may occur in any part of the brain and vary in size from a few millimeters to large malformations. They occur equally in males and females and, occasionally, in families. Although AVMs are usually present at birth, symptoms exhibit a delayed age of onset and commonly occur before 30 years of age.

Pathophysiology

AVMs have abnormal blood vessel structure with abnormally thin walls. There is direct shunting of arterial blood into the venous vasculature without the dissipation of the arterial blood pressure. One or several arteries may feed the AVM. Over time, they become tortuous and dilated, with an increased risk for rupture. With moderate to large AVMs, sufficient blood is shunted into the malformation to deprive surrounding tissue of adequate blood perfusion.

Clinical Manifestations

Twenty percent of persons with an AVM have a characteristic chronic, nondescript headache, although some experience migraine. Approximately 50% of persons experience seizures. The other 50% experience an ICH, SAH, or subdural hemorrhage with progressive neurologic deficits. Bleeding from an AVM into the subarachnoid space causes symptoms identical to those associated with a ruptured aneurysm. If bleeding occurs in the brain tissue, focal signs that develop resemble a stroke that is progressing in severity. Ten percent of persons experience hemiparesis or other focal signs. At times, noncommunicating hydrocephalus (see Chapter 17) develops with a large AVM that extends into the ventricular lining. Some AVMs never cause symptoms.

Evaluation and Treatment

A systolic bruit over the carotid artery in the neck, the mastoid process, or the eyeball in a young person is almost always diagnostic of an AVM. Confirming diagnosis is made by imaging. There is no established medical therapy. Treatment options include evaluation of risk factors, continuing observation with follow-up imaging, direct surgical excision, endovascular embolization, or stereotactic radiosurgery.[94,95]

Primary Headache Syndromes

Headache is a common neurologic disorder and is usually a benign symptom. However, it can be associated with serious disease, such as brain tumor, meningitis, or CVD. The headache syndromes discussed here are the chronic, recurring type not associated with structural abnormalities, systemic disease, or trauma and include migraine, cluster, and

tension headaches. Characteristics of the major types of headache syndromes are summarized in Table 18.14.

Table 18.14

Characteristics of Common Headaches

	MIGRAINE		Cluster Headache/ Proximal Hemicrania	Tension-Type Headache
	Without Aura	**With Aura (25%–30%)**		
Age of onset	Childhood, adolescence, or young adulthood	Childhood, adolescence, or young adulthood	Young adulthood, middle age	Young adulthood, middle age

Migraine

Migraine is an episodic or chronic neurologic disorder. Migraine is broadly classified as (1) *migraine with aura* with visual, sensory, or motor symptoms, (2) *migraine without aura* (most common), and (3) *chronic migraine*. Migraine is diagnosed using the International Headache Society diagnostic criteria: at least five attacks of a headache lasting 4 to 72 hours with at least two of the following four characteristics (1) unilateral location, (2) pulsating quality, (3) moderate or severe pain intensity, and (4) aggravation by or causing avoidance of routine physical activity; during headache at least one of the following: (1) nausea and/or vomiting, (2) photophobia and phonophobia; and not accounted for by another headache diagnosis.[96] Migraine occurs in 18% of women, 6% of men, and 10% of children in the United States. It is more common in those 18 to 44 years of age. There often is a family history of migraine.[97] In susceptible women, migraine occurs most frequently before and during menstruation. The cyclic withdrawal of estrogen and fluctuating levels of estrogen are associated with migraine.[98]

Migraine is caused by a combination of multiple genetic and environmental factors. Migraine may be precipitated by triggers that decrease the threshold for a migraine. Triggers can be genetic or associated with fatigue, oversleeping, missed meals, overexertion, weather change, stress or relaxation from stress, hormonal changes (menstrual periods), excess afferent stimulation (bright lights, strong smells), and chemicals (alcohol or nitrates).[99]

PathophysiologyThe pathophysiologic basis for migraine is complex and not clearly established. There is no identifiable pathology, but there is activation of the trigeminovascular system and associated changes in brain metabolism and blood flow. Current theories include neurologic, vascular, hormonal, and neurotransmitter components. Migraine aura is associated with cortical spreading depression (CSD). CSD is a spontaneous self-propagating wave of glial and neuronal depolarization, starting in the occipital region and spreading across the cortex, resulting in hyperactivity. CSD initiates the release of excitatory neurotransmitters that activate the trigeminal vascular system (afferent projections from cranial nerve V), stimulating vasodilation of dural blood vessels, activation of inflammation, peripheral and central sensitization of pain receptors (hypersensitivity to pain), and activation of areas of the brainstem and forebrain that modulate pain and

prodromal symptoms. Release of inflammatory mediators with sterile meningeal inflammation, edema of blood vessels, and release of neurotransmitters may be important components of migraine pain. Clinical ManifestationsThe clinical phases of a migraine attack are as follows:[100]

1. *Premonitory phase:* Up to one-third of persons have premonitory symptoms hours to days before the onset of the aura or headache. These symptoms may include fatigue, irritability, loss of concentration, stiff neck, and food cravings. There is increased blood flow to the hypothalamic region of the brain.
2. *Migraine aura:* Up to one-third of persons have aura symptoms at least some of the time that may last up to 1 hour. Symptoms can be visual, sensory, or motor and may be associated with CSD.
3. *Headache phase:* Throbbing pain usually begins on one side and spreads to include the entire head. Headache may be accompanied by fatigue, nausea, and vomiting or dizziness. There may be hypersensitivity to anything touching the head. There is activation of the trigeminovascular system and release of inflammatory mediators (e.g., calcitonin gene-related peptide [CGRP], substance P, vasoinhibitory peptide, and pituitary adenylate cyclase-activating polypeptide [PACAP]) with meningeal inflammation, vasodilation, and pain. The inflammatory mediators are targets for emerging treatments.[101] Symptoms may last from 4 to 72 hours (usually about a day).
4. *Recovery (postdrome) phase:* Irritability, fatigue, or depression may take hours or days to resolve. The recovery phase may be associated with continued activation of the brain stem.

Evaluation and TreatmentThe diagnosis of migraine is made from the medical history and physical examination. The differential diagnosis is confirmed by imaging and EEG. The management of migraine includes avoidance of triggers (e.g., darkening the room, applying ice). Sleeping can provide some relief with the onset of acute migraine. Pharmacologic management for the treatment and prevention of migraine is available, including 5-hydroxytryptamine agonists, triptans, and CGRP antagonists. Treatment guidelines are available.[102,103] Several neuromodulation therapies are available for the prevention and treatment of migraine.[104,105]

Chronic migraines usually begin as episodic migraines that increase in frequency over time. Chronic migraine occurs at least 15 days in a month (can occur daily or on a near-daily basis) for more than 3 months.[96] Chronic migraines are associated with overuse of analgesic migraine medications (sometimes called *rebound headaches*), obesity, and caffeine overuse. Treatment is similar to that for episodic migraine, and onabotulinumtoxin A is an effective treatment for chronic migraine.[106]

Cluster Headache

Cluster headaches are one of a group of disorders referred to as *trigeminal autonomic cephalalgias* (headaches involving the autonomic division of the trigeminal nerve). They occur in one side of the head (proximal hemicranias) primarily in men between 20 and 50 years of age. The headache attack usually begins without warning. The pain may alternate sides with each headache episode and is severe, stabbing, and throbbing. These uncommon headaches occur in clusters (up to 8 attacks per day) and last for minutes to hours for a period of days, followed by a long period of spontaneous remission. Cluster headache has an episodic and a

chronic form with extreme pain intensity and short duration. If the cluster of attacks occurs more frequently without sustained spontaneous remission, the condition is classified as *chronic cluster headaches* (10% to 20% of cases) (see Table 18.14). Triggers include caffeine, alcohol, and smoking.

Pathophysiology and Clinical ManifestationsThe trigeminovascular system is activated with release of pain-producing vasoactive peptides and neuroinflammation similar to migraine. Trigeminal-autonomic reflex activation occurs, characterized by sympathetic underactivity and parasympathetic activation. There is unilateral trigeminal distribution of severe pain with ipsilateral autonomic manifestations, including tearing and ptosis of the eye on the affected side, and congestion of the nasal mucosa. Pain often is referred to the midface and teeth. Because of the circadian and rhythmic cycles of headache attacks, hypothalamic dysfunction may be an associated factor.[107]

TreatmentProphylactic drugs (e.g., verapamil, lithium, melatonin, and topiramate) are used to treat cluster headache, and avoidance of triggers also is important. (See Emerging Science Box: Melatonin and the Central Nervous System.) Acute attacks are managed with oxygen inhalation and sumatriptan. New treatments are under investigation.[108]

Tension-Type Headache

Tension-type headache (TTH) is the most common type of recurrent primary headache. The average age of onset is during the second decade of life. Anxiety and depression are common comorbidities. Individuals with migraine headaches frequently have TTH. The headaches are bilateral and mild with a sensation of a tight band or pressure around the head with gradual onset of pain. *Episodic TTH* occurs less than 15 days per month and may last for several hours or several days. It is not aggravated by physical activity and may be triggered by sleep disorders (insomnia). *Chronic TTH* (CTTH) evolves from episodic TTH and represents a headache that occurs at least 15 days per month for at least 3 months.

PathophysiologyBoth central and peripheral mechanisms operate in causing tension headache. It is not a vascular headache. The peripheral sensitization of myofascial nociceptors may contribute to muscular hypersensitivity and the development of episodic TTH. Pericranial muscle tenderness may develop from the activation of peripheral nociceptors around the blood vessels in striated muscle, tendon insertions, and fascia. A myofascial trigger point is associated with CTTH and is a hyperirritable point associated with a taut band of skeletal muscle that is painful on compression and

Emerging Science BoxMelatonin and the Central Nervous System

Melatonin is a hormone synthesized and secreted primarily at night by the pineal gland and other tissues, including the retina, immune cells, and gastrointestinal tract, and is found in most other organs. The rhythm of pineal secretion is generated by the suprachiasmatic nuclei (SCN) of the hypothalamus and entrained (a pattern or rhythm) to the dark phase of the light/dark cycle; dark stimulates secretion, and light inhibits secretion. The extrapineal sources of melatonin have less of an effect on the rhythm functions of melatonin. Melatonin is synthesized from tryptophan taken up from the circulation and transformed to serotonin and converted into melatonin, and tryptophan deficiency is a cause of low melatonin levels. It is rapidly metabolized by the liver, is excreted in the urine, and has a low level of toxicity even at high doses. The secretion of melatonin declines with aging. Melatonin is lipid and water soluble and readily crosses cell

membranes, including the blood-brain barrier, and is present in all bodily fluids. There are three melatonin receptors. M1 and M2 are transmembrane receptors, and M3 is an intracellular receptor. The function of the melatonin receptors in the brain is the regulation of circadian rhythms and sleep. In addition to its chronobiotic functions, melatonin can also activate or suppress the immune system and stimulate or suppress inflammation depending on different physiologic conditions.

Activation of the immune system and the protective inflammatory response can be beneficial in defense against pathogens, including bacterial and viral infections, and meningitis, including the neuroinflammatory effects of SARS CoV-2 infection. In the nervous system, melatonin is cytoprotective and acts as a free radical scavenger and has antioxidant functions by activating antioxidant enzymes (e.g., glutathione peroxidase, superoxide dismutase, and catalase). Melatonin suppresses the secretion of inflammatory cytokines, such as interferon-γ and tumor necrosis factor-α, and increases the amounts of antiinflammatory cytokines interleukin (IL)-4 and IL-10. There is also downregulation of the proinflammatory mediators cyclooxygenase-2 and inducible nitric oxide synthetase. Many of the neurodegenerative diseases, including Alzheimer disease (AD) and Parkinson disease (PD), have low levels of melatonin and are associated with sleep disorders and neuroinflammation. Melatonin is lower in AD individuals than in age-matched controls. A meta-analysis suggests that night time melatonin treatment for greater than 12 weeks may be effective for improvement of cognitive functioning in individuals with mild AD than those with moderate AD. Sleep disturbances are common in AD and may contribute to decreased clearance of beta amyloid. Thus the use of melatonin for the improvement in sleep is a consideration for treatment in early AD. In addition to the management of sleep disorders in PD, it is proposed that melatonin may be neuroprotective and delay disease progression, prevent assembly of α-synuclein proteins, prevent oxidant damage to neurons, maintain normal mitochondrial function, and promote glymphatic elimination of toxic products. Some studies have shown melatonin to be proinflammatory and to have a detrimental effect in multiple sclerosis and rheumatoid arthritis.

Melatonin has been shown to exert neuroprotective effects, but the timing of administration, dosage, and outcome measures in humans need more research. Clinical trials with large sample sizes and standardized methodologies are needed to more effectively guide the use of melatonin in the treatment and prevention of neurodegenerative diseases. Currently there are several studies in progress for the use of melatonin in AD, PD, Huntington disease, multiple sclerosis, and Covid-19.

stretch. Chronic myofascial pain can induce central sensitization (see Chapter 16) with increased central excitability and decreased central pain inhibition.[109]

Evaluation and TreatmentTTH are diagnosed based on the history, pattern of headache, and palpation of pericranial muscles. Other causes of headache need to be ruled out. Mild TTHs are treated with nonsteroidal antiinflammatory drugs. CTTHs are best managed with a tricyclic antidepressant (e.g., amitriptyline) and behavioral and relaxation therapy. Long-term use of analgesics or other drugs, such as muscle relaxants, antihistamines, tranquilizers, caffeine, and ergot alkaloids, should be avoided.[110]

Infection and Inflammation of the Central Nervous System

The CNS may be infected by bacteria, viruses, fungi, parasites, and mycobacteria. The invading organisms enter the nervous system either by spreading through arterial blood vessels or by directly invading the nervous tissue from another site of infection. Neurologic infections produce disease by several mechanisms: direct neuronal or glial infection, mass lesion formation, inflammation with subsequent edema, interruption of CSF pathways, neuronal or vascular damage, and secretion of neurotoxins. An immune process may initiate an inflammatory reaction. Signs and symptoms are produced because of (1) interference with the function of the nervous system tissue being invaded or compressed or (2) the inflammatory response produced by the body in response to infection. The cardinal signs of CNS infection are fever, head or spine pain, altered mental state, and focal neurologic

dysfunction (See Emerging Science Box: SARS-CoV-2 Infection and Neurologic Manifestations.[111])

Meningitis

Meningitis is inflammation of the brain or spinal cord. Infectious meningitis may be caused by bacteria, viruses, fungi, parasites, or toxins. The infection may be acute, subacute, or chronic, with the pathophysiology, clinical manifestations, and treatment differing for each type of microorganism and any accompanying conditions.

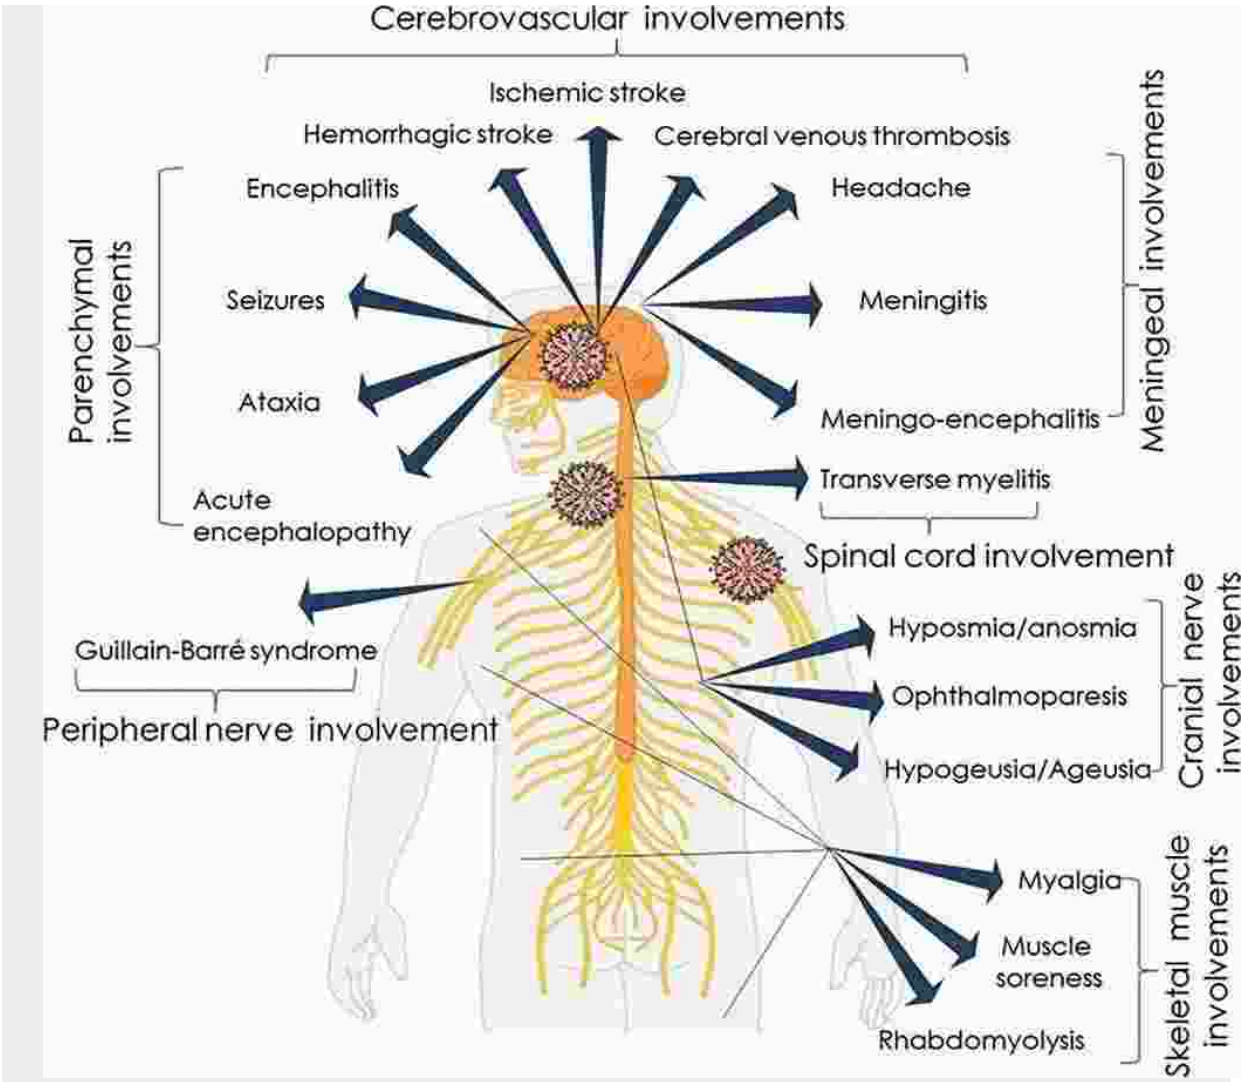
Bacterial Meningitis

Bacterial meningitis is primarily an infection of the pia mater and arachnoid villi, the subarachnoid space, the ventricular system, and the CSF. *Streptococcus pneumoniae* (pneumococcus), *Haemophilus influenzae* type b (Hib), and *Neisseria meningitides* (meningococcus) are the most common pathogens in adults. With pneumococcal meningitis, young persons and those more than 40 years of age are mostly affected with outbreaks in dormitories or military bases. Predisposing conditions are otitis or sinusitis (25%), immunocompromised status (16%), and pneumonia (12%).[112,113] The disease is spread by respiratory droplets and contact with contaminated saliva or respiratory tract secretions (kissing, coughing, sneezing, or sharing utensils, food, and drink). Carriers of the meningococcal bacteria do not develop meningitis but may pass it on to others.

PathophysiologyMeningococci and pneumococci are inhaled and attach to epithelial cells in the nasopharynx, where they cross the mucosal barrier, enter the bloodstream, travel to cerebral blood vessels, cross the blood-brain barrier, and infect the meninges (Fig. 18.24). With bacterial infection, large numbers of neutrophils are recruited to the subarachnoid space. Release of cytotoxic inflammatory agents and bacterial toxins

Emerging Science BOXSARS-CoV-2 Infection and Neurologic Manifestations

Neuroinvasion of the SARS-CoV-2 into the nervous system may include entry through the olfactory epithelium across the cribriform plate to the olfactory bulb; via infected leukocytes that cross the blood-brain barrier; via the blood stream by infecting endothelium and crossing the vascular endothelium; and via the cranial nerves by transsynapic transport (i.e., via the vagus nerve from the gastrointestinal tract). Once in the brain, SARS-CoV-2 may spread through the ACE2 receptor, through other facilitator receptors, or by adsorptive uptake by neurons and glial cells. Neurologic manifestations may also be related to the secondary immune-mediated cytokine storm associated with a systemic hyperinflammatory state that develops in severe cases. The consequences can include increased blood-brain barrier permeability with cerebral edema and an immune driven hypercoagulable state promoting thrombosis and stroke.



The most common neurologic symptoms are loss of taste and smell, headaches, nausea and vomiting, dizziness, and muscle pain. More severe neurologic manifestations, including ischemic and hemorrhagic strokes, encephalitis, and impaired consciousness, have been associated with more severe disease and older individuals with comorbid conditions, including hypertension, diabetes, and higher levels of C-reactive protein. Guillain-Barré syndrome–type symptoms have also been reported (e.g., hyporeflexia, areflexia, and paraesthesias).

Parkinsonian symptoms have developed in some cases of severe disease, with reduced function of the nigrostriatal dopamine system and positive response to dopaminergic treatment. The figure summarizes the diverse neurologic manifestations among individuals with Covid-19 disease. Research regarding the mechanisms of neuroinvasion, development of treatment, and prevention of long-term consequences continues.

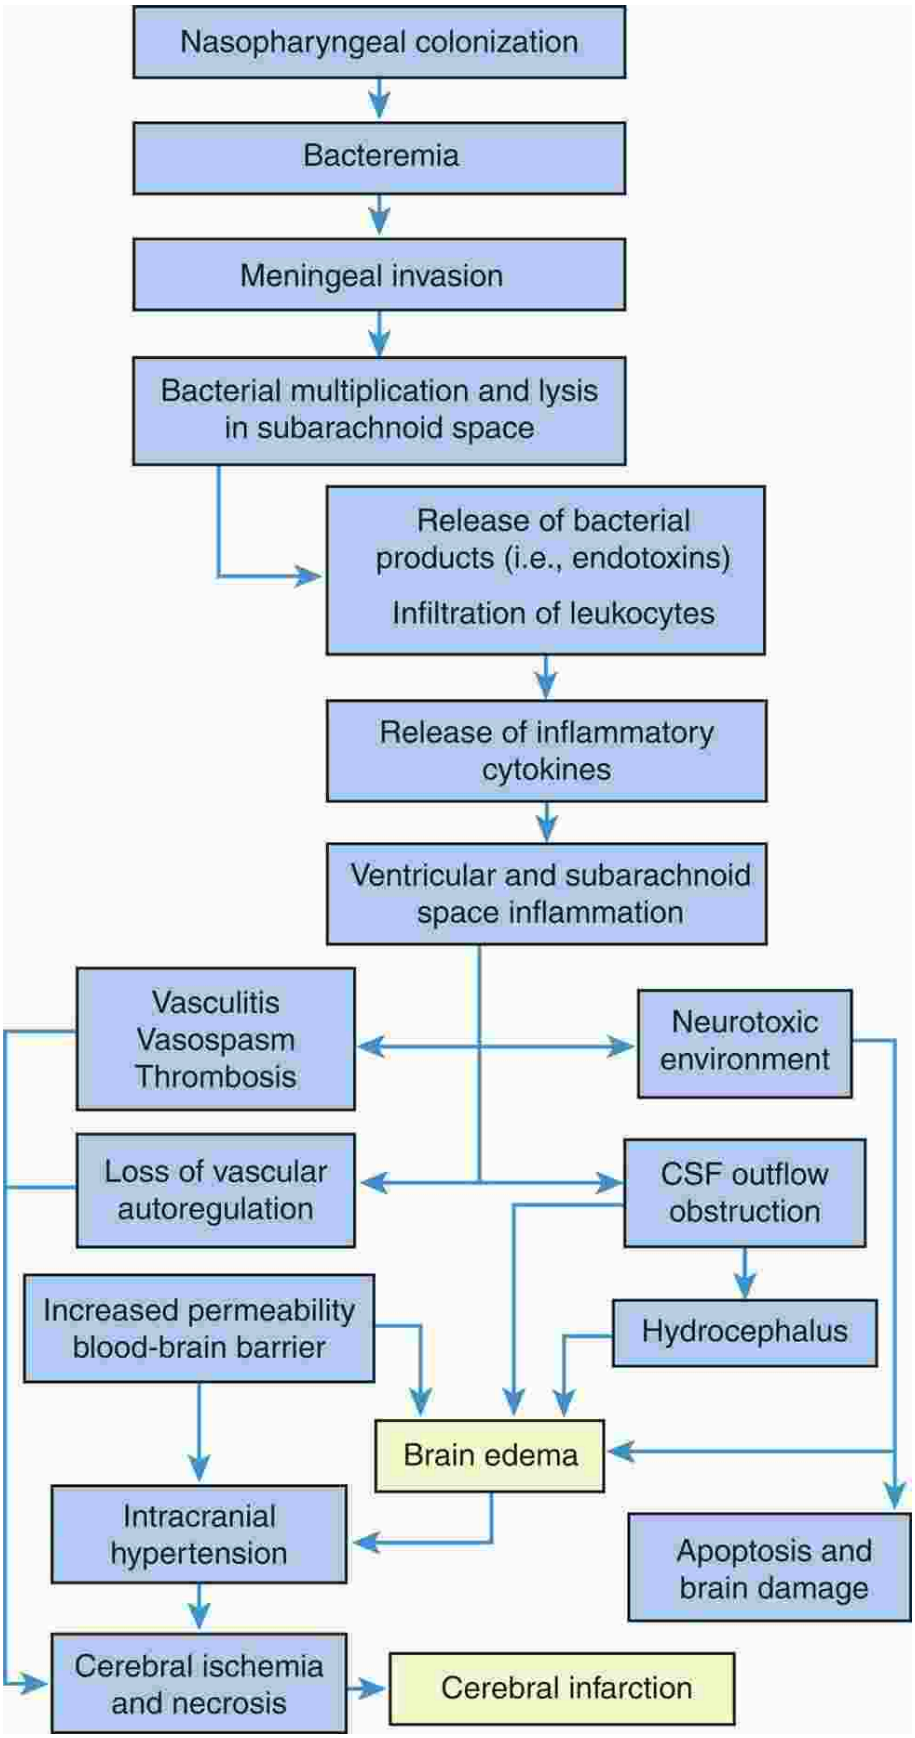
alter the blood-brain barrier, causing cerebral edema and damaging brain tissue. The inflammatory exudate thickens the CSF and interferes with normal CSF flow around the brain and spinal cord, possibly obstructing arachnoid villi and producing hydrocephalus. Meningeal cells become edematous, and the combined exudate and edematous cells increase ICP. Engorged blood vessels and thrombi can disrupt blood flow, causing further injury.



Nasopharyngeal colonization
Bacteremia
Meningeal invasion
Bacterial multiplication and lysis in subarachnoid space
Release of bacterial products (i.e., endotoxins)
Infiltration of leukocytes
Release of inflammatory cytokines
Ventricular and subarachnoid space inflammation
Vasculitis
Vasospasm
Thrombosis
Neurotoxic environment
Loss of vascular autoregulation
CSF outflow obstruction
Increased permeability blood-brain barrier
Hydrocephalus

Intracranial hypertension
Apoptosis and brain damage
Cerebral ischemia and necrosis
Cerebral infarction

FIG. 18.24 Pathogenesis of Meningitis. (Adapted from Cohen J, Powderly WG. *Infectious diseases*, 2nd edition. Mosby: Edinburgh; 2004.)

Clinical ManifestationsThe clinical manifestations of bacterial meningitis can be grouped into infectious signs, meningeal signs, and neurologic signs. The clinical manifestations of systemic infection include fever, tachycardia, and chills. The clinical manifestations of meningeal irritation are a severe throbbing headache, severe photophobia, nuchal rigidity, and positive Kernig and Brudzinski signs (Fig. 18.25). The neurologic signs include a decrease in consciousness, cranial nerve palsies, focal neurologic deficits (e.g., hemiparesis/hemiplegia and ataxia), and seizures. Often there is projectile vomiting. Papilledema develops, as the ICP increases, causing delirium, and may progress to unconsciousness and death. With meningococcal meningitis, a petechial or purpuric rash covers the skin and mucous membranes. A rare complication is acute infectious **purpura fulminans**. It is caused by bacterial endotoxin and inflammatory cytokines and can cause sepsis. This is a rapidly progressive syndrome of hemorrhagic infarction of the skin and disseminated intravascular coagulation that can lead to multiple organ failure, ischemic necrosis of digits and limbs with amputation required, and death.

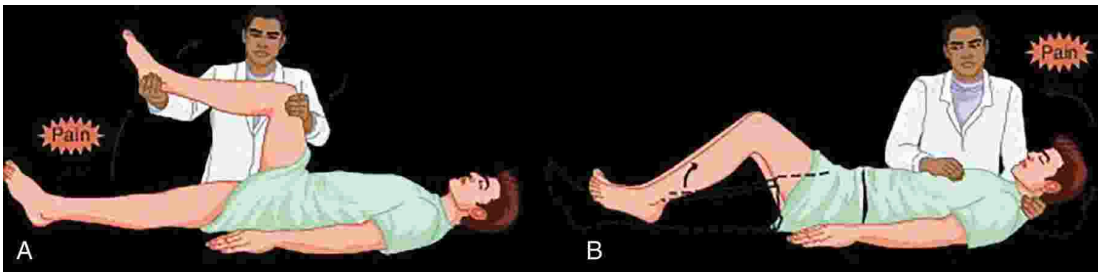

FIG. 18.25 Bacterial Meningitis and Clinical Signs.
(A) Kernig sign, supine position with hip flexed 90 degrees. Knees cannot be fully extended. (B) Brudzinski Sign, neck rigidity causes flexion of both legs and thighs with passive flexion of the neck.

Leads to 11. 18. Cerebral infraction.

Evaluation and TreatmentRapid diagnosis, antibiotic administration, and supportive treatment are important to prevent morbidity and mortality from bacterial meningitis. Diagnosis is based on physical examination, blood cultures, and the results of nasopharyngeal smear and antigen tests. CSF analysis and cultures are required for differential diagnosis. Serious complications, including septic shock, disseminated intravascular coagulation, purpura fulminans, limb damage, and multiple organ failure, require intensive multidisciplinary care. Long-term neurologic complications include seizures, hearing and vision loss, and neuromotor disability. More subtle effects such as cognitive impairment and memory and behavior changes are often overlooked and can have detrimental effects on school and work performance.[114] Vaccinations are available to prevent meningococcal, pneumococcal, and *H. influenzae* meningitis.[115]

Viral Meningitis

Viral meningitis (aseptic meningitis) is thought to be limited to the meninges. An identifiable bacterium cannot be found in the CSF. The term aseptic is used to differentiate

meningeal inflammation that is caused by pathogens other than pus-producing bacteria. The most common viruses are enteroviral viruses (echovirus, coxsackievirus, and nonparalytic poliomyelitis), arboviruses, and herpes simplex type 1 and 2. Viruses enter the nervous system by crossing the blood-brain barrier, by direct spread along peripheral nerves, through transsynaptic transmission, through the choroid plexus epithelium, or from infected immune cell that cross into the brain (Fig. 18.26).[116] The immune response leads to release of inflammatory cytokines with increased permeability of the blood-brain barrier and entry of circulating immunoglobulins that combat the virus. The clinical manifestations of viral meningitis are similar to those of bacterial meningitis but milder. Viral meningitis is managed pharmacologically with antipyretics, antiemetics, analgesics, and antiviral drugs.[117]

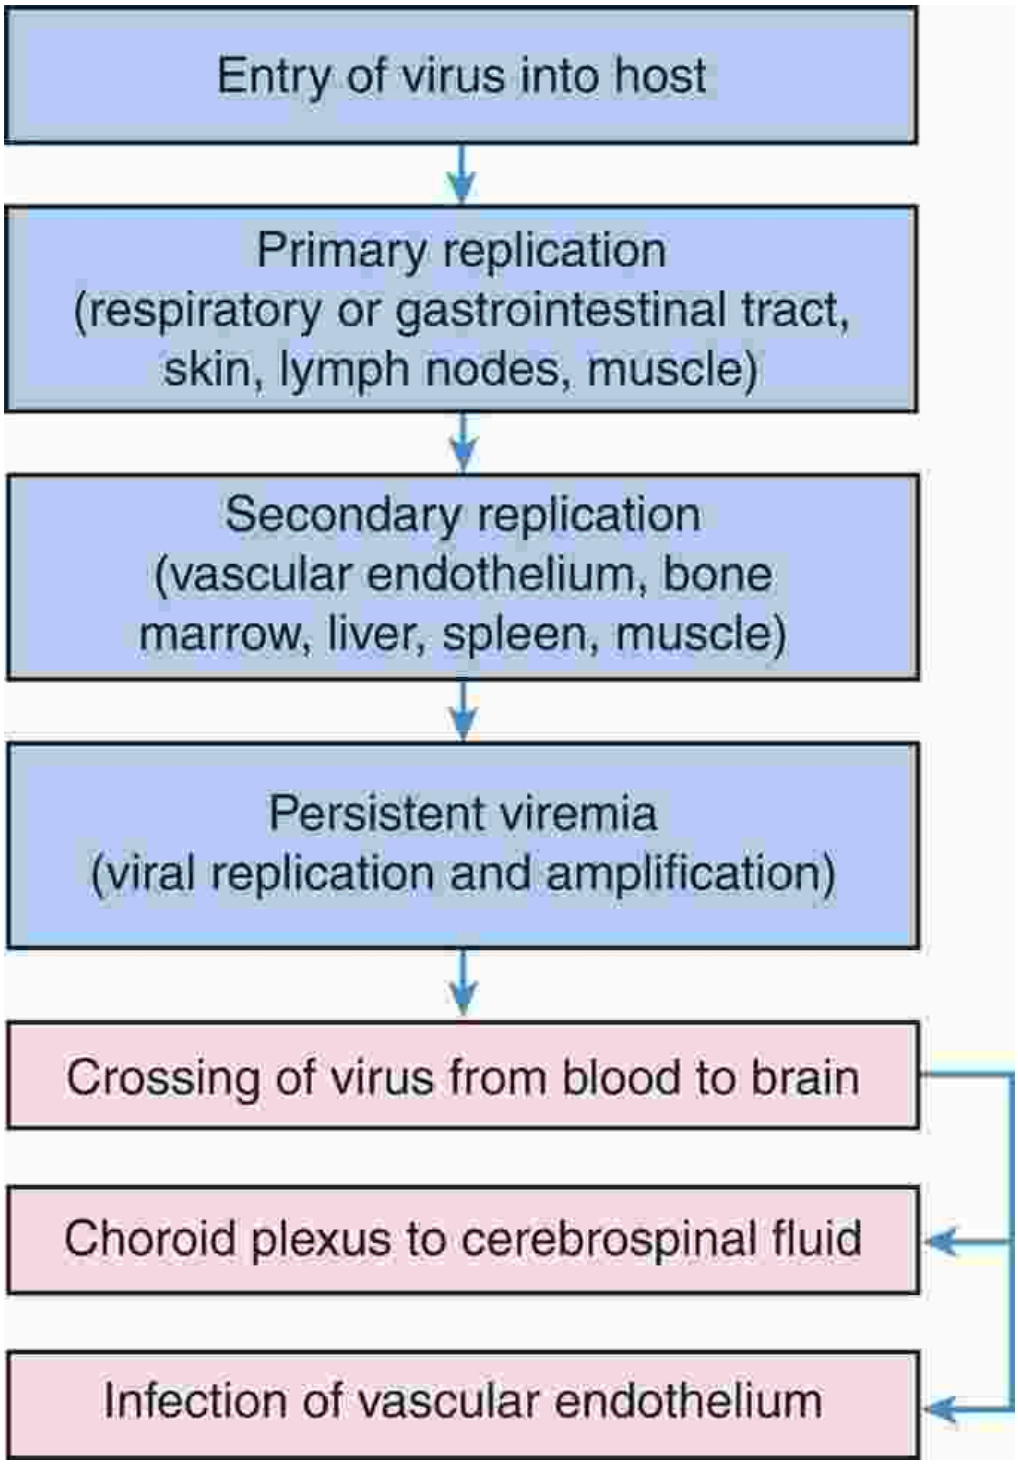

FIG. 18.26 Hematogenous Spread of Viral Pathogens to the Central Nervous System. (Adapted from Cohen J, Powderly WG. *Infectious diseases*. Mosby: Edinburgh, 2007.)

Three illustrations depict the signs of bacterial meningitis. Illustration A depicts the lateral view of the brain with the spinal cord, which shows

the inflammation of the protective membranes covering the brain and spinal cord. Illustration B depicts the coronal section of the brain with inflamed ependyma. Illustration C depicts a boy lying supine with the hip flexed to 90 degrees and the knee partially extended. Illustration D depicts a boy lying supine with both legs flexed along with passive neck flexion.

Fungal Meningitis

Fungal meningitis is a chronic, much less common condition than bacterial or viral meningitis. The most common fungal infections of the nervous system are histoplasmosis, cryptococcosis, coccidioidomycosis, mucormycosis, candidiasis, and aspergillosis. Fungal meningitis develops insidiously, usually over days or weeks. The infection most often occurs in persons with impaired immune responses or alterations in normal body flora. Cryptococcal meningitis remains a leading cause of death in human immunodeficiency virus (HIV)–infected persons in resource-limited settings.[118] Fungi enter the nervous system by transcellular or paracellular migration across endothelial cells or by transport inside phagocytes.[119] Fungi in the nervous system usually produce a granulomatous reaction, forming granulomata or gelatinous masses in the meninges at the base of the brain. Fungi also may extend along the perivascular sites in the subarachnoid space and into the brain tissue, producing arteritis with thrombosis, infarction, and communicating hydrocephalus. Meningeal fibrosis develops later in the inflammatory process. Cranial nerve dysfunction, caused by compression, often results from the granulomata and fibrosis. The first manifestations are often nonspecific including headache, fever, convulsions, weakness, progressive confusion, changed mental status, and focal neurologic deficits. Antifungal treatments are microorganism specific and effective. Surgery can remove granulomas and abscesses.[120]

Tubercular Meningitis

Tubercular meningitis is a common and serious form of CNS tuberculosis (TB), especially in immunosuppressed persons or those with acquired immunodeficiency syndrome (AIDS). Mycobacteria are acquired through inhalation of aerosolized droplet nuclei. The bacteria enter the brain as described for fungal meningitis. Miliary tubercles form in the brain. These tubercles can rupture, and the bacteria are released into the subarachnoid space and are disseminated to the CSF and meninges. The bacteria promote meningeal inflammation and the formation of thick exudate precipitating the signs and symptoms of tubercular meningitis. Cerebral ischemia and infarction can occur from vasculitis.

Symptoms are nonspecific and may develop over many days, making early diagnosis difficult. Symptoms include headache, low-grade fever, nausea and vomiting, irritability, difficulty sleeping, and fatigue and increase to confusion, stiff neck, significant behavioral changes, and seizures. Hydrocephalus and cranial nerve palsies or cerebral infarcts may occur. There is no single clinical guideline for the diagnosis of tubercular meningitis. Diagnosis includes the medical history, clinical assessment, CSF investigations and neuroimaging, mycobacterial culture, and molecular testing (nucleic acid amplification testing).[121] Recovery rate is 90% with early diagnosis and treatment with appropriate anti-TB

therapy. Treatment is difficult in resource-poor countries, and multidrug-resistant TB is emerging as a global threat.[122,123]

Encephalitis

Encephalitis is an acute inflammation of the brain, usually of viral origin. The most common forms are infectious, autoimmune, and postinfectious.[124] Herpes simplex type 1 is the most common sporadic cause of infectious encephalitis. Viruses infect specific cell types in the CNS, as shown in Fig. 18.27. Referred to as infectious viral encephalitides, encephalitis may occur as a complication of systemic viral diseases, such as herpes simplex type 1, rabies, or mononucleosis, or it may arise after recovery from viral infections, such as rubella, varicella, rubeola, or yellow fever. Encephalitis also may follow vaccination with a live, attenuated virus vaccine if the vaccine has an encephalitis component (e.g., measles, mumps, and rubella). Typhus, trichinosis, malaria, and schistosomiasis also are associated with encephalitis.

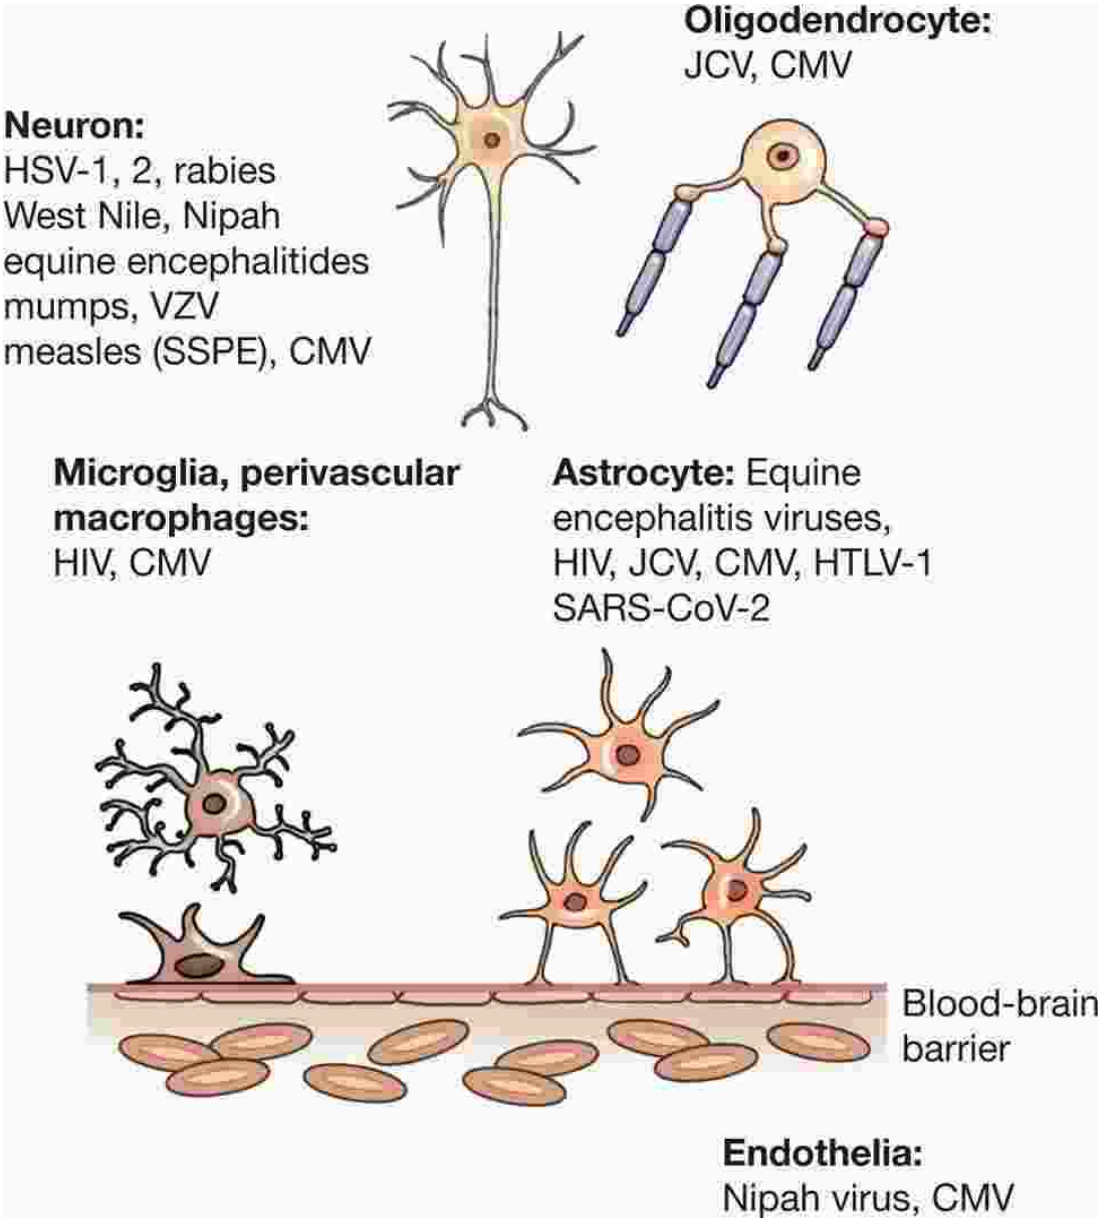

FIG. 18.27 Viral Infection of Specific Cells in the Central Nervous System (CNS).

Viruses infect specific cell types within the CNS, depending on the particular properties of the virus together with individual cell membrane proteins expressed on permissive cell types. Normally the brain is protected from circulating pathogens and toxins by the blood-brain barrier. *CMV*, Cytomegalovirus; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *HTLV-1*, human T-cell lymphotropic virus (causes T-cell leukemia); *JCV*, John Cunningham virus (a polyomavirus causing progressive multifocal leukoencephalopathy); *SARS-CoV-2;* severe acute respiratory syndrome-related coronavirus-2; *SSPE*, subacute sclerosing panencephalitis; *VZV*, varicella-zoster virus. (Adapted from Power C, Noorbakhsh G. Central nervous system viral infections: Clinical aspects and pathogenic

mechanisms. In: Gilman S, eds. *Neurobiology of disease. Burlington*, MA: Elsevier; 2007:488.)

A flowchart shows the hematogenous spread of viral pathogens to the central nervous system. 1. Entry of virus into host. Leads to 2. 2. Primary replication (respiratory or gastrointestinal tract, skin, lymph nodes, muscle). Leads to 3. 3. Secondary replication (vascular endothelium, bone marrow, liver, spleen, muscle). Leads to 4. 4. Persistent viremia (viral replication and amplification). Leads to 5. 5. Crossing of virus from blood to brain. Leads to 6 and 7. 6. Choroid plexus to cerebrospinal fluid. 7. Infection of vascular endothelium.

With the exception of California viral encephalitis, which is endemic, the arthropod-borne (flies, mosquitoes, and ticks) encephalitides occur in epidemics, varying in geographic and seasonal incidence. West Nile virus (WNV) encephalitis is the most common, and Eastern equine encephalitis is the most serious but least common of the encephalitides.

West Nile Virus

West Nile virus (WNV), a *Flavivirus* transmitted predominantly by the *Culex* mosquito, is the most common cause of epidemic meningoencephalitis in North America and the leading cause of arboviral encephalitis in the United States. Humans and horses, as well as other mammals, are incidental hosts. Birds and mosquitoes are life cycle hosts, and the greatest amount of virus is carried by mosquitoes in early fall. WNV also can be transmitted through blood transfusions and organ transplants.

The human incubation period is 2 to 14 days. Most individuals develop no symptoms. Approximately 20% of those infected have mild symptoms that last 4 to 6 days and generally include fever, headache, myalgia, skin rash, and lymphadenopathy. This is known as West Nile fever. Less than 1% of affected persons develop severe illness, but it is the most frequent of the neuroinvasive infections. Identifiable risk factors are advanced age, immunocompromise, diabetes, hypertension, and pregnancy. The virus crosses the blood-brain barrier and reproduces in neurons. Abnormalities can develop in the thalamus, basal ganglia, cerebellum, hippocampus, spinal cord, dorsal root ganglia, and peripheral motor neuron. Manifestations can include headache, disorientation, stupor, coma, seizures, and movement disorders, including tremor, ataxia, extrapyramidal signs, and paralysis, and are related to the infected areas of the brain. West Nile meningitis is characterized by meningeal signs of severe headache, high fever, and nuchal rigidity. Myelitis and polyradiculitis also may be present. Both severe and mild cases can have long-term neurologic sequelae after recovery, including memory loss, depression, fatigue, generalized or limb weakness, and tremors. These disease features are similar to those encountered in neurodegenerative diseases such as Alzheimer disease and Parkinson disease.[125]

Diagnosis is made if WNV RNA is found in blood or other body fluids or immunoglobulin M (IgM) for the virus is found in serum or cerebrospinal fluid. A rapid test became available in 2007. Plaque reduction neutralization assay (PRNA) is the confirmatory test. Treatment is supportive care. No West Nile vaccine has been developed for humans. Environmental

control and prevention of mosquito bites are the best protections. Since 2003, all blood banks use blood-screening tests for WNV. There is a vaccine for horses, but there is not an approved vaccine for humans.[126,127]

Pathophysiology

Viruses gain access to the CNS through the bloodstream, olfactory bulb, or choroid plexus or from peripheral nerves. With *herpes simplex type-1 encephalitis*, the virus may enter the CNS with primary infection or reactivation of the latent virus. In some cases, the viral strain responsible for encephalitis is different from the strain that causes herpetic skin lesions in the same person, indicating the possibility of primary CNS infection.[128] *Autoimmune encephalitis* develops when antibodies form against cell surface antigens, synaptic antigens, and/or intraneuronal antigens on specific neural cells in different parts of the brain. With paraneoplastic neurologic syndromes, there is an underlying cancer, and the autoantibodies (also known as onconeural antibodies) are markers for cytotoxic T cells, which attack the antibodies and disrupt synaptic nerve transmission or destroy the nerve. Virus-induced autoantibody generation against cell surface antigens seems to be a widespread mechanism. Examples include *N*-methyl-D-aspartate receptor (NMDAR) antibodies following herpes simplex type-1 encephalitis. Anti-NMDAR encephalitis and other cell surface antigens are also associated with underlying malignancies. Loss of the NMDAR results in excitotoxicity from excess levels of glutamate.[129,130]

Meningeal involvement is present in all encephalitides. The various encephalitides may cause widespread nerve cell degeneration. Edema, necrosis with or without hemorrhage, and IICP develop.

Clinical Manifestations

Encephalitis ranges from a mild infectious disease to a life-threatening disorder. Mild symptoms include malaise, headache, body aches, nausea, and vomiting. Dramatic clinical manifestations include fever, difficulty with word finding, seizure activity, cranial nerve palsies, paresis and paralysis, involuntary movement, abnormal reflexes, and delirium or confusion progressing to unconsciousness. Signs of marked ICP may be present. The clinical manifestation of autoimmune encephalitis can be acute or subacute and vary with the type of antigen and brain region involved. Deficits of memory and cognition, altered level of consciousness, behavioral and psychiatric symptoms, autonomic disturbances, movement disorders, and seizures are possible manifestations.

Evaluation and Treatment

Diagnosis is made by the history and clinical presentation, aided by CSF examination and culture, serologic studies, white blood cell count, CT scan, or MRI. Empiric treatment is specific to the type of virus and may include antiviral agents, antibiotics, and steroids. Herpes encephalitis is treated with antiviral agents, such as acyclovir. Measures to control the ICP are paramount. Autoimmune encephalitis may be treated with immunotherapy, plasmapheresis, and/or steroids and removal of tumor. When the antibodies are removed (e.g., plasmapheresis or intravenous immunoglobulin), symptoms will improve. Chronic antibody exposure results in neuronal death and irreversible neurologic deficit.[131,132]

Brain or Spinal Cord Abscess

Abscesses are localized collections of pus within the parenchyma of the brain or spinal cord and are rare. Immunosuppressed persons are particularly at risk.

Brain abscesses are classified as epidural, subdural, or intracerebral. *Epidural brain abscesses* (empyemas) are associated with osteomyelitis in a cranial bone. *Subdural brain abscesses* (empyemas) arise from a sinus infection or a vascular source. *Intracerebral brain abscesses* arise from a vascular source. **Spinal cord abscesses** are very rare and classified as epidural or intramedullary (within the spinal cord). Epidural spinal abscesses usually originate as osteomyelitis in a vertebra; the infection then spreads into the epidural space. (Osteomyelitis is discussed in Chapter 44.)

Pathophysiology

Microorganisms gain entrance to the CNS by direct extension or distribution along the wall of a vein (e.g., trauma, mastoiditis, sinusitis, or dental infection). Infective emboli carry organisms from distant sites such as the heart, lungs, pelvic organs, skin, tonsils, abscessed teeth, osteomyelitis (except for cranial bones), and dirty needles.[133] Illegal drug users who share needles are at risk, as are immunosuppressed persons. For example, *Toxoplasma gondii* is producing an ever-increasing number of CNS abscesses in persons with AIDS. Streptococci, staphylococci, and *Bacteroides* sp., often combined with anaerobes, are the most common bacteria that cause abscesses; however, yeast and fungi also may be involved.

Brain abscesses progress from localized inflammation to a necrotic core with the formation of a connective tissue capsule, usually within 14 days or longer.[134] Existing abscesses also tend to spread and form daughter abscesses.

Clinical Manifestations

Early manifestations include low-grade fever, headache (most common symptom), nausea and vomiting, neck pain and stiffness, confusion, drowsiness, sensory deficits, and communication deficits. Later manifestations are associated with an expanding mass and IICP and include decreased attention span, memory deficits, decreased visual acuity and narrowed visual fields, papilledema, ocular palsy, ataxia, dementia, and seizures. The development of symptoms may be very insidious, often making an abscess difficult to diagnose.

Extradural brain abscesses are associated with localized pain, purulent drainage from the nasal passages or auditory canal, fever, localized tenderness, and neck stiffness. Clinical manifestations of spinal cord abscesses have four stages: (1) spinal aching, (2) severe root pain, accompanied by spasms of the back muscles and limited vertebral movement, (3) weakness caused by progressive cord compression, and (4) paralysis.

Evaluation and Treatment

The diagnosis is suggested by clinical features and confirmed by imaging studies. The primary source of infection should be identified and treated. Antibiotics are usually indicated, often in conjunction with corticosteroid therapy to treat the cerebral edema. The ICP and/or hydrocephalus may have to be managed.[135] Cerebral abscesses are considered a neurosurgical emergency. Spinal cord abscesses are treated with surgical decompression or aspiration, antibiotic therapy, and supportive therapy.

Neurologic Complications of Human Immunodeficiency Virus

Neurologic complications of HIV remain common but are milder due to widespread use of combination antiretroviral therapy (ART). The mechanism of neural involvement includes (1) direct effects of HIV (e.g., neurocognitive impairment), (2) immunocompromise secondary to uncontrolled HIV infection (e.g., opportunistic infections), (3) aberrant immune responses in the setting of ART initiation (e.g., immune reconstitution inflammatory syndrome [IRIS]), and (4) adverse effects of ART (e.g., peripheral neuropathy).

The most common neurologic complication associated with HIV is **HIV-associated neurocognitive disorder (HAND)**, a range of disorders that includes mild neurocognitive disorder and HIV-associated dementia, which is rare. Combined antiretroviral therapy (cART) with more efficient CNS drug penetration has reduced the prevalence and improved survival for individuals with HAND. Milder forms of the disease may persist because of longer life and the ability of the virus to survive within brain tissue in some individuals.

The HIV virus can enter the brain after 1 to 2 weeks of systemic infection. Persistent CNS infection and inflammation probably contribute to the development of HAND, which affects approximately 50% of HIV-infected individuals.[136] Various mechanisms have been proposed for HIV transfer into the brain. HIV-infected monocytes (cell-associated virus) or CD4+ T lymphocytes may pass through the brain-blood barrier. The monocytes mature into macrophages and release cytokines, increasing the permeability of the brain-blood barrier and causing the infiltration of more infected monocytes. Cell-free HIV (virus floating free in plasma) may also pass through the brain-blood barrier. Infected CD4+ T lymphocytes may transfer into the brain and come in contact with macrophages, leading to cell fusion and transfer of viruses to macrophages. The cause of the neuronal damage is thought to occur through two proposed mechanisms, the direct and indirect mechanisms. The direct mechanism suggests that monocytes and other infected cells release the virus, causing viral proteins to bind to neurons directly, causing neuronal damage and death. The indirect mechanism suggests that infected and uninfected monocytes, astrocytes, and microglia mount an inflammatory response against the virus, which causes neuronal damage and death. The infected cells serve as a reservoir for the virus.[137] Neuroinflammation leads to neurodegeneration. The symptoms are similar to other forms of dementia, including cognitive slowing, poor concentration, and memory difficulty. Motor signs can include difficulty speaking, progressive loss of balance, gait disturbances, or paralysis. Diagnosis is difficult during early stages of manifestations and requires neurocognitive testing. CSF analysis and imaging help to establish the diagnosis. HIV antiretroviral treatment improves survival for individuals with severe HAND but does not reverse the impairment. Differentiating HAND from Alzheimer disease and other neurodegenerative disorders can be difficult as the HIV-infected population reaches older ages.[138] Treatment with cART has prevented the most severe forms of HAND, but the less severe forms now predominate. There is no specific treatment.

Peripheral Nervous System Disorders

The peripheral nervous system is composed of motor anterior horn cell fibers, sensory dorsal root ganglia fibers, and peripheral autonomic ganglia and their axons. Acute or chronic disease processes, inflammation, or trauma may injure these peripheral nerves and cause neuropathy. Neuropathic pain is reviewed in Chapter 15.

Peripheral Neuropathies

Peripheral neuropathies occur outside the brain or spinal cord and are diseases or injuries to peripheral nerves (Table 18.15).[139] The injury may affect distinct anatomic areas of the axon, or the spinal nerves may be injured at the roots, at the plexus before peripheral nerve formation, or at the peripheral nerves themselves. Autonomic nerve fibers may be injured as they travel in certain cranial nerves or emerge through the ventral root and plexuses to pass through the peripheral nerves of the body. When myelin is damaged, nerve conduction is delayed or stopped. When the cell body, axon, or ganglia are injured, there is loss of function.

Table 18.15

Types of Peripheral Neuropathies

Type	Cause	Example
Mononeuropathy Motor: weakness, paralysis Sensory: numbness, pain	Trauma, compression, infection, inflammation, tumor	Sciatica, carpel tunnel syndrome, radial nerve palsy, facial palsy
Multiple mononeuropathies (multiplex) Motor: weakness, paralysis Sensory: numbness, pain Patchy distribution involving two or more nerves	Metabolic (hyperglycemia, toxins), connective tissue (autoimmune mechanisms) or vascular (hypoxemia) disorders	Usually associated with systemic disease: diabetes mellitus, vasculitis, lupus erythematosus; radiculopathies (spinal nerve roots), and nerve plexus injury
Autonomic neuropathy Affects sympathetic and parasympathetic nerve fibers	Usually associated with systemic disease (i.e., diabetes mellitus, vasculitis, lupus erythematosus)	Alterations in heart rate, blood pressure (dizziness, fainting), bladder function (incontinence or urinary retention), gastrointestinal function (diarrhea or constipation), or thermal regulation
Radiculopathy Affects sensory, motor, and nerves	Nerve root compression from vertebral disease or injury or disc herniation	Degenerative spondyloarthropathy; cervical or lumbar disc herniation
Polyneuropathy Affects sensory, motor and autonomic nerves simultaneously in a symmetric distribution	Systemic metabolic, toxic, autoimmune and infectious diseases	Hyperglycemia, uremia, alcoholism, chemotherapy, Guillain-Barré syndrome, human immunodeficiency virus (HIV) infection

Type	Cause	Example
Mononeuropathy Motor: weakness, paralysis Sensory: numbness, pain	Trauma, compression, infection, inflammation, tumor	Sciatica, carpel tunnel syndrome, radial nerve palsy, facial palsy
Multiple mononeuropathies (multiplex) Motor: weakness, paralysis Sensory: numbness, pain Patchy distribution involving two or more nerves	Metabolic (hyperglycemia, toxins), connective tissue (autoimmune mechanisms) or vascular (hypoxemia) disorders	Usually associated with systemic disease: diabetes mellitus, vasculitis, lupus erythematosus; radiculopathies (spinal nerve roots), and nerve plexus injury
Autonomic neuropathy Affects sympathetic and parasympathetic nerve fibers	Usually associated with systemic disease (i.e., diabetes mellitus, vasculitis, lupus erythematosus)	Alterations in heart rate, blood pressure (dizziness, fainting), bladder function (incontinence or urinary retention), gastrointestinal function (diarrhea or constipation), or thermal regulation
Radiculopathy Affects sensory, motor, and nerves	Nerve root compression from vertebral disease or injury or disc herniation	Degenerative spondyloarthropathy; cervical or lumbar disc herniation
Polyneuropathy Affects sensory, motor and autonomic nerves simultaneously in a symmetric distribution	Systemic metabolic, toxic, autoimmune and infectious diseases	Hyperglycemia, uremia, alcoholism, chemotherapy, Guillain-Barré syndrome, human immunodeficiency virus (HIV) infection

Neuropathies can be acquired, inherited (rare), or idiopathic. Focal nerve injuries involve mononeuropathies and radiculopathies. **Mononeuropathies** affect a single peripheral nerve (e.g., a sensory or motor neuropathy). **Multiple mononeuropathies (multiplex)** involve two or more individual nerves in different areas and can be difficult to distinguish from a polyneuropathy. **Autonomic neuropathies** involve the autonomic nervous system (innervation of the heart, blood vessels, intestine, bladder, sweat glands and pupils). **Radiculopathies** are disorders of spinal nerve roots as they enter (sensory) or exit (motor) the spine (see Fig 15.13). Cervical and lumbar nerve roots are more commonly affected, and pain is the major symptom. *Radiculitis* (radiculoneuritis) refers to an inflammation of the spinal nerve roots. One (focal) or more roots may be affected. An acute intervertebral disk prolapse (herniated disk), degenerative spondyloarthropathies, or a benign tumor are causes of root compression. **Polyneuropathy** is generalized involvement of peripheral nerves that is usually bilateral and symmetric and can involve motor, sensory, and autonomic nerves simultaneously. Pathologic processes that cause neuropathies include autoimmune disorders, inflammation, infection, decreased blood flow, compression, damage to supporting connective or bone tissue, trauma, metabolic disorders (e.g., diabetes mellitus and nutritional deficiencies), toxins (e.g., alcoholism and industrial chemicals) drugs, and tumors.

Pathophysiology

Although distinct pathophysiologic processes are recognized in neuropathy, these are not disease specific and may exist simultaneously in any one neuropathy. Pathologic processes that may be present include *wallerian degeneration*, in which the axon and myelin distal to the site of axonal interruption degenerate (see Chapter 15). This type of degeneration is characteristic of a traumatic nerve injury in which the nerve is severed. *Axonal degeneration* is caused by metabolic failure within an axon or vascular ischemia. In axonal degeneration, distal degeneration of the axon occurs first and is followed by degeneration of the myelin and

the axis cylinder. This results in "stocking and glove" sensory or motor symptoms. In *demyelinating neuropathies*, the axon may be spared and only the myelin degenerates. Electromyography, nerve conduction studies, and imaging can assist in differentiating axonal from demyelination neuropathies.[140,141]

Clinical Manifestations

When the axons are affected, muscle strength, muscle tone, and muscle mass also are affected. Whole muscles or groups of muscles are paretic or paralyzed, and the muscles of the feet and legs often are affected first and more severely than the hands and arms. These long, large axons are thought to (1) be more vulnerable to injury because of their size and length, (2) have more Schwann cells available to be injured, and (3) exhibit a "dying back" phenomenon caused by difficulty of the nerve cell body in maintaining the terminal portion of the axon.

Tone and the deep tendon reflexes in the affected muscles generally are decreased, and atrophy is distributed according to the peripheral nerves involved. Fasciculation may be present, especially with associated ventral root or motor neuron changes, or both, as in Guillain-Barré syndrome (see Chapter 17) and diabetic neuropathy (see Chapter 22). Mild fatigue may be experienced. A few disorders, notably Guillain-Barré syndrome, produce a pattern of paresis and paralysis that involves all limbs, the trunk, and the neck (see Chapter 17). Ataxia of gait or limb may arise from the loss of position and vibratory sensations (i.e., proprioceptive sensory loss) and may be enhanced by motor weakness. Diseases that involve spinal roots typically produce local pain; pain on local percussion; pain and paresthesia in the sensory root distribution (called radicular pain and radicular paresthesia (e.g., cervical root pain causes pain in the arm; see Fig. 15.11); increased pain with movement, stretching of the root, and maneuvers that transiently increase CSF pressure; sensory loss in a radicular pattern; and spasms of the muscles surrounding the vertebral column (e.g., paravertebral muscle spasms).

Reflex-mediated autonomic nervous system functions, such as sweating, pupillary size, bladder, gastric, intestinal, and cardiovascular function, may be affected (see Fig. 15.25). Neuropathies associated with autonomic disturbances include diabetes mellitus, alcoholism and related nutritional neuropathies, amyloidosis, and Guillain-Barré syndrome. In many chronic polyneuropathies, the feet, hands, and spine become deformed.

Evaluation and Treatment

The diagnostic work-up to determine the cause of a neuropathy is often extensive and involves a detailed history and physical examination, laboratory evaluations of serum and CSF, electromyelography, nerve conduction studies, and imaging.[140,141] Early diagnosis and treatment before irreversible neuronal cell damage ensues are of paramount importance. Although axonal regrowth and recovery of function may take months, many neuropathies can be reversed. The therapeutic management is directed at elimination of the cause, control of diseases such as diabetes mellitus, and prevention of further nerve damage.

Nerve plexus injuries involve the nerve plexus distal to the spinal roots but proximal to the formation of the peripheral nerves. Such injuries may be caused by trauma, compression (entrapment), or infiltration, or they may be iatrogenic and caused by positioning during surgery or by an intramuscular injection. Clinical manifestations include motor weakness, muscle atrophy, and sensory loss in affected areas. Paralysis can occur with complete plexus lesions.

The diagnosis is made based on history and clinical manifestations. Therapeutic treatment is directed at removal of the cause, surgical repair and approximation of nervous tissue, nerve transfers, growth factors, prevention of further injury, control of discomfort, prevention of complications, and rehabilitation when appropriate.[142]

Tumors of the Central Nervous System

CNS tumors include both brain and spinal cord tumors. Primary CNS tumors had an estimated 24,530 new cases and 18,600 deaths in the United States in 2021.[143] The incidence of CNS tumors increases to age 70 years and then decreases. From 2013 to 2017, CNS tumors were the most common group of tumors occurring in children ages 0 to 14 years.[144] Approximately 70% to 75% of all intracranial tumors in children are located infratentorially (see Chapter 20), and in adults, 70% are located supratentorially. Peripheral nerve tumors are rare in children and more common in adults. Carcinogenesis is discussed in Chapter 12, pituitary tumors are discussed in Chapter 22, and cerebral tumors in children are discussed in Chapter 20.

Brain Tumors

Tumors within the cranium can be either primary or metastatic. *Primary (intracerebral) brain tumors* originate from brain substance, including neuroglia, neurons, cells of blood vessels, and connective tissue. *Extracerebral tumors* originate outside substances of the brain and include meningiomas, acoustic nerve tumors, and tumors of the pituitary and pineal glands. *Metastatic (secondary) brain tumors* are the most prevalent and arise in organ systems outside the brain and spread to the brain. Sites of intracranial tumors are illustrated in Fig. 18.28.

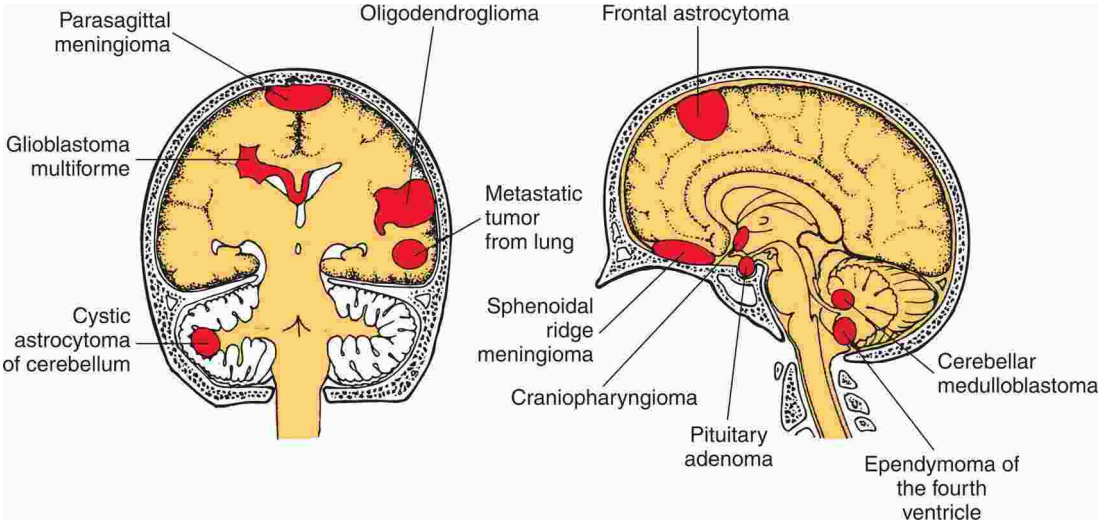

FIG. 18.28 Common Sites of Intracranial Tumors.

An illustration shows the viruses infecting various cell in C N S as follows. â€¢ Neuron: H S V-1, 2, rabies; West Nile; Nipah equine encephalitides mumps; V Z V measles (S S P E), C M V. The illustration shows a neuron with a cell body, dendrites, and an axon. â€¢ Oligodendrocyte: J C V; C M V. The illustration shows a cell body with three branches of myelin sheaths. â€¢ Microglia, perivascular macrophages: H I V; C M V. The illustration shows a cell body with multiple dendritic branches. â€¢ Astrocyte: Equine encephalitis viruses; H I V; J C V; C M V; H T L V-1; S A R S-Co V-2. The illustration shows a distorted cell bod with multiple branches. â€¢ Endothelia: Nipah virus; C M V. The illustration shows a cluster of elliptical cells. An accompanying illustration shows a blood-brain barrier with an endothelial layer. A macrophage and two astrocytes are attached to the surface of the blood-brain barrier.

Local effects of cranial tumors are caused by the destructive action of the tumor itself on a particular site in the brain and by compression, causing decreased cerebral blood flow. For example, frontal lobe tumors might cause personality changes, weakness, or dysphasia; parietal lobe tumors might cause numbness, hemineglect or spatial disorientation, difficulty speaking, reading, or writing; tumors involving the temporal lobe might involve memory loss or seizures; tumors involving the optic radiation might cause visual field defects; and cerebellar tumors might cause gait disturbances, loss of coordination, and dizziness.

Generalized effects result from IICP caused by invasion of the tumor, obstruction of the ventricular system, hemorrhages in and around the tumor, compression of nerve tissue, and cerebral edema. Manifestations include headache, seizures, visual disturbances, unstable gait, nausea and vomiting, and cranial nerve dysfunction.

Intracranial brain tumors do not metastasize as readily as tumors in other organs because there are no lymphatic channels within the brain substance. If metastasis does occur, it is usually through seeding of cerebral blood or CSF during cranial surgery or through artificial shunts.

Primary Brain (Intracerebral) Tumors

Primary brain (intracerebral) tumors, also called **gliomas** (cells that support brain neurons), include astrocytomas, oligodendrogliomas, glioblastomas (the most common malignant brain tumor), and ependymomas. Other CNS tumors include meningiomas (the most common adult brain tumor), nerve sheath tumors (schwannomas), and neurofibromas.[145] Medulloblastomas primarily occur in children. Brain tumors account for nearly 2% of all cancers in the United States.[143] The etiology for primary brain tumors is not clearly known. Ionizing radiation is the only known environmental risk factor.

Treatment for brain tumors is complex because of interindividual variability, intratumoral heterogeneity, and impediment of drug delivery across the blood-brain barrier. Surgical removal of tumor tissue is difficult because of invasiveness of the tumor. Advances now allow profiling of genomic, epigenomic, transcriptomic, proteomic, and metabolomic changes in brain tumors. Efforts are in progress to individualize treatment to the specific characteristics of the tumor.[146] Treatments currently include surgical or radiosurgical excision or surgical decompression if total excision is not possible. Surgical resection allows histologic and molecular diagnosis to guide further treatment. Chemotherapy (temozolomide), radiation therapy (RT), or their combination, targeted molecular therapies, and alternating electrical field therapy may be used. Treatments for grade IV tumors have not produced long-term survival, and there is often recurrence. The blood-brain barrier is an obstacle to the delivery of chemotherapeutic agents. New methods are in progress for penetration of this barrier, including nanoparticle drug carriers, photodynamic strategies, gene therapy, monoclonal antibodies, and focused ultrasound combined with microbubbles. (Cancer treatment is discussed in Chapter 12).[147–149]

Astrocytoma

Astrocytomas are the most common glioma (approximately 75% of all tumors of the brain and spinal cord). The World Health Organization (WHO) divides astrocytomas into four grades based on histopathologic characteristics or phenotypes: cellular density, atypia, mitotic activity, microvascular proliferation, and necrosis. In addition, molecular characteristics (genetic driver mutations) have been identified to differentiate tumor types (Table 18.16). Molecular characteristics of gliomas include mutation of the isocitrate dehydrogenase 1 *(IDH1)* gene, and, less commonly, mutation of the related *IDH2* gene identified in the vast majority of WHO grades II and III astrocytic and oligodendroglial gliomas. Silencing of the *MGMT* gene (methylated-DNA-protein-cysteine methyltransferase, a DNA repair enzyme) is found in astrocytomas. Mutant epidermal growth factor vIII (EGFRvIII) amplification is found in most subtype gliomas. Chromosome 1p and 19q deletions are associated with oligodendrogliomas, and gliomas may arise from cancer-initiating resident stem cells. Identifying these molecular signatures is guiding tumor-specific individualized therapy.[150,151]

Table 18.16

Grades of Astrocytomas Edited

Grade[a]	Selected Types Diffuse Astrocytic and Oligodendroglial	Description	Characteristics
I	Pilocytic astrocytoma	Common in children and young adults and people with neurofibromatosis type 1 or with *BRAF-KIAA* fusion gene mutation; common in cerebellum	Least malignant, well differentiated; grows slowly; frequently cystic, near-normal microscopic appearance, noninfiltrating
II	Diffuse astrocytoma, IDH mutant (fibrillary, gemistocytic, protoplasmic) Oligodendroglioma, IDH mutant and 1p/19q codeleted	Common in young adults; more common in cerebrum but can occur in any part of brain	Cytological atypia; grows slowly; infiltrates to adjacent tissue; may be malignant or nonmalignant; may recur at higher grade
III	Anaplastic astrocytoma, IDH mutant Anaplastic oligodendroglioma, *IDH* mutant and 1p/19q codeleted	Common in young adults	Anaplasia and mitotic activity, malignant—diffusely infiltrates adjacent tissue; slow growing, frequently recurs at higher grade
IV	Glioblastoma, *IDH-wildtype*, Diffuse midline glioma, *H3k27M*-mutant	Common in older adults, particularly men Predominant in cerebral hemispheres Predominant in brain stem glioma in children	Anaplasia, mitotic activity with microvascular proliferation, and/or necrosis, reproduce rapidly and are very aggressive malignant tumors

Grade[a]	Selected Types Diffuse Astrocytic and Oligodendroglial	Description	Characteristics
I	Pilocytic astrocytoma	Common in children and young adults and people with neurofibromatosis type 1 or with *BRAF-KIAA* fusion gene mutation; common in cerebellum	Least malignant, well differentiated; grows slowly; frequently cystic, near-normal microscopic appearance, noninfiltrating
II	Diffuse astrocytoma, IDH mutant (fibrillary, gemistocytic, protoplasmic) Oligodendroglioma, IDH mutant and 1p/19q codeleted	Common in young adults; more common in cerebrum but can occur in any part of brain	Cytological atypia; grows slowly; infiltrates to adjacent tissue; may be malignant or nonmalignant; may recur at higher grade
III	Anaplastic astrocytoma, IDH mutant Anaplastic oligodendroglioma, *IDH* mutant and 1p/19q codeleted	Common in young adults	Anaplasia and mitotic activity, malignant—diffusely infiltrates adjacent tissue; slow growing, frequently recurs at higher grade
IV	Glioblastoma, *IDH-wildtype*, Diffuse midline glioma, *H3k27M*-mutant	Common in older adults, particularly men Predominant in cerebral hemispheres Predominant in brain stem glioma in children	Anaplasia, mitotic activity with microvascular proliferation, and/or necrosis, reproduce rapidly and are very aggressive malignant tumors

1p/19q, Combined loss of the short arm chromosome 1p and the long arm of chromosome 19q (inactivation of tumor suppressor gene); *H3k27M*, histone mutation—substitution of lysine amino acid at position 27 with methionine; *IDH*, isocitrate dehydrogenase (a rate-limiting enzyme in the Krebs cycle that plays an important role in energy metabolism); *wildtype*, no genetic mutation or not otherwise specified.

[a]World Health Organization grading system for central nervous system tumors.

Data from Gupta A, Dwivedi T. A simplified overview of World Health Organization Classification Update of Central Nervous System Tumors 2016. *J Neurosci Rural Pract*, 2017;8(4):629–641.

These tumors may occur anywhere in the brain or spinal cord and are generally located in the cerebrum, hypothalamus, or pons. Low-grade astrocytomas tend to be located laterally or supratentorially in adults and in a midline or near-midline position in children (Fig. 18.29).

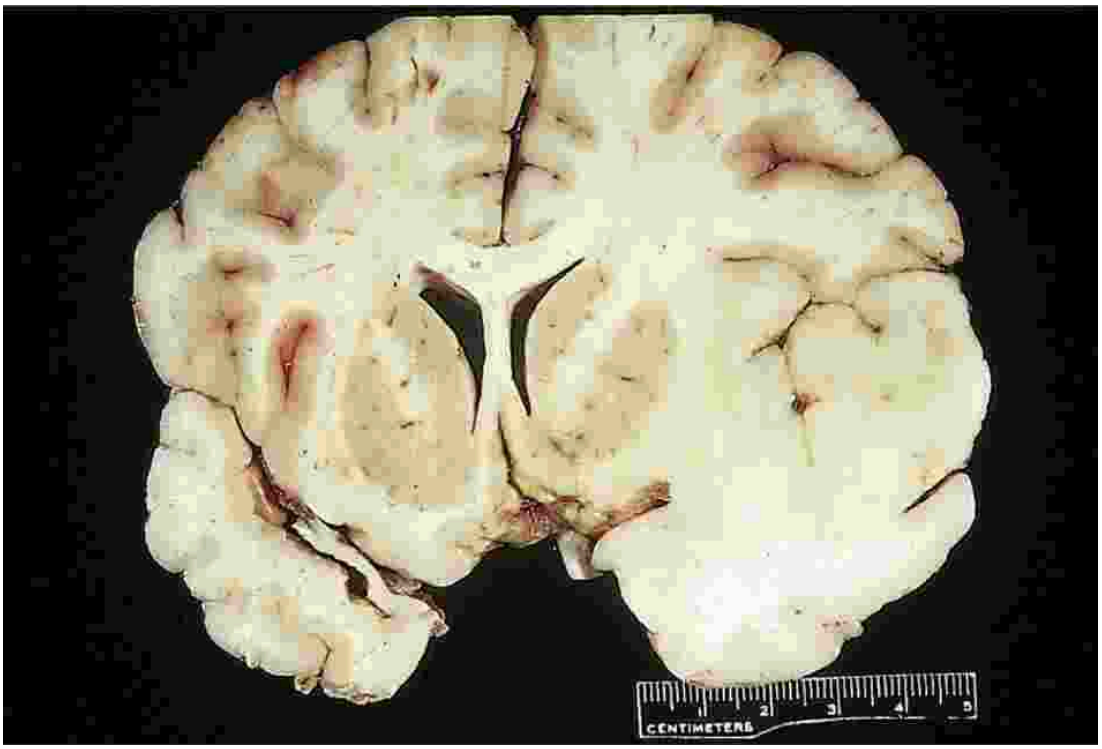

FIG. 18.29 Astrocytoma.

Left panel. The illustration shows the posterior view of a brain. The following sites of intracranial tumors are identified, clockwise from the top: oligodendroglioma, metastatic tumor from lung, cystic astrocytoma of cerebellum, glioblastoma multiforme, and parasagittal meningioma. Right panel. The illustration shows the left lateral view of a brain. The following sires of intracranial tumors are identified, clockwise from the top: frontal astrocytoma, cerebellar medulloblastoma, ependymoma of the fourth ventricle, pituitary adenoma, craniopharyngioma, and sphenoidal ridge meningioma.

Headache (caused by pressure on blood vessels and meninges) and subtle neurobehavioral changes may be early signs. Other neurologic symptoms evolve slowly, and IICP occurs late in the tumor's course. Onset of a focal seizure disorder between the second and sixth decades of life suggests an astrocytoma. Low-grade astrocytomas are treated with surgery or by external radiation. Approximately 50% of persons survive 5 years when surgery is followed by RT.

Grades III and IV astrocytomas are found predominantly in the frontal lobes and cerebral hemispheres, although they may occur in the brainstem, cerebellum, and spinal cord. Men are twice as likely to have astrocytomas as women; in the 15- to 34-year-old age group, they are the third most common brain cancer, whereas in the 35- to 54-year-old age group they are the fourth most common.

A grade IV astrocytoma, known as **glioblastoma**, is the most lethal and common type of primary brain tumor (Fig. 18.30). They are highly vascular and extensively irregular and infiltrative, making them difficult to remove surgically. Fifty percent of glioblastomas are bilateral or at least occupy more than one lobe at the time of death. The typical clinical presentation for a glioblastoma is that of diffuse, nonspecific clinical signs, such as headache, irritability, memory loss, and "personality changes," that progress to more clear-cut manifestations of IICP, including headache on position change, papilledema, vomiting, or seizure activity. Symptoms may progress to include definite focal signs, such as hemiparesis, dysphasia, dyspraxia, cranial nerve palsies, and visual field deficits. Survival at 5 years for grades III and IV astrocytomas is approximately 5% to 10%.

FIG. 18.30 Glioblastoma.

Higher-grade astrocytomas are diagnosed using MRI. 18F-fluorodeoxyglucose positron emission tomography is currently the most common imaging diagnostic tracer for glioblastoma diagnosis and assessment of early therapeutic responses.

These tumors are treated surgically and with radiotherapy and chemotherapy (temozolomide). Recurrence is common, and survival time is less than 5 years for grade III tumors and less than 2 years for grade IV tumors. Bevacizumab is a vascular endothelial growth factor monoclonal antibody that suppresses angiogenesis and blocks the blood supply to the tumor. It has been approved for the treatment of recurrent glioblastoma in the United States and Canada but should not be used prior to entry into a clinical trial because most clinical trials exclude its use.[152] Specificity of treatment is advancing with the development of vaccines, cell therapy (T cells and antibodies), reshaping of the tumor microenvironment (e.g., transforming growth factor [TGF]-β inhibition), RNA-based

therapies, immune checkpoint inhibitors, and modified polio virus. (Cancer treatment is discussed in Chapter 12.)

Oligodendroglioma

Oligodendrogliomas constitute approximately 2% of all primary brain tumors and approximately 10% of all gliomas. They are typically slow-growing, low-grade tumors (grade II). Most oligodendrogliomas are macroscopically indistinguishable from other gliomas, but they often contain mineral deposits, have cysts and areas of bleeding, and carry genetic signatures (*IDH1* or *IDH2* and codeletion of 1p/19q) (see Table 18.16). Histologically they are described as having "fried egg" cells and "chicken-wire" vasculature.[153] Most are found in the frontal and temporal lobes, often in the deep white matter, but they can be found in other parts of the brain and spinal cord. They are slow growing, and malignant degeneration occurs in approximately one-third of affected persons. These tumors are then known as *anaplastic oligodendrogliomas* (grade III).

More than 50% of individuals experience a focal or generalized seizure as the first clinical manifestation. Only half of those with an oligodendroglioma have IICP at the time of diagnosis and surgery, and only one-third develop focal manifestations. Treatment includes surgery, radiotherapy, and chemotherapy or combination therapy, with approximately 74% survival at 5 years.[154,155]

Ependymoma

Ependymomas are nonencapsulated gliomas that arise from ependymal cells (Fig. 18.31). They are rare in adults, usually occurring in the spinal cord. However, in children, ependymomas are typically located in the supratentorial brain or posterior fossa. They constitute approximately 1.6% of all primary brain tumors in adults and approximately 9% of childhood brain and spinal cord tumors.[156] Several molecular subgroups have been identified, and they are guiding the understanding of tumor biology and targeted therapies.[157] Approximately 70% of these tumors occur in the fourth ventricle, with others found in the third and lateral ventricles and posterior portion of the spinal cord. Approximately 40% of infratentorial (cerebellum) ependymomas occur in children younger than 10 years. Cerebral (supratentorial) ependymomas occur at all ages but are more common in children and are WHO grade II or grade III (anaplastic ependymoma). DNA methylation and gene expression profiling has become available to classify these tumors and is used to guide treatment.[158] Fourth ventricle or posterior fossa ependymomas present with difficulty in balance, unsteady gait, uncoordinated muscle movement, and difficulty with fine motor movement. CT scan and MRI imaging are completed for diagnosis. The clinical manifestations of a lateral and third ventricle ependymoma that involves the cerebral hemispheres are seizures, visual changes, and hemiparesis. Blockage of the CSF pathway produces hydrocephalus and presents with headache, nausea, and vomiting. Spinal cord ependymomas cause back pain, lower extremity weakness, and/or bowel and bladder dysfunction. The interval between first manifestations and surgery may be as short as 4 weeks or as long as 7 or 8 years. Ependymomas are treated with surgery, radiotherapy, and chemotherapy. Overall, approximately 80% to 90% of persons survive 5 years, and survival is related to tumor recurrence presence of anaplastic histology and gene profile.[159]

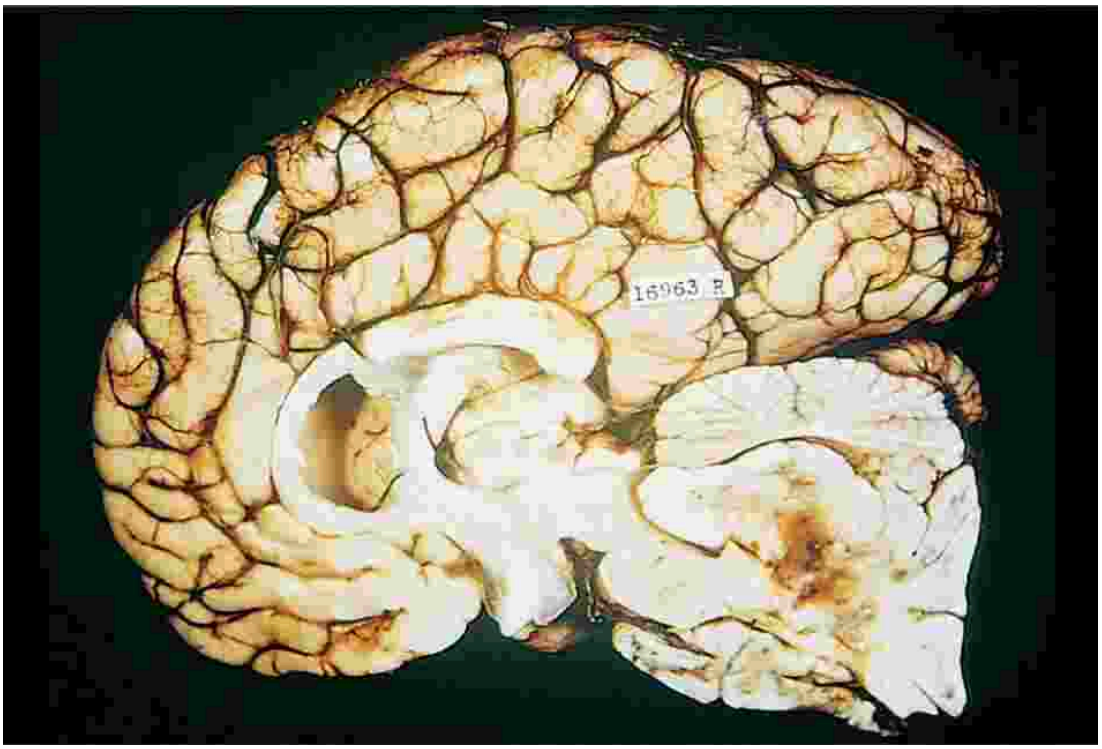

FIG. 18.31 Ependymoma.

A closeup of a cross-section of a brain specimen shows the left hemisphere larger than the right hemisphere and a measuring scale below. The lower left part of the specimen shows discolored areas and lesions.

Primary Extracerebral Tumors

Meningioma

Meningiomas are the most common intracranial tumor and constitute approximately a third of all intracranial tumors and are usually benign and slow growing. Most occur in adults aged 65 years or older.[154] Predisposing factors include neurofibromatosis (NF) type 2 (NF2; see Nerve Sheath Tumors), ionizing radiation exposure after a several-decade latency period, and obesity.[160] Formation of benign meningiomas has been linked to *NF2* gene mutation, chromosome 22q12–2 loss, and *DAL-1* loss on chromosome 18. Atypical and anaplastic meningiomas have been linked to additional gene alterations involving other multiple chromosomes. They are resistant to treatment.[161] These tumors usually originate from the arachnoidal (meningeal) cells in the pia mater and the trabeculae and septae of the subarachnoid space. There are three grades of tumor: grade I benign meningioma (>80%), grade II atypical meningioma (15% to 20%), and grade III anaplastic meningioma (1.0% to 3.0%)

Meningiomas are commonly located within in the olfactory grooves, on the wings of the sphenoid bone (at the base of the skull), in the tuberculum sellae (next to the sella turcica), on

the superior surface of the cerebellum, and in the cerebellopontine angle and spinal cord (Fig. 18.32). Rarely, they can involve the optic nerve sheath, with loss of visual acuity. The cause of meningiomas is unknown.

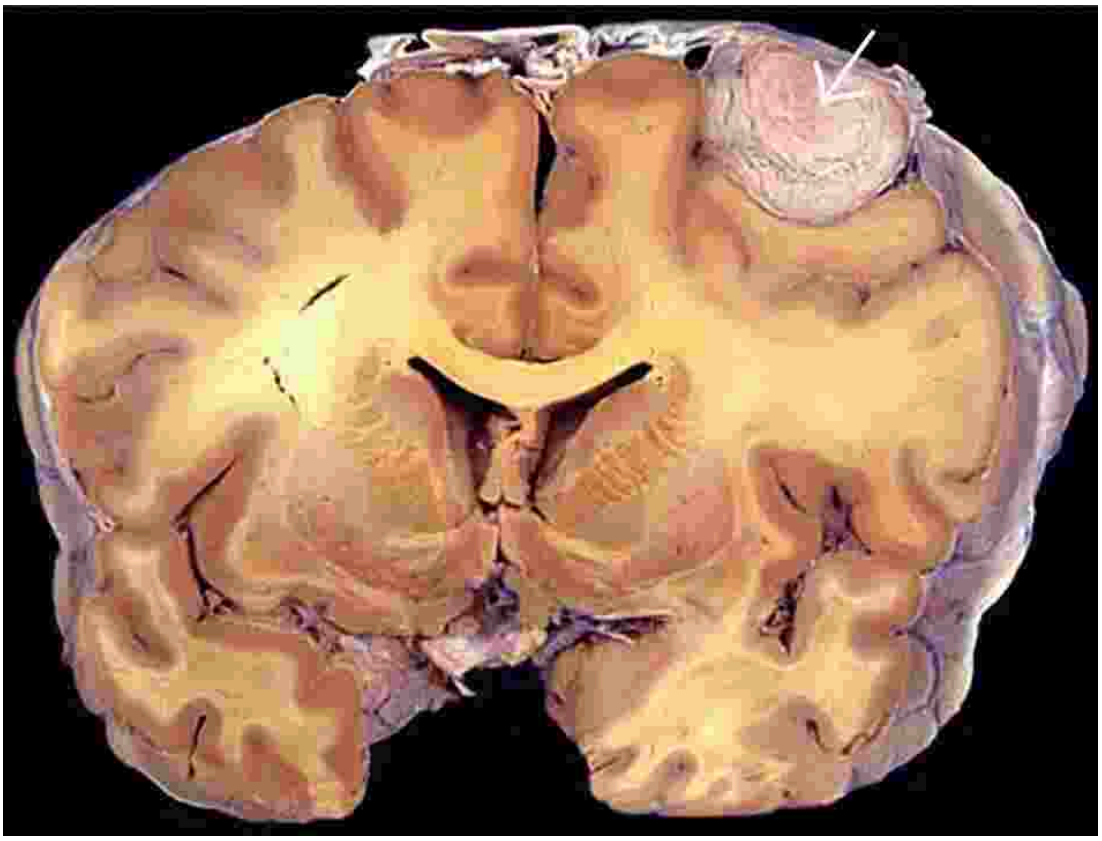

FIG. 18.32 Meningioma.

A meningioma is sharply circumscribed and adapts to the shape it occupies. It may extend to the dural surface and erode the cranial bones or produce an osteoblastic reaction. Meningiomas are slow growing, and clinical manifestations occur when they reach a certain size and begin to press on the brain tissue. Focal seizures are often the first manifestation, and IICP is less common than with gliomas because they are slow growing. Other symptoms are related to the site of tumor location. Diagnosis is made using MRI, contrast-enhanced CT, or both. The primary treatment is surgical resection, radiotherapy, and rarely chemotherapy.[162] The recurrence rate is higher with higher-grade tumors.[163]

Nerve sheath tumors

Neurofibromas (benign nerve sheath tumors) are a group of autosomal dominant disorders of the nervous system. They may be inherited or develop sporadically as a spontaneous mutation. They include neurofibromatosis type 1 (NF1), previously known as von Recklinghausen disease, and NF2. The two types are also known as *peripheral* and *central NF*, respectively. **Schwannomatosis**, also known as NF3, is very rare. It is characterized by multiple schwannomas in the absence of bilateral vestibular schwannomas, and approximately 15% are inherited with mutation in the *MARCB1 or LZTR1* genes (tumor

suppressor genes). The primary symptom is chronic pain. Diagnostic criteria are available for all three types of neurofibromas.[164]

Neurofibromatosis type 1 (NF1) is the most prevalent, with an incidence of approximately 1 in 3500 people. *Neurofibromin 1* is a gene that encodes the protein neurofibromin, a tumor suppressor (prevents cells from growing and dividing too rapidly), primarily in adult neurons. Mutations of *neurofibromin 1* cause multiple cutaneous neurofibromas, cutaneous light brown macular lesions (café au lait spots and freckles). Less commonly, there are bone and soft tissue tumors. Gliomas may develop in some cases.[165] Inactivation of the *neurofibromin 1* gene results in loss of function of neurofibromin in Schwann cells (produce the myelin sheath around axons) and promotes tumorigenesis (neurofibromas). Cognitive and learning disabilities are present in approximately 50% of affected individuals.[166]

Neurofibromatosis type 2 (NF2) is rare and occurs in approximately 1 in 40,000 to 60,000 people. The *neurofibromin 2 (NF2)* gene product is neurofibromin 2 or merlin, a tumor-suppressor protein that inhibits cell growth. Mutations promote development of CNS tumors, particularly schwannomas, although other tumor types can occur (meningiomas, ependymomas, astrocytomas, and neurofibromas). Schwannomas of the vestibular nerves present with hearing loss and deafness, loss of balance, and dizziness. Schwannomas also may develop in other cranial, spinal, and peripheral nerves. In these cases, cutaneous signs of flesh colored skin flaps and muscle wasting occur.

Genetic testing is available for the management of families susceptible to neurofibromas, and prenatal diagnosis is possible. Diagnosis is based on clinical manifestations and neuroimaging studies. Surgery is the major treatment, and tumors may regrow. Targeted therapy has been used with some success, and several agents are in clinical trials.[164] Individuals with NF2 have extensive morbidity and reduced life expectancy, particularly with early age of onset. Genetically tailored drugs are likely to provide personalized therapy for both devastating conditions.

Metastatic brain tumors

Metastatic brain tumors from systemic cancers are 10 times more common than primary brain tumors, and approximately 20% to 40% of persons with cancer have metastasis to the brain.[167] Mechanisms of metastasis are presented in Chapter 12. Common primary sites include the lung, breast, and skin (e.g., melanomas). Metastasis to the brain is thought to be through vascular channels, although some cancer cells may travel along nerves or through the lymphatics.[168] The cancer cells tend to localize to the cerebral hemispheres, where there is the greatest blood flow.[169]

Metastatic brain tumors produce signs resembling those of glioblastomas, although several unusual syndromes do exist. Carcinomatous (metastatic cancer) encephalopathy causes headache, nervousness, depression, trembling, confusion, forgetfulness, and gait disorder. In carcinomatosis of the cerebellum, headache, dizziness, and ataxia are found. Carcinomatosis of the craniospinal meninges (also called *carcinomatous meningitis*) manifests with headache, confusion, and symptoms of cranial or spinal nerve root dysfunction. Diagnosis is made from clinical signs and imaging. Metastatic brain tumors carry a poor prognosis. Treatment is guided by the pathology of the original tumor; the number, size, and location of the brain metastasis; and prior cancer treatments. Treatment options include various combinations of surgery, radiotherapy, targeted agents, and immunotherapy.[170,171] Survival time is approximately 1 year.

Spinal Cord Tumors

Primary spinal cord tumors are rare and represent approximately 2% of CNS tumors. They may be extramedullary extradural, intradural extramedullary, or intradural intramedullary. Intramedullary tumors are least common and originate within the neural tissues of the spinal cord. They are primarily gliomas (astrocytomas, ependymomas, hemangioblastomas). Gliomas are difficult to resect completely, and radiotherapy is required. Spinal ependymomas may be completely resected and are more common in adults. Extramedullary tumors originate from tissues outside the spinal cord. Extramedullary tumors are either peripheral nerve sheath tumors (neurofibromas or schwannomas) or meningiomas. Neurofibromas are generally found in the thoracic and lumbar region, whereas meningiomas are more evenly distributed through the spine. Complete resection of these tumors can be curative.

Metastatic spinal cord tumors are usually carcinomas (i.e., from breast, lung, or prostate cancer), lymphomas, or myelomas. Their location is often extradural, the cancer having proliferated to the spine through direct extension from tumors of the vertebral structures or from extraspinal sources extending through the interventricular foramen or bloodstream.

Pathophysiology

Intramedullary spinal cord tumors produce dysfunction by both invasion and compression. Extramedullary spinal cord tumors produce dysfunction by compressing adjacent tissue, not by direct invasion. Metastases from spinal cord tumors occur from direct extension or seeding through the CSF or bloodstream.

Clinical Manifestations

An acute onset of clinical manifestations suggests a vascular occlusion of vessels supplying the spinal cord, whereas gradual and progressive symptoms suggest compression. The **compressive syndrome (sensorimotor syndrome)** involves both the anterior and the posterior spinal tracts, and motor function and sensory function are affected as the tumor grows. Pain is usually a presenting symptom.

The **irritative syndrome (radicular syndrome)** combines the clinical manifestations of a cord compression with radicular pain that occurs in the sensory root distribution and indicates root irritation. The segmental manifestations include segmental sensory changes, such as paresthesia and impaired pain and touch perception; motor disturbances, including cramps, atrophy, fasciculations, and decreased or absent deep tendon reflexes; and continuous spinal pain.

Evaluation and Treatment

The diagnosis of a spinal cord tumor is made through imaging techniques, CT-guided needle biopsy, or open biopsy. Involvement of specific cord segments is established. Any metastases also are identified. Treatment varies, depending on the nature of the tumor and the person's clinical status, but surgery is essential for all spinal cord tumors. Targeted immunotherapies and image-guided RT are improving survival.[172]

Summary Review

Central Nervous System Disorders

Traumatic Brain Injury

1. TBI is an alteration in brain function caused by an external force. The most common causes of TBI are falls, unintentional blunt trauma, and motor vehicle accidents. TBI is classified as primary or secondary.
2. Primary brain injury is caused by direct impact and involves neural injury, primary glial injury, and vascular responses. Primary brain injuries can be focal (involving only one area of the brain) or diffuse (involving more than one area of the brain).
3. Secondary injury is an indirect consequence of the primary injury.
4. Severity of TBI is graded using the GCS.
5. Causes of focal brain injury include closed (blunt) trauma or open (penetrating) trauma.
6. Closed trauma is more common and involves the head striking a surface or an object striking the head. These injuries include contusion, EDH, SDH, and ICH. Injury may be caused by coup or contrecoup injury or both.
7. A contusion (bruising of the brain) is caused from blood leaking from an injured vessel.
8. Head trauma can result in a hematoma. Hematomas can be classified as an EDH (accumulation of blood above the dura mater), SDH (blood between the dura mater and arachnoid membrane), or ICH (bleeding into the brain).
9. Open brain injury involves a skull fracture with exposure of the cranial vault to the environment and may result from compound skull fractures and missile injuries. Open brain injury can produce both focal and diffuse injuries.
10. DAI results from mechanical forces of acceleration, deceleration, and rotation that cause stretching and shearing of axons and can only be seen microscopically. The injury can be mild, moderate, or severe.
11. Secondary brain injury develops from systemic and intracranial responses to primary brain trauma that result in further brain injury and neuronal death (i.e., trauma or stroke).
12. Categories of TBI are mild, moderate, and severe and are based on the GCS, duration of loss of consciousness, posttraumatic amnesia, and brain imaging results.
13. Complications of TBI include postconcussion syndrome, posttraumatic seizures, and CTE.

Spinal Cord and Vertebral Injury

1. Spinal cord and vertebral injury involve damage to neural tissues by compressing tissue, pulling, or exerting tension on tissue, or shearing tissues so that they slide into one another. Vertebral fracture occurs with direct or indirect trauma.
2. SCI involves primary and secondary injury similar to the processes of TBI. Primary SCI involves damage to vertebral or neural tissues from shearing, compression, or traction forces. Secondary SCI is related to edema, ischemia, excitotoxicity, inflammation, oxidative damage, and activation of necrotic and apoptotic cell death and begins within minutes after injury and continues for weeks.
3. SCI may cause spinal shock with temporary cessation of all motor, sensory, reflex, and autonomic functions below the lesion. Spinal shock generally lasts 2 to 3 days.
4. Neurogenic shock (vasogenic shock) is caused by loss of sympathetic nerve activity and occurs with cervical or upper thoracic cord injury (above T6) and can occur concurrently with spinal shock. Symptoms include vasodilation, hypotension, bradycardia, and loss of temperature control.

5. Loss of motor and sensory function depends on the extent and level of injury. Paralysis of the lower half of the body with both legs involved is called paraplegia. Paralysis involving all four extremities is called quadriplegia.
6. Return of spinal neuron excitability occurs slowly. Spasticity and hyperreflexia are common. Reflex activity can return in 1 to 2 weeks in most people with acute SCI.
7. Autonomic hyperreflexia (dysreflexia) is a severe, life-threatening complication associated with a SCI at level T6 or above where descending inhibition is blocked resulting in autonomic nervous system dysregulation. Autonomic hyperreflexia requires emergency medical management.

Degenerative Disorders of the Spine

1. Degenerative disorders of the spine include LBP, degenerative joint disease, and herniated intervertebral disk.
2. LBP is pain between the lower rib cage and gluteal muscles and often radiates into the thigh. Common causes of chronic LBP include DDD, disk prolapse, tumor, bursitis, synovitis, osteoporosis, hyperparathyroidism, fracture, inflammation, and sprain. Other causes are tension, inflammation, referred pain, and bone diseases.
3. Degenerative joint disease includes DDD, spondylolysis, spondylolisthesis, spinal stenosis, spinal osteochondrosis, and lumbar disk herniation.
4. Spondylolysis is a structural defect of the spine with displacement of the vertebra.
5. Spondylolisthesis involves forward slippage of the vertebra and can include a crack or fracture of the pars interarticularis, usually at the L5 to S1 vertebrae.
6. Spinal stenosis is a narrowing of the spinal canal that causes pressure on the spinal nerves or cord.
7. DDD is an alteration in intervertebral disk tissue and can be related to normal aging, inflammation, and compression.
8. Herniation of an intervertebral disk is a protrusion of part of the nucleus pulposus. Herniation most commonly affects the lumbosacral disks (L5 to S1 and L4 to L5). The extruded pulposus compresses the nerve root, causing pain that radiates along the sciatic nerve course.

Seizure and Epilepsy

1. Seizures represent abnormal, excessive hypersynchronous discharges of cortical neurons with transient alterations in brain function.
2. Epilepsy is a cause of seizures and a disease of the brain. The criterion for epilepsy includes at least two unprovoked seizures occurring more than 24 hours apart and one unprovoked seizure after two unprovoked seizures, occurring over the next 10 years and a diagnosis of an epilepsy syndrome.
3. Seizures may be focal or generalized. The categories of seizures include genetic, structural, metabolic, immune, infectious, and unknown.

Cerebrovascular Disease

1. CVD is the most frequently occurring neurologic disorder and is any abnormality of the brain caused by a pathologic process in the blood vessels The brain abnormalities seen with CVD are either ischemia (with or without infarction) or hemorrhage.

2. CVAs (stroke syndromes) are a common clinical manifestation of CVD. Strokes are classified pathophysiologically as ischemic or hemorrhagic (intracranial hemorrhage).
3. TIAs are temporary decreases in brain blood flow with an increased risk of stroke.
4. Ischemic stroke occurs when there is obstruction to arterial blood flow to the brain from thrombus formation (thrombotic stroke), an embolus (embolic stroke), or hypoperfusion related to decreased blood volume or heart failure (hemodynamic stroke). The inadequate blood supply results in ischemia and can progress to infarction.
5. Lacunar strokes are caused by ischemia from occlusion of a small vessel deep in the brain.
6. Hemorrhagic strokes occur within brain tissue (intracerebral) or in the subarachnoid or subdural space. The primary cause of intracerebral hemorrhagic stroke is chronic hypertension.
7. Intracranial aneurysms result from defects in the vascular wall and are classified based on form and shape. They are often asymptomatic, but the signs vary depending on the location and size of the aneurysm. They are a cause of SAH.
8. An SAH occurs when blood escapes from defective or injured vasculature into the subarachnoid space. When a vessel tears, blood under pressure is pumped into the subarachnoid space. The blood produces an inflammatory reaction in these tissues and IICP.
9. An AVM is a mass of dilated blood vessels. Although sometimes present at birth, AVM exhibits a delayed age of onset with symptoms ranging from headache and dementia to seizures and ICH or SAH. Vasospasm and delayed cerebral ischemia are serious complications.

Primary Headache Syndromes

1. Headache is a common neurologic disorder and is usually a benign symptom. Chronic recurring headaches include migraine, cluster, and tension headaches.
2. Migraine headache is an episodic headache lasting 4 to 72 hours that can be associated with triggers and may have an aura associated with a CSD that alters cortical blood flow. Pain is related to overactivity in the trigeminal vascular system.
3. Cluster headaches are a group of disorders known as trigeminal autonomic cephalalgias and occur primarily in men. They occur in clusters over a period of days, with extreme pain intensity and short duration, and are associated with trigeminal nerve activation.
4. TTH is the most common recurrent headache. Episodic-type headaches involve a peripheral pain mechanism, and the chronic type involves a central pain mechanism and may be related to hypersensitivity of pain fibers from the trigeminal nerve.

Infection and Inflammation of the Central Nervous System

1. Infection and inflammation of the CNS can be caused by bacteria, viruses, fungi, parasites, and mycobacteria.
2. Meningitis is inflammation of the brain or spinal cord and is classified as bacterial (i.e., meningococci), aseptic (viral or nonpurulent), or fungal. Bacterial meningitis primarily is an infection of the pia mater, the arachnoid, and the fluid of the

subarachnoid space. Viral (aseptic) meningitis is thought to be limited to the meninges. Fungal meningitis is a chronic, less common type of meningitis.
3. Encephalitis is an acute inflammation of the brain, usually of viral origin. The most common forms are caused by bites of mosquitos, ticks, or flies and by and herpes simplex type 1. Meningeal involvement appears in all encephalitides. Herpes encephalitis is treated with antiviral agents.
4. WNV is the most common cause of epidemic meningoencephalitis in North America and the leading cause of arboviral encephalitis in the United States.
5. Brain or spinal cord abscesses often originate from infections outside the CNS. Microorganisms gain access to the CNS from adjacent sites or spread along the wall of a vein. Brain abscesses progress from localized inflammation to a necrotic core with the formation of a connective tissue capsule, usually within 14 days or longer.
6. The common neurologic complication of AIDS is HAND, a range of disorders that includes mild neurocognitive disorder and HIV-associated dementia. The onset of clinical manifestations includes neurocognitive impairment, behavioral disturbance, and motor abnormalities.

Peripheral Nervous System and Neuromuscular Junction Disorders

1. Acute or chronic disease processes, inflammation, or trauma may injure these peripheral nerves and cause neuropathy.
2. Injury to peripheral nerves by disease processes, inflammation, or trauma can cause a neuropathy. Neuropathies can be mononeuropathies (affecting a single nerve), multiple mononeuropathies (involving two or more individual nerves), polyneuropathy (generalized involvement of peripheral nerves), or autonomic neuropathies (involving the nervous system).
3. Radiculopathies are disorders of spinal nerve roots as they enter (sensory) or exit (motor) the spine

Tumors of the Central Nervous System

1. Tumors within the cranium can be primary intracerebral, primary extracerebral, or metastatic (secondary).
2. Primary intracerebral tumors originate from brain substance and include astrocytomas, oligodendrogliomas, glioblastoma multiforme, and ependymomas.
3. Extracerebral tumors originate outside of the substances of the brain and include meningiomas and nerve sheath tumors.
4. Metastatic tumors arise in organ systems outside the brain and spread to the brain. Common primary sites include lung, breast, skin, kidney, and colorectal areas.
5. Brain tumors cause local and generalized manifestations. Manifestations include headache, seizures, visual disturbances, unstable gain, and cranial nerve dysfunction.
6. Spinal cord tumors are classified as intramedullary tumors (within the neural tissues) or extramedullary tumors (outside the spinal cord). Metastatic spinal cord tumors are usually carcinomas, lymphomas, or myelomas.
7. Intramedullary spinal cord tumors produce dysfunction by both invasion and compression. Extramedullary spinal cord tumors produce dysfunction by

compression of adjacent tissue, not by direct invasion.

Neurobiology of Schizophrenia, Mood Disorders, Anxiety Disorders, Posttraumatic Stress Disorder, and Obsessive-Compulsive Disorder

Lorey K Takahashi

http://evolve.elsevier.com/Rogers/pathophysiology/

Chapter Outline

OUTLINE

Schizophrenia 618

Mood Disorders: Depression and Bipolar Disorder 623

Anxiety Disorders 630
- Panic Disorder 631
- Social Anxiety Disorder 632
- Generalized Anxiety Disorder 632

Posttraumatic Stress Disorder 633

Obsessive-Compulsive Disorder 634

Mental illnesses are common and found in different cultures and across the socioeconomic spectrum. When left untreated, the consequences can be devastating. This chapter introduces the neurobiology of schizophrenia, mood disorders, posttraumatic stress disorder, obsessive-compulsive disorder, and some anxiety disorders. The etiology and pathophysiology of mental illnesses are diverse and complex. Diagnostic criteria are constantly being updated to more precisely diagnose and effectively treat the disorders. Every mental disorder manifests a range of symptoms that vary in intensity. Symptom variations likely reflect individual differences in pathologic brain structures and functions, which affect treatment. The onset and progression of mental disorders, which may originate in early life, point to the challenge in understanding how gene expression and environmental risk factors interact to disrupt adaptive brain functions.

The use of visual and quantitative structural and functional neuroimaging techniques provides insight into the pathophysiologic basis of mental disorders. In schizophrenia, neuroanatomic, functional, and neurochemical alterations associated with this debilitating illness have uncovered abnormal brain regions along with a host of candidate genes that confer risk. Similarly, in mood and anxiety disorders, brain scans are revealing structural and functional abnormalities. Notably, many brain regions implicated in normal cognitive and emotional processing are found in schizophrenia, mood, and anxiety disorders. The future lies in unraveling how the highly interconnected brain structures modulated by neurotransmitters, neuropeptides, enzymes, and hormones operate in normal to abnormal mental states.

Knowledge of the pathophysiology associated with a specific mental illness has guided the development of new psychopharmacologic medications with fewer side effects. However, some individuals with mental disorders do not respond to current medications or may relapse after a period of treatment. The use of psychotherapies alone or as an adjunct to pharmacotherapy also may be effective in treating some disorders by making the person aware of potential environmental factors that trigger stress and the onset of the illness. Learning to cope with these triggers offers hope for alleviating psychiatric symptoms or attenuating pathophysiologic functions.

Schizophrenia

Schizophrenia is a serious psychiatric illness that strikes 1% of the world's population. The illness is equally prevalent in males and females and emerges in young adults during the late teens and early twenties, with a slightly earlier onset in males than in females. Emil Kraeplin first described schizophrenia as “dementia praecox” in 1883.[1] Later, Eugen Bleuler, in 1911 coined the term schizophrenia to describe a cluster of symptoms characterized by thought disorders, or the discontinuity among thoughts, emotions, and behaviors,[2] which reflect a break in reality or splitting of the cognitive from the

emotional side of one's personality. An individual with schizophrenia may exhibit a feeling of happiness when recollecting a terrible event or emotional indifference when describing a joyful occasion. Today, schizophrenia is characterized by positive and negative symptoms. Positive symptoms include auditory hallucinations; visual hallucinations; olfactory, tactile, and gustatory hallucinations; and paranoid or grandiose delusions. Negative symptoms include anhedonia, avolition, alogia, flattened affect, and cognitive deficits that have devastating effects on the individual and the individual's family.

Genetic Predisposition

Etiology and Pathophysiology

Schizophrenia is a heritable disorder. In monozygotic twins, the concordance rate varies from 30% to 50%. This variability may stem from different diagnostic criteria and methodologic or sampling differences across studies. In dizygotic twins and siblings, the concordance rate decreases to 12%, which is still considerably higher than the 1% figure found in the general population.

Nonetheless, schizophrenia is not a simple genetic disorder in which inherited disease alleles will always lead to illness. Schizophrenia likely involves several genes located on different chromosomes and differs from mendelian disorders, in which genes are fully penetrant and recognized as the primary cause of disease (e.g., genes for Huntington disease). As indicated by the 50% concordance rate in monozygotic twins, the genes for schizophrenia show reduced penetrance, resulting in individuals who carry the disease genes without manifesting the illness.

Studies searching for candidate genes associated with schizophrenia have begun to use genome-wide association studies, to identify a number of genes including dysbindin, neuroregulin 1, and disrupted-in-schizophrenia-1 (DISC1). However, the traits of schizophrenia are complex, and candidate genes have not always been directly implicated in the disease.[3] Thus, variability in biological and phenotypic traits among individuals who manifest

the illness complicates the understanding of specific genetic underpinnings of schizophrenia.

Prenatal and perinatal vulnerability factors

Because the concordance rate of schizophrenia in monozygotic twins is never 100% as in mendelian disorders, environmental factors likely play an important role in increasing or decreasing the risk of developing the disorder. A leading hypothesis suggests that early environmental factors interfere with genetically programmed neural developmental alterations that eventually compromise normal brain structures and functions.[4]

An early brain defect may remain silent and not dramatically affect the individual until subsequent development requires adaptive use of brain structures.[5] Several hypothesized early environmental factors that may alter brain development and increase the risk of developing schizophrenia include exposure to prenatal infection, prenatal nutritional deficiencies, perinatal complications (such as birth defects and neonatal hypoxia), and upbringing in an urban environment.[6,7]

Neuroanatomic and Functional Abnormalities

Neuroanatomic alterations

Advanced neuroimaging techniques have revealed structural brain abnormalities in schizophrenia.[8,9] A consistent finding is the enlargement of the lateral and third ventricles and the widening of frontocortical fissures and sulci (Fig. 19.1). Generally, individuals with schizophrenia and cerebral vascular enlargement exhibit cognitive impairment, negative symptoms, and respond poorly to treatment. Other studies reported a reduction in the thalamus and temporal lobe areas (e.g., amygdala, hippocampus, and parahippocampal gyrus).[10] A reduction in thalamus size may disrupt neurotransmission between the frontal cortex and primary sensory and motor areas. Hippocampal volume loss in the first years of the illness is another consistent finding, and hippocampal volume

reduction accelerates in individuals with schizophrenia older than 50 years of age.[11] This hippocampal atrophy is strongly associated with global cognitive and socio-occupational functional impairments, which also may reflect a fronto-hippocampal disconnection in socio-cognitive processing.

FIG. 19.1 Magnetic Resonance Imaging Comparison of Normal Brain and Brain With Schizophrenia.
Three-dimensional magnetic resonance imaging reconstructions showing (A) the cerebral ventricles *(gray regions)* and hippocampus *(yellow regions)* of an individual with schizophrenia, and (B) those of a healthy individual. Note the enlarged cerebral ventricles and reduced hippocampal volume of the brain of the schizophrenic individual. (From Gershon ES, Rieder RO. Major disorders of mind and brain. *Scientific American*, 1992;267:128. Original illustrations by Nancy C. Andreason, University of Iowa.)

The amygdala plays a central role in the social brain emotional processing network.[12] Abnormal amygdala connectivity is widely reported in schizophrenia and hypothesized to represent the basis underlying pronounced difficulties for individuals with schizophrenia to make appropriate social judgments as found in tests of facial identity, affect recognition, and in emotional processing.[13] Reported amygdala abnormalities in schizophrenia include reduced volume[10] and abnormal functional activation patterns for social and emotion processing.[14] The emergence of abnormal amygdala projections to brain regions such as the hippocampus during late adolescence and young adulthood may be linked to the onset of schizophrenia.

Brain imaging studies in adolescents with early-onset schizophrenia reveal progressive loss of cortical gray matter in temporal lobes, somatosensory and motor cortices, and the dorsolateral cortex (Fig. 19.2). Of clinical concern is the loss of cortical tissue, which is evident by the time the individual seeks treatment and continues throughout the course of the illness despite the use of antipsychotic medication.[15] The progressive loss in frontal lobe volume is accompanied by increased severity of negative

symptoms and further reductions in cognitive functioning. These results highlight the ineffectiveness of current medications for schizophrenia to attenuate or reverse the loss of frontal brain tissue.

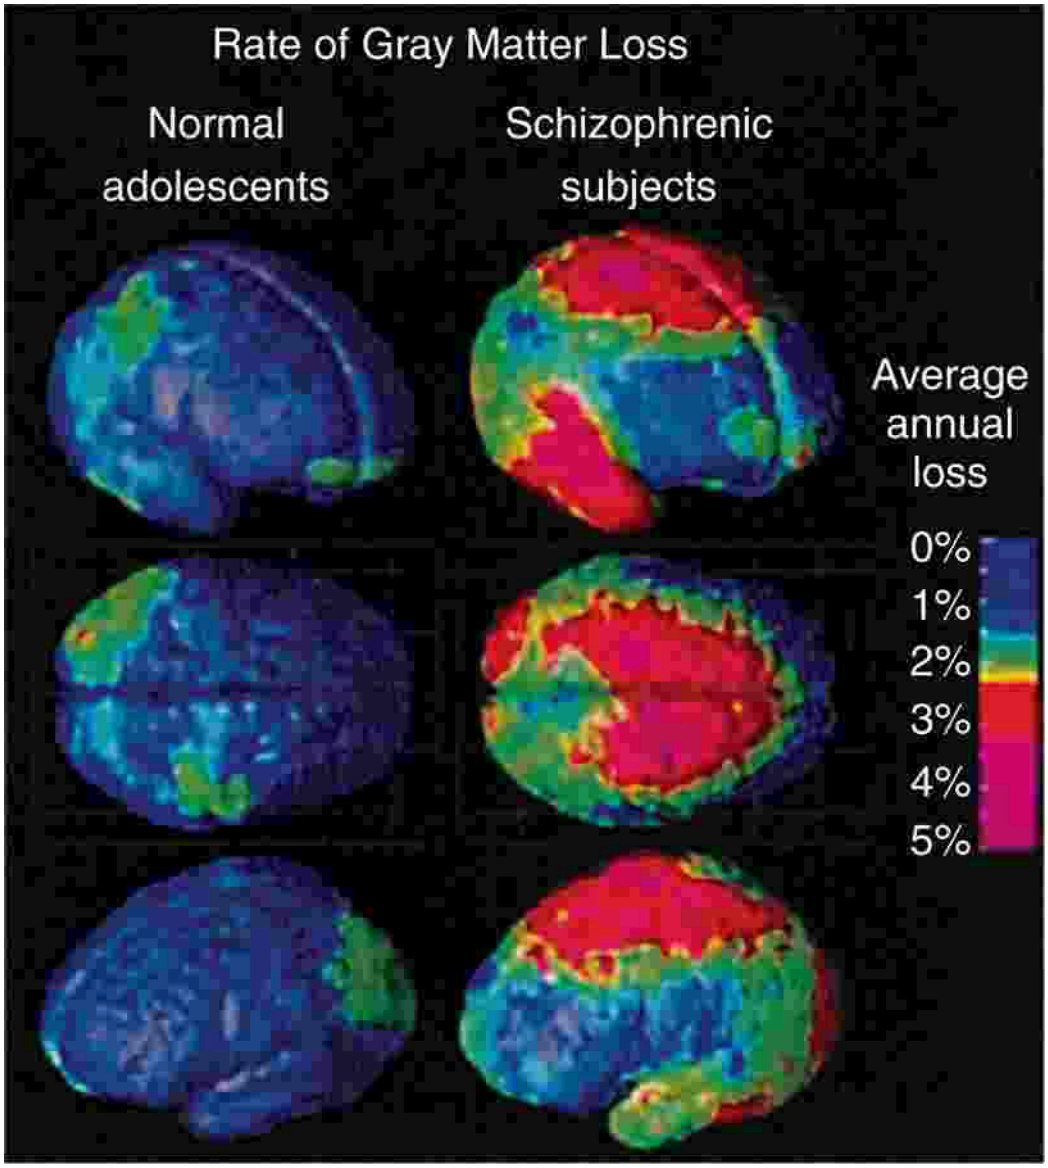

FIG. 19.2 Accelerated Gray Matter Loss in Brains of Early-onset Schizophrenic Adolescents.

Annual gray matter loss ranging from 2% to 5% was found in 13- to 18-year-old schizophrenics—compared with age-matched healthy adolescents. (From Thompson PM, Vidal C, Giedd JN, et al. Mapping adolescent brain change reveals dynamic wave of accelerated gray matter loss in very early-onset schizophrenia. *Proceedings of the National Academy of*

Sciences of the United States of America, 2001;98:11650.)

Three-dimensional maps of brain changes derived from high-resolution magnetic resonance images with scalar fields represent the rate of gray matter loss in parietal, frontal, and temporal cortices observed in independent groups of normal adolescents and schizophrenic subjects. The average annual loss ranges from 0 percent to 1 percent in normal adolescents and 2 percent to 5 percent in schizophrenic subjects.

Brain abnormalities in schizophrenia are believed to originate in the prenatal period of cell proliferation, myelination, receptor functions, and migration. For example, Reelin, an extracellular matrix protein involved in neuronal migration during development and in synaptic function during adulthood, is reduced in the prefrontal cortex and hippocampus of individuals with schizophrenia.[16] Neuregulin-1 (Nrg1) may also alter brain development in schizophrenia. Nrg1 is widely distributed in the frontal cortex, midbrain, and cerebellum and is involved in regulating myelination, neuronal migration, and neurotransmitter receptor functions.[16,17] Deficits in these processes may impair executive functions such as attention and working memory as noted in schizophrenia. Working memory involves the brief storage and use of information to complete cognitive tasks such as language comprehension, learning, and reasoning.

Pathophysiologic changes in the dorsal prefrontal cortex are believed to contribute to the production of negative symptoms in schizophrenia (Fig. 19.3). In particular, the dorsolateral prefrontal cortex (DLPFC) (Brodmann areas 9, 10, 46, and 47) is intricately

involved in the initiation and maintenance of goal-directed activities and in solving cognitive problems related to working memory. Blood flow and metabolism normally increase in the DLPFC during working memory processing but not in schizophrenics, who also perform poorly in tests of working memory. Thus, the DLPFC appears to be hypoactive in schizophrenia.

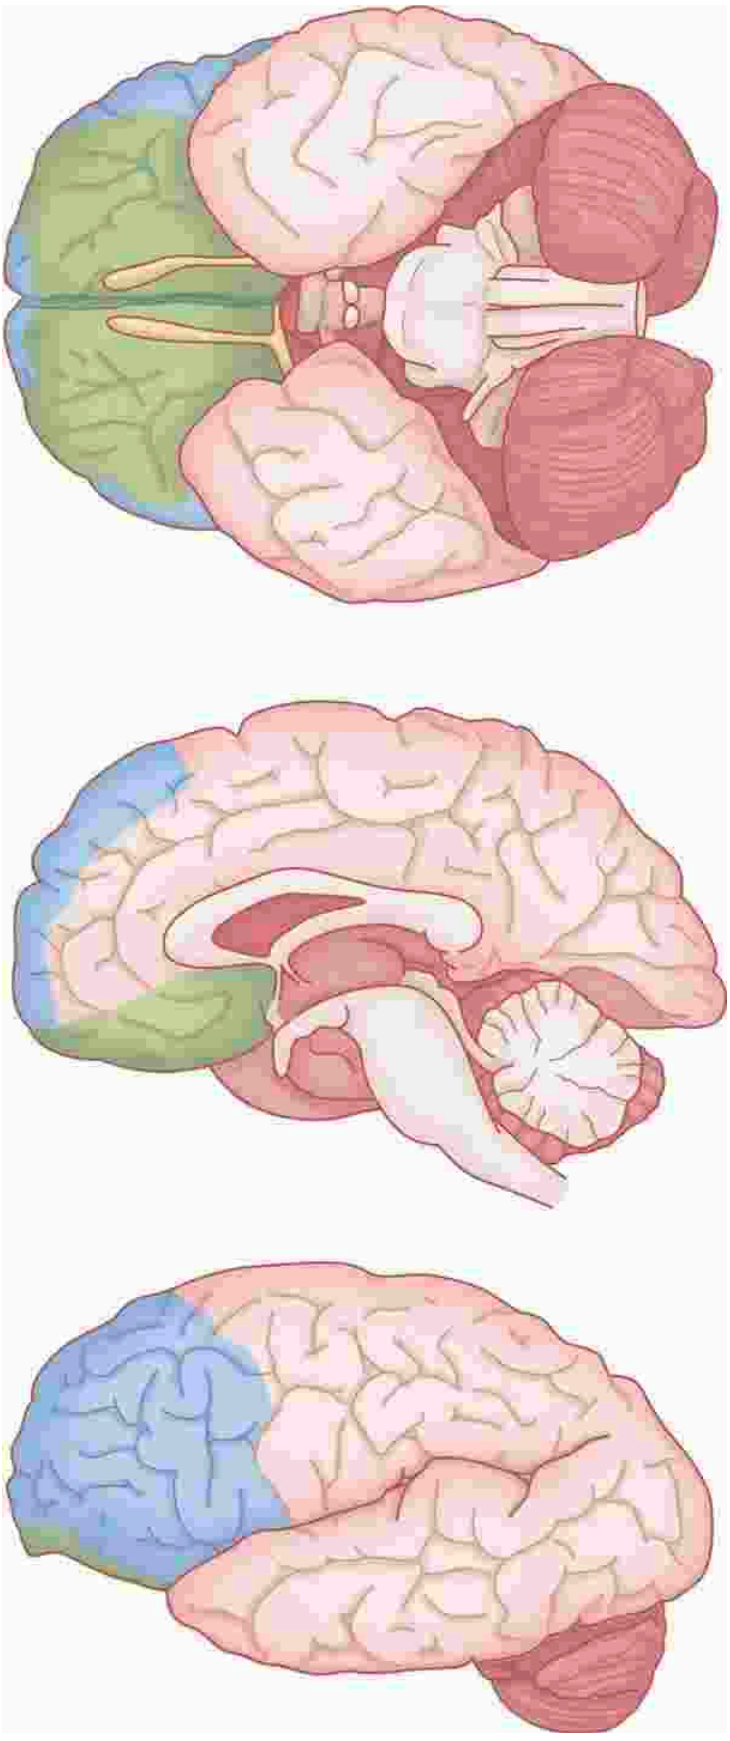

FIG. 19.3 The Prefrontal Cortex.
The prefrontal cortex consists of a dorsolateral *(blue)* and an orbitofrontal *(green)* region.

Three illustrations of the brain show the anatomical position of the prefrontal cortex, indicating dorsolateral and orbitofrontal regions. The first illustration depicts the brainâ€™s ventral view showing the anatomical position of the prefrontal cortex, indicating dorsolateral and orbitofrontal regions. The second illustration depicts the sagittal section of the brain showing the anatomical position of the prefrontal cortex, indicating dorsolateral and orbitofrontal regions. The third illustration depicts the lateral view of the brain showing the anatomical position of the prefrontal cortex, indicating dorsolateral and orbitofrontal regions.

Neurotransmitter alterations

The onset of schizophrenia was initially hypothesized to stem from abnormally high concentrations of the brain neurotransmitter dopamine. This dopamine hypothesis of schizophrenia was proposed on the basis of pharmacologic studies showing that antipsychotic drugs were potent blockers of brain dopamine receptors. A strong positive correlation was found between the clinical potencies of first-generation antipsychotic drugs (e.g., chlorpromazine, fluphenazine, and haloperidol) and their affinity for the dopamine D_2 receptor. In addition, drugs at high doses that dramatically increased dopaminergic transmission—such as levodopa (L-dopa), cocaine, and amphetamine—produced

schizophrenic-like psychosis, which was reversed by dopamine blockers.

A current view of the dopamine hypothesis of schizophrenia is that brain dopamine pathways are altered in different ways (Fig. 19.4). For example, the negative symptoms and cognitive alterations in schizophrenia are proposed to result from reduced dopaminergic neurotransmission in the mesocortical dopamine pathway.[18] This hypodopaminergic transmission in the prefrontal cortex contrasts with the hypothesized hyperdopaminergic secretion in mesolimbic brain regions that may contribute to the production of positive schizophrenia symptoms. The mesolimbic dopamine pathway innervates temporal lobe structures including the hippocampal formation and amygdala, as well as the nucleus accumbens and anterior cingulate cortex.

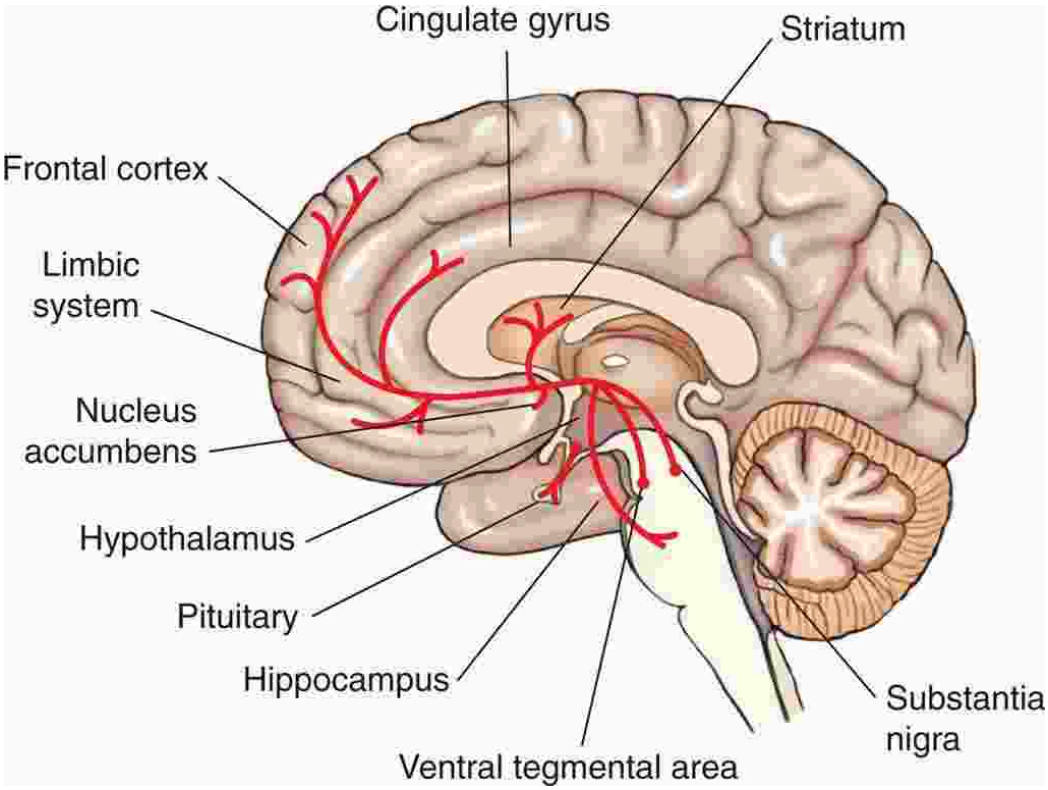

FIG. 19.4 The Dopamine System. Dopamine cell bodies are located in the substantia nigra, where they project to the stratum (nigrostriatal pathway); and in the ventral tegmental area, where they project to the frontal and cingulate cortex (mesocortical pathway), the striatum, the hippocampus, and other limbic structures (mesolimbic pathway). Dopamine nuclei are also located in the hypothalamus and project to the pituitary.

An illustration depicts the sagittal section of the brain with labels indicating the location of dopamine cell bodies clockwise from the left. Ventral tegmental area, hippocampus, pituitary, nucleus accumbens,

limbic system, frontal cortex, cingulate gyrus, striatum, and substantia nigra.

Another neurotransmitter system that may underlie the pathogenesis of schizophrenia is the excitatory neurotransmitter glutamate and its actions on the *N*-methyl-D-aspartate (NMDA) receptor subtype. The glutamate hypothesis of schizophrenia proposes that the underactivation of glutamate receptors contributes to schizophrenia.[19] In schizophrenia, glutamate concentrations in the cerebrospinal fluid (CSF) are reduced along with a decrease in cortical glutamate synthesis. Furthermore, in unaffected individuals, blocking the glutamate NMDA receptor with antagonists, such as phencyclidine (PCP) and ketamine, facilitates the positive and negative symptoms of schizophrenia. PCP users report auditory hallucinations and disorientation and may become violent from their delusions. In monkeys, chronic PCP treatment impairs cognitive performance in a test associated with prefrontal cortical damage.[20]

Clinical Manifestations

The symptoms of schizophrenia are currently divided into three broad categories of positive, negative, and cognitive symptoms (Box 19.1). *Positive symptoms* frequently occur during a psychotic episode, when an individual loses touch with reality and experiences something that should be absent (e.g., hallucinations). *Negative symptoms* are characterized by disruptions in normal emotional states and expressions. *Cognitive symptoms* are fairly common and involve problems with thought processes that severely impair the ability to perform routine daily tasks that involve attention, planning, and social skills. According to the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)*,[21] the diagnosis of schizophrenia begins by eliminating other mental disorders and symptoms not caused by substance abuse, medication, or medical condition. The individual will then be diagnosed with

schizophrenia when at least two of the following symptoms (1) delusions, (2) hallucinations, (3) disorganized speech, (4) disorganized or catatonic behavior, and (5) negative symptoms are experienced most of the time during a 1-month-period with some disturbance present over 6 months. In addition, one of the symptoms must be delusions, hallucinations, or disorganized speech.

Box 19.1

Major Symptoms of Schizophrenia

Positive Symptoms

Hallucinations

- Auditory
- Olfactory
- Somatic-tactile
- Visual
- Voices commenting
- Voices conversing

Delusions

- Delusions of being controlled
- Delusions of mind reading
- Delusions of reference
- Grandiosity
- Guilt
- Persecutory
- Religious
- Somatic
- Thought broadcasting
- Thought insertion
- Thought withdrawal

Positive Formal Thought Disorder

Circumstantiality
Derailment
Distractible speech
Illogicality
Incoherence
Pressure of speech
Tangentiality

Bizarre Behavior

Aggressive, agitated
Clothing, appearance
Repetitive, stereotyped
Social, sexual behavior

Negative Symptoms

Affective Flattening

Affective nonresponsivity
Decreased spontaneous movements
Inappropriate affect
Lack of vocal inflections
Paucity of expressive gestures
Poor eye contact
Unchanging facial expression

Alogia

Blocking
Increase in response latency
Poverty of speech
Poverty of speech content

Anhedonia-Asociality

Few recreational interests
Few social relationships
Impaired intimacy
Little sexual interest

Attention

Social inattentiveness
Inattentiveness during testing

Avolition-Apathy

Impaired personal hygiene
Lack of persistence
Physical anergia

Cognitive Symptoms

Inability to understand information and make proper decision to complete a task
Difficulty paying attention
Problems with working memory or the inability to use recently learned information
Lack of insight

Psychotic Dimension

Psychotic dimension refers to hallucinations and delusions and reflects a person's confusion or loss of touch with the external world. Hallucinations and delusions are classified as positive symptoms and are the most common in schizophrenia.

Hallucinations

A hallucination is a perception experienced without external stimulation of the sense organs. Sensory hallucinations can be auditory, tactile, visual, gustatory, and olfactory. For example, the

individual with schizophrenia may hear voices, experience touch or electrical sensations, report images of animate and inanimate objects, or complain of unpleasant tastes and odors. These hallucinations may occur alone or together.

Delusions

A delusion is a persistent belief contrary to the educational and cultural background of the individual. Delusions may involve grandiose, nihilistic, persecutory, somatic, sexual, and religious themes. Paranoid beliefs are common and may involve spying, conspiracy, persecution, and ridicule. Delusions also may be referential in that particular stimuli or events become highly personalized, such as believing a television talk show host is directing information specifically at them.

Disorganized Behavior

Disorganized behavior includes disorganized speech and disorganized or bizarre behavior. Incongruity of affect is another dimension of disorganized behavior.

Disorganized speech

A common form of disorganized speech is formal thought disorder, which involves fluent speech that is difficult to comprehend. The speech often moves from one topic to another unexpectedly (loose associations) and illogically, and the person becomes easily distracted when talking.

Another form of disorganized speech is called poverty of content. Here, the use of vocabularies to convey information is severely hindered despite a fair amount of spoken words. For instance, the same phrases are used repeatedly throughout a conversation.

Disorganized behavior

Disorganized (or bizarre) behavior is the conceptual equivalent of disorganized speech. The individual has difficulty engaging in goal-directed activities. Repetitive (e.g., stereotyped rocking) or aimless

behavior and poor personal hygiene are exhibited. Another feature is the incongruity of affect or the manifestation of inappropriate situational affect as exemplified by hostility without provocation or child-like silliness in sober situations.

Negative Dimensions

Negative dimensions reflect a deficit in normal functioning and are characterized by affective flattening, anhedonia, alogia (poverty of speech), and avolition. Affective flattening is the near absence of emotional or facial expressions throughout a conversation or in different situations. In anhedonia, individuals are unable to experience emotions such as pleasure or pain and report a sense of detachment from the environment. Alogia is the absence of spontaneous speech production for the purpose of answering questions or expressing oneself. Avolition is a deficit in spontaneous or goal-directed behavior, such as completing simple daily tasks.

Treatment

The use of chlorpromazine in the mid-1950s dramatically altered the treatment of schizophrenia, which previously required extensive institutional hospitalization. The drug was especially effective in reducing positive symptoms such as hallucinations and delusions, as well as thought disorders and hyperactivity. The mechanism of action of chlorpromazine and similar first-generation antipsychotic drugs, such as haloperidol, stem from their ability to block dopaminergic neurotransmission. These first-generation antipsychotics have relative affinities for the dopamine D_2 receptor but may also block histamine-1, muscarinic-1, and alpha-1 receptors.

Antipsychotics that block the D_2 receptor are not without notable neurologic side effects. Parkinsonism (e.g., tremor, shuffling gait, stooped posture, and masked face) are prominent side effects that resemble Parkinson disease, a disorder associated with degeneration of dopamine cell bodies in the substantia nigra that project to the striatum. Another related side effect of conventional antipsychotics that develops in 15% to 30% of individuals with schizophrenia after

several months or years of treatment is a condition called tardive dyskinesia.[22] This condition is characterized by delayed onset, irregular, involuntary movements of the tongue, mouth, face, limbs, and trunk. Movements can present as choreiform and/or athetoid. Choreiform movements are characterized as jerky and dance-like. Athetoid movements present as slow, writhing, and snake-like. Other side effects may include sedation, hypotension, akathisia (motor restlessness), constipation, weight gain, amenorrhea, and, less frequently, hepatotoxicity and electrocardiographic changes.

Although the majority of individuals with schizophrenia obtained some positive symptom relief from the first-generation or conventional antipsychotics, approximately, 20% failed to respond to D_2-blocking drugs (Table 19.1), especially those with pronounced symptoms of apathy, disorientation, and social withdrawal. Due to the limitations of the first generation of antipsychotic medications, a second generation of drugs was developed that became known as *atypical antipsychotic drugs*.[23] Atypical antipsychotics also were shown to have superior efficacy in reducing not only the positive but also the negative symptoms in comparison with conventional antipsychotics. For example, clozapine improves some cognitive functions (such as verbal fluency, verbal learning, and memory) and some physical functions (such as psychomotor speed). In addition, the notable neurologic side effects that accompany the use of conventional antipsychotics were diminished.

Table 19.1

Medications Used in the Treatment of Schizophrenia

Generic Name	Brand Name
Conventional Antipsychotics	
Chlorpromazine	Thorazine
Fluphenazine	Prolixin
Haloperidol	Haldol
Perphenazine	Trilafon
Pimozide	Orap
Prochlorperazine	Compazine
Thioridazine	Mellaril
Thiothixene	Navane
Trifluoperazine	Stelazine
Second-Generation Atypical Antipsychotics	
Aripiprazole	Abilify
Clozapine	Clozaril
Loxapine	Loxitane
Lurasidone	Latuda
Molindone	Moban
Olanzapine	Zyprexa
Paliperidone	Invega
Quetiapine	Seroquel
Risperidone	Risperdal

Generic Name	Brand Name
Ziprasidone	Geodon

Generic Name	Brand Name

Quetiapine	Seroquel
Risperidone	Risperdal
Ziprasidone	Geodon

Unlike conventional antipsychotics (first generation), atypical drugs (second generation) have activity at multiple receptor sites. For example, clozapine has much lower binding affinity for the D_2 receptors but also binds to D_1, D_3, D_4, and D_5 receptors and serotonin (5-hydroxytryptamine, i.e., HT_2, 5-HT_6, 5-HT_7); norepinephrine; and cholinergic and histamine receptors. Risperidone and ziprasidone have higher affinities for blocking 5-HT_2 than D_2 receptors. The higher 5-HT_2/D_2-receptor binding ratio of atypical antipsychotics in comparison with conventional drugs may reflect a normalization of serotonin-dopamine interactions leading to a decreased risk for neurologic side effects observed with D_2-receptor blockade alone.

Atypical antipsychotics are not without adverse effects; tardive dyskinesia occurs in 7%[22] of individuals, and neurologic side effects

do occur. However, the most notable are the metabolic abnormalities including regulation of glucose and lipid levels and weight gain. For example, long-term clozapine or olanzapine treatment increases body weight gain, which becomes a risk factor for diabetes and cardiovascular disease. Individuals with schizophrenia treated with clozapine also are required to consent to ongoing lab monitoring due to the risk of developing agranulocytosis, a potentially lethal blood disorder involving the loss of white blood cells and a compromised immune system.

In conjunction with antipsychotic medication, psychosocial therapy can facilitate the management of schizophrenia. Psychosocial relationships assist the individual in developing coping strategies and in identifying stressors and relapse symptoms. Cognitive-behavioral therapy (CBT), a talking therapy that initiates cognitive and behavioral change based on an individualized reappraisal of the person's faulty beliefs, is effective in supporting individuals with schizophrenia who have been stabilized with antipsychotic medications.[24] An important benefit of psychosocial and family support is the encouragement of adherence with antipsychotic medication that requires both consistency and time before the emergence of clinical efficacy.

Mood Disorders: Depression And Bipolar Disorder

Mood refers to a sustained emotional state as opposed to brief emotional feelings, which are termed *affective states*. Healthy individuals are normally capable of experiencing a variety of affective states including euphoria, joy, surprise, fear, sadness, anxiety, and depression. When emotional states, such as sadness, become chronic and uncontrollable, individuals may be diagnosed with a mood disorder called *depression*. The two major classifications of mood disorder are (1) unipolar or major depressive disorder, also known as *major depression* or *clinical depression*; and (2) bipolar disorder, which is further classified into bipolar I and bipolar II

disorders. **Major (unipolar) depressive disorder** consists of depressed mood, loss of interest/pleasure, changes in activity, guilt/worthlessness, death/suicide, fatigue/loss of energy, decreased concentration, and changes in sleep, appetite, or weight. In addition, two new specifiers were added in *DSM-5*. One specifier with mixed symptoms allows for the occurrence of manic symptoms as part of the diagnosis in depressed individuals who do not meet the criteria for a manic episode. Another specifier with anxious distress was added because anxiety may affect treatment choices for major depressive disorder. A manic episode consists of elevated, expansive, and irritable mood, as well as changes in energy and activity levels. In bipolar I disorder, the individual experiences at least one manic episode that may be preceded or followed by hypomanic or major depressive episodes. Mania symptoms may significantly impair the individual, trigger psychosis, and require hospitalization. In bipolar II disorder, the individual experiences one major depressive episode for at least 2 weeks and at least one hypomanic episode for at least 4 days. Box 19.2presents the major criteria of major depression and bipolar disorder according to the American Psychiatric Association's *DSM-5*.[21] Major (unipolar) depressive disorder is the most common mood disorder and the leading cause of disability in the United States and throughout the world.[25]

Box 19.2

Major Symptoms of Depression and Mania

Symptoms of Depression[aa]

Depressed or irritable mood
Loss of interests and pleasure
Significant (>5%) weight gain or loss in a month
Insomnia or hypersomnia
Psychomotor agitation or retardation

Fatigue or loss of energy
Feelings of worthlessness or excessive guilt
Poor concentration or indecisiveness
Recent thoughts of death or suicide

Symptoms of Manic Episode[ba]

Elevated mood
Irritable mood
Inflated self-esteem
Decreased need for sleep
Excessive talking
Racing/crowded thoughts
Distractibility
Increase in goal-directed activity
Excessive risky activities

[a]Five or more of the symptoms are present in a 2-week period and at least one of the symptoms is either depressed mood or loss of interests or pleasure.

[b]Three or more symptoms (four if the mood is only irritable) during a distinct period of abnormally and persistently elevated, expansive, or irritable mood occurring for at least 1 week.

Unipolar depression appears in all age groups including young children. In the United States, the lifetime prevalence rate is 16.2% of the population with a twofold greater risk in women than men after adolescence. In children and adolescents, 2% to 6% suffer from depression. The prevalence of bipolar disorder ranges from 3% to 5% in the general population. Bipolar I disorder occurs equally in men and women in comparison with bipolar II disorder, which afflicts more women than men. When left untreated, a number of depressed and bipolar individuals are at risk of developing a host of medical illnesses, including cardiovascular disease, obesity, diabetes, and thyroid disease.

Genetic Predisposition and Environmental Influences

Etiology and Pathophysiology

Family and twin studies indicate a strong basis for mood disorders. Concordance rates for bipolar disorder ranged up to 62% and 42% for monozygotic and dizygotic twins, respectively.[26] Concordance rates of 62% and 28% for unipolar disorder were reported in monozygotic and dizygotic twins, respectively. Even among adoptees with a biological family history of mood disorders, the incidence of developing major depression or manic-depressive illness is higher than among control adoptees. The strong tendency for mood disorders to run in families has encouraged a search for the abnormal gene or genes. Interestingly, loci on chromosomes 18 and 22 have been linked to both bipolar disorder and schizophrenia. Bipolar individuals, who may exhibit psychotic behavior, have deficits in reelin expression linked to genetic loci, located on chromosome 22, which confers susceptibility to schizophrenia (see the preceding section on Schizophrenia). However, the large variation in clinical symptoms suggests that developmental and environmental factors are as important as genetic factors in contributing to the etiology of mood disorders.

Neurochemical Dysregulation

Modern theories of mood disorders began with the important observations that drugs, such as imipramine, elevated norepinephrine levels within the synapse and reduced depression, whereas drugs that depleted monoamine levels (e.g., reserpine) increased depression. These studies led to the dominant monoamine hypothesis of depression, in which a deficit in the concentration of brain norepinephrine, dopamine, and/or serotonin is the underlying cause of depression, in contrast to mania, which results from elevated concentrations of monoamines. Three major classes of antidepressant drugs were initially developed and included monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants

(TCAs), and selective serotonin reuptake inhibitors (SSRIs). These antidepressants shared the common property, albeit through different mechanisms, that increasing monoamine neurotransmitter levels within the synapse is the basis for their antidepressant effects (Fig. 19.5).

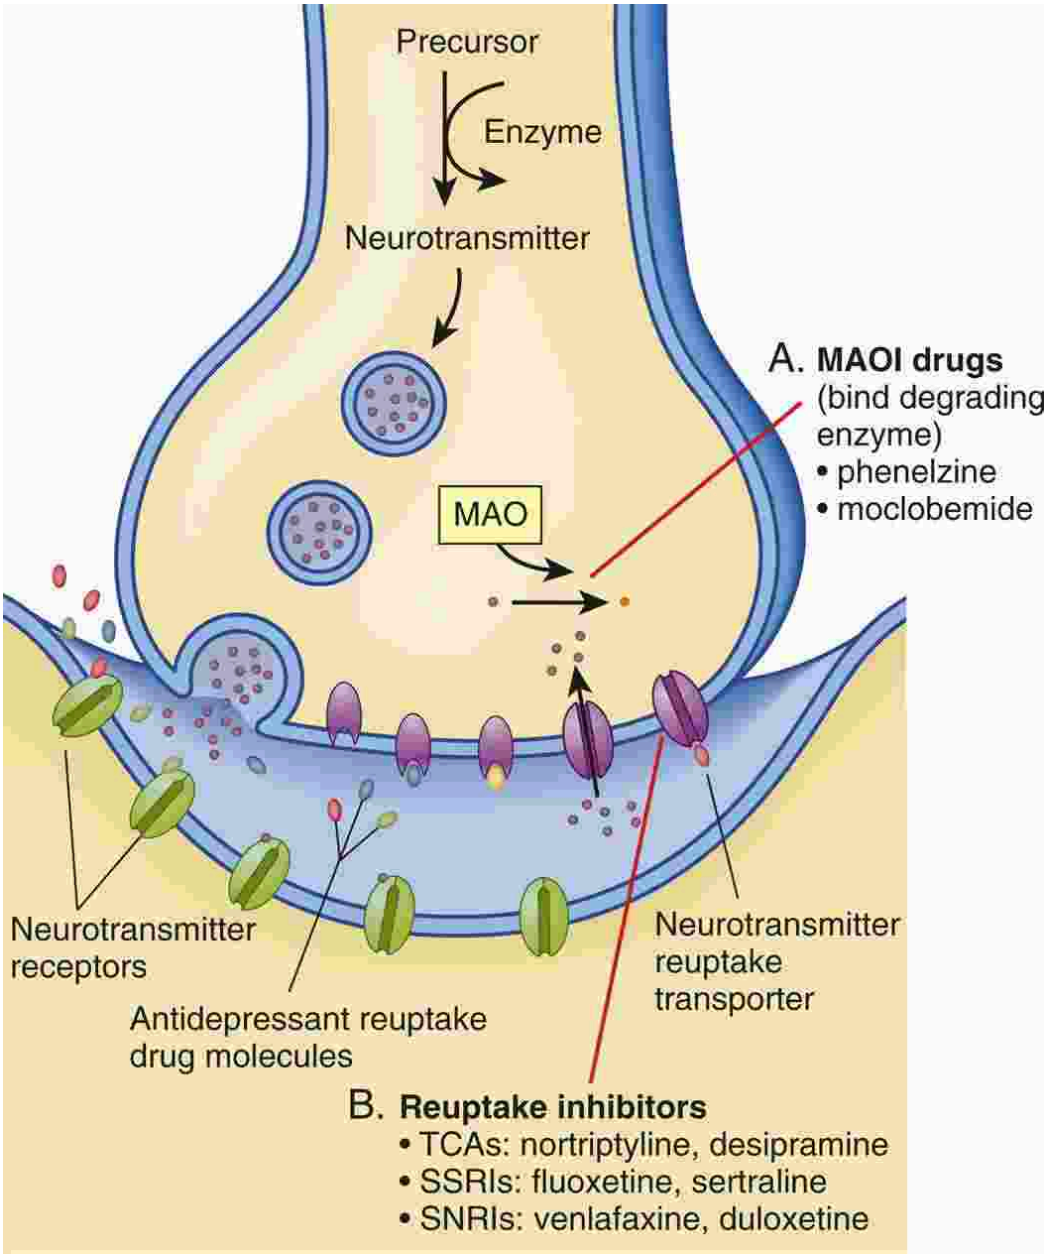

FIG. 19.5 Schematic Diagrams Showing the Sites of Actions of Antidepressants and Their Effects on Neurotransmitter Levels.
(A) Monoamine oxidase inhibitors *(MAOIs)* act by blocking the enzyme that normally degrades neurotransmitters, such as norepinephrine and serotonin increasing their presynaptic concentration. (B) The tricyclic antidepressants *(TCAs)*, selective serotonin reuptake inhibitors

(SSRIs), and serotonin-norepinephrine reuptake inhibitors *(SNRIs)* act by reducing the uptake of neurotransmitters from the synapse, which leads to increased neurotransmitter levels.

An illustration depicts the sites of action of antidepressants and their effects on neurotransmitter receptors which shows the M A O I drugs such as phenelzine and moclobemide (bind degrading enzymes) in the presynaptic neuron. Reuptake inhibitors such as T C As: nortriptyline, desipramine; S S R Iâ€™s: fluoxetine, sertraline; and S N R Is: Venlafaxine, duloxetine acts on the neurotransmitter reuptake transporter. The labels indicate the precursor acts on the neurotransmitter in the presence of an enzyme in the presynaptic neuron where the M A O I binds and degrades the enzyme.

Additional support for the monoamine hypothesis of depression came from studies showing a reduction of monoamine metabolites in the CSF of depressed people. Other work demonstrated that dietary depletion of tryptophan, the precursor of serotonin synthesis, or alpha-methylparatyrosine (AMPT), a drug that inhibits dopamine and norepinephrine synthesis, produced a rapid return to depression in individuals successfully treated with antidepressants.[27]

Neuroendocrine Dysregulation

Stress and hypothalamic-pituitary-adrenal system dysregulation

The hypothalamic-pituitary-adrenal (HPA) system plays an essential role in an individual's ability to cope with stress (see Chapter 11). However, chronic stress-induced activation of the HPA system and elevated glucocorticoid secretion are found in a large percentage (30% to 70%) of people with major depression, suggesting that mechanisms responsible for increased HPA hormone secretion contribute to the pathophysiology of depression.[28]

Notably, antidepressant drugs effective in normalizing the HPA system are associated with a good clinical response, whereas persistent dysregulation of the HPA system is related to continued depression or relapse. Psychosocial stress-induced activation of the immune system increases secretion of proinflammatory cytokines, such as interleukin-1α (IL-1α) and IL-β, tumor necrosis factor-alpha (TNF-α), and IL-6, which modulates signaling pathways throughout the periphery and brain and augments further secretion of HPA hormones and monoamine metabolism. See the Emerging Science Box: Genetic Basis of Anxiety and Depression for further insight on the genetic links between anxiety and depression.

Evidence suggests that inflammation is another risk factor that triggers the onset of depression. For example, a study involving 73,131 Danish individuals from the general population reported elevated levels of C-reactive protein, a commonly used marker of inflammatory disease, was associated with increased risk of psychologic distress and depression.[29] Another study reported that depressed people treated with antidepressants, a combination of antidepressants and psychotherapy, or psychotherapy alone initially exhibited elevated cytokine levels that returned to normal levels after recovery from depression.[30]

Although there are currently no known effective anti-inflammatory treatments for depression, two omega-3 polyunsaturated fatty acids (PUFAs), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), may have anti-inflammatory effects that could reduce depression. A study examined whether

Emerging Science BoxGenetic Basis of Anxiety and Depression

Large-scale genome-wide association studies offer insight into the genetic basis of anxiety and depression. A large genome-wide association study found genetic links between anxiety and major depressive disorder. Over 199,000 participants were sampled to identify genetic risk variants near genes in people with anxiety. Of further relevance, the researchers found significant genetic overlap between anxiety and depression. One finding was the *SATB1* gene, a major regulator of multiple genes that modulates the expression of the Corticotropin Releasing Hormone (*CRH*) gene. The CRH neuropeptide plays a major role in the activation of the hypothalamic-pituitary-adrenal axis and the expression of stress and emotional fear and anxiety responses. Individuals with increased secretion of CRH may be at greater risk of developing anxiety disorders and depression. The study found another gene called ESR1, which encodes for several receptors for estrogen. The association between ESR1 and anxiety may have relevance in understanding sex differences in stress-related anxiety disorders such as post-traumatic stress disorder, which is more prevalent in females. The comorbidity and the genetic overlap between disorders offer new insights and molecular targets to better understand the basis of serious mental illnesses.

Data from Levey DF, et al. Reproducible genetic risk Loci for anxiety: Results from-200,000 participants in the Million Veteran Program. *American Journal of Psychiatry*, 2020;177:223–232.

the breakdown of EPA and DHA and some of their metabolites (known as lipid mediators) are able to protect the brain from the harmful effects of inflammation.[31] The research showed that in vitro human hippocampal cells pretreated with EPA or DHA before exposure to proinflammatory cytokines prevented increased cell death and a reduction in neurogenesis. Of clinical relevance, individuals with major depression and were administered high doses of EPA or DHA for 12 weeks, exhibited higher levels of lipid

metabolites in their plasma that correlated with less severe symptoms of depression. The investigators note that plasma concentrations of EPA and DHA found in the study are unlikely to be achieved with the typical consumption of food rich in omega-3 fatty acids. Rather, therapeutic doses that reach high omega-3 PUFA levels may be required to produce the beneficial effects of reducing depression.

Increasing evidence from animal models of stress-induced depression shows that depression-like behavior is accompanied by atrophy of neurons in the hippocampus, a reduction in the development of new hippocampal neurons (i.e., neurogenesis), and a deficit in hippocampal brain-derived neurotrophic factor (BDNF) levels.[32] Consistent with animal studies, human postmortem work indicates low hippocampal BDNF levels in depression. Because the growth factor BDNF supports the survival of neurons and facilitates neurogenesis from hippocampal stem cells, a neurotrophic hypothesis of depression has been proposed as an extension of the monoamine hypothesis of depression to broadly account for the pathophysiologic basis of depression. That is, stress-induced depression and the accompanying reduction in levels of monoamines are caused by deficits in neurogenesis and BDNF levels. Of clinical relevance, administration of antidepressants to animals reverses the depression-like state and increases the development of neurogenesis and BDNF levels.

Hypothalamic-pituitary-thyroid system dysregulation

Alterations in thyroid function and mental illnesses, particularly major depression and anxiety disorders, have long been recognized. People with hyperthyroidism often manifest symptoms of dysphoria, anxiety, irritability, emotional lability, and cognitive impairments. On the other hand, individuals with severe hypothyroid exhibit features of major depression, apathy, psychomotor slowing, and dementia.[33] Notably, although thyroid dysfunction may be linked to symptoms of depression and anxiety, people diagnosed with primary depression generally have normal

thyroid function.[34] The causal mechanisms or basis underlying altered thyroid secretion and depression remain to be determined.

Neuroanatomic and Functional Abnormalities

The dorsal and median raphe nuclei, located in the central gray matter of the caudal mesencephalon and rostral pons, contain a large group of serotonin-synthesizing neurons that project extensively to all regions of the cortex, basal ganglia, limbic system, hypothalamus, cerebellum, and brainstem (Fig. 19.6). Postmortem and/or brain imaging studies of depressed individuals revealed a widespread decrease in serotonin 5-HT_{1A} receptor subtype binding in the frontal, temporal, and limbic cortex as well as serotonin transporter binding in the cerebral cortex and hippocampus. Mood disorders in some individuals may reflect a dysfunctional raphe-serotonin system, which normally modulates homeostasis, emotionality, and tolerance to aversive experiences.

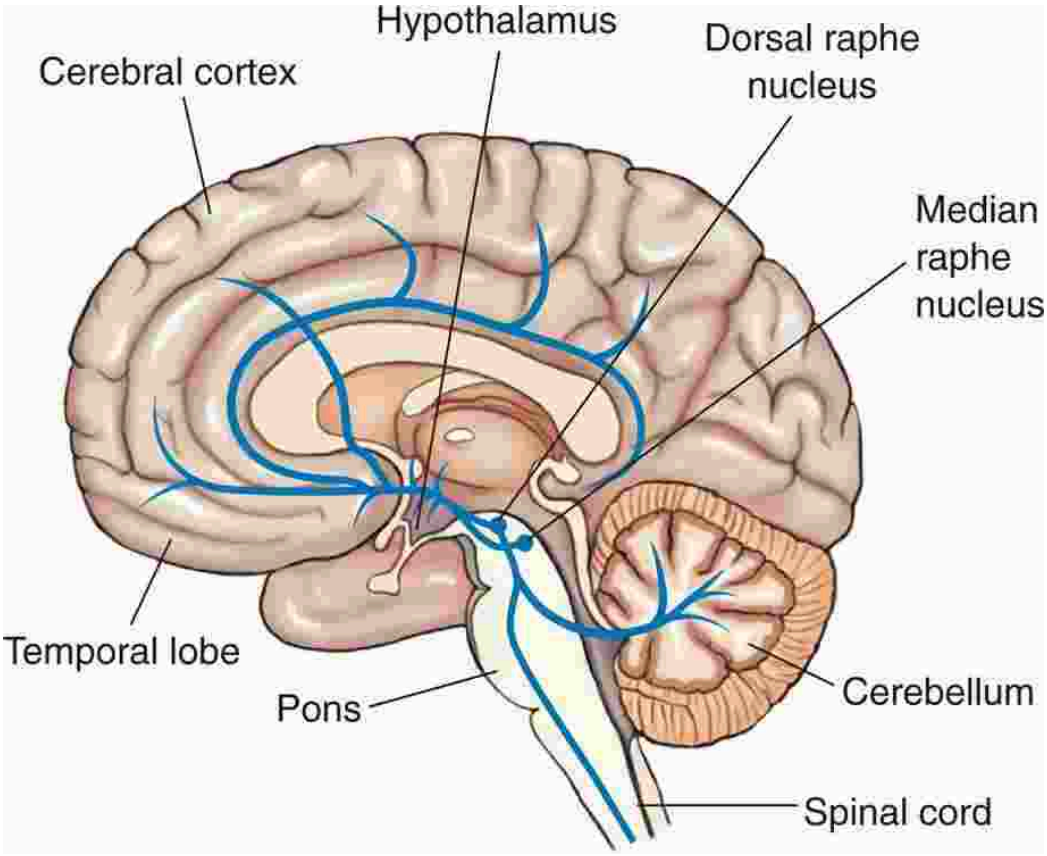

FIG. 19.6 The Serotonin System. Serotonin neurons are located in the brainstem raphe nuclei.
They project diffusely to all regions of the cortex, temporolimbic regions, hypothalamus, basal ganglia, cerebellum, the brainstem, and spinal cord.

An illustration depicts the sagittal section of the brain with labels indicating the location of the serotonin system clockwise from the left. Pons, temporal lobe, cerebral cortex, hypothalamus, dorsal raphe nucleus, median raphe nucleus, cerebellum, and spinal cord.

A group of norepinephrine-containing cells, located in the locus ceruleus of the rostral pons, project to vast areas of the forebrain, brainstem, and spinal cord (Fig. 19.7). The locus ceruleus–norepinephrine system is implicated in global psychologic processes including attention, vigilance, and orientation to novel, aversive, or threatening stimuli. Activation of the locus ceruleus–norepinephrine system is also capable of inhibiting the raphe-serotonin system, suggesting an indirect role in modulating serotonin functions. Norepinephrine receptor alterations (e.g., α- and β-adrenergic receptor subtypes) are found in the frontal cortex of some suicide victims with major depression. Alterations in norepinephrine systems may be linked to attention or concentration difficulties as well as sleep and arousal disturbances in depression.

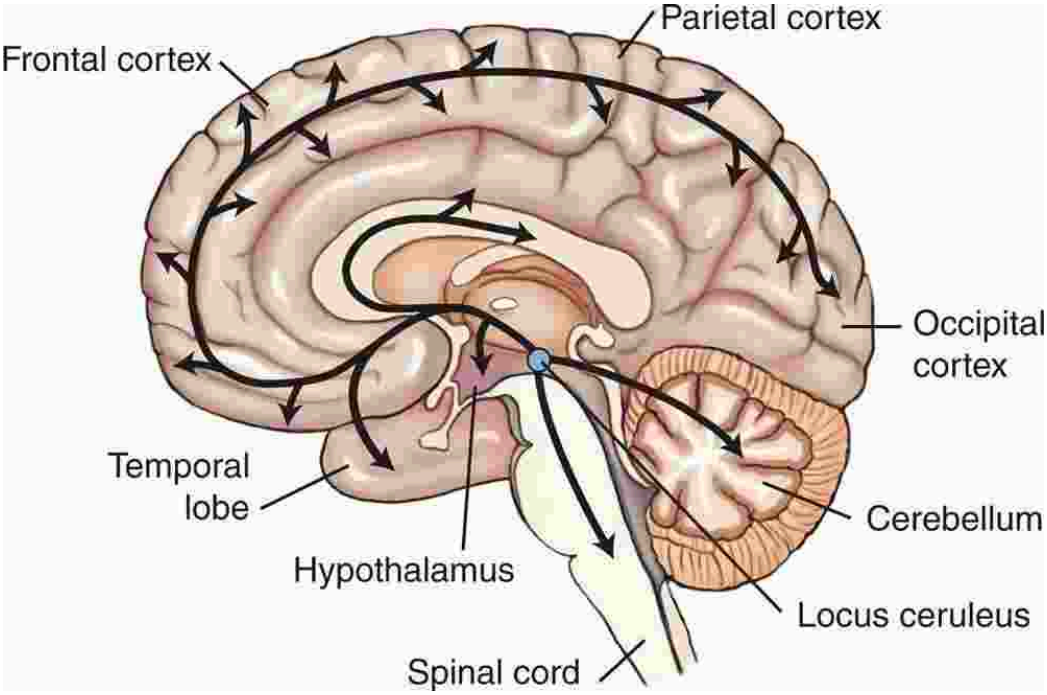

FIG. 19.7 The norepinephrine system.
The norepinephrine cell bodies originate in the locus ceruleus and project throughout the brain, including the hypothalamus, the temporal lobe, the entire cortex, the cerebellum, and spinal cord.

An illustration depicts the sagittal section of the brain with labels indicating the location of the norepinephrine system clockwise from the left. Hypothalamus, temporal lobe, frontal cortex, parietal cortex, occipital cortex, cerebellum, and spinal cord.

Functional abnormalities associated with mood disorders are found in frontal and limbic regions such as the amygdala.[35,36]

Postmortem studies report a reduction in glial cell numbers in people with unipolar and bipolar disorders. There are also reports of reduced frontal lobe volume in depressed individuals and decreased or asymmetric temporal lobe volume in individuals with bipolar illness and depression.

Functional neuroimaging studies indicate decreased cerebral blood flow and glucose metabolism in the dorsolateral and dorsomedial prefrontal cortex of individuals affected by major depression or bipolar disorder. Dorsolateral prefrontal abnormalities in depression may be responsible for the delay in cognitive processing and speech deficits similar to those found in schizophrenia. Dorsomedial frontal dysfunction may be associated with mnemonic and attentional impairments that accompany mood disorders. Other frontocortical regions, including the ventrolateral, ventromedial, and orbital areas, exhibit increased blood flow and metabolism in unipolar depression (Fig. 19.8). These frontal brain areas have extensive interconnections with the amygdala, especially in the right, and are positively related to negative affect in depressed individuals. These functional changes in brain activity begin to normalize with successful antidepressant treatments, suggesting they are state rather than trait related.

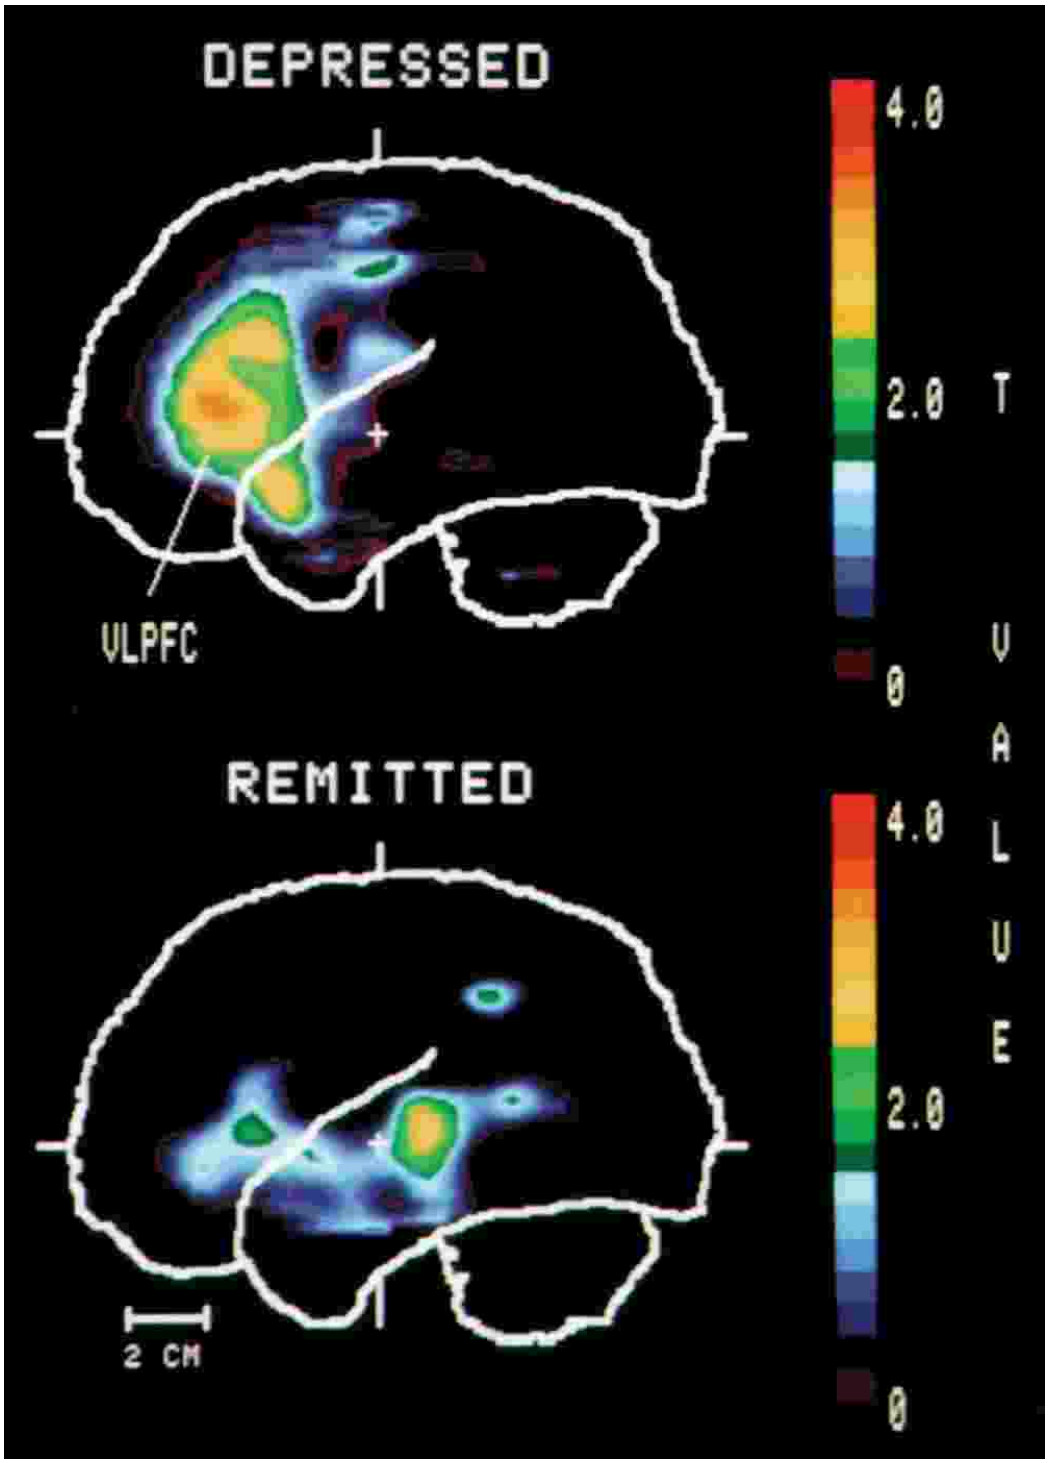

FIG. 19.8 Positron-Emission Tomography (PET). PET comparison of brain activity in depression and in remittance.
PET scan showing increased activity in the left prefrontal cortex in a depressed person but not in

the remitted person. *VLPFC*, Ventrolateral prefrontal cortex. (From Drevets WC, Videen TO, Price JL, et al. A functional anatomical study of unipolar depression. *Journal of Neuroscience*, 1992;12:3628. Copyright ©1992 by the Society for Neuroscience.)

Color map of the sagittal section of brain changes derived from positron-emission tomographic images represent the increased activity of the prefrontal cortex in the depressed person and decreased activity of the prefrontal cortex in the remitted person.

Hippocampal volume reduction in major depression is a widely reported finding, especially in individuals with a history of recurrent major depression.[37]

Similar to the hippocampus, the amygdala is reduced in volume after experiencing a number of major depressive episodes, and in individuals with a family history of depression, albeit enlarged in the first episode of depression.[38] The cumulative effects of stress may be responsible for a reduction in hippocampal and amygdala volume. MRI studies showed an increased volume of the amygdala in bipolar illness and larger lateral ventricles in people suffering multiple bipolar episodes compared to those with only a single episode or healthy controls.[39] Ventricular enlargement suggests progressive brain tissue loss resulting from multiple bipolar episodes.

The glutamate system

Because of the delayed onset of action of current antidepressants and poor remission rates, investigators are constantly searching for new drugs with novel mechanisms of actions. An emerging body of evidence suggests that elevated cortical levels of glutamate, the

major excitatory neurotransmitter in the central nervous system, may be involved in the pathophysiology of major depression. A potential promising target is the glutamate NMDA receptor. At nontoxic doses, the glutamate receptor antagonist ketamine was found in animal models to rapidly increase synaptic density and signaling in cortical neurons. Of clinical relevance, ketamine is reported to be effective in inducing rapid but transient antidepressant effects in treatment-resistant depressed individuals.[40,41] Investigators have begun to study the possibility of extending the antidepressant effects of ketamine by administrating rapamycin, the mechanistic target of rapamycin complex 1 (mTORC1 inhibitor), to refractory depression individuals prior to ketamine infusion. Individuals with depression treated with rapamycin before ketamine administration continued to show a clinical antidepressant response after two weeks (41%), with 29% in full remission compared to 13% response and 7% remission in the placebo followed by ketamine group. Rapamycin is an immunosuppressant and the results suggest rapamycin may prolong the antidepressant effects of ketamine by protecting newly made synapses and may restore the impaired cellular functions in depressed people.[42]

Recently, esketamine (Spravato), a rapidly acting glutamate receptor antagonist drug, similar to ketamine, was approved by the FDA in a nasal spray form for treatment-resistant depression and works to reduce the symptoms of depression within hours. By blocking the NMDA receptor, esketamine increases glutamate release acting on dendritic spines compromised by stress and depression in brain circuits involved in the regulation of mood. Although the beneficial effects of esketamine are the rapid effects of antidepressant activity, the effects of long-term treatment are still unknown and some side effects of esketamine are reported to include sedation, dizziness, dissociation reactions, and increased blood pressure.[43,44]

Depression

Clinical Manifestations

Major depression is characterized by unremitting feelings of sadness and despair (see Box 19.2). The dysphoric mood or intensely painful mood is accompanied frequently by insomnia, loss of appetite and body weight, and reduced interest in pleasurable activities and interpersonal relationships. Sleep disturbances may include difficulty in initially falling asleep and awakening in the middle of the night, lying awake for several hours with an inability to subsequently fall asleep. Individuals may have reduced motor activity and suffer marked fatigue. Others complain of restlessness and agitation. Feelings of worthlessness and guilt are common, and pessimistic or negative outcomes are often perceived even in routine situations. The ability to function (e.g., work) and concentrate is greatly diminished. Depressive episodes may occur or recur suddenly or gradually and continue from a few weeks to months, and 20% may exhibit a chronic form of depression.

Suicidal risk increases in depression. Factors such as living alone or being divorced, having a prior history of drug abuse or suicide attempt, or having depression at midlife or older ages contribute to suicide in 10% to 15% of depressed individuals.

Bipolar Disorder: Mania

Individuals with mania experience elevated levels of euphoria and self-esteem and feelings of grandiosity. Energy levels are greatly enhanced even after only a few hours of sleep each night. The increased energy, however, does not lead to organized plans and thoughts. The individual may show poor judgment in spending money, may become hypersexual, or may make poor business commitments. Other hallmarks of mania are excessive, rapid, loud, and pressured speech. The individual with mania frequently skips from one topic of conversation to another and is easily distracted both when speaking and when performing tasks. Approximately 50% of manic individuals develop psychotic symptoms, such as delusions or hallucinations, which require hospitalization. The onset and termination of manic symptoms (see Box 19.2) are usually

abrupt and may last for a few days or months followed by depression. The risk of recurrence of bipolar disorder is high, especially without immediate treatment.

Depression

Treatment

Approximately 80% of depressed persons will respond to antidepressant drugs such as MAOIs, TCAs, and SSRIs (Table 19.2); psychotherapy; or a combination of both treatment modalities. Although SSRIs have become the standard first-line treatment for major depression, the initial selection of an antidepressant often includes an assessment of the person's symptoms and age as well as the side effects, safety, cost, and convenience of the prescribed medication. For example, medications that produce sedation may be helpful for the treatment of sleep disturbances. Approximately 50% of depressed individuals may not show a favorable response during initial treatment to an antidepressant drug, and 10% to 20% may continue to exhibit symptoms after 2 years. Individuals who are nonresponsive to a specific antidepressant during a 2-month period may be given another antidepressant medication. Atypical antidepressants, such as nefazodone, trazodone, and mirtazapine, presumably produce their clinical effects by blocking specific receptors (e.g., 5-HT_{2A}). A new generation of antidepressants that selectively block serotonin and norepinephrine reuptake is available in the United States (e.g., venlafaxine) and Europe (i.e., milnacipran, reboxetine).

Table 19.2

FDA-Approved Medications Used in the Treatment of Depression and Anxiety Disorders

Generic Name	Brand Name
Monoamine Oxidase Inhibitors	
Isocarboxazid	Marplan
Phenelzine	Nardil
Tranylcypromine	Parnate
Selegiline	Emsam
Tricyclics	
Amitriptyline	Elavil, Endep, Levate
Amoxapine	Asendin
Clomipramine	Anafranil
Desipramine	Norpramin, Pertofrane
Doxepin	Adapin, Sinequan
Imipramine	Tofranil
Maprotiline	Ludiomil
Nortriptyline	Aventyl, Pamelor
Protriptyline	Vivactil
Trimipramine	Surmontil
Selective Serotonin Reuptake Inhibitors	
Citalopram	Celexa

Generic Name	**Brand Name**
Escitalopram	Lexapro
Fluoxetine	Prozac
Fluvoxamine	Luvox
Paroxetine	Paxil
Sertraline	Zoloft
Serotonin and Norepinephrine Reuptake Inhibitors	
Desvenlafaxine	Pristiq
Duloxetine	Cymbalta
Levomilnacipran	Fetzima
Venlafaxine	Effexor, Effexor XR
Serotonin Reuptake Inhibitor and 5-HT_{1A} Receptor Partial Agonist	
Vilazodone	Viibryd
Norepinephrine and Specific Serotonergic Modulator	
Mirtazapine	Remeron
Norepinephrine–Dopamine Reuptake Inhibitor	
Bupropion	Wellbutrin, Zyban
Serotonin Modulator	
Nefazodone	Serzone
Trazodone	Desyrel, Oleptro
Vortioxetine	Trintellix
Non-competitive *N*-methyl-D-aspartate (NMDA) receptor antagonist	

Generic Name	Brand Name
Esketamine	Spravato

Non-competitive *N*-methyl-D-aspartate (NMDA) receptor antagonist	
Esketamine	Spravato

In bipolar depression, antidepressant medications may lead to cycle acceleration or induction of mania. However, SSRIs and bupropion may be less likely to induce these effects than MAOIs or TCAs.

A number of side effects are reported with MAOIs, TCAs, and SSRIs. Commonly reported side effects of MAOIs include sedation or agitation, insomnia, dry mouth, impotence, and weight gain. MAOIs also may induce acute and heightened elevations in blood pressure (e.g., hypertensive crisis) after intake of tyramine-rich foods, such as aged cheeses, sour cream, pods of broad beans, pickled herring, liver, canned figs, raisins, and avocados. In addition, MAOI interactions with TCAs, SSRIs, stimulants, and over-the-counter flu medications are dangerous and should be avoided. Because of these adverse side effect issues, MAOIs are used less often than other antidepressants.

TCAs may produce sedation, insomnia, orthostatic hypotension, seizures, and weight gain. Some TCAs have moderate anticholinergic side effects, including constipation, urinary hesitancy or retention, dry mouth, blurred vision, and memory impairment. These side effects may be an issue when considering TCA treatment of older adults, in which case, the TCAs desipramine and nortriptyline may be preferred because of their reduced anticholinergic, cardiovascular, and sedating effects.

Common side effects of SSRIs include sleep disturbances (e.g., insomnia) and nausea. However, agitation, allergic skin reactions, dry mouth, anxiety, altered appetite, and sexual dysfunction have been reported. Unlike MAOIs and TCAs, SSRIs do not have pronounced effects on the cardiovascular or cholinergic systems. SSRIs are potent inhibitors of cytochrome P-450 isoenzymes, which are involved in drug metabolism. Therefore, SSRIs may lead to dangerous elevations in blood concentrations of other psychiatric medications when taken together. SSRIs should not be taken with MAOIs or immediately after discontinuing MAOI treatment. A serotonin syndrome characterized by excitement or autonomic hyperactivity, abdominal pain, rigidity, and hyperthermia may develop, leading to coma or death.

Side effects of atypical antidepressants may include sedation, dry mouth, weight gain, and constipation. Nefazodone and trazodone have been associated with hepatic toxicity. Venlafaxine and reboxetine lack many of the serious side effects associated with TCAs; however, sweating, dry mouth, and some sedation may occur. Adjunctive therapy with atypical antipsychotics, such as aripiprazole and brexpiprazole, has been FDA approved for treatment-resistant depression. Electroconvulsive therapy (ECT) may be used when individuals fail to respond to antidepressants or when they are severely depressed, pregnant, suicidal, or psychotic. ECT effectively alleviates depressive symptoms in about 50% to 80% of individuals, who may then begin to respond to antidepressant medications. Recent work suggests that ECT increases the volume of the hippocampus and amygdala, brain structures linked to emotion, mood, and cognitive functions.[43,45] Individuals with depression with relatively small hippocampal volumes were most likely to show hippocampal volume increases and improved clinical response after ECT. Neurotrophic processes activated by ECT, including neurogenesis, may underlie these structural changes and clinical benefits.

Deep brain stimulation (DBS) is another treatment showing promise to alleviate major depression in individuals resistant to current antidepressant medications, ECT, and psychotherapy.[46,47] The treatment involves implanting electrodes during neurosurgery into brain regions such as the subcallosal cingulate gyrus (SCG [Brodmann area 25 and parts of 24 and 32]) and the nucleus accumbens.[48] This SCG region was targeted because abnormal SCG brain activity, a suggested pathophysiologic cause of major depression, is reversed by effective antidepressant treatment. A 3- to 6-year follow-up study of 20 treatment-resistant depressed individuals who received DBS in the SCG found that more than half eventually returned to work and improved their quality of life.[49] Preliminary work with DBS in the nucleus accumbens, a region involved in rewarding experiences, was shown to reverse treatment-resistant depression in people unresponsive to pharmacotherapy,

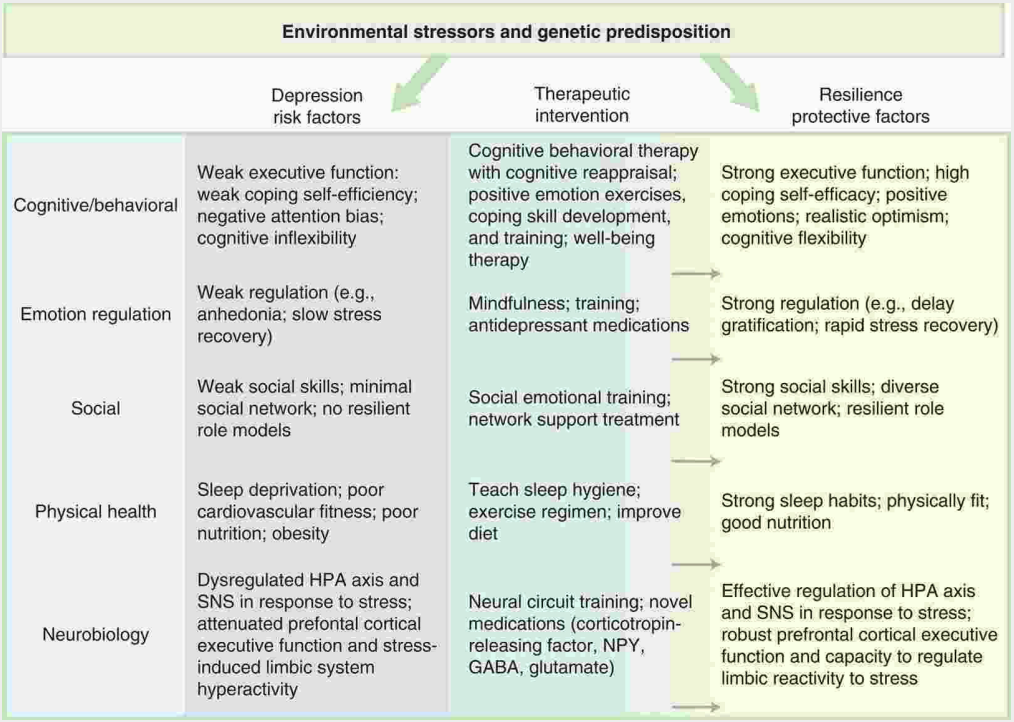
psychotherapy, and ECT. Pathophysiology in the nucleus accumbens may be linked to impairments in reward processing and underlie the anhedonic symptom of depression. Preclinical studies suggest that the mechanism responsible for reversing the anhedonic state of depression is caused by the rapid increase in monoamine release in the prefrontal cortical areas following DBS stimulation in the nucleus accumbens.[50]

Another therapy for treatment-resistant depression is transcranial magnetic stimulation (TMS). This FDA-approved treatment involves noninvasive focal brain stimulation—unlike DBS, which requires neurosurgery, or ECT seizure induction. The procedure uses an electromagnetic coil to create a magnetic field that passes from the scalp to the brain, where the electrical current flow stimulates neurons. Daily repeated left prefrontal TMS was shown to induce acute antidepressant effects with few side effects and remission in 30% to 40% of individuals with depression.[51]

A weakness of many antidepressant treatments is that, even among individuals who receive the gold standard of antidepressant pharmacotherapy with psychotherapy, at least 50% of people who recover from a first episode of depression will, nonetheless, experience another one or more depression episodes in their lifetime. The recurrence rate of depression increases to approximately 80% in those with a history of two episodes.[52] One contributing factor for relapse is the failure of individuals to continue with their treatment plan by stopping their therapy sessions or drug medications. Another related factor is low social support and perceived loneliness. Studies reported low social support predicts poor response to depression treatment, early drop-out, and heightened risk of relapse.[53,54] Interventions aimed at increasing social interactions may prove to be valuable in reducing depression symptoms and relapse (Box 19.3).[55]

Box 19.3

Comprehensive Treatment of Risk Factors May Promote Resilience and Rapid Recovery From Depression



(From Southwick SM, Charney DS. The science of resilience: implications for the prevention and treatment of depression. *Science*. 2012;338(6103):79–82.)

Genetic and environmental factors, such as uncontrollable stress, interact to increase the risk of developing major depression. These factors interact in complex ways that are not fully understood to dysregulate neurobiologic systems that compromise adaptive cognitive, emotional, social, and physiologic/health functions. For example, exaggerated stress-induced arousal of sympathetic and neuroendocrine systems may be due, in part, to genetic polymorphisms in serotonin, endocrine, and neuropeptide systems. However, the extent to which a genetic predisposition contributes to severe depression also may arise

from the individual's inability to cope with stressors, inexperience in exhibiting flexible psychosocial and emotional skills, and lack of physical health, among others. Identifying and addressing these varied genetic and cognitive/behavioral/socioemotional/health risk factors of depression may open new doors to effective treatment. In particular, combined treatments or behavioral programs that promote resilience, the ability to recover from adversity—such as cognitive-behavioral therapy; social support; and improved diet, sleep, and exercise used in conjunction with current or novel drug medications that lessen or reverse the neuropathophysiology associated with heightened activation of stress systems—may quickly lead to remission. Although in its early stages, the development of comprehensive resilience programs holds promise not only for treating depressed individuals but also for proactively serving to diminish or prevent the risk of acquiring stress-related disorders.

Bipolar Disorder

FDA-approved treatments are available for bipolar disorders.[56] Individuals with bipolar I disorder are treated with lithium and in some cases with SSRIs. Several medications are also used, including anticonvulsants (e.g., carbamazepine, valproate, gabapentin, lamotrigine, or topiramate). Many individuals with bipolar disorder are currently prescribed second-generation antipsychotics (e.g., clozapine, risperidone, ziprasidone, quetiapine) in an outpatient setting. However, the comparative effectiveness of mood stabilizers and antidepressants compared to second-generation antipsychotics in individuals with bipolar disorder remains unknown.[57] As in

depression, ECT is administered when manic individuals fail to respond to medication, are pregnant, or have cardiovascular disease.

Increasing evidence reveals that pharmacotherapy alone is not effective in preventing the recurrences of bipolar disorder. Randomized clinical trials are beginning to show that bipolar persons treated with medication may benefit when exposed to various forms of psychotherapy. Here, pharmacotherapy and psychosocial interventions reduce episode recurrences and promote symptom management strategies and coping skills. Furthermore, individuals with bipolar disorder are more likely to continue the combined treatments when conducted in family or group formats or when brief psychoeducation is used, as opposed to formalized versions of individual psychoeducation in an outpatient setting.[58]

The treatment of bipolar II in children has raised concerns because of complications with its diagnosis. For example, bipolar II and attention-deficit/hyperactivity disorder (ADHD) share the common features of elevated behavioral activity levels, excessive talking, restlessness, and distractibility. Misdiagnosing bipolar II as ADHD has negative consequences for treatment because the stimulant drugs Ritalin and Adderall, which are frequently used to treat ADHD, will potentially exacerbate the symptoms of a child with bipolar II disorder. On the other hand, when ADHD is misdiagnosed as bipolar disorder, the child may begin an ineffective treatment regimen. To reduce misdiagnosis of children with bipolar and other similar symptomatic characteristics, such as ADHD as well as conduct disorder and oppositional defiant disorder, the *DSM-5*[21] now includes a category called *disruptive mood dysregulation disorder*. This diagnosis will be used to describe a young child (6 to 10 years of age) who exhibits only some of the symptoms of bipolar II, such as frequent temper outbursts, irritability, and bad moods. This category is hoped to exclude children from being diagnosed with bipolar disorder and reduce possible unwarranted treatment with strong medications.[59]

Anxiety Disorders

Fear and anxiety are normal feelings expressed in threatening or harmful situations. The symptoms may include arousal, tenseness, and increased autonomic activity such as heart rate, blood pressure, and respiration. In addition, individuals often engage in protective behavioral responses such as flight or avoidance. These physiologic and behavioral responses allowed humans to adapt and cope under a variety of situational challenges. However, when fear and anxiety become too intense and undermine the ability to function on a daily basis, the individual may develop an anxiety disorder. Anxiety disorders are the most prevalent psychiatric illness, occurring in approximately 10% to 30% of the general population. Notably, many individuals with anxiety disorders also exhibit symptoms of major depression, and the high comorbidity of anxiety disorders and depression suggests a common neural pathophysiologic basis linking these two illnesses. Nonetheless, a single gene is unlikely to be a major factor linking the occurrence of complex disorders such as depression and anxiety. A recent study identified 509 genes in depression and anxiety. Of interest, nearly 40% of the variation in a neurotic personality correlate strongly with self-doubt, anxiety, and depression and overlap with genes found in people with comorbid conditions of anxiety disorders and major depression. Connecting a number of genes to symptoms of anxiety and depression may offer a broader insight into the shared genetic risk factors and biological mechanisms between psychiatric disorders.[60] This section presents an overview of several anxiety disorders, including panic disorder (PD), social anxiety disorder (SAD), generalized anxiety disorder (GAD), and posttraumatic stress disorder, which in *DSM-5* is listed in the chapter on trauma- and stressor-related disorders.[21]

Panic Disorder

PD consists of multiple disabling panic attacks and is characterized by intense autonomic arousal involving a wide variety of symptoms, including lightheadedness, a rapid heart rate (tachycardia), difficulty breathing, chest discomfort, generalized sweating, general weakness, trembling, abdominal distress, and chills or hot flashes. Between

panic attacks, the individual often worries about future panic attacks and fear of losing control and dying. Symptoms originally occur spontaneously and vary in length from several minutes to an hour.

A notable complication of panic disorder is the development of agoraphobia or phobic avoidance of places or situations where escape or help is not readily available. The agoraphobic individual will avoid being away from home, standing in line or in a crowd, or traveling in a train, plane, or automobile. Severely agoraphobic individuals become housebound.

Etiology and Pathophysiology

Genetic factors play a major role in PD. The risk is nearly 20% among first-degree relatives, and the prevalence of PD is about 1.5% in men and up to 3.0% in women with no family history of the illness. Some studies suggest that the cholecystokinin (CCK) receptor gene on chromosome 11p may be linked to PD.[61]

The etiology of PD is not known, but the ability to elicit physical symptoms of panic attacks by chemicals, called *panicogens*, provides insight into its pathophysiology. Panic-prone individuals respond to panicogens that include carbon dioxide, caffeine, CCK, sodium lactate, and adrenergic receptor agonists, such as yohimbine. Carbon dioxide and sodium lactate, two well-studied panicogens, alter brain pH balance that panic-prone people are sensitive in detecting. Brain pH chemosensors are located in the brainstem medulla and pons, the midbrain serotonergic raphe neurons, the hypothalamus, and the amygdala. Heightened pH sensitivity in the amygdala may play a key role in generating fearful perceptions and activating the cerebral cortex and neural circuits in the temporal lobe and brainstem, which further facilitates the production of panic symptoms (see Figs. 19.7 and 19.9).[62] Exaggerated activation of physiologic and behavioral arousal stemming from the noradrenergic locus ceruleus neurons also may enhance the symptoms of panic. Thus, panic-prone individuals appear especially sensitive in detecting pH alterations in brain sites that modulate fear and arousal.

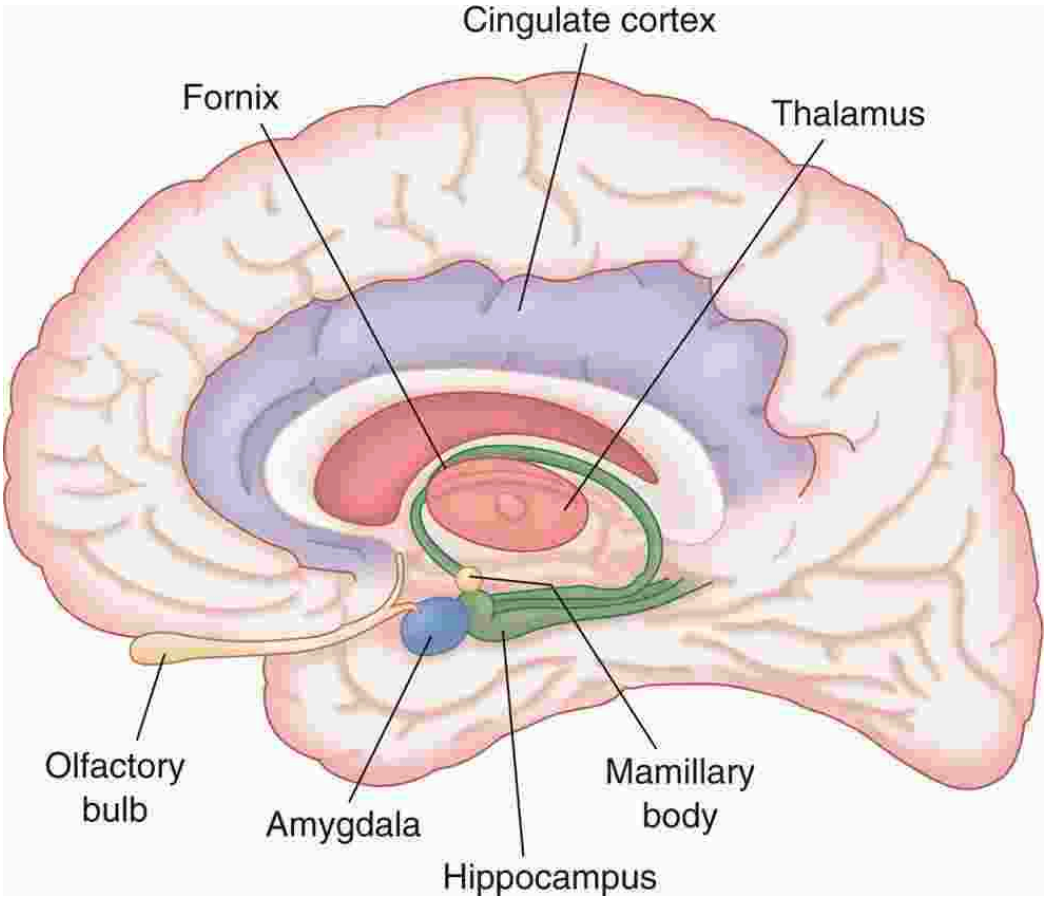

FIG. 19.9 The Lsimbic System. Structures of the limbic system play important roles in emotion, learning, and memory.
Pathophysiology in limbic structures is frequently found in mental disorders.

An illustration depicts the sagittal section of the brain with labels indicating the structure of the limbic system clockwise from the left. The olfactory bulb, fornix, cingulate cortex, thalamus, mamillary body, hippocampus, and amygdala.

PD also may involve the GABA-benzodiazepine (BZ) receptor system. BZ increases the $GABA_A$ ion channel response to GABA,

thereby elevating chloride ion influx and producing a neuronal inhibitory effect. Brain imaging work reveals a reduction in BZ receptor binding in brain regions including the hippocampus, insular, and prefrontal cortex.[63] Drugs that block the BZ receptor are reported to increase panic attacks and feelings of anxiety, suggesting that an alteration in inhibitory neuromodulation contributes to PD.

Treatment

Up to 80% of individuals affected by PD respond to CBT and antidepressant drugs, either separately or in combination. In CBT, the individual learns that the physical symptoms are not fatal and attempts to exert control over the anxiety and panic. For example, breathing exercises to control hyperventilation serve to lessen the intense physiologic symptoms of panic, such as elevated heart and respiration rates. Another benefit of CBT is awareness of adherence with drug medications. However, for individuals with mild agoraphobia, CBT alone may be effective.

Antidepressants such as SSRIs are considered first-line medications for PD. Among the SSRIs, paroxetine and sertraline have received FDA approval specifically for PD. Venlafaxine, a serotonin-norepinephrine reuptake blocker, also is effective.

BZs, such as alprazolam and clonazepam, are other medications for treating PD. These medications also serve as an adjunct or augmentation therapy for individuals who do not fully respond to SSRIs. Short-term effects of BZs include sedation, ataxia, and cognitive impairments. Long-term BZ treatment may lead to potential physiologic and psychologic dependence. Abrupt BZ withdrawal induces a withdrawal syndrome of heightened reemergence of anxiety, insomnia, photophobia, and diarrhea. A gradual reduction in BZ medication or adjunct CBT may reduce the reliance and withdrawal symptoms of BZs.

Social Anxiety Disorder

SAD, also known as *social phobia*, is characterized by fear and avoidance of social situations. For example, the anxious person may

feel very uncomfortable having a conversation or interacting with others and very conscious of being scrutinized and humiliated or rejected by others. A person diagnosed with SAD suffers significant distress or impairment that interferes with ordinary routines in everyday social settings, at work or at school.[21] Epidemiologic surveys indicate that SAD is one of the most common psychiatric disorders with 12-month and lifetime prevalence rates of 6.8% and 12.1%, respectively.[64] The onset of SAD often occurs during adolescence.[65] As with adults, children with SAD exhibit fear of speaking, reading, and eating in public; going to parties; speaking to authority figures; and engaging in informal social interactions.

Etiology and Pathophysiology

A prominent finding from brain imaging work with SAD people is the increased activity found in limbic and frontal cortical areas. Exposure to facial expressions of threat, which individuals with hypersensitive SAD are likely to perceive as extreme dislike, rejection, or criticism, often implicates the amygdala and its connections to other brain regions. Heightened anxiety in SAD may arise from deficits in an inhibitory tone from prefrontal cortical areas to the amygdala resulting in increased amygdala activation and a fear bias in threat-related processing.[66] Support of abnormal signaling comes from work showing decreased white matter connectivity between the amygdala and orbitofrontal cortex.[67]

Neuroimaging studies have also implicated neurotransmitter systems. One study in individuals with SAD noted altered serotonergic neurotransmission,[68] which may be caused by a reduction in the serotonin 5-HT1A-binding protein in the amygdala, anterior cingulate, and insula. Another study found a reduction in GABA in the thalamus of individuals with SAD.[69] Impaired GABAergic function may contribute to amygdala hyperactivity observed in SAD.

The neuropeptide oxytocin (OXT) has attracted considerable research attention. OXT is produced in the hypothalamic

paraventricular and supraoptic nuclei and secreted by the posterior pituitary gland. OXT is well known to be secreted during childbirth and lactation. In addition, an increasing body of work indicates that OXT secretion has antianxiety effects by reducing HPA activation; promoting social, attachment, and maternal behavior; and increasing empathy and trust.

Of relevance to SAD, OXT plasma levels are reduced in individuals with SAD before and after playing a trust game, which normally increases OXT levels and promotes cooperation and reciprocation in control groups.[70] The reduction in OXT may account for the amygdala hyperactivity accompanied by excessive social avoidance and fear in SAD.[71] Indeed, intranasal OXT administration is reported to attenuate amygdala reactivity to threatening facial expressions,[72] perhaps by promoting GABAergic inhibition in the amygdala.[73]

Intranasal OXT also improves self-reported speech performance compared with placebo.[74] The oxytocin system is further implicated in SAD on a genetic level. An OXT receptor single nucleotide polymorphism was found to be associated with negative emotionality[75] and moral judgments.[76] On the basis of these studies, the OXT system is a promising target to potentially develop treatments for SAD and disorders related to social dysfunctioning, such as autism.[77]

Treatment

The antidepressant SSRIs that include fluoxetine, paroxetine, sertraline, and fluvoxamine along with the serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine are considered first-line pharmacotherapies for SAD. These medications shared similar efficacy profiles and are approved by the FDA for treatment of SAD. However, drug-related side effects, such as agitation and sexual dysfunction, can be distressing for some individuals with SAD. Also, discontinuation of medication increases the risk for relapse. One study reported that 60% of indviduals with SAD relapsed after

discontinuation of sertraline treatment.[78] Alternatives to SSRI and SNRI treatments may include psychologic or cognitive and group behavioral therapies.[79,80] Individuals with SAD are reported to respond well to CBT compared to placebo. The choice between pharmacotherapy and CBT may depend on the person's preference and access to treatment. Of note, psychologic interventions at the end of acute drug treatment appear beneficial in continuing to alleviate the symptoms of SAD and may lower the side effects of long-term drug treatment.

Generalized Anxiety Disorder

Excessive and persistent worries are the hallmarks of GAD. The individual worries about life events such as marital relationships, job performance, health, money, or social status. The lifetime prevalence rates of GAD range from 4.1% to 6.6%, with somewhat higher rates in women than in men. GAD usually emerges in the early twenties but can occur in childhood. Six major symptoms of GAD have been identified and include restlessness, muscle tension, irritability, being easily fatigued, difficulty concentrating, and difficulty sleeping. The individual startles easily and frequently suffers from depression and panic attacks. The severity of symptoms fluctuates over time and may be linked to the changing nature of stress. Although GAD tends to be chronic, the symptoms may lessen with age. A frequent complication of GAD is substance abuse, which may result from self-medication with alcohol or drugs to relieve anxiety symptoms.

Etiology and Pathophysiology

Female twin studies suggest a concordance rate of 30%, but disease genes linked to specific chromosomes have yet to be identified. Abnormalities in the norepinephrine and serotonin systems were reported in GAD.[81] For example, there is a reduction in α_2-adrenergic receptor binding, a decrease in serotonin levels in CSF, and reduced platelet binding of paroxetine, an SSRI. Another reported alteration in GAD is a reduction of BZ binding in the left

temporal hemisphere.[82] Two functional magnetic resonance imaging (fMRI) studies have revealed alterations in specific brain regions in adults and adolescents with GAD. One study in GAD adults showed that increased anticipatory anxiety was associated with elevated cingulate cortex activity, and both the heightened anxiety and cingulate cortex activation were reduced after 8 weeks of treatment with the SNRI venlafaxine.[83] This study suggests that a decrease in pathophysiologic cingulate cortex activity is a predictor of GAD treatment efficacy. In children and adolescents with GAD, brief exposure to masked angry faces induced heightened right amygdala activation, which correlated positively with the severity of anxiety.[84] This study underscores the role of abnormal amygdala activity in attentional bias or vigilance to threats in GAD.

Treatment

GAD is diagnosed when a person spends at least 6 months worrying excessively and engages in at least three of the six major symptoms.[21] SNRIs, such as venlafaxine or the SSRIs paroxetine and escitalopram, have become first-line therapeutics for managing GAD. These medications may produce relief of GAD symptoms within 1 week and are effective in treating comorbid symptoms of depression. Buspirone, which has an affinity for serotonin receptors (5-HT_{1A}), is another treatment option, although the onset of clinical efficacy may take 2 weeks. The primary side effects of buspirone, which lessen over time, include dizziness, headaches, nausea, and mild nervousness. GAD nonresponders to SNRIs or buspirone may be treated with BZs. However, because GAD tends to be chronic, and comorbid with depression or other anxiety disorders,[85] BZs are usually limited to short-term use and uncomplicated cases of GAD. In addition to drug therapy, behavioral therapy is used to acquire relaxation techniques that control anxiety.

Posttraumatic Stress Disorder

Exposure to a terrifying or life-threatening event may produce posttraumatic stress disorder (PTSD).[86,87] Although the disorder was initially described in combat situations and called "shell shock," "war neurosis," or "traumatic neurosis," PTSD does not develop only from exposure to traumatic experiences in the battlefield. PTSD may develop after exposure to threat of death, serious injury, or sexual violation. The disorder may develop within hours of the traumatic experience or after several months or years. The *DMS-5* criteria for PTSD list four diagnostic clusters described as re-experiencing, avoidance, negative cognitions and mood, and arousal. *Re-experiencing* refers to spontaneous recollection of the traumatic event, recurrent nightmares, flashbacks, or other intense or chronic psychologic distress. *Avoidance* refers to distressing memories, feelings, or external reminders of the traumatic event. *Negative cognitions and mood* may occur from a persistent and distorted sense of blame of self or others, from estrangement from others or diminished interest in activities, or from an inability to remember key aspects of the event. *Arousal* is marked by aggressive, reckless, or self-destructive behavior, sleep disturbances, hypervigilance, or related problems. The "flight" or "fight" behavioral aspects also are associated with the arousing nature of PTSD.

The lifetime prevalence rate of PTSD is 7% to 8%. In men, PTSD is usually found among combat veterans, whereas PTSD in women is often related to rape or assault. Abused children also may develop PTSD. Individuals with a history of psychiatric illness (major depression and panic disorder) or those lacking strong social support appear more sensitive to the effects of traumatic stress.

Etiology and Pathophysiology

The primary etiology of PTSD is exposure to a terrifying life-threatening event and likely involves stress-induced alterations in several neural structures and neurotransmitter systems. The amygdala and prefrontal cortex are highly involved in the pathophysiology of PTSD because these brain structures normally

play important roles in how fearful memories are stored, retrieved, and extinguished. Individuals with PTSD who are exposed to trauma-related stimuli generally exhibit increased activity in the amygdala and diminished activity in prefrontal cortical areas. Persistent dysregulation of this fear-based memory system may underlie chronic PTSD—that is, the failure of prefrontal cortical inhibition to control amygdala-induced activation of fear compromises the extinction of fear memory.[88] Structural brain imaging studies show that combat-exposed PTSD victims also have a smaller hippocampus, a brain structure involved in endocrine functions and memory formation. Pediatric PTSD studies reveal a more generalized effect of trauma on reducing total brain volume. Other brain sites exhibiting increased activity in PTSD are the dorsal anterior cingulate cortex and insula, albeit similar findings were reported in other anxiety disorders (e.g., GAD, obsessive-compulsive disorder).[89]

A recent study reported PTSD is linked to neurodegeneration by cortical thinning, cellular aging, and a shorter-than-expected lifespan. Increased neurodegeneration and thinning in the brain occurred in the right lateral orbitofrontal cortex and right posterior cingulate cortex, which are brain areas associated with the regulation of emotions and threats; such neurodegenerative effects are also found in depression and cognitive impairments.[90]

Treatment

Chronic PTSD lasting for years may occur in 30% of diagnosed individuals. Paroxetine and sertraline are considered first-line SSRI medications for chronic PTSD because of their tendency to lessen the recurrent nightmares and flashbacks and to treat the high accompanying prevalence of depression and substance abuse. Other antidepressants, such as the TCAs (amitriptyline and imipramine), have moderate effects and are second-line drugs; drugs such as nefazodone and bupropion may provide benefits. BZs should be avoided as they have been found to be clinically ineffective for PTSD

treatment and are associated with increased risks such as severity of PTSD symptoms, aggression, depression, and substance use.[91] Individuals with PTSD may undergo psychotherapy or exposure therapy that re-exposes them to controlled situations that elicit the fear responses. However, some individuals with PTSD are unable to tolerate the fear re-experiencing event. See the Emerging Science Box: Chronic Post-traumatic Stress Disorder Treatment for investigatory treatment options.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is a chronic, disabling illness characterized by the two core symptoms of obsessions and compulsions. Obsessions are recurrent, intrusive thoughts or impulses that provoke intense anxiety that leads the individual to perform compulsive repetitive behavioral acts to alleviate the anxiety activated by the obsessions. Although *DSM-5* no longer classifies OCD as an anxiety disorder,[21] obsessions are associated with significant distress and compulsions that are consciously performed to reduce the obsession-related anxiety. OCD is a time-consuming illness that significantly impairs a range of everyday functions, such as social relationships, job performance, and academic success.

Examples of obsessions may include preoccupation with contamination, doubting, religious or sexual themes, or the belief that a negative outcome will occur if a specific act is not performed. Compulsions are ritualized acts such as washing,

Emerging Science BoxChronic Posttraumatic Stress Disorder Treatment

A treatment that rapidly reduces the symptoms of chronic posttraumatic stress disorder (PTSD) is currently under investigation. A recent randomized control trial found that repeated intravenous ketamine administration over 2 weeks in people with chronic PTSD significantly and rapidly reduced the

symptoms of PTSD in 24 hours and continued over a median of 27.5 days. In addition to an improvement in PTSD symptoms which included intrusive thoughts, avoidance, and negative alterations in cognition and mood, comorbid depressive symptom severity was also significantly reduced compared to midazolam treated groups. Midazolam is a BZ used in this study as psychoactive anxiolytic control drug and found to temporarily reduced symptoms of anxiety in only a few people with PTSD. Esketamine, the s-enantiomer of ketamine, was approved by the FDA for intranasal use for people with treatment-resistant depression. Whether the easy intranasal application of esketamine produces the same beneficial effects of ketamine for chronic PTSD and comorbid depression remains to be determined.

Data from Feder A, et al. A randomized controlled trial of repeated ketamine administration for chronic posttraumatic stress disorder. *American Journal of Psychiatry*, 2021;178:193–202.

cleaning, checking, counting, organizing, and repeating specific thoughts or prayers. Performing the compulsions may provide temporary relief of the anxiety but also reinforces the dysfunctional thoughts and neural circuits that underlie the negative obsessions that generate the compulsive anxiety.

The lifetime prevalence rates of OCD range from 2% to 3% with a slightly higher onset in males during childhood or adolescence. In many cases, the OCD individual also is diagnosed with major depression, PD, or GAD.[92–94]

Among children with OCD, common comorbid disorders include Tourette syndrome, oppositional defiant disorder, ADHD, and depression;[95] 30% to 50% of adults report experiencing OCD in childhood.[96]

Etiology and Pathophysiology

Family and twin studies demonstrate that OCD involves polygenetic and environmental risk factors.[97] First-degree relatives of affected

adults also are at increased risk (4.6%) of Tourette syndrome and tics in comparison with control relatives (1%). Thus, OCD and Tourette syndrome may share common genes and pathophysiology.

Functional brain imaging studies have identified a pathologic brain circuit consisting of increased metabolism in the anterior thalamus, orbitofrontal cortex, dorsal anterior cingulate cortex, and especially in the basal ganglia (Fig. 19.10) subregions of the caudate and putamen.[93,94] Abnormalities in caudate volume in OCD also are found using structural neuroimaging techniques. This neural circuit is activated in OCD people by symptom provocation and reduced by effective pharmacotherapy or psychotherapy. Some studies suggest that genes affecting the serotonergic, dopaminergic, and glutamate systems may contribute to the pathophysiologic basis of this OCD neural circuit.[95] One particular abnormality in the neural circuit of OCD is the dorsal anterior cingulate cortex (dACC). Several functional neuroimaging studies reported hyperactivity of the dACC in OCD people compared to controls. Furthermore, electrophysiologic studies showed altered biomarkers of cognitive control in the dACC. The dACC is hypothesized to be a key center that receives negative emotional and reinforcing information and integrates that information to direct motivated behavior.[98,99]

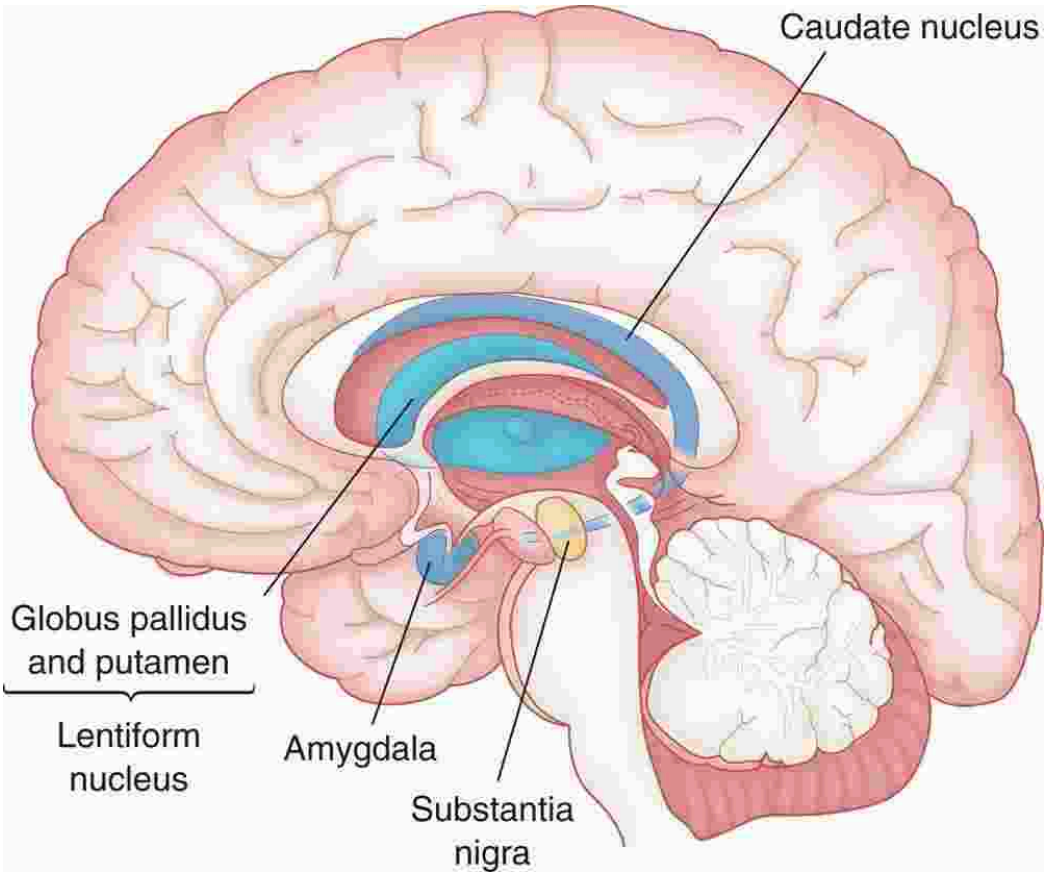

FIG. 19.10 Basal Ganglion.
Structures of the basal ganglion, which include the caudate nucleus, putamen, globus pallidus, and substantia nigra, are important in movement.

An illustration depicts the sagittal section of the brain with labels indicating the structure of the basal ganglion clockwise from the left. Globus pallidus and putamen comprising lentiform nucleus, caudate nucleus, substantia nigra, and amygdala.

Treatment

SSRIs, including fluoxetine, fluvoxamine, paroxetine, escitalopram, and sertraline, are the first drugs of choice for OCD.[100] Approximately 70% to 80% of OCD individuals show a partial positive response that may be further improved by other medications. For example, clonazepam, a BZ, is found to improve the effects of fluoxetine and clomipramine therapy. The TCA clomipramine is also used if SSRIs are not effective or are not tolerated by the individual with OCD. The therapeutic effects of SSRIs and clomipramine may be the result of blocking serotonin reuptake and increasing serotonin availability in the brain of individuals with OCD.

Antipsychotic drugs (e.g., aripiprazole, haloperidol, risperidone, or quetiapine) in combination with SSRIs also are effective, especially in comorbid OCD and tic disorders. Here, the normalization of dysfunctional serotonin and dopamine brain systems in OCD may underlie the therapeutic effects of SSRIs and dopamine receptor-related drugs.[101,102]

Psychotherapy involves verbal interactions between a therapist and the individual to overcome the mental disorder. Several types of psychotherapy are available, but CBT and response preventive therapy are effective in treating OCD. CBT is a problem-focused, goal-directed, and time-limited treatment of the abnormal learned obsessions and compulsive actions. Response prevention therapy involves exposure to cues that elicit distress followed by preventing the individual from engaging in compulsive rituals for at least an hour or until the anxiety subsides. CBT employing response prevention therapy is found to produce long-term symptom remission.[103]

Because of the chronic nature of OCD, treatment in adults may involve pharmacotherapy, psychotherapy, a combination of pharmacotherapy and psychotherapy, brain modulation, or invasive brain methods.[104] In children, the American Academy of Child and Adolescent Psychiatry (AACAP)[105] recommends a combination of SSRI and CBT for those with moderate or severe OCD. However, recent meta-analysis studies find no strong evidence for the

superiority of SSRI and CBT combination treatment in comparison to CBT alone for children with OCD.[106,107]

In people with severe OCD who are resistant to pharmaco- or psychotherapy, ECT and TMS may be used to provide some relief of OCD symptoms. Although the FDA recently approved TMS for severe treatment-resistant OCD, its long-term efficacy requires further studies.[108] An alternative, promising treatment for OCD is DBS, which also is used for intractable depression.[109] DBS in the anterior limb of internal capsule, striatum/ventral capsule, nucleus accumbens, subthalamic nucleus, and inferior thalamic peduncle is effective in alleviating some OCD symptoms.[110,111]

Stimulating these brain regions may be reducing abnormal neuronal firing in the neuroanatomic circuitry linked to OCD. The long-term treatment effects of DBS are still under investigation.

Another invasive treatment for individuals with severe treatment-resistant OCD is neurosurgery. One focus of neurosurgery is to disconnect the basal ganglia from the frontal cortex.[112] Dorsal anterior cingulotomy also is used in the treatment of refractory OCD.[113] Neurosurgery offers significant relief of obsessions and compulsions in nearly 50% of treatment-resistant OCD individuals.

Summary Review

Schizophrenia

1. Schizophrenia is characterized by thought disorders that reflect discontinuity between emotion, thought, behavior, and cognition.
2. Symptoms of schizophrenia are classified into positive, negative, and cognitive categories. Positive symptoms include hallucinations, delusions, formal thought disorder, and bizarre behavior. Negative symptoms include flattened affect, alogia, anhedonia, attention deficits, and apathy.

Cognitive symptoms are the inability to perform daily tasks requiring attention and planning.

3. Schizophrenia has a strong genetic predisposition but environmental factors (e.g., viral infection, nutritional deficiencies, prenatal birth complications, urban upbringing) may interfere with genetically programmed neural development to alter brain structure and function.
4. Brain imaging studies reveal structural brain abnormalities including an enlargement of the cerebral ventricles and widening of the fissures and sulci in the frontal cortex. In addition, there is a reduction in the volumes of both the thalamus, which may disrupt communication among cortical brain regions, and the temporal lobe, which may be responsible for the manifestations of positive symptoms.
5. In schizophrenia, the frontal lobe shows a progressive loss in volume and a worsening of negative symptoms despite the use of antipsychotic medications. Blood flow and metabolism are reduced in the dorsolateral prefrontal cortex, compromising the ability to engage in goal-directed and cognitive problem-solving behavior.
6. Neurochemical abnormalities in dopamine and glutamate systems are found in schizophrenia.
7. The first generation of antipsychotic drugs blocks the dopamine D_2 receptor. The second generation, called atypical antipsychotics, blocks not only D_2 receptors but also dopamine, serotonin, and other neurotransmitter receptors. Antipsychotic medications are not always effective in treating the negative symptoms of schizophrenia. Talk therapies are used to improve medication adherence and to encourage coping strategies.

Mood Disorders: Depression and Bipolar Disorder

1. Major depression and bipolar disorder are two common mood disorders. Major depression is characterized by an intense

and sustained unpleasant state of sadness and hopelessness. In bipolar disorder, individuals show recurrent patterns of depression and mania, the latter characterized by extreme levels of energy and euphoria.

2. Environmental triggers such as psychosocial stress appear to facilitate the onset of depression in individuals with a genetic vulnerability.
3. A reduction in brain monoamine neurotransmission is linked to depression, whereas an elevated monoamine level is associated with mania.
4. Exposure to uncontrollable stress elevates secretion of the stress hormone cortisol, which increases both the secretion of proinflammatory cytokines and the risk of developing depression. Abnormalities involving thyroid hormones also are found in depression.
5. Stress-induced depression is accompanied by deficits in brain-derived neurotrophic factor (BDNF) and neurogenesis in the hippocampus. In animal models, stress-induced depression-like behavior and the accompanying deficits in hippocampal BDNF and neurogenesis are reversed by antidepressant treatment.
6. The frontal lobe and limbic system volumes are reduced in major depression and bipolar illness. In addition, blood flow is altered in prefrontal and limbic brain regions that include the amygdala, a structure implicated in emotional behavior.
7. Pharmacotherapy involves the use of monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and atypical antipsychotics. Manic and bipolar individuals are treated with lithium, mood stabilizers, and atypical antipsychotic medications. Severely depressed and manic people may be administered electroconvulsive therapy (ECT). Deep brain stimulation is another promising treatment for intractable depression.

Anxiety Disorders

1. When normal fear and anxiety mental states persist and become uncontrollable, an individual may develop an anxiety disorder. Panic disorder (PD), social anxiety disorder (SAD), and generalized anxiety disorder (GAD) are examples of uncontrollable fear and anxiety states that require medical attention.
2. Panic disorder consists of panic attacks characterized by intense autonomic arousal that occurs spontaneously and is accompanied by symptoms including lightheadedness, tachycardia, and difficulty breathing. In addition, the intense occurrence of autonomic responses is accompanied by heightened fear and anxiety that often continue between panic attacks.
3. Panic-prone people are sensitive in detecting pH alterations in the amygdala, a brain structure that modulates fear. An activated amygdala recruits the cerebral cortex and neural circuits in the temporal lobe and brainstem, which may further exacerbate symptoms of panic.
4. A reduction in benzodiazepine (BZ) receptor binding in brain regions, including the hippocampus, insula, and prefrontal cortex, also may contribute to the pathophysiology of panic disorder.
5. Panic disorder is generally treatable with cognitive-behavioral therapy (CBT) and antidepressants such as TCAs and SSRIs. BZs are used as an adjunct or augmentation therapy for individuals who are nonresponsive to SSRIs or TCAs.
6. Social anxiety disorder is a common anxiety disorder that often emerges in adolescence and is characterized by fear and avoidance of social situations. SAD people are very sensitive in being evaluated and embarrassed or rejected by others.
7. Neuroimaging studies in SAD people are revealing abnormal connections between the prefrontal cortex and the amygdala.
8. The neuropeptide oxytocin (OXT) promotes social behavior, empathy, and trust. Secretion of OXT is reduced in SAD people, and a single nucleotide polymorphism of an OXT

receptor gene is found to be altered in SAD, both of which suggest that OXT plays a major role in the pathophysiology of SAD.

9. SAD treatment may involve SSRI or serotonin-norepinephrine reuptake inhibitor (SNRI) drug or cognitive therapies.
10. GAD is characterized by excessive and persistent worries about life events. Individuals exhibit varying levels of motor disturbances, irritability, and fatigue that may be linked to fluctuations in psychosocial stress. Many GAD individuals manifest symptoms of depression.
11. Pathophysiologic changes in the cingulate cortex and amygdala may have prominent roles in stimulating anticipatory anxiety and attentional bias to threats in people with GAD.
12. Treatment of GAD usually involves a combination of behavioral therapy and drug medications, especially 5-HT/norepinephrine reuptake inhibitors.

Post-traumatic Stress Disorder

1. Posttraumatic stress disorder (PTSD) develops after exposure to a life-threatening or traumatic experience. Individuals experience recurring thoughts and flashbacks and nightmares of the terrifying event.
2. In PTSD, structural and/or functional alterations exist in the amygdala, prefrontal cortex, and hippocampus, which likely contribute to dysfunction in an emotional fear memory system.
3. Treatment of chronic PTSD is difficult and may involve psychotherapy and SSRI pharmacotherapy. Esketamine, a recently FDA-approved drug for treatment-resistant PTSD appears promising in rapidly alleviating the chronic symptoms of PTSD.

Obsessive-Compulsive Disorder

1. Obsessive-compulsive disorder (OCD) is a chronic illness characterized by irrational obsessions and ritualized acts that impair normal functioning and cause severe distress. It is a chronic disabling illness.
2. OCD is a time-consuming illness, which significantly impairs everyday functions, such as social relationships, job performance, and academic success. Examples of obsessions include preoccupation with doubting, religious or sexual themes, or the belief that a negative outcome will occur if a specific act is not performed.
3. A pathophysiologic brain circuit consisting of the anterior thalamus, orbitofrontal cortex, dorsal anterior cingulate cortex, and especially in the basal ganglia subregions of the caudate and putamen is involved in OCD.
4. OCD requires long-term treatment that may include psychotherapy and pharmacotherapy. In OCD people who are resistant these treatments, electroconvulsive therapy and transcranial magnetic stimulation may be used. People with severe OCD may require neurosurgery to disconnect regions of pathophysiologic brain circuit to provide relief of OCD symptoms. DBS may be another option for uncontrollable OCD.

Chapter Outline

OUTLINE

Development of the Nervous System in Children 640

Structural Malformations 641
- Defects of Neural Tube Closure 641
- Craniosynostosis 645
- Malformations of Brain Development 646

Alterations In Function: Encephalopathies 649
- Static (Nonprogressive) Encephalopathies 649
- Inherited Metabolic Disorders of the Central Nervous System 649
- Intoxications of the Central Nervous System 651
- Infections of the Central Nervous System 652

Cerebrovascular Disease in Children 653
- Perinatal Stroke 653
- Childhood Stroke 653

Epilepsy and Seizure Disorders in Children 654

Childhood Tumors 654
- Brain Tumors 654
- Embryonal Tumors 655

Neurologic disorders in children can occur from infancy through adolescence and include congenital malformations, genetic defects in metabolism, brain injuries, infection, tumors, and other disorders that affect neurologic function.

Development of the Nervous System in Children

The nervous system develops from the embryonic ectoderm through a complex, sequential process. A neural tube starts to form 2 and one-half weeks from conception and "zippers shut" by 4 weeks. The spinal cord, spine, brain, and skull form from this neural tube. By approximately day 175, the brain has developed into all of its parts (Fig. 20.1A–C). The brain continues the formation of network connections and synapses from birth to many years postnatally. Many different events happen simultaneously, and critical periods must pass uninterrupted if the vulnerable fetus is to develop normally. Genetic and environmental factors (e.g., nutrition, hormones, oxygen levels, toxins, alcohol, drugs, maternal infections, maternal disease) can have a significant effect on neural development.[1,2]

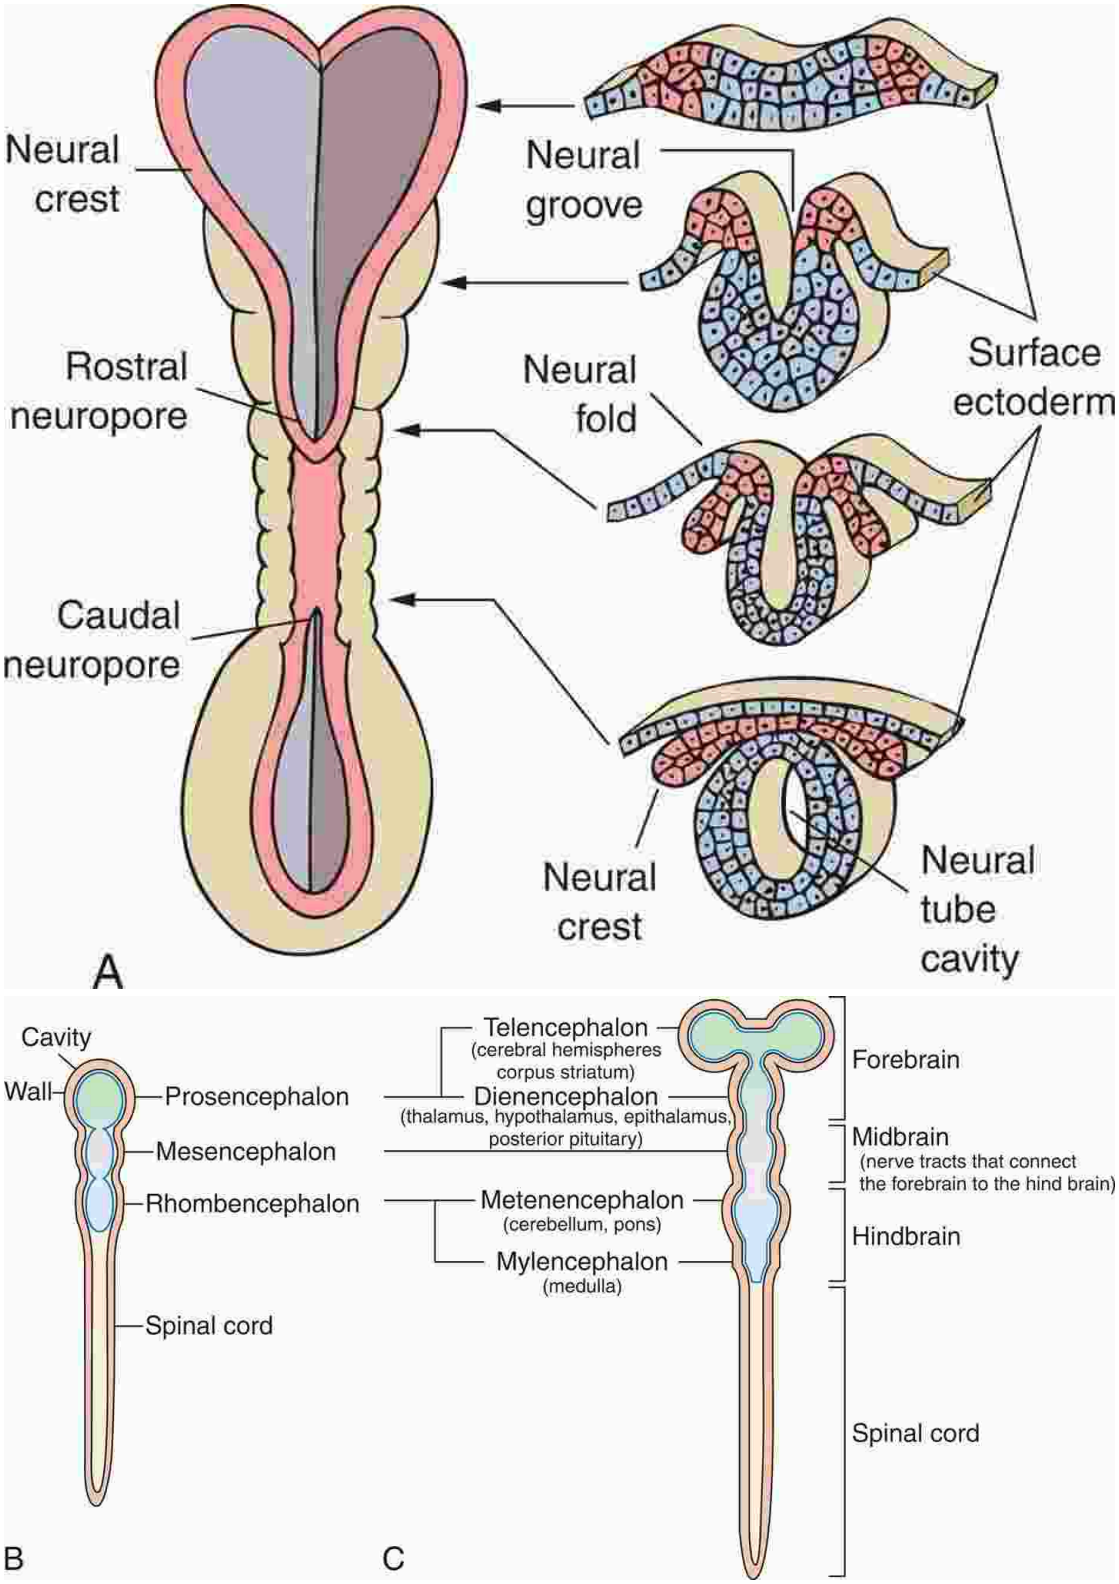

FIG. 20.1 Development of the Brain and Spinal Cord.
(A) Neural tube at 3 weeks' gestation. Neural folds have begun to fuse at the cervical level of the future spinal cord. *Right*, Cross sections of the neural tube at four different levels; at any given level the embryonic central nervous system goes

through a series of stages resembling these four cross sections. Total length of neural tube at this time is approximately 2.5 mm. **(B)** The anterior part of the neural tube enlarges to form the 3 primary vesicles of the brain. The narrow posterior part forms the spinal cord. **(C)** Primary and secondary vesicles develop into various parts of the brain.

Illustration A shows the lateral and cross-sectional views of the neural crest, the rostral neuropore, and the caudal neuropore. Accompanying illustrations show the stages of the folding of the neural cells and the surface ectoderm. â€¢ The illustration shows wavy layers of tissues made of alternating neural and ectoderm cells. â€¢ The illustration shows the neural cells forming a groove and the ectoderm cells clustered. â€¢ The illustration shows the neural fold with the ectoderm cells curving inward. â€¢ The illustration shows a neural tube cavity with a neural crest and a surface ectoderm. Illustration B shows and labels the following structures in a neural tube from the top to the bottom: cavity, wall, prosencephalon, mesencephalon, rhombencephalon, and spinal cord. Illustration C shows a neural tube develop into the primary and secondary vesicles. The following structures are labeled from the top to the bottom: forebrain, midbrain (nerve tracts that connect the forebrain to the hind brain), hindbrain, and spinal cord. The forebrain comprises the telencephalon (cerebral hemispheres corpus striatum) and the diencephalon (thalamus, hypothalamus, epithalamus, posterior pituitary). The hindbrain comprises metencephalon (cerebellum, pons) and myelencephalon (medulla).

The growth and development of the brain occur rapidly from the third month of gestation through the first year of life, reflecting the proliferation of neurons and glial cells. Although basically all of the neurons that an individual will ever have are present at birth, development of skills, such as walking, talking, and thinking, depends on these cells making correct connections with other cells and on myelination of the axons making those connections. The head is the fastest-growing body part during infancy. One-half of postnatal brain growth is achieved by the first year and is 90% complete by age 6 years. The cortex thickens with maturation, and the sulci deepen as a result of rapid expansion of the surface area of the brain. Cerebral blood flow and oxygen consumption during these years are approximately twice those of the adult brain.

The bones of the infant's skull are separated at the suture lines, forming two fontanelles, or “soft spots”: one diamond-shaped anterior fontanelle and one triangular-shaped posterior fontanelle. The sutures allow for expansion of the rapidly growing brain. The sutures remain open, allowing for brain and skull growth into early and mid-adulthood. The posterior fontanelle may be open until 2 to 3 months of age; the anterior fontanelle normally does not fully close until 18 months of age (Fig. 20.2). Head growth almost always reflects brain growth. Monitoring the fontanelles and careful measurement and plotting of the head circumference on standardized growth charts are essential elements of the pediatric examination.

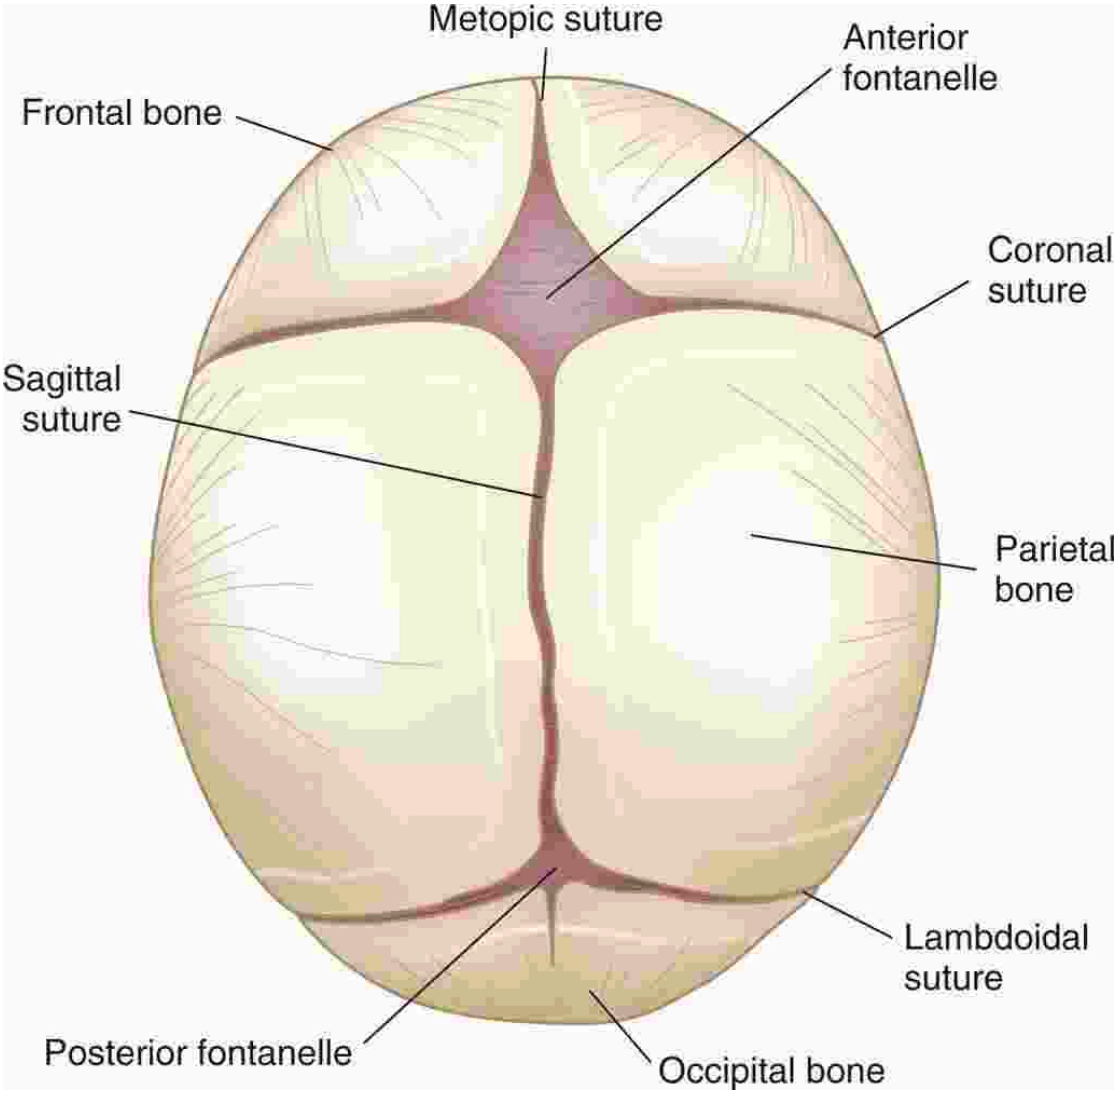

FIG. 20.2 Cranial Sutures and Fontanelles in Infancy.
Fibrous union of the suture lines and interlocking of the serrated edges occurs by 6 months; solid union requires approximately 12 years. (Head growth charts are available from the Centers for Disease Control and Prevention at www.cdc.gov/nchs/data/series/sr_11/sr11_246.pdf).

A coronal view of the skull shows and labels the following parts, clockwise from the top: metopic suture, anterior fontanelle, coronal suture, parietal bone, lambdoidal suture, occipital bone, posterior fontanelle, sagittal suture, and frontal lobe.

Because of the immaturity of much of the human forebrain at birth, neurologic examination of the infant detects mostly reflex responses that require an intact spinal cord and brainstem. A maturing brain tends to inhibit most reflexes, so as the brain matures, reflexes of infancy are normally lost. Persistent infantile reflexes can indicate developmental delay or a central nervous system (CNS) lesion. Absence of expected reflex responses at the appropriate age indicates general depression of central or peripheral

motor functions. Asymmetric responses may indicate lesions in the motor cortex or peripheral nerves or may occur with fractures of bones after traumatic delivery or postnatal injury (Table 20.1).

Table 20.1

Reflexes of Infancy

Reflex	Age of Appearance	Age at Which Reflex Should No Longer Be Obtainable
Moro	Birth	3 months
Stepping	Birth	6 weeks
Sucking	Birth	4 months awake
		7 months asleep
Rooting	Birth	4 months awake
		7 months asleep
Palmar grasp	Birth	6 months
Plantar grasp	Birth	10 months
Tonic neck	2 months	5 months
Neck righting	4–6 months	24 months
Landau	3 months	24 months
Parachute reaction	9 months	Persists indefinitely

Reflex	Age of Appearance	Age at Which Reflex Should No Longer Be Obtainable
Moro	Birth	3 months
Stepping	Birth	6 weeks

Plantar grasp	Birth	10 months
Tonic neck	2 months	5 months
Neck righting	4–6 months	24 months
Landau	3 months	24 months
Parachute reaction	9 months	Persists indefinitely

Structural Malformations

Malformations of the CNS affect approximately 5 to 10 children per 1000 births. CNS malformations are responsible for 75% of fetal deaths and 40% of deaths during the first year of life. CNS malformations account for 33% of all apparent congenital malformations, and 90% of CNS malformations are defects of neural tube closure.

Defects of Neural Tube Closure

Neural tube defects (NTDs) are an arrest of the normal development of the brain and spinal cord during the first month of embryonic development. They occur in approximately 3000 pregnancies in the United

States each year, although there are significant regional prevalence variations.[3] Fetal death often occurs in the more severe forms, thereby reducing the actual prevalence of neural defects at birth.

The cause of NTDs is believed to be multifactorial (a combination of genes and environment). No single gene has been found to cause NTDs. Folic acid deficiency during preconception and early stages of pregnancy increases the risk for NTDs, and supplementation (400 mcg of folic acid per day) ensures adequate folate status. In 1996 the United States mandated folate fortification in many foods, and since that time NTDs have decreased by 20% to 30%. Guidelines are available for folic acid supplementation for women at high risk for NTDs.[4] Other risk factors include a previous NTD pregnancy, maternal diabetes or obesity, use of anticonvulsant drugs (particularly valproic acid), and maternal hyperthermia.[5] Defects of neural tube closure are divided into two categories: (1) anterior midline defects (ventral induction) and (2) posterior defects (dorsal induction). Anterior midline defects may cause brain and face abnormalities, with the most extreme form being cyclopia, in which the child has a single midline orbit and eye with a protruding nose-like proboscis above the orbit. Anencephaly (*an*, "without"; *enkephalos*, "brain") and encephalocele are also anterior midline defects. Spina bifida (split spine) is the most common NTD. Vertebrae fail to close in spina bifida, and the defect includes meningocele, myelomeningocele, and spina bifida occulta. Disorders of embryonic neural development are summarized in Fig. 20.3.

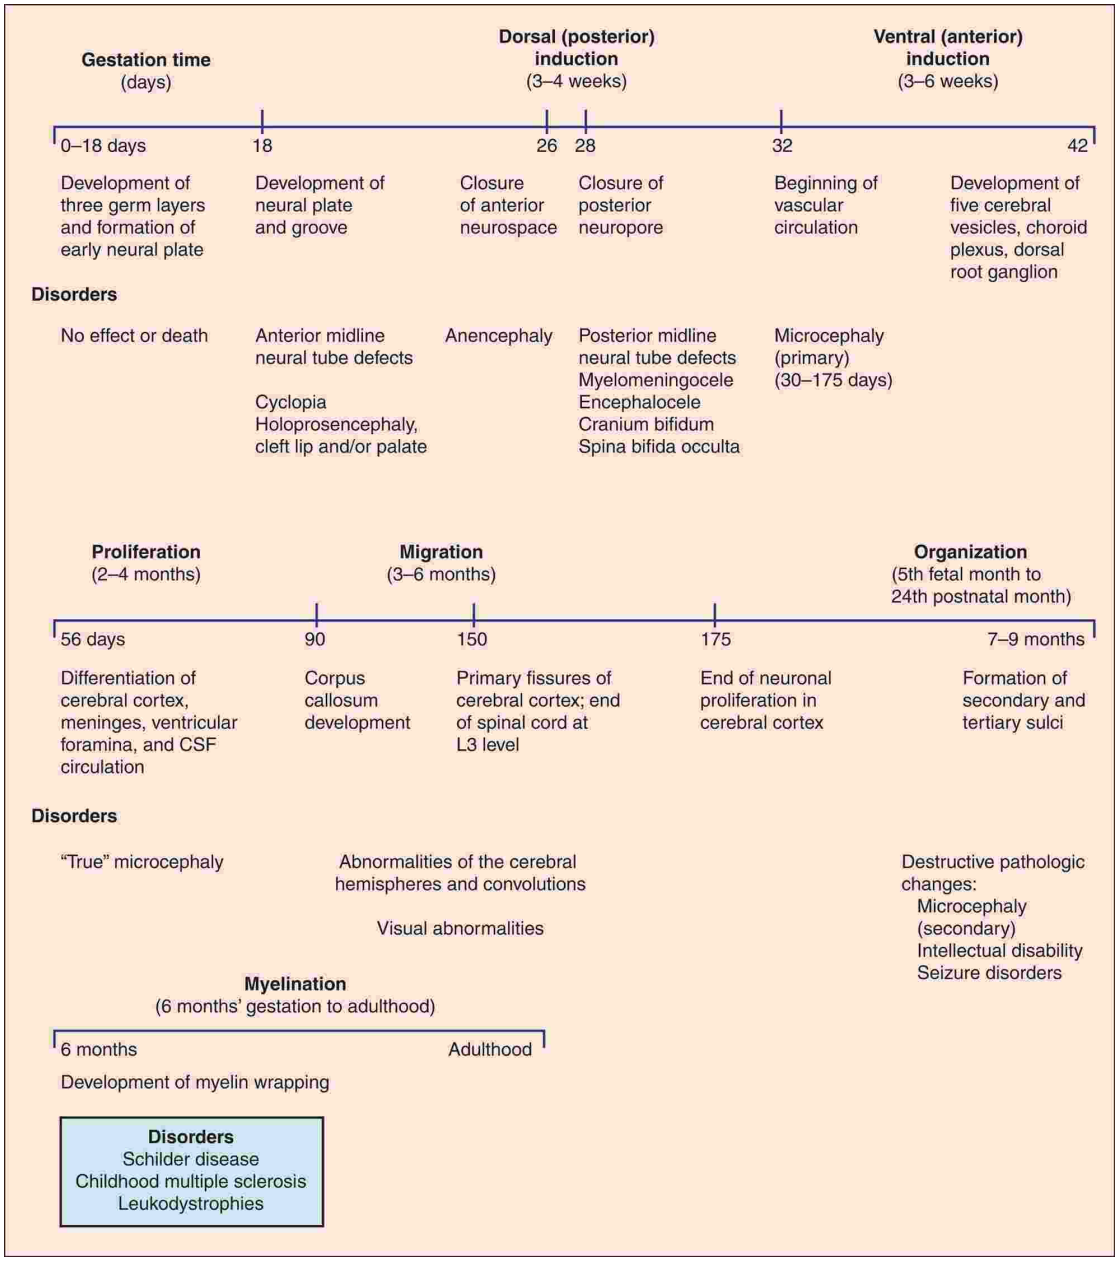

FIG. 20.3 Disorders Associated With Specific Stages of Embryonic Development.
CSF, Cerebrospinal fluid.

Three timelines show disorders associated with specific stages of embryonic development. Top panel. The timeline shows three sections: gestation time (days), dorsal (posterior) induction (3 to 4 weeks), and ventral (anterior) induction (3 to 6 weeks). The data from the timeline are as follows. â€¢ 0 to 18 days. Development of three germ layers and formation of early neural plate. Disorders have no effect or death. â€¢ 18 days. Development of neural plate and groove. Disorders include anterior midline neural tube defects, cyclopia holoprosencephaly, and cleft lip and or palate. â€¢ 26 days. Closure of anterior

neurospace. Disorder includes anencephaly. â€¢ 28 days. Closure of posterior neuropore. Disorders include posterior midline neural tube defects, myelomeningocele, encephalocele, cranium bifidum, and spina bifida occulta. â€¢ 32 days. Beginning of vascular circulation. Disorder includes microcephaly (primary; 30 to 175 days). â€¢ 42 days. Development of five cerebral vesicles, choroid plexus, and dorsal root ganglion. Middle panel. The timeline shows three sections: proliferation (2 to 4 months), migration (3 to 6 months), and organization (fifth fetal month to twenty-fourth postnatal month). The data from the timeline are as follows. â€¢ 56 days. Differentiation of cerebral cortex, meninges, ventricular foramina, and C S F circulation. Disorder includes true microcephaly. â€¢ 90 days. Corpus callosum development. â€¢ 150 days. Primary fissures of cerebral cortex; end of spinal cord at L 3 level. Disorders include abnormalities of the cerebral hemispheres and convolutions, and visual abnormalities. â€¢ 175 days. End of neuronal proliferation in cerebral cortex. â€¢ 7 to 9 months. Formation of secondary and tertiary sulci. The disorder includes destructive pathologic changes: microcephaly (secondary), intellectual disability, and seizure disorders. Bottom panel. The timeline shows two segments between myelination (6 months' gestation to adulthood). The data from the timeline are as follows. â€¢ 6 months. Development of myelin wrapping. Disorders include Schilder disease, childhood multiple sclerosis, and leukodystrophies. â€¢ Adulthood.

Anencephaly is an anomaly in which the soft, bony component of the skull and part of the brain are missing. This disorder occurs in approximately 1 in 4600 births in the United States each year.[6] These infants are stillborn or die within a few days after birth. The pathologic mechanism is unknown. Diagnosis is often made prenatally by using ultrasound or evaluating the maternal serum alpha fetoprotein (AFP).

Encephalocele refers to a herniation or protrusion of the brain and meninges through a defect in the skull, resulting in a sac-like structure. The incidence is approximately 1 in 10,500 live births in the United States each year.[7] Encephalocele treatment involves surgical closure of the skull opening. The complexity of the surgery depends on the location and content of the defect. Often several surgeries may be needed with variable long-term neurologic sequelae.

Meningocele is a sac-like cyst of meninges filled with spinal fluid and is a mild form of spina bifida (Fig. 20.4). It develops during the first 4 weeks of pregnancy when the neural tube fails to close completely and is the rarest type of spina bifida. The cystic dilation of meninges protrudes through the vertebral defect but does not involve the spinal cord or nerve roots and may produce no neurologic deficit or symptoms. Meningoceles occur most commonly in the lumbar spine.

FIG. 20.4 (A) Meningoencephalocele of the Occipital Region. (B1) Meningocele, Myelomeningocele. (B2) Normal Spine, Spina Bifida. (C) Myelomeningocele with an Intact Sac. (From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*. 10th ed. St Louis: Mosby; 2015.). (A from (From GilbertBarness: Potter's pathology of the fetus, infant and child, ed 2, Philadelphia: Mosby 2007, B from Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

Closeup A shows an infant on the side with a large herniation, the size of the infantâ€™s head, at the base of the head. Two pairs of accompanying illustrations show lateral and cross-sectional views of the spine. One pair shows meningocele and the other pair shows myelomeningocele. Closeup B shows an infant lying on its stomach with the legs curled toward to the abdomen. There is a large herniation on the lower back. Two pairs of accompanying illustrations show lateral and cross-sectional views of a normal spine and a spine affected by spina bifidia. Some of the vertebrae are missing in the spine with spina bifida.

Myelomeningocele (meningomyelocele; spina bifida cystica) is a hernial protrusion of a sac-like cyst (containing meninges, spinal fluid, and a portion of the spinal cord with its nerves) through a defect in the posterior arch of a vertebra. It is most commonly located as a sac on the lumbar and lumbosacral regions, the last regions of the neural tube to close. Myelomeningocele is one of the most common and severe developmental anomalies of the nervous system, with an incidence of approximately 1 per 4000 live births.[8] It accounts for 75% of all spina bifida cases.

Meningocele and myelomeningoceles are evident at birth as a pronounced skin defect on the infant's back (see Fig. 20.4). The bony prominences of the unfused neural arches can be palpated at the lateral border of the defect. The defect usually is covered by a transparent membrane that may have neural tissue attached to its inner surface. This membrane may be intact at birth or may leak cerebrospinal fluid (CSF), thereby increasing the risks of infection and neuronal damage. The spinal cord and nerve roots are malformed below the level of the lesion, resulting in loss of motor, sensory, reflex, and autonomic functions. A brief neurologic examination concentrating on motor function in the legs, reflexes, and sphincter tone is usually sufficient to determine the level above which spinal cord and nerve root function is preserved (Table 20.2). This is useful to predict if the child will ambulate, require bladder catheterization, or be at high risk for developing scoliosis (see Chapter 45).

Table 20.2

Functional Alterations in Myelomeningocele Related to Level of Lesion

Level of Lesion	Functional Implications
Thoracic	Flaccid paralysis of lower extremities; variable weakness in abdominal trunk musculature; high thoracic level may mean respiratory compromise; absence of bowel and bladder control
High lumbar	Voluntary hip flexion and adduction; flaccid paralysis of knees, ankles, and feet; may walk with extensive braces and crutches; absence of bowel and bladder control
Mid lumbar	Strong hip flexion and adduction; fair knee extension; flaccid paralysis of ankles and feet; absence of bowel and bladder control
Low lumbar	Strong hip flexion, extension, and adduction and knee extension; weak ankle and toe mobility; may have limited bowel and bladder function
Sacral	Normal function of lower extremities; normal bowel and bladder function

Modified from Sandler AD. Children with spina bifida: Key clinical issues. *Pediatric Clinics of North America*, 2010;57(4):879–892.

Hydrocephalus occurs in 85% of infants with myelomeningocele.[9] Seizures also occur in 30% of those with myelomeningoceles. Visual and perceptual problems, including ocular palsies, astigmatism, and visuoperceptual deficits, are common. Motor and sensory functions below the level of the lesions are altered. *These* problems *should not* worsen as the child grows. If a neurologic decline is identified in a child with spina bifida, the cause needs to be investigated.

Myelomeningoceles are almost always associated with the Chiari II malformation.[9] This is a complex malformation of the brainstem and cerebellum in which the cerebellar tonsils are displaced downward through the foramen magnum and into the cervical spinal canal. The upper medulla and lower pons are elongated and thin, and the medulla is also displaced downward and sometimes has a "kink" (Fig. 20.5). The Chiari II malformation is associated with hydrocephalus from pressure that blocks the flow of CSF. The Chiari II malformation is also associated with syringomyelia, an abnormality resulting from CSF migrating into the center of the spinal cord forming a pocket or cyst (syrinx) that can expand and cause pressure on the spinal cord, resulting in bowel, bladder, sensory, and motor dysfunction. The incidence of Chiari II malformation is reduced in those children operated on in utero for myelomeningocele.

FIG. 20.5 Normal Brain and Arnold-Chiari II Malformation.
(A) Diagram of a normal brain. **(B)** Diagram of an Arnold-Chiari II malformation, showing downward displacement of the cerebellar tonsils and medulla through the foramen magnum causing, compression and obstruction of cerebrospinal fluid flow.
(B, Modified from Barrow Neurological Institute of St Joseph's Hospital and Medical Center. Reprinted with permission.)

Illustration A is a left lateral view of the brain with the following parts labeled: cerebellum, cerebral tonsils, fourth ventricle, pons, and medulla. Illustration B is a left lateral view of the base of the brain with the following parts labeled: tentorium, fourth ventricle, pons, downward displacement of cerebellar tonsils through foramen magnum, area of compression, and medulla.

Other types of Chiari malformations are not associated with spina bifida. In type I Chiari malformation the cerebellar tonsils protrude into the foramen magnum and the brainstem is not involved. Type I Chiari is the most common of all Chiari malformations and may be asymptomatic or symptomatic (e.g., neck pain, dizziness, difficulty with gait and swallowing), sometimes requiring neurosurgical intervention. In type III, the brainstem or cerebellum extends into a high cervical myelomeningocele and can cause serious neurologic defects. Type IV is characterized by lack of cerebellar development (cerebellar hypoplasia).

Most cases of meningocele and myelomeningocele are diagnosed prenatally by a combination of maternal serologic testing (AFP) and prenatal ultrasound. In these cases, the fetus is usually delivered by elective cesarean section to minimize trauma during labor. Surgical repair is critical and can be performed by in utero fetal surgery or during the first 72 hours of life.[10] It is possible for a defect to occur without any visible exposure of meninges or neural tissue, and the term spina bifida occulta is then used. The defect is common and occurs to some degree in 10% to 25% of infants. Spina bifida occulta usually causes no neurologic dysfunction because the spinal cord and spinal nerves are normal. A sacral dimple on examination of a newborn infant can be associated with spina bifida occulta and should be further evaluated. Any midline skin abnormality such as a hairy tuft, hemangioma type lesion, or unusual dimple may indicate underlying spinal pathology and should be evaluated. Tethered cord syndrome may develop after surgical correction for myelomeningocele. The cord becomes abnormally attached or tethered in the lumbar cistern as a result of scar tissue as the cord ascends in the vertebral canal with growth.[11] Although radiographically almost all persons affected by myelomeningocele will appear to be tethered, only those with symptoms or new neurologic decline warrant further investigation, and prompt neurosurgical release of the tethering is appropriate. Special attention should be given to children whose myelomeningocele was corrected in utero, because their risks of spinal cord retethering is increased (see Emerging Science Box: In Utero Myelomeningocele Surgery).

Craniosynostosis

Skull malformations range from minor, insignificant defects to major defects that are incompatible with life. Craniosynostosis (craniostenosis) is the premature closure of one or more of the cranial sutures (sagittal, coronal, lambdoid, metopic) during the first 18 to 20 months of the infant's life. The incidence of craniosynostosis is approximately 1 per 2500 live births.[12] Males are affected twice as often as females. Fusion of a cranial suture prevents growth of the skull perpendicular to the suture line, resulting in an asymmetric shape of the skull. The general term *plagiocephaly*, meaning "misshapen skull," is used to describe deformities that result from craniosynostosis or from asymmetric head posture (positional). When a single coronal suture fuses prematurely, the head is flattened on that side in front. When the sagittal suture fuses prematurely, the head is elongated in the anteroposterior direction (known as scaphocephaly). Single suture craniosynostosis requires early surgical intervention

because it is not just a cosmetic issue. When multiple sutures fuse prematurely, surgical intervention is necessary. Brain growth may be restricted, and surgical repair may prevent neurologic dysfunction (Fig. 20.6). *Syndromic craniosynostosis* involves deformities in other systems (i.e., the heart, limbs, and CNS).

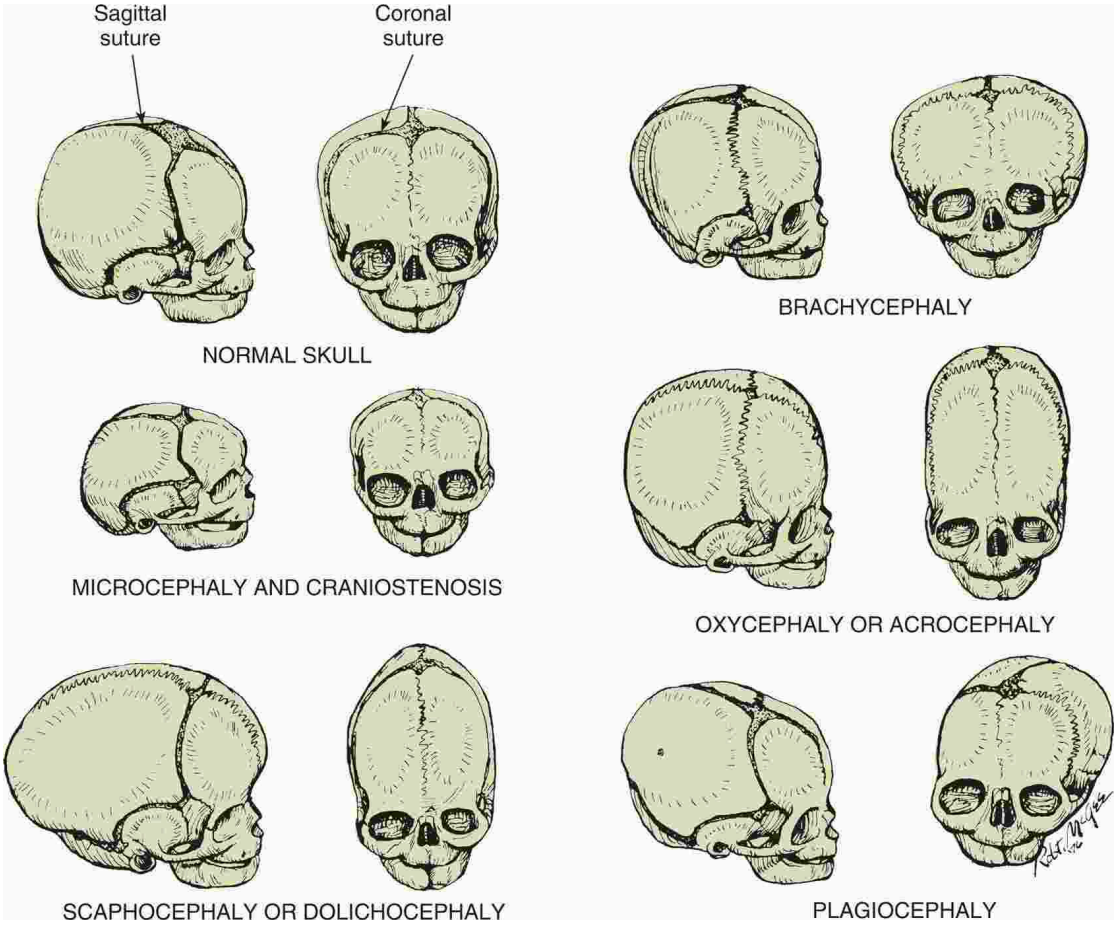

FIG. 20.6 Normal and Abnormal Head Configurations.
Normal skull: The bones are separated by membranous seams until the sutures gradually close. *Microcephaly and craniostenosis:* In microcephaly, the head circumference is more than 2 standard deviations below the mean for age, gender, race, and gestation, reflecting a small brain. Craniosynostosis is premature closure of the sutures. *Scaphocephaly or dolichocephaly* (frequency 56%): Premature closure of the sagittal suture, resulting in restricted lateral growth. *Brachycephaly:* Premature closure of the coronal suture, resulting in excessive lateral growth. *Oxycephaly or acrocephaly* (frequency 5.8% to 12%): Premature closure of all coronal and sagittal sutures, resulting in accelerated upward growth and a small head circumference. *Plagiocephaly* (frequency 13%): Unilateral premature closure of the coronal suture, resulting in asymmetric growth. (From Hockenberry MJ, Wilson *D. Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

Six pairs of illustrations of skulls show normal and abnormal head configurations. Each pair shows the right lateral view and the anterior view of the skull. Top left, normal skull. The sagittal suture is identified in the lateral view. The coronal suture is identified in the anterior view. Top right, brachycephaly. The sagittal suture in the lateral view is shrunken. The coronal suture in the anterior view is almost non-existent. The head is unusually large. Middle left, microcephaly and craniostenosis. The skulls are smaller than normal. The sagittal suture in the lateral view is shrunken. The coronal suture in

the anterior view is minimal. Middle right, oxycephaly or acrocephaly. The sagittal suture in the lateral view and the coronal suture are almost non-existent. The head is almost twice as long as normal. Bottom left, scaphocephaly or dolichocephaly. The skulls are larger and narrower. The sagittal suture and the coronal suture are minimal. Bottom right, plagiocephaly. The skulls are misshapen. The left and the right side are disproportional. The sagittal suture is present. The coronal suture is only partially present.

Malformations of Brain Development

Reduced proliferation or accelerated apoptosis (programmed cell death) of brain cells causes congenital microcephaly (microencephaly—small brain). Increased proliferation of brain cells causes megalencephaly (macrencephaly—abnormally large brain). Both disorders are rare. Diagnosis is made by clinical history, family history, and brain imaging.[13,14]

Microcephaly (small head) is associated with a defect in brain growth as a whole (see Fig. 20.6). Cranial size is significantly below average for the infant's age, gender, race, and gestation. The small size of the skull reflects a small brain (microencephaly), which is caused by reduced proliferation or accelerated apoptosis. *True (primary) microcephaly* is usually caused by an autosomal recessive genetic or chromosomal defect. *Secondary (acquired) microcephaly* is associated with various causes, such as intrauterine infection (including emergence of the Zika virus)[15]; trauma; metabolic disorders; maternal anorexia experienced during the third trimester of pregnancy; in utero exposure to alcohol, toxins, or certain medications; and the presence of other genetic syndromes. Children with microcephaly are usually developmentally delayed. Microcephaly can be familial and, if so, can be associated with normal development.

Cortical dysplasias (malformations) are defects in brain development and related to failure of embryonic neurons to migrate to the right places in the brain. These disorders may range from a small area of abnormal tissue to an entire brain that is smooth and without the normal configuration of gyri and sulci, known as *lissencephaly* (Fig. 20.7), or a brain that has too many small gyri (folds), known as *polymicrogyria*. There is a specific genetic defect for some of these disorders; others are multifactorial or acquired (e.g., intrauterine trauma or infection). Cortical dysplasias increase the risk for seizures that are difficult to control and cause developmental delay and motor dysfunction. Genetic testing assesses risk in other family members and guides therapy.[16,17] Congenital hydrocephalus is present at birth and characterized by increased CSF pressure and enlargement of the ventricles. The overall incidence of hydrocephalus is approximately 1 to 2 per 1000 live births.[18] Hydrocephalus may be caused by blockage within the ventricular system where the CSF flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF. The increased pressure within the ventricular system dilates the ventricles and pushes and compresses the brain tissue against the skull cavity (Fig. 20.8A and B). When hydrocephalus develops before fusion of the cranial sutures, the skull can expand to accommodate this additional space-occupying volume and preserve neuronal function (Types of hydrocephalus are discussed in Chapter 17).

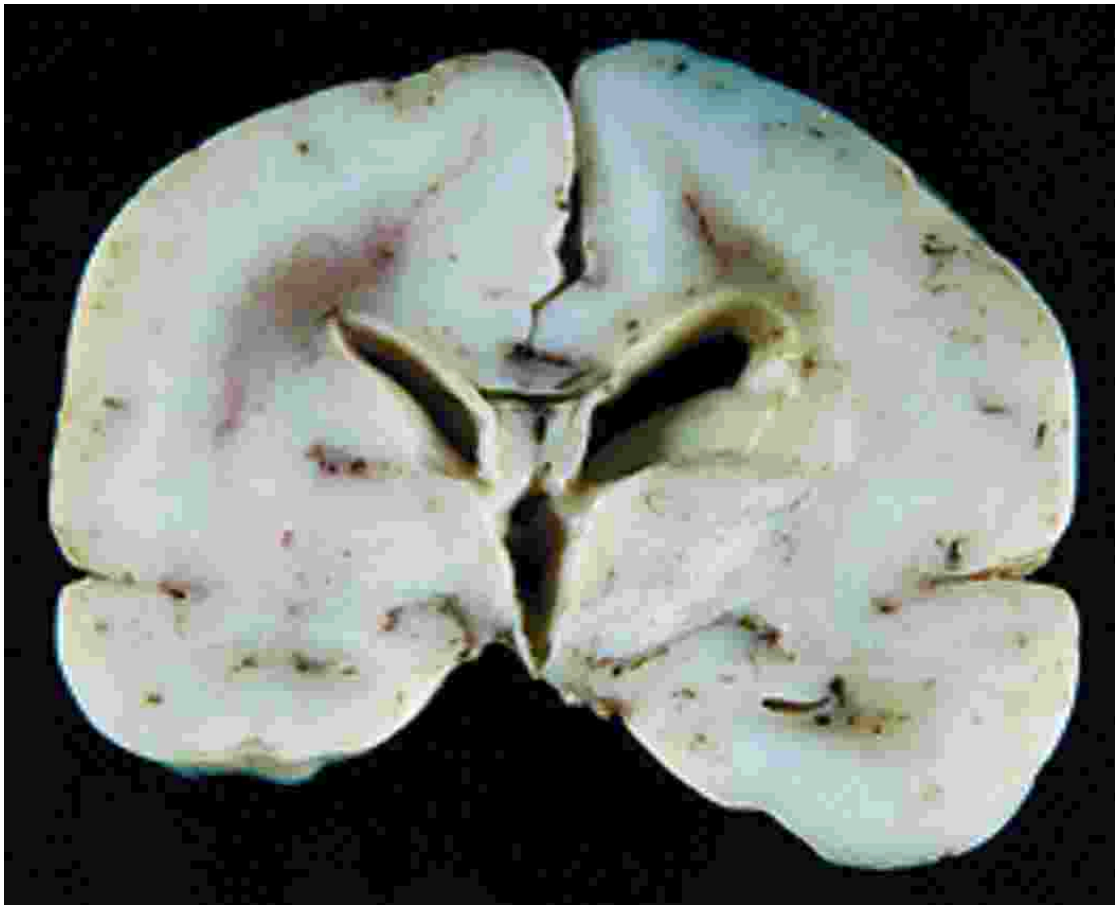

FIG. 20.7 Lissencephaly.
The absence of cortical gyri defines this abnormality, seen here in the brain from a full-term infant. (From Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 8th edition. Philadelphia: Saunders; 2010.)

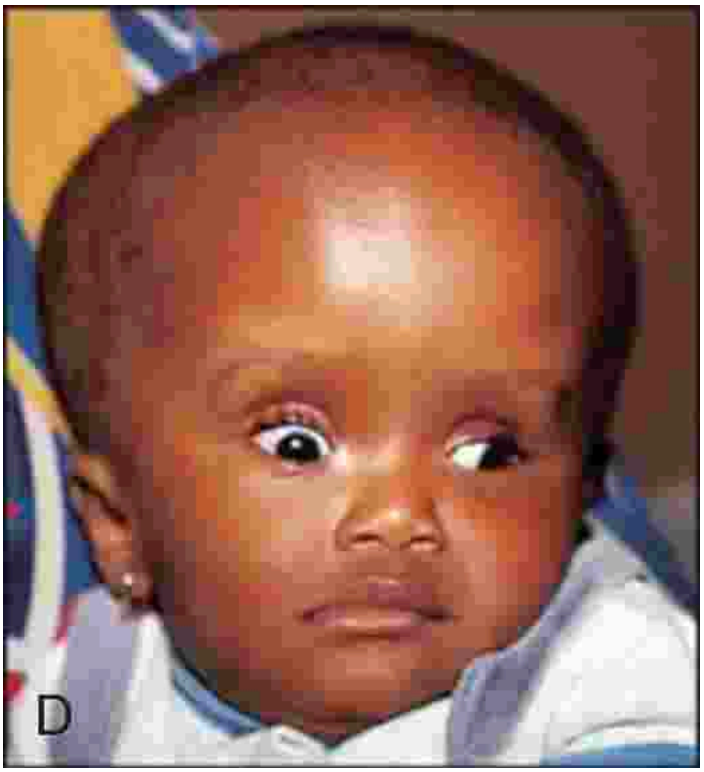

FIG. 20.8 Hydrocephalus.
Fluid accumulation in the brain because of blockage in the flow of cerebrospinal fluid (CSF). **(A)** Patent cerebrospinal fluid circulation. **(B)** Enlarged lateral and third ventricles caused by obstruction of circulation of CSF—stenosis of aqueduct of Sylvius. **(C)** Child with enlarged head caused by hydrocephalus. **(D)** Congenital hydrocephalus with sunsetting of the eyes. (C, From McLaurin DC. *Pediatric neurosurgery*, 2nd edition. Philadelphia: Saunders; 1989. D, From Lissauer T, ed. *Illustrated textbook of paediatrics*, 5th edition. Elsevier; 2018.)

Illustration A shows the right lateral view of a childâ€™s head and a superior view of the brain, both with nonhydrocephalus. Illustration B shows the right lateral view of a childâ€™s head and a superior view of the brain, both with hydrocephalus. The structures in the hydrocephalus are different from those in the nonhydrocephalus in the following ways. â€¢ Lateral ventricle covers most of the brain. â€¢ Third ventricle is almost twice as large. â€¢ Aqueduct of Sylvius is thinner. â€¢ Fourth ventricle is about thrice as large. â€¢ Foramen of Luschka is bigger. â€¢ Cisternal magna is bigger. â€¢ Foramen of Magendie is shorter. â€¢ Compression of brain tissue with ischemia and necrosis. Closeup C shows the right lateral profile of an infant with hydrocephalus. The infantâ€™s head is abnormally large. Closeup D shows the front profile of an infant with hydrocephalus. The infantâ€™s head is abnormally large.

Congenital hydrocephalus may cause fetal death in utero, or the increased head circumference may require cesarean delivery of the infant. Symptoms depend directly on the cause and rate of hydrocephalus development. When there is separation of the cranial sutures, a resonant note sounds

when the skull is tapped, a manifestation called the Macewen sign, or "cracked pot" sign. The eyes may assume a staring expression, *unable to look upwards*, with sclera visible above the cornea, called *sunsetting* (see Fig. 20.8D). Treatment outcomes are variable. Cognitive impairment in children with hydrocephalus is often related to associated brain malformations or episodes of shunt failure or infection. Approximately 40% to 65% of children with uncomplicated congenital hydrocephalus complete schooling and are employed when treated successfully with shunting or endoscopic third ventriculostomy with or without choroid plexus cauterization.[19–21]

The Dandy-Walker malformation (DWM) is a congenital defect of the cerebellum characterized by a large posterior fossacyst that communicates with the fourth ventricle, cerebellar hypoplasia, and macrocephaly. DWM is commonly associated with hydrocephalus. Other causes of obstructions within the ventricular system that can result in hydrocephalus include brain tumors, cysts, trauma, arteriovenous malformations, blood clots, infections, and the Chiari malformations (Emerging Science Box: Gene Therapy for Pediatric Neurologic Conditions).

Alterations In Function: Encephalopathies

Encephalopathy, meaning brain pathology, is a general category that includes a number of syndromes and diseases (see Chapter 18). These disorders may be acute or chronic, as well as static or progressive. Some common neurologic disorders with a genetic basis are summarized in Table 20.3.

Table 20.3

Selected Neurological Disorders With a Genetic Basis

Syndrome/Disorders	Currently Known Genetic Components	Pathophysiology	Major Neurologic Features
Angelman syndrome	Microdeletion on chromosome 15 leading to loss of function of the *UBE3A* gene (ubiquitin protein ligase); can be acquired from mother	Protein, important in degradation of proteins in the brain	Little to no verbal language, intellectual disability, seizure disorder, sleep disorder, movement/balance disorder
Batten disease	Autosomal recessive; mutation of the *CLN3* gene (ceroid-lipofuscinosis, neuronal 3) (chromosome 16)	Lysosomal storage defect resulting in abnormal storage of cerebral lipofuscins	Develops normally until 6 months to 2 years of age when progressive brain disease becomes apparent; seizures, intellectual disability, blindness, and death
Branched-chain ketoaciduria (maple syrup urine disease)	Autosomal recessive; most common type is classic caused by mutation of the *BCKDHA* gene (2-oxoisovalerate dehydrogenase subunit alpha, a mitochondrial enzyme) (chromosome 19)	All types result in inability to metabolize three amino acids; these acids accumulate and are toxic at high levels	Intellectual disability, seizures, and death; treatable with early diagnosis
Cri du chat syndrome	Autosomal dominant; deletion on the short arm of chromosome 5 (also called *5p minus syndrome*)	Deletion of multiple genes responsible for phenotype; evidence that deletion of telomerase reverse transcriptase gene contributes to phenotype	High-pitched cry; intellectual disability, microcephaly, low birth weight, failure to thrive; widely spaced eyes (ocular hypertelorism), unusually small jaw (micrognathia)
Lesch-Nyhan syndrome	X-linked recessive; mutation of the *HPRT* gene (hypoxanthine phosphoribosyltransferase 1)	Metabolism disturbance of purines; excessive production of uric acid	Intellectual disability, progressive neurologic disorder, compulsively bitten lips and fingers; self-mutilating
Neurofibromatosis (NF)	Autosomal dominant	Variable expressivity	Multiple café au lait spots, neurofibromas, learning disability, seizure disorder

Syndrome/Disorders	Currently Known Genetic Components	Pathophysiology	Major Neurologic Features
NF1 (von Recklinghausen disease)	Mutation of the *NF1* gene (neurofibromin) (chromosome 17)	A large, complex protein; this protein may act as a switch to regulate cell growth; mutation may lessen or inhibit the normal output of this protein and allow irregular cell growth that may lead to tumor development	Increased risk for nerve sheath tumors and brain tumors
NF2 (bilateral acoustic NF)	Autosomal dominant: mutation of either the *NF2* gene (merlin; moesin-ezrin-radixin-like protein or schwannomin) (chromosome 22)	A tumor-suppressor protein (merlin or schwannomin)	Multiple tumors (schwannomas) on cranial and spinal nerves, acoustic neuromas, hearing loss
Progressive myoclonic epilepsy (Unverricht-Lundborg disease)	Autosomal recessive; mutation *CSTB* gene (cystatin B, a cysteine protease inhibitor) (chromosome 21)	This protein regulates enzymes that break down other proteins	Onset at age 6–15 years, severe incapacitating stimulus-sensitive progressive myoclonus, tonic-clonic epileptic seizures, and characteristic abnormalities on electroencephalogram; also may develop other neurologic symptoms such as ataxia, incoordination, and dysarthria
Lafora disease	Autosomal recessive; mutation of the *EMP2A* gene (epilepsy, progressive myoclonus type 2A or laforin) and *EMP2B* gene (malin) (chromosome 6)	Concentric amyloid (Lafora) bodies found in neurons, liver, skin, bone, and muscle; defects in protein degradation and clearance	Grand mal seizures and/or myoclonus at about age 15; rapid and severe motor and coordination impairments, rapid mental deterioration, often with psychotic features; survival is short, less than 10 years after onset

Syndrome/Disorders	Currently Known Genetic Components	Pathophysiology	Major Neurologic Features
Rett syndrome	X-linked dominant; appears to occur only in girls; defective *MECP2* gene (methyl CpG binding protein 2) (X-chromosome)	Protein involved in regulation of gene expression; defects in this gene allow other genes to be expressed at inappropriate times in development	Progressive neurologic disorder; develops normally in first year of life, then loss of mental capacity and motor skills begins; loss of purposeful hand movements; stereotypical hand wringing and flapping
Tay-Sachs disease	Autosomal recessive; mutation of the *HEXA* gene (chromosome 15)	Caused by a deficiency of hexosaminidase, an enzyme, which results in accumulation of a material that damages the brain	Failure to thrive, blindness, seizures, progressive paralysis; usually death by age 4
Tuberous sclerosis	Autosomal dominant; mutation of either the *TSC1* gene (hamartin) (chromosome 9) or the *TSC2* gene (tuberin) (chromosome 16)	These proteins act as tumor growth suppressors	Develops in early childhood; seizures, intellectual disability, skin and eye lesions; multiple benign tumors in brain and other vital organs

Syndrome/Disorders	Currently Known Genetic Components	Pathophysiology	Major Neurologic Features
Angelman syndrome	Microdeletion on chromosome 15 leading to loss of function of the *UBE3A* gene (ubiquitin protein ligase); can be acquired from mother	Protein, important in degradation of proteins in the brain	Little to no verbal language, intellectual disability, seizure disorder, sleep disorder, movement/balance disorder
Batten disease	Autosomal recessive; mutation of the *CLN3* gene (ceroid-lipofuscinosis, neuronal 3) (chromosome 16)	Lysosomal storage defect resulting in abnormal storage of cerebral lipofuscins	Develops normally until 6 months to 2 years of age when progressive brain disease becomes apparent; seizures, intellectual disability, blindness, and death
Branched-chain ketoaciduria (maple syrup urine disease)	Autosomal recessive; most common type is classic caused by mutation of the *BCKDHA* gene (2-oxoisovalerate dehydrogenase subunit alpha, a mitochondrial enzyme) (chromosome 19)	All types result in inability to metabolize three amino acids; these acids accumulate and are toxic at high levels	Intellectual disability, seizures, and death; treatable with early diagnosis
Cri du chat syndrome	Autosomal dominant; deletion on the short arm of chromosome 5 (also called *5p minus syndrome*)	Deletion of multiple genes responsible for phenotype; evidence that deletion of telomerase reverse transcriptase gene contributes to phenotype	High-pitched cry; intellectual disability, microcephaly, low birth weight, failure to thrive; widely spaced eyes (ocular hypertelorism), unusually small jaw (micrognathia)
Lesch-Nyhan syndrome	X-linked recessive; mutation of the *HPRT* gene (hypoxanthine phosphoribosyltransferase 1)	Metabolism disturbance of purines; excessive production of uric acid	Intellectual disability, progressive neurologic disorder, compulsively bitten lips and fingers; self-mutilating
Neurofibromatosis (NF)	Autosomal dominant	Variable expressivity	Multiple café au lait spots, neurofibromas, learning disability, seizure disorder
NF1 (von Recklinghausen disease)	Mutation of the *NF1* gene (neurofibromin) (chromosome 17)	A large, complex protein; this protein may act as a switch to regulate cell growth; mutation may lessen or inhibit the normal output of this protein and allow irregular cell growth that may lead to tumor development	Increased risk for nerve sheath tumors and brain tumors
NF2 (bilateral acoustic NF)	Autosomal dominant: mutation of either the *NF2* gene (merlin; moesin-ezrin-radixin-like protein or schwannomin) (chromosome 22)	A tumor-suppressor protein (merlin or schwannomin)	Multiple tumors (schwannomas) on cranial and spinal nerves, acoustic neuromas, hearing loss
Progressive myoclonic epilepsy (Unverricht-Lundborg disease)	Autosomal recessive; mutation *CSTB* gene (cystatin B, a cysteine protease inhibitor) (chromosome 21)	This protein regulates enzymes that break down other proteins	Onset at age 6–15 years, severe incapacitating stimulus-sensitive progressive myoclonus, tonic-clonic epileptic seizures, and characteristic abnormalities on electroencephalogram; also may develop other neurologic symptoms such as ataxia, incoordination, and dysarthria
Lafora disease	Autosomal recessive; mutation of the *EMP2A* gene (epilepsy, progressive myoclonus type 2A or laforin) and *EMP2B* gene (malin) (chromosome 6)	Concentric amyloid (Lafora) bodies found in neurons, liver, skin, bone, and muscle; defects in protein degradation and clearance	Grand mal seizures and/or myoclonus at about age 15; rapid and severe motor and coordination impairments, rapid mental deterioration, often with psychotic features; survival is short, less than 10 years after onset
Rett syndrome	X-linked dominant; appears to occur only in girls; defective *MECP2* gene (methyl CpG binding protein 2) (X-chromosome)	Protein involved in regulation of gene expression; defects in this gene allow other genes to be expressed at inappropriate times in development	Progressive neurologic disorder; develops normally in first year of life, then loss of mental capacity and motor skills begins; loss of purposeful hand movements; stereotypical hand wringing and flapping
Tay-Sachs disease	Autosomal recessive; mutation of the *HEXA* gene (chromosome 15)	Caused by a deficiency of hexosaminidase, an enzyme, which results in accumulation of a material that damages the brain	Failure to thrive, blindness, seizures, progressive paralysis; usually death by age 4

(Continued...)

Syndrome/Disorders	Currently Known Genetic Components	Pathophysiology	Major Neurologic Features
Tuberous sclerosis	Autosomal dominant; mutation of either the *TSC1* gene (hamartin) (chromosome 9) or the *TSC2* gene (tuberin) (chromosome 16)	These proteins act as tumor growth suppressors	Develops in early childhood; seizures, intellectual disability, skin and eye lesions; multiple benign tumors in brain and other vital organs

Static (Nonprogressive) Encephalopathies

Static or nonprogressive encephalopathy describes a neurologic condition caused by a fixed lesion without active and ongoing disease. Causes include brain malformations or brain injury that may occur during gestation or birth or at any time during childhood. The degree of neurologic impairment is directly related to the extent of the injury or malformation and the stage of development at the time of injury. Anoxia, trauma, and infections are the most common causes of injury to the nervous system in the perinatal period. Infections, metabolic disturbances (acquired or genetic), trauma, toxins, and vascular disease may injure the nervous system in the postnatal period.[22]

Cerebral palsy is a disorder of movement, muscle tone, or posture that is caused by injury or abnormal development in the immature brain, before, during, or after birth up to 1 year of age. Cerebral palsy is one of the most common crippling disorders of childhood, affecting nearly 764,000 children in the United States alone. Although the exact incidence is unknown, studies suggest that the prevalence is approximately 1 in 345 children in the United States.[23]

Risk factors include prenatal or perinatal cerebral hypoxia, hemorrhage, infection, genetic abnormalities, or low birth weight (Table 20.4). Cerebral palsy can be classified on the basis of neurologic signs and motor symptoms, with the major types being spasticity, dystonia, ataxia, or a combination of these symptoms (mixed). Diplegia, hemiplegia, or tetraplegia may be present.

Table 20.4

Cerebral Palsy: Predisposing Factors and Known Causes

Risk Factors	Associated Causes
Prenatal	
Maternal	Metabolic diseases
	Nutritional deficiencies (e.g., anemia)
	Twin or multiple births
	Bleeding
	Toxemia
	Blood incompatibilities
	Exposure to radiation
	Infection (e.g., rubella, toxoplasmosis, cytomegalic inclusion disease)
	Premature labor
Prematurity	Asphyxia leading to cerebral hemorrhage
Genetic factors	Absence of corpus callosum, aqueductal stenosis, cerebellar hypoplasia
Congenital anomalies of the brain	Unknown causes not evident on clinical examination
Perinatal	Anesthesia or analgesia during labor and delivery
	Mechanical trauma or hypoxia during delivery
	Immaturity at birth
	Metabolic disorders (e.g., hyperbilirubinemia, hypoglycemia, amino acid disorders, hyperosmolality)
	Electrolyte disturbances (e.g., hypernatremia, hypoglycemia)
Postnatal	Head trauma
	Infections (e.g., meningitis, encephalitis)
	Cerebrovascular accidents
	Toxicosis
	Environmental toxins (e.g., lead ingestion, methyl mercury ingestion from contaminated fish)

Pyramidal/spastic cerebral palsy is the most common. It results from damage to corticospinal pathways (upper motor neurons) and is associated with increased muscle tone, persistent primitive reflexes, hyperactive deep tendon reflexes, clonus, rigidity of the extremities, scoliosis, and contractures. Extrapyramidal/nonspastic cerebral palsy is less common and is caused by damage to cells in the basal ganglia or cerebellum and includes two subtypes: dystonic and ataxic. Dystonic (dyskinetic) cerebral palsy is associated with injury to the basal ganglia with extreme difficulty in fine motor coordination and purposeful movements. Movements are stiff, uncontrolled, and abrupt. Ataxic cerebral palsy is caused by damage to the cerebellum, with alterations in coordination and movement. There is a broad-based gait in an attempt to maintain balance, and tremor is common with intentional movements. A child may have symptoms of each of these cerebral palsy types, which leads to a mixed disorder.[24]

Children with cerebral palsy often have associated neurologic disorders, such as seizures and intellectual impairment ranging from mild to severe. Other complications include visual impairment, communication disorders, respiratory problems, bowel and bladder problems, and orthopedic disabilities, such as hip pain or dislocation, balance problems, or hand dysfunction.[25]

Inherited Metabolic Disorders of the Central Nervous System

A large number of inherited metabolic disorders have been identified, typically leading to diffuse brain dysfunction. Early diagnosis and treatment are vital if these infants are to survive without severe neurologic problems. Newborn metabolic screening for 28 metabolic conditions (in most states) has led to most of these children being identified before symptoms develop. Inborn errors of metabolism are present at birth, and most cause disturbances of the nervous system, although they may not manifest until childhood or even adulthood. Defects in amino acid and lipid metabolism are among the most common and are presented here.

Defects in Amino Acid Metabolism

Defects in amino acid metabolism are caused by genetic defects resulting in lack of a normal protein and absence of enzymatic activity. The defects include (1) those in which the transport of an amino acid is impaired; (2) those involving an enzyme or cofactor deficiency; and (3) those encompassing certain chemical components, such as branched-chain or sulfur-containing amino acids.

Phenylketonuria

Phenylketonuria (PKU) is an example of an inborn error of metabolism characterized by phenylalanine hydroxylase deficiency and the inability of the body to convert the essential amino acid phenylalanine to tyrosine (Fig. 20.9). PKU is an autosomal recessive inborn error of metabolism characterized by mutations of the phenylalanine hydroxylase *(PAH)* gene. PKU has an incidence of 1 per 10,000 to 15,000 live births in the United States.[19]

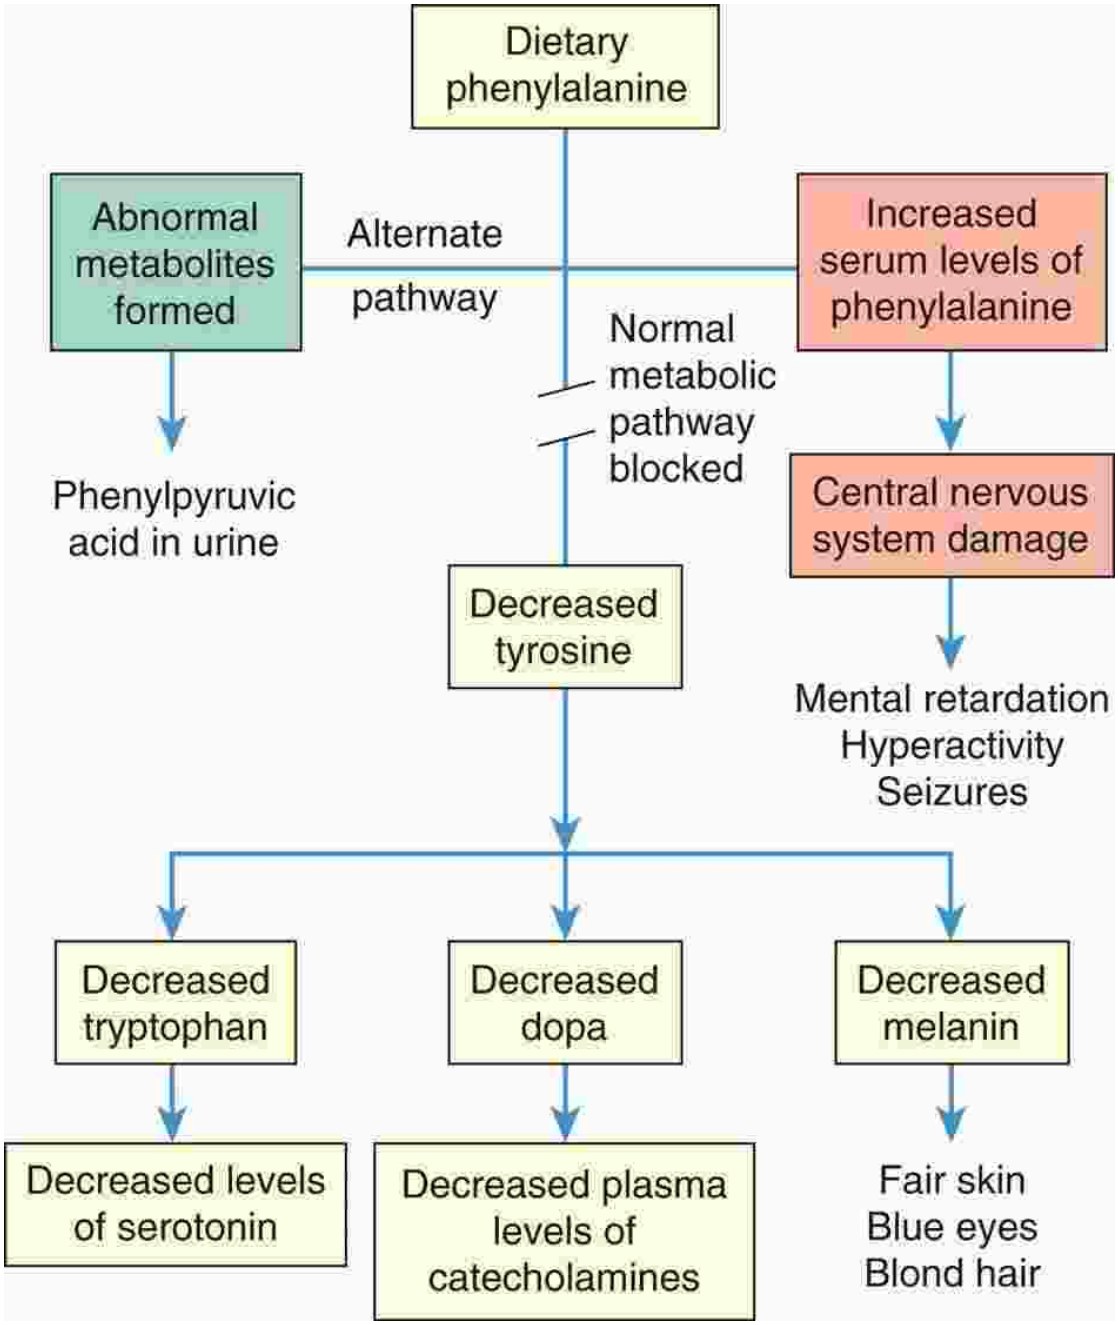

FIG. 20.9 Metabolic Error and Consequences in Pheny-lketonuria. (From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

A flowchart shows metabolic error and consequences in phenylketonuria. There are three pathways from dietary phenylalanine. â€¢ Alternate pathway: abnormal metabolites formed, leading to phenyl pyruvic acid in urine. â€¢ Normal metabolic pathway blocked. â€¢ Increased serum levels of phenylalanine lead to central nervous system damage and subsequently to mental retardation, hyperactivity, and seizures. Decreased tyrosine leads to the

following conditions. â€¢ Decreased tryptophan, leading to decreased levels of serotonin. â€¢ Decreased dopa, leading to decreased plasma levels of catecholamines. â€¢ Decreased melanin, leading to fair skin, blue eyes, and blond hair.

Most natural food proteins contain approximately 15% phenylalanine, an essential amino acid. Phenylalanine hydroxylase controls the conversion of this essential amino acid to tyrosine in the liver. The body uses tyrosine in the biosynthesis of proteins, melanin, thyroxine, and the catecholamines in the brain and adrenal medulla. Phenylalanine hydroxylase deficiency causes an accumulation of phenylalanine in the serum. Elevated phenylalanine levels result in developmental abnormalities of the cerebral cortical layers, defective myelination, and cystic degeneration of the gray and white matter. Unfortunately, brain damage occurs before the metabolites can be detected in the urine, and damage continues as long as phenylalanine levels remain high. Nonselective newborn screening is used to detect PKU in the United States and in more than 30 other countries. Treatment, consisting of reduction of dietary phenylalanine (PKU diet), is effective and allows for normal development. Mutations in the *PAH* gene are by far the most common cause of PKU, although there are other types of PKU. In one such variation, there is impaired synthesis of cofactors (e.g., tetrahydrobiopterin [BH_4]), which contributes to elevated levels of phenylalanine. Individuals with impaired synthesis of BH_4 have a positive response when sapropterin, a synthetic form of BH_4, is included in their treatment.[20]

Defects in Lipid Metabolism

Disorders of lipid metabolism are termed lysosomal storage diseases because each disorder in this group can be traced to a missing lysosomal enzyme needed for the breakdown and recycling of many cellular products. Lysosomal storage disorders include more than 50 known genetic disorders. The incidence of lysosomal storage disorders is approximately 1 in 5000 live births.[21] These disorders cause an excessive accumulation of a particular cell product, occurring in the brain, liver, spleen, bone, and lung and thus involving several organ systems; these disorders often are highly debilitating and cause progressive physical and neurologic disability. In general, these disorders are not included in newborn screening. Some of these disorders may be treated with enzyme replacement therapy.[26] Perhaps the best known of the lysosomal storage disorders is GM_2 gangliosidosis (Tay-Sachs disease), an autosomal recessive disorder caused by deficiency of the lysosomal enzyme hexosaminidase A (HexA), an enzyme that degrades GM_2 gangliosides (fatty acids) within nerve cell lysosomes. Eighty percent of individuals diagnosed are of Jewish ancestry, although sporadic cases appear in the non-Jewish population. Onset of this disease usually occurs when the infant is 4 to 6 months old. Symptoms of Tay-Sachs include an exaggerated startle response to loud noise, seizures, developmental regression, dementia, and blindness. Death from this disease is almost universal and occurs by 5 years of age. Screening for carriers of the gene defect concomitant with counseling to prevent disease transmission is possible.[27]

Intoxications of the Central Nervous System

Drug-induced encephalopathies must always be considered a possibility in the child with unexplained neurologic changes. Such encephalopathies may result from accidental ingestion, therapeutic overdose, intentional overdose, or ingestion of environmental toxins. There were 37.7/1000 children younger than 6 years of age with poison exposures in 2018. Approximately 44.2% of all poison exposures occurred in children younger than 6 years of age, with the highest incidence being 1- and 2-year-old children. The most commonly ingested poisons in children younger than 6 years are cosmetics and personal care products, cleaning substances, and over-the-counter analgesics and other medications (Table 20.5).[28]

Table 20.5

Common Poisons

Pharmacologic Agents	Heavy Metals	Miscellaneous Agents
Analgesics (acetaminophen, salicylates)	Lead Acute Chronic	Cosmetics and personal care products
Topical preparations	Mercury	Household cleaning substances
Antihistamines	Thallium	Alcohols Ethyl, isopropyl, methyl
Vitamins/dietary supplements/herbs/homeopathic	Arsenic	Pesticides Organophosphates Chlorinated hydrocarbons
Gastrointestinal preparationsCardiovascular drugsSleeping medications	Cadmium	Mushrooms
Antidepressants		Venoms Snake bite Tick paralysis
Stimulants/street drugs Barbiturates Amphetamines		Ethylene glycol
Sedatives/hypnotics/antipsychotic Pain medications/opioids		Aliphatic hydrocarbons Gasoline, kerosene, lamp oil

Lead poisoning results in high blood levels of lead. If lead poisoning is untreated, lead encephalopathy results and is responsible for serious and irreversible neurologic damage. Those at greatest risk are children ages 2 to 3 years and children prone to the practice of pica—the habitual, purposeful, and compulsive ingestion of nonfood substances, such as clay, soil, and paint chips or paint dust. Lead intoxication also may occur from chronic exposure to lead in cosmetics, inhalation of gasoline vapors, and ingestion of airborne lead.[29] Fetal neurotoxicity occurs with maternal lead exposure, particularly during the first trimester.[30] Details related to lead intoxication are described in Chapter 2. Refer to Fig. 20.10 for a summary of toxic lead effects.

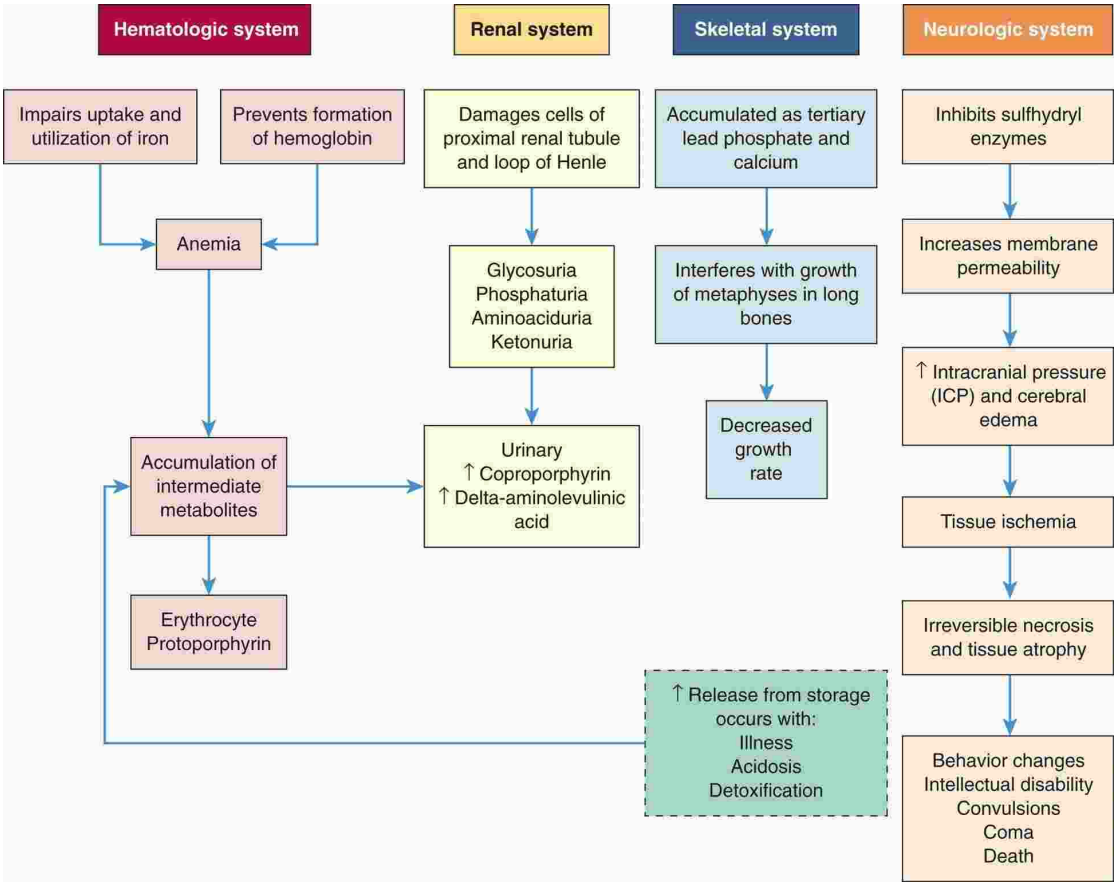

FIG. 20.10 **Systemic Effects of Increased Lead Absorption in Children.**

A flowchart tracks a systemic effects of increased lead absorption in children. The flowchart shows four systems. The hematologic system is as follows. Impaired update and utilization of iron and prevention of formation of hemoglobin leads to anemia. Anemia leads to accumulation of intermediate metabolites, which in turn results in either of the following: â€¢ Erythrocyte, protoporphyrin. â€¢ Urinary, increased coproporphyrin, increased delta-aminolaevulinic acid. The renal system undergoes the following changes. â€¢ Damages cells of proximal rental tubule and loop of Henle. â€¢ Glycosuria, phosphaturia, aminoaciduria, and ketonuria. â€¢ Urinary, increased coproporphyrin, increased delta-aminolaevulinic acid. The skeletal system undergoes the following changes. â€¢ Accumulated as tertiary lead phosphate and calcium. â€¢ Interferes with growth of metaphysis in long bones. â€¢ Decreased growth rate. The neurologic system undergoes the following changes. â€¢ Inhibits sulfhydryl enzymes. â€¢ Increases membrane permeability. â€¢ Increased intracranial pressure (I C P) and cerebral edema. â€¢ Tissue ischemia. â€¢ Irreversible necrosis and tissue atrophy. â€¢ Behavior changes, intellectual disability, convulsions, coma, and death. Increased release

from storage occurs with illness, acidosis, and detoxification leads to accumulation of intermediate metabolites.

Infections of the Central Nervous System

Meningitis is an infection of the meninges and subarachnoid space of the brain and spinal cord. Encephalitis is inflammation within the brain. In many infections of the meninges, encephalitis also is present and the term *meningoencephalitis* is used. The origin of such inflammation and acute encephalopathy can be caused by bacteria, viruses, or other microorganisms. Aseptic meningitis has no evidence of bacterial infection but may be associated with viral infection, systemic disease, or drugs.

Bacterial meningitis

Acute bacterial meningitis is one of the most serious infections to which infants and children are susceptible. The introduction of conjugate vaccines against *Haemophilus influenzae* type B, *Streptococcus pneumoniae*, and *Neisseria meningitidis* (meningococcus) has decreased the incidence of bacterial meningitis.[31] Vaccines for serogroup B *N. meningitidis* are now available.[32]

Group B *Streptococcus* causes lethal meningitis and sepsis in neonates; it is transmitted to the child from the mother's birth canal and is the most common cause of meningitis in newborns. *S. pneumoniae* is the most common microorganism in children 1 to 23 months of age. Staphylococcal or streptococcal meningitis can occur in children of any age but shows a predilection for children who have had neurosurgery, skull fracture, or a complication of systemic bacterial infection. Infections that originate in the middle ear, sinuses, or mastoid cells also may lead to *S. pneumoniae* infection in children. Children with sickle cell disease or who have had a splenectomy are particularly at high risk for infection.

Escherichia coli and group B beta-hemolytic streptococci are the most common causes of meningitis in the newborn period. The second most common microorganism causing bacterial meningitis, particularly in children younger than 4 years, is *N. meningitidis* (meningococcus) and it has the potential to occur in epidemics. Approximately 2% to 5% of healthy children are carriers of *N. meningitidis*. Because the incidence of *N. meningitidis* infection increases in adolescence and with crowded environments, such as in dormitories and among military personnel, it is recommended that all individuals 11 to 12 years of age receive two immunizations against this pathogen. Teens and young adults (16 through 23 year olds) also may be vaccinated with a serogroup B meningococcal vaccine.[33]

Pathophysiology

Pathogens enter the nervous system by direct extension from a contiguous source (e.g., paranasal sinuses or mastoid cells) or, more commonly, by hematogenous spread (e.g., infective endocarditis, pneumonia, neurosurgical procedures, severe burns). Pathogens then cross the blood-brain barrier, enter the CSF, and multiply. Bacterial toxins increase cerebrovascular permeability, causing alterations in blood flow and edema. Increased intracranial pressure (ICP) may be increased further by obstruction to the CSF circulation. Herniation of the brainstem causes death.

Clinical manifestations

Acute bacterial meningitis often is preceded by an upper respiratory tract or a gastrointestinal infection. Inflammation leads to the general symptoms of fever, headache, vomiting, and irritability and the CNS symptoms of photophobia, nuchal and spinal rigidity, decreased level of consciousness, and seizures. Irritation of the meninges and spinal roots causes pain and resistance to neck flexion (nuchal rigidity), a positive Kernig sign (resistance to knee extension in the supine position with the hips and knees flexed against the body), and a positive Brudzinski sign (flexion of the knees and hips when the neck is flexed forward rapidly). With severe meningeal irritation the child may demonstrate opisthotonic posturing (rigid arching of the back with the head extended). Infants may have bulging fontanelles. Meningococcal meningitis can produce a characteristic petechial rash.

Viral meningitis may result from a direct infection caused by a virus, or it may be secondary to disease, such as measles, mumps, herpes, or leukemia. The hallmark of viral meningitis, or aseptic meningitis, is a mononuclear response in the CSF and the presence of normal glucose levels. The clinical manifestations are similar to those in bacterial meningitis, although usually milder.

Evaluation and treatment

A definitive diagnosis is made by examination of CSF obtained from a lumbar puncture and by CSF and blood cultures. The principles of treatment are similar to those followed for adults (see Chapter 18) and are based on the culture results in which the causative microorganism is identified. Empirical antibiotic therapy should be initiated and continued until CSF cultures are negative or changed if the empirical therapy is not correct for the bacteria cultured from the CSF. Bacterial lysis induced by antibiotics can cause subarachnoid inflammation; the severity may be reduced with corticosteroid treatment. The factors that influence outcomes are the age of the child (mortality is highest in infants younger than 1 year), the infective microorganisms (the lowest mortality is in meningococcal meningitis and the highest in meningitis caused by gram-negative enteric microorganisms), and the duration and extent of inflammation before treatment. Approximately 8% of children with *H. influenzae* meningitis die; 35% of the survivors have serious and permanent sensory or motor dysfunction caused by pressure on the peripheral nerves during the early phases of the illness. Approximately 5% of the children who survive meningitis have hearing deficits; 15% to 30% have cerebral damage, hydrocephalus, motor deficits, or sensory impairments.

Viral encephalitis in children is similar to viral encephalitis in adults (see Chapter 18, and Fig. 18.28) and can be difficult to distinguish from viral meningitis. Viruses are obligate intracellular pathogens which can directly invade the brain, causing inflammation. Postinfectious encephalitis can develop as a result of an autoimmune response. Inflammatory and autoimmune causes of encephalitis may be treatable if identified early in an individual's course of illness.[34] (Encephalopathy resulting from infection with the human immunodeficiency virus [HIV] is discussed in Chapters 9 and 18.)

Cerebrovascular Disease in Children

Perinatal Stroke

Perinatal stroke is defined as stroke occurring from 28 weeks' gestation to 28 days postnatal.[35] Perinatal arterial ischemic stroke is estimated at 1 in 4000 live births and is a leading cause of perinatal brain injury, cerebral palsy, and lifelong disability. Although a cause for perinatal stroke is usually not found, clotting abnormalities may make the child prone to further vascular events. Up to 80% are ischemic with the remainder secondary to hemorrhage or cerebral sinovenous thrombosis (CSVT).

Childhood Stroke

Childhood stroke occurs in 1.3 to 1.6 per 100,000 children per year and may be divided into two categories: ischemic and hemorrhagic.[35,36] According to the Center for Disease Control and Prevention, cerebrovascular disease (stroke) is one of the 10 leading causes of death in children and adolescents from 1 to 24 years of age. Ischemic (occlusive) stroke in children may result from embolism, Cerebral sinovenous thrombosis (CSVT), or congenital or iatrogenic narrowing of vessels, leading to decreased flow of blood and oxygen to areas of the brain. Although rare, it is more common than hemorrhagic stroke. Children with arterial ischemic stroke do not have the typical adult risk factors of atherosclerosis and hypertension. Many children with acute ischemic stroke have no identifiable risk factors.[35] Arteriopathies, cardiac anomalies, sickle cell disease, infections, head and neck disorders, systemic conditions, and prothrombic states are the common disorders associated with arterial ischemic stroke.[35]

Hemorrhagic stroke is most commonly caused by bleeding from congenital cerebral arteriovenous malformations and is rare in children younger than 19 years. Intraventricular hemorrhage associated with premature birth is related to immature blood vessels and unstable blood pressure. There is a high risk of developing posthemorrhagic hydrocephalus in very low birth weight (<1000 g) preterm infants with increased risk of developmental disabilities.[37]

The clinical presentation of stroke varies according to the vessels involved and the age of the individual. Symptoms include hemiplegia, weakness, seizures, headaches, high fever, nuchal rigidity, hemianopia, sensory changes, facial palsy, and temporary aphasia. Obtaining a thorough history of evolving symptoms and risk factors is important for diagnosis. Laboratory studies may be indicated. Neuroimaging studies assist in determining the extent of the disease. Surgery is an option for treatment, and anticoagulants and antithrombotics may be used in selected cases.

Moyamoya disease is a rare, chronic, progressive vascular stenosis of the circle of Willis of unknown etiology. There is obstruction of arterial flow to the brain and the development of small basal arterial collateral vessels that vascularize the hypoperfused brain distal to the occluded vessels.[38] Moyamoya means a *puff of smoke* in Japanese and represents the appearance of these small vessels on cerebral angiography. The disease is most common in East Asia and is associated with genetic factors, particularly those associated with vascular growth factors. These children often present with transient ischemic attacks (TIAs) because the new vessels fail to provide adequate perfusions.[39] Diagnosis is made by cerebral angiography, and the most effective treatment is surgical revascularization.

Epilepsy and Seizure Disorders in Children

The incidence of epilepsy varies greatly with age, geographic location, and study design. Approximately 470,000 children in the United States had epilepsy in 2015.[40] Seizures are the abnormal discharge of electrical activity within the brain. When a sufficient number of neurons become overexcited, they discharge abnormally, which sometimes results in clinical manifestations (seizures) with alterations in motor function, sensation, autonomic function, behavior, and consciousness. The manifestations depend on the site and spread of abnormal electrical activity within the brain. If a child has more than *two* unprovoked seizures more than 24 hours apart, that child is said to have epilepsy, although there are a few exceptions—one example being febrile seizures (see Chapter 16). Seizures may result from diseases that are primarily neurologic (CNS) or are systemic and affect CNS function secondarily (e.g., diabetes). Seizures can be caused by structural abnormalities of the brain, hypoxia, intracranial hemorrhage, CNS infection, traumatic injury, electrolyte imbalance, or inborn metabolic disturbances (see Chapter 18). Febrile Seizures are benign and the most common type of childhood seizure. Seizures are sometimes clearly familial. Often the cause of epilepsy is unknown and presumed to have a genetic basis. (Table 18.10 summarizes the classification of seizures.)

Antiepileptic drugs (AEDs) stabilize ion channels and neurotransmitters and are effective in treating seizures in 70% of persons. The 30% of individuals with medication-refractory epilepsy are increasingly effectively treated with other modalities. A ketogenic diet with high-fat and low-carbohydrate consumption replaces energy metabolism with ketone bodies instead of glucose and appears to increase the seizure threshold.[41] Neuromodulation (e.g., vagus nerve stimulation) can be effective to suppress epileptogenic activity.[42] Surgery to remove epileptic brain areas or disconnect eliptogenic pathways can reduce seizure activity.[43]

Epileptic spasms (also known as infantile spasms) are rare, severe types of seizures associated with electroencephalogram (EEG) abnormalities and varying clinical manifestations. The cause can be related to underlying brain abnormalities such as intrauterine stroke, cortical dysplasias, or tuberous sclerosis (a benign tumor), whereas others may be caused by mutations in one of several genes. Clinical manifestations of the resulting spasms may range from subtle head nods to violent body contractions, commonly referred to as *jackknife seizures*. Onset of infantile spasms usually is during infancy or early childhood. An EEG will display a classic hypsarrhythmic pattern on a slow, disorganized chaotic background. After infantile spasms begin, there is usually a typical clinical course. The "spasms" usually occur in clusters and transpire 5 to 150 times per day. They are commonly worse when the infant is waking up or falling asleep. Once begun, the seizure activity increases in intensity and severity over time. Invariably, a loss of developmental milestones and disability is associated with this syndrome. Treatment is the administration of adrenocorticotrophic hormone, vigabatrin (particularly for children with tuberous sclerosis), and corticosteroids. Surgery is an option when pharmacologic treatment has failed.[44]

Childhood Tumors

Brain Tumors

Brain tumors are the most common solid tumor, are the second most common primary neoplasm in children (after leukemia), and can be benign or malignant.[45,53] They are the leading cause of cancer-related death in children, and the 5-year survival is approximately 74%, varying significantly by tumor type. Primary brain tumors arise from brain tissue and do not metastasize outside the brain. The cause of brain tumors is unknown, although genetic, environmental, and immune factors have been investigated. Exposure to radiation therapy has been the only environmental factor consistently related to the development of brain tumors.[46,53]

Brain tumors can arise from any CNS cell, and tumors are classified by cell type *and molecular markers*. The most common tumors are embryonal tumors, including medulloblastoma, atypical medulloblastoma, atypical teratoid rhabdoid tumors, CNS primitive neuroectodermal tumors, and high-grade gliomas, including glioblastomas, diffuse pontine gliomas, and other malignant astrocytomas. Other tumor types are less common, including low-grade astrocytomas (especially pilocytic astrocytomas), neuronal and mixed neuronal-glial tumors, and ependymal tumors (ependymomas). Brain tumors in children are often located in the posterior fossa (Fig. 20.11). The types and characteristics of the more common childhood brain tumors are summarized in Table 20.6.

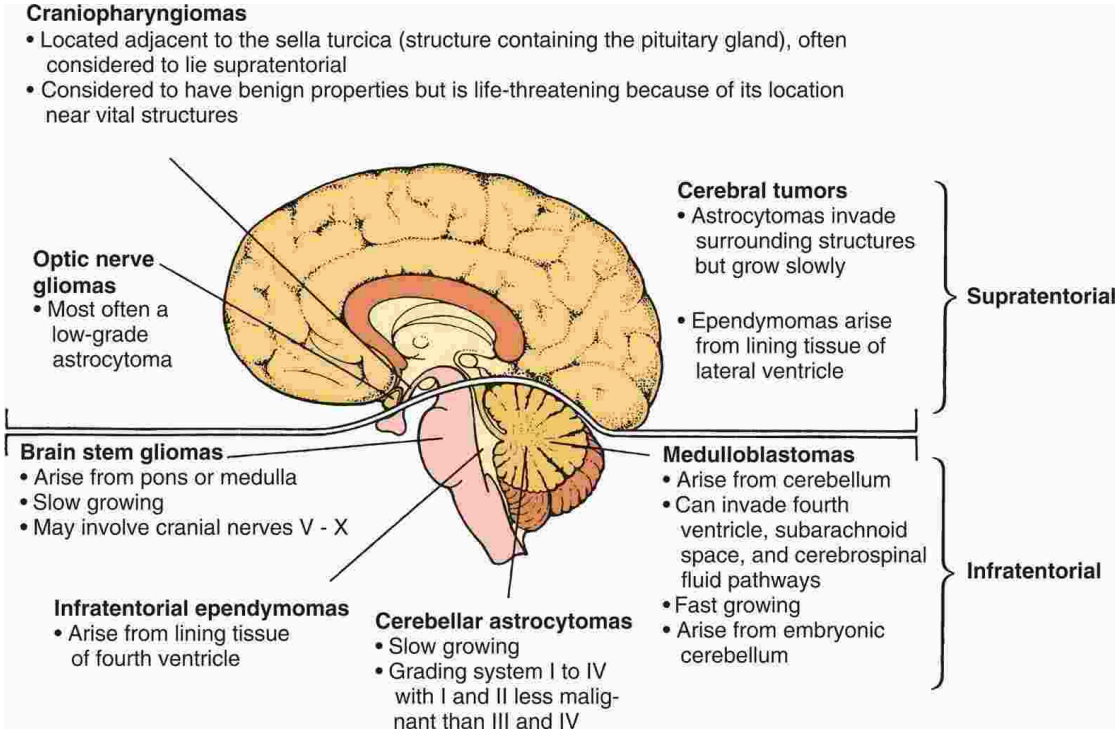

FIG. 20.11 Location of Brain Tumors in Children. (From Ostrom QT, et al. *Neuro-Oncology*, 2017;19(suppl_5):v1-v88.)

An illustration of the left lateral view of a child's brain identifies the location of brain tumors. The data from the illustration are as follows. Craniopharyngiomas. â€¢ Located adjacent to the Sella turcica (structure containing the pituitary gland), often considered to lie supratentorial. â€¢ Considered to have benign properties but is life threatening because of its location near vital structures. Optic nerve gliomas. â€¢ Most often a low-grade astrocytoma. Cerebral tumors (supratentorial). â€¢ Astrocytomas invade surrounding structures but grow slowly. â€¢ Ependymomas arise from lining tissue of lateral ventricle. Brain stem gliomas. â€¢ Arise from pons or medulla. â€¢ Slow growing. â€¢ May involve cranial nerves V to X. Medulloblastomas (infratentorial). â€¢ Arise from cerebellum. â€¢ Can invade fourth ventricle, subarachnoid space, and cerebrospinal fluid pathways. â€¢ Fast growing. â€¢ Arise from embryonic cerebellum. Infratentorial ependymomas. â€¢ Arise from lining tissue of fourth ventricle. Cerebellar Astrocytomas. â€¢ Slow growing. â€¢ Grading system 1 to 4 with 1 and 2 less malignant than 3 and 4.

Table 20.6

More Common Brain Tumors in Children

Type	Characteristics	Treatment
Astrocytoma	Arises from astrocytes, often in cerebellum or lateral cerebral hemisphere Slow growing, solid or cystic Often very large before diagnosed Varies in degree of malignancy	*Cerebellar astrocytoma* Surgery can be curative for juvenile pilocytic astrocytomas Radiation, chemotherapy, and newer targeted therapies can play important role in improving outcome.
Medulloblastoma (neuroectodermal tumor)	Often located in cerebellum, extending into fourth ventricle and spinal fluid pathway Can extend outside central nervous system Rapidly growing malignant tumor	Treatment is age and tumor type dependent Surgery, important to not only reopen cerebrospinal fluid pathways but also to improve outcome Radiation as primary treatment; may include spinal radiation Chemotherapy often helpful in conjunction with craniospinal radiation Targeted therapies for molecular subgroups are in development
Ependymoma	Arises from ependymal cells lining ventricles Circumscribed, solid, nodular tumors	Tumor possibly indolent for many years Surgery resection highly correlated with outcome. Radiation for palliation (current controversy over whether local or craniospinal radiation is best) Chemotherapy used for recurrent disease but with disappointing results Targeted therapies for molecular subgroups are in development
Brainstem glioma		

Type	Characteristics	Treatment
	Arises from pons Numerous cell types Compresses cranial nerves V through X	Surgery, resection rarely possible Radiation, primarily palliative treatment Chemotherapy not yet proven beneficial New protocols and agents being studied

Type	Characteristics	Treatment

Signs and symptoms of brain tumors in children vary from generalized and vague to localized and related specifically to an anatomic area. Signs of elevated ICP may occur, including headache, vomiting, lethargy, and irritability. If a young child complains of repeated and worsening headache, a thorough investigation should take place because headache is an uncommon complaint in young children. Headache caused by elevated ICP usually is worse in the morning and gradually improves during the day, when the child is upright and venous drainage is enhanced. The frequency of headache and other symptoms increases as the tumor grows. Irritability or possible apathy and increased somnolence also may result. Like headache, vomiting occurs more commonly in the morning. Often it is *not* preceded by nausea and may become projectile, differing from a gastrointestinal disturbance in that the child may be ready to eat immediately after vomiting. Persistent headaches with vomiting in a child should be

evaluated promptly. Other signs and symptoms include increased head circumference with bulging fontanelles in the child younger than 2 years, cranial nerve palsies, and papilledema (Box 20.1).

Box 20.1

Clinical Manifestations of Brain Tumors

Headache

Recurrent and progressive
In frontal or occipital area
Worse on arising; pain lessens during the day
Intensified by lowering head and straining, such as when defecating, coughing, sneezing

Vomiting

With or without nausea or feeding
Progressively more projectile
More severe in morning
Relieved by moving and changing position

Neuromuscular Changes

Incoordination or clumsiness
Loss of balance (use of wide-based stance, falling, tripping, banging into objects)
Poor fine motor control
Weakness
Hyporeflexia or hyperreflexia
Positive Babinski sign
Spasticity
Paralysis

Behavioral Changes

Irritability
Decreased appetite
Failure to thrive
Fatigue (frequent naps)
Lethargy
Coma
Bizarre behavior (staring, automatic movements)

Cranial Nerve Neuropathy

Cranial nerve involvement varies according to tumor location. The most common signs are:
Head tilt
Visual defects (nystagmus, diplopia, strabismus, episodic "graying out" of vision, and visual field defects)

Vital Sign Disturbances

Decreased pulse and respiratory rates

Increased blood pressure
Decreased pulse pressure
Hypothermia or hyperthermia

Other Signs

Seizures
Cranial enlargement[a]
Tense, bulging fontanelle at rest[a]
Separating suture[a]
Nuchal rigidity
Papilledema (edema of optic nerve)

From Hockenberry MN. *Wong's essentials of pediatric nursing*, 7th edition. St. Louis: Mosby; 2007.

[a]Present only in infants and young children.

Localized findings relate to the degree of disturbance in physiologic functioning in the area where the tumor is located. The majority of pediatric brain tumors involve the cerebellum, brain stem, and fourth ventricle affecting all pediatric age groups. Children with infratentorial tumors (posterior fossa) exhibit localized signs of impaired coordination and balance, including ataxia, gait difficulties, truncal ataxia, and loss of balance. Supratentorial tumors of the cerebral hemispheres are more common in children younger than 3 years of age.[46] Most pediatric brain tumors require surgical resection. Aggressive radiation and chemotherapy are required for high-grade tumors, although radiation therapy is rarely offered to children younger than 4 years of age, due to significant long-term side effects. Advances are being made in areas of immunotherapy and targeted molecular therapy (see Emerging Science Box: The New Evolving Classification System for Pediatric Brain Tumors).[47]

Embryonal Tumors

Neuroblastoma

Neuroblastoma is an embryonal tumor originating from neural crest tissues of the sympathetic nervous system outside the CNS. It is the most common cancer in infants younger than 1 year of age. Although it accounts for only approximately 6% of pediatric malignancies (approximately 800 new cases per year), neuroblastoma causes approximately 15% of cancer deaths in children.[48] More than with any other cancer, neuroblastoma has been associated with spontaneous remission, commonly in infants. Prognosis is worse for children older than 2 years of age with disseminated disease. Although familial tendency has been noted in individual cases, a nonfamilial or sporadic pattern is found in most children with neuroblastoma. Familial cases of neuroblastoma are considered to have an autosomal dominant pattern of inheritance (mechanisms of inheritance are discussed in Chapter 4).

The most common location of neuroblastoma is in the retroperitoneal region, most often in the adrenal medulla. The tumor is evident as an abdominal mass and may cause anorexia, bowel and bladder alteration, and sometimes spinal cord compression. The second most common location of neuroblastoma is the mediastinum (15% of cases), where the tumor may cause dyspnea or infection related to airway obstruction. Rarely, neuroblastoma may arise from the cervical sympathetic ganglion.

A number of systemic signs and symptoms are characteristic of neuroblastoma, including weight loss, irritability, fatigue, and fever. Intractable diarrhea occurs in some children and is caused by tumor secretion of a hormone called *vasoactive intestinal polypeptide (VIP)*. Most children with neuroblastoma have increased amounts of catecholamines and associated metabolites in their urine (e.g., urinary vanillylmandelic acid [VMA] and homovanillic acid [HVA]). High levels of urinary catecholamines and serum ferritin are associated with a poor prognosis. Immunotherapeutic treatments are undergoing continuing investigation and hold promise for good outcomes without toxicity.[49]

Retinoblastoma

Retinoblastoma (RB) is the most common intraocular congenital eye tumor of young children that originates in the retina of one or both eyes (Fig. 20.12A and B). Two forms of RB are exhibited: inherited and acquired. Both forms of the disease are a consequence of loss of function of the RB gene *(RB1)*. The inherited form of the disease generally is diagnosed during the first year of life. The acquired disease is diagnosed before the age of 5 in 90% of the cases.[50] Approximately 40% of RBs are inherited as an autosomal dominant trait with incomplete penetrance (see Fig. 4.24). The remaining 60% are acquired somatic mutations. The "two-hit" hypothesis explains the occurrence of both hereditary and acquired forms of the disease.[51] This hypothesis predicts that two separate transforming events or "hits" must occur in a normal retinoblast cell to cause the cancer. Furthermore, it proposes that in the inherited form, the first hit or mutation occurs in the germ cell (inherited from either parent), and the mutation is contained in every cell of the child's body. Only a second, random mutation in a retinoblast cell is needed to transform that cell into cancer. Multiple tumors are observed in the inherited form because these second mutations are likely to occur in several of the approximately 1 to 2 million retinoblast cells. In contrast, the acquired form of RB requires two *independent* hits or mutations to occur in the same somatic cell (after the egg is fertilized) for the transformation to cancer. This is much less likely to happen. Fig. 20.13 illustrates the "two-hit" model for these two patterns of mutation. Epigenetic mechanisms (i.e., inactivating the gene without changing its DNA sequence) also play a role in dysregulation of the tumor suppressor and oncogenic pathways of RB, and they may become markers for difficult to diagnose tumors.[52] The primary sign of RB is leukocoria, a white pupillary reflex (white reflex) also called *cat's eye reflex*, which is caused by the mass behind the lens (see Fig. 20.12B). This easy to identify sign can be missed. Other signs and symptoms include strabismus; a red, painful eye; and limited vision.

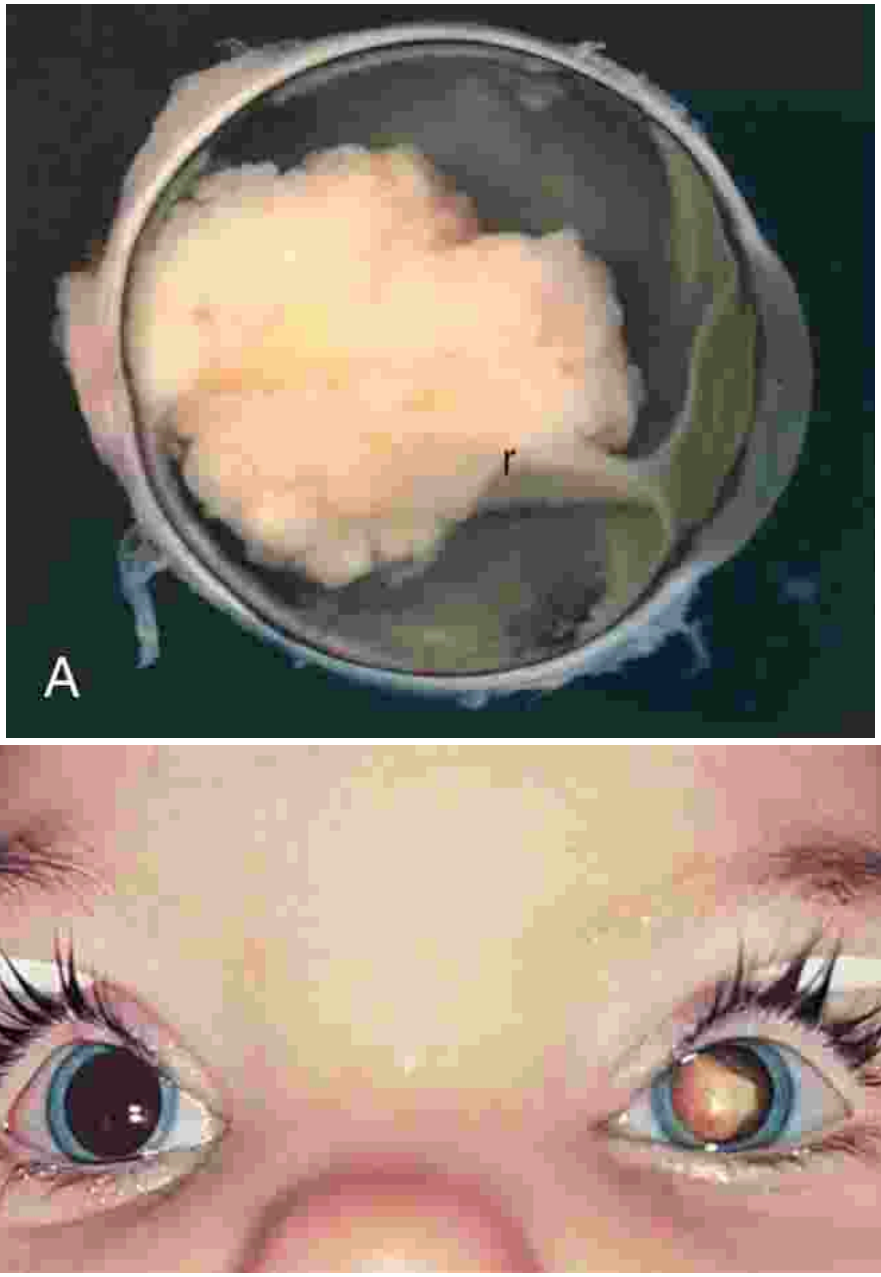

FIG. 20.12 Retinoblastoma.
(A) Presence of white mass surrounding the detached retina *(r)*. **(B)** The tumor occupies a large portion of the inside of the eye globe. (A, From Roberts F. Macroscopic techniques for ophthalmic tumor specimens. *Seminars in Diagnostic Pathology*, 2016;33(3):114–121. B, From Damjanov I. *Pathology for the health professions*, 3rd edition. St. Louis: Saunders; 2006. Courtesy Dr. Walter Richardson and Dr. Jamsheed Khan, Kansas City, KS.)

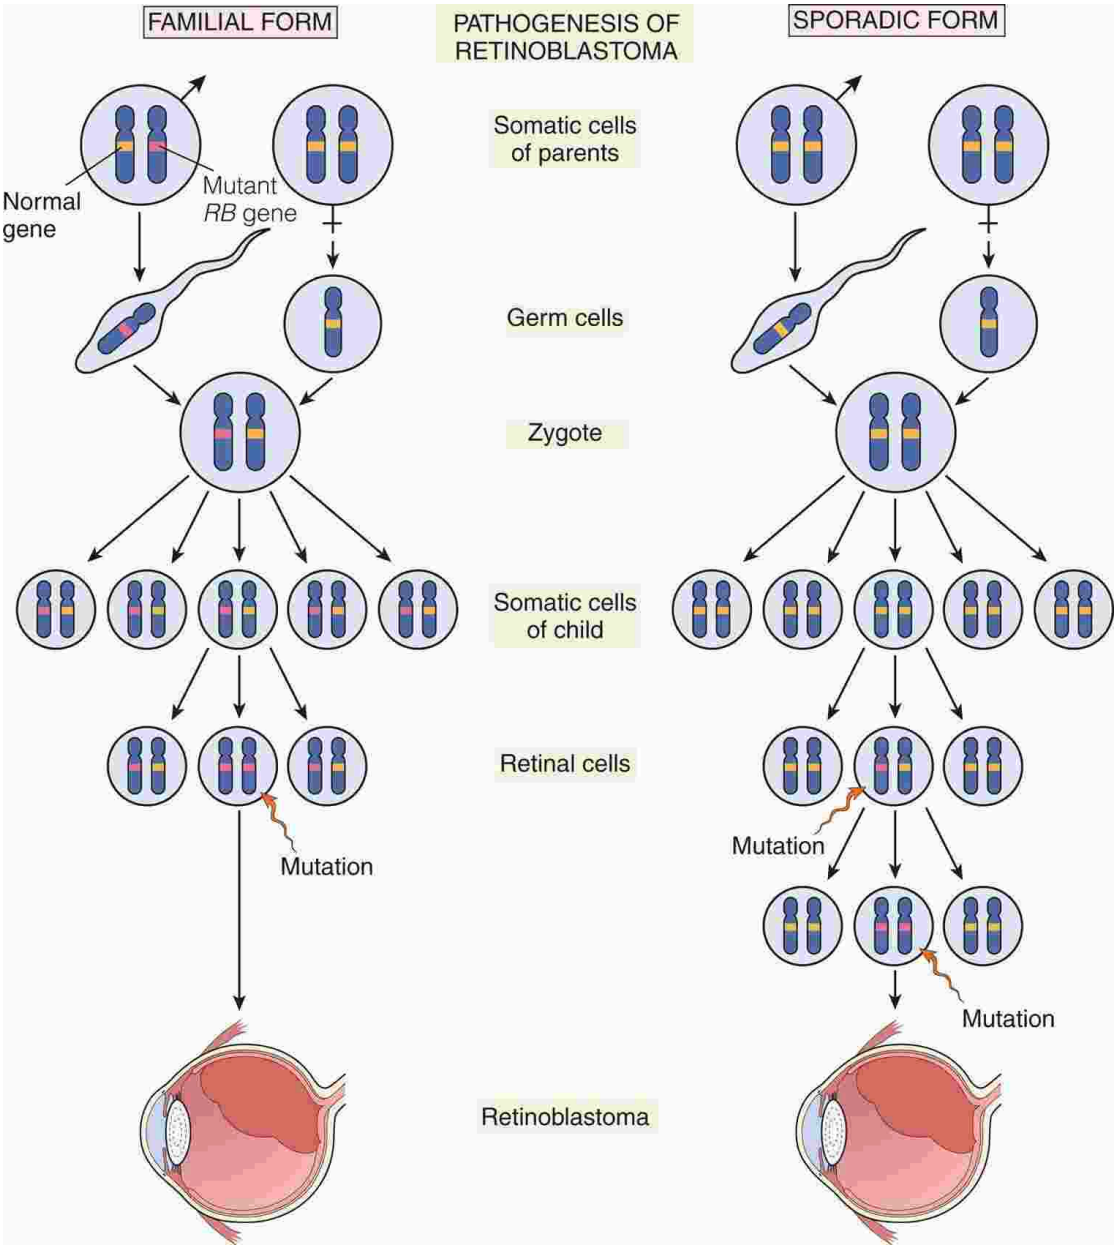

FIG. 20.13 The Two-Mutation Model of Retinoblastoma Development.
In inherited retinoblastoma, the first mutation is transmitted through the germline of an affected parent. The second mutation occurs somatically in a retinal cell, leading to development of the tumor. In sporadic retinoblastoma, development of a tumor requires two somatic mutations.

Two sets of illustrations show mutations leading to retinoblastoma development. Left panel, familial form. Somatic cells of parents show a pair of chromosomes each. Male cell contains 1 chromosome containing normal gene and 1 containing mutant gene. Mutant gene is passed into the zygote, multiplying into pairs, where each pair has one normal gene and one mutated gene. Mutation of the somatic cells of the child result in a pair of two mutated

genes, leading to retinoblastoma. Right panel, sporadic form. Somatic cells of parents are both normal, that form a normal zygote, that multiply into normal somatic cells of the child. Mutation in one pair of cells leads to one mutated gene and one normal gene. Additional mutation leads to a cell with two mutated genes, leading to retinoblastoma.

Because RB is a treatable tumor, dual priorities are saving the child's life and restoring useful vision. The prognosis for most children with RB is excellent, with a greater than 90% long-term survival.

Summary Review

Development of the Nervous System in Children

1. Growth and development of the brain occur most rapidly during fetal development and during the first year of life.
2. The bones of the skull are joined by sutures, and the wide, membranous junctions of the sutures (known as *fontanelles*) allow for brain growth and close by 18 months of age *typically*.
3. At birth, the forebrain is immature, so neurologic examination is primarily of reflex responses that require an intact spinal cord and brainstem.

Structural Malformations

1. Neural tube defects (NTDs) are an arrest of the normal development of the brain and spinal cord during the first month of embryonic development. Risk factors include folic acid deficiency, previous NTD pregnancy, maternal diabetes or obesity, use of anticonvulsants, and maternal hyperthermia.
2. Spina bifida (failure of vertebral closure) is the most common NTD and includes meningocele (a sac-like meningeal cyst of spinal fluid that protrudes through a vertebral defect), myelomeningocele (like a meningocele that also contains a portion of the spinal cord with its nerves), and spina bifida occulta.
3. Premature closure of the cranial sutures causes craniosynostosis, resulting in an asymmetric skull shape. If multiple sutures fuse prematurely, brain growth may be restricted.
4. Microencephaly is a defect in brain cell proliferation that leads to a small brain, small skull, and usually developmental delays.
5. Cortical dysplasias are defects in brain development caused by defects in neuronal cell migration and subsequent abnormalities in connection between cells.
6. Congenital hydrocephalus, characterized by increased cerebrospinal fluid (CSF) pressure, results from impaired absorption or blockage of circulation of CSF and rarely overproduction of CSF. Dandy-Walker deformity, which is commonly associated with hydrocephalus, is associated with cystic dilation of the fourth ventricle and aqueductal compression.

Alterations in Function: Encephalopathies

1. Static (nonprogressive) encephalopathies (e.g., cerebral palsy and epilepsy) are disorders of the brain caused by a fixed lesion without active and ongoing disease. They can occur during gestation, birth, or childhood and can be caused by endogenous or exogenous factors.
2. Cerebral palsy (CP) can be caused by prenatal or perinatal cerebral hypoxia or perinatal trauma, with symptoms of motor dysfunction (including increased muscle tone, increased reflexes, and loss of fine motor coordination), mental retardation, seizure disorders, or developmental disabilities. CP can be extrapyramidal/nonspastic or pyramidal/spastic.

3. Inherited metabolic disorders that damage the nervous system include defects in amino acid metabolism (phenylketonuria) and lysosomal storage defects (GM_2 gangliosidosis/Tay-Sachs disease) and result in abnormal behavior, seizures, and deficient psychomotor development.
4. Seizure disorders are abnormal discharges of electrical activity within the brain. They are associated with numerous nervous system disorders and more often are a generalized rather than a partial type of seizure.
5. Accidental ingestion, therapeutic overdose, intentional overdose, or ingestion of environmental toxins, such as in lead poisoning, can cause serious neurologic damage.
6. Bacterial meningitis is commonly caused by *Neisseria meningitidis* or *Streptococcus pneumoniae* and may result from respiratory tract or gastrointestinal infections; symptoms include fever, headaches, photophobia, seizures, rigidity, and stupor.
7. Viral meningitis may result from direct infection or be secondary to a systemic viral infection (e.g., measles, mumps, herpes, or leukemia).

Cerebrovascular Disease in Children

1. Perinatal arterial ischemic stroke is a leading cause of perinatal brain injury, cerebral palsy, and lifelong disability.
2. Ischemic (occlusive) stroke is rare in children but can occur from embolism, sickle cell disease, cerebral arteriopathies, and cardiac anomalies.
3. Hemorrhagic stroke can occur in association with immature blood vessel associated with prematurity or cerebral arteriovenous malformations.
4. Moyamoya is a rare, progressive vascular stenosis of the circle of Willis that obstructs arterial blood flow to the brain and is associated with transient ischemic attacks.

Epilepsy and Seizure Disorders in Children

1. Seizures are abnormal discharges of electrical activity within the brain. Epilepsy is the occurrence of more than two unprovoked seizures separated by over 24 hours.
2. Seizures can be caused by structural abnormalities of the brain, hypoxia, intracranial hemorrhage, CNS infection, traumatic injury, electrolyte imbalance, or inborn metabolic disturbances.
3. Epileptic spasms (infantile spasms) are a rare severe type of seizure associated with brain injury that occur in clusters of 10 to 150 spasms affecting the whole body or just the arms and legs.

Childhood Brain Tumors

1. Brain tumors are the second most common type of childhood cancer and are the leading cause of cancer related death in children.
2. Symptoms of brain tumors may be generalized or localized. The most common general symptoms are the result of increased intracranial pressure and include headache, irritability, vomiting, somnolence, and bulging of fontanelles.
3. Localized findings relate to the degree of disturbance in physiologic functioning in the area where the tumor is located. Localized signs of infratentorial tumors in the cerebellum include impaired coordination and balance.
4. Neuroblastoma is an embryonal tumor of the sympathetic nervous system and can be located anywhere there is sympathetic nervous tissue. Symptoms include weight loss, irritability, fatigue, fever, and intractable diarrhea. Neuroblastoma has been associated with spontaneous remission in infants.
5. Retinoblastoma is a congenital eye tumor that has two forms: inherited and acquired; both are related to loss of function of the *RB* gene.

Emerging Science Box In Utero Myelomeningocele Surgery

Operating on a fetus in utero with spina bifida reduces the risk of developing hydrocephalus and Chiarimalformation and may improve motor function. This can have a very positive impact for the child in terms quality of life. Prenatal repair of myelomeningocele continues to evolve since first reported by Bruner and Tulipan in 1997. Typically after myelomeningocele has been confirmed and the mother is 18 years of age or older and between 19 and 25.9 weeks' gestation, the surgery is performed either endoscopically or by small open hysterotomy. Candidates for this surgery are typically screened very carefully, and the spinal defect must be below thoracic level 1. Maternal and fetal risks are increasingly being reduced with further experience. Preterm delivery remains a significant problem such that this operation is best performed by an experienced team with delivery by cesarean section. The child may have increased risk of retethering and intraspinal dermoid cysts. Long-term evaluation of neurologic function and quality of life are ongoing.

Emerging Science Box Gene Therapy for Pediatric Neurologic Conditions

Much has been learned from studies and trials from the 1980's and 1990's. Due to the high risk of germ line gene therapy, where changes made to correct the genetic variants of the reproductive cells would be passed on to offspring, only somatic gene therapies are under trial. Somatic gene therapy involves either in vivo or ex vivo introduction of genetic material into cells in the body or those

harvested, altered and then placed back into the body. Three pediatric FDA approved therapies exist at this time for spinal muscular atrophy, B-cell acute lymphoblastic leukemia and a specific retinal dystrophy. Many other trials are underway and being developed due to the great promise this therapy has for certain genetic neurologic conditions. A recent search of the National Cancer Institute website for gene therapy or gene transfer yields 10 trials for CNS childhood tumors, 13 trials for pediatric neurologic disorders including Duchenne muscular dystrophy, Hunter Syndrome, gangliosidosis, Danon disease and others. Currently the Clinical Trials.gov web site lists 45 studies involving children receiving or being evaluated for the outcomes of gene therapy for specific diseases or conditions (Accesses April 20, 2021, Available at https://clinicaltrials.gov/ct2/results?cond=Pediatric+ALL&term=+gene+therapy&cntry=&state=&city=&dist=&Search=Search&recrs=a&recrs=b&age=0).

In 2012 a revolutionary new gene editing technique called CRISPR (clusters of regularly interspaced short palindromic [reads the same in both directions] repeats [sequences of nucleotides]) was first introduced. This technique allows for precise gene editing by inserting a cut or break in the DNA and allowing a cell's natural DNA repair mechanisms to introduce the desired changes. Gene editing is being investigated for neurologic disorders such as genetic blindness, muscular dystrophy, Huntington disease. cancer, blood disorders, cystic fibrosis and other medical conditions that may likely benefit from CRISPR.

Emerging Science Box The New Evolving Classification System for Pediatric Brain Tumors

Ongoing advances in molecular biology are revolutionizing how we categorize and treat pediatric brain tumors. Brain tumors have historically been categorized by what the cells look like under the microscope. Tumor cells from one person may look like another person's tumor cells but behave very differently and react differently to treatment. The emerging new classification system relies less on how the cells look and more on how they behave and what molecular pathways have been altered to make the cell a tumor. Some low-grade gliomas have significant alterations in the BRAF gene, allowing for targeted therapies incorporating MEK inhibitors. The most common pediatric brain tumor medulloblastoma is now categorized into 4 separate types. Each category has a different prognosis. The most favorable group is the WNT (Wingless/Integrated). Trials using no radiation or reduced dose radiation are underway for that group. Ependymomas have nine recognized subsets.

Understanding the molecular make up of each tumor can open new treatment options as more targeted therapies become available. Even the most highly malignant tumors such as diffuse intrinsic pontine glioma (DPG) may warrant biopsy to understand molecular make up and potential new treatment options.

The endocrine system is composed of various glands located throughout the body (Fig. 21.1). These glands can synthesize and release special chemical messengers called *hormones*. The endocrine, nervous, and immune systems work together to regulate responses to internal and external environments. The endocrine system has five general functions: (1) differentiation of the reproductive and central nervous systems in the developing fetus; (2) stimulation of sequential

growth and development during childhood and adolescence; (3) coordination of the male and female reproductive systems, which makes sexual reproduction possible; (4) maintenance of an optimal internal environment throughout life; and (5) initiation of corrective and adaptive responses when emergency demands occur. Hormones convey specific regulatory information among cells and organs and are integrated with the nervous system to maintain communication and control. The mechanisms of communication and control occur within a cell *(autocrine)*, between local cells *(paracrine)*, and between cells located remotely from each other *(endocrine)*.

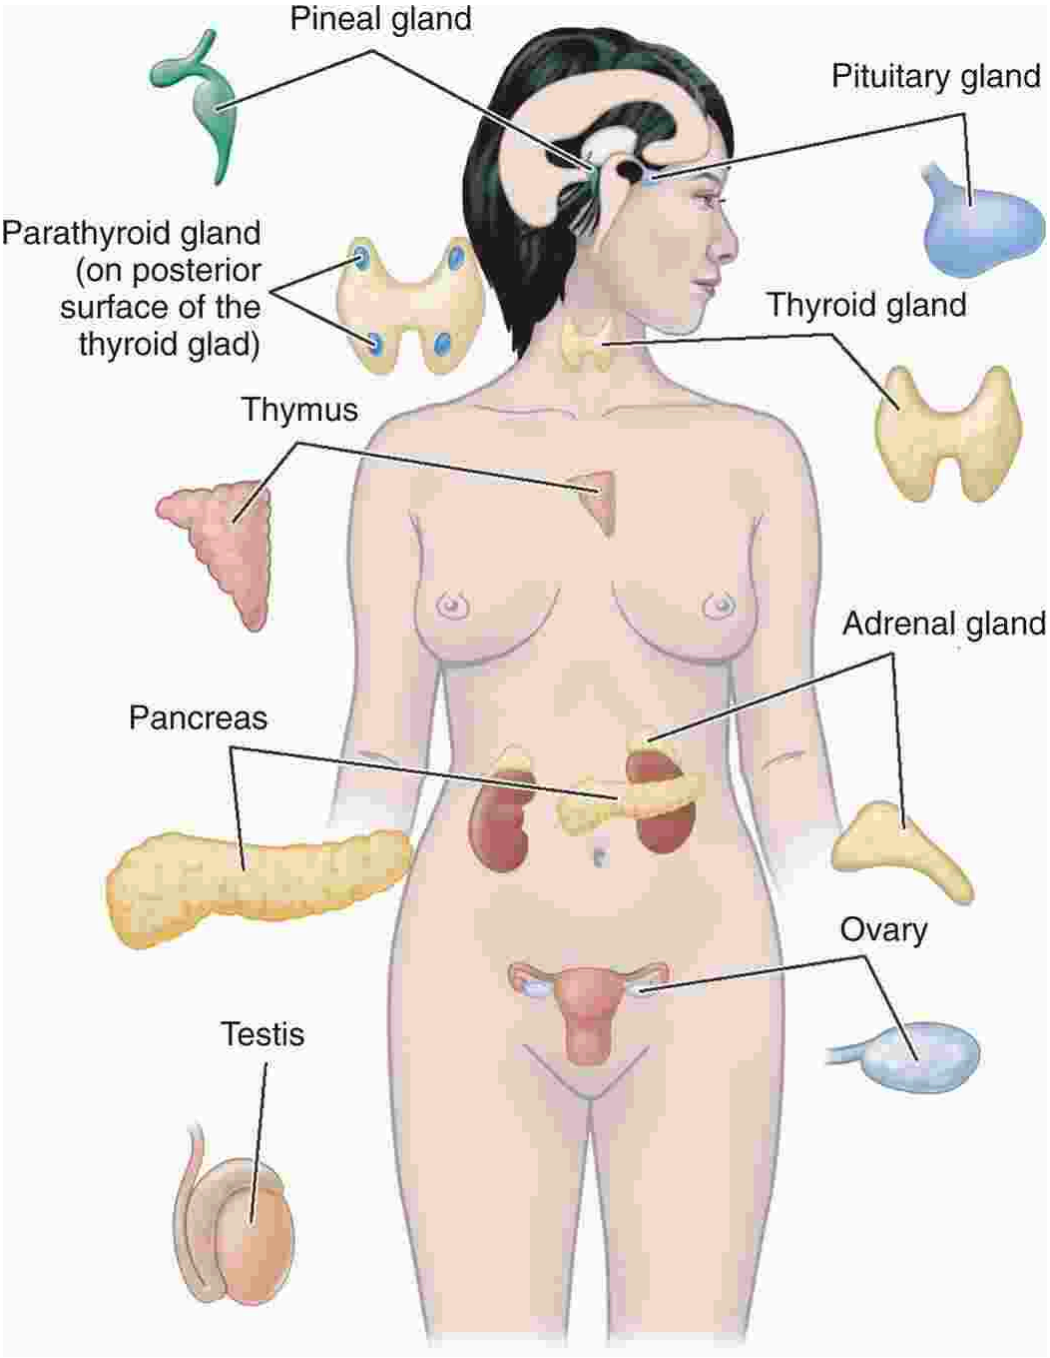

FIG. 21.1 Major Endocrine Glands. (From Applegate E. *The anatomy and physiology learning system*, 4th edition. St. Louis: Saunders; 2011.)

An illustration of a human figure identifies and labels the following major endocrine glands, from the top to

the bottom: pineal gland, pituitary gland, thyroid gland, parathyroid gland (on posterior surface of the thyroid gland), thymus, adrenal gland, pancreas, ovary, and testis.

Mechanisms of Hormonal Regulation

Endocrine glands respond to specific signals by synthesizing and releasing hormones into circulation, which then trigger intracellular responses. All hormones share certain general characteristics:

1. Hormones have specific rates and rhythms of secretion. Three basic patterns of secretion are (a) diurnal patterns, (b) pulsatile and cyclic patterns, and (c) patterns that depend on levels of circulating substrates (e.g., calcium, sodium, potassium, or the hormones themselves).
2. Hormones operate within feedback systems, either negative or positive, to maintain an optimal internal environment.
3. Hormones affect only target cells with specific receptors for the hormone and then act on these cells to initiate specific cell functions or activities.
4. Steroid hormones are either excreted directly by the kidneys or metabolized (conjugated) by the liver, which inactivates them and renders the hormone more water soluble for renal excretion. Peptide hormones are catabolized by circulating enzymes and eliminated in the feces or urine.

Hormones may be classified according to structure, gland of origin, effects, or chemical composition. (Table 21.1 categorizes known hormones based on structure.) The mechanisms of action and secretion of hormones represent an extremely complex system of integrated hormonal and neural responses.

Table 21.1

Structural Categories of Hormones

Structural Category	Examples
Water Soluble	
Peptides	Growth hormone Insulin Leptin Parathyroid hormone Prolactin
Glycoproteins	Follicle-stimulating hormone Luteinizing hormone Thyroid-stimulating hormone
Polypeptides	Adrenocorticotropic hormone Antidiuretic hormone Calcitonin Endorphins Glucagon Hypothalamic hormones

Structural Category	Examples
	Lipotropins Melanocyte-stimulating hormone Oxytocin Somatostatin Thymosin Thyrotropin-releasing hormone
Amines	Epinephrine Norepinephrine
Lipid Soluble	
Thyroxine (an amine but lipid soluble)	Both thyroxine (T_4) and triiodothyronine (T_3)
Steroids (cholesterol is a precursor for all steroids)	Estrogens Glucocorticoids (cortisol) Mineralocorticoids (aldosterone) Progestins (progesterone) Testosterone

Structural Category	**Examples**
Derivatives of arachidonic acid (autocrine or paracrine action)	Leukotrienes Prostacyclins Prostaglandins Thromboxanes

Structural Category	Examples
Water Soluble	
Peptides	Growth hormone Insulin Leptin Parathyroid hormone Prolactin
Glycoproteins	Follicle-stimulating hormone Luteinizing hormone Thyroid-stimulating hormone
Polypeptides	Adrenocorticotropic hormone Antidiuretic hormone Calcitonin Endorphins Glucagon Hypothalamic hormones Lipotropins Melanocyte-stimulating hormone Oxytocin Somatostatin Thymosin Thyrotropin-releasing hormone
Amines	Epinephrine Norepinephrine
Lipid Soluble	
Thyroxine (an amine but lipid soluble)	Both thyroxine (T_4) and triiodothyronine (T_3)
Steroids (cholesterol is a precursor for all steroids)	Estrogens Glucocorticoids (cortisol) Mineralocorticoids (aldosterone) Progestins (progesterone) Testosterone
Derivatives of arachidonic acid (autocrine or paracrine action)	Leukotrienes Prostacyclins Prostaglandins Thromboxanes

Regulation of Hormone Release

Hormones are released to respond to an altered cellular environment or to maintain the level of another hormone or substance. One or

more of the following mechanisms regulates hormone release: (1) chemical factors (such as blood glucose or calcium levels), (2) endocrine factors (a hormone from one endocrine gland controlling another endocrine gland), and (3) neural control. For example, insulin is secreted by the (1) chemical stimulation of increased plasma glucose levels, (2) the hormone cortisol from the adrenal cortex, and (3) direct stimulation of the insulin-secreting cells of the pancreas by the autonomic nervous system, which is a form of neural control.

Feedback systems provide precise monitoring and control of the cellular environment. Both negative- and positive-feedback systems are important for maintaining hormone levels within physiologic ranges. Positive feedback occurs when a neural, chemical, or endocrine response increases the synthesis and secretion of a hormone. Negative feedback, which is more common, occurs when a changing chemical, neural, or endocrine response to a stimulus decreases the synthesis and secretion of a hormone. Fig. 21.2A illustrates both positive and negative feedback within the hypothalamus-pituitary axis and the thyroid gland. Positive feedback occurs when thyrotropin-releasing hormone (TRH) is released from the hypothalamus in response to low thyroid hormone levels. TRH stimulates the secretion of thyroid-stimulating hormone (TSH), which then stimulates the synthesis and secretion of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). Negative feedback occurs when increasing levels of T_4 and T_3 feedback on the pituitary and hypothalamus inhibit TRH and TSH synthesis and decrease the synthesis and production of thyroid hormones. Fig. 21.2B illustrates a more complex model for feedback mechanisms across the hormonal system. The lack of positive or negative feedback on hormonal release often results in pathologic changes in hormone production (see Chapter 22).

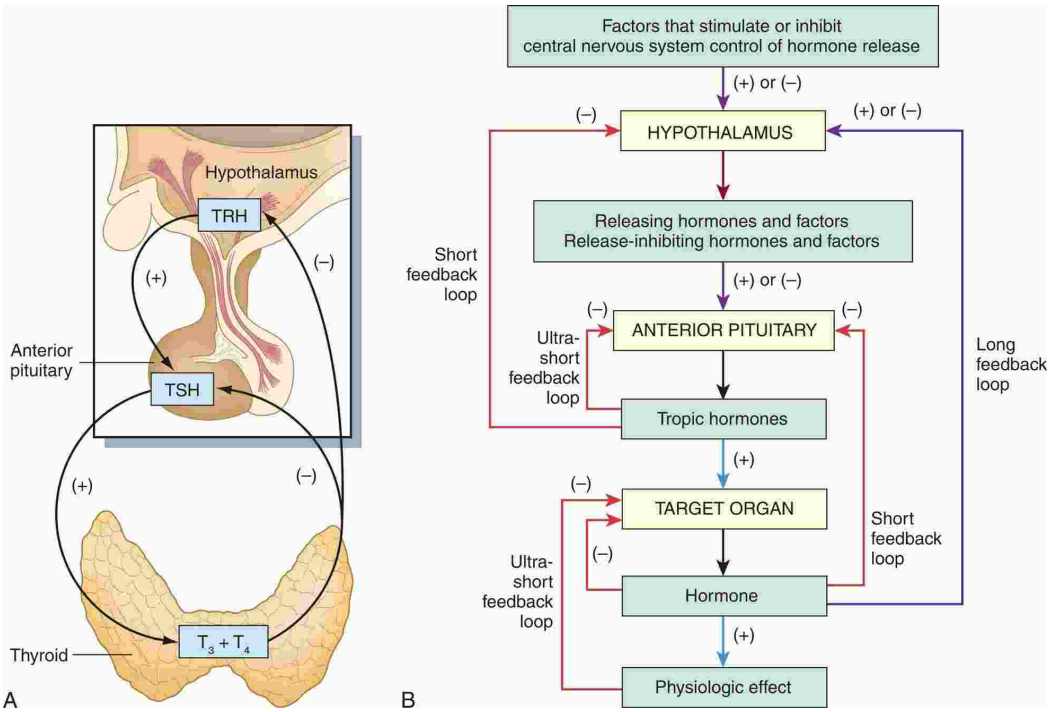

FIG. 21.2 Feedback Loops.
(A) Endocrine feedback loops for the thyroid gland: *TRH*, Thyroid-releasing hormone; *TSH*, thyroid-stimulating hormone; T_3, triiodothyronine; T_4, tetraiodothyronine (thyroxine). **(B)** General model for feedback mechanisms in the regulation of hormone secretion., Negative feedback regulation (−) is possible at three levels: target organ (ultrashort feedback), anterior pituitary (short feedback), and hypothalamus (long feedback).

Illustration A shows the endocrine feedback loop between the thyroid and the hypothalamus. T R H from hypothalamus releases T S H into the anterior pituitary. T sub 3 and T sub 4 are then released into the thyroid. The thyroid provides negative feedback to the anterior pituitary and the hypothalamus.

Flowchart B shows the following mechanisms. â€¢ The hypothalamus is positively or negatively regulated by factors that stimulate or inhibit central nervous system control of hormone release. â€¢ The anterior pituitary is positively or negatively regulated by releasing hormones and factors and release-inhibiting hormones and factors. â€¢ The target organ is positively regulated by tropic hormones from the anterior pituitary. â€¢ The hormones from the target organ positively regulates the physiologic effect. The feedback loops through the mechanisms are as follows. â€¢ Tropic hormones provide an ultra-short negative feedback loop to the anterior pituitary. â€¢ Tropic hormones provide a short negative feedback loop to the hypothalamus. â€¢ Hormones from the target organ provide a negative feedback loop to the target organ. â€¢ Hormones from the target organ provide a short negative feedback loop to the anterior pituitary. â€¢ Hormones from the target organ provide a long positive or negative feedback loop to the hypothalamus. â€¢ Physiologic effect provides an ultra-short negative feedback loop to the target organ.

Hormone Transport

Once hormones are released into the circulatory system, they are distributed throughout the body. The protein (peptide) hormones (see Table 21.1) are water soluble and generally circulate in free

(unbound) forms. Water-soluble hormones generally have a half-life of seconds to minutes because they are catabolized by circulating enzymes. For example, insulin has a half-life of 3 to 5 minutes and is catabolized by insulinases. Lipid-soluble hormones (see Table 21.1), such as cortisol and adrenal androgens, are transported bound to a water-soluble carrier or transport protein and can remain in the blood for hours to days. Only free hormones (those not bound to a carrier protein) can signal a target cell. At the cell membrane, lipid-soluble hormones dissociate from their carrier protein and diffuse into the cell. Because there is equilibrium between the concentrations of free hormones and hormones bound to plasma proteins, a significant change in the concentration of binding (carrier) proteins can affect the concentration of free hormones in the plasma. For example, malnutrition and liver disease can lower the serum levels of the carrier protein albumin, causing a decrease in the lipid-soluble hormones thyroxine, cortisol, and aldosterone. (Mechanisms of hormone binding are discussed in Chapter 1.) Free hormone levels can be measured using a variety of measurement techniques, including radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), or bioassay.

Hormone Receptors

Although a hormone is distributed throughout the body, only those cells with appropriate receptors for that hormone, termed target cells, are affected. Target cell response depends on blood levels of the hormone, the concentration of target cell receptors, and affinity of the receptor for the hormone. Hormone receptors of the target cell have two main functions: (1) to recognize and bind specifically and with high affinity (sensitivity) to their particular hormones, and (2) to initiate a signal to appropriate intracellular effectors.

The sensitivity of the target cell to a particular hormone is related to the total number of receptors per cell or the affinity of the receptors for the hormone: the more receptors or the higher the affinity of the receptors, the more sensitive the cell to the stimulating effects of the hormone. Low concentrations of hormone increase the number or

affinity of receptors per cell; this is called up-regulation (Fig. 21.3A). High concentrations of hormone decrease the number or affinity of receptors; this is called down-regulation (Fig. 21.3B). Thus, the cell can adjust its sensitivity to the concentration of the signaling hormone. The receptors on the plasma membrane are continuously synthesized and degraded, so that changes in receptor concentration or affinity may occur within hours. Various physiochemical conditions can affect both the receptor number and the affinity of the hormone for its receptor. Some of these physiochemical conditions are the fluidity and structure of the plasma membrane, pH, temperature, ion concentration, diet, and the presence of other chemicals (e.g., drugs). Finally, mutations may affect receptor number or structure. For example, mutations in TSH receptors can lead to resistance to thyroid hormone and can contribute to defective thyroid hormone production.[1]

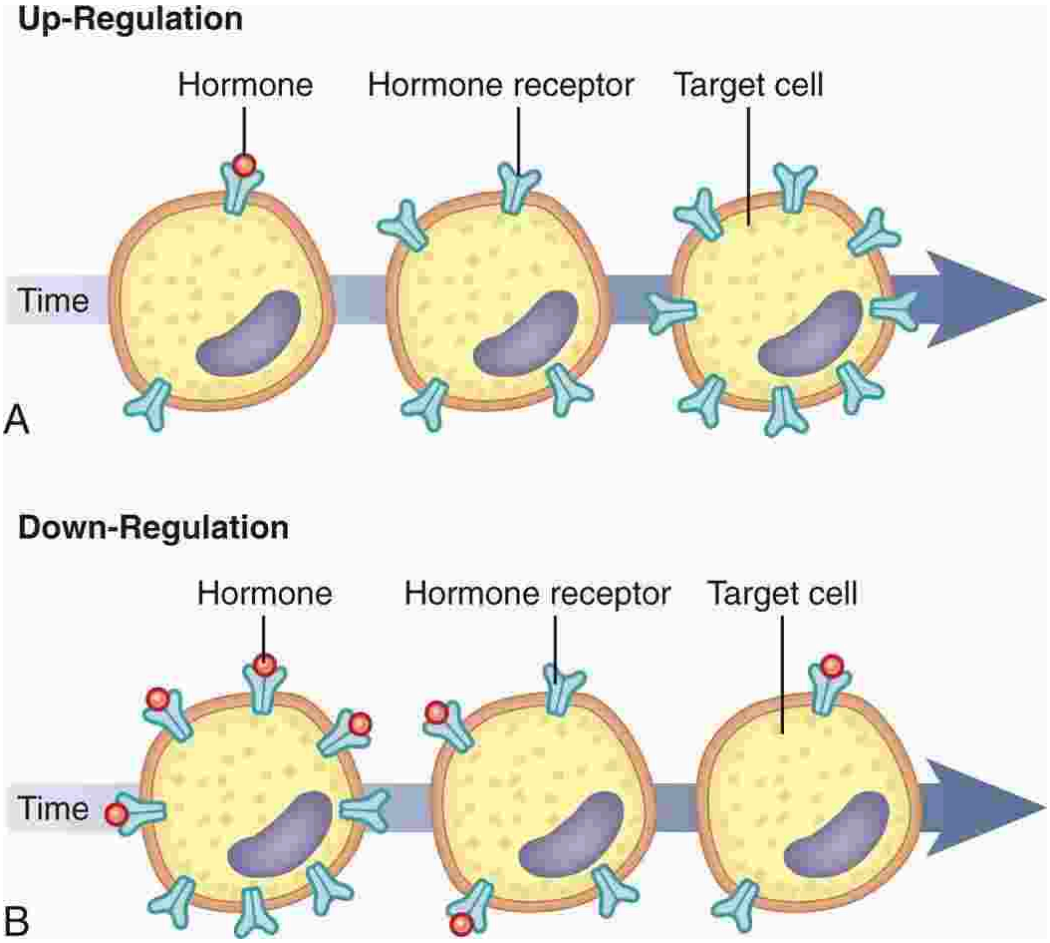

FIG. 21.3 Regulation of Target Cell Sensitivity. **(A)** Low hormone level and up-regulation, or an increase in the number of receptors. **(B)** High hormone level and down-regulation, or a decrease in the number of receptors.

Illustration A is a timeline representing an up-regulation. There are three illustrations on the timeline, from the left to the right. â€¢ The target cell has two hormone receptors, with a hormone in one. â€¢ The target cell has four hormone receptors, with no hormones in any. â€¢ The target cell has eight hormone receptors, with no hormones in any.

Illustration B is a timeline representing a down-regulation. There are three illustrations on the timeline, from the left to the right. â€¢ The target cell has eight hormone receptors, with hormones in four. â€¢ The target cell has four hormone receptors, with hormones in two. â€¢ The target cell has two hormone receptors, with a hormone in one.

Hormone receptors may be located in the plasma membrane or in the intracellular compartment of the target cell (Fig. 21.4). Water-soluble hormones (peptide or nonsteroid hormones), which include the protein hormones and the catecholamines, have a high molecular weight and cannot diffuse across the cell membrane. They interact or bind with receptors located in or on the cell membrane and activate a second messenger to mediate short-acting responses. Lipid-soluble hormones (steroid hormones) diffuse freely across the plasma and nuclear membranes and bind with cytosolic or nuclear receptors, although receptors for some lipid-soluble hormones are located in or near the plasma membrane and facilitate rapid (non-genomic) effects.[2]

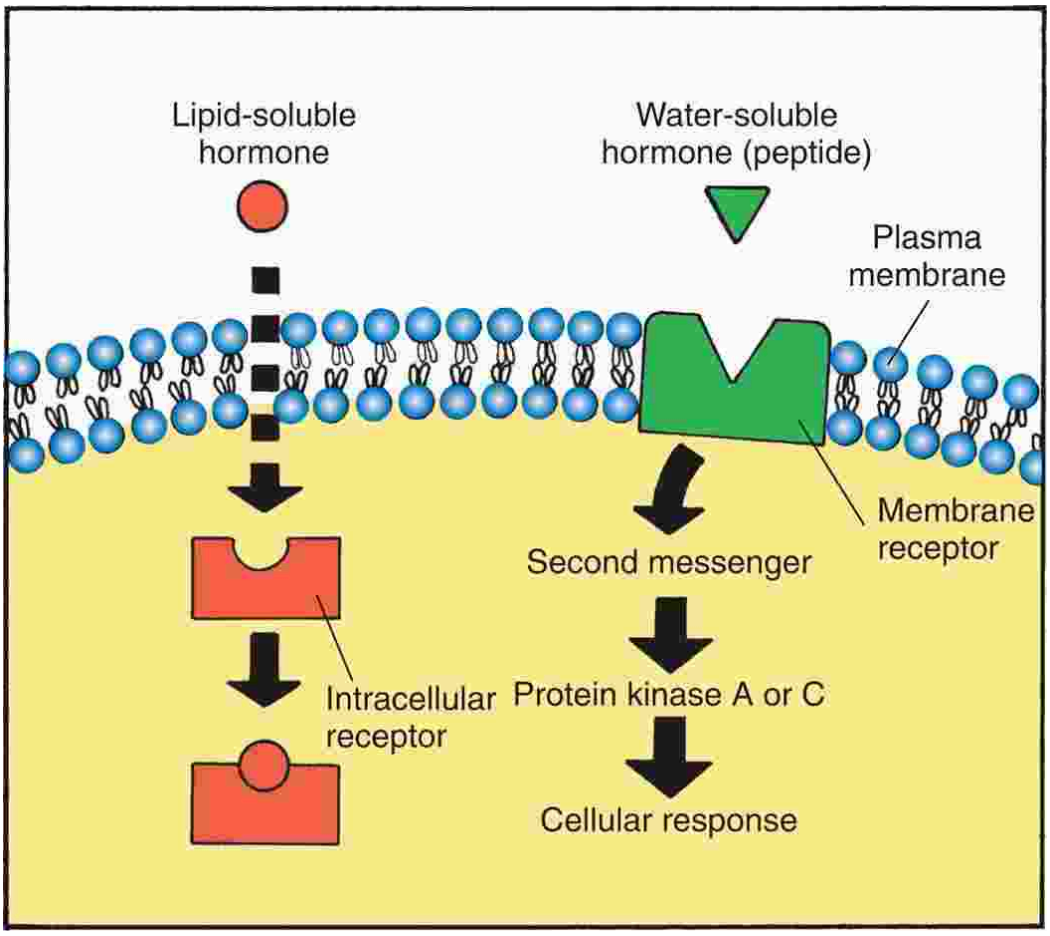

FIG. 21.4 Hormone Binding at Target Cell.

An illustration shows how hormones bind at the target cell. The illustration shows a target cell with a plasma membrane. A lipid-soluble hormone passes through the plasma membrane and attaches itself to the intracellular receptor. A membrane receptor embedded in the plasma membrane attracts a water-soluble hormone (peptide), activating the second messenger. The second messenger releases the protein kinase A or C, generating a cellular response.

Water-Soluble Hormone Receptors

Water-soluble hormone binding with plasma membrane receptors initiates a complex cascade of intracellular effects. In this cascade, the hormone is termed the first messenger. The hormone-receptor interaction initiates a signal that generates a small molecule inside the cell, called the second messenger. The second messenger conveys the signal from the receptor to the cytoplasm and nucleus of the cell and mediates the effect of the hormone on the target cell. Second messengers include cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), calcium, inositol triphosphate (IP_3), and the tyrosine kinase system (Table 21.2).

Table 21.2

Second Messengers Identified for Specific Hormones

Second Messenger	Associated Hormones
Cyclic AMP	Adrenocorticotropic hormone (ACTH) Luteinizing hormone (LH) Human chorionic gonadotropin (hCG) Follicle-stimulating hormone (FSH) Thyroid-stimulating hormone (TSH) Antidiuretic hormone (ADH) Thyrotropin-releasing hormone (TRH) Parathyroid hormone (PTH) Glucagon
Cyclic GMP	Atrial natriuretic peptide
Calcium and IP_3	Angiotensin II Gonadotropin-releasing hormone (GnRH) Antidiuretic hormone (ADH) Luteinizing hormone–releasing hormone (LHRH)

Second Messenger	Associated Hormones
Tyrosine kinases	Insulin Growth hormone Leptin Prolactin

Second Messenger	Associated Hormones
Cyclic AMP	Adrenocorticotropic hormone (ACTH) Luteinizing hormone (LH) Human chorionic gonadotropin (hCG) Follicle-stimulating hormone (FSH) Thyroid-stimulating hormone (TSH) Antidiuretic hormone (ADH) Thyrotropin-releasing hormone (TRH) Parathyroid hormone (PTH) Glucagon
Cyclic GMP	Atrial natriuretic peptide
Calcium and IP_3	Angiotensin II Gonadotropin-releasing hormone (GnRH) Antidiuretic hormone (ADH) Luteinizing hormone–releasing hormone (LHRH)
Tyrosine kinases	Insulin Growth hormone Leptin Prolactin

AMP, Adenosine monophosphate; *GMP*, guanosine monophosphate; *IP_3*, inositol triphosphate.

The second messenger cAMP increases when first messengers from the anterior pituitary gland, such as adrenocorticotropic hormone (ACTH) and TSH, bind to a cell membrane receptor. Increased levels of intracellular cAMP activate protein kinases, leading to activation or deactivation of intracellular enzymes (Fig. 21.5). cGMP also

functions as a second messenger following receptor binding of first messengers (e.g., atrial natriuretic peptide and nitric oxide). These hormones and signaling molecules play crucial roles in cardiovascular and pulmonary health and disease. Drugs, such as phosphodiesterase inhibitors that sustain the action of cGMP are used in the treatment of erectile dysfunction and are being explored for the treatment of vascular and pulmonary hypertension and cognitive dysfunction.[3,4]

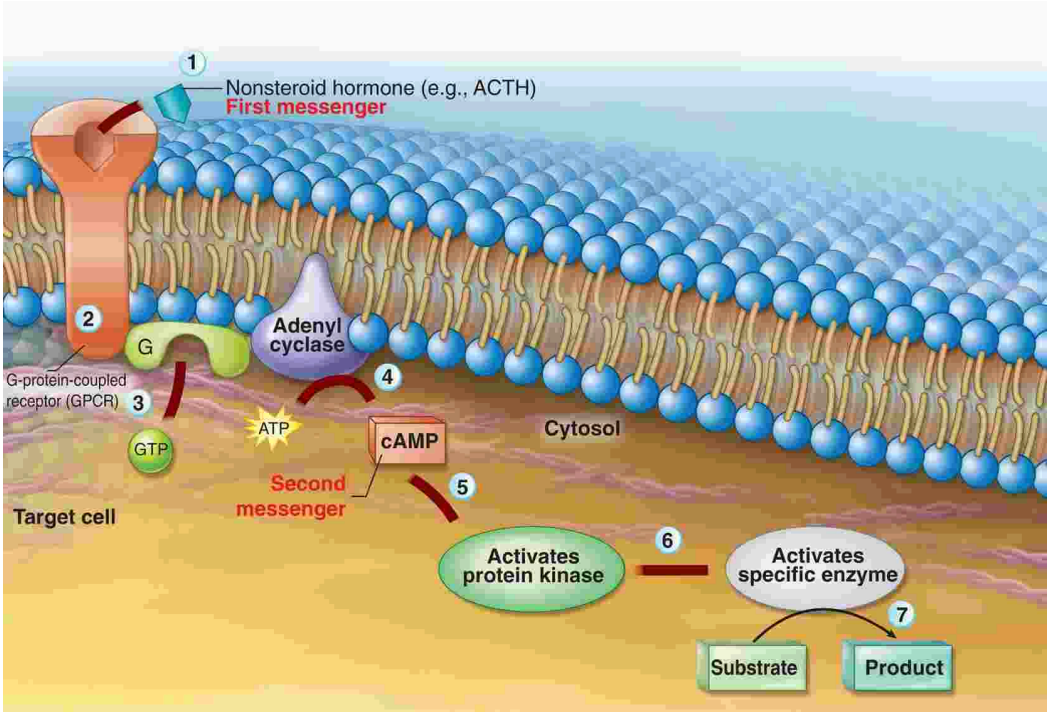

FIG. 21.5 Examples of First- and Second-Messenger Signaling.

A water-soluble (nonsteroid) hormone acts as a first messenger and binds to a fixed receptor of the target cell *(1)*. The hormone-receptor complex activates the G protein *(2)*. The activated G protein *(G)* reacts with guanosine triphosphate *(GTP)*, which in turn activates the membrane-bound enzyme adenylyl cyclase *(3)*. Adenylyl cyclase catalyzes the conversion of adenosine triphosphate *(ATP)* to cyclic adenosine monophosphate (*cAMP;* second messenger) *(4)*. cAMP activates protein kinase *(5)*. Protein kinases activate specific intracellular enzymes *(6)*. These activated enzymes then influence specific cellular reactions and metabolic pathways, thus producing the target cell's response to the hormone *(7)*. *ACTH*, Adrenocorticotropic hormone. (From Patton

KT, Thibodeau GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

The second messenger IP_3 is increased in response to angiotensin II and antidiuretic hormone (ADH) receptor binding and triggers a release of intracellular calcium. This leads to the formation of the calcium-calmodulin complex, which mediates the effects of calcium on intracellular activities that are crucial for cell metabolism, growth, and smooth muscle contraction.

Some hormone first messengers, such as insulin, growth hormone (GH), and prolactin, bind to surface receptors that directly activate second messengers of the tyrosine kinase family. These tyrosine kinases include the Janus family of tyrosine kinases (JAK) and signal transducers and activators of transcription (STAT). They regulate a wide range of intracellular processes that contribute to cellular metabolism, immunity, growth, apoptosis, and oncogenesis. They can be targeted for inhibition in treatments aimed at moderating immune-mediated responses, as in rheumatoid arthritis and cancer.[5,6]

Lipid-Soluble Hormone Receptors

With the exception of thyroid hormones, the lipid-soluble hormones are synthesized from cholesterol (giving rise to the term "steroid") (see Table 21.1). Receptors for lipid-soluble hormones are in the cytosol and nucleus, and directly modulate gene expression without complex second messengers (Fig. 21.6). Because these are relatively small, lipophilic, hydrophobic molecules, lipid-soluble hormones can cross the lipid plasma membrane by simple diffusion (see Chapter 1). They bind with cytosolic or nuclear receptors, which keeps them from diffusing back out of the cell. The effects of lipid-soluble hormones on cytosol and nuclear receptors can take hours to days. However, lipid hormone receptors for estrogen, thyroid hormone, and aldosterone are located in the plasma membrane and are associated with rapid responses (seconds or minutes) (see Fig. 21.6). These receptors, when activated, have primarily intracellular nongenomic (membrane-initiated steroid signaling) effects. Through

crosstalk, nongenomic responses and gene transcription modulate each other, allowing cells to adapt rapidly to environmental changes.[7,8]

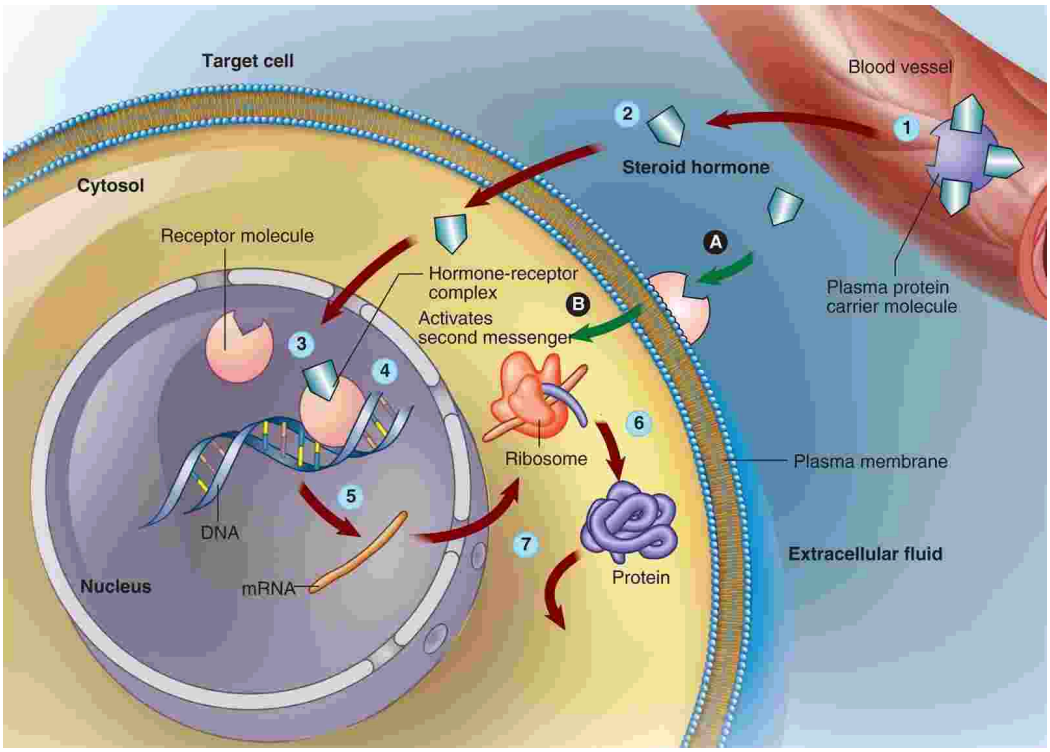

FIG. 21.6 Steroid Hormone Mechanism. Lipid-soluble steroid hormone molecules detach from the carrier protein *(1)* and pass through the plasma membrane *(2)*. Hormone molecules then diffuse into the nucleus, where they bind to a receptor to form a hormone-receptor complex *(3)*. This complex then binds to a specific site on a deoxyribonucleic acid *(DNA)* molecule *(4)*, triggering transcription of the genetic information encoded there *(5)*. The resulting messenger ribonucleic acid *(mRNA)* molecule moves to the cytosol, where it associates with a ribosome, initiating synthesis of a new protein *(6)*. This new protein—usually an enzyme or channel protein—produces specific effects on the target cell *(7)*. The classic genomic action is typically slow *(red arrows)*. Steroids also may exact rapid effects *(green arrows)* by binding to receptors on the plasma membrane *(A)* and activating an intercellular second messenger *(B)*. (From Patton KT,

Thibodeau GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

Hormone Effects

The binding of hormones with their receptors stimulates three general types of effects by:

1. Acting on preexisting channel-forming proteins to alter membrane channel permeability
2. Activating preexisting proteins through a second-messenger system
3. Activating genes to cause protein synthesis (genomic effects)

Hormones affect target cells directly or permissively. Direct effects are the obvious changes in cell function that specifically result from stimulation by a particular hormone. Permissive effects are less obvious hormone-induced changes that facilitate the maximal response or functioning of a cell and require the presence of another hormone. For example, thyroid hormone has a direct effect on lipid metabolism, causing increased concentration of serum fatty acids and a permissive effect on epinephrine by increasing the number of adrenergic receptors.

Structure and Function of the Endocrine Glands

Hypothalamic–Pituitary System

The hypothalamic–pituitary axis (HPA) forms the structural and functional basis for central integration of the neurologic and endocrine systems, creating what is called the *neuroendocrine system*. The HPA produces several hormones that affect a number of diverse body functions (Fig. 21.7), including thyroid, adrenal, and reproductive functions.

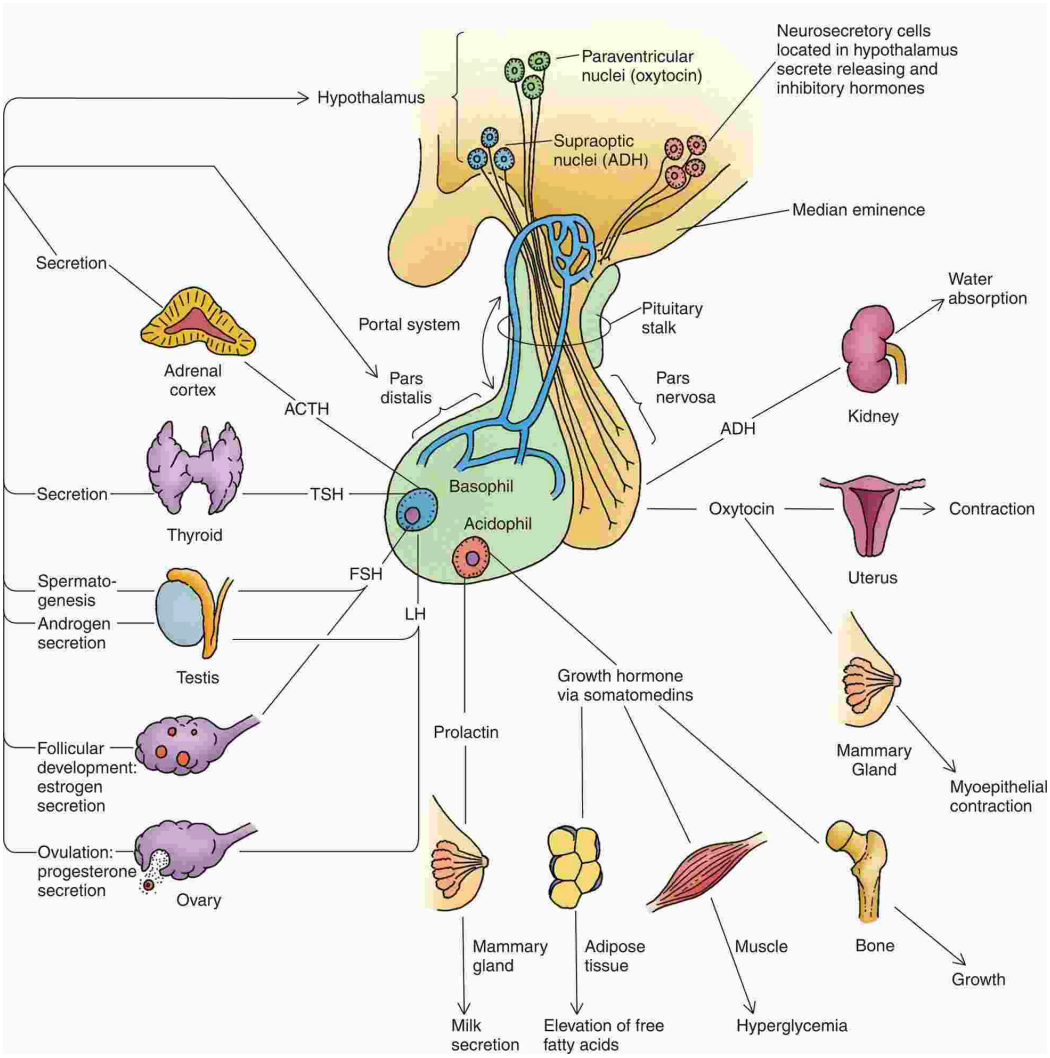

FIG. 21.7 The Hypothalamic-Pituitary Axis and Its Target Organs.
ACTH, Adrenocorticotropic hormone; *ADH*, antidiuretic hormone; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *TSH*, thyroid-stimulating hormone. (From Gartner LP, Hiatt JL. *Color textbook of histology*, 3rd edition. Philadelphia: Saunders; 2007.)

An illustration shows the hypothalamic-pituitary axis and its target organs. The followings structures and their target organs are identified, clockwise from the

top. â€¢ Neurosecretory cells located in hypothalamus secrete releasing and inhibitory hormones. â€¢ Median eminence. â€¢ Pituitary stalk. â€¢ Pars nervosa. â€¢ A D G: kidney (water absorption). â€¢ Oxytocin: uterus (contraction) and mammary gland (myoepithelial contraction). â€¢ Acidophil: growth hormone via somatomedins (adipose tissue, elevation of free fatty acids; muscle, hyperglycemia; bone, growth) and prolactin (mammary gland, milk secretion). â€¢ Basophil. â€¢ Pars distalis. â€¢ Portal system. â€¢ Hypothalamus: paraventricular nuclei (oxytocin) and supraoptic nuclei (A D H). The hormones from basophil (acting on hypothalamus) and their corresponding target organs are as follows. â€¢ L H. Ovulation: progesterone secretion. â€¢ L H and F S H. Testis: spermatogenesis and androgen secretion. â€¢ F S H. Follicular development: estrogen secretion. â€¢ T S H. Thyroid: secretion. â€¢ A C T H. Adrenal cortex: secretion.

Hypothalamus

The hypothalamus is located at the base of the brain. It is connected to the pituitary gland by the infundibulum (pituitary stalk) (Fig. 21.8). The hypothalamus is connected to the anterior pituitary through hypophysial portal blood vessels (Fig. 21.9) and to the posterior pituitary via a nerve tract referred to as the *hypothalamohypophysial tract* (Fig. 21.10). These connections are vital to

the functioning of the hypothalamic–pituitary system. The hypothalamus contains special neurosecretory cells that synthesize and secrete the hypothalamic-releasing hormones that regulate the release of hormones from the anterior pituitary. In addition, these cells synthesize the hormones ADH (also called *vasopressin*) and oxytocin, which are stored and released from the posterior pituitary gland. ADH and oxytocin travel to the posterior pituitary by way of the hypothalamohypophysial nerve tract. Releasing and inhibitory hormones are synthesized in the hypothalamus and are secreted into the portal blood vessels, through which they travel to their target tissues within the anterior pituitary and control the release of tropic hormones. These releasing/inhibitory hormones from the hypothalamus include prolactin-inhibiting hormone (PIH), prolactin-releasing hormone (PRH), TRH, gonadotropin-releasing hormone (GnRH), hypothalamic somatostatin, growth hormone-releasing hormone (GHRH), corticotropin-releasing hormone (CRH), and substance P. These hormones are summarized in Table 21.3.

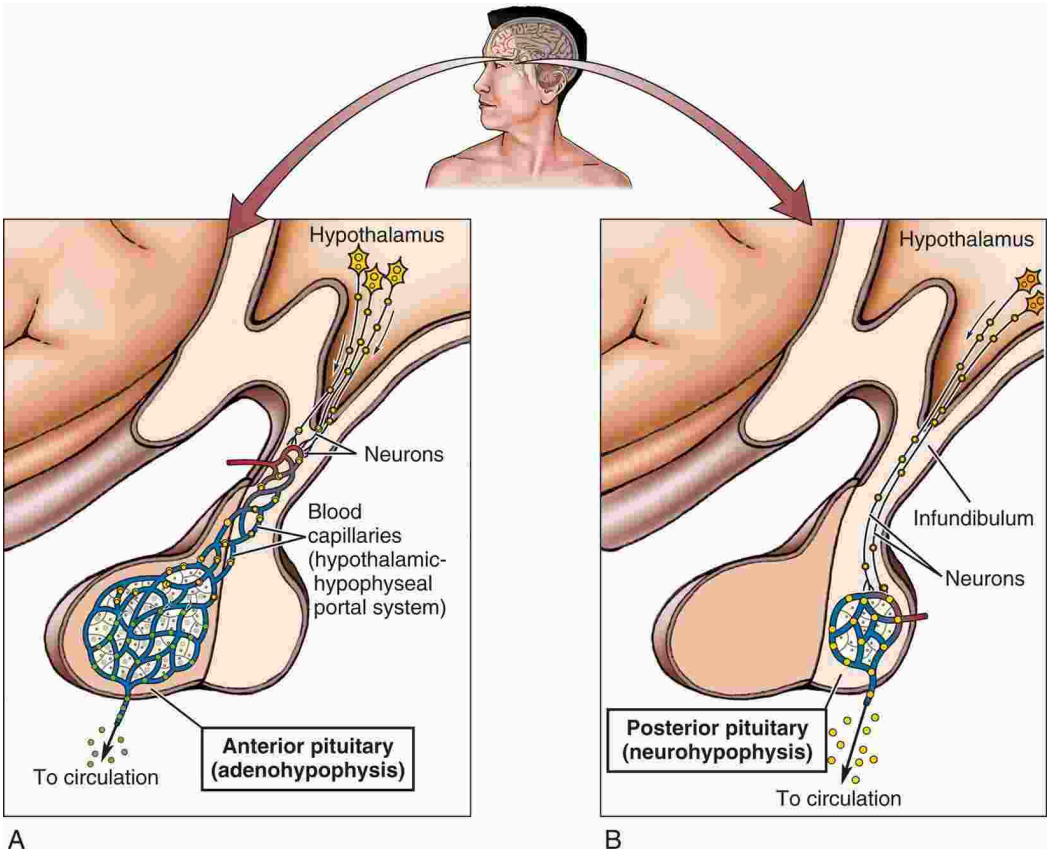

FIG. 21.8 Pituitary Gland.
The pituitary gland sits within the sella turcica of the sphenoid bone of the skull. **(A)** Relationship of the hypothalamus to the anterior pituitary gland. **(B)** Relationship of the hypothalamus to the posterior pituitary gland. (From Herlihy B. *The human body in health and illness*, 5th edition. St. Louis: Saunders; 2015.)

Illustration A shows the anterior pituitary (adenohypophysis) and labels the following structures: hypothalamus, neurons, and blood capillaries (hypothalamic-hypophyseal portal system). The capillaries release neurons into circulation. Illustration B shows the posterior pituitary (neurohypophysis) and labels the following

structures: hypothalamus, infundibulum, and neurons. The capillaries release neurons into circulation.

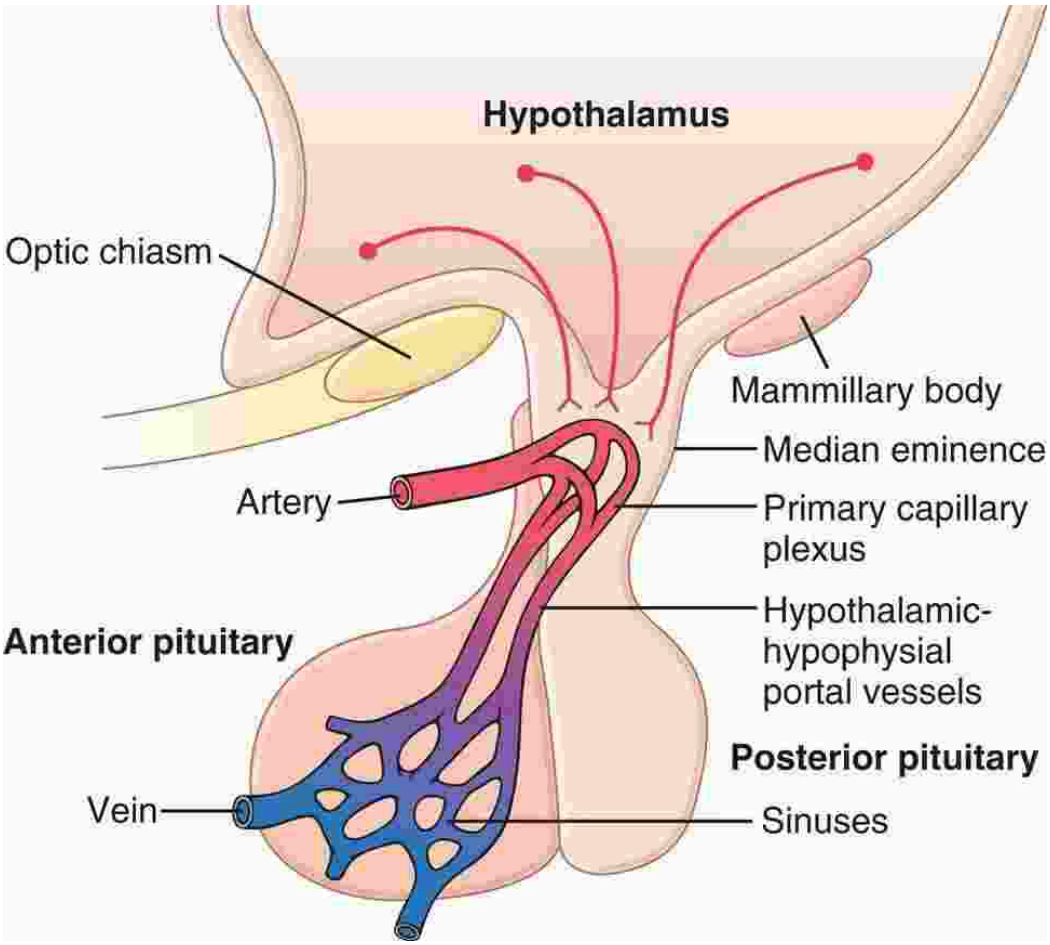

FIG. 21.9 Hypophysial Portal System. (From Hall JE. *Guyton and Hall textbook of medical physiology*, 13th edition. Philadelphia: Saunders; 2016.)

An illustration of the pituitary gland (anterior and posterior) shows and labels the following structures: hypothalamus, mammillary body, median eminence, primary capillary plexus, hypothalamic-hypophysial portal vessels, sinuses, vein, artery, and optic chiasm.

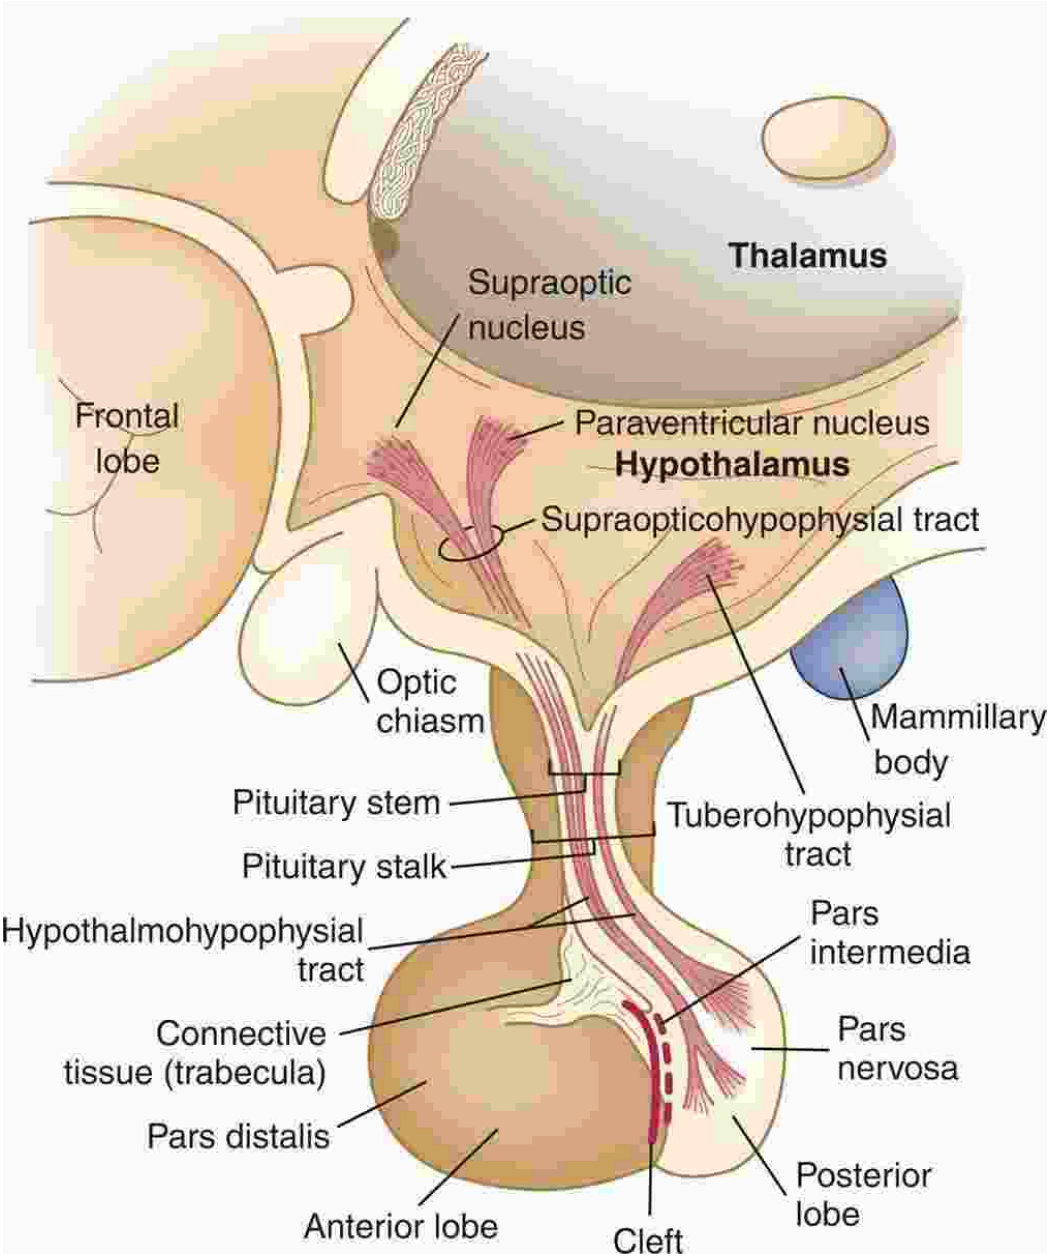

FIG. 21.10 Nerve Tracts from Hypothalamus to Posterior Lobe of Pituitary Gland.

An illustration shows the frontal lobe, thalamus, hypothalamus, and the pituitary gland. The following structures in the illustration are labeled from the top to the bottom: supraoptic nucleus, paraventricular nucleus, supraopticohypophysial tract, optic chiasm,

tuberohypophysial tract, mammillary body, pituitary stem, pituitary stalk, hypothalmohypophysial tract, connective tissue (trabecula), pars distalis, pars intermedia, pars nervosa, posterior lobe, cleft, anterior lobe.

Table 21.3

Hypothalamic Hormones

Hormone	Action
Target the Anterior Pituitary for Release	
Thyrotropin-releasing hormone (TRH)	Stimulates release of thyroid-stimulating hormone (TSH); modulates prolactin secretion
Gonadotropin-releasing hormone (GnRH)	Stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
Somatostatin	Inhibits release of growth hormone (GH) and TSH
Growth hormone–releasing hormone (GHRH)	Stimulates release of GH
Corticotropin-releasing hormone (CRH)	Stimulates release of adrenocorticotropic hormone (ACTH) and β-endorphin
Substance P	Inhibits synthesis and release of adrenocorticotropic hormone (ACTH); stimulates secretion of GH, FSH, LH, and prolactin
Prolactin-inhibiting hormone (PIH, dopamine)	Inhibits synthesis and secretion of prolactin
Prolactin-releasing hormone (PRH)	Stimulates secretion of prolactin
Travel to Posterior Pituitary for Release	

Hormone	Action
Antidiuretic hormone (ADH)	Increases water reabsorption through the renal collecting ducts to reduce plasma osmolarity
Oxytocin	Stimulates contraction of the uterus and milk ejection in lactating women

Hormone	Action
Target the Anterior Pituitary for Release	
Thyrotropin-releasing hormone (TRH)	Stimulates release of thyroid-stimulating hormone (TSH); modulates prolactin secretion
Gonadotropin-releasing hormone (GnRH)	Stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
Somatostatin	Inhibits release of growth hormone (GH) and TSH
Growth hormone–releasing hormone (GHRH)	Stimulates release of GH
Corticotropin-releasing hormone (CRH)	Stimulates release of adrenocorticotropic hormone (ACTH) and β-endorphin
Substance P	Inhibits synthesis and release of adrenocorticotropic hormone (ACTH); stimulates secretion of GH, FSH, LH, and prolactin
Prolactin-inhibiting hormone (PIH, dopamine)	Inhibits synthesis and secretion of prolactin
Prolactin-releasing hormone (PRH)	Stimulates secretion of prolactin
Travel to Posterior Pituitary for Release	
Antidiuretic hormone (ADH)	Increases water reabsorption through the renal collecting ducts to reduce plasma osmolarity
Oxytocin	Stimulates contraction of the uterus and milk ejection in lactating women

Pituitary Gland

The pituitary gland is located in the sella turcica (a saddle-shaped depression of the sphenoid bone at the base of the skull). It weighs approximately 0.5 g, except during pregnancy, when its weight increases by about 30%. It is composed of two distinctly different lobes: (1) the anterior pituitary, or adenohypophysis, and (2) the posterior pituitary, or neurohypophysis (see Fig. 21.8). These two lobes differ in their embryonic origins, cell types, and functional relationship to the hypothalamus.

Anterior Pituitary

The anterior pituitary (adenohypophysis) accounts for 75% of the total weight of the pituitary gland and is composed of three regions: (1) the pars distalis, (2) the pars tuberalis, and (3) the pars intermedia.

The pars distalis is the major component of the anterior pituitary and is the source of the anterior pituitary hormones. The pars tuberalis is a thin layer of cells on the anterior and lateral portions of the pituitary stalk. The pars intermedia lies between the two and secretes melanocyte-stimulating hormone in the fetus. In the adult, the distinct pars intermedia disappears, and the individual cells are distributed diffusely throughout the pars distalis and pars nervosa (neural lobe) of the posterior pituitary.

The anterior pituitary is composed of two main cell types: (1) the chromophobes, which appear to be nonsecretory, and (2) the chromophils, which are the secretory cells of the adenohypophysis. The chromophils are subdivided into seven secretory cell types, and each cell type secretes a specific hormone or hormones. In general, the anterior pituitary hormones are regulated by (1) secretion of hypothalamic releasing factors, (2) feedback effects of the hormones secreted by target glands, and (3) direct effects of other mediating neurotransmitters.

The anterior pituitary secretes tropic hormones that affect the physiologic function of specific target organs (see Fig. 21.7). These hormones can be grouped into three categories: corticotropin-related hormones, glycoproteins, and somatotropins (Table 21.4). Corticotropin-related hormones include melanocyte-stimulating hormone (MSH), which promotes the pituitary secretion of melanin to darken skin color, and adrenocorticotropic hormone (ACTH), which regulates the release of cortisol from the adrenal cortex. Also included in the corticotropic hormones are β-lipotropin, which plays a role in fat catabolism, and β-endorphins, which impact pain perception, body temperature, and food and water intake.

Table 21.4

Tropic Hormones of the Anterior Pituitary and Their Functions

Hormone	Target Organs	Functions
Corticotropin-Related Hormones		
Adrenocorticotropic hormone (ACTH)	Adrenal gland (cortex)	Increased steroidogenesis (cortisol and androgenic hormones); synthesis of adrenal proteins contributing to maintenance of adrenal gland
Melanocyte-stimulating hormone (MSH)	Anterior pituitary	Promotes secretion of melanin and lipotropin by anterior pituitary; makes skin darker
Somatotropic Hormones		
Growth hormone (GH)	Muscle, bone, liver	Regulates metabolic processes related to growth and adaptation to physical and emotional stressors, muscle growth, increased protein synthesis, increased liver glycogenolysis, increased fat mobilization
	Liver	Induces formation of somatomedins, or insulin-like growth

Hormone	Target Organs	Functions
		factors (IGFs) that have actions similar to insulin
Prolactin	Breast	Milk production
Glycoprotein Hormones		
Thyroid-stimulating hormone (TSH)	Thyroid gland	Increased production and secretion of thyroid hormoneIncreased iodide uptake; promotes hypertrophy and hyperplasia of thymocytes
Luteinizing hormone (LH)	*In women:* granulosa cells *In men:* Leydig cells	Ovulation, progesterone production Testicular growth, testosterone production
Follicle-stimulating hormone (FSH)	*In women:* granulosa cells *In men:* Sertoli cells	Follicle maturation, estrogen production Spermatogenesis
β-Lipotropin	Adipose cells	Fat breakdown and release of fatty acids
β-Endorphins	Adipose cells; brain	Analgesia; may regulate body temperature, food

Hormone	Target Organs	Functions
	opioid receptors	and water intake

Hormone	Target Organs	Functions
Corticotropin-Related Hormones		
Adrenocorticotropic hormone (ACTH)	Adrenal gland (cortex)	Increased steroidogenesis (cortisol and androgenic hormones); synthesis of adrenal proteins contributing to maintenance of adrenal gland
Melanocyte-stimulating hormone (MSH)	Anterior pituitary	Promotes secretion of melanin and lipotropin by anterior pituitary; makes skin darker
Somatotropic Hormones		
Growth hormone (GH)	Muscle, bone, liver	Regulates metabolic processes related to growth and adaptation to physical and emotional stressors, muscle growth, increased protein synthesis, increased liver glycogenolysis, increased fat mobilization
	Liver	Induces formation of somatomedins, or insulin-like growth factors (IGFs) that have actions similar to insulin
Prolactin	Breast	Milk production
Glycoprotein Hormones		
Thyroid-stimulating hormone (TSH)	Thyroid gland	Increased production and secretion of thyroid hormoneIncreased iodide uptake; promotes hypertrophy and hyperplasia of thymocytes
Luteinizing hormone (LH)	*In women:* granulosa cells *In men:* Leydig cells	Ovulation, progesterone production Testicular growth, testosterone production
Follicle-stimulating hormone (FSH)	*In women:* granulosa cells *In men:* Sertoli cells	Follicle maturation, estrogen production Spermatogenesis
β-Lipotropin	Adipose cells	Fat breakdown and release of fatty acids
β-Endorphins	Adipose cells; brain opioid receptors	Analgesia; may regulate body temperature, food and water intake

The glycoprotein hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) influence reproductive function and are discussed in Chapter 24. Thyroid-stimulating hormone (TSH), also a glycoprotein hormone, regulates the activity of the thyroid gland. The roles of ACTH and TSH are discussed later in this chapter.

The somatotropic hormones have diverse effects on body tissues and include GH and prolactin. Growth hormone secretion is controlled by two hormones from the hypothalamus: GHRH, which increases GH secretion; and somatostatin, which inhibits GH secretion. GH is essential to normal tissue growth and maturation and also impacts aging, sleep, nutritional status, stress, and

reproductive hormones. In the bone, GH stimulates epiphyseal growth and increases osteoclast and osteoblast activity, resulting in increased bone mass. GH also increases amino acid transport in muscles. Other functions of GH include lipolysis and enhancement of hepatic protein synthesis.

Many of the anabolic functions of GH are mediated, at least in part, by the insulin-like growth factors (IGFs), also known as the *somatomedins*. There are two primary forms of IGF, IGF-1 and IGF-2, of which IGF-1 is the most biologically active. They both circulate bound to a group of IGF-binding proteins (IGFBPs) modulating their availability. IGF-1 binds to IGF-1 receptors, mediating the anabolic effects of GH. IGF-1 also binds to insulin receptors, providing an insulin-like effect on skeletal muscle. IGF-2 has important effects on fetal growth but suppresses GH in the adult. Because of the anabolic effects of GH and IGF-1, they can be used to treat growth disorders, increase muscle mass, and potentially slow the aging process; however, there are concerns about their safety, with potential links to increased rates of cancer.[9]

Prolactin primarily functions to induce milk production during pregnancy and lactation. It has immune stimulatory effects and modulates immune and inflammatory responses with both physiologic and pathologic reactions. Its synthesis and release are increased by stimulation of the nipples and mammary gland during nursing. Vasoactive intestinal polypeptide, serotonin, and growth factors also stimulate the synthesis of prolactin. Release of prolactin is inhibited by dopamine.

Posterior Pituitary

The embryonic posterior pituitary (neurohypophysis) is derived from the hypothalamus and is comprised of three parts: (1) the median eminence, located at the base of the hypothalamus; (2) the pituitary stalk; and (3) the infundibular process, also known as the *pars nervosa* or *neural lobe*. The median eminence is composed largely of the nerve endings of axons from the ventral hypothalamus. It often is designated as part of the posterior pituitary and contains at least 10 biologically active hypothalamic releasing hormones, as well as the

neurotransmitters dopamine, norepinephrine, serotonin, acetylcholine, and histamine. The pituitary stalk contains the axons of neurons that originate in the supraoptic and paraventricular nuclei of the hypothalamus and connects the pituitary gland to the brain. Axons originating in the hypothalamus terminate in the pars nervosa, which secretes the hormones of the posterior pituitary (see Fig. 21.10).

The posterior pituitary secretes two polypeptide hormones: (1) ADH, also called *arginine vasopressin*; and (2) oxytocin. These hormones differ by only two amino acids. They are synthesized—along with their binding proteins, the neurophysins—in the supraoptic and paraventricular nuclei of the hypothalamus (see Fig. 21.10). They are packaged in secretory vesicles and are moved down the axons of the pituitary stalk to the pars nervosa for storage. The posterior pituitary thus can be seen as a site for both storing and releasing hormones synthesized in the hypothalamus. The release of ADH and oxytocin is mediated by cholinergic and adrenergic neurotransmitters. The major stimulus to both ADH and oxytocin release is glutamate, whereas the major inhibitory input is through gamma-aminobutyric acid (GABA). Before release into the circulatory system, ADH and oxytocin are split from the neurophysins and are secreted in unbound form.

Antidiuretic hormone

The major homeostatic function of the posterior pituitary is the control of plasma osmolality as regulated by antidiuretic hormone (ADH) (see Chapter 3). At physiologic levels, ADH increases the permeability of the distal renal tubules and collecting ducts (see Chapter 37). This increased permeability leads to increased water reabsorption into the blood, thus concentrating the urine and reducing serum osmolality. These effects may be inhibited by hypercalcemia, prostaglandin E, and hypokalemia.

The secretion of ADH is regulated primarily by the osmoreceptors of the hypothalamus, located near or in the supraoptic nuclei. As plasma osmolality increases, these osmoreceptors are stimulated, the rate of ADH secretion increases, thirst is stimulated (which increases

water intake), and more water is reabsorbed by the kidney. This causes the plasma to become diluted back to its set-point osmolality. ADH has no direct effect on electrolyte levels, but by increasing water reabsorption, serum electrolyte concentrations may decrease because of a dilutional effect.[2]

ADH secretion also is stimulated by decreased intravascular volume, as monitored by baroreceptors in the left atrium, in the carotid arteries, and in the aortic arches. A volume loss of 7% to 25% acts through these receptors to stimulate ADH secretion. Stress, trauma, pain, exercise, nausea, nicotine, exposure to heat, and drugs, such as morphine, also increase ADH secretion. ADH secretion decreases with decreased plasma osmolality, increased intravascular volume, hypertension, alcohol ingestion, and an increase in estrogen, progesterone, or angiotensin II levels.

Physiologic levels of ADH do not significantly impact vessel tone. However, ADH was originally named *vasopressin* because, at extremely high levels, it causes vasoconstriction and a resulting increase in arterial blood pressure. For example, high doses of ADH (given as the drug vasopressin) may be administered to achieve hemostasis during hemorrhage and to raise blood pressure in shock states.

Oxytocin

Oxytocin is responsible for contraction of the uterus and milk ejection in lactating women and may affect sperm motility in men. In both genders, oxytocin has an antidiuretic effect similar to that of ADH. In women, oxytocin is secreted in response to suckling and mechanical distention of the female reproductive tract. Oxytocin binds to its receptors on myoepithelial cells in the mammary tissues and causes contraction of those cells, which increases intramammary pressure and milk expression ("let-down" reflex). Oxytocin acts on the uterus near the end of labor to enhance the effectiveness of contractions, promote delivery of the placenta, and stimulate postpartum uterine contractions, thereby preventing excessive bleeding. The function of this hormone is discussed in detail in Chapter 24.

Pineal Gland

The pineal gland is located near the center of the brain (see Fig. 21.1) and is composed of photoreceptive cells that secrete melatonin. It is innervated by noradrenergic sympathetic nerve terminals controlled by pathways within the hypothalamus. Melatonin release is stimulated by exposure to dark and inhibited by light exposure. It is synthesized from tryptophan, which is first converted to serotonin and then to melatonin. Melatonin regulates circadian rhythms and reproductive systems, including the secretion of the GnRHs and the onset of puberty. It also plays an important role in immune regulation and is postulated to impact the aging process. Further effects of melatonin include increasing nitric oxide release from blood vessels, removing toxic oxygen free radicals, and decreasing insulin secretion. Melatonin has been used therapeutically in humans to help with sleep disturbances, jet lag, and psychological and inflammatory disorders. Its utility for numerous other disorders is being explored.

Thyroid and Parathyroid Glands

The thyroid gland, located in the neck just below the larynx, produces hormones that control the rates of metabolic processes throughout the body. The four parathyroid glands are near the posterior side of the thyroid and function to control serum calcium levels (Fig. 21.11).

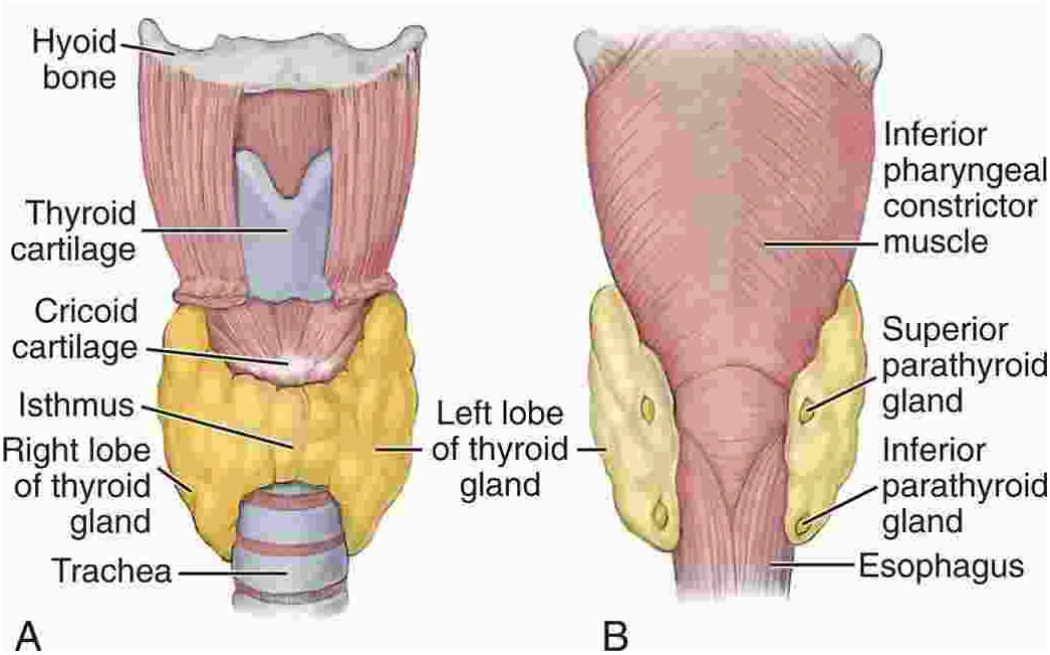

FIG. 21.11 Thyroid and Parathyroid Glands. **(A)** Anterior view. **(B)** Posterior view. (From Fehrenbach MJ, Herring SW. *Illustrated anatomy of the head and neck*, 4th edition. St. Louis: Saunders; 2012.)

Illustration A is the anterior view of the thyroid and parathyroid glands. The following structures are labeled from the top to the bottom: hyoid bone, thyroid cartilage, cricoid cartilage, isthmus, right lobe of thyroid gland, left lobe of thyroid gland, and trachea. Illustration B is the posterior view of the thyroid and parathyroid glands. The following structures are labeled from the top to the bottom: inferior pharyngeal constrictor muscle, superior parathyroid gland, inferior parathyroid gland, and esophagus.

Thyroid Gland

Two lobes of the thyroid gland lie on either side of the trachea, inferior to the thyroid cartilage and joined by a small band of tissue termed the isthmus (see Fig. 21.11). The pyramidal lobe is superior to the isthmus. The normal thyroid gland is not visible on inspection, but it may be palpated on swallowing, which causes it to be displaced upward.

The thyroid gland consists of follicles that contain follicular cells surrounding a viscous substance called *colloid* (Fig. 21.12). The follicular cells synthesize and secrete the thyroid hormones. Neurons terminate on blood vessels within the thyroid gland and on the follicular cells themselves, so neurotransmitters (acetylcholine, catecholamines) may directly affect the secretory activity of follicular cells and thyroid blood flow. Approximately a 2-month supply of thyroid hormone is stored in the gland.

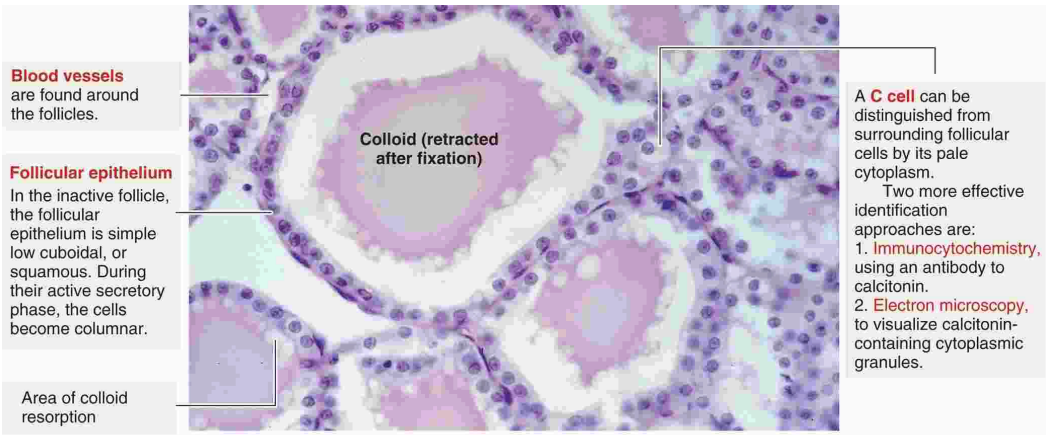

FIG. 21.12 Thyroid Follicle Cells.

A photomicrograph of thyroid follicle cells. The colloid (retracted after fixation) is labeled. Other structures labeled and described are as follows. â€¢ Blood vessels are found around the follicles. â€¢ Follicular epithelium. In the inactive follicle, the follicular epithelium is simple low cuboidal, or squamous. During their active secretory phase, the cells become columnar. â€¢ Area of colloid resorption. â€¢ A C cell can be distinguished from surrounding follicular cells by its pale cytoplasm. Two more effective identification approaches are: 1. Immunocytochemistry, using an antibody to calcitonin. 2. Electron microscopy, to visualize calcitonin-containing cytoplasmic granules.

Also found in the thyroid are parafollicular cells, or C cells (see Fig. 21.12). C cells secrete various regulatory peptides, including calcitonin and, in much smaller quantities, the neuropeptides ghrelin, serotonin, and somatostatin. At high levels, calcitonin, also called *thyrocalcitonin*, lowers serum calcium levels by inhibiting bone-

resorbing osteoclasts. However, in humans the metabolic consequences of calcitonin deficiency or excess do not appear to be significant. (Bone resorption is explained in Chapter 43). Calcitonin can be used therapeutically to treat a number of bone disorders, including osteogenesis imperfecta, osteoporosis, osteoarthritis, hypercalcemia, Paget bone disease, and metastatic cancer of the bone. The precursor molecule to calcitonin, called *procalcitonin*, is a stress hormone that is elevated in infectious and inflammatory disorders, and its measurement can aid in the diagnosis of these serious diseases.[10,11]

Regulation of thyroid hormone secretion

Thyroid hormone (TH) is regulated through a negative-feedback loop involving the hypothalamus, the anterior pituitary, and the thyroid gland (see Fig. 21.2A). This loop is initiated by thyrotropin-releasing hormone (TRH), which is synthesized and stored within the hypothalamus. TRH is released into the hypothalamic-pituitary portal system and circulates to the anterior pituitary, where it stimulates the release of TSH. TRH levels increase with exposure to cold or stress and from decreased levels of T_4.

Thyroid-stimulating hormone (TSH) is a glycoprotein synthesized and stored within the anterior pituitary. When TSH is secreted by the anterior pituitary, it circulates to bind with TSH receptors on the plasma membrane of the thyroid follicular cells. The primary effects of TSH on the thyroid gland include (1) an immediate increase in the release of stored thyroid hormones, (2) an increase in iodide uptake and oxidation, (3) an increase in thyroid hormone synthesis, and (4) an increase in the synthesis and secretion of prostaglandins by the thyroid. TSH also increases growth of the thyroid gland by stimulating thymocyte hyperplasia and hypertrophy and decreasing apoptosis. As TH levels rise, there is a negative-feedback effect on the HPA to inhibit TRH and TSH release, which then results in decreased TH synthesis and secretion. TH synthesis is also controlled by serum iodide levels and by circulating selenium-dependent enzymes, called *deiodinases*, which inactivate the precursor molecule thyroxine.

Thyroid gland hormones and their regulation and function are summarized in Table 21.5.

Table 21.5

Thyroid Gland Hormones and Their Regulation and Functions

Hormone	Regulation	Functions
Thyroxine (T_4) and triiodothyronine (T_3)	Levels are controlled by TSH Released in response to metabolic demand Influences on amount secreted: Sex Pregnancy Gonadal and adrenocortical-increased steroids = ↑ levels Exposure to extreme cold = ↑ levels Nutritional state Chemicals	Regulates protein, fat, and carbohydrate catabolism in all cells Regulates metabolic rate of all cells Regulates body heat production Insulin antagonist Maintains growth hormone secretion, skeletal maturation Affects CNS development Necessary for muscle tone and vigor Maintains cardiac rate, force, and output Maintains secretion of GI tract Affects respiratory rate and oxygen

Hormone	Regulation	Functions
	GHIH = ↓ levels Dopamine = ↓ levels Catecholamines = ↑ levels	utilization Maintains calcium mobilization Affects RBC production Stimulates lipid turnover, free fatty acid release, and cholesterol synthesis
Calcitonin	Elevated serum calcium—major stimulant for calcitonin Other stimulants Gastrin Calcium-rich foods (regardless of serum Ca^{++} levels) Pregnancy Lowered serum calcium—suppresses	Lowers serum calcium by opposing bone-resorbing effects of PTH, prostaglandins, and calciferols by inhibiting osteoclastic activity Lowers serum phosphate levels May also decrease calcium and phosphorus absorption in GI tract

Hormone	Regulation	Functions
	calcitonin release	

Hormone	Regulation	Functions
Thyroxine (T_4) and triiodothyronine (T_3)	Levels are controlled by TSH Released in response to metabolic demand Influences on amount secreted: Sex Pregnancy Gonadal and adrenocortical-increased steroids = ↑ levels Exposure to extreme cold = ↑ levels Nutritional state Chemicals GHIH = ↓ levels Dopamine = ↓ levels Catecholamines = ↑ levels	Regulates protein, fat, and carbohydrate catabolism in all cells Regulates metabolic rate of all cells Regulates body heat production Insulin antagonist Maintains growth hormone secretion, skeletal maturation Affects CNS development Necessary for muscle tone and vigor Maintains cardiac rate, force, and output Maintains secretion of GI tract Affects respiratory rate and oxygen utilization Maintains calcium mobilization Affects RBC production Stimulates lipid turnover, free fatty acid release, and cholesterol synthesis
Calcitonin	Elevated serum calcium—major stimulant for calcitonin Other stimulants Gastrin Calcium-rich foods (regardless of serum Ca^{++} levels) Pregnancy Lowered serum calcium—suppresses calcitonin release	Lowers serum calcium by opposing bone-resorbing effects of PTH, prostaglandins, and calciferols by inhibiting osteoclastic activity Lowers serum phosphate levels May also decrease calcium and phosphorus absorption in GI tract

CNS, Central nervous system; *GHIH*, growth hormone–inhibiting hormone; *GI*, gastrointestinal; *PTH*, parathyroid hormone; *RBC*, red blood cell; *TSH*, thyroid-stimulating hormone.

From Monahan FD, Sands JK, Neighbors M, et al. *Phipps' medical-surgical nursing: Health and illness perspectives*, 8th edition. St. Louis: Mosby; 2007.

Synthesis of thyroid hormone

Thyroid hormone synthesis is summarized in these steps:

1. Uniodinated thyroglobulin (a large glycoprotein) is produced by the endoplasmic reticulum of the thyroid follicular cells.
2. Tyrosine (an amino acid) is incorporated into the thyroglobulin of follicular cells as it is synthesized.
3. Iodide (the inorganic form of iodine) is actively transferred from the blood into the colloid by carrier proteins located in the outer membrane of the follicular cells. This active transport system is called the *iodide trap* and is very efficient at accumulating the trace amounts of iodide from the blood.
4. Iodide is oxidized and quickly attaches to tyrosine within the thyroglobulin molecule.
5. Coupling of iodinated tyrosine forms thyroid hormones. Triiodothyronine (T_3) is formed from the coupling of monoiodotyrosine (one iodine atom and tyrosine) and diiodotyrosine (two iodine atoms and tyrosine). Tetraiodothyronine (T_4), commonly known as thyroxine, is formed from the coupling of two diiodotyrosines.
6. Thyroid hormones are stored attached to thyroglobulin within the colloid until they are released into the circulation.

The thyroid gland normally produces 90% T_4 and 10% T_3. Once released into the circulation, T_3 and T_4 are primarily transported bound to thyroxine-binding globulin (TBG), though some TH is transported by thyroxine-binding prealbumin (transthyretin), albumin, or lipoproteins. The bound form serves as a reservoir, whereas the unbound (free) form is active. In the body tissues, most of the T_4 is converted to T_3, which acts on the target cell.

Actions of thyroid hormone

TH has a significant effect on the growth, maturation, and function of cells and tissues throughout the body. TH binds to intracellular receptor complexes and then influences the genetic expression of specific proteins. TH is essential for normal growth and neurologic development in the fetus and infant and affects metabolic, neurologic, cardiovascular, and respiratory functioning across the life

span. In addition, TH is required for the metabolism and function of blood cells, normal muscle functioning, the integrity of skin, nails, and hair, and for normal skeletal growth and maintenance of bone mass. Similar to some steroid hormones, TH also affects cell metabolism by altering protein, fat, and glucose metabolism and, as a result, increasing heat production and oxygen consumption.

TH has permissive effects throughout the body, optimizing the actions of other hormones and neurotransmitters. These effects can become very pronounced when there are either high or low levels of circulating thyroid hormones. For example, in the heart, T_3 stimulates the synthesis of specific contractile proteins, sarcolemmal ion pumps, and membrane receptors. Therefore, in hyperthyroidism, which is associated with elevated levels of thyroid hormones, cardiac effects include increased heart rate and cardiac output, as well as the development of cardiomyopathy. Thyroid hormones also affect the respiratory center, contributing to the normal hypoxic and hypercapnic drives. In severe hypothyroidism, ventilation can become very depressed. Thyroid hormone also plays a role in metabolic disorders and liver disease (see Emerging Science Box: Thyromimetics and Liver Disease). Hypothyroidism is also associated with impaired bone formation, and hyperthyroidism is associated with osteoporosis, hypercalcemia, and hypercalciuria.

Parathyroid Glands

Normally, two pairs of small parathyroid glands are present behind the upper and lower poles of the thyroid gland (see Fig. 21.11). However, their number may range from two to six. The parathyroid glands produce parathyroid hormone (PTH), which is the single most important factor in the regulation of the serum calcium concentration. The overall effect of PTH secretion is to increase serum calcium concentration and decrease the concentration of serum phosphate. A decrease in serum-ionized calcium level stimulates PTH secretion. On release, PTH enters the circulation in unbound form and attaches to plasma membrane receptors in target tissues. To achieve regulation of serum calcium concentration, PTH acts directly on bone with at least two effects. In acute hypocalcemia, PTH

secretion stimulates osteoblasts to release factors that cause osteoclast proliferation, maturation, and release of acidic enzymes, such as cathepsin. These enzymes mobilize calcium release from bone (bone resorption), which increases the serum calcium level (Fig. 21.13). There is bone remodeling with chronic stimulation by PTH, a process in which bone is broken down and re-formed. Paradoxically, when PTH is administered intermittently and at a low dose, it stimulates bone formation. This observation led to the use of synthetic PTH for treatment of osteoporosis.[12]

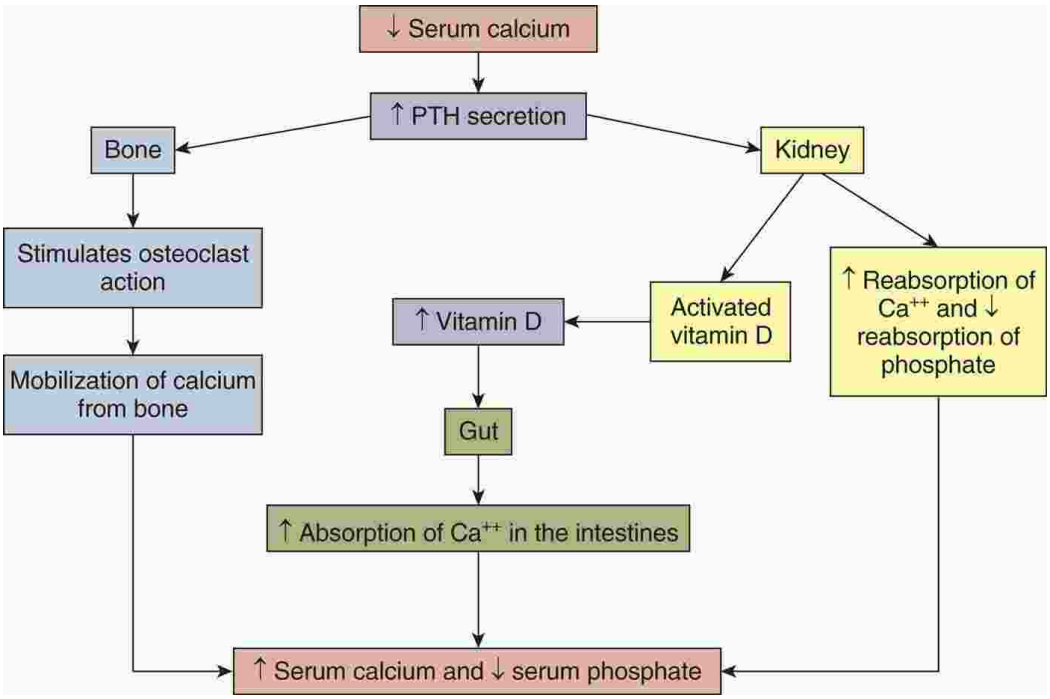

FIG. 21.13 The Role of Parathyroid Hormone *(PTH)* and Vitamin D in Calcium Metabolism.

A flowchart shows the role of parathyroid hormone and vitamin D in calcium metabolism. â€¢ Decreased serum calcium leads to increased P T H secretion. â€¢ Increased P T H secretion affects bone and kidney. â€¢ Bone stimulates osteoclast action leading to mobilization of calcium from bone. â€¢ Kidney activates vitamin D leading to increased vitamin D, affecting the gut, which leads to increased absorption of calcium ions in the intestines. â€¢ Kidney increases reabsorption of calcium ions and decreases reabsorption of phosphate. Mobilization of calcium from bone, increased absorption of calcium ions in the intestines, and increased reabsorption of calcium ions and decreased reabsorption of phosphate leads

to increased serum calcium and decreased serum phosphate.

PTH also acts on the kidney to increase calcium reabsorption in the distal tubules of the nephron while phosphate and bicarbonate reabsorption are decreased in the proximal tubules. The resultant increase in the serum calcium concentration inhibits PTH secretion. 1,25-Dihydroxy-vitamin D3 (the active form of vitamin D) is activated by the kidney and works as a cofactor with PTH to promote calcium and phosphate absorption in the gut and enhance bone mineralization. Vitamin D also plays an important role in metabolic processes and controlling inflammation. It has been found to be deficient in the majority of individuals in the United States (see Emerging Science Box: Vitamin D Deficiency).

Phosphate and magnesium concentrations also affect PTH secretion. An increase in the serum phosphate level decreases the serum calcium level by causing calcium-phosphate precipitation into soft tissue and bone, which indirectly stimulates PTH secretion. Hypomagnesemia in persons with normal calcium levels acts as a mild stimulant to PTH secretion; however, in persons with hypocalcemia, hypomagnesemia decreases PTH secretion.

Another hormone that plays an important role in calcium and bone physiology is parathyroid hormone–related protein (PTHrP). This hormone is synthesized in many adult and fetal tissues and affects tissues around it in a paracrine fashion with multiple metabolic effects. It has similar biologic properties to PTH and uses the same receptors but has other actions mediated by different regions within the molecule. It is important for endochondral bone formation and bone remodeling.[13]

Endocrine Pancreas

The pancreas is both an endocrine gland that produces hormones and an exocrine gland that produces digestive enzymes. (The exocrine function of the pancreas is discussed in Chapter 40.) The pancreas is

located behind the stomach, between the spleen and the duodenum (Fig. 21.14). The pancreas houses pancreatic islets (islets of Langerhans), which are small islands of hormone-producing cells. The islets of Langerhans have four types of hormone-secreting cells: alpha cells, which secrete glucagon; beta cells, which secrete insulin and amylin; delta cells, which secrete gastrin and somatostatin; and F (or PP) cells, which secrete pancreatic polypeptide. These hormones regulate carbohydrate, fat, and protein metabolism. (The pancreas is illustrated in Fig. 21.14.) Nerves from both the sympathetic and the parasympathetic divisions of the autonomic nervous system innervate the pancreatic islets.

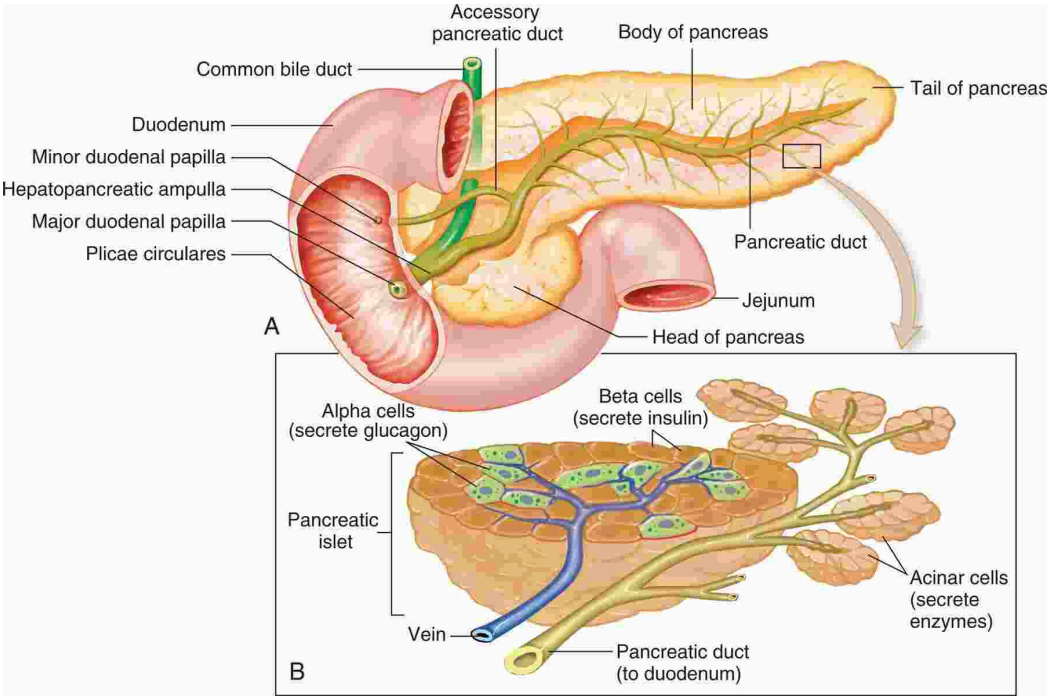

FIG. 21.14 The Pancreas.
(A) Pancreas dissected to show main and accessory ducts. The main duct may join the common bile duct, as shown here, to enter the duodenum by a single opening at the major duodenal papilla, or the two ducts may have separate openings. The accessory pancreatic duct is usually present and has a separate opening into the duodenum. **(B)** Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic juice, alpha endocrine cells secrete glucagon, and beta cells secrete insulin.
(From Patton KT, Thibodeau GA. *Structure & function of the body*, 15th edition. St. Louis: Mosby; 2016.)

Illustration A is a cross-section of the pancreas. The following structures on the illustration are labeled clockwise from the left: plicae circulares, major

duodenal papilla, hepatopancreatic ampulla, minor duodenal papilla, duodenum, common bile duct, accessory pancreatic duct, body of pancreas, tail of pancreas, pancreatic duct, jejunum, and head of pancreas. Illustration B is a cross-section of the head of pancreas. The following structures are labeled: â€¢ Alpha cells (secrete glucagon). â€¢ Beta cells (secrete insulin). â€¢ Acinar cells (secrete enzymes). â€¢ Pancreatic duct (to duodenum). â€¢ Vein. â€¢ Pancreatic islet.

The perfusion of the anterior lobe of the pancreas, where alpha, beta, and delta cells are most numerous, comes from branches of the superior mesenteric artery. The posterior lobe is perfused by branches of the celiac artery. The pancreatic islets receive 10% of the pancreatic blood flow but represent only 1% of pancreatic mass. This is necessary for oxygenation and delivery of islet hormones to target cells.

Insulin

The beta cells of the pancreas synthesize insulin from the precursor proinsulin, which is formed from a larger precursor molecule, preproinsulin. Proinsulin is composed of A peptide and B peptide, which are connected by a C peptide and two disulfide bonds. C peptide is cleaved by proteolytic enzymes, leaving the bonded A and B peptides as the insulin molecule. Insulin circulates freely in the plasma and is not bound to a carrier. C peptide level can be measured in the blood and used as an indirect measurement of serum insulin synthesis.

Secretion of insulin is regulated by chemical, hormonal, and neural control. The primary stimulus for insulin secretion is an increase in blood levels of glucose. Insulin secretion also is stimulated by the

parasympathetic nervous system, usually before eating a meal. Other factors stimulating insulin secretion include some amino acids (leucine, arginine, and lysine) and gastrointestinal hormones (glucagon, gastrin, cholecystokinin, secretin). Insulin secretion diminishes in response to low blood levels of glucose (hypoglycemia), high levels of insulin (through negative feedback to the beta cells), and sympathetic stimulation of the beta cells in the islets. Prostaglandins also inhibit insulin secretion.

Insulin is an anabolic hormone that promotes glucose uptake, primarily in liver, muscle, and adipose tissue. It also increases the synthesis of proteins, carbohydrates, lipids, and nucleic acids. The net effect of insulin in these tissues is to stimulate protein and fat synthesis and decrease blood glucose level. Insulin also facilitates the intracellular transport of potassium (K^+), phosphate, and magnesium. Table 21.6 summarizes the actions of insulin. Insulin is metabolized in the liver and kidney by enzymes that split disulfide bonds. Very little insulin is excreted unchanged in the urine.

Table 21.6

Insulin Actions

Actions	Sites of Insulin-Promoted Synthesis		
	Liver Cells	**Muscle Cells**	**Adipose Cells**
Glucose uptake	Increased	Increased	Increased
Glucose use	—	—	Increased glycerol phosphate
Glycogenesis	Increased	Increased	—
Glycogenolysis	Decreased	Decreased	—
Glycolysis	Increased	Increased	Increased
Gluconeogenesis	Increased	—	—
Other	Increased fatty acid synthesis	Increased amino acid uptake	Increased fat esterification
	Decreased ketogenesis	Increased protein synthesis	Decreased lipolysis
	Decreased urea cycle activity	Decreased proteolysis	Increased fat storage

	Decreased ketogenesis	Increased protein synthesis	Decreased lipolysis
	Decreased urea cycle activity	Decreased proteolysis	Increased fat storage

At the target cell, insulin signaling is initiated when insulin binds and activates its cell surface receptor tyrosine kinase. These receptors are found on cells throughout the body.[4] Insulin receptor binding sends a cascade of signals to activate glucose transporters (GLUT) for entry of glucose into the cell. The primary GLUT is called GLUT4. It is stored in cellular vesicles until activated by the insulin receptor and is then translocated to the cell surface where it facilitates the diffusion of glucose into the cell. Translocation of GLUT4 to the cell surface is associated with a 10- to 21-fold increase in glucose diffusion into the cell, particularly in skeletal and cardiac muscle, liver, and adipose cells (Fig. 21.15). The brain, red blood cells, kidney, and lens of the eye do not require insulin for glucose transport.

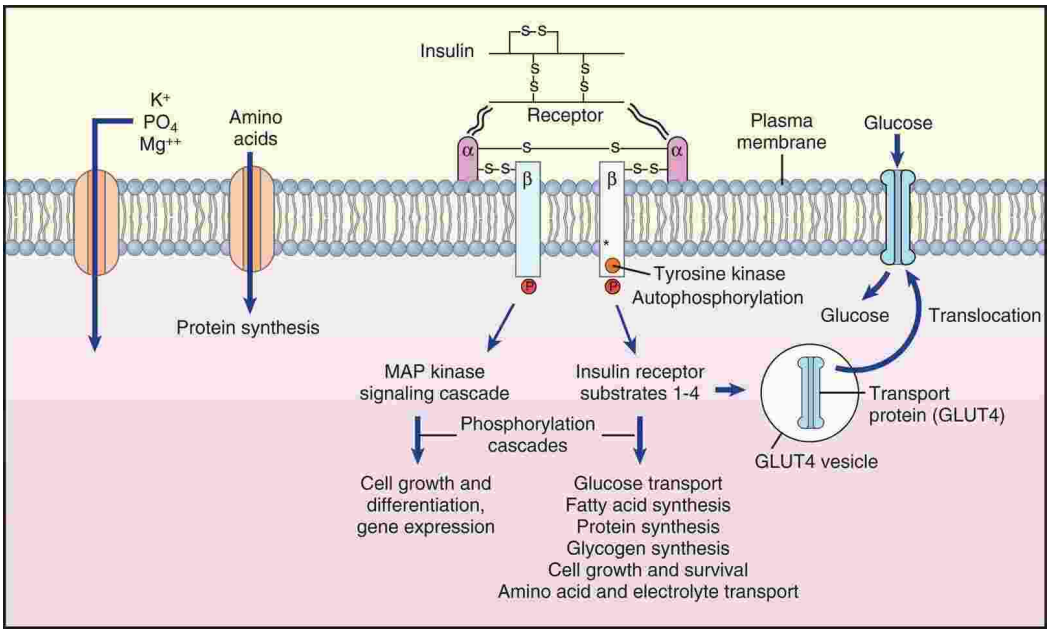

FIG. 21.15 Insulin Action on Cells.
Binding of insulin to its receptor causes autophosphorylation of the receptor, which then itself acts as a tyrosine kinase that phosphorylates insulin receptor substrates 1-4 *(IRS-1-4)*. Numerous target enzymes, such as protein kinase B and mitogen-activated protein (MAP) kinase, are activated, and these enzymes have a multitude of effects on cell function. The glucose transporter *(GLUT4)* is recruited to the plasma membrane, where it facilitates glucose entry into the cell. The transport of amino acids, potassium, magnesium, and phosphate into the cell is also facilitated. The synthesis of various enzymes is induced or suppressed, and cell growth is regulated by signal molecules that modulate gene expression. (Redrawn from Levy MN, Koeppen BM, Stanton BA, eds. *Berne & Levy principles of physiology*, 4th edition. St. Louis: Mosby; 2006.)

An illustration shows a plasma membrane of lipid bilayers. Potassium ions, phosphate, and magnesium

ions pass through an uniport and into the cell. Amino acids pass through a second uniport and undergo protein synthesis. Insulin is attached to the alpha receptors on the plasma membrane. Tyrosine kinase from the beta channels undergo autophosphorylation. M A P kinase signaling cascade, amplified by phosphorylation cascades, lead to cell growth and differentiation ang gene expression. Insulin receptor substrates 1 to 4, amplified by phosphorylation cascades, leading to the following: â€¢ Glucose transport. â€¢ Fatty acid synthesis. â€¢ Protein synthesis. â€¢ Glycogen synthesis. â€¢ Cell growth and survival. â€¢ Amino acid and electrolyte transport. Glucose passes through the transport protein (G L U T 4) in the G L U T 4 vesicle that translocate to the plasma membrane.

The sensitivity of the insulin receptor is a key component in maintaining normal cellular function. Insulin sensitivity is affected by age, weight, abdominal fat, and physical activity. Insulin resistance has been implicated in numerous diseases, including hypertension, heart disease, and type 2 diabetes mellitus. Adipocytes release a number of hormones and cytokines that are altered in obesity and have an important impact on insulin sensitivity (see Chapter 23). The most effective measures shown to improve insulin sensitivity in humans are weight loss and exercise.

Amylin

Amylin (or islet amyloid polypeptide) is a peptide hormone co-secreted with insulin by beta cells in response to nutrient stimuli. It regulates blood glucose concentration by delaying gastric emptying and suppressing glucagon secretion after meals. Amylin also has a satiety effect, which reduces food intake. Through these mechanisms, amylin works with insulin to prevent hyperglycemia.

Glucagon

Glucagon is antagonistic to the effects of insulin, acting to increase blood glucose during fasting, exercise, and hypoglycemia. Glucagon release is stimulated by low glucose levels and sympathetic stimulation and is inhibited by high glucose levels. Amino acids, such as alanine, glycine, and asparagine, also stimulate glucagon secretion. A protein-rich meal has the same effect. Glucagon is produced by the alpha cells of the pancreas and by cells lining the gastrointestinal tract. Glucagon acts primarily in the liver and increases the blood glucose concentration by stimulating glycogenolysis and gluconeogenesis in muscle and lipolysis in adipose tissue. The lypolysis has a ketogenic effect caused by the metabolism of free fatty acids in the liver. These effects have led to the hypothesis that increased glucagon secretion is as important as insulin insufficiency in the pathogenesis of type 2 diabetes mellitus.[14]

Pancreatic Somatostatin

Pancreatic somatostatin is produced by delta cells of the pancreas in response to food intake and is essential in carbohydrate, fat, and protein metabolism. It is different from hypothalamic somatostatin, which inhibits the release of GH and TSH. Pancreatic somatostatin is involved in regulating alpha-cell and beta-cell function within the islets by inhibiting secretion of insulin, glucagon, and pancreatic polypeptide.

Incretins

The incretin hormones are secreted from endocrine cells in the gastrointestinal tract in the presence of carbohydrates, proteins, and fats. The incretin hormones control postprandial glucose levels by

promoting glucose-dependent insulin secretion, inhibiting glucagon synthesis, promoting hepatic glucose secretion, and delaying gastric emptying. Incretins also enhance beta-cell mass and replenish intracellular stores of insulin. Gastric inhibitory polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) are incretin hormones.

Gastrin, Ghrelin, and Pancreatic Polypeptide

Pancreatic gastrin stimulates the secretion of gastric acid. It is postulated that fetal pancreatic gastrin secretion is necessary for adequate islet cell development. Ghrelin stimulates GH secretion, controls appetite, and plays a role in obesity and the regulation of insulin sensitivity. Pancreatic polypeptide is released in response to hypoglycemia and protein-rich meals. It decreases pancreatic secretion of fluid and bicarbonate, promotes gastric secretion, antagonizes cholecystokinin, and is frequently increased in pancreatic tumors and in diabetes.[15]

Adrenal Glands

The adrenal glands are paired, pyramid-shaped organs behind the peritoneum and close to the upper pole of each kidney (see Fig. 21.1). Each gland is surrounded by a capsule, embedded in fat, and well supplied with blood from the aorta and phrenic and renal arteries. Venous return from the left adrenal gland is to the renal vein, and from the right adrenal gland is to the inferior vena cava.

Each adrenal gland consists of two separate portions—an outer cortex and an inner medulla. These two portions have different embryonic origins, structures, and hormonal functions. The adrenal cortex and medulla function like two separate but interrelated glands (Fig. 21.16).

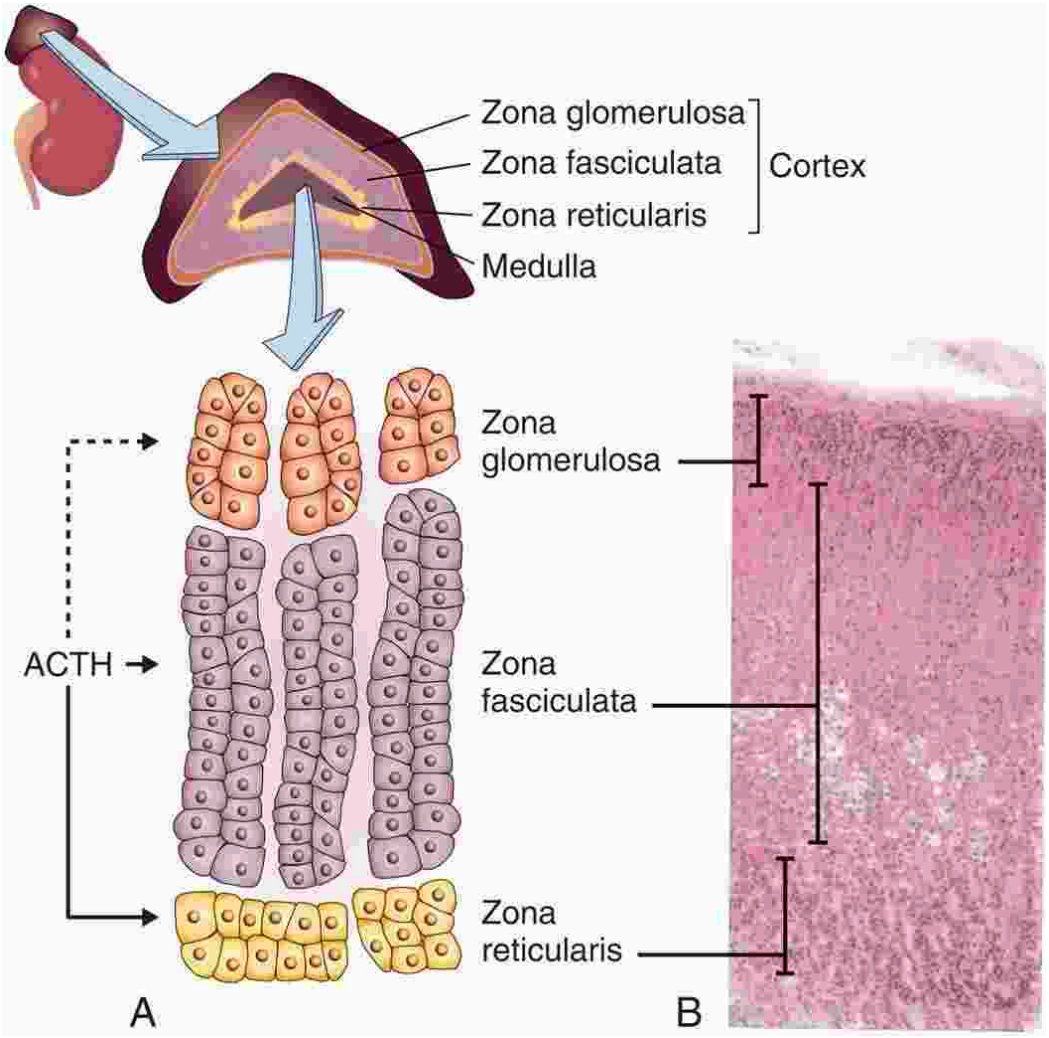

FIG. 21.16 Structure of the Adrenal Gland Showing Cell Layers (Zonae) of the Cortex. **(A)** Adrenal glands. Each gland consists of a cortex and a medulla. The cortex has three layers: zona glomerulosa, zona fasciculata, and zona reticularis. **(B)** A portion of the medulla is visible at the lower right in the photomicrograph (×35) and at the bottom of the drawing. *ACTH*, Adrenocorticotropic hormone. (A, From Damjanov I. *Pathophysiology*. Philadelphia: Saunders; 2008; B, From Kierszenbaum A. *Histology and cell biology*. St. Louis: Mosby; 2002.)

Illustration A of the adrenal glands shows and labels the following structures of the cortex: A C T H, zona glomerulosa, zona fasciculata, zona reticularis, and medulla. Photomicrograph B shows the following layers of the cortex, from the top to the bottom: zona glomerulosa, zona fasciculata, and zona reticularis.

Adrenal Cortex

The adrenal cortex accounts for 80% of the weight of the adult gland. The cortex is histologically subdivided into the following three zones:

1. The zona glomerulosa, the outer layer, constitutes about 15% of the cortex and primarily produces the mineralocorticoid aldosterone.
2. The zona fasciculata, the middle layer, constitutes 78% of the cortex and secretes the glucocorticoids cortisol, cortisone, and corticosterone.
3. The zona reticularis, the inner layer, constitutes 7% of the cortex and secretes mineralocorticoids (aldosterone), adrenal androgens and estrogens, and glucocorticoids.

The cells of the adrenal cortex are stimulated by ACTH from the pituitary gland. All hormones of the adrenal cortex are synthesized from low-density lipoprotein cholesterol. The best-known pathway of steroidogenesis involves the conversion of cholesterol to pregnenolone, which is then converted to the major corticosteroids.

Glucocorticoids

Functions of the glucocorticoids

The glucocorticoids are steroid hormones that have metabolic, neurologic, anti-inflammatory, and growth-suppressing effects (Fig. 21.17). These functions have direct effects on carbohydrate

metabolism. These hormones increase the blood glucose concentration by promoting gluconeogenesis in the liver and by decreasing uptake of glucose into muscle cells, adipose cells, and lymphatic cells and by suppressing insulin secretion. They are released under stress conditions, which results in increased glucose for the brain.[34] In extrahepatic tissues, the glucocorticoids stimulate protein catabolism and inhibit amino acid uptake and protein synthesis. In extrahepatic tissues, the glucocorticoids stimulate protein catabolism and inhibit amino acid uptake and protein synthesis. The ultimate long-term effect of chronic stress on the body is protein catabolism and muscle wasting, increased lipolysis, insulin resistance, and hyperglycemia.[16]

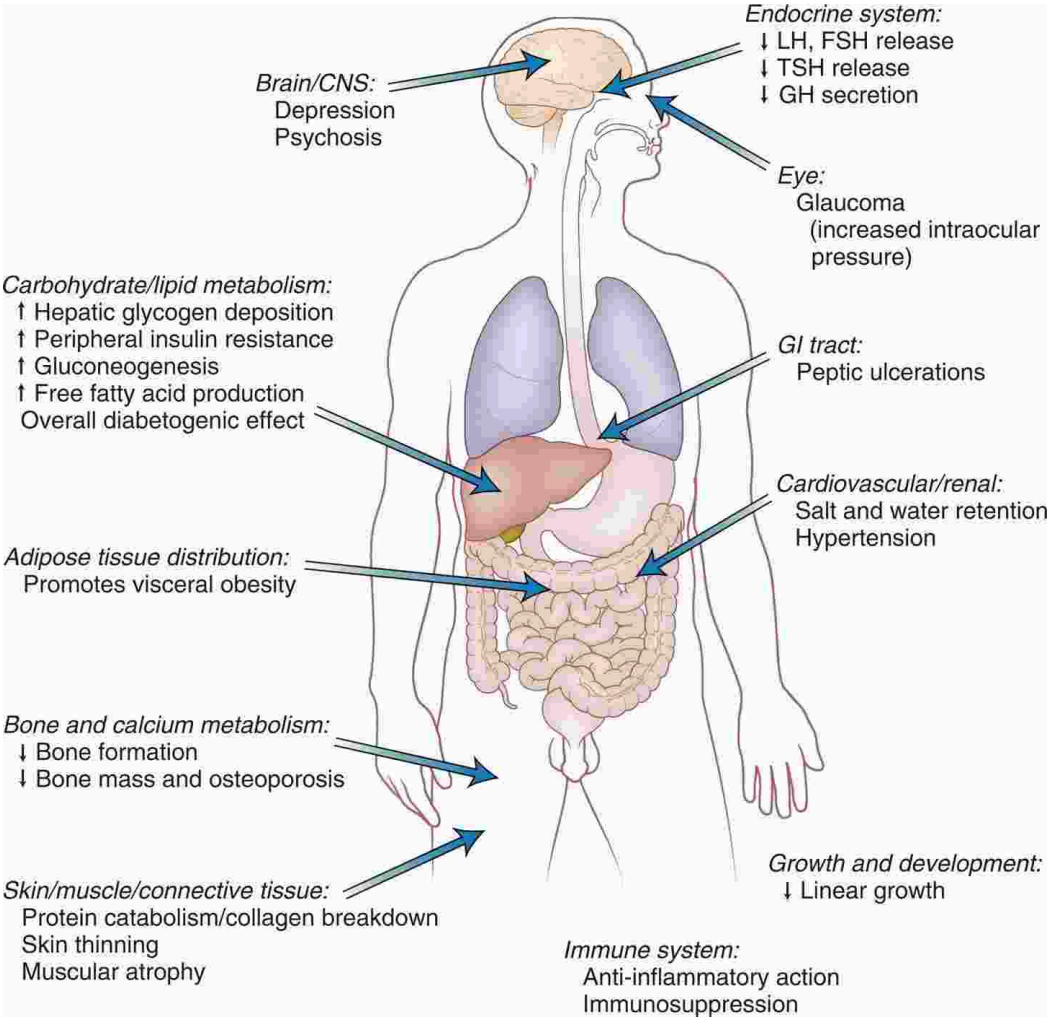

FIG. 21.17 Effects of Glucocorticoids on the Body.

CNS, Central nervous system; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *GI*, gastrointestinal; *LH*, Luteinizing hormone; *TSH*, thyroid-stimulating hormone. (From Stewart PM, Krone NP. The adrenal cortex. In: Melmed S, Polonsky KS, Larsen PR, et al., eds. *Williams textbook of endocrinology*, 12th edition. Philadelphia: Saunders; 2011.)

An illustration of the anterior view of a human figure shows and labels its different parts with corresponding effects. â€¢ Brain and C N S:

depression and psychosis. â€¢ Endocrine system: decreased L H and F S H release, decreased T S H release, and decreased G H secretion. â€¢ Eye: Glaucoma (increased intraocular pressure). â€¢ G I tract: peptic ulcerations. â€¢ Carbohydrate or lipid metabolism: increased hepatic glycogen deposition, increased peripheral insulin resistance, increased glucogenesis, increased free fatty acid production, and overall diabetogenic effect. â€¢ Cardiovascular or renal: salt and water retention and hypertension. â€¢ Adipose tissue distribution: promotes visceral obesity. â€¢ Bone and calcium metabolism: decreased bone formation and decreased bone mass and osteoporosis. â€¢ Skin or muscle or connective tissue: protein catabolism or collagen breakdown, skin thinning, and muscular atrophy. â€¢ Growth and development: decreased linear growth. â€¢ Immune system: anti-inflammatory action and immunosuppression.

The glucocorticoids act at several sites to suppress immune and inflammatory reactions. Adaptive immunity is affected by a glucocorticoid-mediated inhibitory effect on the proliferation of T lymphocytes, primarily T-helper lymphocytes. There is a greater adverse effect on T-helper 1 cell cytokine production (including antiviral interferons) than there is on T-helper 2 cell cytokine production, and therefore, greater depression of cellular immunity than humoral immunity (see Chapter 8). They affect innate immunity through several pathways, including inhibition of antigen presentation by dendritic cells and decreased activity of pattern

recognition receptors on the surface of macrophages (see Chapter 7). Glucocorticoids also decrease immune and inflammatory responses by decreasing natural killer cell activity; by blocking phospholipase A and the synthesis of prostaglandins, thromboxanes, and leukotrienes; and by inhibiting inflammatory gene expression. In addition, glucocorticoids suppress the synthesis, secretion, and actions of chemical mediators involved in inflammatory and immune responses, including histamine, adhesion molecules, inducible cyclooxygenase, and inducible nitric oxide synthase.[17]

Glucocorticoids increase resistance to the severe inflammatory response to lipopolysaccharide (LPS, a bacterial endotoxin) through the inhibition of cytokines, chemokines, certain hormones, and neurotransmitters. In addition, glucocorticoids stimulate anti-inflammatory cytokines. Lysosomal membranes are also stabilized, decreasing the release of proteolytic enzymes. This suppression of innate and adaptive immunity by glucocorticoids means that infection and poor wound healing are some of the most problematic complications of the use of glucocorticoids in the treatment of disease. Similarly, psychologic and physiologic stress increases glucocorticoid production, which provides a pathway for the well-described decrease in immunity seen in both acute and chronic stress conditions (see Chapter 11).[18,19]

Glucocorticoids appear to potentiate the effects of catecholamines, including sensitizing the arterioles to the vasoconstrictive effects of norepinephrine, thus increasing the blood pressure. Thyroid hormone and GH effects on adipose tissue are also potentiated by glucocorticoids. Other effects of glucocorticoids include inhibition of bone formation, inhibition of ADH secretion, and stimulation of gastric acid secretion. A metabolite of cortisol may act like a barbiturate and depress nerve cell function in the brain, accounting for the noted effects on mood, such as anxiety and depression, associated with steroid level fluctuation in disease or stress. Pathologically high levels of glucocorticoids increase the number of circulating erythrocytes (leading to polycythemia), increase the appetite, promote fat deposition in the face and cervical areas, increase uric acid excretion, decrease serum calcium levels, suppress

the secretion and synthesis of ACTH, and interfere with the action of GH so that somatic growth is inhibited.[20]

Cortisol

The most potent naturally occurring glucocorticoid is cortisol. It is the main secretory product of the adrenal cortex and is needed to maintain life and protect the body from stress (see Fig. 11.2). Cortisol circulates in bound form attached to albumin but is primarily bound to the plasma protein transcortin. A smaller amount circulates in free form and diffuses into cells with specific intracellular receptors for cortisol. Cortisol has a biologic half-life of approximately 90 minutes. It is primarily metabolized by the liver.

Cortisol secretion is regulated primarily by the hypothalamus and the anterior pituitary gland (Fig. 21.18). Corticotropin-releasing hormone (CRH) is produced by several nuclei in the hypothalamus and stored in the median eminence. Once released, CRH travels through the portal vessels to stimulate the production of ACTH, which is the main regulator of cortisol secretion.

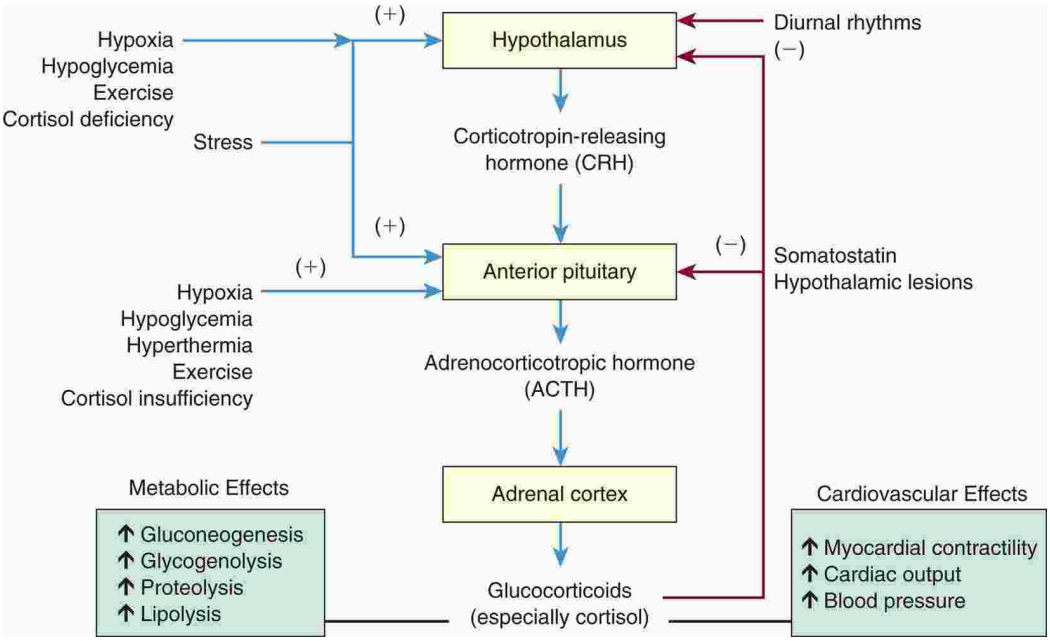

FIG. 21.18 Feedback Control of Glucocorticoid Synthesis and Secretion.

A flowchart shows the feedback control of glucocorticoid synthesis and secretion. The hypothalamus generates corticotropin-releasing hormone (C R H), triggering the anterior pituitary. Adrenocorticotropic hormone (A C T H) from the anterior pituitary triggers the adrenal cortex. Glucocorticoids (especially cortisol) from the adrenal cortex results in the following effects. â€¢ Metabolic effects: increased gluconeogenesis, increased glycogenolysis, increased proteolysis, and increased lipolysis. â€¢ Cardiovascular effects: increased myocardial contractility, increased cardiac output, and increased blood pressure. The feedback mechanisms are as follows. â€¢ Hypothalamus receives positive feedback from hypoxia,

hypoglycemia, exercise, cortisol deficiency, and stress. â€¢ Hypothalamus receives negative feedback from diurnal rhythms, somatostatin, hypothalamic lesions, and glucocorticoids. â€¢ Anterior pituitary receives positive feedback from hypoxia, hypoglycemia, hyperthermia, exercise, cortisol insufficiency, and stress. â€¢ Anterior pituitary receives negative feedback from somatostatin, hypothalamic lesions, and glucocorticoids.

Three factors appear to be primarily involved in regulating the secretion of ACTH: (1) negative-feedback effects of high circulating levels of cortisol; (2) diurnal rhythms, with peak levels during sleep; and (3) psychological and physiologic stress increases ACTH secretion, leading to increased cortisol levels. (Neurologic mechanisms regulating sleep are discussed in Chapter 16.)

There also is evidence that there is synthesis and secretion of glucocorticoids from extra-adrenal tissue including the thymus, lung, intestine, skin, brain, and possibly heart in response to immune stimulation. This is thought to provide autocrine and paracrine immune regulation and control of inflammation. Dysregulation of extra-adrenal glucocorticoid production can contribute to autoimmune and inflammatory diseases.[21]

Once ACTH is secreted, it binds to specific plasma membrane receptors on the cells of the adrenal cortex and on other extra-adrenal tissues. Because both adrenal and extra-adrenal tissues have ACTH receptors, a number of effects result from stimulation by ACTH (Box 21.1). ACTH stimulates the cells of the adrenal cortex to immediately synthesize and secrete cortisol. In healthy people, the secretory patterns of ACTH and cortisol are nearly identical. After secretion, 10% to 15% of cortisol circulates unbound, while the rest is bound to albumin or a plasma glycoprotein called *transcortin*. The levels of transcortin play a role in the HPA feedback system controlling

cortisol secretion. Transcortin levels are significantly elevated by increased estrogen levels that occur with pregnancy and hormone therapy. The unbound portion is free to diffuse into cells, but only those cells with specific intracellular glucocorticoid receptors respond to cortisol stimulation. ACTH is rapidly inactivated in the circulation, and the liver and kidneys eliminate the deactivated hormone.

Box 21.1

Effects of Adrenocorticotropic Hormone

Adrenal

Maintenance of gland size
Depletion of ascorbic acid
Activation of adenylyl cyclase
Conversion of cholesterol to pregnenolone
Accumulation of cholesterol for steroid hormone synthesis
Secretion of cortisol and adrenal androgens

Extra-Adrenal

Stimulation of melanocytes
Activation of tissue lipase

Mineralocorticoids: aldosterone

Mineralocorticoid steroids directly affect ion transport by epithelial cells, causing sodium retention and potassium and hydrogen loss. Aldosterone is the most potent naturally occurring mineralocorticoid and conserves sodium by increasing the activity of the sodium pump of epithelial cells in the nephron. (The sodium pump is described in Chapter 1.)

The initial stages of aldosterone synthesis occur in the adrenal zona fasciculata and zona reticularis. The final conversion of corticosterone

to aldosterone occurs in the zona glomerulosa. Aldosterone synthesis and secretion is regulated primarily by the renin-angiotensin system (described in Chapter 37). The renin-angiotensin system is activated by sodium and water depletion, increased potassium levels, and a diminished effective blood volume (Fig. 21.19). Angiotensin II is the primary stimulant of aldosterone synthesis and secretion; however, sodium and potassium levels also may directly affect aldosterone secretion. ACTH acutely stimulates aldosterone secretion but is secondary to angiotensin II and potassium.

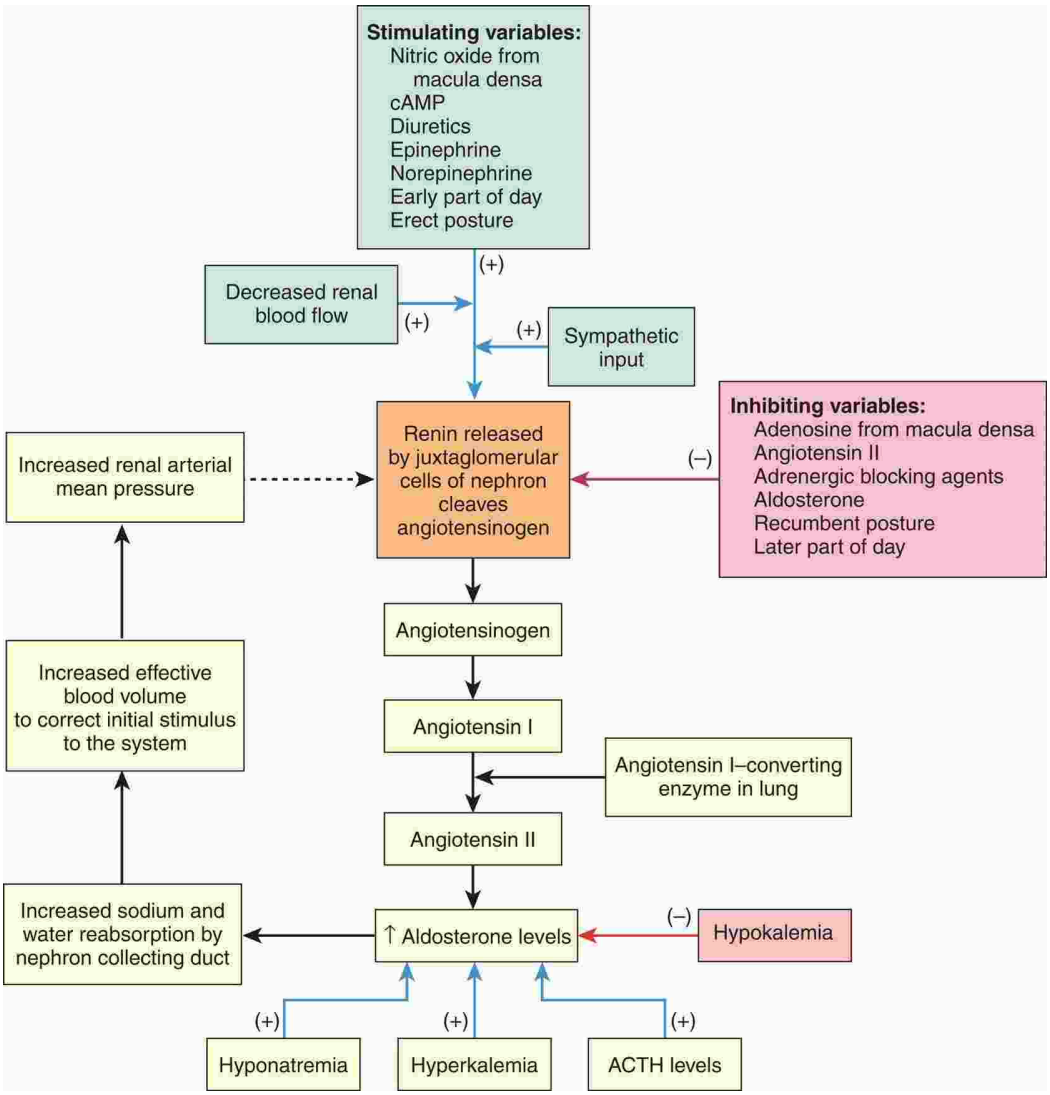

FIG. 21.19 Feedback Mechanisms Regulating Aldosterone Secretion.
ACTH, Adrenocorticotropic hormone; *cAMP*, cyclic adenosine monophosphate.

A flowchart shows the feedback mechanisms in regulating aldosterone secretion. The general loop in the regulating process I as follows. â€¢ Renin released by juxtaglomerular cells of nephron cleaves angiotensinogen. â€¢ Angiotensinogen. â€¢ Angiotensin 1. â€¢ Angiotensin 2 (also from

angiotensin 1-converting enzyme in lung). â€¢ Increased aldosterone levels. â€¢ Increased sodium and water reabsorption by nephron collecting duct. â€¢ Increased effective blood volume to correct initial stimulus to the system. â€¢ Increased renal arterial mean pressure. The positive feedback mechanisms impacting the first stage of the regulation are as follows. â€¢ Stimulating variables: nitric oxide from macula densa, c A M P, diuretics, epinephrine, norepinephrine, early part of day, and erect posture. â€¢ Decreased renal blood flow. â€¢ Sympathetic input. The negative feedback mechanisms (inhibiting variables) impacting the first stage of the regulation are as follows. â€¢ Adenosine from macula densa. â€¢ Angiotensin 2. â€¢ Adrenergic blocking agents. â€¢ Aldosterone. â€¢ Recumbent posture. â€¢ Later part of day. The positive feedback mechanisms impacting the increased aldosterone levels are as follows. â€¢ Hyponatremia. â€¢ Hyperkalemia. â€¢ A C T H levels. Hypokalemia is the negative feedback mechanisms impacting the increased aldosterone levels.

When sodium and potassium levels are within normal limits, approximately 50 to 250 mg of aldosterone is secreted daily. Of the secreted aldosterone, 50% to 75% binds to plasma proteins. The proportion of unbound aldosterone contributes to its rapid metabolic turnover in the liver, its low plasma concentration, and its short half-

life (about 15 minutes). Aldosterone is metabolized in the liver and is excreted by the kidney.

Aldosterone maintains extracellular volume and blood pressure by acting on distal nephron epithelial cells to increase reabsorption of sodium and excretion of potassium and hydrogen. This renal effect takes 90 minutes to 6 hours. Fluid and electrolyte regulation is addressed in more detail in Chapter 3. Other effects of aldosterone include enhancement of cardiac muscle contraction, stimulation of ectopic ventricular activity through secondary cardiac pacemakers in the ventricles, stiffening of blood vessels with increased vascular resistance, and decrease in fibrinolysis. Pathologically elevated levels of aldosterone have been implicated in the myocardial changes associated with heart failure.[22]

Adrenal estrogens and androgens

The healthy adrenal cortex secretes minimal amounts of estrogen and androgens. ACTH appears to be the major regulator. Some of the weakly androgenic substances secreted by the cortex (dehydroepiandrosterone [DHEA], androstenedione) are converted by peripheral tissues to stronger androgens, such as testosterone, thus accounting for some androgenic effects initiated by the adrenal cortex. Peripheral conversion of adrenal androgens to estrogens is enhanced in aging or obese persons, as well as in those with liver disease or hyperthyroidism. The biologic effects and metabolism of the adrenal sex steroids do not vary from those produced by the gonads (see Chapter 24).

Adrenal Medulla

The adrenal medulla, together with the sympathetic division of the autonomic nervous system, is embryonically derived from neural crest cells. The chromaffin cells (pheochromocytes) of the adrenal medulla secrete and store the catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline). Both are synthesized from the amino acid phenylalanine (Fig. 21.20). Only 30% of circulating epinephrine comes from the adrenal medulla (the other 70% is released from nerve terminals), and the medulla is only

a minor source of norepinephrine. The adrenal medulla functions as a sympathetic ganglion without postganglionic processes. Sympathetic cholinergic preganglion fibers terminate on the chromaffin cells and secrete catecholamines directly into the bloodstream. The catecholamines acting in the blood are therefore hormones and not neurotransmitters.

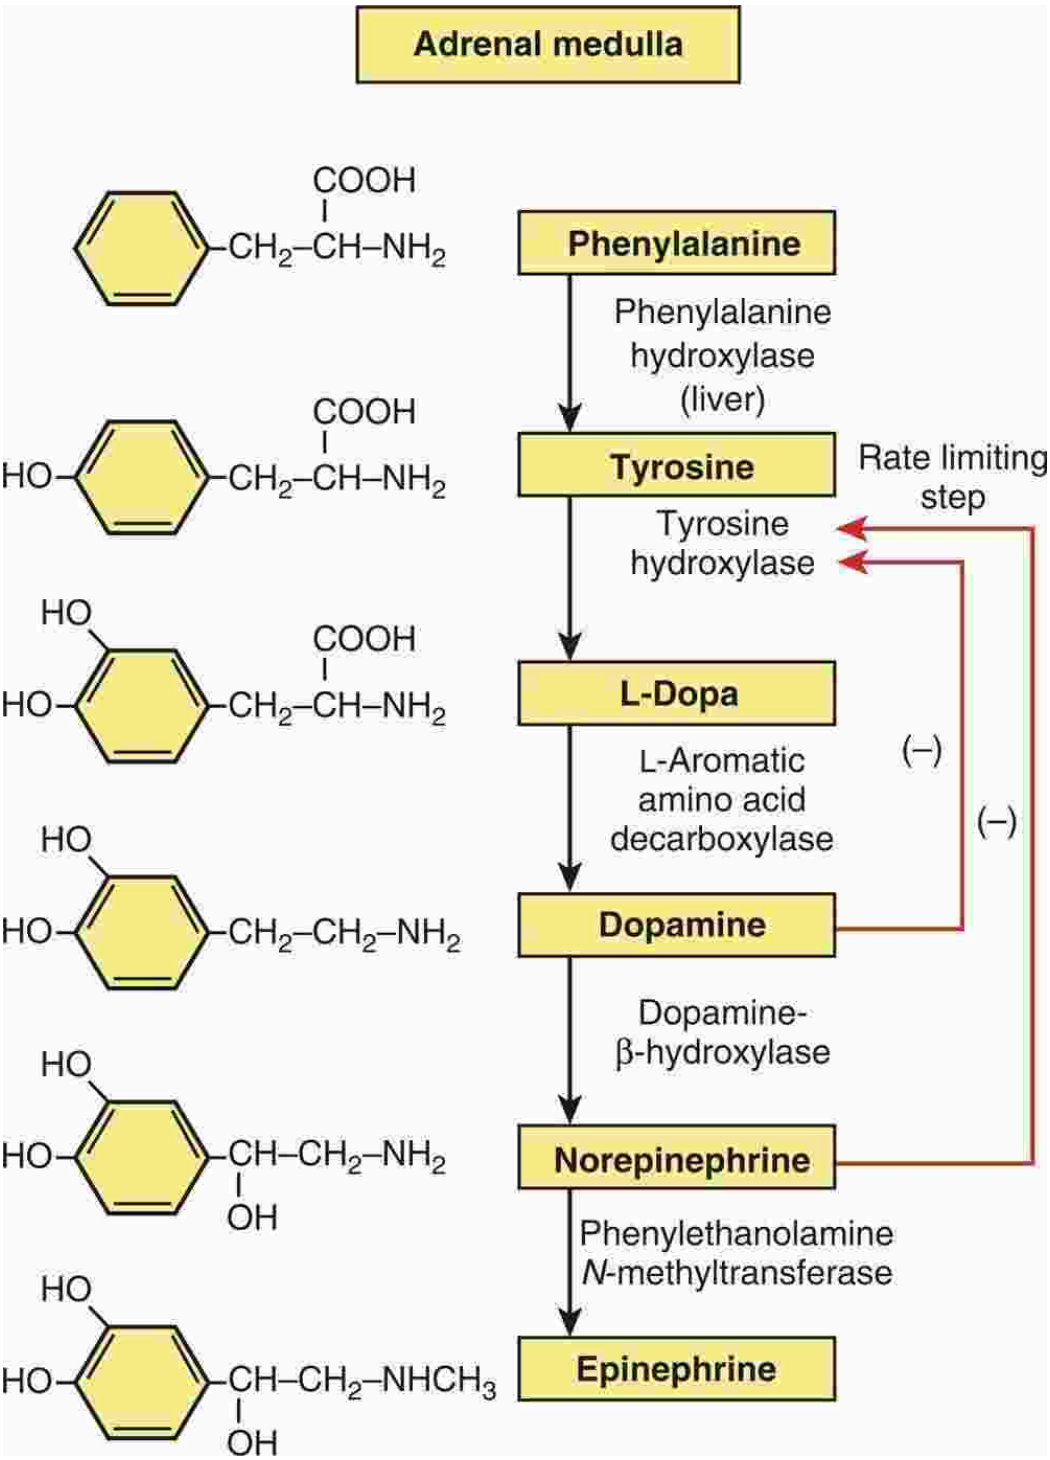

FIG. 21.20 Synthesis of Catecholamines.

An illustration depicts the pathway of catecholamine biosynthesis accompanied by the chemical structures

of the compounds. 1. Phenylalanine converted to tyrosine by hydroxylase. 2. Tyrosine is converted to Dopa by hydroxylase. 3. Dopa is converted to Dopamine by beta-hydroxylase. 4. Dopamine is converted to norepinephrine by N-methyltransferase. 5. Norepinephrine is converted to epinephrine. 6. The rate-limiting step is indicated by the sublimation of dopamine and norepinephrine by tyrosine hydroxylase.

Physiologic stress to the body (e.g., traumatic injury, hypoxia, hypoglycemia) triggers the exocytosis of the storage granules from chromaffin cells, with release of epinephrine and norepinephrine into the bloodstream. Secretion of adrenal catecholamines is also increased by ACTH and the glucocorticoids. Once released, the catecholamines remain in the plasma for only seconds to minutes. The catecholamines exert their biologic effects after binding to plasma membrane receptors (α_1, α_2, β_1, β_2, and β_3) in target cells. This binding activates the adenylyl cyclase system (an intracellular second messenger system). Catecholamines have diverse effects on the entire body. Their release and the body's response have been characterized as the “fight or flight” response (stress response) (see Figs. 11.2 and 11.4 and Tables 11.3 and 11.4). Metabolic effects of catecholamines promote hyperglycemia through a variety of mechanisms, including interference with the usual glucose regulatory feedback mechanisms. Catecholamines are rapidly removed from the plasma by neuron absorption for storage in new cytoplasmic granules, or metabolically inactivated and excreted in the urine. Catecholamines also directly inhibit secretion by decreasing the formation of the enzyme tyrosine hydroxylase (the rate-limiting step, see Fig. 21.20).

Tests of Endocrine Function

Evaluation of the endocrine system is challenging because of (1) the complexity of the clinical presentation as a result of multiple organ system involvement, (2) the nonspecific nature of complaints frequently associated with endocrine dysfunction, and (3) the inappropriate use of laboratory test interpretations.

Tests of the endocrine system involve several general types of clinical evaluation. Measurement of hormone level is accomplished by RIA, by ELISA, and, less commonly, by bioassay. Radioimmunoassay (RIA), a technique for measuring the minute quantities of hormones in the blood, uses antibodies and radiolabeled hormones to determine the quantity of hormone in the plasma. Enzyme-linked immunosorbent assay (ELISA) also is used to determine circulating hormone levels. This method is similar to that of RIA but is less expensive and easier to conduct. Instead of radiolabeled hormones, an enzyme-labeled hormone is used. A bioassay involves the use of graded doses of hormone in a reference preparation and then comparison of the results with an unknown sample. Bioassays are used more commonly in investigative endocrinology than in clinical laboratories. If the serum level is greater or less than the reference values, more definitive tests are required to determine the source of the problem.

Measurement of individual hormones does not always permit differentiation between normal and abnormal values when hormone levels are changing over time. For an accurate interpretation, the broad normal range of some hormones requires knowledge of previous hormonal levels and timed sampling. Stimulation and suppression tests that determine the response to exogenous stimulants or inhibitors can help to decipher some of these complexities.

Indirect assessment of hormonal function often includes measurement of concentrations of serum glucose and electrolytes that are affected by the endocrine process. Evaluation of hormonal function also may include radiographic imaging of specific glands.

Aging and the Endocrine System

The precise relationship between aging and the endocrine system is not clear. Perhaps most important, the question of whether changes in endocrine function are a consequence or a cause of aging has yet to be resolved. These relationships have been difficult to identify, in part because of a number of age-related variables that may coexist, such as acute and chronic nonendocrine disease; use of medications; alterations in diet, body composition, and weight; and changes in sleep-wake cycles. However, the endocrine system is so integral to health that changes in endocrine function have been used as "biomarkers" for unhealthy aging.

Investigation into the role of the endocrine glands and their interactions in the aging process has generated much data, although the evidence is contradictory. There are complex changes within the HPA; altered biologic activity of hormones, altered circulating levels of hormones, altered secretory response of the endocrine glands, altered metabolism of hormones, loss of circadian control of hormone secretion, and effects of oxidative stress and inflammation are among the findings. Changes in secretion of hypothalamic regulatory factors and hormones or changes in hypothalamic feedback sensitivity may contribute to alterations in control of an optimal internal environment.[23]

The dynamic equilibrium of the endocrine system also may be affected by altered secretion of neurotransmitters within certain areas of the brain, affecting hypothalamic and pituitary function. Such alterations may include an excess or deficit in secretion of pituitary hormones and loss of appropriate secretory pattern of those hormones. Loss of endocrine steady states may be associated with or contribute to aging.[24]

Thyroid Gland

Changes in thyroid structure and function occur with aging.[25] Structurally, some glandular atrophy and fibrosis occur with nodularity and increasing inflammatory infiltrates. These infiltrative

changes may reflect age-related autoimmune damage. Clinical signs of thyroid disease are more difficult to detect in older adults. Overall, it is estimated that there is some evidence of thyroid dysfunction in 5% to 10% of older adult women. The presence of thyroid nodules increases after the age of 70 years. Changes relative to thyroid hormone and its function are more difficult to assess and much of the available data are contradictory. Overall, TSH secretion is thought to increase slightly, but there is controversy regarding whether this is normal aging or the presence of hypothyroidism with risk for adverse consequences.[26]

Treatment for thyroid deficiency is also affected by aging. The appropriate dose for TH replacement is often lower in older adults because the peripheral metabolism of TH decreases with age. In addition, TH must be replaced slowly in older adults with coronary artery disease to prevent angina and myocardial infarction.

Endocrine Pancreas

It is estimated that 40% to 50% of individuals older than age 65 have impaired glucose tolerance or diabetes, and there is an age-dependent decline in beta-cell function.[27] With aging, pancreatic cell regeneration declines, and there is fibrosis and shrinkage of the extracellular matrix and fat accumulation in the exocrine tissues.[28]

Dysfunction of the pancreas with decreased insulin secretion of beta cells and insulin receptors and increased insulin resistance have all been documented and may be related to changes in adipokine physiology.[29] These changes have significant implications for many target organs, particularly the cardiovascular system, which is increasingly at risk for both vascular (hypertension, atherosclerosis, glomerulosclerosis) and cardiac (infarction, failure) disorders.

Growth Hormone and Insulin-Like Growth Factors

The amounts of GH and IGF decline with aging, a process that has been called the *somatopause*. This decline in anabolic stimuli is linked to decreases in muscle size and function, decreased amounts of fat

and bone mass, and changes in reproductive and cognitive function. Some studies have shown that GH resistance and declines in GH are associated with longevity in animals, but there is inconsistent data for humans.[30]

Parathyroid Glands

Age-related increases in PTH secretion, known as secondary hyperparathyroidism, occur in older adults. It is associated with low levels of calcitriol and calcium and related to a decline in renal conversion of vitamin D3 to calcitriol. Calcium malabsorption and hypocalcemia lead to increased bone remodeling and cortical bone thinning and porosity. Calcium intake, especially in women, also tends to decrease with aging and, combined with a decline in estrogen, contributes to osteoporosis (see Chapter 44).[31] The average daily intake of 450 to 500 mg/day causes a negative calcium balance greater than 40 mg/day and may be related to the absolute bone loss of approximately 1.5% per year. Older adults show decreased intestinal adaptation to variations in calcium intake. The elevated levels of parathyroid hormone have been linked to an increase in mortality in older adults, many of whom also have a mild, persistent hypercalciuria, which indicates a defective renal mechanism for responding to decreased calcium intake. Decreased circulating levels of vitamin D are common in older adults, especially those in long-term care institutions. Vitamin D deficiency has been linked to not only osteoporosis but also cancer, autoimmune diseases, diabetes, cardiovascular disease, and mental health disorders. The parathyroid gland, kidney, and choroid plexus secrete the Klotho protein, which, when overexpressed, has antiaging effects (see Emerging Science Box: Klotho Protein and Aging).

Adrenal Glands

The adrenal cortex loses some weight and has more fibrous tissue after the age of 50 years. Age diminishes negative feedback on the secretion of cortisol, due to impaired sensitivity of the hypothalamic-

pituitary axis. There is an age-related decrease in the metabolic clearance rate of the glucocorticoids. The metabolic clearance of cortisol decreases with an age-related decline in liver and kidney function. Decreased clearance and reduced use of cortisol contribute to higher circulating cortisol levels, but diurnal variation is maintained. Because feedback mechanisms are intact, the higher cortisol levels cause a decrease in cortisol secretion. The chronic elevation in cortisol can impair recovery from stressful stimuli and contribute to loss of muscle mass, hypertension, osteopenia, visceral obesity, diabetes, suppressed immunity, and a decline in cognitive function.[32]

Plasma levels of the adrenal androgens, as well as urinary excretion of the metabolic end products, decrease gradually but dramatically with age, to as much as 50% to 70% of the young adult level. This change in adrenal function has been called the *adrenopause* and is correlated with decreased synthesis activity of DHEA.

This change appears to reflect a decline in the function of the zona reticularis. In postmenopausal women, this decline in adrenal androgen secretion is especially important because nearly all sex steroids after menopause come from adrenal and ovarian production of androgen precursors converted to estrogens in the periphery. In older adult men, adrenal androgen production accounts for more than half of circulating testosterone levels.

Antidiuretic Hormone and Aldosterone

Although hyponatremia is a common finding in older adults, it appears related to changes in renal function or sensitivity rather than to ADH-related mechanisms. Morphologic studies have not shown significant age-related degenerative changes in the neuroendocrine pathways that regulate the synthesis and secretion of ADH. However, it appears that ADH secretion is augmented when stimulated by changes in osmotic concentration, whereas baroreceptor-mediated ADH secretion is reduced, producing the syndrome of inappropriate ADH secretion (SIADH), common in older adults.[33] The secretion of aldosterone from the adrenal cortex

declines with aging and is associated with decreased renin and an increased risk for hyperkalemia.[32]

Summary Review

Mechanisms of Hormonal Regulation

1. The endocrine system has five general functions: (1) differentiation of the reproductive and central nervous systems in the developing fetus; (2) stimulation of sequential growth and development during childhood and adolescence; (3) coordination of the male and female reproductive systems, which makes sexual reproduction possible; (4) maintenance of an optimal internal environment throughout life; and (5) initiation of corrective and adaptive responses when emergency demands occur.
2. Hormones are chemical messengers synthesized by endocrine glands and, when released, trigger intracellular responses.
3. Hormones have specific rates and rhythms of secretion: diurnal, pulsatile/cyclic, and patterns dependent on other circulating substances.
4. Hormones have specific negative- and positive-feedback mechanisms. Positive feedback occurs when a neural, chemical, or endocrine response increases the synthesis and secretion of a hormone. Negative feedback occurs when a changing chemical, neural, or endocrine response to a stimulus decreases the synthesis and secretion of a hormone.
5. Hormones affect only target cells with appropriate receptors and then act on these cells to initiate specific cell functions or activities.
6. Hormone receptors on target cells have two main functions: (1) to recognize and bind specifically and with high affinity to their particular hormones; and (2) to initiate a signal to appropriate intracellular effectors.
7. Receptors for hormones may be located on the plasma membrane or in the intracellular compartment of a target cell.

8. Water-soluble (peptide) hormones circulate throughout the body in unbound form. They bind with a receptor on a target cell's plasma membrane, acting as a first messenger. This binding signals the cell to generate a second messenger inside the cell. The second messenger communicates with the cell nucleus and mediates the action of the hormone on the target cell.
9. Lipid-soluble (steroid) hormones freely cross the plasma membrane by diffusion. These hormones diffuse directly into the cell nucleus and bind to nuclear receptors. Rapid responses of steroid hormones (non-genomic responses) may be mediated by plasma membrane receptors.

Structure and Function of the Endocrine Glands

1. The hypothalamic-pituitary axis (HPA) forms the structural and functional basis for the neuroendocrine system.
2. The hypothalamus is connected to the pituitary gland by the pituitary stalk. The hypothalamus regulates anterior pituitary function by secreting releasing or inhibiting hormones and factors into the portal circulation.
3. Hypothalamic hormones include prolactin-releasing hormone (PRH), which stimulates secretion of prolactin; prolactin-inhibiting hormone (PIH, dopamine), which inhibits prolactin secretion; thyrotropin-releasing hormone (TRH), which affects release of thyroid hormones; growth hormone-releasing hormone (GHRH), which stimulates the release of growth hormone (GH); somatostatin, which inhibits the release of GH and thyroid-stimulating hormone (TSH); gonadotropin-releasing hormone (GnRH), which facilitates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH); corticotropin-releasing hormone (CRH), which facilitates the release of adrenocorticotropic hormone (ACTH) and endorphins; and substance P, which

inhibits ACTH release and stimulates the release of a variety of other hormones.

4. The pituitary gland consists of anterior and posterior portions that have different functional relationships to the hypothalamus.
5. Hormones of the anterior pituitary are regulated by (1) secretion of hypothalamic-releasing factors, (2) feedback effects from hormones secreted by target organs, and (3) mediating effects of neurotransmitters.
6. Hormones of the anterior pituitary include corticotropin-related hormones (ACTH, melanocyte-stimulating hormone [MSH], β-lipotropin, β-endorphins), somatotropic hormones (GH, prolactin), and glycoprotein hormones (FSH, LH, TSH).
7. The posterior pituitary secretes antidiuretic hormone (ADH), which also is called vasopressin, and oxytocin.
8. ADH controls serum osmolality, increases permeability of the renal tubules to water, and causes vasoconstriction when administered pharmacologically in high doses.
9. Oxytocin causes uterine contraction and lactation in women and may have a role in sperm motility in men. In both men and women, oxytocin has an antidiuretic effect similar to that of ADH.
10. The pineal gland secretes melatonin, which regulates circadian rhythms and reproduction.
11. The two-lobed thyroid gland contains follicles, which secrete some of the thyroid hormones, and C cells, which secrete calcitonin.
12. Regulation of thyroid hormone (TH) involves a negative-feedback loop initiated by TRH and involving the hypothalamus, anterior pituitary, thyroid gland, and numerous biochemical variables.
13. TSH, which is synthesized and stored in the anterior pituitary, stimulates secretion of TH by activating intracellular processes, including uptake of iodine necessary for the synthesis of TH in the thyroid gland.

14. Synthesis of TH depends on the glycoprotein thyroglobulin, which contains a precursor of TH, tyrosine. Tyrosine then combines with iodine to form precursor molecules of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). These hormones are then stored within thyroid colloid until released into the circulation.
15. When released into the circulation, T_3 and T_4 are bound by carrier proteins in the plasma, which store these hormones and provide a buffer for rapid changes in hormone levels. The free form is the active form.
16. Thyroid hormones alter protein synthesis and have a wide range of metabolic effects on proteins, carbohydrates, lipids, vitamins, and other hormones and neurotransmitters. TH also affects heat production and cardiac function.
17. The paired parathyroid glands are located behind the upper and lower poles of the thyroid. These glands secrete parathyroid hormone (PTH), an important regulator of serum calcium and phosphate levels.
18. PTH secretion increases levels of ionized calcium and decreases levels of phosphate in the plasma. In the kidney, PTH increases reabsorption of calcium and decreases reabsorption of phosphorus.
19. The endocrine pancreas contains the islets of Langerhans, which consist of alpha cells, beta cells, delta cells, and F cells. These cells secrete hormones that regulate carbohydrate, fat, and protein metabolism in the body.
20. Alpha cells produce glucagon, which is secreted inversely to blood glucose concentrations and helps increase blood glucose.
21. Beta cells synthesize insulin and secrete amylin. Insulin is a hormone that regulates blood glucose concentrations and overall body metabolism of fat, protein, and carbohydrates. Amylin suppresses glucagon secretion and has a satiety effect.
22. Delta cells secrete somatostatin, which inhibits glucagon and insulin secretion.

23. F cells secrete pancreatic polypeptide, which inhibits gallbladder contraction and exocrine pancreatic secretion.
24. The paired adrenal glands are situated above the kidneys. Each gland consists of an outer adrenal cortex, which secretes steroid hormones, and an inner adrenal medulla, which secretes catecholamines.
25. The steroid hormones secreted by the adrenal cortex are synthesized from cholesterol. These hormones include glucocorticoids, mineralocorticoids, and adrenal androgens and estrogens.
26. Glucocorticoids directly affect carbohydrate metabolism by increasing blood glucose concentration through gluconeogenesis in the liver and by decreasing uptake of glucose. Glucocorticoids also inhibit immune and inflammatory responses, suppress growth, and promote protein catabolism.
27. The most potent naturally occurring glucocorticoid is cortisol, which is necessary for the maintenance of life and for protection from stress. Secretion of cortisol is regulated by the hypothalamus and anterior pituitary.
28. Cortisol secretion is related to secretion of ACTH, which is stimulated by corticotropin-releasing hormone (CRH). ACTH binds with receptors of the adrenal cortex, which activates intracellular mechanisms and leads to cortisol release.
29. Mineralocorticoids are steroid hormones that directly affect ion transport epithelial cells, causing sodium retention and potassium and hydrogen loss.
30. Aldosterone is the most potent of the naturally occurring mineralocorticoids. Its primary role is conserving sodium by increasing the activity of the sodium pump of epithelial cells. The principal site of aldosterone action is the kidney, where it causes sodium reabsorption and potassium and hydrogen excretion. Aldosterone secretion is regulated primarily by the renin-angiotensin system and by sodium and potassium levels.

31. Androgens and estrogens secreted by the adrenal cortex act in the same way as those secreted by the gonads.
32. The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Physiologic stress to the body triggers their release.
33. Catecholamines bind with various target cells and are taken up by neurons or excreted in the urine. Catecholamines cause a range of metabolic effects (e.g., hyperglycemia) characterized as the "fight or flight" response.
34. Several assay methods are used to measure levels of hormones in the plasma. Radioimmunoassay (RIA) compares the proportion of radiolabeled and nonradiolabeled hormone against standard reference curves. Enzyme-linked immunosorbent assay (ELISA) is a method similar to RIA, but uses a radiolabeled enzyme rather than a radiolabeled hormone. Bioassays use graded doses of hormone in a reference preparation and then compare the results with an unknown sample to determine the hormone level.

Aging and the Endocrine System

1. Endocrine changes that may be associated with aging include altered biologic activity of hormones, altered circulating levels of hormones, altered secretory responses of endocrine glands, altered metabolism of hormones, loss of circadian control of hormone release, and changes in secretion of hypothalamic regulatory hormones.
2. Cellular damage associated with aging, genetically programmed cell change, and chronic wear and tear may contribute to endocrine gland dysfunction or alterations in the responsiveness of target organs.
3. Aging apparently causes atrophy of the thyroid gland and is associated with infiltrative glandular changes. Secretion of thyroid hormones may diminish with age.

4. Aging causes pancreatic fat deposition and is associated with a decrease both in insulin secretion and in insulin sensitivity. In addition, there is an age-dependent decline in beta-cell function.
5. Growth hormone levels decrease with aging, leading to decreased bone and muscle mass.
6. Aging is associated with alterations in calcium steady states, which may be related to alterations in PTH secretion from the parathyroid glands.
7. Age-related changes in adrenal function include synthesis of glucocorticoids and a decrease in levels of adrenal androgens. The effects of these changes, however, are offset by feedback mechanisms that maintain glucocorticoid levels and by gonadal secretion of androgens.
8. The kidney, choroid plexus, and parathyroid gland secrete the Klotho protein, which has antiaging effects.

Emerging Science BoxThyromimetics and Liver Disease

An emerging field of research is focusing on thyromimetics due to the possible role thyroid hormones may play in the pathogenesis of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) disease. These two liver diseases are closely linked to metabolic syndrome (diabetes mellitus type 2, dyslipidemia, and obesity), which also plays a role in endocrine disorders such as hypothyroidism. While the pathophysiologic processes continue to be explored through research, insulin resistance, both hepatic and peripheral, as well as metabolic syndrome are proposed as possible mechanisms. Currently, possible treatment options for NAFLD are in phase 3 clinical trials. These treatments focus on substitution therapy for hypothyroidism, specifically thyroid hormone receptor (THR) agonist and its metabolites, along with lifestyle modifications.

Emerging Science BoxVitamin D Deficiency

Vitamin D is essential for bone health and is widely used for the prevention and treatment of postmenopausal osteoporosis and renal osteodystrophy. Inadequate serum levels of vitamin D have been linked to numerous disorders, including infections, cancer, heart disease, dementia, diabetes, chronic pain syndromes, and autoimmune disorders, but cause and effect has never been established. However, recent reviews have found that there is still inadequate evidence that vitamin D supplementation reduces the risk for any of these nonskeletal conditions. Still, many health organizations recommend an increased intake of vitamin D–containing foods (seafood, vitamin D–fortified juices, and milk products), increased exposure to sunlight, and supplementation with vitamin D. The Institute of Medicine currently recommends 400 to 800 units of vitamin D per day for children and adults and 400 units for infants up to 12 months of age.

Vitamin D deficiency has been found to affect more than 75% of all Americans, and more than 90% of Americans with pigmented skin. Interestingly, in a "vitamin D paradox," Black Americans with markedly low levels of vitamin D are still found to have high bone density levels compared to white Americans. Further research in this area is needed to determine next steps and gather data on the actual benefits of treating Black Americans for vitamin D deficiency.

Emerging Science BoxKlotho Protein and Aging

Klotho is a protein known to have antiaging effects and is expressed primarily in the kidney distal tubules, parathyroid glands, and choroid plexus of the brain and in lesser amounts in many other organ tissues. The transmembrane form of Klotho protein functions as an obligatory co-receptor with endocrine fibroblast growth factor-23 (FGF23), which is important for the regulation of vitamin D metabolism and subsequently blood phosphate levels. In addition, the extracellular domain of the protein is secreted into the blood, cerebrospinal fluid, and urine. Decreased plasma, urinary, and renal Klotho levels are associated with normal aging, chronic kidney disease, salt-sensitive hypertension, cancers, osteoporosis, atherosclerosis, coronary artery disease, and increased mortality. Klotho also is known to have a tumor suppressor function. In contrast, overexpression of the Klotho gene results in reversal of the aging process, neuroprotection, and increased longevity in mammals. Klotho may derive much of its antiaging powers from its ability to regulate telomerase length and activity in stem cells. Finally, the Klotho protein is a powerful regulator of a wide variety of cellular transport systems, including ion channels, transport proteins, and the Na^+-K^+-ATPase pump. These functions can be stimulatory or inhibitory, and more research is needed to determine how these processes have antiaging effects and how their disruption contributes to disease. Recombinant human Klotho protein has been developed, and efforts are in progress to target its function in both health and disease.

Chapter Outline

OUTLINE

Mechanisms of Hormonal Alterations 688

Alterations of the Hypothalamic–Pituitary System 688
- Diseases of the Posterior Pituitary 688
- Syndrome of Inappropriate Antidiuretic Hormone Secretion 689
- Diseases of the Anterior Pituitary 691

Alterations of Thyroid Function 694
- Thyrotoxicosis/Hyperthyroidism 694
- Hypothyroidism 697

Alterations of Parathyroid Function 700
- Hyperparathyroidism 700
- Hypoparathyroidism 701

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus 702
- Types of Diabetes Mellitus 702
- Acute Complications of Diabetes Mellitus 709
- Chronic Complications of Diabetes Mellitus 711

Alterations of Adrenal Function 715
- Disorders of the Adrenal Cortex 715
- Tumors of the Adrenal Medulla 718

Functions of the endocrine system involve complex interactions between hormones and most body systems that maintain dynamic steady states and influence tissue growth and reproductive capabilities. Endocrine system dysfunction is usually caused by hypersecretion or hyposecretion of the various hormones, leading to abnormal hormone concentrations in the blood. Dysfunction also may result from abnormal cell receptor function or from altered intracellular response to the hormone–receptor complex.

Mechanisms of Hormonal Alterations

Significantly elevated or significantly depressed hormone levels may result from two primary mechanisms: (1) inappropriate amounts of hormone delivered to the target cell, or (2) inappropriate responses by the target cell (Table 22.1). Inappropriate amounts of hormone can result from disorders of endocrine glands, causing them to synthesize too little or too much hormone, failure of feedback systems designed to control hormone release, dysfunctional or ectopically produced hormones (hormones produced from nonendocrine sources), or defects in delivery of the hormone in the bloodstream.

Table 22.1

Mechanisms of Hormone Alterations

Inappropriate Amounts of Hormone Delivered to Target Cell	**Inappropriate Response by Target Cell**
Inadequate Hormone Synthesis	**Cell Surface Receptor–Associated Disorders**
1. Inadequate quantity of hormone precursors 2. Secretory cell unable to convert precursors to active hormone	1. Decrease in the number of receptors 2. Impaired receptor function 3. Presence of antibodies against specific receptors
Failure of Feedback Systems	
1. Do not recognize positive feedback, leading to inadequate hormone synthesis 2. Do not recognize negative feedback, leading to excessive hormone synthesis	
Dysfunctional or Ectopic Hormones	Intracellular Disorders
1. Inadequate biologically free hormone 2. Hormone degraded at an altered rate 3. Circulating inhibitors 4. Ectopic production of hormones	1. Inadequate synthesis of a second messenger 2. Intracellular enzymes or proteins are altered
Dysfunctional Delivery System	

Inappropriate Amounts of Hormone Delivered to Target Cell	Inappropriate Response by Target Cell
Inadequate Hormone Synthesis	**Cell Surface Receptor–Associated Disorders**
1. Inadequate blood supply 2. Inadequate carrier proteins	

Inappropriate Amounts of Hormone Delivered to Target Cell	Inappropriate Response by Target Cell
Inadequate Hormone Synthesis	**Cell Surface Receptor–Associated Disorders**
1. Inadequate quantity of hormone precursors 2. Secretory cell unable to convert precursors to active hormone	1. Decrease in the number of receptors 2. Impaired receptor function 3. Presence of antibodies against specific receptors
Failure of Feedback Systems	
1. Do not recognize positive feedback, leading to inadequate hormone synthesis 2. Do not recognize negative feedback, leading to excessive hormone synthesis	
Dysfunctional or Ectopic Hormones	Intracellular Disorders
1. Inadequate biologically free hormone 2. Hormone degraded at an altered rate 3. Circulating inhibitors 4. Ectopic production of hormones	1. Inadequate synthesis of a second messenger 2. Intracellular enzymes or proteins are altered
Dysfunctional Delivery System	
1. Inadequate blood supply 2. Inadequate carrier proteins	

Target cells may not respond appropriately to hormonal stimulation for a number of reasons. Target cells may have too many or too few cell surface receptors. Those receptors may be abnormal and insensitive, or they may be blocked or stimulated by antibodies. There also may be intracellular disorders that cause a failure of the target cell to respond to receptor stimulation. For example, there may be inadequate synthesis of second messengers, such as cyclic adenosine monophosphate (cAMP), or the cell may respond abnormally to the second messenger if levels of intracellular enzymes or proteins are altered (second messengers for various hormones are listed in Table 21.2).

Alterations of the Hypothalamic–Pituitary System

The most common cause of apparent hypothalamic dysfunction is interruption of the pituitary stalk. Such interruptions prevent hypothalamic hormones from reaching the pituitary gland. Damage to the

pituitary stalk can be caused by destructive lesions, rupture after head injury, surgical transection, or tumor. Without hypothalamic hormones, the pituitary releases inadequate amounts of follicle-stimulating hormone (FSH), luteinizing hormone (LH), adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and growth hormone (GH) (Fig. 22.1). The control of prolactin is predominantly inhibitory by hypothalamic dopamine. It does not have endocrine target tissue and therefore lacks a regulatory feedback pathway. The effects of these changes in pituitary hormones are discussed later in this chapter.

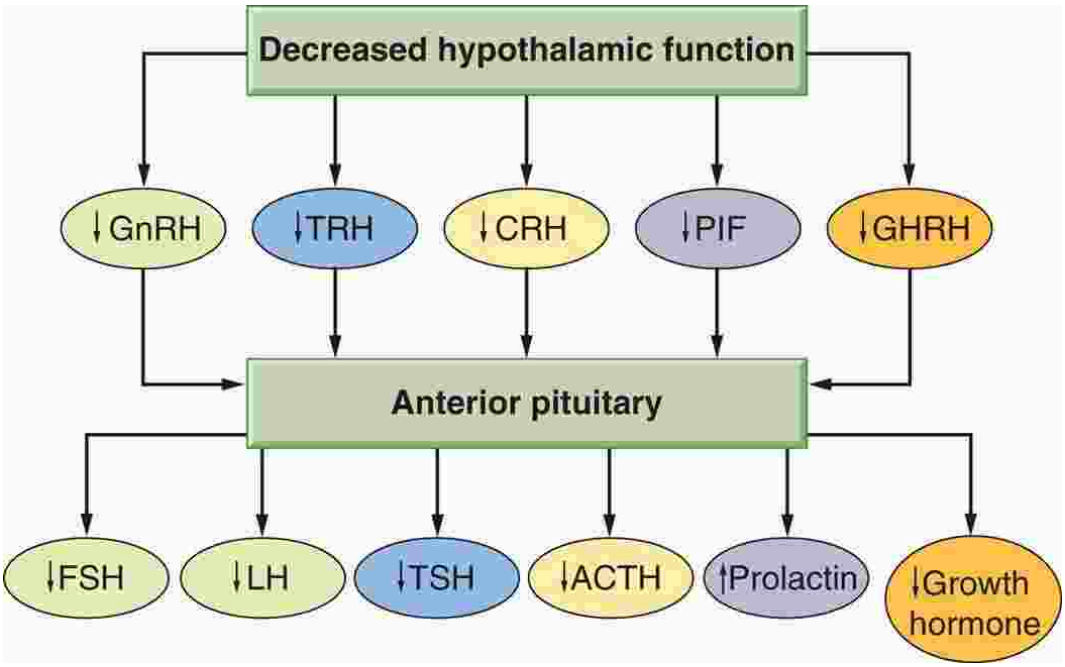

FIG. 22.1 Loss of Hypothalamic Hormones.
ACTH, Adrenocorticotropic hormone; *CRH*, corticotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *GHRH*, growth hormone–releasing hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *PIF*, prolactin inhibitory factor (probably dopamine); *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

A flowchart represents the loss of hypothalamic hormones. Decreased hypothalamic functions include decreased G n R H, T R H, C R H, P I F, and G H R H, which trigger the anterior pituitary in releasing the following: â€¢ Decreased F S H. â€¢ Decreased L H. â€¢ Decreased T S H. â€¢ Decreased A C T H. â€¢ Increased Prolactin. â€¢ Decreased Growth Hormone.

Diseases of the Posterior Pituitary

Diseases of the posterior pituitary cause either increased or decreased secretion of antidiuretic hormone (ADH, arginine vasopressin [AVP]). An excess amount of this hormone results in water retention, whereas deficiencies in the amount or response to ADH result in water loss. These complex pathophysiologic states not only have significant clinical effects on the modulation of body fluids and electrolytes, but also affect cognitive and emotional responses to stress.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The syndrome of inappropriate ADH secretion (SIADH) results from ADH release in the absence of normal physiologic stimuli from the pituitary gland, nonpituitary sources of ADH, or the continued action of ADH on vasopressin receptors.[1,2] SIADH is characterized by hypotonic and euvolemic hyponatremia along with urinary hyperosmolarity. SIADH can be idiopathic or due to multiple causes including neurological disease, pulmonary disease, malignant diseases, medications, or acute conditions such as stress, pain, and general anesthesia. Non-osmotic stimuli also mediate release of ADH via the afferent parasympathetic nervous system from high- and low-pressure receptors in the atria and carotid and artery during hemodynamic stress. Central nervous system disorders that may cause SIADH include encephalitis, meningitis, intracranial hemorrhage, tumors, and trauma. Pulmonary disorders associated with SIADH include pneumonia (e.g., tuberculosis), asthma, cystic fibrosis, and respiratory failure requiring mechanical ventilation. A common cause of SIADH is the ectopic production of ADH by tumors, such as cancers of the lung, stomach, pancreas, bladder, prostate, and endometrium; lymphomas; and sarcomas.

Iatrogenic causes of SIADH include surgery and medications. Any surgery can result in increased ADH secretion for as long as 5 to 7 days after surgery. The precise mechanism is uncertain, but likely related to fluid and volume changes after surgery, the amount and type of intravenous fluids given, and the use of narcotic analgesics. Medications are an important cause of SIADH, especially in the elderly. These include narcotics, general anesthetics, antidepressants, antipsychotics, chemotherapeutic agents, and nonsteroidal anti-inflammatory drugs.[2]

Pathophysiology

The cardinal features of SIADH are the result of enhanced renal free water retention. ADH induces the insertion of a water channel protein, called *aquaporin-2*, into the tubular luminal membrane, which increases water reabsorption by the kidneys (renal function is discussed in Chapter 37). This results in an expansion of extracellular fluid volume that leads to dilutional hyponatremia (low serum sodium concentration), high urinary osmolarity, high urinary sodium concentration, absence of edema, or clinical signs of volume depletion.[3] Urine is inappropriately concentrated with respect to serum osmolarity because water is reabsorbed that normally would be excreted.

Clinical Manifestations

The symptoms of SIADH result from hyponatremia (see Chapter 3) and are determined by its severity and rapidity of onset. Thirst, impaired taste, anorexia, dyspnea on exertion, fatigue, and dulled sensorium occur when the serum sodium level decreases rapidly. Gastrointestinal (GI) symptoms, including vomiting and abdominal cramps, occur with a drop in sodium concentration from 130 to 120 mEq/L. There is weight gain from water retention, but peripheral edema is absent. Serum sodium levels below 115 mEq/L cause confusion, lethargy, muscle twitching, and convulsions; severe and sometimes irreversible neurologic damage may occur. Symptoms usually resolve with correction of hyponatremia.

Evaluation and Treatment

A diagnosis of SIADH is based on these findings: (1) serum hypoosmolality and hyponatremia, (2) urine hyperosmolarity (i.e., urine osmolality is greater than expected for the concomitant serum osmolality), and (3) the absence of conditions that can alter volume status (e.g., adrenal or thyroid dysfunction, congestive heart failure, or renal insufficiency) (Table 22.2). It is important to remember that the diagnosis of SIADH requires normal renal, cardiac, hepatic, adrenal, and thyroid function. In particular, hypothyroidism and adrenal insufficiency must be excluded.[4]

Table 22.2

Signs and Symptoms of Diabetes Insipidus and Syndrome of Inappropriate Antidiuretic Hormone Secretion

Signs and Symptoms	DI	SIADH
Urine output	High	Low (no hypovolemia)
Urine osmolality	Low (<100–200 mOsm/L)	High (>800 mOsm/L)
Urine specific gravity	Low (<1.010)	High (>1.020)
Serum sodium	Hypernatremia (>145 mEq/L)	Hyponatremia (<135 mEq/L)
Serum osmolality	Hyperosmolar (>300 mOsm/L)	Hypoosmolar (<285 mOsm/L)
Symptoms	Polyuria, thirst, high urine output, signs of dehydration	Water retention, low urine output, nausea, vomiting, mental changes

DI, Diabetes insipidus; *SIADH*, syndrome of inappropriate antidiuretic hormone.

The treatment of SIADH involves the correction of any underlying causal problems, as well as fluid restriction with careful monitoring of serum sodium and neurologic symptoms. In severe SIADH, emergency correction of severe hyponatremia by careful administration of hypertonic saline and administration of vasopressin receptor antagonists (vaptans) may be required. Resolution usually occurs within 3 days. If hyponatremia is corrected too rapidly, a severe neurologic syndrome called *central pontine myelinolysis* can ensue.

Diabetes Insipidus

Diabetes Insipidus (DI) is characterized by insufficient ADH activity, leading to polyuria (frequent urination) and polydipsia (frequent drinking). The three major forms of DI are:

1. *Neurogenic* or *central DI*. Caused by the insufficient secretion of ADH, it occurs when any organic lesion of the hypothalamus, pituitary stalk, or posterior pituitary interferes with ADH synthesis, transport, or release. Causative lesions include primary brain tumors, traumatic brain injury, hypophysectomy, aneurysms, thrombosis, infections, and immunologic disorders. It can also be caused by hereditary disorders that affect ADH genes or result in structural changes in the pituitary gland.
2. *Nephrogenic DI*. Caused by inadequate response of the renal tubules to ADH. Acquired nephrogenic DI is caused by disorders and drugs that damage the renal tubules. These disorders include pyelonephritis, amyloidosis, destructive uropathies, and polycystic kidney disease. Drugs that may induce a reversible form of nephrogenic DI include lithium carbonate, colchicine, amphotericin B, loop diuretics, general anesthetics, and demeclocycline. There are several genetic causes of nephrogenic DI, including a mutation in the gene that codes for aquaporin-2, which is one of the water transport channels in the renal tubule.[5]
3. *Primary polydipsia or Excessive thirst appreciation*. A rare form of DI, called *gestational DI*, is associated with pregnancy in which the level of the vasopressin-degrading enzyme vasopressinase is increased, resulting in ADH deficiency. Clinical manifestations are usually mild and do not require treatment.

Pathophysiology

Individuals with DI have a partial to total inability to concentrate urine. Insufficient ADH activity causes excretion of large volumes of dilute urine, leading to increased plasma osmolality. In conscious individuals, the thirst mechanism is stimulated and induces polydipsia. Dehydration develops rapidly without ongoing fluid replacement. If the individual with DI cannot conserve as much water as is lost in the urine, serum hypernatremia and hyperosmolality occur. Concentrations of other serum electrolytes generally are not affected. Neurogenic (central) DI is the clinical manifestation of destruction of the neurons of the hypothalamus/posterior pituitary axis, with consequent loss of AVP secretion. The syndrome is caused by a wide variety of acquired or congenital lesions.[6]

Clinical Manifestations

The clinical manifestations of DI include polyuria, nocturia, continuous thirst, and polydipsia. The urine output is varied but can increase from the normal output of 1 to 2 L/day to as much as 8 to 12 L/day. Individuals with long-standing DI develop a large bladder capacity and hydronephrosis (see Chapter 38). Neurogenic DI usually has an abrupt onset, whereas nephrogenic DI usually has a more gradual onset. Table 22.2 compares the signs and symptoms of DI and SIADH. A history of lithium therapy may raise the possibility of NDI, whereas previous brain injury or neurosurgical intervention may indicate neurogenic (central) DI.[6]

Evaluation and Treatment

The criteria for the diagnosis of DI include polyuria, polydipsia, low urine specific gravity (<1.010), low urine osmolality (<200 mOsm/kg), hypernatremia, high serum osmolality (300 mOsm or more depending on water intake), and continued diuresis despite a serum sodium level of 145 mEq/L or greater. The diagnosis of DI is generally confirmed through a two-step water deprivation testing in which urine output is maintained despite dehydration. Other measurements that are useful in diagnosis are serum and urine osmolality, serum electrolytes, ADH levels, and radioimmunoassay for AVP. DI must be distinguished from other polyuric states, including diabetes mellitus, osmotically induced diuresis, and psychogenic polydipsia. Therefore, an evaluation for underlying reversible central or renal causes should be undertaken.

Dipsogenic or *primary polydipsia* may be confused with DI, but it is particularly important not to misdiagnose primary polydipsia as neurogenic (central) DI, because inappropriate therapy with desmopressin can lead to dangerous hyponatremia in individuals who continue to drink excessively.[6] Primary polydipsia is usually the result of a psychiatric condition that causes the chronic ingestion of extremely large quantities of fluid, which washes out the renal concentration gradient, resulting in partial resistance to ADH.

Treatment of neurogenic (central) DI is based on the extent of the ADH deficiency. Fluid replacement using oral or intravenous routes is usually adequate. Some individuals require ADH replacement with the synthetic vasopressin analog desmopressin (DDAVP). Once a diagnosis of neurogenic (central) DI is made, magnetic resonance imaging (MRI) of the hypothalamic-pituitary region is required to establish whether there is a structural lesion that is responsible for AVP deficiency. Management of

nephrogenic DI requires treatment of any reversible underlying disorders, discontinuation of etiologic medications, and correction of associated electrolyte disorders.[6] Drugs that potentiate the action of otherwise insufficient amounts of endogenous ADH, such as thiazide diuretics, chlorpropamide, carbamazepine, and clofibrate, may be used in individuals with incomplete ADH deficiency.

Diseases of the Anterior Pituitary

Hypopituitarism

Hypopituitarism is characterized by the absence of one or more anterior pituitary hormones or the complete failure of all anterior pituitary hormone functions.[7] The most common causes of hypopituitarism are pituitary infarction or space-occupying lesions. Pituitary infarction may occur when there is significant blood loss or hypovolemic shock. This also may occur in women during the postpartum period (Sheehan syndrome). Space-occupying lesions include pituitary adenomas or aneurysms, which can enlarge and compress the pituitary gland. Other causes of hypopituitarism include traumatic brain injury, removal or destruction of the gland, infections (e.g., meningitis, syphilis, tuberculosis), autoimmune hypophysitis, and certain drugs (e.g., bexarotene, carbamazepine, ipilimumab). A rare congenital form of hypopituitarism results from an early mutation of the prophet of pituitary transcription factor *(PROP-1)* gene, which affects embryonic pituitary development.

Pathophysiology

The pituitary gland is highly vascular and relies heavily on portal blood flow from the hypothalamus. It is therefore vulnerable to ischemia and infarction. Infarction results in tissue necrosis and edema with swelling of the gland. Over time, fibrosis of pituitary tissue occurs, and the symptoms of hypopituitarism develop. Adenomas and aneurysms may compress otherwise normal secreting pituitary cells and lead to compromised hormonal output. These lesions further impede blood supply because of enlargement of the pituitary within the fixed compartment of the sella turcica.

Clinical Manifestations

The signs and symptoms of hypofunction of the anterior pituitary are variable and depend on which hormones are affected. In panhypopituitarism, all hormones are deficient, and the individual suffers from multiple complications.

ACTH deficiency with associated loss of cortisol is a potentially life-threatening disorder. Symptoms of cortisol insufficiency include nausea, vomiting, anorexia, fatigue, and weakness. Hypoglycemia results from increased insulin sensitivity, decreased glycogen reserves, and decreased gluconeogenesis associated with hypocortisolism. ACTH deficiency also is associated with changes in aldosterone secretion, with resulting decreases in the glomerular filtration rate and urine output.

TSH deficiency causes cold intolerance, skin dryness, lethargy, and decreased metabolic rate. The symptoms usually are less severe than those of primary hypothyroidism.

The onset of FSH and LH deficiencies in women of reproductive age is associated with amenorrhea and atrophy of the vagina, uterus, and breasts. In postpubertal males, the testicles atrophy and facial hair growth is diminished. Both men and women experience decreased body hair and diminished libido.

GH deficiency in children is manifested by growth failure and a condition known as *hypopituitary dwarfism* (Fig. 22.2). Symptoms of chronic adult GH deficiency syndrome include increased body fat, decreased strength and lean body mass, osteoporosis, reduced sweating, dry skin, and psychological problems, including depression, social withdrawal, fatigue, loss of motivation, and a diminished feeling of well-being. Dyslipidemias and atherosclerotic cardiovascular disease may occur.

FIG. 22.2 Hypopituitary Dwarfism and Pituitary Giantism.
A pituitary giant and dwarf contrasted with normal-size men. Excessive secretion of growth hormone by the anterior lobe of the pituitary gland during the early years of life produces giants of this type, whereas deficient secretion of this substance produces well-formed dwarfs. (From Enderle A. Dwarfism and gigantism in historical picture postcards. *Journal of the Royal Society of Medicine*, 1998;91(5):273–278. https://doi.org/10.1177/014107689809100511)

A black-and-white historical photo shows the brothers, Hugo and Adrien, both 230 centimeters tall, standing together. While the brothers have pituitary giantism. Adrien, 69 centimeters, standing between them, has hypopituitary dwarfism and stands just as tall as the brothersâ€™ knees.

Evaluation and Treatment

The diagnostic evaluation of suspected pituitary disease includes simultaneous measurements of the levels of tropic hormones from the pituitary and target endocrine glands. Imaging of the pituitary (MRI or computed tomography [CT] scans) is critical to assess for anatomic lesions, such as tumors.

Management of hypopituitarism requires correction of the underlying disorder as quickly as possible. Replacement of target gland hormones that are deficient is essential (such as cortisol, thyroid hormone (TH), GH, and sex-specific steroid hormones). In cases of acute circulatory collapse, immediate therapy with glucocorticoids and intravenous fluids is critical.

Hyperpituitarism: Primary Pituitary Neuroendocrine Tumors

Pituitary neuroendocrine tumors (previously known as pituitary adenomas) usually are benign, slow-growing tumors that arise from cells of the anterior pituitary.[8] The cause of pituitary neuroendocrine tumors is

not known, and most occur sporadically. Altered gene expression is commonly detected, and familial pituitary neuroendocrine tumors occur as part of syndromes affecting other organs, such as multiple endocrine neoplasia type 1. About 50% are microscopic (microadenomas) found incidentally, are hormonally silent, and do not pose significant hazards to the individual. Larger tumors (macroadenomas) are associated with morbidity and mortality attributable to alterations in hormone secretion or to invasion or impingement of surrounding structures.[9,10]

Pathophysiology

Local expansion of the neuroendocrine tumor may impinge on the optic chiasma and cause various visual disturbances. If the tumor is locally aggressive, invasion of the cavernous sinuses may occur, resulting in compromise of cranial nerve function. Extension to the hypothalamus disturbs control of wakefulness, thirst, appetite, and temperature.

Hormonal effects of a neuroendocrine tumor include hypersecretion from the tumor itself and hyposecretion from surrounding pituitary cells. The adenomatous tissue secretes the hormone of the cell type from which it arose, without regard to regulatory feedback mechanisms (autonomous function). Because of the pressure exerted by the tumor in the unexpandable bony sella turcica, hyposecretion from those cells that are most sensitive to pressure is common (FSH-and LH-secreting cells).

Clinical Manifestations

The clinical manifestations of pituitary neuroendocrine tumors are related to tumor growth and hormone hypersecretion or hyposecretion. Increased tumor size causes headache, fatigue, neck pain or stiffness, and seizures. Visual changes include visual field impairments (often beginning in one eye and progressing to the other) and temporary blindness. If the tumor infiltrates other cranial nerves, neuromuscular function is affected.

Pituitary neuroendocrine tumors are most often associated with increased secretion of GH and prolactin. Gonadotropic hyposecretion results in menstrual irregularity in women, decreased libido, and receding secondary sex characteristics in both men and women. If the tumor exerts sufficient pressure, thyroid and adrenal hypofunction may occur because of a lack of TSH and ACTH, resulting in the symptoms of hypothyroidism and hypocortisolism, respectively.

Evaluation and Treatment

Diagnosis of pituitary neuroendocrine tumor involves physical and laboratory evaluations, including pertinent hormone assays and radiographic examination of the skull (MRI [preferred] or contrast-enhanced CT). The goal of treatment is to protect the individual from the effects of tumor growth and to control hormone hypersecretion while minimizing damage to appropriately secreting portions of the pituitary. Depending on tumor size and type, individuals may be treated by administration of specific medications to suppress tumor growth, transsphenoidal tumor resection, or radiation therapy, including stereotactic treatments.

Hypersecretion of Growth Hormone: Acromegaly

Acromegaly results from increased release of GH and insulin-like growth factor 1 (IGF-1). It almost always is caused by a GH-secreting pituitary neuroendocrine tumor.[11] Acromegaly is usually diagnosed in adults in the 40- to 59-year-old age group, although it is often present for years before diagnosis. It is a slow progressive disease and, if untreated, is associated with a decreased life expectancy. Deaths from acromegaly are caused by heart disease secondary to hypertension and coronary artery disease, stroke, diabetes mellitus, or malignancy (colon or lung cancers).

Pathophysiology

With a GH-secreting neuroendocrine tumor, only slight elevations of GH and IGF-1 can stimulate growth. In children and adolescents whose epiphyseal plates have not yet closed, the effect of increased GH levels is termed giantism (see Fig. 22.2). Skeletal growth is excessive, with some individuals becoming 8 or 9 feet tall. In the adult, epiphyseal closure has occurred, and increased amounts of GH and IGF-1 cause connective tissue proliferation and increased cytoplasmic matrix, as well as bony proliferation that results in the characteristic appearance of acromegaly (Fig. 22.3).

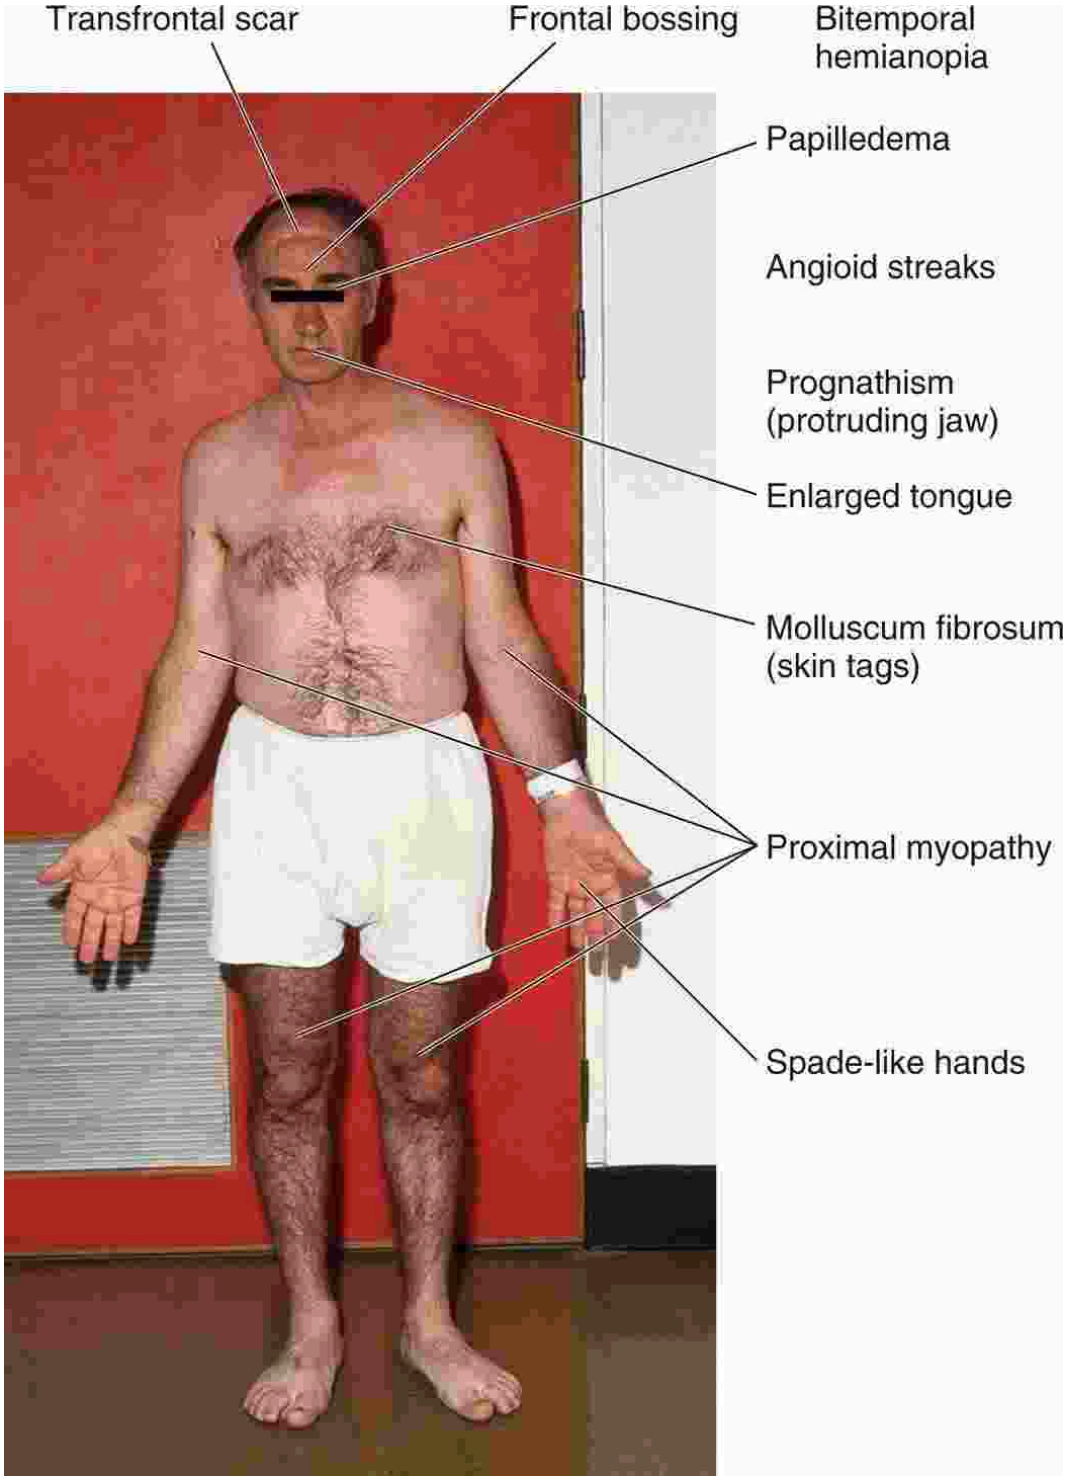

FIG. 22.3 Acromegaly. (From Talley NJ, O'Connor S. Clinical examination, 7th edition. Australia: Churchill Livingstone; 2014.)

A photo of the anterior profile of a person with acromegaly shows and labels the different conditions on the body, from the top to the bottom: transfrontal scar, frontal bossing, bitemporal hemianopia, papilledema, angioid streaks, prognathism (protruding jaw), enlarged tongue, molluscum fibrosum (skin tags), proximal myopathy, and spade-like hands.

GH also has significant effects on glucose, lipid, and protein metabolism. Hyperglycemia results from adipocyte inflammation and GH inhibition of peripheral glucose uptake and increased hepatic glucose production, followed by compensatory hyperinsulinism and, finally, insulin resistance. Diabetes mellitus occurs when the pancreas cannot secrete enough insulin to offset the effects of GH. Excessive levels of GH and IGF-1 also affect the cardiovascular system with calcium influx in cardiomyocytes, enhanced cardiac contractility, and cardiomyocyte growth. Hypertension, cardiomegaly, and left ventricular heart failure are seen in one-third to one-half of individuals with acromegaly. GH also acts on the renal tubules to increase phosphate reabsorption, leading to mild hyperphosphatemia. Approximately 20% of GH-secreting tumors also secrete prolactin. Because the adenoma becomes increasingly a space-occupying lesion, hypopituitarism may occur because of compression of surrounding hormone-secreting cells.

Clinical Manifestations

With connective tissue proliferation, individuals with acromegaly have an enlarged tongue, interstitial edema, enlarged and overactive sebaceous and sweat glands (leading to increased body odor), and coarse skin and body hair. Bony proliferation involves periosteal vertebral growth and enlargement of the bones of the face, hands, and feet (see Fig. 22.3). The lower jaw and forehead also protrude.

Increased IGF-1 levels cause ribs to elongate at the bone–cartilage junction, leading to a barrel-chested appearance, and increased proliferation of cartilage in joints, which causes backache and arthralgias. With bony and soft tissue overgrowth, nerve entrapment occurs, leading to

peripheral nerve damage manifested by weakness, muscular atrophy, foot drop, and sensory changes in the hands.

Symptoms of diabetes mellitus, such as polyuria and polydipsia, may occur. Acromegaly-associated hypertension is usually asymptomatic until heart failure symptoms develop. Increased tumor size results in central nervous system symptoms of headache, seizure activity, visual disturbances, and papilledema. If compression hypopituitarism occurs, gonadotropin secretion may be affected, causing amenorrhea in women and sexual dysfunction in men. Increased prolactin results in hypogonadism.

Evaluation and Treatment

Diagnosis is confirmed by clinical features of the disease, MRI scans, and elevated levels of GH and IGF-1. The goals of treatment are to normalize or reduce GH secretion and relieve or prevent complications related to tumor expansion. The treatment of choice is transsphenoidal surgical removal of the GH-secreting neuroendocrine tumor. Radiation therapy may be effective when rapid control of GH levels is not essential, when the individual is not a good surgical candidate, or when hyperfunction persists after subtotal resection. Somatostatin analogs (e.g., octreotide or lanreotide) normalize IGF-1 and GH levels. Dopaminergic agonists may be helpful, especially if the tumor also secretes prolactin. Cardiovascular, metabolic, and symptoms of tumor compression often improve with treatment. Skeletal abnormalities are irreversible.

Prolactinoma

Pituitary tumors that secrete prolactin, prolactinomas, are the most common hormonally active pituitary tumors. Other conditions, such as renal failure, polycystic ovarian disease, primary hypothyroidism, breast stimulation, or even the stress of venipuncture, can increase prolactin levels. Prolactin is under tonic inhibitory hypothalamic control through the secretion of dopamine. Thus, medications that block the effects of dopamine can increase prolactin levels. These include some antipsychotics, metoclopramide, tricyclic antidepressants, and methyldopa. Estrogens can increase prolactin concentration by stimulating hyperplasia of prolactin-secreting cells. Any process that interferes with the delivery of dopamine from the hypothalamus to the lactotrophs (pituitary stalk tumor, pituitary stalk transection, or compressive pituitary tumor) also results in hyperprolactinemia. Because thyrotropin-releasing hormone (TRH)

stimulates prolactin secretion, prolactin may be elevated in individuals with primary hypothyroidism.

Pathophysiology

The hallmark of a prolactinoma is sustained increases in the levels of serum prolactin, also known as hyperprolactinemia, which has multiple effects on female and male reproductive organs.[12] Pathologic elevations of prolactin suppress LH and FSH, resulting in estrogen and progesterone deficiency in women and low testosterone levels in men.

Hypopituitarism may occur because of the compression of surrounding hormone-secreting cells. Central nervous system symptoms may develop because of growth and pressure of the tumor within the sella turcica. These complications are especially common with what are called macro (>1 cm in diameter) or giant (>4 cm in diameter) prolactinomas.

Clinical Manifestations

Women with hyperprolactinemia generally present with galactorrhea (nonpuerperal milk production) and menstrual disturbances, including amenorrhea. Estrogen deficiency also may cause hirsutism, and fractures may occur because of osteopenia or osteoporosis. Hyperprolactinemia in men causes gynecomastia, hypogonadism, and erectile dysfunction, although they often are not diagnosed until they develop symptoms related to the increasing size of the tumor (i.e., headache or visual impairment).

Evaluation and Treatment

The diagnostic evaluation of hyperprolactinemia includes a careful history to exclude medications that may cause elevations in prolactin concentration. Screening for hypothyroidism is mandatory. MRI scanning of the pituitary is indicated to determine the size and location of an adenoma.

Dopaminergic agonists (bromocriptine and cabergoline) are the treatment of choice for prolactinomas. Decreases in tumor size and restoration of fertility in previously anovulatory women are common. In individuals resistant or intolerant to these medications, transsphenoidal surgery and radiotherapy are options. New chemotherapeutic and targeted molecular therapies are being explored in selected cases.

Alterations of Thyroid Function

Disorders of thyroid function develop as a result of primary dysfunction or disease of the thyroid gland or, secondarily, as a result of pituitary or hypothalamic alterations. Primary thyroid disorders result in either increased or decreased TH levels. These disorders also cause secondary feedback effects on pituitary TSH. For example, when there are primary elevations in the TH level, the TSH level will secondarily decrease because of negative feedback. When the TH level is decreased because of a condition affecting the thyroid gland, the TSH level will be elevated. Central (secondary) thyroid disorders are related to disorders of the anterior pituitary gland that affect thyroid function. When there is excessive TSH production, the thyroid follicular cells are stimulated and secrete excessive THs. The TH levels become elevated secondary to the primary elevation of the TSH concentration. The reverse is true with inadequate TSH production.

The majority of primary thyroid diseases are idiopathic and caused by autoimmune mechanisms that affect the gland. Although the exact genetic and environmental influences are not known, some individuals experience a predominantly cellular autoimmune response (some antithyroid autoantibodies also are involved) with resultant destruction of the thyroid gland, leading to hypothyroidism. Others experience a predominantly antibody-mediated autoimmune response that stimulates the gland, leading to hyperthyroidism. The most common autoimmune hypothyroid condition is called *chronic lymphocytic thyroiditis (also called Hashimoto thyroiditis)* with thyroid infiltration of T lymphocytes and follicular destruction.[13] The most common autoimmune hyperthyroid condition is called *Graves disease* (Fig. 22.4).[14,15]

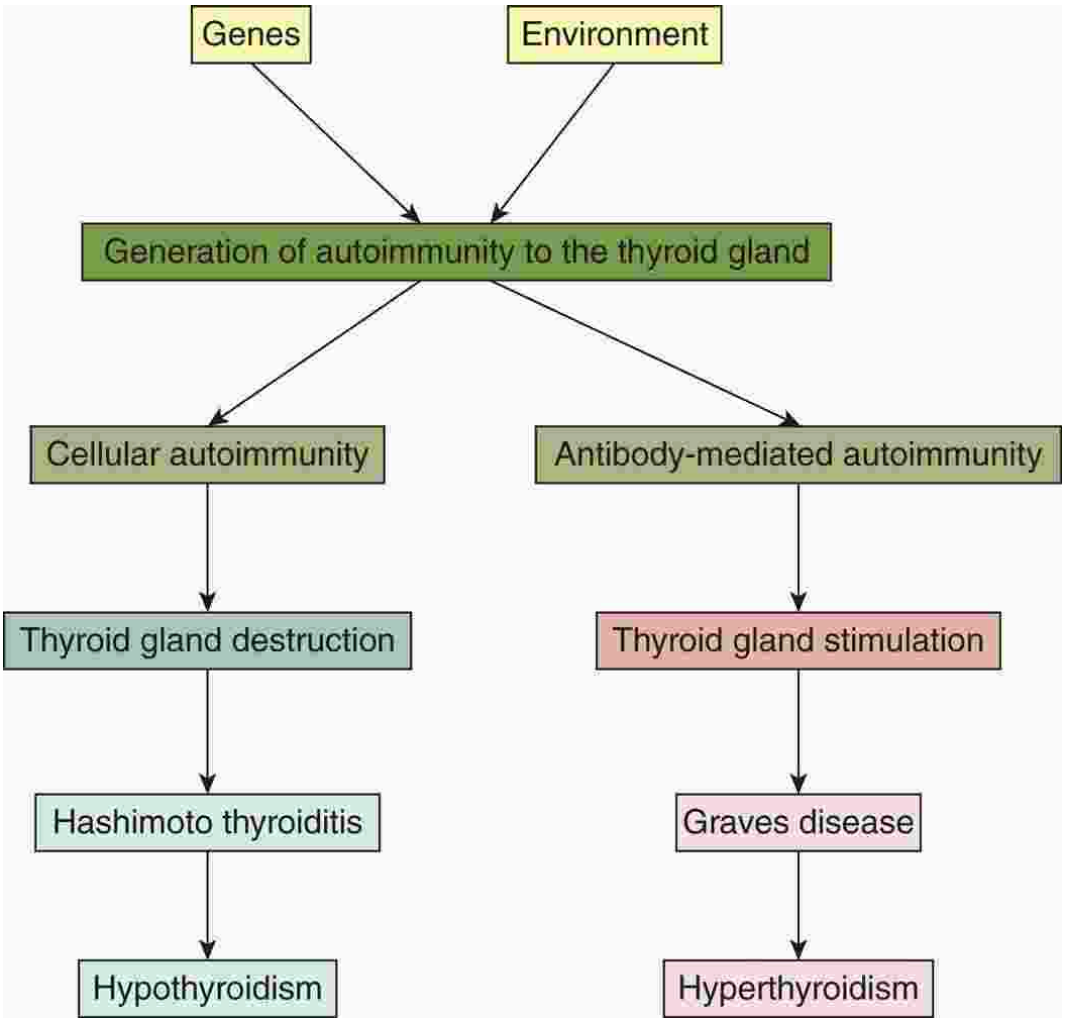

FIG. 22.4 Autoimmune Mechanisms in Primary Thyroid Disease.

A flowchart represents the autoimmune mechanisms in primary thyroid disease. Genes and environment impact the generation of autoimmunity to the thyroid gland. Two pathways are charted. The pathway leading to hypothyroidism is as follows. â€¢ Cellular autoimmunity. â€¢ Thyroid gland destruction. â€¢ Hashimoto thyroiditis. â€¢ Hypothyroidism. The pathway leading to hyperthyroidism is as follows. â€¢ Antibody-mediated

autoimmunity. â€¢ Thyroid gland stimulation. â€¢ Graves disease. â€¢ Hyperthyroidism.

Thyrotoxicosis/Hyperthyroidism

Pathophysiology

Thyrotoxicosis is a condition that results from any cause of increased TH levels and can result from dysfunction of the pituitary, the thyroid gland, ectopic thyroid tissue, or the ingestion of excessive amounts of TH medication. Hyperthyroidism is a form of thyrotoxicosis in which excess amounts of TH are secreted from the thyroid gland (Fig. 22.5).[16] *Primary hyperthyroidism* results from thyroid gland dysfunction and is most commonly caused by Graves disease, toxic multinodular goiter, and solitary toxic adenoma. *Central (secondary) hyperthyroidism* is less common and is caused by TSH-secreting pituitary adenomas. Each condition is associated with a specific pathophysiology and manifestations; however, all forms of thyrotoxicosis share some common characteristics.

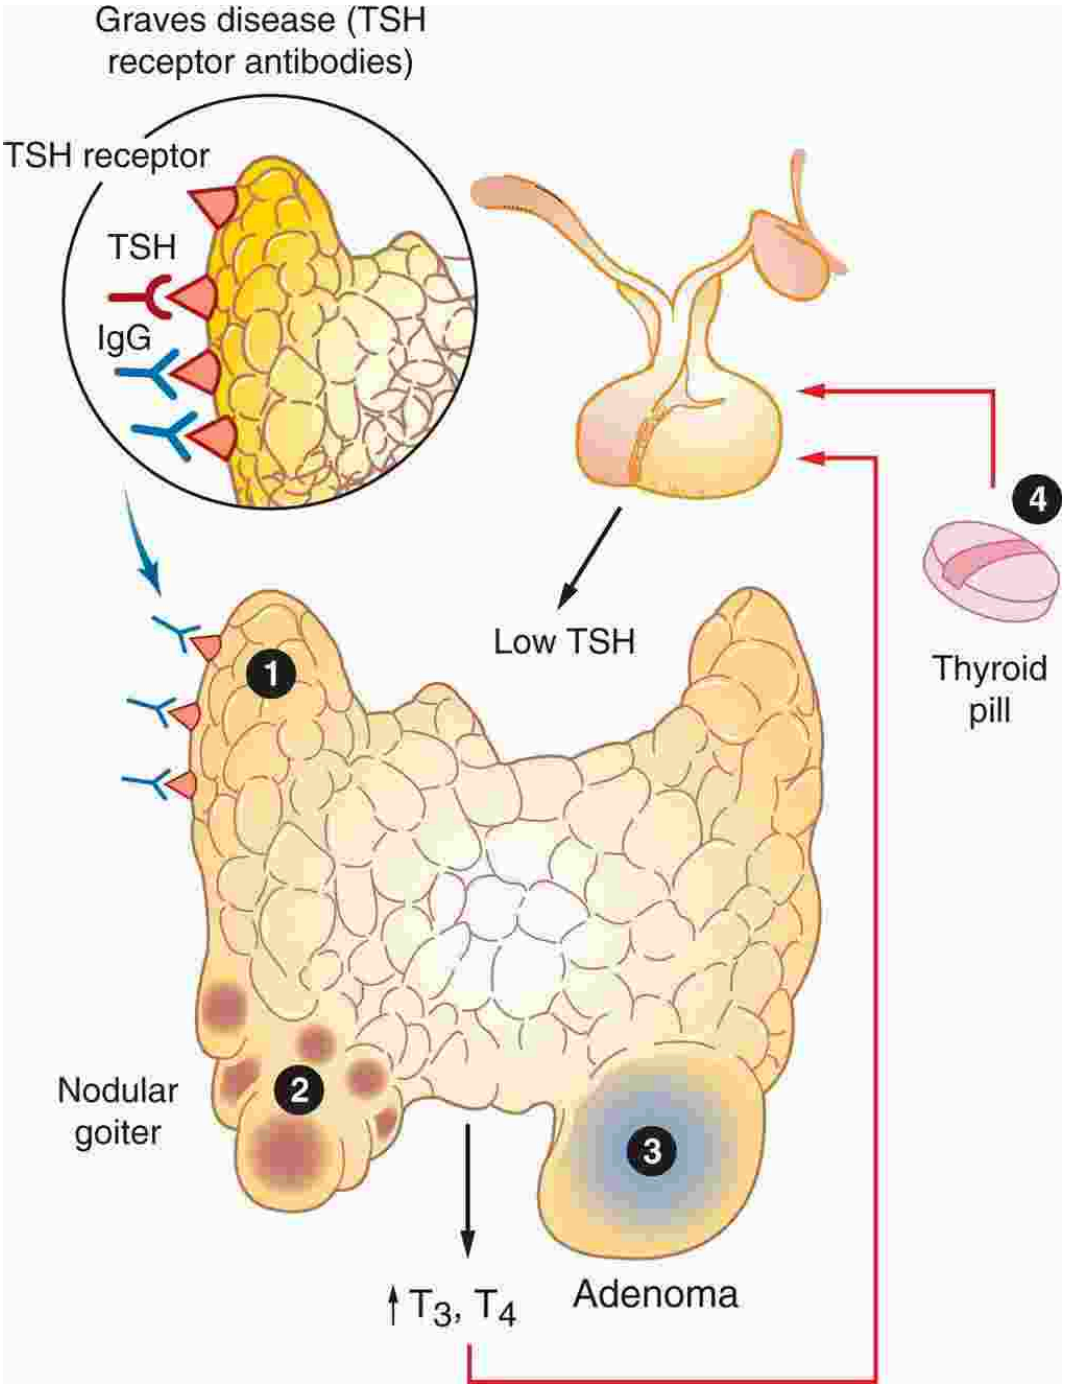

FIG. 22.5 Common Causes of Hyperthyroidism. Hyperthyroidism may have several causes, among them: *1*, Graves disease; *2*, toxic multinodular goiter; *3*, follicular adenoma; *4*, thyroid medication. *TSH*, thyroid stimulating hormone. (Adapted from Damjanov I. *Pathology for the health professions*, 4th edition. St Louis: Saunders; 2012.)

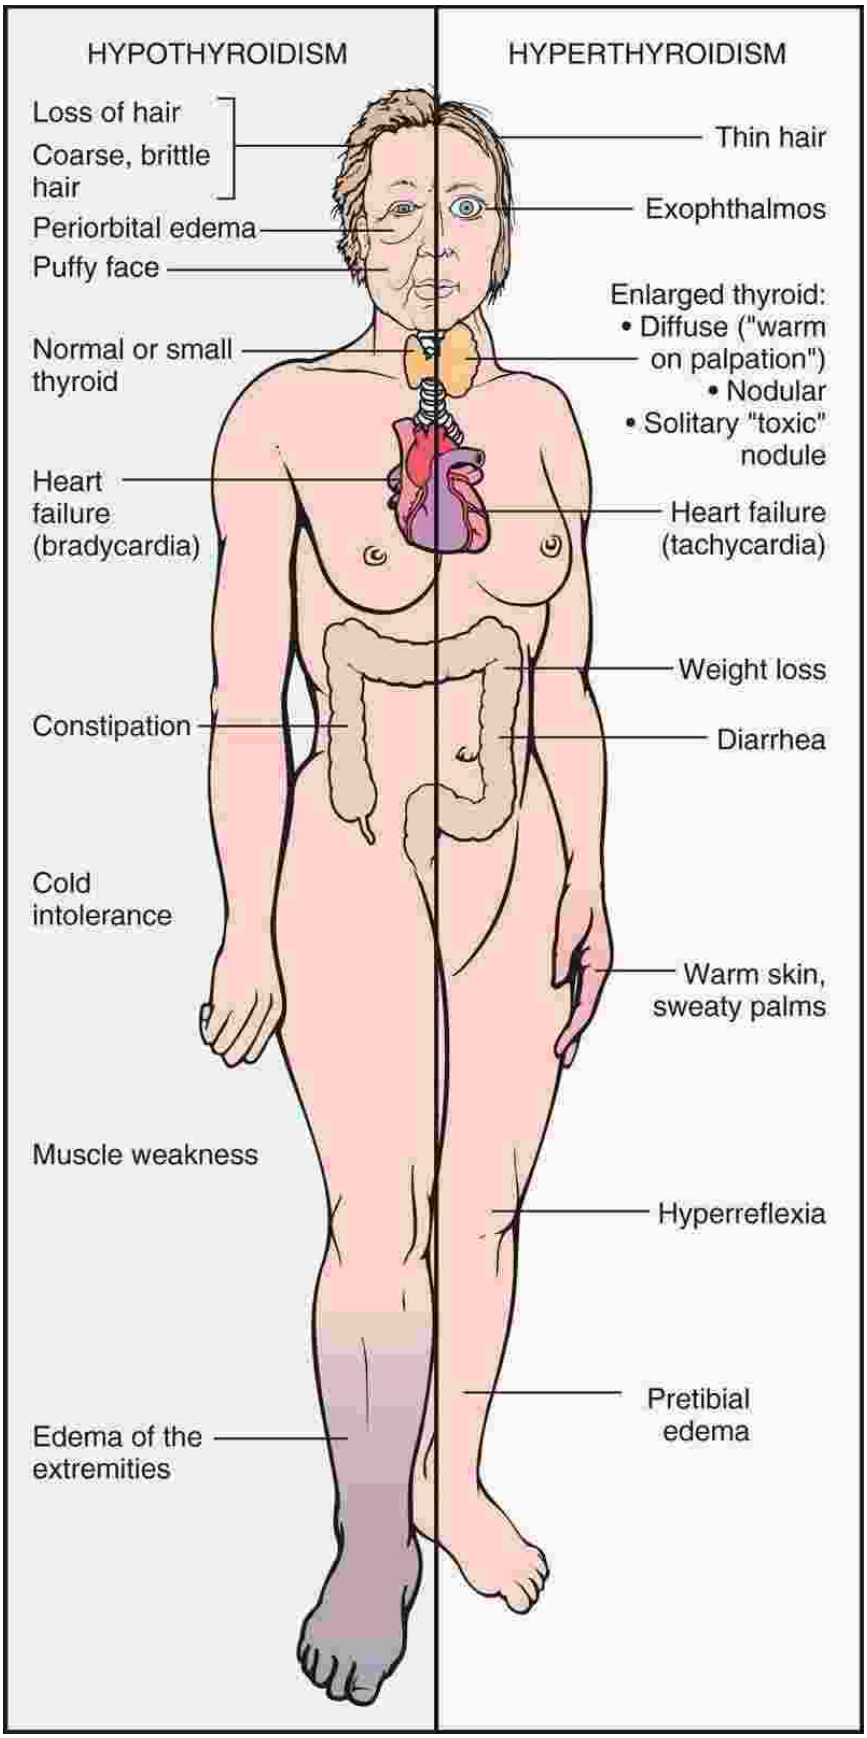
An illustration of the thyroid highlights the following common causes of hyperthyroidism. 1. Graves disease (T S H receptor antibodies). T S H receptors attract T S H and I g G. 2. Nodular goiter. The illustration shows multiple fluid-filled lumps on the thyroid. 3. Adenoma. The illustration shows a large tumor on the thyroid. 4. Thyroid pill. The illustration shows that the ingestion of the pill results in a low T S H, leading to increased T 3 and T 4, which provides a feedback loop.

Clinical Manifestations

The clinical features of thyrotoxicosis are attributable to the metabolic effects of increased circulating levels of THs. This results in an increased metabolic rate, with heat intolerance and increased tissue sensitivity to stimulation by the sympathetic nervous system. The major manifestations are summarized in Fig. 22.6 and Table 22.3.



HYPOTHYROIDISM
HYPERTHYROIDISM
Loss of hair
Coarse, brittle hair
Periorbital edema
Puffy face
Normal or small thyroid
Heart failure (bradycardia)
Constipation
Cold intolerance
Muscle weakness
Edema of the extremities
Thin hair
Exophthalmos
Enlarged thyroid:
• Diffuse ("warm on palpation")
• Nodular
• Solitary "toxic" nodule
Heart failure (tachycardia)
Weight loss
Diarrhea
Warm skin, sweaty palms
Hyperreflexia
Pretibial edema

FIG. 22.6 Clinical Manifestations of Hyperthyroidism and Hypothyroidism. (From Damjanov I. *Pathology for the health professions*, 4th edition. St Louis: Saunders; 2012.)

An illustration of the anterior view of a person highlights the manifestations for hypothyroidism and hyperthyroidism. The manifestations for hypothyroidism, identified from the top to the bottom, are as follows. â€¢ Loss of hair or coarse, brittle hair. â€¢ Periorbital edema. â€¢ Puffy face. â€¢ Normal or small thyroid. â€¢ Heart failure (bradycardia). â€¢ Constipation. â€¢ Cold intolerance. â€¢ Muscle weakness. â€¢ Edema of the extremities. The manifestations for hyperthyroidism, identified from the top to the bottom, are as follows. â€¢ Thin hair. â€¢ Exophthalmos. â€¢ Enlarged thyroid: diffuse (warm on palpation), nodular, solitary toxic nodule. â€¢ Heart failure (tachycardia). â€¢ Weight loss. â€¢ Diarrhea. â€¢ Warm, skin, sweaty palms. â€¢ Hyperreflexia. â€¢ Pretibial edema.

Table 22.3

Systemic Manifestations of Hyperthyroidism

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
Endocrine	Enlarged thyroid gland (goiter) (97%–99% of cases); systolic or continuous bruit over thyroid; increased cortisol degradation; hypercalcemia and decreased parathyroid hormone secretion; diminished sensitivity to exogenous insulin	Hyperactivity of the thyroid gland; excess bone resorption leading to hypercalcemia and a disruption of PTH-regulating mechanisms; increased insulin degradation
Reproductive	Oligomenorrhea or amenorrhea; erectile dysfunction and decreased libido; increased serum estradiol and estrone levels but lower than normal levels of free estradiol and estrone	Menstrual cycle alterations that may be related to hypothalamic or pituitary disturbances; increase in sex hormone–binding globulin
Gastrointestinal	Weight loss; increased peristalsis leading to less formed and more frequent stools; nausea, vomiting, anorexia, abdominal pain; increased use of hepatic glycogen stores and of adipose and protein stores; decrease in serum lipid levels (including	Increased catabolism leading to the body's inability to meet its metabolic needs; increased glucose absorption; increase in cholesterol excretion in feces and cholesterol conversion to bile salts; impaired

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
	triglycerides, phospholipids, and cholesterol); changes in vitamin metabolism leading to decrease in tissue stores of vitamins	conversion of B vitamins to their coenzymes, causing increased need for water-soluble and fat-soluble vitamins
Integumentary	Excessive sweating, flushing, and warm skin; heat intolerance; hair fine, soft, and straight; temporary hair loss; nails that grow away from nail beds, palmar erythema	Hyperdynamic circulatory state
Sensory (eyes)	Ocular manifestations including elevated upper eyelid leading to decreased blinking and a staring quality; fine tremor of lid; infiltrative ocular changes associated with Graves disease	Overactivity of Müller muscle; inflammation of retroorbital contents
Cardiovascular	Increased cardiac output and decreased peripheral resistance; tachycardia at rest; loud heart sounds; supraventricular dysrhythmias, left ventricular dilation and hypertrophy	Hypermetabolism and need to dissipate heat
Nervous	Restlessness; short attention span; compulsive	Not clearly defined; alterations in cerebral

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
	movement; fatigue; tremor; insomnia; increased appetite; emotional lability	metabolism resulting from excess thyroid hormone
Pulmonary	Dyspnea; reduced vital capacity	Weakness of respiratory muscles

Evaluation and Treatment. Elevated serum thyroxine (T_4) and triiodothyronine (T_3) levels and suppressed serum TSH levels are diagnostic for primary hyperthyroidism. By contrast, central (secondary) hyperthyroidism caused by TSH-secreting pituitary tumors is characterized by normal to increased TSH levels despite elevated TH concentrations. Treatment is directed at controlling excessive TH production, secretion, or action and involves antithyroid drug therapy, radioactive iodine therapy (absorbed only by thyroid tissue, causing death of cells), or surgical removal of nodules or part of the thyroid gland. A major complication of all forms of treatment for hyperthyroidism is excessive ablation of the gland, leading to hypothyroidism.

Hyperthyroid Conditions

Graves disease

Graves disease is the underlying cause of 60% to 80% of cases of hyperthyroidism with a prevalence of approximately 3% of women and 0.5% of men in the United States.[17] Although the exact cause of Graves disease is not known, genetic factors interacting with environmental triggers play an important role in the pathogenesis. Graves disease is classified as an autoimmune disease and results from a form of type II hypersensitivity (see Chapter 9) in which there is stimulation of the thyroid by autoantibodies directed against the TSH receptor. These autoantibodies, called *thyroid-stimulating immunoglobulins* (TSIs; also called *thyroid-stimulating antibodies* [TSAbs] or *thyroid receptor antibodies* [TRAbs]), override the normal regulatory mechanisms. TSI stimulation of TSH receptors in the gland results in hyperplasia of the gland (goiter) and increased synthesis of TH, especially of T_3. Increased levels of TH result in the classic signs and symptoms of hyperthyroidism illustrated in Fig. 22.6.

TSH production by the pituitary is inhibited through the usual negative feedback loop.

Autoimmunity also contributes to the two major distinguishing clinical manifestations of Graves disease (ophthalmopathy and dermopathy [pretibial myxedema]) (Fig. 22.7). Two categories of ophthalmopathy associated with Graves disease are (1) functional abnormalities resulting from hyperactivity of the sympathetic division of the autonomic nervous system (lag of the globe on upward gaze and of the upper lid on downward gaze) and (2) infiltrative changes involving the orbital contents with enlargement of the ocular muscles. These changes affect more than half of individuals with Graves disease. Orbital connective tissue accumulation, inflammation, and edema of the orbital contents result in exophthalmos (protrusion of the eyeball), periorbital edema, and extraocular muscle weakness leading to diplopia (double vision). The individual may experience irritation, pain, lacrimation, photophobia, blurred vision, decreased visual acuity, papilledema, visual field impairment, exposure keratosis, and corneal ulceration.

FIG. 22.7 Ophthalmopathy and Pretibial Edema in Graves Disease.
(A**)** Exophthalmos (large and protruding eyeballs, often in association with a large goiter). **(B)** Pretibial myxedema associated with Graves disease; note lumpy and swollen appearance from accumulation of connective tissue and pinkish purple discoloration. (A, From Belchetz P, Hammond P. *Mosby's color atlas and text of diabetes and endocrinology*. Edinburgh: Mosby; 2003; B, From Habif T. *Clinical dermatology*, 5th edition. St Louis: Mosby; 2009.)

A small number of individuals with Graves disease who have very high levels of TSI experience pretibial myxedema (Graves dermopathy), characterized by subcutaneous swelling on the anterior portions of the legs and by indurated and erythematous skin. Graves dermopathy is associated with TSI stimulation of fibroblasts and T lymphocytes, causing excessive amounts of hyaluronic acid production in the dermis and subcutaneous tissue. These manifestations occasionally appear on the hands, giving the appearance of clubbing of the fingers (thyroid acropachy). Fig. 22.8 provides an overview of the pathophysiology of Graves disease.

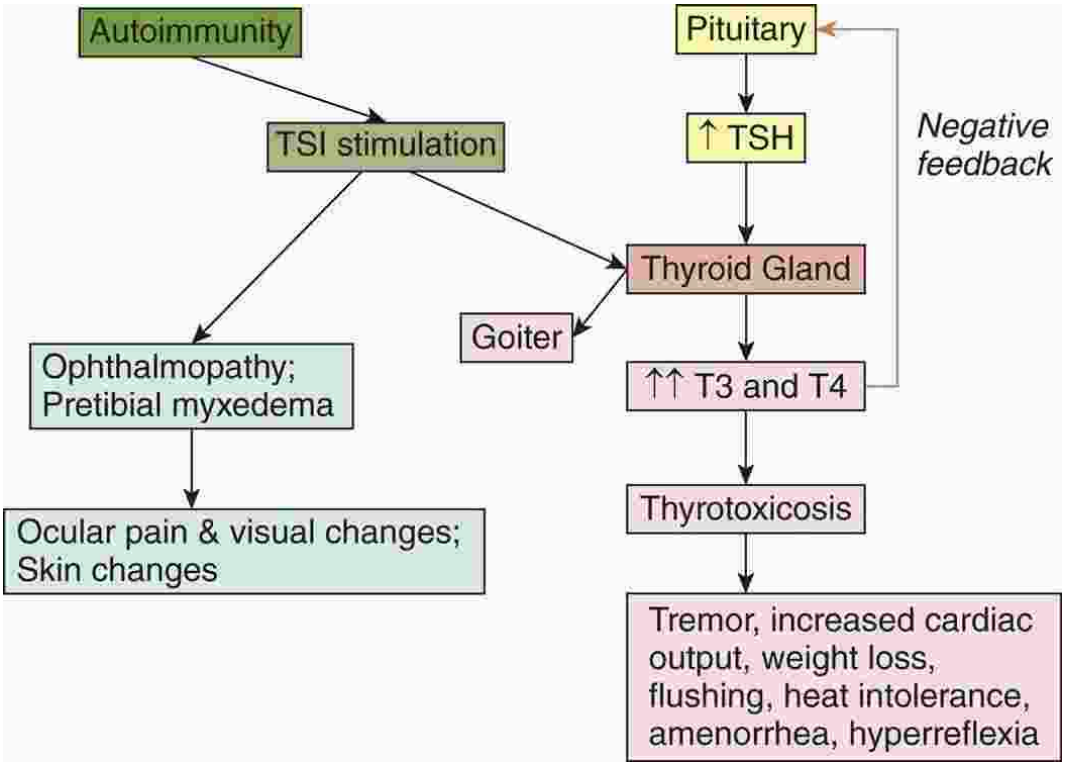


FIG. 22.8 Pathophysiology of Graves Disease.
TSI, Thyroid-stimulating immunoglobulins (antibodies); *TSH*, thyroid-stimulating hormone; T_3, triiodothyronine; T_4, tetraiodothyronine.

A flowchart shows the pathophysiology of Graves disease. There are three pathways. The first pathway is as follows. â€¢ Autoimmunity. â€¢ T S I stimulation. â€¢ Ophthalmopathy; pretibial myxedema. â€¢ Ocular pain and visual changes; skin changes. The second pathway is as follows. â€¢ Autoimmunity. â€¢ T S I stimulation. â€¢ Thyroid gland. â€¢ Goiter. The third pathway is as follows. â€¢ Pituitary. â€¢ Increased T S H. â€¢ Thyroid gland. â€¢ Increased T 3 and T 4. (negative feedback to pituitary) â€¢ Thyrotoxicosis. â€¢ Tremor, increased

cardiac output, weight loss, flushing, heat intolerance, amenorrhea, and hyperreflexia.

Hyperthyroidism resulting from nodular thyroid disease

The thyroid gland normally enlarges in response to the increased demand for TH that occurs in puberty, pregnancy, and iodine-deficient states, as well as in individuals with immunologic, viral, or genetic disorders. When the condition resulting in increased TH resolves, TSH secretion normally subsides, and the thyroid gland returns to its original size.

Irreversible changes can occur in some follicular cells so that these cells form nodules that function autonomously and produce excessive amounts of TH. Toxic multinodular goiter occurs when there are several hyperfunctioning nodules leading to hyperthyroidism. Unlike Graves disease, there is absence of an autoimmune stimulus. If only one nodule is hyperfunctioning, it is termed toxic adenoma.

The classic clinical manifestations of hyperthyroidism (see Fig. 22.6) usually develop slowly, and exophthalmos and pretibial myxedema do not occur. Nodules may be palpable on physical examination, and there is increased uptake of radioactive iodine.

There is an increased incidence of malignancy in toxic nodular goiter, so most individuals should undergo a fine-needle aspiration biopsy of suspicious nodules before treatment. Treatment consists of a combination of radioactive iodine (may increase risk of solid cancer-related death, including breast cancer death),[18] surgery, and antithyroid medications.

Thyrotoxic crisis

Thyrotoxic crisis (thyroid storm) is a rare but dangerous worsening of the thyrotoxic state in which TH levels rise dramatically and death can occur within 48 hours without treatment. The condition may develop spontaneously but usually occurs in individuals who have undiagnosed or partially treated Graves disease and who are subjected to physiologic stress, such as infection, pulmonary or cardiovascular disorders, trauma, seizures, surgery (especially thyroid surgery), obstetric complications, or dialysis.

The systemic manifestations of thyrotoxic crisis include hyperthermia; tachycardia, especially atrial tachydysrhythmias; heart failure; agitation or

delirium; and nausea, vomiting, or diarrhea contributing to fluid volume depletion. Treatment includes drugs that block TH synthesis (i.e., propylthiouracil or methimazole), β blockers, glucocorticoids, iodine, and supportive care.

Hypothyroidism

Hypothyroidism results from deficient production of TH by the thyroid gland. Primary hypothyroidism is the most common disorder of thyroid function, affecting 4% to 7% of the U.S. population, and occurs more commonly in women.[19] It may be primary, central, or subclinical. Primary hypothyroidism accounts for the majority of all cases. Central (secondary) hypothyroidism is much less common and is related to either pituitary or hypothalamic failure. Subclinical hypothyroidism is a mild thyroid failure estimated to occur in 13 million U.S. adults, most commonly in women and older adults.[20] It is characterized by elevated serum TSH levels with normal levels of circulating TH (T3, Free T4, Total T4). Progression to blatant hypothyroidism is common over time.[19]

Pathophysiology

In *primary hypothyroidism*, loss of thyroid function leads to decreased production of TH and increased secretion of TSH and TRH. The most common causes of primary hypothyroidism in adults include autoimmune thyroiditis (chronic lymphocytic thyroiditis), iatrogenic loss of thyroid tissue after surgical or radioactive treatment for hyperthyroidism or after head and neck radiation therapy, medications (e.g., lithium and amiodarone), and endemic iodine deficiency. Iodine, required for the production of TH, is not produced naturally by the body and is obtained through dietary intake. Iodine deficiency is relatively rare in the United States because of the use of iodized salt and fortified foods.[19] Infants and children may present with hypothyroidism because of congenital defects. *Central (secondary) hypothyroidism* is caused by the pituitary's failure to synthesize adequate amounts of TSH or a lack of TRH. Pituitary tumors that compress surrounding pituitary cells or the consequences of their treatment are the most common causes of central hypothyroidism. Other causes include traumatic brain injury, subarachnoid hemorrhage, pituitary infarction, or metabolic disorders including insulin resistance or

hyperglycemia, dyslipidemia, obesity, and endothelial dysfunction.[21] Hypothalamic dysfunction results in low levels of TH, TSH, and TRH.

Clinical Manifestations

Hypothyroidism generally affects all body systems and occurs insidiously over months or years. Decreased TH levels lower energy metabolism and heat production. The individual develops a low basal metabolic rate, cold intolerance, lethargy, and slightly lowered basal body temperature (see Fig. 22.6). The decrease in the level of TH leads to excessive TSH production, which stimulates thyroid tissue and causes a goiter (Table 22.4).

Table 22.4

Systemic Manifestations of Hypothyroidism

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
Neurologic	Confusion, syncope, slowed speech and thinking, memory loss; lethargy, headaches, hearing loss, night blindness; slow, clumsy movements; cerebellar ataxia; slow α-wave activity and loss of amplitude in EEG; reduced cAMP response to epinephrine, glucagons, and PTH stimulation; decreased appetite	Decreased cerebral blood flow leading to cerebral hypoxia; reduced intracellular processes caused by decreased β-adrenergic activity that may be related to a decrease in the number of β-adrenergic receptor sites
Endocrine	Increased TSH production in primary hypothyroidism; enlarged pituitary thyrotropes, increase in serum prolactin levels with galactorrhea; decreased rate of cortisol turnover but with normal serum cortisol levels	Impaired TH synthesis or defects in iodide trapping leading to compensatory TSH production; chronic overstimulation of thyrotropes of TRH and by TSH synthesis; stimulation of lactotropes by TRH related to increased prolactin levels; decreased deactivation of cortisol

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
Reproductive	Decreased androgen secretion in men, increased estriol formation in women; low total hormone values but with increased amounts of unbound hormone; anovulation, decreased libido, menorrhagia, and a high incidence of spontaneous abortion in women; erectile dysfunction, decreased libido, and oligospermia in men	Altered metabolism of estrogens and androgens; decreased levels of sex hormone–binding globulin
Hematologic	Decrease in red cell mass leading to normocytic, normochromic anemia; macrocytic anemia associated with vitamin B_{12} deficiency and inadequate folate or iron absorption in the GI tract	Decreased basal metabolic rate and reduced oxygen requirements; decreased production of erythropoietin; possible relationship between TH and optimal hematologic response to vitamin B_{12}
Cardiovascular	Reduction in stroke volume and heart rate causing lowered cardiac output; increased peripheral vascular resistance to maintain systolic	Decreased metabolic demands and loss of regulatory and rate-setting effects of TH; protein-mucopolysaccharide–rich fluid in the

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
	blood pressure can cause hypertension; normal response to exercise but with alterations in circulatory system at rest (prolonged circulation time and decreased blood flow to tissues); cool skin and cold tolerance; enlarged heart; decreased intensity of heart sounds and variety of ECG changes (sinus bradycardia, prolonged PR interval, depressed P waves, flattened or inverted T waves, and low-amplitude QRS complexes); cardiac tamponade (although rare) (see Chapter 32)	pericardial sac associated with enlarged heart; pericardial effusions associated with heart sounds and ECG changesIncreases in peripheral vascular resistance and increased blood volume can cause hypertension
Pulmonary	Dyspnea; myxedematous changes in respiratory muscles leading to hypoventilation and carbon dioxide retention, which contribute to myxedema coma	Pleural effusions associated with dyspnea, although effusions may be asymptomatic

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
Renal	Reduced renal blood flow and glomerular filtration rate leading to decreased renal excretion of water; increase in total body water and dilutional hyponatremia; reduced production of erythropoietin	Hemodynamic alterations associated with reduced blood flow and filtration; increased total body water related to decreased excretion and mucinous deposits in tissue
GI	Constipation, weight gain, and fluid retention; decreased absorption of most nutrients; decreased protein metabolism leading to retarded skeletal and soft tissue growth and slightly positive nitrogen balance; edema; decreased glucose absorption and delayed glucose uptake; elevated serum lipid values	Reduced intake and reduced peristaltic activity that may progress to fecal impaction; water absorption related to prolonged transit time; fluid retention associated with myxedematous changes; edema associated with high concentrations of exchangeable albumin in the extravascular space caused by increased capillary permeability to proteins; depressed insulin degradation; depressed lipid synthesis and degradation
Musculoskeletal	Muscle aching and stiffness; slow movement and slow tendon jerk reflexes;	Decreased rate of muscle contraction and relaxation contributing

System	Clinical Manifestations	Mechanisms Underlying Clinical Manifestations
	decreased bone formation and resorption, increased bone density; aching and stiffness in joints	to slow movement and reflexes
Integumentary	Dry, flaky skin; dry, brittle head and body hair; reduced growth of nails and hair; slow wound healing	Reduced sweat and sebaceous gland secretion
	Myxedema	Accumulation of hyaluronic acid, which binds water and causes a puffy appearance
	Cool skin	Decreased circulation to skin

cAMP, Cyclic adenosine monophosphate; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *GI*, gastrointestinal; *PTH*, parathyroid hormone; *TH*, thyroid hormone; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

The characteristic sign of severe or long-standing hypothyroidism is myxedema, which results from the altered composition of the dermis and other tissues. The connective tissue fibers are separated by large amounts of protein and mucopolysaccharide. This complex binds water, producing nonpitting, boggy edema, especially around the eyes, hands, and feet and in the supraclavicular fossae (Fig. 22.9). The tongue and laryngeal and pharyngeal mucous membranes thicken, producing thick, slurred speech and hoarseness. Myxedema coma, a medical emergency, is a diminished level of consciousness associated with severe hypothyroidism. Signs and symptoms include hypothermia without shivering, hypoventilation, hypotension, hypoglycemia, and lactic acidosis. Older individuals with comorbid conditions, such as pulmonary or urinary infections, congestive heart failure, or cerebrovascular accident, and with moderate or untreated hypothyroidism are particularly at risk for developing myxedema coma. It also may occur after overuse of narcotics or sedatives or after an acute

illness in hypothyroid individuals. Symptoms of hypothyroidism in older adults should not be attributed to expected age-related changes.

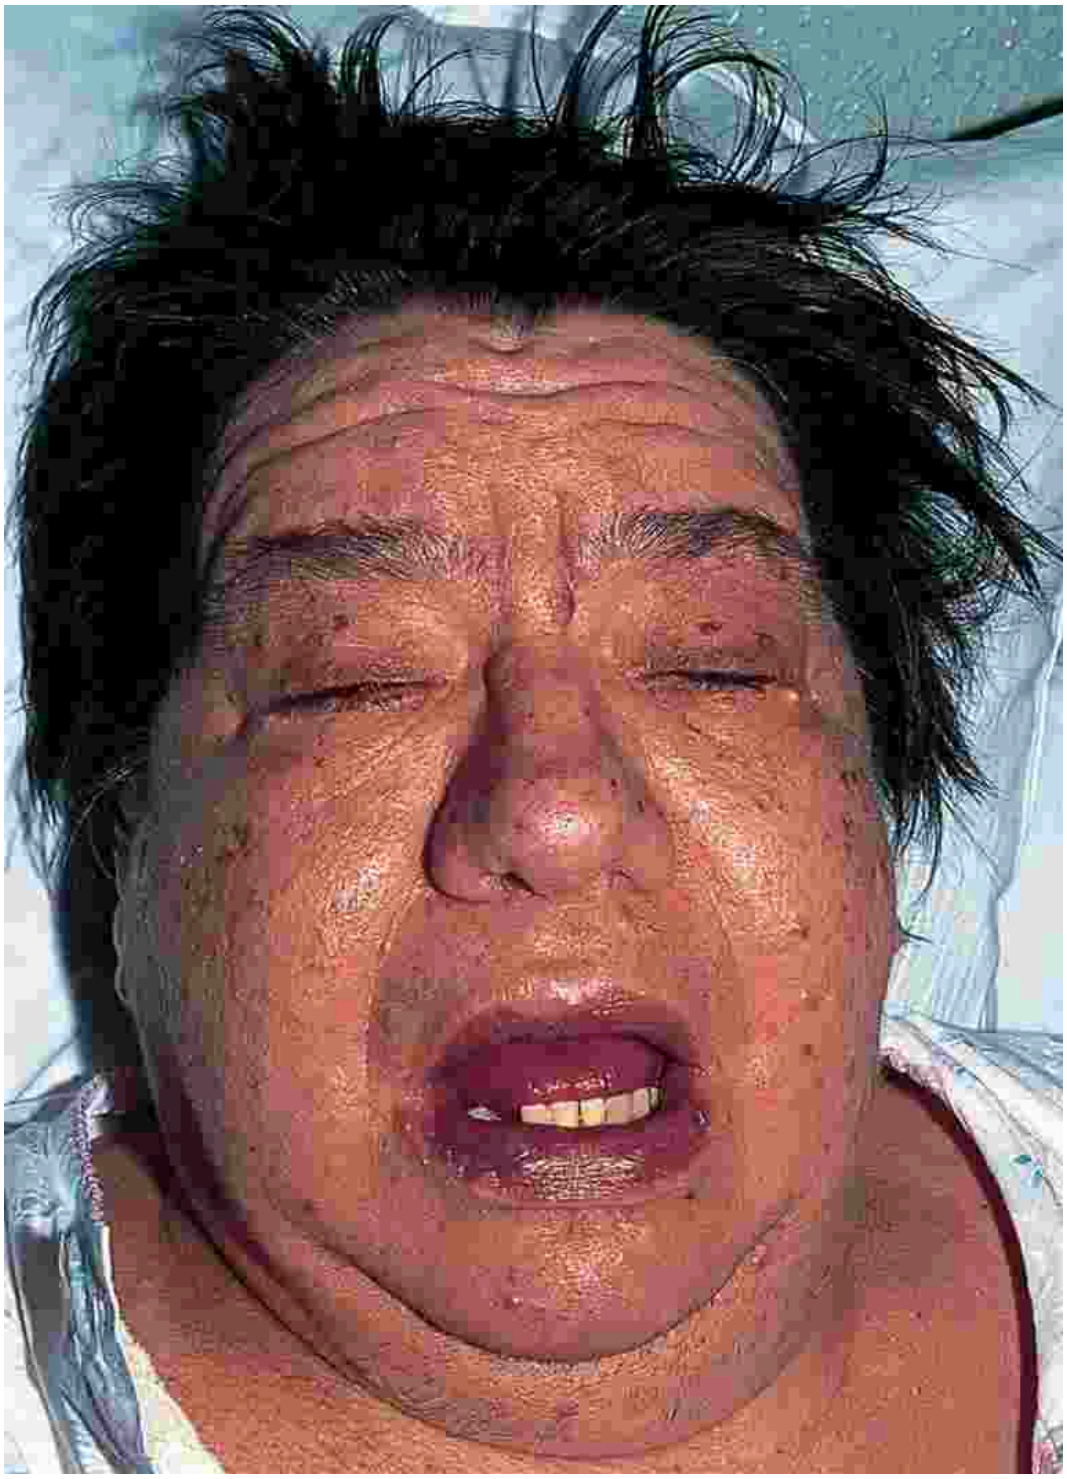

FIG. 22.9 Myxedema. Note edema around eyes and facial puffiness.
The hair is dry. (From Bolognia JL, et al. *Dermatology*, 3rd edition. St. Louis: Mosby; 2012.)

Evaluation and Treatment

The diagnosis of primary hypothyroidism is made by documentation of the clinical symptoms of hypothyroidism and measurement of increased serum levels of TSH and decreased serum levels of TH (total T_3 and both total and free T_4). Central hypothyroidism is diagnosed by finding low TH and low serum TSH levels. Alluded to earlier, subclinical hypothyroidism is diagnosed by an elevation in TSH level with normal levels of circulating TH. Hormone replacement therapy with the hormone levothyroxine is the treatment of choice for both primary and central thyroid disorders (Emerging Science Box: Combination Therapy for the Treatment of Hypothyroidism).

Hypothyroid Conditions

Chronic lymphocytic thyroiditis (Hashimoto disease)

The most common cause of primary hypothyroidism in the United States is chronic lymphocytic thyroiditis (Hashimoto disease), which results in gradual, inflammatory destruction of thyroid tissue. This disorder is linked with several genetic risk factors and is often associated with other autoimmune conditions. Infiltration of the thyroid with autoreactive T lymphocytes, antithyroid antibodies (antithyroid peroxidase and antithyroglobulin antibodies), and natural killer cells induces inflammation, glandular apoptosis, and tissue destruction (Fig. 22.10).

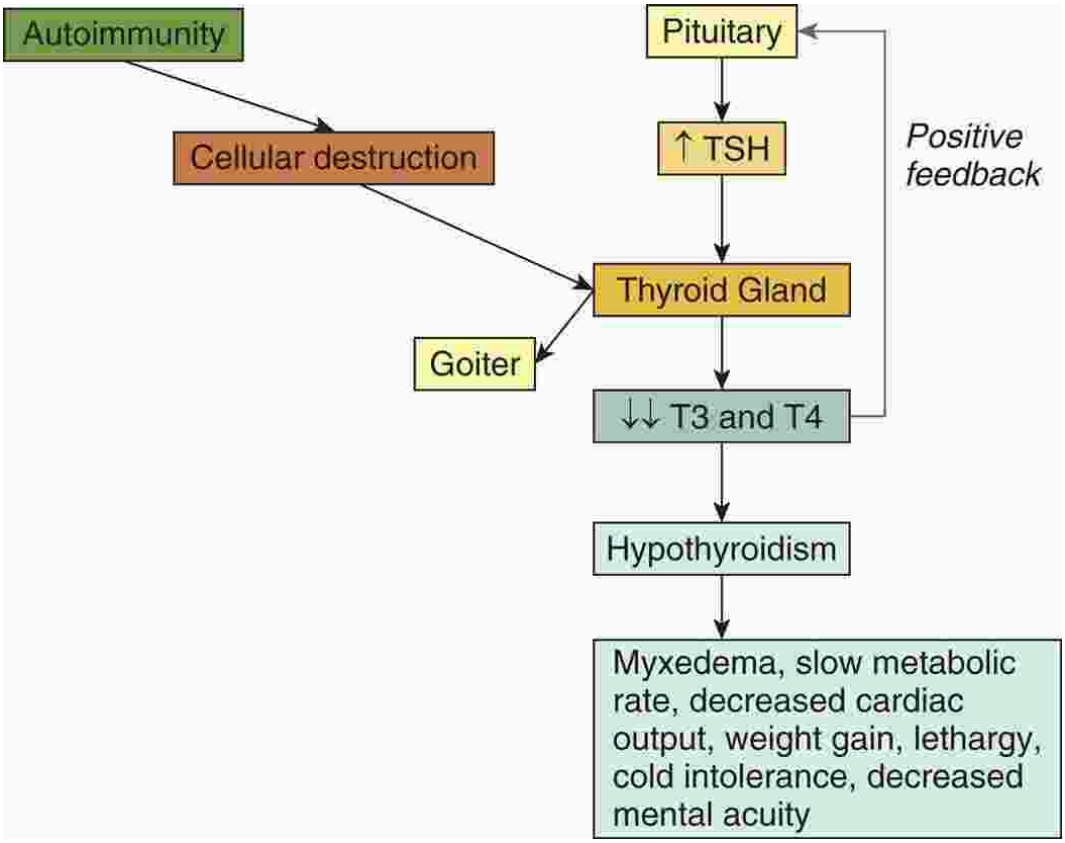

FIG. 22.10 Pathophysiology of Hashimoto Thyroiditis.
TSH, Thyroid-stimulating hormone; T_3, triiodothyronine; T_4, tetraiodothyronine.

A flowchart shows two pathways representing the pathophysiology of Hashimoto thyroiditis. One of the pathways is as follows. â€¢ Autoimmunity. â€¢ Cellular destruction. â€¢ Thyroid gland. â€¢ Goiter. The other pathway is as follows. â€¢ Pituitary. â€¢ Increased T S H. â€¢ Thyroid gland. â€¢ Decreased T 3 and T 4. (positive feedback to pituitary) â€¢ Hypothyroidism. â€¢ Myxedema, slow metabolic rate, decreased cardiac output, weight gain, lethargy, cold intolerance, and decreased mental acuity.

Uncommon causes of hypothyroidism

Other, less common causes of hypothyroidism are subacute thyroiditis and postpartum thyroiditis. Subacute thyroiditis (de Quervain thyroiditis) is a rare nonbacterial inflammation of the thyroid gland often preceded by a viral infection. It is accompanied by fever, tenderness, an increase in erythrocyte sedimentation rate, enlargement of the thyroid gland, and transient hypothyroidism before the gland recovers normal activity. Symptoms may last for 2 to 4 months, and nonsteroidal anti-inflammatory drugs or corticosteroids usually resolve symptoms. Postpartum thyroiditis (PPT) is an autoimmune disease associated with antibodies to thyroid peroxidase. PPT has a prevalence of about 5% and generally occurs up to 6 months after birthing with a course similar to that seen in subacute thyroiditis. Individuals who develop PPT need to be monitored for permanent hypothyroidism. Iatrogenic hypothyroidism results from ablation of the thyroid gland during treatment for hyperthyroid conditions.

Congenital hypothyroidism

Hypothyroidism in infants occurs when thyroid tissue is absent (thyroid dysgenesis) or with hereditary defects in TH synthesis. Thyroid dysgenesis occurs more often in female infants, with permanent abnormalities in about 1 of every 4000 live births. The affected fetus is dependent on maternal thyroxine for the first 20 weeks of gestation, then becomes deficient in TH. TH is essential for fetal growth and for the development of brain tissue, so the infant will suffer developmental and cognitive disabilities if left untreated. Hypothyroidism may not be evident at birth. Symptoms may include high birth weight, hypothermia, delay in passing meconium, and neonatal jaundice. Cord blood can be examined in the first days of life for measurement of T_4 and TSH levels. The probability of normal growth and intellectual function is high if treatment with levothyroxine is started before the child is 3 or 4 months old. The earlier TH replacement is initiated, the better the child's outcome.

Without early screening, hypothyroidism may not be evident until after 4 months of age. Symptoms include difficulty eating, hoarse cry, and protruding tongue caused by myxedema of oral tissues and vocal cords; hypotonic muscles of the abdomen with constipation, abdominal protrusion, and umbilical hernia; subnormal temperature; lethargy; excessive sleeping; slow pulse rate; and cold, mottled skin. Skeletal growth

is stunted because of impaired protein synthesis, poor absorption of nutrients, and lack of bone mineralization. The child will be dwarfed with short limbs, if not treated. Dentition is often delayed. Cognitive disability varies with the severity of hypothyroidism and the length of delay before treatment is initiated.

Thyroid carcinoma

Thyroid carcinoma is the most common endocrine malignancy and is the seventh most common cancer in the United States in women.[22] Exposure to ionizing radiation, especially during childhood, is the most consistent causal factor. Papillary and follicular thyroid carcinomas are the most frequent, and medullary and anaplastic thyroid carcinomas are less common.

The cancer is typically discovered as a small thyroid nodule or metastatic tumor in the lungs, brain, or bone. Changes in voice and swallowing and difficulty breathing are related to tumor growth impinging on the trachea or esophagus. The diagnosis of thyroid cancer is generally made by ultrasonography and then by fine-needle aspiration of a thyroid nodule. Most individuals with thyroid carcinoma have normal T_3 and T_4 levels and are therefore euthyroid.

Treatment may include partial or total thyroidectomy, TSH suppression therapy (levothyroxine), radioactive iodine therapy (in iodine-concentrating tumors), postoperative radiation therapy, and chemotherapy (especially in anaplastic carcinoma).[23] New insights into the molecular pathogenesis of thyroid carcinoma are leading to new therapies.

Alterations of Parathyroid Function

Hyperparathyroidism

Hyperparathyroidism is characterized by greater than normal secretion of parathyroid hormone (PTH) with associated hypercalcemia. Hyperparathyroidism is classified as primary, secondary, or tertiary.

Pathophysiology

Primary hyperparathyroidism is characterized by inappropriate excess secretion of PTH by one or more of the parathyroid glands.[24] It is one of the most common endocrine disorders. Approximately 80% to 85% of cases are caused by parathyroid adenomas, another 10% to 15% result from

parathyroid hyperplasia, and approximately 1% of cases are caused by parathyroid carcinoma. In addition, primary hyperparathyroidism may be caused by a variety of genetic causes, especially the genes that cause multiple endocrine neoplasia.

In primary hyperparathyroidism, PTH secretion is increased and is not under the usual feedback control mechanisms. The calcium level in the blood rises because of increased bone resorption and GI absorption of calcium but fails to inhibit PTH secretion by the parathyroid gland. Some individuals with primary hyperparathyroidism maintain normal levels of calcium despite elevated levels of PTH and are diagnosed only when they develop osteoporosis.

Secondary hyperparathyroidism is a compensatory response of the parathyroid glands to chronic hypocalcemia, which is commonly associated with decreased activation of vitamin D in individuals with renal failure (see Chapter 38). Secretion of PTH is elevated, but not enough to achieve normal calcium levels because of insufficient levels of activated vitamin D. Other causes of secondary hyperparathyroidism include a dietary deficiency of vitamin D or calcium; decreased intestinal absorption of vitamin D or calcium; and ingestion of drugs, such as phenytoin, phenobarbital, and laxatives, which either accelerate the metabolism of vitamin D or decrease intestinal absorption of calcium.

Tertiary hyperparathyroidism can develop after any long-standing period of hypocalcemia, such as is seen with chronic dialysis, renal transplantation, or GI malabsorption. Parathyroid chief cell hyperplasia leads to excessive secretion of PTH and may cause hypercalcemia (cellular adaptation is discussed in Chapter 2).

Clinical Manifestations

Hypercalcemia and hypophosphatemia are the hallmarks of primary hyperparathyroidism. Hypercalcemia and hypophosphatemia may be asymptomatic or affected individuals may present with symptoms related to the muscular, nervous, and GI systems, including fatigue, headache, depression, anorexia, and nausea and vomiting. Excessive osteoclastic and osteocytic activity causes bone resorption, resulting in osteoporosis, pathologic fractures, kyphosis of the dorsal spine, and compression fractures of the vertebral bodies (bone resorption is discussed in Chapter 44).

Hypercalcemia means that the renal tubules must filter large amounts of calcium, leading to hypercalciuria and production of an abnormally

alkaline urine. PTH hypersecretion enhances renal phosphate excretion and results in hypophosphatemia and hyperphosphaturia (see Chapter 3). The combination of these three variables—hypercalciuria, alkaline urine, and hyperphosphaturia—predisposes the individual to the formation of calcium stones, particularly in the renal pelvis or renal collecting ducts. These stones may be associated with infections and impaired renal function. Chronic hypercalcemia also is associated with mild insulin resistance, necessitating increased insulin secretion to maintain normal glucose levels (Table 22.5).

Table 22.5

Manifestations of Primary Hyperparathyroidism

Symptoms	Responsible Derangements	Mechanisms
Renal colic, nephrolithiasis, recurrent urinary tract infections, renal failure	Hypercalciuria, hyperphosphaturia, proximal renal tubular bicarbonate leak, urine pH >6	Calcium phosphate salts precipitate in alkaline urine, renal pelvis, and collecting ducts; calcium oxalate stones also formed
Abdominal pain, peptic ulcer disease	Hypercalcemia-stimulated hypergastrinemia	Elevated hydrochloric acid secretion
Pancreatitis	Hypercalcemia	Etiology of relationship unknown
Bone disease, osteitis fibrosa and osteitis cystica, osteoporosis	PTH-stimulated bone resorption, metabolic acidosis	Osteoporosis now more commonly encountered, but other disorders are more specific for hyperparathyroidism
Muscle weakness, myalgia	PTH excess, possible direct effect on striated muscle and on nerves	Characteristic myopathic changes in muscle histology (neuropathy of type I and type II muscle fibers)
Neurologic and psychiatric problems (impaired memory, confusion, depression,	Hypercalcemia	Neuropathy; electroencephalographic changes present

Symptoms	Responsible Derangements	Mechanisms
anxiety, psychosis)		
Polyuria, polydipsia	Hypercalcemia	Direct effect on renal tubule to decrease responsiveness to antidiuretic hormone
Constipation	Hypercalcemia	Decreased peristalsis of gastrointestinal tract
Anorexia, nausea, and vomiting	Hypercalcemia	Central stimulation of vomiting center
Hypertension	Renal disease, direct effect of calcium on arterial smooth muscle, pheochromocytoma	Plasma renin activity elevated or normal
Arthralgia and arthritis	Gout, pseudogout, periarticular classification	Hyperuricemia, chronic renal failure with high calcium phosphate product

PTH, Parathyroid hormone.

Data from Flint PW, et al. *Cummings otolaryngology: Head & neck surgery*, 5th edition. St. Louis: Mosby.

Secondary hyperparathyroidism, caused by renal disease, presents clinically not only with the complications of bone resorption but also with the symptoms of hypocalcemia and hyperphosphatemia, such as muscle spasms and cardiovascular complications (see Chapter 3).

Evaluation and Treatment

The diagnosis of primary hyperparathyroidism is suggested by the concurrent findings of elevated PTH levels and an increased ionized calcium concentration. Imaging procedures are used to localize adenomas

before surgery. Observation of asymptomatic individuals with mild hypercalcemia is recommended; these individuals are advised to avoid dehydration and limit dietary calcium intake. Definitive treatment of more severe primary hyperparathyroidism involves surgical removal of the solitary adenoma or, in the case of hyperplasia, complete removal of three and partial removal of the fourth hyperplastic parathyroid glands.

If the serum calcium concentration is low despite elevated levels of PTH, secondary hyperparathyroidism is likely. Evaluation for renal function may indicate chronic renal disease. Treatment for secondary hyperparathyroidism in chronic renal disease requires calcium replacement, dietary phosphate restriction and phosphate binders, and vitamin D replacement. Treatment also may include calcimimetics, which work to increase parathyroid calcium receptor sensitivity, thus lowering PTH levels.

Hypoparathyroidism

Hypoparathyroidism (abnormally low PTH levels) is most commonly caused by damage to the parathyroid glands during thyroid surgery. This occurs because of the anatomic proximity of the parathyroid glands to the thyroid (Fig. 21.11). Hypomagnesemia is another cause of low PTH levels. Hypoparathyroidism also is associated with genetic syndromes, including familial hypoparathyroidism and DiGeorge syndrome (see Chapter 9). There is an inherited condition called *pseudohypoparathyroidism* that causes a defect in tissue responsiveness to PTH. Pseudohypoparathyroidism is associated with hypocalcemia despite normal to elevated levels of PTH.

Pathophysiology

No matter the cause, the absence of PTH impairs resorption of calcium from bone and the renal tubules, leading to hypocalcemia. Deficient PTH also stimulates increased renal reabsorption of phosphate, leading to hyperphosphatemia. Hyperphosphatemia further lowers the calcium concentration by inhibiting the activation of vitamin D, thereby lowering the GI absorption of calcium.

Hypomagnesemia inhibits PTH secretion. Hypomagnesemia may be related to chronic alcoholism, malnutrition, malabsorption, increased renal clearance of magnesium caused by the use of aminoglycoside antibiotics or certain chemotherapeutic agents, or prolonged magnesium-deficient

parenteral nutritional therapy. When serum magnesium levels return to normal, however, PTH secretion returns to normal.

Clinical Manifestations

Symptoms associated with hypopara thyroidism are primarily those of hypocalcemia (see Chapter 3). Hypocalcemia causes muscle spasms, which can progress to tetany, dry skin, and loss of body and scalp hair. Irreversible complications include hypoplasia of developing teeth, horizontal ridges on the nails, cataracts, basal ganglia calcifications (which may be associated with a parkinsonian syndrome), and bone deformities, including brachydactyly and bowing of the long bones.

Evaluation and Treatment

A low PTH level, along with a low serum calcium concentration and a high phosphorus level in the absence of renal failure, intestinal disorders, or nutritional deficiencies, suggests hypoparathyroidism. Measurement of the serum magnesium level and urinary calcium excretion also can help in diagnosis. Treatment is directed toward alleviation of the hypocalcemia. In acute states, this involves parenteral administration of calcium, which corrects the serum calcium concentration within minutes. Chronic maintenance of the serum calcium level is achieved with pharmacologic doses of cholecalciferol (vitamin D_3) and oral calcium. PTH hormone replacement with recombinant human parathyroid hormone (rhPTH) is safe and effective.

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus

Diabetes mellitus is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. In 2018, an estimated 34.2 million individuals (10.5%) in the United States had diabetes, and another 7.3 million (21.4%) were estimated to be undiagnosed.[25] The American Diabetes Association (ADA)[26] classifies four categories of diabetes mellitus:

1. Type 1 diabetes (caused by autoimmune β-cell destruction, usually leading to absolute insulin deficiency)

2. Type 2 diabetes (caused by progressive loss of β-cell insulin secretion, frequently with a background of insulin resistance)[27]
3. Gestational diabetes mellitus (GDM) (diabetes diagnosed in the second or third trimester of pregnancy that was not clearly overt diabetes prior to gestation)
4. Specific types of diabetes mellitus due to other causes

Specific types of diabetes include monogenic diabetes syndromes (e.g., neonatal diabetes and maturity-onset diabetes of the young [MODY]), disease of the exocrine pancreas (e.g., cystic fibrosis and pancreatitis), and drug- or chemical-induced diabetes (e.g., glucocorticoid use in the treatment of human immunodeficiency virus [HIV] infection and/or acquired immunodeficiency syndrome [AIDS] or after organ transplantation) (Table 22.6).

Table 22.6

Classification and Characteristics of Diabetes Mellitus

Name	Characteristics
Type 1β-cell destruction leading to absolute insulin deficiency; immune-mediated diabetes is most common form (≈90%)	Cellular-mediated autoimmune destruction of pancreatic β cells Individual prone to ketoacidosis Little or no insulin secretion Insulin dependent 75% of individuals develop before 30 years of age; can occur up to the tenth decade Usually not obese
Idiopathic (≈10%)	No defined etiologies; absolute requirement for insulin replacement therapy in affected individuals may be sporadic
Type 2Progressive loss of b-cell insulin secretion frequency on the background of insulin resistance	Usually not insulin dependent but may be insulin requiring Individual not ketosis prone (but may form ketones under stress) Obesity common in the abdominal region Generally occurs in those older than 40 years, but the frequency is rapidly increasing in children Strong genetic predisposition

Name	Characteristics
	Often associated with hypertension and dyslipidemia
Other Specific Types	
Genetic defects of β-cell function	1. Genetic abnormalities that decrease the ability of the β cell to secrete insulin: 2. Maturity-onset diabetes of youth (MODY) includes six specific autosomal dominant mutations including genes for hepatocyte nuclear factor-1α (HNF-1α; *MODY 3*), glucokinase (*MODY 2*), HNF-4α (*MODY 1*), insulin-promoter factor-1(IPF-1; *MODY 4*), HNF-1β (*MODY 5*), and NeuroD1 (*MODY 6*) 3. Defects in mitochondrial deoxyribonucleic acid (DNA) Other (including an inability to convert proinsulin to insulin)
Genetic defects in insulin action	Mutations in the insulin receptor with hyperinsulinism or hyperglycemia or severe diabetes
Diseases of the exocrine pancreas	Any process that diffusely injures the pancreas, including pancreatitis, neoplasia, and cystic fibrosis
Endocrinopathies	Endocrine disorders including acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, and aldosteronoma
Drug- or chemical-induced β-cell dysfunction	Commonly associated drugs include glucocorticoids, treatment of HIV/AIDS, and after organ transplantation although many others may be implicated

Name	Characteristics
Infections	β-cell destruction by viruses including cytomegalovirus, congenital rubella
Uncommon forms of immune-mediated diabetes mellitus	Anti–insulin receptor antibodies Reported with "stiff man syndrome" and individuals receiving interferon-α
Other genetic syndromes sometimes associated with diabetes mellitus	Down, Klinefelter, Turner, and Wolfram syndromes
Gestational Diabetes Mellitus (GDM)	
Any degree of glucose intolerance with onset or first recognition during pregnancy	Insulin resistance combined with inadequate insulin secretion in relation to hyperglycemia Women who are obese, older than 25 years of age, have a family history of diabetes, have a history of previous GDM, or are of certain ethnic groups (Hispanic, Native American, Asian, or black) are at increased risk of developing GDM The metabolic stress of pregnancy may uncover a genetic tendency for type 2 diabetes mellitus

Name	Characteristics
Type 1β-cell destruction leading to absolute insulin deficiency; immune-mediated diabetes is most common form (≈90%)	Cellular-mediated autoimmune destruction of pancreatic β cells Individual prone to ketoacidosis Little or no insulin secretion Insulin dependent 75% of individuals develop before 30 years of age; can occur up to the tenth decade Usually not obese
Idiopathic (≈10%)	No defined etiologies; absolute requirement for insulin replacement therapy in affected individuals may be sporadic
Type 2Progressive loss of b-cell insulin secretion frequency on the background of insulin resistance	Usually not insulin dependent but may be insulin requiring Individual not ketosis prone (but may form ketones under stress) Obesity common in the abdominal region Generally occurs in those older than 40 years, but the frequency is rapidly increasing in children Strong genetic predisposition Often associated with hypertension and dyslipidemia
Other Specific Types	
Genetic defects of β-cell function	1. Genetic abnormalities that decrease the ability of the β cell to secrete insulin: 2. Maturity-onset diabetes of youth (MODY) includes six specific autosomal dominant mutations including genes for hepatocyte nuclear factor-1α (HNF-1α; *MODY 3*), glucokinase (*MODY 2*), HNF-4α (*MODY 1*), insulin-promoter factor-1(IPF-1; *MODY 4*), HNF-1β (*MODY 5*), and NeuroD1 (*MODY 6*) 3. Defects in mitochondrial deoxyribonucleic acid (DNA) Other (including an inability to convert proinsulin to insulin)
Genetic defects in insulin action	Mutations in the insulin receptor with hyperinsulinism or hyperglycemia or severe diabetes
Diseases of the exocrine pancreas	Any process that diffusely injures the pancreas, including pancreatitis, neoplasia, and cystic fibrosis
Endocrinopathies	Endocrine disorders including acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, and aldosteronoma
Drug- or chemical-induced β-cell dysfunction	Commonly associated drugs include glucocorticoids, treatment of HIV/AIDS, and after organ transplantation although many others may be implicated
Infections	β-cell destruction by viruses including cytomegalovirus, congenital rubella
Uncommon forms of immune-mediated diabetes mellitus	Anti–insulin receptor antibodies Reported with "stiff man syndrome" and individuals receiving interferon-α
Other genetic syndromes sometimes associated with diabetes mellitus	Down, Klinefelter, Turner, and Wolfram syndromes
Gestational Diabetes Mellitus (GDM)	
Any degree of glucose intolerance with onset or first recognition during pregnancy	Insulin resistance combined with inadequate insulin secretion in relation to hyperglycemia Women who are obese, older than 25 years of age, have a family history of diabetes, have a history of previous GDM, or are of certain ethnic groups (Hispanic, Native American, Asian, or black) are at increased risk of developing GDM The metabolic stress of pregnancy may uncover a genetic tendency for type 2 diabetes mellitus

GDM, Gestational diabetes mellitus; *MODY*, maturity-onset diabetes of youth.

Data from American Diabetes Association. *Diabetes Care*. 2017;40(Suppl. 1):S11–S24.

The diagnosis of diabetes mellitus is based on glycated hemoglobin (HbA_{1C}) levels; fasting plasma glucose (FPG) levels; oral glucose tolerance testing (OGTT); or random glucose levels in an individual with symptoms (Box 22.1).[26] Glycated hemoglobin refers to the permanent attachment of glucose to hemoglobin molecules and reflects the average plasma glucose exposure over the life of a red blood cell (RBC) (approximately 120 days). It provides a more accurate measure for monitoring long-term control of blood glucose levels.

Box 22.1

Diagnostic Criteria for Diabetes Mellitus

1. HbA_{1C} (as measured in a DCCT-referenced assay) ≥6.5%
   OR
2. FPG ≥126 mg/dL; fasting is defined as no caloric intake for at least 8 h
   OR
3. 2-h plasma glucose ≥200 mg/dL during OGTT
   OR
4. In an individual with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥200 mg/dL

In the absence of unequivocal hyperglycemia, criteria 1 through 3 diagnosis requires two abnormal test results from the same sample or in two separate test samples.

Categories of Increased Risk for Diabetes

1. FPG 100–125 mg/dL
2. 2-h PG 140–199 mg/dL during OGTT
3. HbA_{1C} 5.7%–6.4%

DCCT, Diabetes Control and Complications Trial; *FPG*, fasting plasma glucose; *HbA_{1C}*, hemoglobin A_{1C} or glycated hemoglobin; *OGTT*, oral glucose tolerance testing; *PG*, plasma glucose.

Data from American Diabetes Association. Classification and diagnosis of diabetes: standards of medical care in diabetes—2020. *Diabetes Care*. 2020;43(Suppl. 1):S14–

S31. Available from https://care.diabetesjournals.org/content/diacare/suppl/2019/12/20/43.Supplement_1.DC1/Standards_of_Care_2020.pdf.

The ADA classification "categories at increased risk for diabetes" (or prediabetes) describes nondiabetic elevations of the HbA_{1C}, FPG, or 2-hour plasma glucose value during an OGTT (see Box 22.1).[26] The Centers for Disease Control and Prevention (CDC) estimates that 88 million U.S. adults (34.5%) aged 18 years or older have prediabetes.[24]

This classification includes impaired glucose tolerance (IGT), which results from diminished insulin secretion; and impaired fasting glucose (IFG), which is caused by enhanced hepatic glucose output. Individuals with IGT and IFG are at increased risk of cardiovascular disease and premature death and carry up to a 50% 5-year risk of developing diabetes, particularly type 2 diabetes. Thus, prevention of diabetes with lifestyle interventions is essential.

Types of Diabetes Mellitus

Diabetes Mellitus Type 1

Diabetes mellitus type 1 accounts for 5% to 10% of diabetes cases and is the most common pediatric chronic disease. It currently affects approximately 187,000 U.S. children younger than 20, and the incidence is increasing.[25] Between 10% and 13% of individuals with newly diagnosed type 1 diabetes have a first-degree relative (parent or sibling) with type 1 diabetes, and there is a 50% concordance rate in twins. Diagnosis is rare during the first 9 months of life and peaks at 12 years of age (Table 22.7).

Table 22.7

Epidemiology and Etiology of Diabetes Mellitus in the United States

	Type 1 Diabetes: Primary β-Cell Defect or Failure	Type 2 Diabetes: Insulin Resistance With Inadequate Insulin Secretion
Incidence		
Frequency	5%–10% of all cases of diabetes mellitus Prevalence rate is 0.17%	Accounts for most cases (≈90%–95%) Prevalence rate for adults is 10.9%
Change in incidences	Incidence is increasing	Incidence in adults more than tripled in the past 3 decades
Characteristics		
Age at onset	Peak onset at age 11–13 years (slightly earlier for girls than for boys); rare in children younger than 9 months and adults older than 30 years	Risk of developing diabetes increases after age 40 years
Sex	Similar in males and females	Similar in males and females
Racial distribution	Rates for whites 1.5–2 times higher than for other ethnic groups	Risk is highest for African Americans and Native Americans
Weight	Generally normal or underweight	Obesity is common and is a frequent contributing factor to precipitate type 2 diabetes among those susceptible

	Type 1 Diabetes: Primary β-Cell Defect or Failure	Type 2 Diabetes: Insulin Resistance With Inadequate Insulin Secretion
Etiology		
Common theory	*Autoimmune:* genetic and environmental factors, resulting in gradual process of autoimmune destruction in genetically susceptible individuals *Nonautoimmune:* Unknown	Genetic susceptibility (polygenic) combined with environmental determinants; defects in β-cell function combined with insulin resistance Associated with long-duration obesity
Presence of antibody	Autoantibodies to insulin and to glutamic acid decarboxylase (GAD_{65})	Autoantibodies not present
Insulin resistance	Insulin resistance at diagnosis is unusual, but may occur as individual ages and gains weight	Insulin resistance is virtually universal and multifactorial in origin
Insulin secretion	Severe insulin deficiency or no insulin secretion at all	Typically increased at time of diagnosis, but progressively declines over course of illness

	Type 1 Diabetes: Primary β-Cell Defect or Failure	Type 2 Diabetes: Insulin Resistance With Inadequate Insulin Secretion
Incidence		
Frequency	5%–10% of all cases of diabetes mellitus Prevalence rate is 0.17%	Accounts for most cases (≈90%–95%) Prevalence rate for adults is 10.9%
Change in incidences	Incidence is increasing	Incidence in adults more than tripled in the past 3 decades
Characteristics		
Age at onset	Peak onset at age 11–13 years (slightly earlier for girls than for boys); rare in children younger than 9 months and adults older than 30 years	Risk of developing diabetes increases after age 40 years

National diabetes statistics report. https://www.cdc.gov/diabetes/data/statistics/statistics-report.html.

Pathophysiology

Two distinct types of type 1 diabetes have been identified: idiopathic and autoimmune. *Idiopathic diabetes mellitus type 1* is far less common than autoimmune diabetes, has a strong genetic component, and occurs mostly in people of Asian or African descent. Affected individuals have no evidence of β-cell autoimmunity and have varying degrees of insulin deficiency.

Autoimmune diabetes mellitus type 1 is a slowly progressive disease that destroys β cells of the pancreas. There are strong genetic associations with histocompatibility leukocyte antigen (HLA) class II alleles *HLA-DQ* and

HLA-DR. Environmental factors that have been implicated include exposure to certain drugs, foods, and viruses. These gene-environment interactions result in the formation of autoantigens that are expressed on the surface of pancreatic β cells and circulate in the bloodstream and lymphatics (see Fig. 22.11). Cellular immunity (T-cytotoxic cells and macrophages) and humoral immunity (autoantibodies against islet cells, insulin, glutamic acid decarboxylase [GAD], and other cytoplasmic proteins) are stimulated, resulting in β-cell destruction and apoptosis. Over time, 80% to 90% of the insulin-secreting β cells of the islet of Langerhans are destroyed, insulin synthesis declines, and hyperglycemia develops.

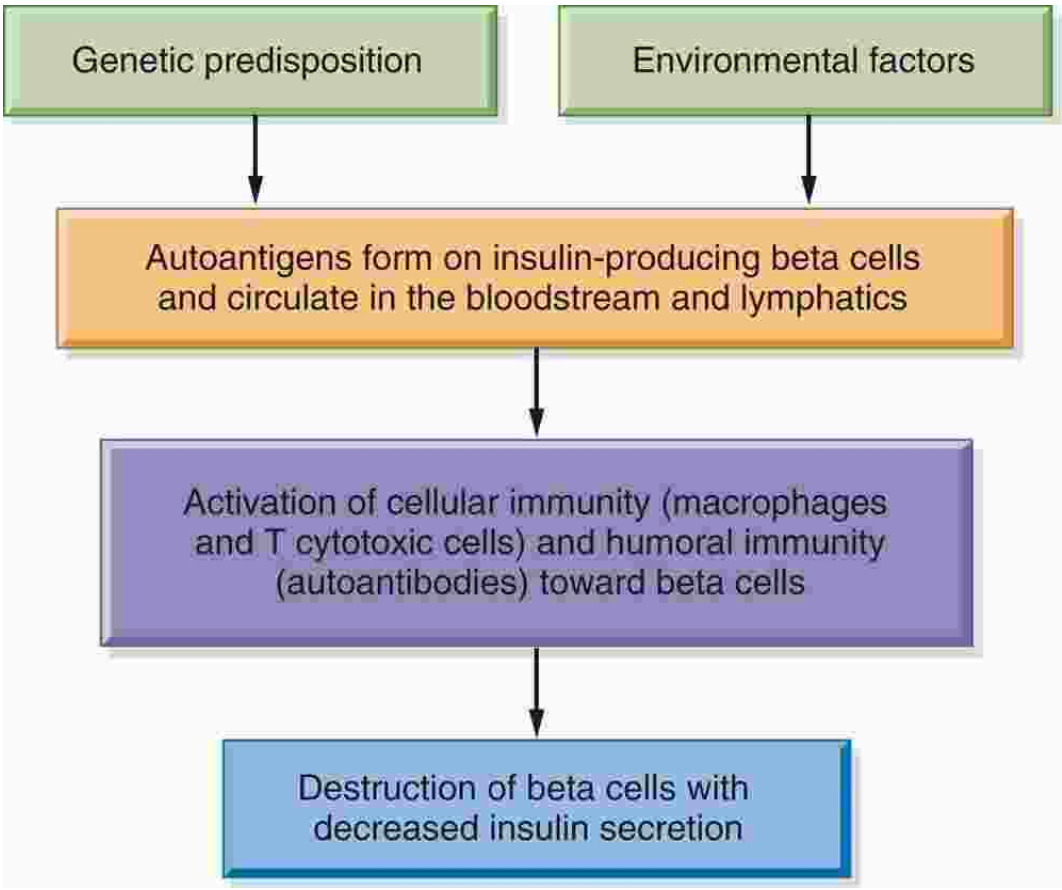

FIG. 22.11 Pathophysiology of Type 1 Diabetes Mellitus.

A flowchart represents the pathophysiology of type 1 diabetes mellitus. Genetic predisposition and environmental factors impact the autoantigens form on insulin-producing beta cells and circulate in the bloodstream and lymphatics, which leads to the following sequence. â€¢ Activation of cellular immunity (macrophages and T cytotoxic cells) and humoral immunity (autoantibodies) toward beta cells. â€¢ Destruction of beta cells with decreased insulin secretion.

Insulin normally suppresses secretion of glucagon, and thus hypoinsulinemia leads to a marked increase in glucagon secretion. In addition to the decline in insulin secretion, there is decreased secretion of

amylin (another β-cell hormone), which also leads to an increase in glucagon. Glucagon, a hormone produced by the α cells of the islets, acts in the liver to increase the blood glucose level by stimulating glycogenolysis and gluconeogenesis. Thus, both a lack of insulin and a relative excess of glucagon contribute to hyperglycemia in type 1 diabetes.

The natural history of type 1 diabetes involves a long preclinical period before insulin deficiency and hyperglycemia develop. Glucose accumulates in the blood and appears in the urine as the renal threshold for glucose is exceeded, producing an osmotic diuresis and symptoms of polyuria and thirst (Table 22.8). Wide fluctuations in blood glucose levels occur. Insulin deficiency also causes protein and fat breakdown, resulting in weight loss. Excessive metabolism of fats and proteins leads to high levels of circulating ketones, causing a condition known as *diabetic ketoacidosis* (DKA) (see the Acute Complications of Diabetes section).

Table 22.8

Clinical Manifestations and Mechanisms for Type 1 Diabetes Mellitus

Manifestation	Rationale
Polydipsia	Because of elevated blood glucose levels, water is osmotically attracted from body cells, resulting in intracellular dehydration and stimulation of thirst in hypothalamus
Polyuria	Hyperglycemia acts as an osmotic diuretic; amount of glucose filtered by glomeruli of kidney exceeds that which can be reabsorbed by renal tubules; glycosuria results, accompanied by large amounts of water lost in urine
Polyphagia	Depletion of cellular stores of carbohydrates, fats, and protein results in cellular starvation and a corresponding increase in hunger
Weight loss	Weight loss occurs because of fluid loss in osmotic diuresis and loss of body tissue as fats and proteins are used for energy
Fatigue	Metabolic changes result in poor use of food products, contributing to lethargy and fatigue
Recurrent infections (e.g., boils, carbuncles, and bladder infection)	Growth of microorganisms is stimulated by increased glucose levels; tissue ischemia and neuropathy contribute to the risk of infection; diabetes also is associated with systemic immunocompromise
Prolonged wound healing	Impaired blood supply hinders healing
Genital pruritus	Hyperglycemia and glycosuria favor fungal growth; candidal infections, resulting in

Manifestation	Rationale
	pruritus, are a common presenting symptom in women
Visual changes	Blurred vision occurs as water balance in eye fluctuates because of elevated blood glucose levels; microvascular disease resulting in diabetic retinopathy may ensue
Paresthesias	Paresthesias are common manifestations of diabetic neuropathies
Cardiovascular symptoms (e.g., chest pain, extremity pain, and neurologic deficits)	Diabetes contributes to macrovascular disease with formation of atherosclerotic plaques that involve coronary, peripheral, and cerebral vessels

Although most individuals with type 1 diabetes are of normal or decreased weight, there are increasing numbers of individuals who have both type 1 diabetes and the clinical manifestations of metabolic syndrome, including obesity, dyslipidemia, and hypertension (Box 22.2). These individuals are at high risk for chronic complications of diabetes, including heart disease and stroke.

Box 22.2

Criteria for the Diagnosis of Metabolic Syndrome

Three of these five traits must be present:

1. Increased waist circumference as determined by population- and country-specific definitions (>40 inches in men; >35 inches in women in the United States)
2. Plasma triglycerides ≥150 mg/dL
3. Plasma high-density lipoprotein cholesterol <40 mg/dL (men) or <50 mg/dL (women)
4. Blood pressure: systolic ≥130 and/or diastolic ≥85 mm Hg

5. Fasting plasma glucose ≥100 mg/dL and <126 mg/dL, or 2-h OGTT ≧140 mg/dL, or HbA_{1c} ≥5.7% to 6.4% or currently on oral drug treatment for elevated glucose without diagnosis of diabetes mellitus

Drug treatment for these conditions is an alternative indicator.

From Rosenzweig JL, Bakris GL, Berglund LF, et al. Primary prevention of ASCVD and T2DM in patients at metabolic risk: An endocrine society clinical practice guideline. *Journal of Clinical Endocrinology Metabolism*, 2019;9(104):3939–3985. https://academic.oup.com/jcem/article/104/9/3939/5540926.

Clinical Manifestations

The common clinical manifestations of type 1 diabetes result from both insulin deficiency and hyperglycemia. These manifestations are described in Table 22.8. Acute complications also may include hypoglycemia and DKA, which are described later in this chapter. Chronic complications include renal, nervous system, cardiac, peripheral vascular, retinal, and bony tissue dysfunction.

Evaluation and Treatment

The criteria for diagnosis of type 1 diabetes are the same as those for type 2 diabetes (see Box 22.1). To estimate the severity of β-cell destruction, C-peptide, a component of proinsulin released during insulin production, can be measured in the serum as a surrogate for insulin levels. An individual with residual pancreatic β cell function will have detectable levels of C-peptide, but a negligible amount of C-peptide can point to the diagnosis of type 1 diabetes. Individuals with hyperglycemia and at risk for type 1 diabetes can be tested for a variety of autoantibodies, such as zinc transporter 8 (ZnT8Ab) or tyrosine phosphatases. If two or more of the autoantibodies are positive in conjunction with diagnostic hyperglycemia, then the diagnosis of type 1 diabetes is confirmed. It is important to note that antibody testing itself is not a diagnostic requirement for type 1 diabetes. Other important aspects of evaluation include looking for evidence of acute and chronic complications of type 1 diabetes.

There are no approved treatments for preventing destruction of the β cells. Currently, treatment regimens are designed to achieve optimal glucose level control (as measured by the HbA_{1C} value) without causing episodes of significant hypoglycemia. A comprehensive, person-centered collaborative management plan is essential.[26] Management requires individual planning according to type of disease, age, and activity level,

but all individuals require some combination of insulin therapy, meal planning, an exercise regimen, and glucose monitoring. There are several different types of insulin preparations available, and there are new technologies for more physiologic insulin delivery systems. Many different kinds of therapies are being tested to prevent the autoimmune destruction of β cells, including immunosuppression with antirejection drugs and stem cell transplantation (Emerging Science Box: Pancreatic β Cell Regeneration as a Plausible Diabetic Therapy).

Diabetes Mellitus Type 2

Diabetes mellitus type 2 (non–insulin-dependent diabetes mellitus) is a metabolic disorder that has reached pandemic dimensions all over the world, affecting 400 million people worldwide, and 10.9% of adults in the United States.[26,28] Prevalence is highest among American Indians and Alaska Natives (14.7%) and lowest among non-Hispanic whites (7.5%). There also is an increased prevalence of type 2 diabetes in children, especially in obese children (see Table 22.7).

Genetic abnormalities combined with environmental influences result in the basic pathophysiologic mechanisms of type 2 diabetes, which are insulin resistance and decreased insulin secretion by β cells (Fig. 22.12). The most well-recognized risk factors are family history, age, obesity, hypertension, poor diet, and physical inactivity. More than 60 genes have been identified that are associated with type 2 diabetes, including those that code for β-cell mass, β-cell function (ability to sense blood glucose levels, insulin synthesis, and insulin secretion), proinsulin and insulin molecular structures, insulin receptors, hepatic synthesis of glucose, glucagon synthesis, and cellular responsiveness to insulin stimulation.

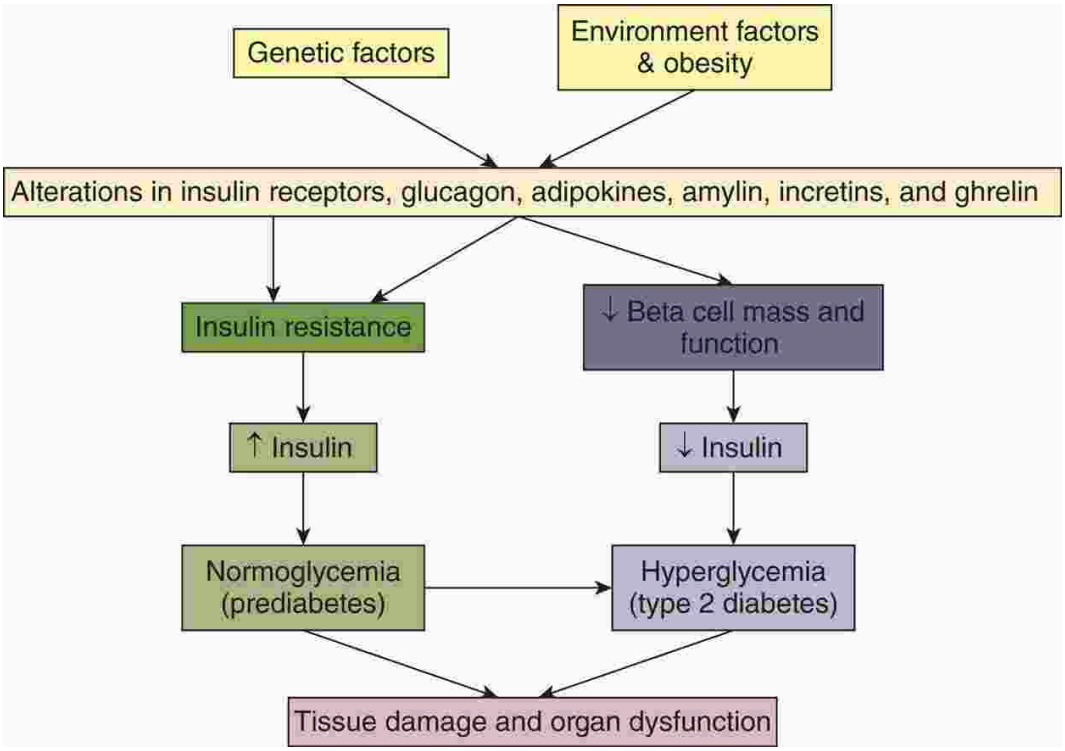

FIG. 22.12 Pathophysiology of Type 2 Diabetes Mellitus.

A flowchart represents the pathophysiology of type 2 diabetes mellitus. Genetic factors and environmental factors and obesity impact the alterations in insulin receptors, glucagon, adipokines, amylin, incretins, and ghrelin. Two pathways are charted; both of which lead to tissue damage and organ dysfunction. One pathway is as follows. â€¢ Insulin resistance. â€¢ Increased insulin. â€¢ Normoglycemia (prediabetes) (also to hyperglycemia). The other pathway is as follows. â€¢ Decreased beta cell mass and function. â€¢ Decreased insulin. â€¢ Hyperglycemia (type 2 diabetes).

There is increasing evidence that diet, including diet during pregnancy (both undernutrition and overnutrition), influences the long-term risk of type 2 diabetes in children and adults. Diets high in fruits, vegetables, fiber, and nuts reduce risk; diets high in simple carbohydrates, saturated fats,

and red meat are associated with an increased risk. Weight gain and a lack of exercise also contribute to the risk for diabetes mellitus type 2.

Pathophysiology

Diabetes mellitus type 2 is a chronic and metabolic disease characterized by defects in pancreatic insulin secretion and (or) insulin effect on target tissues, generating a persistent state of hyperglycemia, inducing metabolic alteration, cell death, and inflammation.[28] Insulin resistance is defined as a suboptimal response of insulin-sensitive tissues (especially liver, muscle, and adipose tissue) to insulin. Several mechanisms are involved in abnormalities of the insulin signaling pathway and contribute to insulin resistance. These include an abnormality of the insulin molecule, high amounts of insulin antagonists, down-regulation of the insulin receptor, and alteration of glucose transporter (GLUT) proteins.

Obesity is one of the most important contributors to insulin resistance and diabetes and acts through several important mechanisms:

1. Adipokines (cytokines produced by adipose tissue): Increased serum levels of leptin (leptin resistance) and decreased levels of adiponectin result in inflammation and decreased insulin sensitivity.
2. Free fatty acids (FFAs): Increased FFAs, along with intracellular deposits of triglycerides and cholesterol, lead to decreased tissue responses to insulin.
3. Inflammation: Adipocyte-associated proinflammatory macrophages and inflammatory cytokines released from adipocytes induce insulin resistance and are cytotoxic to β cells.
4. Mitochondrial dysfunction: Decreased insulin-induced mitochondrial activity leads to insulin resistance.
5. Hyperinsulinemia: Obesity is correlated with hyperinsulinemia and decreased insulin receptor density.

Compensatory hyperinsulinemia prevents the clinical appearance of diabetes for many years. Eventually, however, a decrease in β-cell mass and a reduction in normal β-cell function develops and leads to a relative deficiency of insulin activity.

The glucagon concentration is increased in type 2 diabetes because pancreatic α cells become less responsive to glucose inhibition, resulting in

an increase in glucagon secretion. These abnormally high levels of glucagon increase the blood glucose level by stimulating glycogenolysis and gluconeogenesis. As was discussed under type 1 diabetes, type 2 diabetes also is associated with a deficiency in amylin, further increasing glucagon levels. Pramlintide, a synthetic analog of amylin, is used for treatment in type 2 diabetes.

Hormones released from the GI tract play a role in insulin resistance, β-cell function, and diabetes. Ghrelin is a peptide produced in the stomach and pancreatic islets that regulates food intake, energy balance, and hormonal secretion. Decreased levels of circulating ghrelin have been associated with insulin resistance and increased fasting insulin levels. The incretins are a class of peptides that are released from the GI tract in response to food intake and function to increase the secretion of insulin and have many other positive effects on metabolism. The most studied incretin is called *glucagon-like peptide 1* (GLP-1), and studies have demonstrated that β-cell responsiveness to GLP-1 is reduced both in prediabetes and in type 2 diabetes. Incretin therapies include GLP-1 receptor agonists (GLP-1 RAs) and dipeptidyl peptidase IV (DPP-IV) inhibitors, which can help control postprandial glucose levels by promoting glucose-dependent insulin secretion.

The kidneys also influence the pathophysiology of type 2 diabetes. Renal reabsorption of glucose through the sodium-glucose cotransporter 2 (SGLT2) is an important controller of serum glucose levels, and medications aimed at blocking it have resulted in decreased measurements for blood glucose level, weight, and blood pressure.

As you have learned, many organs contribute to insulin resistance, chronic hyperglycemia, and the consequences of type 2 diabetes. These causes and consequences are summarized in Fig. 22.13, and the complications of type 2 diabetes will be discussed later in this chapter.

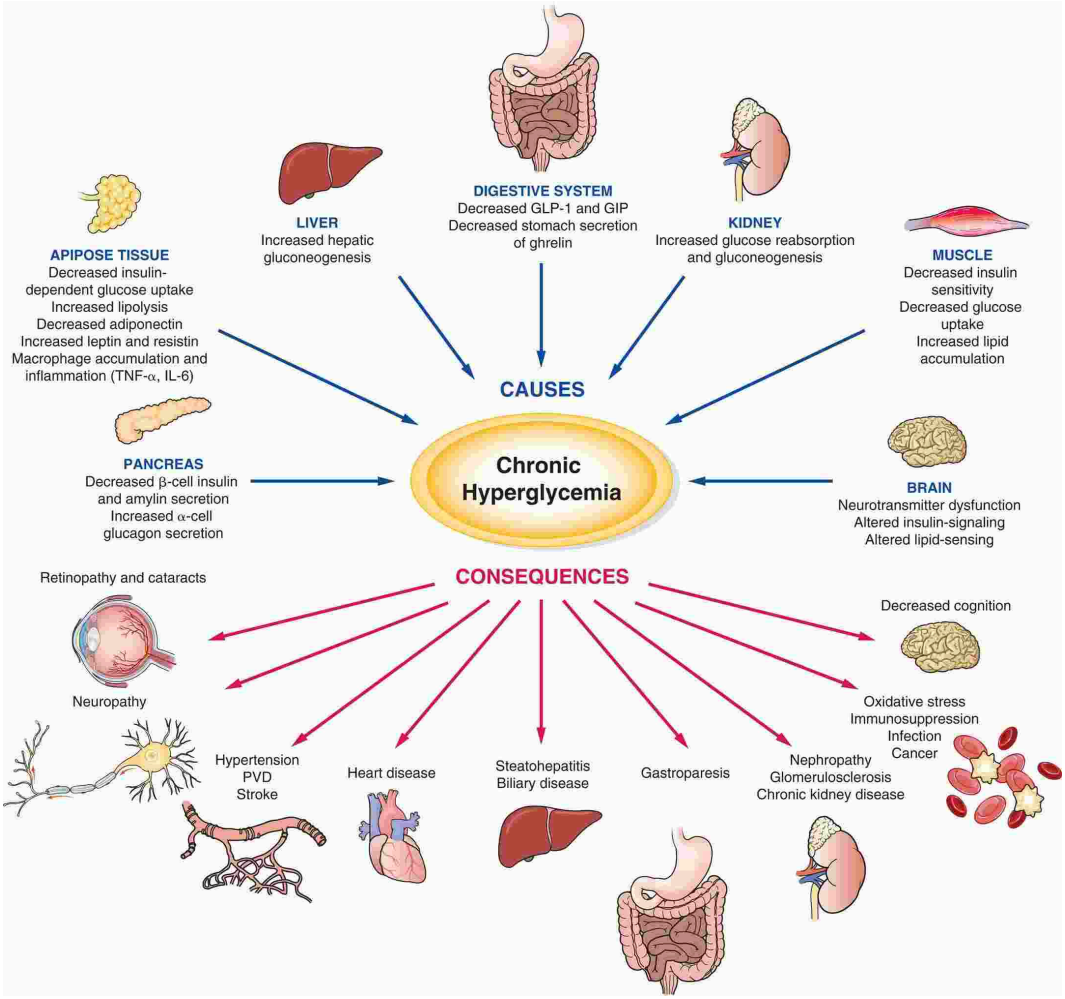

FIG. 22.13 Multiorgan Causes and Common Consequences of Chronic Hyperglycemia in Type 2 Diabetes.
GLP-1, Glucagon-like peptide 1; *GIP*, gastric inhibitory polypeptide; *IL*, interleukin; *PVD*, peripheral vascular disease; *TNF*, tumor necrosis factor.

An illustration lists the causes and consequences of chronic hyperglycemia. The causes of chronic hyperglycemia are as follows. â€¢ Pancreas. Decreased beta-cell insulin and amylin secretion. Increased alpha-cell glucagon secretion. â€¢ Adipose tissue. Decreased insulin-dependent glucose uptake. Increased lipolysis. Decreased adiponectin. Increased leptin and resistin.

Macrophage accumulation and inflammation (T N F-alpha, I L-6). â€¢ Liver. Increased hepatic gluconeogenesis. â€¢ Digestive system. Decreased G L P-1 and G I P. Decreased stomach secretion of ghrelin. â€¢ Kidney. Increased glucose reabsorption and gluconeogenesis. â€¢ Muscle. Decreased insulin sensitivity. Decreased glucose uptake. Increased lipid accumulation. â€¢ Brain. Neurotransmitter dysfunction. Altered insulin-signaling. Altered lipid-sensing. The consequences of chronic hyperglycemia are as follows. â€¢ Decreased cognition. â€¢ Oxidative stress. Immunosuppression. Infection. Cancer. â€¢ Nephropathy. Glomerulosclerosis. Chronic kidney disease. â€¢ Gastroparesis. â€¢ Steatohepatitis. Biliary disease. â€¢ Heart disease. â€¢ Hypertension. P V D. Stroke. â€¢ Neuropathy. â€¢ Retinopathy and cataracts.

Clinical Manifestations

The clinical manifestations of type 2 diabetes are nonspecific. The individual with type 2 diabetes may show some classic symptoms of diabetes, such as polyuria and polydipsia, but more often will have nonspecific symptoms, such as fatigue, pruritus, recurrent infections, visual changes, or symptoms of neuropathy (paresthesia or weakness). The affected individual is often overweight, dyslipidemic, and hypertensive. The increased morbidity and mortality rates related to diabetes mellitus type 2 are often associated with vascular complications, such as cardiovascular diseases, nephropathy, retinopathy, endothelial dysfunction, dyslipidemia, and an increase of oxidative stress, which is also due to inflammation (Emerging Science Box: Inflammation and Its Importance to the Pathophysiology of Insulin Resistance in Prediabetes and Diabetes Mellitus Type 2).[29,30]

Evaluation and Treatment

The diagnostic criteria for type 2 diabetes are the same as those for type 1 (see Box 22.1). Metabolic syndrome is a constellation of disorders (central obesity, dyslipidemia, prehypertension, and an elevated FPG) that confer a high risk of developing type 2 diabetes and associated cardiovascular complications (see Box 22.2).

As with type 1 diabetes, the goal of treatment for individuals with type 2 diabetes (and metabolic syndrome) is the restoration of near-euglycemia (normal blood glucose) levels and correction of related metabolic disorders. Prevention and treatment of type 2 diabetes, especially in those individuals with prediabetes, focuses on lifestyle modifications as the cornerstone modality.[31] Diet should match activity levels and include more complex carbohydrates (rather than simple sugars), foods low in fats, adequate protein, and fiber. Obesity management results in improved glucose tolerance. Bariatric surgery improves glycemic control, decreases the risk of cardiovascular disease, and promotes weight loss in those morbidly obese.[26]

For individuals who require further intervention, oral and/or non-insulin antidiabetic agents are indicated (Table 22.9).[26] Currently, metformin is considered the primary pharmacologic choice for the treatment of type 2 diabetes. If the HbA_{1C} target is not maintained over 3 months, a GLP-1 receptor agonist (incretin) may be added.[26,31]

Table 22.9

Non-insulin Antidiabetic Medications

Drug Type	Mechanisms of Metabolic Control
α-Glycosidase inhibitor (miglitol and acarbose)	Delays carbohydrate absorption in gut by inhibiting disaccharidases
Biguanide (metformin)	Decreases hepatic glucose production and increases insulin sensitivity and peripheral glucose uptake
Meglitinides (glinides; repaglinide and nateglinide)	Stimulate insulin release from pancreatic β cells
Sulfonylureas (glyburide, glipizide, glimepiride)	Stimulate insulin release from pancreatic β cells
Peroxisome proliferator–activated receptor-γ agonists (thiazolidinediones, pioglitazone, and rosiglitazone)	Increase insulin sensitivity, particularly in adipose tissue
Bile acid sequestrant (colesevelam, cholestyramine, and colestipol)	Unknown; theories include decreased hepatic glucose production, increased insulin secretion, and increased incretin release
GLP-1 receptor agonists (exenatide, liraglutide, lixisenatide, exenatide extended-release, albiglutide, and dulaglutide)	Increase insulin secretion, decrease glucagon secretion, decrease rate of gastric emptying, decrease appetite, weight loss
DPP-IV inhibitors (sitagliptin, saxagliptin, alogliptin, and linagliptin)	Increase insulin secretion, decrease glucagon secretion, decrease rate of gastric emptying, decrease appetite

Drug Type	Mechanisms of Metabolic Control
Amylin mimetics (pramlintide)	Decrease glucagon secretion, decrease rate of gastric emptying, and decrease appetite
SGLT2 inhibitor; In clinical trials: canagliflozin, dapagliflozin, empagliflozin	Inhibits proximal tubular renal transport of glucose, decreasing glucose reabsorption and increasing renal excretion of glucose independent of insulin
Bromocriptine mesylate	Increases CNS dopamine, reducing sympathetic nervous activity, hepatic glucose production, and lipolysis

CNS, Central nervous system; *DPP-IV*, dipeptidyl peptidase-IV; *GLP-1*, glucagon-like peptide-1; *SGLT2*, sodium-glucose cotransporter 2.

Data from Brietzke SA. Oral antihyperglycemic treatment options for type 2 diabetes mellitus. *Medical Clinics of North America*, 2015;99(1):87–106; Tran L, Zielinski A, Roach AH, et al. Pharmacologic treatment of type 2 diabetes: Oral medications. *Annals of Pharmacotherapy*, 2015;49(5):540–556.

If treatment goals are still not met, a combination of drugs, including SGLT2 inhibitors, may be required. Insulin therapy may be needed in the later stage of type 2 diabetes because of loss of β-cell function, which is progressive over time (Emerging Science Box: Smart Pens for Improved Safety and Efficacy of Insulin Therapy).

Gestational Diabetes Mellitus and Specific Types of Diabetes Mellitus From Other Causes

As listed in Table 22.7 the ADA classification of diabetes mellitus not only includes the most common forms of diabetes (type 1 and type 2) but also encompasses GDM and specific types of diabetes mellitus from other causes.

Gestational diabetes mellitus (GDM) complicates approximately 7% of pregnancies and is defined as diabetes diagnosed in the second or third trimester of pregnancy that was not clearly overt diabetes prior to gestation.[26] In most cases, this hyperglycemia is the result of IGT due to

pancreatic β-cell dysfunction on a background of chronic insulin resistance. Risk factors for GDM include overweight and obesity, advanced maternal age, and a family history of any form of diabetes.[32] An OGTT is used to confirm the diagnosis. However, this definition means that many women with previously undiagnosed type 1 or type 2 diabetes are diagnosed with GDM, and many of them have progressive disease after delivery. Therefore, the ADA recommends that women with risk factors for diabetes be screened at their initial prenatal visit and that women diagnosed during pregnancy should continue to be monitored postpartum and at least every 3 years for persistent or recurrent diabetes.[26] Careful glucose control prenatally, during pregnancy, and after delivery is essential to the short- and long-term health of both mother and baby.

Specific types of diabetes from other causes include monogenic diabetes syndromes (e.g., MODY), disease of the exocrine pancreas (e.g., cystic fibrosis), and drug- or chemical-induced diabetes (e.g., with glucocorticoid use, in the treatment of HIV/AIDS, or after organ transplantation). Maturity-onset diabetes of youth (MODY) usually presents before 25 years of age and includes at least 13 genetic mutations that affect critical enzymes involved in β-cell function but with little impact on insulin action.[26] The diagnosis of MODY should be considered in individuals who have atypical clinical presentations, who are diagnosed within the first 6 months of life (neonatal diabetes), and who have a strong family history of diabetes. Diagnosis includes genetic testing for the three most common forms of MODY. Management is similar to that used for type 2 diabetes. Diabetes also can result from pancreatic damage incurred through the effects of cystic fibrosis, medications, and immunosuppression after organ transplantation.

Acute Complications of Diabetes Mellitus

The major acute complications of diabetes mellitus are hypoglycemia, DKA, and hyperosmolar hyperglycemic nonketotic syndrome (HHNKS).[33] A comparison of these complications is summarized in Table 22.10.

Table 22.10

Common Acute Complications of Diabetes Mellitus

Hypoglycemia in Persons With Diabetes Mellitus	Diabetic Ketoacidosis	Hyperglycemic Nonketotic Syndromes
Synonyms		
Insulin shock, insulin reaction	Diabetic coma syndrome	Hyperosmolar hyperglycemia nonketotic coma
Persons at Risk		
Individuals taking insulin Individuals with rapidly fluctuating blood glucose levels Individuals with type 2 diabetes taking non-insulin antidiabetic medications	Individuals with type 1 diabetes Individuals with undiagnosed diabetes	Older adults with type 2 diabetes, nondiabetic persons with predisposing factors, such as pancreatitis; individuals with undiagnosed diabetes
Predisposing Factors		
Excessive insulin or non-insulin antidiabetic agents, lack of sufficient food intake, excessive physical exercise, abrupt decline in insulin needs (e.g.,	Stressful situation such as infection, accident, trauma, emotional stress; omission of insulin; medications that antagonize insulin	Infection, medications that antagonize insulin, comorbid condition

Hypoglycemia in Persons With Diabetes Mellitus	Diabetic Ketoacidosis	Hyperglycemic Nonketotic Syndromes
Synonyms		
renal failure, immediately postpartum), simultaneous use of insulin-potentiating agents or β-blocking agents that mask symptoms		
Typical Onset		
Rapid	Slow	Slowest
Presenting Symptoms		
Adrenergic reaction: pallor, sweating, tachycardia, palpitations, hunger, restlessness, anxiety, tremors Neurogenic reaction: fatigue, irritability, headache, loss of concentration, visual disturbances, dizziness, hunger, confusion, transient sensory or motor defects,	Malaise, dry mouth, headache, polyuria, polydipsia, weight loss, nausea, vomiting, pruritus, abdominal pain, lethargy, shortness of breath, Kussmaul respirations, fruity or acetone odor to breath	Polyuria, polydipsia, hypovolemia, dehydration (parched lips, poor skin turgor), hypotension, tachycardia, hypoperfusion, weight loss, weakness, nausea, vomiting, abdominal pain, hypothermia, stupor, coma, seizures

Hypoglycemia in Persons With Diabetes Mellitus	**Diabetic Ketoacidosis**	**Hyperglycemic Nonketotic Syndromes**
Synonyms		
convulsions, coma, death		
Laboratory Analysis		
Serum glucose <30 mg/dL in newborn (first 2–3 days) and <55–60 mg/dL in adults	Glucose levels >250 mg/dL, reduction in bicarbonate concentration, increased anion gap, increased plasma levels of β-hydroxybutyrate, acetoacetate, and acetone	Glucose levels >600 mg/dL, lack of ketosis, serum osmolarity >320 mOsm/L, elevated blood urea nitrogen and creatinine levels

Hypoglycemia in Persons With Diabetes Mellitus	Diabetic Ketoacidosis	Hyperglycemic Nonketotic Syndromes
Synonyms		
Insulin shock, insulin reaction	Diabetic coma syndrome	Hyperosmolar hyperglycemia nonketotic coma
Persons at Risk		
Individuals taking insulin Individuals with rapidly fluctuating blood glucose levels Individuals with type 2 diabetes taking non-insulin antidiabetic medications	Individuals with type 1 diabetes Individuals with undiagnosed diabetes	Older adults with type 2 diabetes, nondiabetic persons with predisposing factors, such as pancreatitis; individuals with undiagnosed diabetes
Predisposing Factors		
Excessive insulin or non-insulin antidiabetic agents, lack of sufficient food intake, excessive physical exercise, abrupt decline in insulin needs (e.g., renal failure, immediately postpartum), simultaneous use of insulin-potentiating agents or β-blocking agents that mask symptoms	Stressful situation such as infection, accident, trauma, emotional stress; omission of insulin; medications that antagonize insulin	Infection, medications that antagonize insulin, comorbid condition
Typical Onset		
Rapid	Slow	Slowest
Presenting Symptoms		
Adrenergic reaction: pallor, sweating, tachycardia, palpitations, hunger, restlessness, anxiety, tremors Neurogenic reaction: fatigue, irritability, headache, loss of concentration, visual disturbances, dizziness, hunger, confusion, transient sensory or motor defects, convulsions, coma, death	Malaise, dry mouth, headache, polyuria, polydipsia, weight loss, nausea, vomiting, pruritus, abdominal pain, lethargy, shortness of breath, Kussmaul respirations, fruity or acetone odor to breath	Polyuria, polydipsia, hypovolemia, dehydration (parched lips, poor skin turgor), hypotension, tachycardia, hypoperfusion, weight loss, weakness, nausea, vomiting, abdominal pain, hypothermia, stupor, coma, seizures
Laboratory Analysis		
Serum glucose <30 mg/dL in newborn (first 2–3 days) and <55–60 mg/dL in adults	Glucose levels >250 mg/dL, reduction in bicarbonate concentration, increased anion gap, increased plasma levels of β-hydroxybutyrate, acetoacetate, and acetone	Glucose levels >600 mg/dL, lack of ketosis, serum osmolarity >320 mOsm/L, elevated blood urea nitrogen and creatinine levels

Hypoglycemia in diabetes is sometimes called *insulin shock* or *insulin reaction*. Individuals with type 1 diabetes require insulin to manage their diabetes and are at more risk for hypoglycemia than those with type 2 diabetes because they have more severe deficits in their ability to control serum glucose levels. Significant drops in blood sugar most often occur when there is an unexpected change in caloric intake or exercise without appropriate modification of insulin dosing. Hypoglycemia sometimes occurs in type 2 diabetes during treatment with insulin or non-insulin antidiabetic medications. Symptoms include pallor, tremor, anxiety, tachycardia, palpitations, diaphoresis, headache, dizziness, irritability, fatigue, poor judgment, confusion, visual disturbances, hunger, seizures, and coma. Treatment requires immediate replacement of glucose either orally or intravenously. Glucagon for home use can be prescribed for individuals who are at high risk. Prevention is achieved with

individualized management of medications and diet, monitoring of blood glucose levels, and education.

Diabetic ketoacidosis (DKA) is a serious complication related to a deficiency of insulin and an increase in the levels of insulin counterregulatory hormones (catecholamines, cortisol, glucagon, GH) (Fig. 22.14). DKA is much more common in type 1 diabetes because insulin is more deficient (see Table 22.10). It is characterized by hyperglycemia, acidosis, and ketonuria. Insulin normally stimulates lipogenesis and inhibits lipolysis, thus preventing fat catabolism. With insulin deficiency, lipolysis is enhanced and there is an increase in the amount of nonesterified fatty acids delivered to the liver. The consequence is increased glyconeogenesis, contributing to hyperglycemia and the production of ketone bodies (acetoacetate, hydroxybutyrate, and acetone) by the mitochondria of the liver at a rate that exceeds peripheral use. Accumulation of ketone bodies causes a drop in pH, resulting in metabolic acidosis and transient hyperkalemia. Symptoms of DKA include Kussmaul respirations (hyperventilation in an attempt to compensate for the acidosis), postural dizziness, central nervous system depression, ketonuria, anorexia, nausea, abdominal pain, thirst, and polyuria. DKA is managed with a combination of fluids, insulin, and electrolyte replacement.

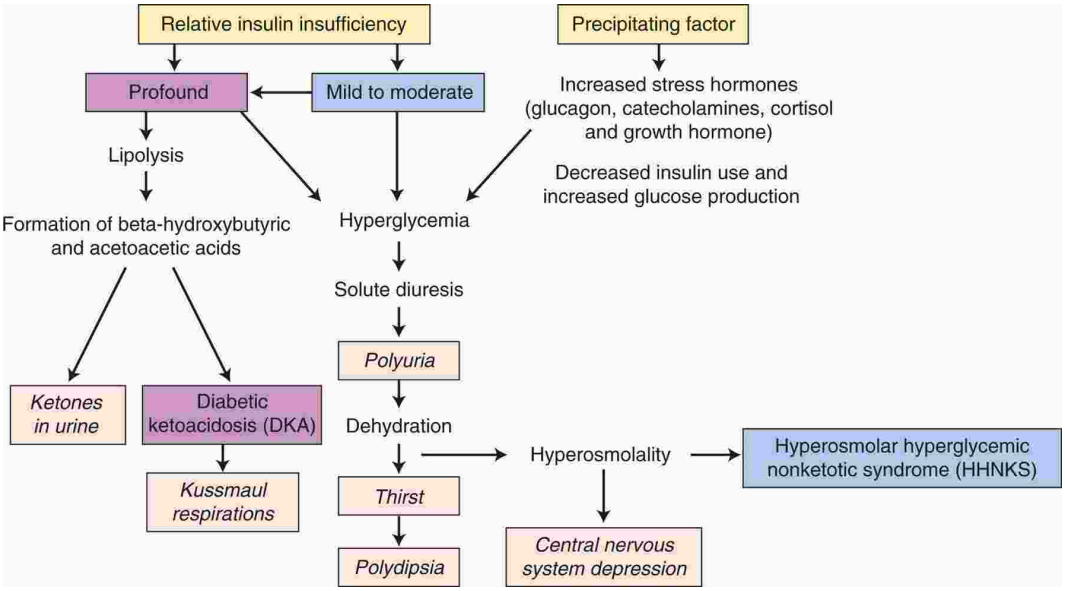

FIG. 22.14 Pathophysiology of Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic Nonketotic Syndrome in Diabetes Mellitus.

A flowchart represents the pathophysiology of diabetic ketoacidosis and hyperosmolar hyperglycemia nonketotic syndrome in diabetes mellitus. The sequence and relationships are as follows. 1. Relative insulin insufficiency. Could be of type 2 and 3. 2. Profound. Leads to 4 and 9. 3. Mid to moderate. Could aggravate to 2 or lead to 10. 4. Lipolysis. Leads to 5. 5. Formation of beta-hydroxybutyric and acetoacetic acids. Leads 6 and 7. 6. Ketones in urine. 7. Diabetic ketoacidosis (D K A). Leads to 8. 8. Kussmaul respirations. 9. Hyperglycemia. Leads to 10. 10. Solute diuresis. Leads to 11. 11. Polyuria. Leads to 12. 12. Dehydration. Leads 13 and 15. 13. Thirst. Leads to 14. 14. Polydipsia. 15. Hyperosmolality. Leads to 16 and 17. 16. Hyperosmolar hyperglycemic nonketotic syndrome (H H N K S). 17. Central nervous system depression. 18. Precipitating factor. Leads to 19 and 20. 19.

Increased stress hormones (glucagon, catecholamines, cortisol and growth hormone). 20. Decreased insulin use and increased glucose production.

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS) is an uncommon but significant complication of diabetes mellitus type 2 with a high overall mortality. It occurs more often in elderly individuals who have other comorbidities, including infections or cardiovascular or renal disease. HHNKS differs from DKA because type 2 diabetes is characterized by a lesser degree of insulin deficiency, which therefore prevents lipolysis and the production of ketones (see Fig. 22.14). However, hyperglycemia is usually more profound in HHNKS leading to more polyuria and fluid deficiency. Therefore, the clinical features of HHNKS include a very high serum glucose concentration and osmolarity without metabolic acidosis. Clinical manifestations include severe dehydration; loss of electrolytes (especially potassium); and neurologic changes, such as stupor. Management includes fluid, insulin, and electrolyte replacement.

Chronic Complications of Diabetes Mellitus

A number of serious complications are associated with any type of poorly controlled diabetes mellitus. Most complications are associated with insulin resistance or deficit and chronic hyperglycemia. Insulin resistance or deficit renders cells unable to process glucose normally, so they resort to a number of alternative pathways for glucose metabolism, particularly through activation of the polyol pathway. This pathway results in the accumulation of sorbitol and glutathione, both of which contribute to chronic tissue damage. Hyperglycemia leads to a number of deleterious effects, including abnormalities in intracellular communication (e.g., protein kinase C pathways) and the attachment of glucose to proteins, lipids, and nucleic acids (glycation). Therefore, glycation creates what are called *advanced glycation end products* (AGEs), which interfere with many crucial cellular processes. The cumulative effect of these abnormal processes leads to the microvascular (damage to capillaries; retinopathies, nephropathies, and neuropathies) and macrovascular (damage to larger vessels; coronary artery, peripheral vascular, and cerebral vascular disease) complications of chronic diabetes mellitus (Table 22.11).

Table 22.11

Chronic Complications of Diabetes Mellitus

Complications	Pathologic Mechanisms	Associated Symptoms
Microvascular		
Retinopathy	Microaneurysms, exudates, hemorrhages, formation of new blood vessels, scarring, retinal detachment. Macular edema may also occur.	Progresses from no visual changes to loss of visual acuity and blindness. Symptoms worsened by hyperosmolar lens edema and cataract formation.
Nephropathy	Glomerulosclerosis, glomerular perfusion and pressure changes, protein glycation	Microalbuminuria and hypertension slowly progressing to end-stage kidney failure

Complications	Pathologic Mechanisms	Associated Symptoms
Microvascular		
Neuropathy	Oxidative stress, poor perfusion and ischemia, loss of nerve growth factor	Sensorimotor polyneuropathy progressing to distal paresthesias in feet and hands, muscle wasting, Charcot joints, falls and injuries. Autonomic neuropathy progressing to postural hypotension, gastroparesis, urinary retention, and erectile dysfunction.
Skin and foot lesions	Loss of sensation, poor perfusion, suppressed immunity, and increased risk of infection	Pressure ulcers and delayed wound healing; abscess formation; necrosis and gangrene of toes and feet; infection and osteomyelitis
Macrovascular		
Cardiovascular	Accelerated atherosclerosis	Hypertension, coronary artery disease, cardiomyopathy, and heart failure
Cerebrovascular	Same as above	Increased risk for ischemic and thrombotic stroke
Peripheral vascular	Same as above	Claudication, nonhealing ulcers, gangrene
Infection		

Complications	Pathologic Mechanisms	Associated Symptoms
Microvascular		
	Impaired immunity, tissue ischemia, recurrent trauma, delayed wound healing, urinary retention	Skin and wound infections, urinary tract infections, increased risk for sepsis

Complications	Pathologic Mechanisms	Associated Symptoms
Microvascular		
Retinopathy	Microaneurysms, exudates, hemorrhages, formation of new blood vessels, scarring, retinal detachment. Macular edema may also occur.	Progresses from no visual changes to loss of visual acuity and blindness. Symptoms worsened by hyperosmolar lens edema and cataract formation.
Nephropathy	Glomerulosclerosis, glomerular perfusion and pressure changes, protein glycation	Microalbuminuria and hypertension slowly progressing to end-stage kidney failure
Neuropathy	Oxidative stress, poor perfusion and ischemia, loss of nerve growth factor	Sensorimotor polyneuropathy progressing to distal paresthesias in feet and hands, muscle wasting, Charcot joints, falls and injuries. Autonomic neuropathy progressing to postural hypotension, gastroparesis, urinary retention, and erectile dysfunction.
Skin and foot lesions	Loss of sensation, poor perfusion, suppressed immunity, and increased risk of infection	Pressure ulcers and delayed wound healing; abscess formation; necrosis and gangrene of toes and feet; infection and osteomyelitis
Macrovascular		
Cardiovascular	Accelerated atherosclerosis	Hypertension, coronary artery disease, cardiomyopathy, and heart failure
Cerebrovascular	Same as above	Increased risk for ischemic and thrombotic stroke
Peripheral vascular	Same as above	Claudication, nonhealing ulcers, gangrene
Infection		
	Impaired immunity, tissue ischemia, recurrent trauma, delayed wound healing, urinary retention	Skin and wound infections, urinary tract infections, increased risk for sepsis

Microvascular Disease

Diabetic microvascular complications are characterized by occlusion of capillaries, with associated ischemia of tissues.[34] It is a leading cause of blindness, diabetic nephropathy (including end-stage kidney failure), and various neuropathies. Approximately half of the individuals diagnosed with diabetes mellitus type 2 develop peripheral neuropathy. This progressive disorder is chronic, affecting the peripheral nervous system and characterized by allodynia, pain, and paresthesia symptoms. Neuropathies are caused by axonal degeneration and segmental demyelination. The frequency and severity of complications appear to be

proportional to the duration of the disease (more or less than 10 years) and the status of glycemic control. Hypoxia and ischemia accompany microvascular disease, especially in the eye, kidney, and nerves. Many individuals with type 2 diabetes will present with microvascular complications because of the long duration of asymptomatic hyperglycemia that generally precedes diagnosis. This underscores the need to screen for diabetes.

Diabetic retinopathy

Diabetic retinopathy is a leading cause of blindness worldwide and is a common complication of type 2 diabetes because of the likelihood of long-standing hyperglycemia before diagnosis. Most individuals with diabetes will eventually develop retinopathy and also are more likely to develop cataracts and glaucoma (see Chapter 16).

Diabetic retinopathy results from relative hypoxemia, damage to retinal blood vessels, RBC aggregation, and hypertension (Fig. 22.15).[35] The three stages of retinopathy that lead to loss of vision are *nonproliferative* (stage I), characterized by an increase in retinal capillary permeability, vein dilation, microaneurysm formation, and superficial (flame-shaped) and deep (blot) hemorrhages; *preproliferative* (stage II), a progression of retinal ischemia, with areas of poor perfusion that culminate in infarcts; and *proliferative* (stage III), the result of neovascularization (angiogenesis) and fibrous tissue formation within the retina or optic disc. Traction of the new vessels on the vitreous humor may cause retinal detachment or hemorrhage into the vitreous humor, with severe blurring or loss of vision. Macular edema is the leading cause of blurred vision among persons with diabetes. Blurring of vision also can be a consequence of hyperglycemia and sorbitol accumulation in the lens. Dehydration of the lens, aqueous humor, and vitreous humor also reduces visual acuity.

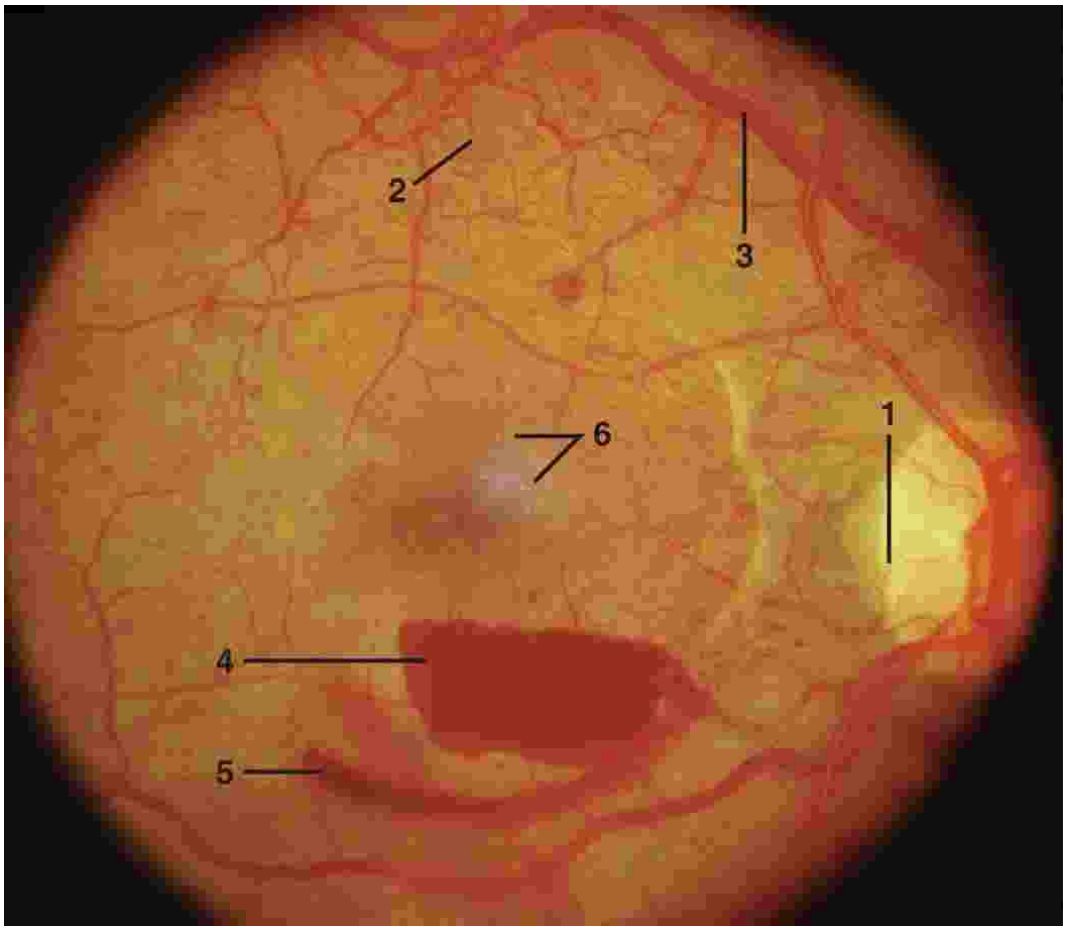

FIG. 22.15 Diabetic Retinopathy.
Neovascularization is present at the optic nerve ***(1)*** and along vascular pathways ***(2)***. Retinal veins are engorged ***(3)*** and a preretinal boat-shaped hemorrhage ***(4)*** is present below the fovea. A more diffuse mild vitreous hemorrhage ***(5)*** is present below the preretinal hemorrhage. A few small, hard exudates are visible in the fovea ***(6)***. (From Palay DA, Krachmer JH. *Primary care ophthalmology*, 2nd edition. St. Louis: Mosby; 2006.)

Diabetic nephropathy

Diabetes is the most common cause of chronic kidney disease and end-stage renal disease in the world. Nearly half of individuals with diabetes mellitus develop diabetic nephropathy.[36] Renal glomerular changes occur early in diabetes mellitus, occasionally preceding the overt manifestation of the disease. The glomeruli are injured by hyperglycemia with protein

glycation (bonding of a glucose molecule to a protein), high renal blood flow (hyperfiltration), and intraglomerular hypertension exacerbated by systemic hypertension (Fig. 22.16). There is progressive glomerulosclerosis and decreased glomerular blood flow and glomerular filtration that can progress to renal failure. Tubulointerstitial fibrosis also develops in advanced stages of disease. Loss of autoregulation of renal blood flow and anemia contribute to hypoxia. Hyperglycemia and glomerular hyperfiltration increase tubular reabsorption of glucose promoting inflammation and activation of growth factors and fibroblasts. The consequence is tubulointerstitial fibrosis which contributes to renal failure.[37]

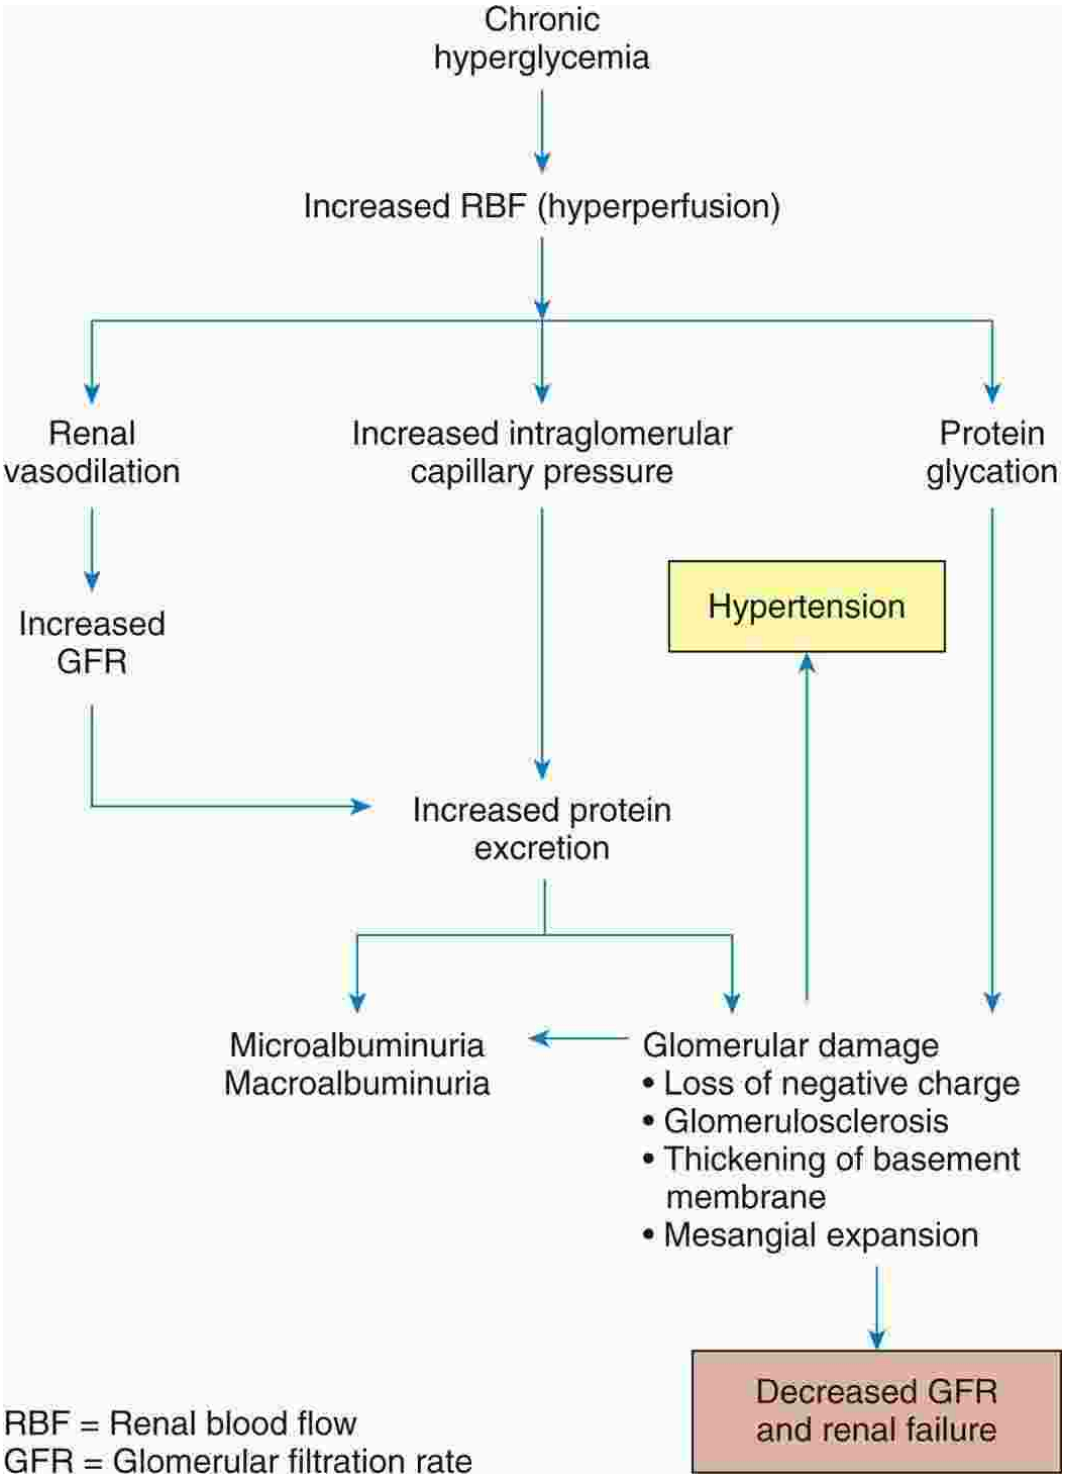

FIG. 22.16 Diabetic Nephropathy.

A flowchart represents diabetic nephropathy. 1. Chronic hyperglycemia. Leads to 2. 2. Increased R B F

(hyperperfusion). Leads to 3, 5, and 7. 3. Renal vasodilation. Leads to 4. 4. Increased G F R. Leads to 8. 5. Increased intraglomerular capillary pressure. Leads to 6. 6. Increased protein excretion. Leads to 8 and 9. 7. Protein glycation. Leads to 9. 8. Microalbuminuria, macroalbuminuria. 9. Glomerular damage: loss of negative charge; glomerulosclerosis; thickening of basement membrane; mesangial expansion. Leads to 8, 10, and 11. 10. Decreased G F R and renal failure. 11. Hypertension.

Microalbuminuria is the first manifestation of diabetic kidney dysfunction and signals the onset of systemic diabetic complications. Before proteinuria, no clinical signs or symptoms of progressive glomerulosclerosis are likely to be evident. Later, hypoproteinemia, reduction in plasma oncotic pressure, fluid overload, anasarca (generalized body edema), and hypertension may occur. As renal function continues to deteriorate, individuals with type 1 diabetes may experience hypoglycemia (because of loss of renal insulin metabolism), which necessitates a decrease in insulin therapy. As the glomerular filtration rate drops below 10 mL/min, uremic signs, such as nausea, lethargy, acidosis, anemia, and uncontrolled hypertension, occur (see Chapter 38 for a discussion of renal failure). Early diagnosis and control of hypertension and hyperglycemia decreases the severity of nephropathy and delays the onset of end-stage kidney disease.

Diabetic neuropathies

Diabetic neuropathy is the most common complication of diabetes. The underlying pathologic mechanism includes metabolic and vascular factors related to chronic hyperglycemia with ischemia and demyelination contributing to neural changes and delayed conduction. Both somatic and peripheral nerve cells show diffuse or focal damage, resulting in polyneuropathy.[38,39] Loss of pain, temperature, and vibration sensation is more common than motor involvement and often involves the extremities first in the hands and feet. Motor neuropathies can affect muscle groups,

particularly of the legs and feet, contributing to deformity and unstable balance. Peripheral neuropathy can cause Charcot arthropathy, a progressive deterioration of weight-bearing joints, typically in the foot and ankle. Distal neuropathies combined with vascular complications, infection, or injury can lead to amputation (Fig. 22.17).

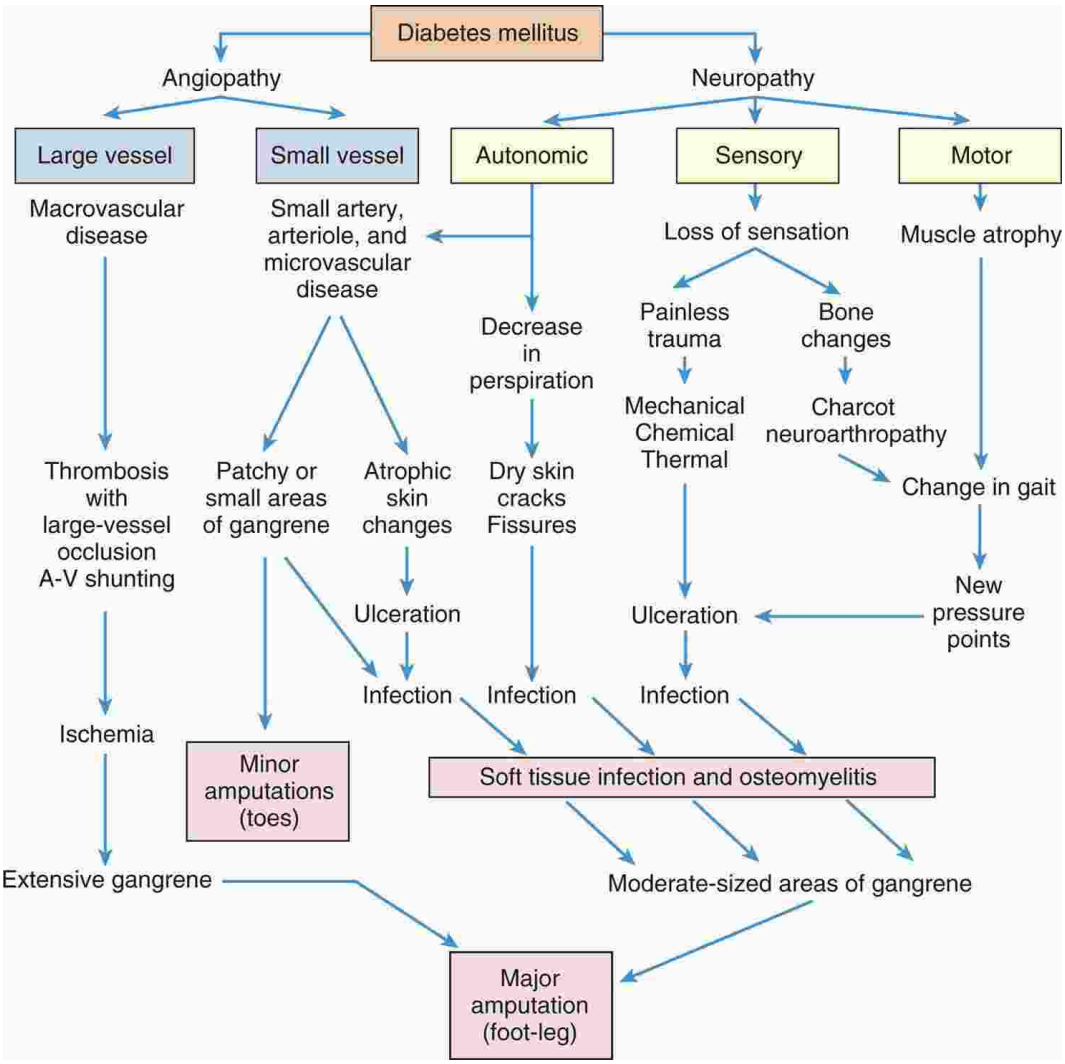

FIG. 22.17

How Foot Lesions of Diabetes Lead to Amputation.

(From Levin ME, et al. *The diabetic foot*, 5th edition. St. Louis: Mosby; 1993.)

A flowchart shows how foot lesions of diabetes lead to amputation. Diabetes can lead to angiopathy or neuropathy. The pathways that lead to amputation (foot-leg) are as follows. 1. Large vessel (from angiopathy); macrovascular disease. Leads to 2. 2. Thrombosis with large-vessel occlusion A-V shunting. Leads to 3. 3. Ischemia. Leads to 4. 4. Extensive gangrene. Leads major

amputation (foot-leg). 5. Small vessel (small artery, arteriole, and microvascular disease). Leads to 6 and 7. 6. Patchy or small areas of gangrene. Leads to minor amputations (toes) and 9. 7. Atrophic skin changes. Leads to 8. 8. Ulceration. Leads to 9. 9. Infection. Leads to 10. 10. Soft tissue infection and osteomyelitis. Leads to 11. 11. Moderate-sized areas of gangrene. Leads to major amputation (foot-leg). 12. Autonomic (from neuropathy). Leads to 5 and 13. 13. Decrease in perspiration. Leads to 14. 14. Dry skin cracks; fissures. Leads to 9. 15. Sensory (from neuropathy). Leads to 16. 16. Loss of sensation. Leads to 17 and 18. 17. Painless trauma. Leads to 19. 18. Bone changes. Leads to 21. 19. Mechanical, chemical, thermal. Leads to 20. 20. Ulceration. Leads to 9. 21. Charcot neuroarthropathy. Leads to 24. 22. Motor (from neuropathy). Leads to 23. 23. Muscle atrophy. Leads to 24. 24. Change in gait. Leads to 25. 25. New pressure points. Leads to 20.

Autonomic neuropathies include delayed gastric emptying, diabetic diarrhea, altered bladder function (e.g., decreased sensation of bladder fullness, urge or overflow incontinence), impotence, orthostatic hypotension, and heart rate variability, with both tachycardia and bradycardia. Neuropathy may occur during periods of "good" glucose control and may be the initial clinical manifestation of diabetes mellitus type 2. Chronic hyperglycemia also can cause cognitive dysfunction with alterations in learning and memory.

Macrovascular Disease

Macrovascular disease (lesions in large- and medium-sized arteries) increases morbidity and mortality and increases the risk for hypertension, accelerated atherosclerosis, cardiovascular disease, stroke, and peripheral vascular disease (PVD), particularly among individuals with diabetes

mellitus type 2 (atherosclerosis is discussed in Chapter 32). Children with poorly controlled diabetes have higher risk for macrovascular complications within 1 to 2 decades. The process tends to be more severe and accelerated in the presence of other risk factors, including obesity, hyperlipidemia, and smoking.

Cardiovascular disease

Cardiovascular disease is the primary cause of death of people with diabetes, with higher risk for women. Hypertension often coexists with diabetes mellitus. Diabetes also is associated with deleterious changes in serum lipids, including high levels of low-density lipoproteins (LDLs), and low levels of high-density lipoproteins (HDLs). The combination of diabetes, hypertension dyslipidemia, and obesity (metabolic syndrome) greatly increases the risk for atherosclerotic cardiovascular disease, particularly CAD and stroke. CAD results from vessel injury related to insulin resistance and hyperglycemia, leading to accelerated atherosclerosis (see Chapter 32). In general, the prevalence of CAD increases with the duration but not the severity of diabetes, and the onset can be silent.

The incidence of *congestive heart failure* is higher in individuals with diabetes, even without myocardial infarction. This may be related to cardiomyopathy and the presence of increased amounts of collagen in the ventricular wall and ventricular hypertrophy. There is reduced mechanical compliance of the heart during filling with diastolic and, eventually, systolic failure (heart disease is described in Chapter 32).

Stroke

Stroke is twice as common in those with diabetes (particularly type 2 diabetes) as in the nondiabetic population. As in CAD, accelerated atherosclerosis of the cerebral vessels results from insulin resistance and hyperglycemia, especially when associated with hypertension and hyperlipidemia (see Chapter 18).

Peripheral vascular disease

Diabetes mellitus increases the incidence of PVD. Age, duration of diabetes, genetics, and additional risk factors (smoking, hyperlipidemia, hypertension) influence the development and management of PVD. PVD in those with diabetes is more diffuse and often involves arteries below the knee. Occlusions of the small arteries and arterioles can lead to

claudication (pain from reduced blood flow during exercise), ulcers, gangrene, and amputation. The lesions begin as ulcers and progress to osteomyelitis or gangrene, requiring amputation (see Fig. 22.17). Peripheral neuropathies and an increased risk for infection advance the disease.

Infection

Diabetic individuals are more prone to develop common infections, like cystitis, enteric infections, skin and soft tissue infections, external otitis, pneumonia, appendicitis, and peritonitis as well as rare and severe infections, such as emphysematous pyelonephritis.[40]

The individual with diabetes is at an increased risk for infection throughout the body for several reasons:

1. *The senses*. Impaired vision caused by retinal changes and impaired touch caused by neuropathy lead to loss of protection, with injury and repeated trauma, open wounds, and soft tissue or osseous infection, particularly in the legs and feet.
2. *Hypoxia*. Once skin integrity is compromised, susceptibility to infection increases as a result of hypoxia. In addition, the glycated hemoglobin in the RBCs impedes the release of oxygen to tissues and contributes to delayed wound healing.
3. *Pathogens*. Some pathogens proliferate rapidly because of increased glucose in body fluids, which provides an excellent source of energy.
4. *Blood supply*. Decreased blood supply results from vascular changes and reduces the supply of white blood cells to the affected area.
5. *Suppressed immune response*. Chronic hyperglycemia impairs both innate and adaptive immune responses, including abnormal chemotaxis and vasoactive responses, and defective phagocytosis.

Alterations of Adrenal Function

Disorders of the Adrenal Cortex

Disorders of the adrenal cortex are related either to hyperfunction or to hypofunction. Hyperfunction that causes increased secretion of cortisol (hypercortisolism) leads to Cushing disease or Cushing syndrome. Hyperfunction that causes increased secretion of adrenal androgens or estrogens leads to virilization or feminization. Hyperfunction that causes

increased levels of aldosterone leads to hyperaldosteronism, which may be primary or secondary. These syndromes often have overlapping features. Hypofunction of the adrenal cortex leads to Addison disease.

Hypercortical Function (Cushing Syndrome, Cushing Disease)

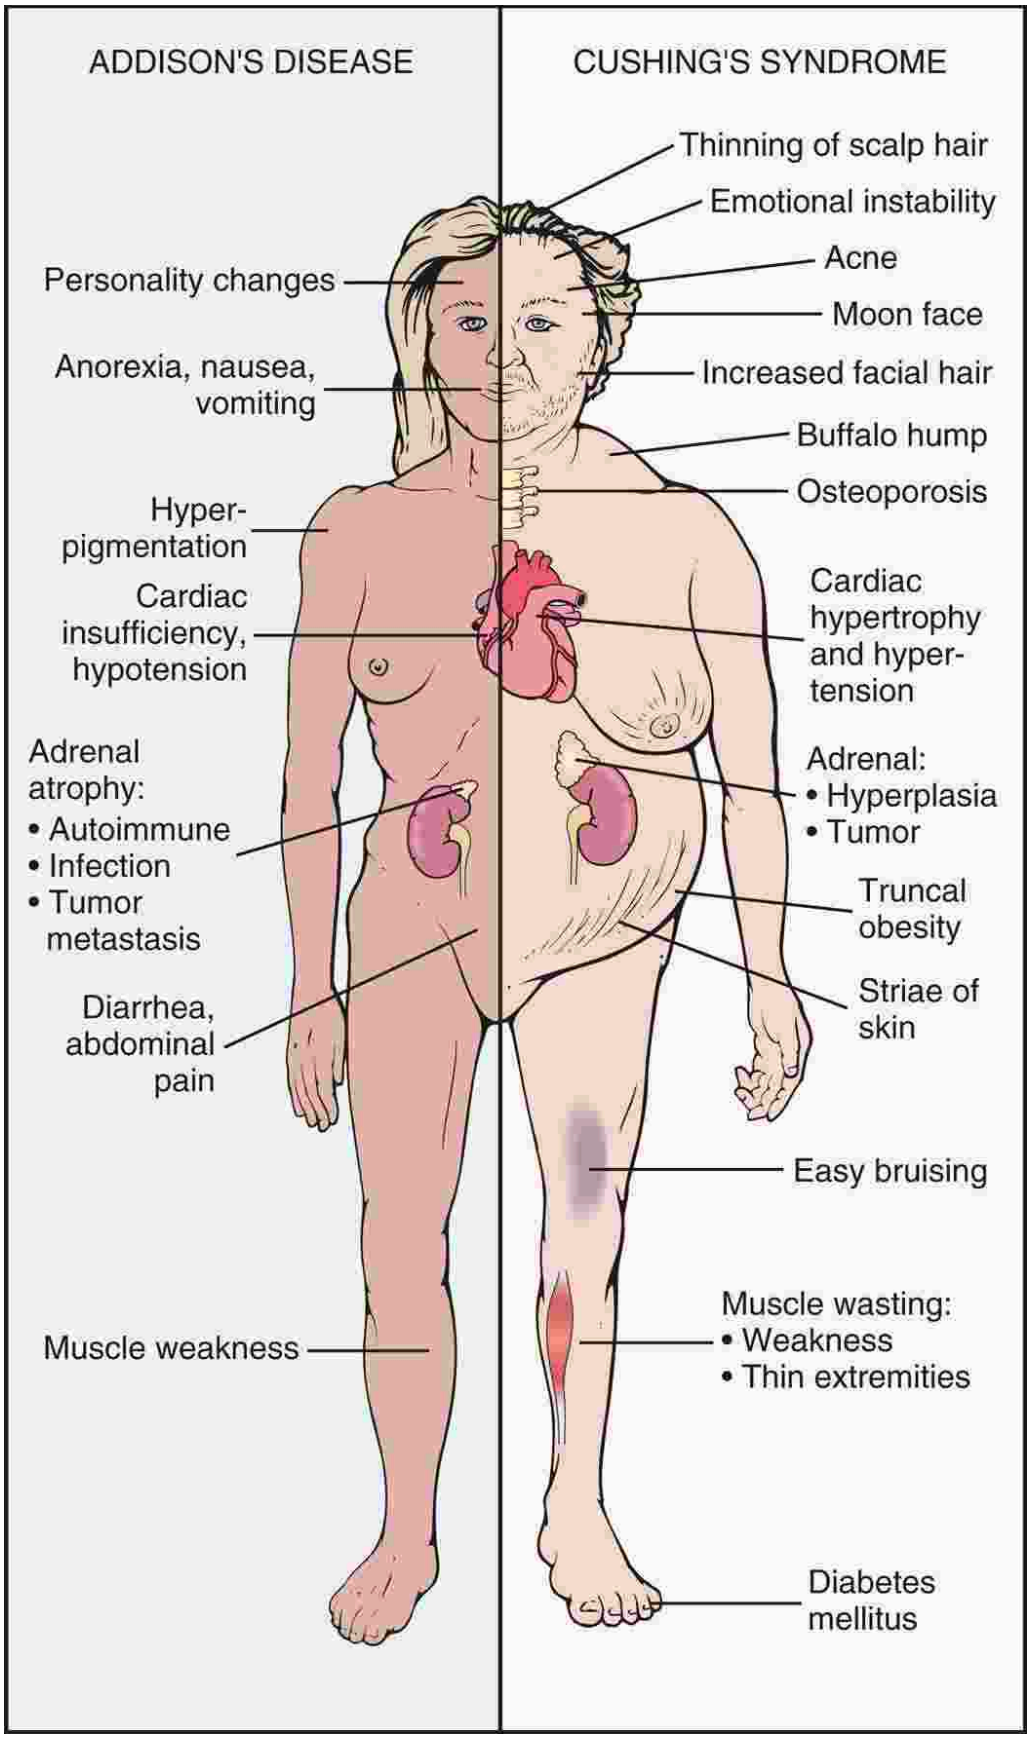
Cushing syndrome (chronic hypercortisolism) refers to the clinical manifestations resulting from chronic exposure to excess cortisol regardless of cause. Cushing disease refers to excess endogenous secretion of ACTH.[41,42] *ACTH-dependent hypercortisolism* (about 80% of cases) results from overproduction of pituitary ACTH by a primary pituitary corticotroph adenoma (most common and can occur at any age) or by an ectopic secreting nonpituitary tumor, such as a small cell carcinoma of the lung (more common in older adults). *ACTH-independent hypercortisolism* is caused by cortisol secretion from a rare benign or malignant tumor of one or both adrenal glands (more common in children). A Cushing-like syndrome may develop as a side effect of long-term pharmacologic administration of glucocorticoids.

Pathophysiology

With ACTH-dependent hypercortisolism, the excess ACTH stimulates excess production of cortisol and there is loss of feedback control of ACTH secretion. In individuals with ACTH-dependent hypercortisolism, secretion of both cortisol and adrenal androgens is increased, and cortisol-releasing hormone is inhibited. In contrast, ACTH-independent secreting tumors of the adrenal cortex generally secrete only cortisol. Elevated cortisol levels suppress CRH and ACTH levels. When the secretion of cortisol by the tumor exceeds normal cortisol levels, symptoms of hypercortisolism develop.

Clinical Manifestations

Weight gain is the most common feature and results from the accumulation of adipose tissue in the trunk, facial, and cervical areas. These characteristic patterns of fat deposition have been respectively described as “truncal obesity,” “moon face,” and “buffalo hump” (Figs. 22.18 and 22.19).



ADDISON'S DISEASE
CUSHING'S SYNDROME
Thinning of scalp hair
Emotional instability
Acne
Moon face
Increased facial hair
Buffalo hump
Osteoporosis
Cardiac hypertrophy and hyper-tension
Adrenal:
• Hyperplasia
• Tumor
Truncal obesity
Striae of skin
Easy bruising
Muscle wasting:
• Weakness
• Thin extremities
Diabetes mellitus
Personality changes
Anorexia, nausea, vomiting
Hyper-pigmentation
Cardiac insufficiency, hypotension
Adrenal atrophy:
• Autoimmune
• Infection
• Tumor metastasis
Diarrhea, abdominal pain
Muscle weakness

FIG. 22.18
Symptoms of Addison and Cushing Diseases. (From Goodman CC, Kelly Snyder TE. *Differential diagnosis for physical therapists*, 5th edition. Philadelphia: Saunders; 2013.)

An illustration of the anterior view of a person identifies and labels the symptoms for Addisonâ€™s disease and Cushingâ€™s syndrome. The symptoms of Addisonâ€™s disease are as follows. â€¢ Personality changes. â€¢ Anorexia, nausea, vomiting. â€¢ Hyperpigmentation. â€¢ Cardiac insufficiency, hypotension. â€¢ Adrenal atrophy: autoimmune, infection, and tumor metastasis. â€¢ Diarrhea, abdominal pain. â€¢ Muscle weakness. The symptoms of Cushingâ€™s syndrome are as follows. â€¢ Thinning of scalp hair. â€¢ Emotional instability. â€¢ Acne. â€¢ Moon face. â€¢ Increased facial hair. â€¢ Buffalo hump. â€¢ Osteoporosis. â€¢ Cardiac hypertrophy and hypertension. â€¢ Adrenal: hyperplasia and tumor. â€¢ Truncal obesity. â€¢ Striae of skin. â€¢ Easy bruising. â€¢ Muscle wasting: weakness and thin extremities. â€¢ Diabetes mellitus.

A
B

FIG. 22.19 Cushing Syndrome. **(A)** Individual before onset of Cushing syndrome. **(B)** Individual 4 months later. Moon facies is clearly demonstrated. (From Zitelli BJ, et al. *Zitelli and Davis' atlas of pediatric physical diagnosis*, 6th edition. London: Saunders; 2012.)

Glucose intolerance occurs because of cortisol-induced insulin resistance and increased gluconeogenesis and glycogen storage by the liver. Overt diabetes mellitus develops in approximately 20% of individuals with hypercortisolism. Polyuria is a manifestation of hyperglycemia and resultant glycosuria.

Protein wasting is caused by the catabolic effects of cortisol on peripheral tissues. Muscle wasting leads to muscle weakness. In bone, loss of the protein matrix leads to osteoporosis, with pathologic fractures, vertebral compression fractures, bone and back pain, kyphosis, and reduced height. Cortisol interferes with the action of GH in long bones; thus, children who present with short stature may be experiencing growth retardation related to Cushing syndrome rather than GH deficiency. Bone disease may contribute to hypercalciuria and resulting renal stones.

In the skin, loss of collagen leads to thin, weakened integumentary tissues through which capillaries are more visible and are easily stretched by adipose deposits. Together, these changes account for the characteristic purple striae seen in the trunk area. Loss of collagenous support around small vessels makes them susceptible to rupture, leading to easy bruising, even with minor trauma. Thin, atrophied skin is also easily damaged, leading to skin breaks and ulcerations. Bronze or brownish hyperpigmentation of the skin, mucous membranes, and hair occurs when there are very high levels of ACTH.

With elevated cortisol levels, vascular sensitivity to catecholamines increases significantly, leading to vasoconstriction and hypertension. Mineralocorticoid effects promote hypokalemia and sodium and water retention with transient weight gain. Suppression of the immune system and increased susceptibility to infections also occur. Approximately 50% of individuals with Cushing syndrome experience irritability and depression, disturbed sleep, difficulty concentrating, memory loss, and, rarely, schizophrenia-like psychosis. Females with ACTH-dependent hypercortisolism may experience symptoms of increased adrenal androgen levels (virilism), with increased hair growth (especially facial hair), acne, and oligomenorrhea. Rarely, unless an adrenal carcinoma is involved, do

androgen levels become high enough to cause changes of the voice, recession of the hairline, and hypertrophy of the clitoris.

Evaluation and Treatment

Routine laboratory examinations may reveal hyperglycemia, glycosuria, hypokalemia, and metabolic alkalosis. A variety of laboratory tests are used to confirm the diagnosis of hypercortisolism and to determine the underlying disorder. These include serum and urinary cortisol levels, serum ACTH levels, and dexamethasone suppression testing. Late-evening salivary cortisol levels are used as a screening. Tumors are diagnosed using imaging procedures.

Treatment is specific for the cause of hypercorticoadrenalism and includes surgery, medication, and radiation. Differentiation between pituitary, ectopic, and adrenal causes is essential for effective treatment. Without treatment, individuals with Cushing syndrome have a high risk for developing overwhelming infection and significant complications from generalized arteriosclerosis and hypertensive disease.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia results from an inherited deficiency of an enzyme that is critical in cortisol biosynthesis in the adrenal gland. Because cortisol is not produced efficiently, the concentration of ACTH increases and causes adrenal hyperplasia, which results in the overproduction of mineralocorticoids or androgens, or both. The most common form is a 21-hydroxylase deficiency, which involves both mineralocorticoid and cortisol synthesis. Affected female children are virilized, and infants of both sexes exhibit salt wasting. Prenatal diagnosis is available, and treatment guidelines have been developed. Disease management requires treatment with glucocorticoids and mineralocorticoids and management of sex steroid excess.

Hyperaldosteronism

Hyperaldosteronism is characterized by excessive adrenal secretion of aldosterone. Both primary and secondary forms of hyperaldosteronism can occur.

Primary hyperaldosteronism (Conn syndrome, primary aldosteronism) is caused by excessive secretion of aldosterone from an abnormality of the adrenal cortex, usually a single benign aldosterone-producing adrenal

adenoma.[43,44] Bilateral adrenal nodular hyperplasia and adrenal carcinomas account for the remainder of cases.

Secondary hyperaldosteronism results from an extra-adrenal stimulus of aldosterone secretion, most often through the secretion of excess angiotensin II in response to decreased circulating blood volume (e.g., in dehydration, shock, or hypoalbuminemia) and decreased delivery of blood to the kidneys (e.g., renal artery stenosis, heart failure, or hepatic cirrhosis). Here, the activation of the renin-angiotensin system and subsequent aldosterone secretion may be seen as compensatory, although in some instances (e.g., congestive heart failure) the increased circulating volume further worsens the condition. Other causes of secondary hyperaldosteronism are Bartter syndrome, a renal tubular defect causing hypokalemia, and renin-secreting tumors of the kidney.

Pathophysiology

In *primary hyperaldosteronism*, pathophysiologic alterations are caused by excessive aldosterone secretion and the fluid and electrolyte imbalances that ensue. Hyperaldosteronism promotes (1) increased renal sodium and water reabsorption with corresponding hypervolemia (see Chapter 3) and hypertension and (2) renal excretion of hydrogen and potassium (see Chapter 3). The extracellular fluid volume overload, hypertension, and suppression of renin secretion are characteristic of primary disorders. Hypokalemic alkalosis, changes in myocardial conduction, and skeletal muscle weakness may be seen, particularly with severe potassium depletion.

In *secondary hyperaldosteronism*, renin secretion is stimulated by pressure-initiated cellular changes at the juxtaglomerular apparatus (see Chapter 37). This leads to an increase in angiotensin II and aldosterone with sodium and water retention and increased circulating blood volume.

Clinical Manifestations

Hypertension, hypokalemia, and hypervolemia are the hallmarks of primary hyperaldosteronism, and renin levels are suppressed. Hypertension is resistant to treatment and can lead to the development of left ventricular dilation and hypertrophy, vascular disease, and kidney disease. Edema is often absent.

Evaluation and Treatment

Various clinical and laboratory evaluations are useful in assessing hyperaldosteronism:

1. Measurement of blood pressure: hypertension is usually present.
2. Serum and urinary electrolyte levels: hypernatremia and metabolic alkalosis may be present.
3. Plasma aldosterone-to-renin ratio and aldosterone suppression testing: an increased aldosterone-to-renin ratio is present in primary hyperaldosteronism.
4. Imaging techniques may be used to localize an aldosterone-secreting adenoma.

Treatment includes management of hypertension, hypervolemia, and hypokalemia, most often with aldosterone receptor antagonists, such as spironolactone, eplerenone, or angiotensin-converting enzyme (ACE) inhibitors. If an aldosterone-secreting adenoma is present, it must be surgically removed.

Hypersecretion of Adrenal Androgens and Estrogens

Hypersecretion of adrenal androgens and estrogens may be caused by adrenal tumors (adenomas or carcinomas), Cushing syndrome, or defects in steroid synthesis. The clinical syndrome that is manifested depends on the hormone secreted, the sex of the individual, and the age at which the hypersecretion is initiated. Hypersecretion of estrogens causes feminization, the development of female secondary sex characteristics. Hypersecretion of androgens causes virilization, the development of male secondary sex characteristics (Fig. 22.20).

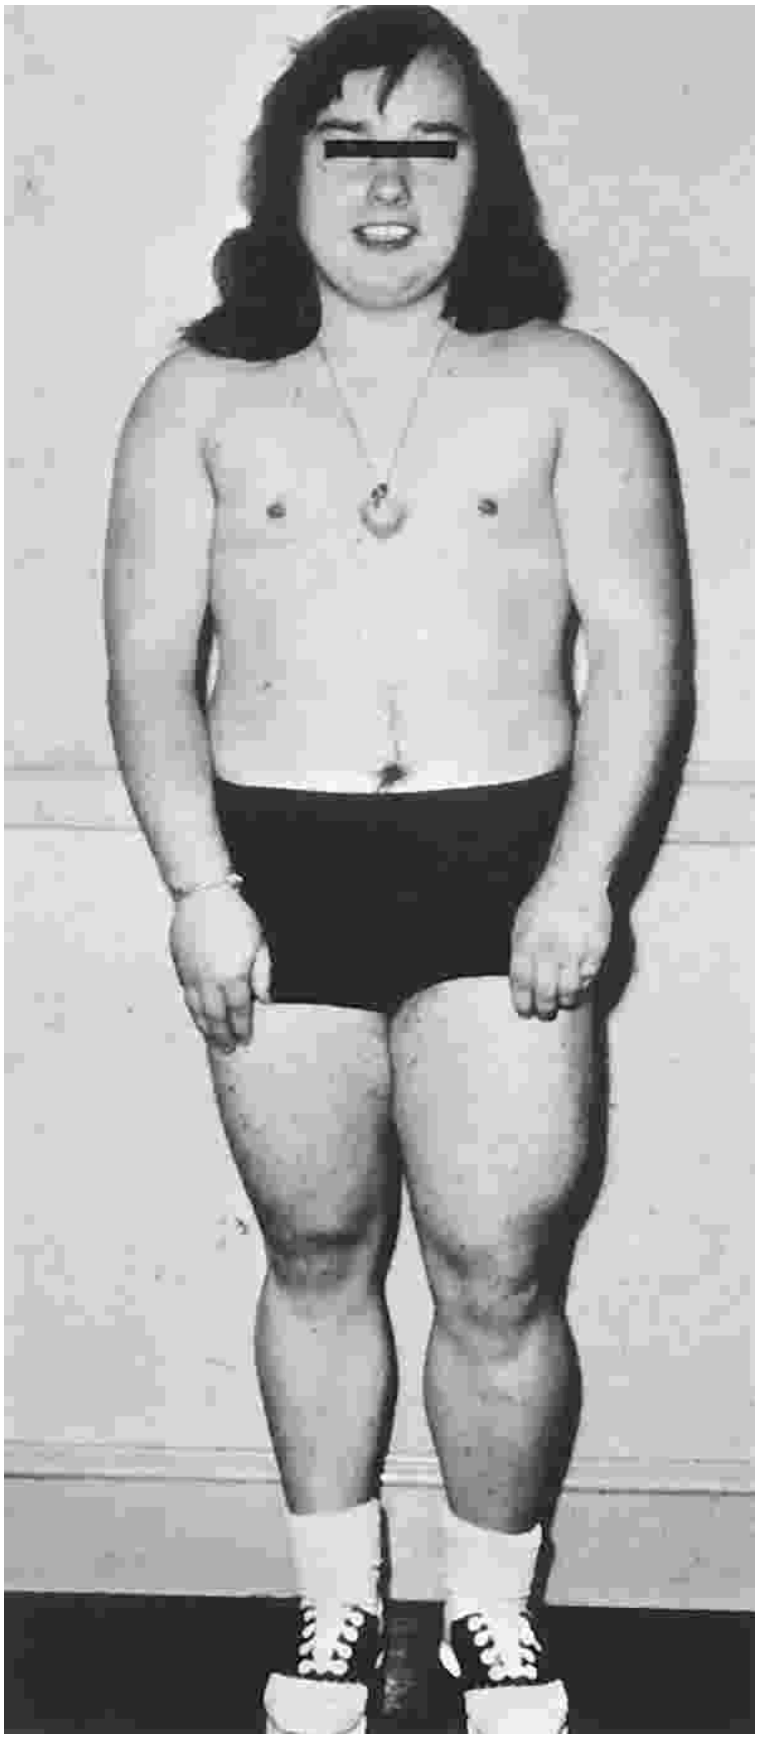


FIG. 22.20 Virilization.
Virilization of a young girl by an androgen-secreting tumor of the adrenal cortex. Masculine features include lack of breast development, increased muscle bulk, and hirsutism (excessive hair). (From Thibodeau GA, Patton KT. *The human body in health & disease*, 4th edition. St. Louis: Mosby; 2010.)

The effects of an estrogen-secreting tumor are most evident in males and result in gynecomastia, testicular atrophy, and decreased libido. In female children, such tumors may lead to early development of secondary sex characteristics. The changes caused by an androgen-secreting tumor are more easily observed in females and include excessive face and body hair (hirsutism), clitoral enlargement, deepening of the voice, amenorrhea, acne, and breast atrophy. In children, virilizing tumors promote precocious sexual development and bone aging. Treatment of adrenal tumors usually involves surgical excision.

Adrenocortical Hypofunction

Hypocortisolism (low levels of cortisol secretion) develops either because of inadequate stimulation of the adrenal glands by ACTH or because of a primary inability of the adrenals to produce and secrete the adrenocortical hormones. Sometimes there is partial dysfunction of the adrenal cortex, so only synthesis of cortisol, aldosterone, or the adrenal androgens is affected.

Addison disease

Primary adrenal insufficiency is termed Addison disease. It is relatively rare, occurring most often in adults aged 30 to 60 years, although it may appear at any time. In the United States, Addison disease is most commonly caused by autoimmune mechanisms that destroy adrenal cortical cells. Chronic infections that affect the adrenal gland, such as tuberculosis, account for the majority of cases of primary adrenal insufficiency in underdeveloped countries.

Pathophysiology

Addison disease is characterized by inadequate corticosteroid and mineralocorticoid synthesis and elevated levels of serum ACTH (loss of negative feedback). Idiopathic Addison disease (organ-specific

autoimmune adrenalitis) causes adrenal atrophy and hypofunction and is an organ-specific autoimmune disease resulting from autoantibodies and autoreactive T cells that attach the adrenal cortical cells. It may occur in childhood (type 1) or adulthood (type 2) and is associated with other autoimmune diseases, especially Hashimoto thyroiditis, pernicious anemia, and idiopathic hypoparathyroidism. In some cases, Addison disease may be inherited as an autosomal recessive trait (Mechanisms of inheritance are described in Chapter 4). The adrenal glands in idiopathic Addison disease are smaller than normal and may be misshapen.

Clinical Manifestations

The symptoms of Addison disease are the result of hypocortisolism and hypoaldosteronism and are often nonspecific. With mild to moderate hypocortisolism, symptoms begin with weakness and easy fatigability. Skin changes, including hyperpigmentation and vitiligo, may occur. As the condition progresses, anorexia, nausea, vomiting, and diarrhea may develop. Of greatest concern is the development of hypotension that can progress to complete vascular collapse and shock. This is known as *adrenal crisis*, or Addisonian crisis, and most often develops in individuals who have undiagnosed disease and experience a physiologic stress.

Evaluation and Treatment

Serum and urine levels of cortisol are depressed with primary hypocortisolism, and ACTH levels are increased. Because of dehydration, blood urea nitrogen levels may increase. The serum glucose level is low. Eosinophil and lymphocyte counts often are elevated. Hyperkalemia is seen in Addison disease and may cause mild alkalosis (see Chapter 3). The ACTH stimulation test may be used to evaluate serum cortisol levels.

The treatment of Addison disease involves lifetime glucocorticoid and mineralocorticoid replacement therapy, together with dietary modifications and correction of any underlying disorders. The individual's diet should include at least 150 mEq of sodium per day; sodium intake should be increased if the individual experiences excessive sweating or diarrhea. With acute stressors (e.g., infection, surgery, or trauma), additional cortisol must be administered.

Secondary hypocortisolism

Secondary hypocortisolism commonly results from prolonged administration of exogenous glucocorticoids; they suppress ACTH

secretion and cause adrenal atrophy, resulting in inadequate corticosteroidogenesis once the exogenous glucocorticoids are withdrawn. Decreased ACTH secretion also can result from pituitary infarction, pituitary tumors that compress ACTH-secreting cells, or hypophysectomy. In all instances of low ACTH levels, adrenal atrophy occurs, and endogenous adrenal steroidogenesis is depressed. Clinical manifestations of secondary hypocortisolism are similar to those of Addison disease, although hyperpigmentation usually does not occur. The renin-angiotensin system usually is normal, so aldosterone and potassium levels also tend to be normal.

Tumors of the Adrenal Medulla

Hyperfunction of the adrenal medulla is caused by pheochromocytomas (chromaffin cell tumors) or sympathetic paragangliomas of the adrenal medulla. These are rare tumors, but 10% to 20% are malignant and may metastasize. Occurrence is usually sporadic, although nearly half are associated with genetic markers that may be inherited.

Pathophysiology

Pheochromocytomas and sympathetic paragangliomas cause excessive production of norepinephrine, although large tumors secrete both epinephrine and norepinephrine. Approximately 5% of people with these tumors have no symptoms, apparently because the tumor is nonfunctioning. Such tumors can, however, release catecholamines, especially in response to a stressor, such as surgery.

Clinical Manifestations

The clinical manifestations of a pheochromocytoma and sympathetic paragangliomas are related to the chronic effects of catecholamine secretion and include persistent hypertension, headache, pallor, diaphoresis, tachycardia, and palpitations. Hypertension results from increased peripheral vascular resistance and may be sustained or paroxysmal. An acute episode of hypertension related to hypersecretion of catecholamines may follow specific events, such as exercise, excessive ingestion of tyrosine-containing foods (aged cheese, red wine, beer, yogurt), ingestion of caffeine-containing foods, external pressure on the tumor, and induction of anesthesia. Hypertension unresponsive to drug therapy is often the first indication of a pheochromocytoma. Headaches

appear because of sudden changes in catecholamine levels in the blood, affecting cerebral blood flow. Hypermetabolism and sweating are related to chronic activation of sympathetic receptors in adipocytes, hepatocytes, and other tissues. Glucose intolerance may occur because of catecholamine-induced inhibition of insulin release by the pancreas. These tumors tend to be extremely vascular and can rupture, causing massive and potentially fatal hemorrhage.

Evaluation and Treatment

Symptoms of pheochromocytoma can be insidious or intermittent and difficult to diagnose. A diagnosis is made when increased catecholamine production is found in the blood or urine. The site of the tumor is then determined using abdominal imaging techniques. Because of the possibility of metastasis, whole-body scanning may be done. Genetic testing can guide therapy.

Management of catecholamine excess is essential to prevent hypertensive emergencies and requires the use of α- and β-adrenergic blockers. The usual treatment of pheochromocytoma is surgical excision of the tumor. Medical therapy is continued to stabilize blood pressure before, during, or after surgery. Malignant pheochromocytoma is rarely curable and is usually managed by a combination of surgical debulking of the tumor combined with chemotherapy.

Summary Review

Mechanisms of Hormonal Alterations

1. Abnormalities in endocrine function may be caused by elevated or depressed hormone levels that result from (1) disorders within glands that cause them to synthesize abnormal amounts of hormone, (2) faulty feedback systems, (3) dysfunctional or ectopically produced hormones, or (4) defects in carrying the hormone in the bloodstream.
2. Target cells may fail to respond to hormones because of (1) cell surface receptor–associated disorders, or (2) intracellular disorders.

Alterations of the Hypothalamic–Pituitary System

1. Dysfunction in the action of hypothalamic hormones is most commonly related to interruption of the connection between the hypothalamus and pituitary—the pituitary stalk.
2. Disorders of the posterior pituitary include syndrome of inappropriate antidiuretic hormone (ADH) secretion (SIADH) and diabetes insipidus. SIADH is characterized by abnormally high ADH secretion; diabetes insipidus is characterized by abnormally low ADH secretion.
3. In SIADH, high ADH levels cause retention of excess free water, leading to hyponatremia and hypoosmolality. SIADH is caused by ectopic production of ADH by tumors, surgical procedures, pulmonary disorders, and central nervous system disorders.
4. Diabetes insipidus may be neurogenic, also known as central (caused by insufficient amounts of ADH), or nephrogenic (caused by an inadequate response to ADH). Low ADH results in excess free water loss leading to hypernatremia and hyperosmolality. Its principal clinical features are polyuria and polydipsia.
5. Diseases of the anterior pituitary include hypopituitarism, hyperpituitarism, acromegaly, and prolactinoma.
6. Hypopituitarism is characterized by the absence of anterior pituitary hormones or the complete failure of all anterior pituitary hormone functions. The most common causes of hypopituitarism are pituitary infarction or space-occupying lesions.
7. Hypopituitarism can affect any or all of the pituitary hormones and symptoms may range from mild to life-threatening, depending on the hormone affected. Adrenocorticotropic hormone (ACTH) deficiency is a potentially life-threatening disorder. Growth hormone (GH) deficiency causes increased body fat, decreased muscle mass, and psychologic problems in adults, and hypopituitary dwarfism in children.
8. Hyperpituitarism is caused by pituitary neuroendocrine tumors. These are usually benign, slow-growing tumors that arise from cells of the anterior pituitary.
9. Expansion of a pituitary neuroendocrine tumor causes both neurologic and secretory effects. Pressure from the expanding tumor causes hyposecretion of surrounding cells, dysfunction of the optic chiasma (leading to visual disturbances), dysfunction of the hypothalamus, and some cranial nerves.

10. Hypersecretion of GH in adults causes acromegaly and is most commonly the result of a pituitary neuroendocrine tumor. Prolonged, abnormally high levels of GH lead to proliferation of body and connective tissue and slowly developing renal, thyroid, and reproductive dysfunction.
11. Excessive GH secretion in children with open epiphyseal plates causes giantism.
12. Prolactinomas, pituitary tumors that secrete prolactin, result in galactorrhea, hirsutism, amenorrhea, hypogonadism, and osteopenia.

Alterations of Thyroid Function

1. Alterations in thyroid function can be primary or secondary. Primary thyroid diseases are caused by dysfunction or disease of the thyroid gland, usually the result of autoimmunity, leading to either increased or decreased thyroid hormone (TH) levels. Secondary thyroid disorders are related to disorders of pituitary gland thyroid-stimulating hormone (TSH) function.
2. Thyrotoxicosis is a general condition resulting from elevated TH levels. Hyperthyroidism is defined as excessive secretion of TH from the thyroid gland. Common clinical manifestations include increased metabolic rate, heat intolerance, and weight loss.
3. Graves disease, the most common form of hyperthyroidism, is caused by an autoimmune mechanism that stimulates the TSH receptors on the thyroid gland. It is characterized by thyrotoxicosis and circulating thyroid-stimulating immunoglobulins. The two distinguishing clinical manifestations are ophthalmopathy and dermopathy (pretibial myxedema).
4. Toxic nodular goiter and toxic multinodular goiter occur when there are independently functioning follicular cells that form adenomas, which produce excessive TH.
5. Thyrotoxic crisis is a severe form of hyperthyroidism that is often associated with physiologic stress.
6. Hypothyroidism is caused by deficient production of TH by the thyroid gland. Primary hypothyroidism has increased levels of TSH and is caused by autoimmune thyroiditis, loss of thyroid tissue, medications, and iodine deficiency. Secondary

hypothyroidism has decreased levels of TSH and is caused by hypothalamic or pituitary dysfunction.

7. Symptoms of hypothyroidism depend on the degree of TH deficiency. Common manifestations include decreased energy metabolism, cold intolerance, decreased heat production, lethargy, and myxedema.
8. Myxedema is a sign of hypothyroidism caused by alterations in connective tissue with water-binding proteins that lead to edema and thickened mucous membranes. Myxedema coma is a severe form of hypothyroidism that may be life-threatening without emergency medical treatment.
9. Autoimmune thyroiditis (Hashimoto disease) is the most common cause of primary hypothyroidism in the United States and involves autoimmune destruction of the thyroid gland and gradual loss of thyroid function.
10. Subacute thyroiditis is a nonbacterial inflammation of the thyroid gland that is often preceded by a viral infection.
11. Postpartum thyroiditis generally occurs up to 6 months after giving birth. Iatrogenic hypothyroidism results from ablation of the thyroid gland during treatment for hyperthyroid conditions.
12. Congenital hypothyroidism is the absence of thyroid tissue during fetal development or defects in hormone synthesis and, if untreated, can lead to severe physical and cognitive disorders.
13. Thyroid carcinoma is associated with exposure to ionizing radiation, especially in childhood.

Alterations of Parathyroid Function

1. Hyperparathyroidism, which may be primary, secondary, or tertiary, is characterized by greater than normal secretion of parathyroid hormone (PTH). Hyperparathyroidism leads to neuromuscular symptoms, bone damage, and renal stones.
2. Primary hyperparathyroidism is caused by an interruption of the normal mechanisms that regulate calcium and PTH levels. Hallmark manifestations include hypercalcemia and hypophosphatemia.
3. Secondary hyperparathyroidism is a compensatory response to hypocalcemia and often occurs with chronic renal failure and

vitamin D deficiency.
4. Tertiary hyperparathyroidism develops after long-standing hypocalcemia, especially in individuals undergoing renal dialysis or transplantation.
5. Hypoparathyroidism, defined by abnormally low PTH levels, is caused by thyroid surgery, autoimmunity, or genetic mechanisms.
6. The lack of circulating PTH in hypoparathyroidism causes hypocalcemia, hyperphosphatemia, and decreased bone resorption.

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus

1. Diabetes mellitus is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both.
2. A diagnosis of diabetes mellitus is based on elevated plasma glucose concentrations and measurement of glycated hemoglobin. Classic signs and symptoms are often present as well.
3. Diabetes mellitus is classified as type 1, type 2, or gestational.
4. Diabetes mellitus type 1 is caused by autoimmune β-cell destruction, usually leading to absolute insulin deficiency. It is characterized by loss of β cells, presence of islet cell antibodies, lack of insulin, excess of glucagon, and altered metabolism of fat, protein, and carbohydrates.
5. In diabetes mellitus type 1, hyperglycemia causes polyuria and polydipsia resulting from osmotic diuresis. Hypoglycemia and diabetic ketoacidosis may be seen.
6. Diabetes mellitus type 2 is caused by progressive loss of β-cell insulin secretion frequently on the background of insulin resistance. Genetic susceptibility is triggered by environmental factors. The most compelling environmental risk factor for type 2 diabetes is obesity.
7. In the obese, many factors, including metabolic syndrome, altered adipokines, increased fatty acids, inflammation, and hyperinsulinemia, contribute to the development of insulin resistance and hyperglycemia.
8. Early in the course of diabetes mellitus type 2, hyperinsulinemia occurs in order to overcome underlying insulin resistance. Over

time, however, the weight and number of β cells decrease, and insulin levels decline. There also are decreased levels of amylin, ghrelin, and incretins and glucagon concentration is increased. All contribute to chronic hyperglycemia.

9. Gestational diabetes is glucose intolerance diagnosed during the second or third trimester of pregnancy.
10. The category other specific types of diabetes include monogenetic forms of diabetes called maturity-onset diabetes of youth (MODY).
11. Acute complications of diabetes mellitus include hypoglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome.
12. Hypoglycemia in diabetes is a complication related to insulin treatment.
13. Diabetic ketoacidosis (DKA) develops when there is an absolute or relative deficiency of insulin and an increase in the insulin counterregulatory hormones of catecholamines—cortisol, glucagon, and growth hormone. DKA presents with hyperglycemia, acidosis, and ketonuria.
14. Hyperosmolar hyperglycemic nonketotic syndrome is pathophysiologically similar to DKA, although a lack of ketosis resulting in acidosis indicates some level of insulin action. Severe dehydration and electrolyte imbalance are present.
15. Chronic complications of diabetes mellitus include microvascular disease (e.g., neuropathy, retinopathy, nephropathy), macrovascular disease (e.g., coronary artery disease, stroke, peripheral vascular disease), and infection.
16. Microvascular disease is characterized by obstruction of capillaries and decreased tissue perfusion.
17. Macrovascular disease associated with diabetes mellitus is most often related to the proliferation of atherosclerotic plaques in the arterial wall.
18. The incidence of coronary heart disease, peripheral vascular disease, and stroke is greater in those with diabetes than in nondiabetic individuals.
19. Individuals with diabetes are at risk for a variety of infections. Infection may be related to sensory impairment and resulting injury, hypoxia, increased proliferation of pathogens in elevated concentrations of glucose, decreased blood supply associated with vascular damage, and impaired immune protection.

Alterations of Adrenal Function

1. Disorders of the adrenal cortex are related to hyperfunction (secreting too much hormone) or hypofunction (secreting too little hormone).
2. Increased secretion of cortisol (hypercortisolism) is usually caused by Cushing disease (pituitary-dependent) and very rarely can be caused by ectopic production of ACTH. Complications include obesity, diabetes, protein wasting, immune suppression, and mental status changes.
3. Congenital adrenal hyperplasia is a genetic disorder with overproduction of mineralocorticoids or androgens, or both.
4. Excessive aldosterone secretion causes hyperaldosteronism, which may be primary or secondary. Primary hyperaldosteronism is caused by an abnormality of the adrenal cortex. Secondary hyperaldosteronism involves renin and angiotensin secretion in response to renal underperfusion.
5. Hyperaldosteronism promotes increased sodium reabsorption (with corresponding hypervolemia), increased extracellular volume (which is variable), hypokalemia related to renal reabsorption of sodium, and excretion of potassium.
6. Hypersecretion of adrenal androgens and estrogens can be a result of adrenal tumors, either adenomas or carcinomas; Cushing syndrome; or defects in steroid synthesis. Hypersecretion of estrogens causes feminization, the development of female secondary sexual characteristics. Hypersecretion of androgens causes virilization, the development of male secondary sexual characteristics.
7. Hypocortisolism, or low levels of cortisol, is caused secondarily by inadequate adrenal stimulation by ACTH or because of primary adrenal insufficiency, termed Addison disease.
8. Addison disease is characterized by elevated ACTH levels with inadequate corticosteroid and mineralocorticoid synthesis.
9. Manifestations of Addison disease are related to hypocortisolism and hypoaldosteronism. Symptoms include weakness, fatigability, hyperpigmentation, vitiligo, anorexia, vomiting, and diarrhea. The development of hypotension can progress to complete vascular collapse and shock, known as adrenal crisis, or Addisonian crisis.

10. Secondary hypocortisolism commonly results from prolonged administration of exogenous glucocorticoids that suppress ACTH secretion. Decreased ACTH secretion also can result from pituitary infarction, pituitary tumors, or hypophysectomy. In all instances of low ACTH levels, adrenal atrophy occurs, and endogenous adrenal steroidogenesis is depressed.
11. Hyperfunction of the adrenal medulla is usually caused by a pheochromocytoma, a catecholamine-producing tumor. Symptoms of catecholamine excess include hypertension, palpitations, tachycardia, glucose intolerance, excessive sweating, and constipation.

Emerging Science BoxCombination Therapy for the Treatment of Hypothyroidism

Combination therapy for hypothyroidism was the mainstay of treatment during the late 1800s–mid 1900s. The therapy could include thyroid transplant, thyroid extracts, thyroglobulin, and/or desiccated thyroid. A combination levothyroxine (LT4) and liothyronine (LT3) were noted to restore metabolic effects of thyroid hormone secretions. Due to thyrotoxic symptoms related to this combination therapy, monotherapy with levothyroxine was introduced in the 1970s. Now decades later, clinicians are noting trends in the ability of LT4 alone to normalize basal metabolic rate, cholesterol levels, and satisfaction due to persistent signs and symptoms of hypothyroidism. There is a growing body of evidence supporting physiologic thyroid replacement regimens with the goal of restoring thyroid hormone action within all tissues. This knowledge creates a shift back toward combination therapy as the standard of treatment. A slow-release form of oral LT3 has been developed and applied to rats with hypothyroidism, showing a stabilization of serum T3 levels. There have been no results from human trials as of this writing. Researchers are confident that the development of a long-acting formulation of LT3 in conjunction with LT4 will minimize risk of thyrotoxic symptoms and mimic endogenous thyroid signaling. We could see more individuals with euthyroidism, improvement in cholesterol levels, and overall well-being. What is old could be new again.Data from McAninch EA, et al. Emerging Science BoxPancreatic β Cell Regeneration as a Plausible Diabetic Therapy

The key pathophysiologic indicator for diabetes is an absolute deficiency (diabetes mellitus type 1) or inadequate supply (diabetes mellitus type 2) of functioning β-cells that produce insulin. Insulin resistance is a biproduct of the lack of functional β cells and is the primer for the cascade of negative health effects associated with a diabetes diagnosis. Replenishing β cells can alleviate the burden of disease and research has been underway to better understand regeneration of β cells via animal studies. Emerging science has shown that transdifferentiation of pancreatic cells such as ductal cells, acinar cells, and islet cells have produced functional β cells in mice and rats. There have been recent findings that propose the possibility of endogenous regeneration in humans. Understanding pathophysiology of diabetes brings many questions to the forefront: What is the ability to regenerate β cells in humans in vivo? How is the autoimmune characteristic of diabetes mellitus type 1 addressed so that regeneration is not merely immediate, but long lasting? How do β cells become re-sensitized after prolonged deactivation, secondary to hyperglycemia, as with diabetes mellitus type 2? Regardless, the research continues, and the foundation has been laid for identification of drugs already approved that have the potential to increase regenerative pathways for β cell functionality.Data from Aguayo Mazzucato C, et al. Pancreatic β cell regeneration as a possible therapy for diabetes. *Cell Metabolism*, 2018;27(1):57–67; Balak JRA, et al. Highly efficient ex vivo lentiviral transduction of primary human pancreatic exocrine cells. *Scientific Reports*, 2019;9(1):15870.

Emerging Science BoxInflammation and Its Importance to the Pathophysiology of Insulin Resistance in Prediabetes and Diabetes Mellitus Type 2

Insulin resistance is the hallmark of prediabetes and progression to diabetes mellitus type 2 with a myriad of pathophysiologic mechanisms

that contribute to its occurrence. Systemic inflammation is an underlying current among these mechanisms, contributing to cardiometabolic conditions commonly identified with the diagnosis of diabetes mellitus type 2. A persistent state of hyperglycemia in prediabetes can trigger oxidative stress and inappropriate uptake of proinflammatory markers, which promote vascular dysfunction. Data from the Framingham Offspring study has shown a positive association between frequency of insulin resistance and the amount of urinary 8-epi-prostaglandin F2α (8-epi-PGF2α), an oxidative stress marker, present. This marker was specifically identified in groups with an elevated risk of diabetes such as those with IFG and obesity. Angiopoietin-like protein 2 (ANGPTL2), a proinflammatory cytokine, is predominantly secreted from adipose tissue and the macrophages that accumulate within it. These macrophages influence chronic low-grade inflammation which lead to systemic inflammation, insulin resistance, and increased lipid accumulation in the liver. High serum levels of ANGPTL2 have been identified in the development of renal diabetic disease due to the positive correlation with albumin-to-creatinine ratio and negative correlations with the glomerular filtration rate. Understanding the cascade of inflammation that occurs with insulin resistance can aid in identification of priority lifestyle modifications to combat it with the diagnosis of prediabetes and use of appropriate pharmacologic measure that contribute to the decrease of inflammation with the diagnosis of diabetes mellitus type 2.Data from Luc K, et al. Oxidative stress and inflammatory markers in prediabetes and diabetes. *Journal of Physiology and Pharmacology*, 2019;70(6):10.26402/jpp.2019.6.01. doi:10.26402/jpp.2019.6.01; Pivari F, et al. Curcumin and type 2 diabetes mellitus: Prevention and treatment. *Nutrients*, 2019;11(8):1837. Published August 8, 2019. doi:10.3390/nu11081837; Sasaki Y, et al. Angiopoietin life protein 2 (ANGPTL2) promotes adipose tissue macrophage and T lymphocyte accumulation and leads to insulin resistance. *PLoS One*, 2015;10(7):e0131176. Published July 1, 2015. doi:10.1371/journal.pone.0131176.

Emerging Science BoxSmart Pens for Improved Safety and Efficacy of Insulin Therapy

Insulin pens have improved convenience, accuracy of dosing, medication adherence, and decreased hypoglycemia risk since

introduced as an option for insulin administration. Despite these benefits, there have been challenges for clinicians to optimize glycemic control due to limited information on insulin dose and timing of injection. FDA-approved smart insulin pens provide a record of the amount of insulin and timing of each dose which is transmitted wirelessly to a mobile application on a smartphone. The application, which is user-specific, can track current insulin-on-board, make dose recommendations, and will prepare a report to send to a preferred healthcare provider. The automaticity of the information going to the person and clinician supports treatment plan adherence, insulin dose accuracy and appropriateness, and continuity of care between person and provider. Emerging science boasts a new digital diabetes bionetwork where physiology, behavior, and environment can be evaluated in real time to prevent adverse drug effects, such as hypoglycemia, with insulin use. If cost can be controlled, smart pens could reduce the risk and burden of insulin use and improve overall diabetes care.Data from Klonoff DC, et al. Smart pens will improve insulin therapy. *Journal of Diabetes Science and Technology*, 2018;12(3):551–553; Gildon BW. InPen Smart insulin pen system: Product review and user experience. *Diabetes Spectrum*, 2018;31(4):354–358.

Chapter Outline

OUTLINE

Adipose Tissue, 723
- Adipose Tissue as an Endocrine Organ, 724
- Regulation of Food Intake and Energy Balance, 724

Obesity, 724

Starvation, 730

Anorexia of Aging, 731

Obesity is one of the most common and costly chronic diseases in the world. The causes are complex, multifactorial, and associated with an increased risk of many comorbid diseases. Alternatively, starvation and anorexia of aging also are common conditions. This chapter presents an overview of the function of adipose tissue and the pathophysiology of obesity, starvation, and anorexia of aging.

Adipose Tissue

Adipose tissue provides insulation and mechanical support, secretes hormone like signaling molecules known as *adipokines*, and contributes to immune cell function. It is the body's major energy reserve to fuel other tissues. Adipocytes are fat-storing cells that store calories in the form of triglycerides (triglycerol), synthesize triglycerides from glucose, and mobilize energy in the form of free fatty acids (FFAs) and glycerol. Adipose tissue is classified according to color as white adipose tissue (WAT), brown adipose tissue (BAT), and beige adipose tissue (bAT). These tissue types are found in

different locations within the body and have different functions.[1] Most adipose tissue in the body is WAT.

White adipocytes, which are derived from connective tissue, are located in visceral (central) and subcutaneous (peripheral) stores of WAT. WAT also is found in muscle, providing mechanical protection and sliding of muscle bundles, as well as in bone marrow. WAT contains various cells, including macrophages, mast cells, neutrophils, fibroblasts, endothelial cells, blood vessels, nerves, and precursor adipocytes. White adipocytes contain a single triglyceride fat droplet or vacuole. A low nutritional state, stimulation of the beta adrenergic sympathetic nervous system and release of catecholamines (epinephrine and norepinephrine), activates lipolysis in WAT to release FFAs and glycerol into the circulation. FFAs and glycerol can then be used for energy metabolism.

Subcutaneous or peripheral adipose tissue expands by increased adipocyte size (hypertrophy) and number (hyperplasia).[2] The alterations in precursor cell commitment and subcutaneous adipose tissue adipogenesis are associated with metabolic complications of obesity. Adipogenesis is the formation of new fat cells from preadipocytes. These adipocytes are smaller and have a greater fat storage capacity. Subcutaneous fat has higher leptin production, lower adiponectin production, lower production of inflammatory cytokines, and lower association with insulin resistance. Expansion of subcutaneous fat is a healthier expansion of fat tissue and is associated with fewer complications of obesity.

Visceral adipose tissue is located in the abdomen and surrounding intra-abdominal organs. Visceral WAT is more likely to store fat by adipocyte hypertrophy. Visceral adipocytes store fat as triglycerides, primarily in the form of very-low-density lipoprotein (VLDL), derived from hepatic and dietary sources. Visceral fat is more hormonally active than subcutaneous fat and releases leptin and inflammatory mediators. Excess visceral fat is associated with impaired lipid and glucose metabolism, insulin resistance, metabolic syndrome, and an increased risk of cardiovascular disease and

cancer.[1] Thus, the complications of obesity are related to where fat is stored, not just the accumulation of fat stores.

Estrogen and estrogen receptors have a role in fat metabolism. They enhance the deposition of WAT in the subcutaneous tissue and inhibit it in visceral tissue. This may explain the higher incidence of peripheral obesity among premenopausal women and the increase in central obesity with menopause and in men.[3]

Bone marrow adipose tissue (MAT) is found in all bones, and it increases with obesity and age in long bones. With obesity, MAT releases adipokines that affect osteoblast and osteoclast function and alters hematopoiesis. In general, excessive MAT is associated with osteoporosis and fractures.[4]

Brown adipocytes form BAT and are derived from muscle tissue and have multiple lipid droplets. They are rich in mitochondria that contain iron, which gives them a brown color. Exposure to cold, activation of the sympathetic nervous system, catecholamines, and activation of triiodothyronine (T_3) stimulate BAT to generate heat rapidly through the oxidation of FFAs, acids, and glucose. This is known as *nonshivering thermogenesis;* it occurs at a rate 50-fold greater than in WAT and protects against obesity and metabolic syndrome.[5] Estrogen-related receptors also participate in nonshivering thermogenesis in BAT.[6] Neonates generate body heat from BAT primarily located in the interscapular and perirenal regions. It traditionally was thought that BAT did not persist into adult life. However, positron emission tomography (PET) scanning has shown that adults also have BAT. It is most common in lean individuals, usually located in the neck, supraclavicular, axillary, paravertebral, and mediastinal regions.[7]

There is an inverse relationship between the amount of BAT and both body mass index (BMI) and age. Interindividual differences in BAT-mediated thermogenesis may explain some of the variability in obesity susceptibility and the increased prevalence of obesity with aging. Variation in BAT and bAT also may be factors in the natural regulation of weight reduction.

Located within WAT, particularly in subcutaneous fat stores, are beige—or "brite" (from "brown in white")—adipocytes that form bAT. Beige adipocytes are a subpopulation of white adipocytes that also contain multiple mitochondria but not in the numbers associated with BAT. Beige adipocytes emerge within WAT with chronic exposure to cold and exercise, produce heat, and increase energy expenditure. This is known as the *beiging* or *browning* of WAT. The bAT disappear with elevated ambient temperatures and with warm adaptation revert to WAT.[8] Leptin and insulin together promote bAT, increasing energy expenditure and weight loss. bAT is diminished in obesity. Because the beiging (browning) of adipose tissue protects against obesity and metabolic syndrome, efforts are in progress to discover whether there is a therapeutic way to stimulate the synthesis and activity of BAT and bAT as an approach to preventing or treating obesity and diabetes mellitus.[9]

Adipose Tissue as an Endocrine Organ

Adipose tissue is an endocrine organ, and adipocytes secrete adipokines. Adipokines are cell-signaling proteins that function like hormones, having autocrine, paracrine, and endocrine actions. Adipokines include all the biologically active substances synthesized by WAT. They are necessary for numerous functions in body tissues.[10] These substances function in the regulation of appetite, food intake and energy expenditure, lipid storage, insulin secretion and sensitivity, immune and inflammatory responses, coagulation, fibrinolysis, angiogenesis, fertility, vascular homeostasis, blood pressure regulation, and bone metabolism. Excess WAT causes dysregulation of the secretion and function of adipokines, contributing to the many complications of obesity.

Adipokines are important to understand because they are targets of both experimental and currently available drugs and weight loss programs used to treat obesity and its complications. Examples of adipokines are provided as a reference in Box 23.1 (a summary of adipokines and their role in caloric intake, energy metabolism, and

obesity is presented later in this chapter). The regulation of food intake and energy balance is summarized next.

Box 23.1

Examples of Adipokines Secreted by Adipose Tissue

Adipokines

Increased in Obesity

Leptin (Leptin Resistance)

Inhibits appetite and stimulates energy expenditure
Satiety (hunger/appetite suppression) and regulation of eating behavior by hypothalamus
Sympathoactivation
Insulin sensitizing in liver and skeletal muscle
Modulating role in reproduction, angiogenesis, immune response, blood pressure control, and osteogenesis
Promotes inflammation (a harmful effect)

Angiopoietin-Related Protein 2 (a Vascular Endothelial Growth Factor)

Insulin resistance
Promotes inflammation

Angiotensinogen, Angiotensin Type 1 and Type 1 Receptors, Renin, and Angiotensin-Converting Enzyme

Vasoconstriction
Inflammation
Lipogenesis
Insulin resistance

Retinol-Binding Protein 4 (RBP4) (From Visceral White Adipose Tissue [WAT]; Role Not Clear)

Promotes insulin resistance in muscle
Promotes angiogenesis

Visfatin (From Visceral WAT)

Mimics insulin, binds to insulin receptors, and promotes insulin sensitivity
Promotes adhesion of monocytes to endothelial cells and promotes plaque instability (harmful in cardiac disease)

Decreased in Obesity

Adiponectin

Insulin sensitizing
Anti-inflammatory
Antiatherogenic

Apelin

Improves insulin sensitivity in muscle
Promotes vasodilation by blocking angiotensin
Promotes cardiac contractility

Proinflammatory Cytokines (Increased in Obesity)

Interleukin-6

Promotes insulin resistance
Inhibits adipogenesis
Decreases adiponectin secretion
Promotes inflammation

Monocyte Chemoattractant Protein 1

Attracts macrophages
Promotes insulin resistance
Promotes atherogenesis

Macrophage Products

Plasminogen activator inhibitor 1 (from visceral WAT)
Promotes clot formation (inhibits fibrinolysis) by inhibiting tissue plasminogen activator and urokinase (also released by endothelial cells)
Promotes insulin resistance
Prostaglandin E2 and leukotriene B4
Promotes inflammation
Tumor necrosis factor-alpha
Promotes insulin resistance
Promotes inflammation

Data from Giralt M, Cereijo R, Villarroya F. Adipokines and the endocrine role of adipose tissues. *Handbook of Experimental Pharmacology*, 2016;233:265–282; Luo L, Liu M. Adipose tissue in control of metabolism. *Journal of Endocrinology*, 2016;231(3):R77–R99.

Regulation of Food Intake and Energy Balance

Regulation of food intake and energy balance is a complex process controlled by central and peripheral physiological signals.[11] Centrally, the arcuate nucleus (ARC) in the hypothalamus regulates food intake and energy metabolism by balancing the opposing effects of two sets of neurons. One set of neurons promotes appetite, stimulates eating, and decreases metabolism (anabolic). These are known as *orexigenic neurons*, which are stimulated by molecules called *orexins*. Another set of neurons suppresses appetite, inhibits eating, and increases metabolism. These are known as *anorexigenic neurons*, which are stimulated by molecules called *anorexins*. The hypothalamic orexin and anorexin signaling pathways are transmitted through the autonomic nervous and endocrine systems to regulate and balance appetite, food intake, energy metabolism, and body temperature. The hypothalamus also communicates with

higher brain centers related to reward, pleasure, memory, and addictive behavior. These higher centers can override hypothalamic control of food intake and satiety, which increases consumption of highly palatable foods and results in increased fat stores.[12] Peripherally, the gastrointestinal tract secretes a number of hormones (Box 23.2) that also control hunger and satiety. In addition, adipokines can function as orexins or anorexins and provide peripheral signals for the control of food intake and energy expenditure. They are described in the Adipokines and Obesity section later in the chapter.

Box 23.2

Gastrointestinal Hormones and Obesity

Ghrelin: Stomach (decreased in obesity, but increased after eating; role in obesity not clear)
Stimulates hunger and controls gastric motility and acid secretion, stimulates growth hormone

Glucagon-like peptide 1 (GLP-1): Large intestine (decreased in obesity)
Stimulates insulin secretion; inhibits glucagon release; slows gastric emptying to reduce postprandial hyperglycemia, increases satiety

Peptide YY: Small intestine (decreased in obesity)
Reduces appetite, inhibits gastric motility, increases energy expenditure

Cholecystokinin: Small intestine (probably increased in obesity)
Increases satiation; reduces food intake; stimulates gallbladder contraction, release of pancreatic enzymes and insulin; slows gastric emptying

Obesity

Obesity is an increase in body adipose tissue and an endocrine and metabolic disorder that has become epidemic worldwide. Obesity is defined differently in adults and children. In adults, it is a BMI that exceeds 30 kg/m^2. In children, it is a BMI greater than or equal to the age- and sex-specific 95th percentile of the growth charts published in 2000 by the Centers for Disease Control and Prevention (CDC).[13]

Obesity develops when caloric intake exceeds caloric expenditure in genetically susceptible individuals. Between 2017 and 2018, the prevalence of obesity among U.S. adults was 42.4% and 19.3% among children and adolescents between ages 2 and 19 years.[14,15] Children tend to become obese adults. Ethnic differences also are seen in the rates of obesity: Hispanics (44.8%), non-Hispanic blacks (49.6%), non-Hispanic whites (42.2%), and non-Hispanic Asians (17.4%).[15]

Obesity is the fifth leading cause of death globally and accounts for high health care costs worldwide.[16] Three leading causes of death in the United States are associated with obesity: cardiovascular disease, type 2 diabetes mellitus, and cancer (liver, advanced prostate, ovarian, gallbladder, kidney, colorectal, esophageal, postmenopausal breast, pancreatic, endometrial, and stomach).[17] Obesity is also a risk factor for hypertension, stroke, hyperlipidemia, gallstones, nonalcoholic steatohepatitis (NASH), gastroesophageal reflux, hiatal hernia, osteoarthritis, infectious disease, asthma, obstructive sleep apnea, and chronic kidney disease.[18] However, some studies have shown that mild obesity in older individuals is associated with lower mortality (the obesity paradox), particularly in individuals with hypertension and coronary heart disease, but the mechanisms are not clear.[19] The causes and consequences of obesity are multiple and complex, and rapidly advancing research is underway on the causal mechanisms, complications, and treatment.

Genotype and gene–environment interactions are important predisposing factors. Single-gene defects (monogenic defects) are rare, and obesity is usually polygenic and associated with other

phenotypes, such as endocrine disorders (e.g., diabetes mellitus and hypothyroidism) and intellectual disability (e.g., Down and Prader-Willi syndromes).[20] Metabolic abnormalities that contribute to obesity include Cushing syndrome, Cushing disease, polycystic ovary syndrome, growth hormone (GH) deficiency, hypothyroidism, and hypothalamic injury. Contributing environmental factors include food intake (low nutrient, energy-dense foods), physical inactivity, obesogens, and socioeconomic status (both high and low income). Obesity also is associated with adverse social and psychological consequences, including depression and mood disorders.[21]

Pathophysiology

The pathophysiology of obesity is complex and involves the interaction of peripheral and central neuroendocrine pathways, numerous adipokines, hormones, and neurotransmitters (Fig. 23.1).[22,23] The adipocyte is the cellular basis of obesity. Excess fat is stored in mature white adipocytes when energy balance is positive (excess caloric intake in relation to energy expenditure). These adipocytes undergo hypertrophy and adipogenesis (hyperplasia), store triglycerol, and secrete adipokines. Adipokines circulate in the blood at concentrations that increase or decrease in relation to body fat mass and provide signals to the central nervous system for regulation of hunger, satiety, and energy balance, as described previously. WAT accumulation causes dysfunction in the regulation and interaction of this signaling system and contributes to the complications and consequences of obesity.[24]

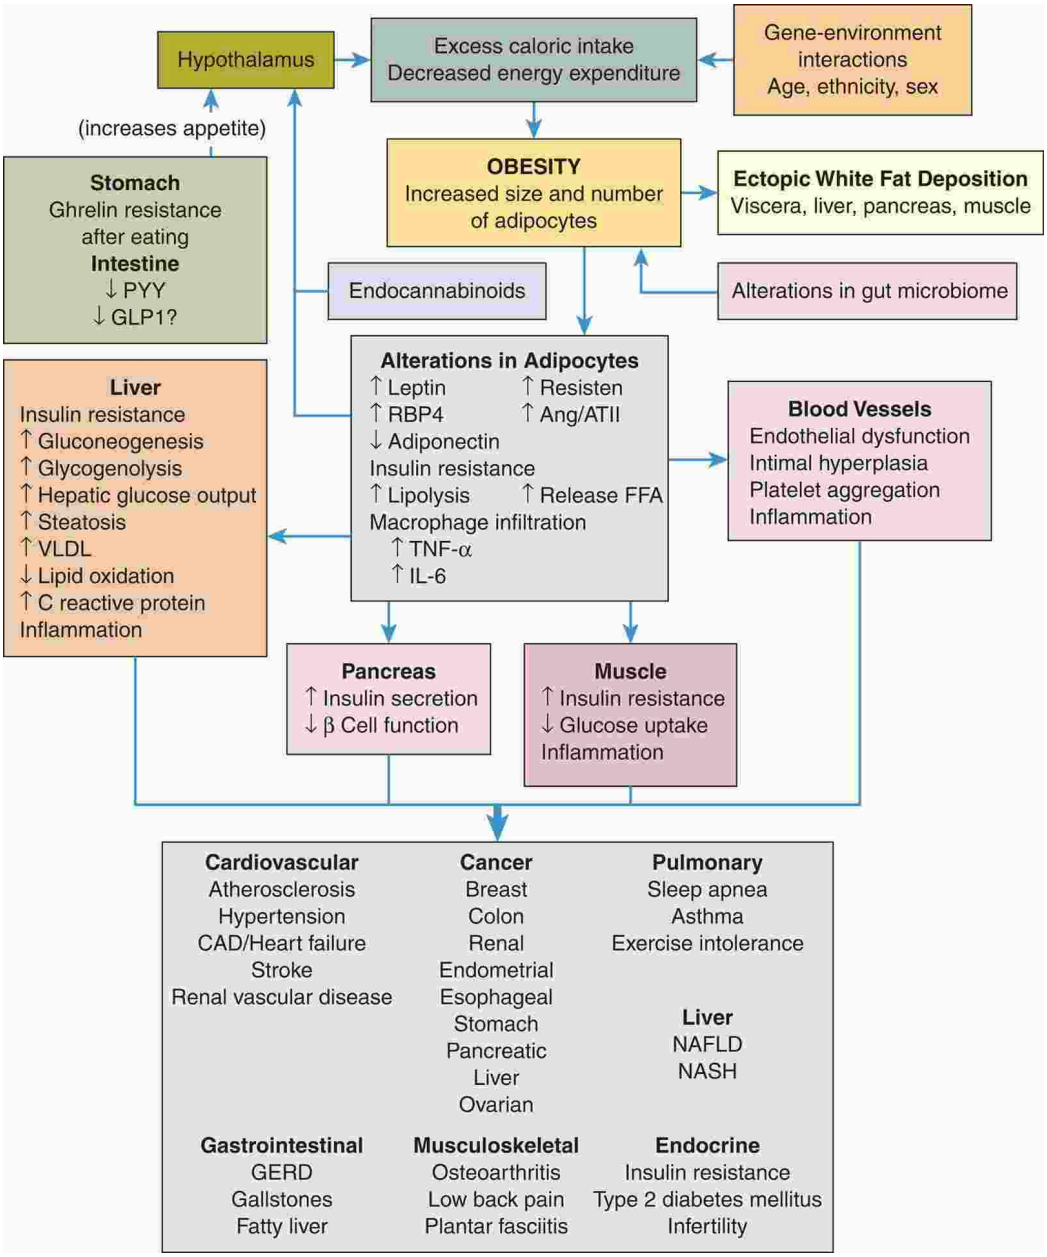

FIG. 23.1 Pathophysiology and Common Complications of Obesity.
See text for details. *Ang/ATII*, Angiotensinogen/angiotensin 2; *CAD*, coronary artery disease; *FFA*, free fatty acids; *GERD*, gastroesophageal reflux disease; *GLP1*, glucagon-like peptide 1; *IL-6*, interleukin-6; *PYY*, intestinal peptide YY; *RBP4*, retinol-binding protein 4; *TNF*-α, tumor necrosis factor-alpha;

VLDL, very-low-density lipoprotein. *NAFLD*, nonalcoholic fatty liver disease and *NASH*, nonalcoholic steatohepatitis.

“A flowchart represents the pathophysiology and common complications of obesity. 1. Hypothalamus. Leads to 3. 2. Gene-environment interactions. Age, ethnicity, sex. Leads to 3. 3. Excess caloric intake. Decreased energy expenditure. Leads to 4. 4. Obesity: increased size and number of adipocytes. Leads to 5 and 7. 5. Ectopic white fat deposition. Viscera, liver, pancreas, muscle. 6. Alterations in gut microbiome. Leads to 4. 7. Alterations in adipocytes. Increased leptin, increased R B P 4, decreased adiponectin, increased resisten, and increased Ang or A T I I. Insulin resistance: increase lipolysis and increased release F F A. Macrophage infiltration: increased T N F-alpha and I L-6. Leads to 8, 9, 10, and 11. 8. Pancreas. Increased insulin secretion; decreased beta cell function. Leads 12. 9. Muscle. Increased insulin resistance; decreased glucose uptake; inflammation. Leads 12. 10. Blood vessels. Endothelial dysfunction; intimal hyperplasia; platelet aggregation; inflammation. Leads 12. 11. Liver. Insulin resistance: increased gluconeogenesis, increased glycogenolysis, increased hepatic glucose output, increased steatosis, increased V L D L, decreased lipid oxidation, increased C reactive

protein; inflammation. Leads 12. 12. Cardiovascular (atherosclerosis, hypertension, C A D or heart failure, stroke, and renal vascular disease); cancer (breast, colon, renal, endometrial, esophageal, stomach, pancreatic, liver, and ovarian); pulmonary (sleep apnea, asthma, exercise intolerance); liver (N A F L D, N A S H); gastrointestinal (G E R D, gallstones, fatty liver); musculoskeletal (osteoarthritis, low back pain, and plantar fasciitis); endocrine (insulin resistance, type 2 diabetes mellitus, infertility). 13. Stomach. Ghrelin resistance after eating. Intestine: decreased P Y Y, decreased G L P 1. Leads to 14. 14. Increases appetite. Leads to 1. 15. Endocannabinoids. Leads to 1."

Adipokines and Obesity

Leptin is a product of the obesity gene (*Ob* gene) and is expressed primarily by adipocytes. Leptin levels increase after eating and act on the hypothalamus to inhibit orexigenic neurons and stimulate anorexigenic neurons to suppress appetite and increase energy expenditure. At low leptin levels (i.e., during fasting), leptin stimulates food intake and reduces energy expenditure. This balance regulates body weight and energy expenditure within a fairly narrow range. Leptin levels increase as the number of adipocytes increases. However, high leptin levels are ineffective at decreasing appetite and energy expenditure, a condition associated with obesity and known as central *leptin resistance* (Fig. 23.2).

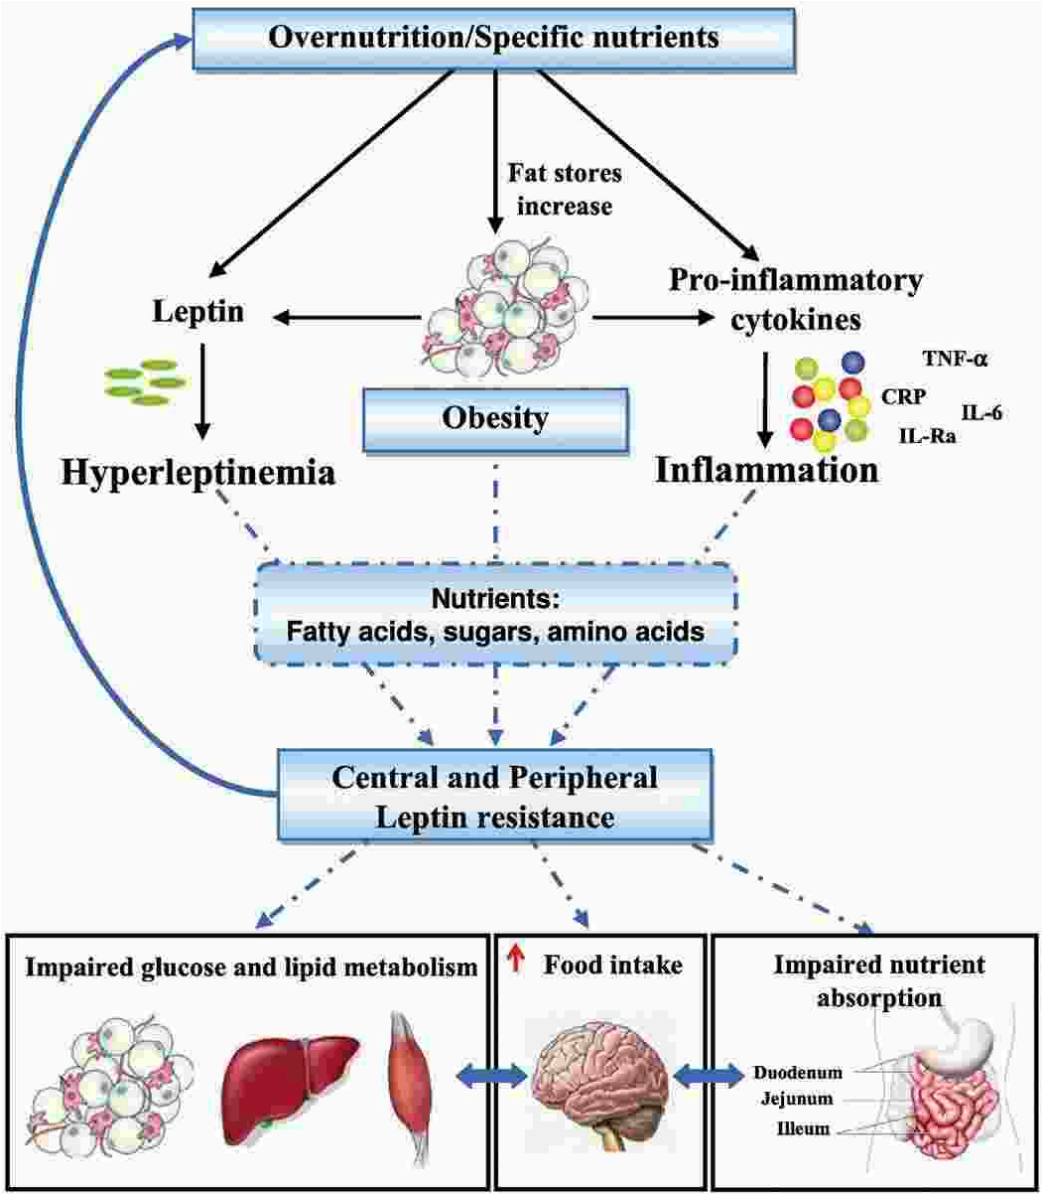

FIG. 23.2 Leptin Resistance and Obesity.
IL, Interleukin; *TNF-α*, tumor necrosis factor-alpha; *CRP*, C-reactive protein. (From Sáinz N, Barrenetxe J, Moreno-Aliaga MJ, et al. Leptin resistance and diet-induced obesity: Central and peripheral actions of leptin. *Metabolism*, 2015;64(1):35–46. https://doi.org/10.1016/j.metabol.2014.10.015)

"A flowchart represents pathways to leptin resistance and obesity. 1. Overnutrition or specific nutrients.

Leads 2, 3, and 4. 2. Leptin. Leads to 5. 3. Fat stores increase. Leads to 6. 4. Pro-inflammatory cytokines (T N F-alpha, C R P, I L-6, I L-R a). Leads to 7. 5. Hyperleptinemia. Leads to 8. 6. Obesity. Leads to 8. 7. Inflammation. Leads to 8. 8. Nutrients: fatty acids, sugars, amino acids. 9. Central and peripheral; leptin resistance. Leads to 1, 10, 11, and 12. 10. Impaired glucose and lipid metabolism. Interrelated to 11. 11. Increased food intake. Interrelated to 12. 12. Impaired nutrient absorption (duodenum, jejunum, and ileum).”

Leptin resistance fails to inhibit orexigenic hypothalamic satiety signaling and promotes overeating and excessive weight gain. Leptin also regulates hepatic gluconeogenesis, insulin sensitivity, and glucose and lipid metabolism in liver, muscle, and adipose tissue. Peripheral leptin resistance (i.e., in muscle and adipose tissue) results in hyperglycemia, hyperinsulinemia, and hyperlipidemia and also stimulates macrophages and endothelial cells to produce proinflammatory mediators. The cause of leptin resistance is unknown. It may be related to a defect in leptin transport, an inability of leptin to cross the blood–brain barrier, an alteration in the permissive effect of leptin, or a defect in or suppression of the leptin receptor. The low-grade inflammation that accompanies obesity also is thought to contribute to leptin resistance. Chronic hyperleptinemia also stimulates the sympathetic nervous system, oxidative stress, chronic low-grade inflammation, and ventricular hypertrophy and contributes to the pathogenesis of hypertension, atherosclerosis, cardiovascular disease, type 2 diabetes, and cancer associated with obesity.[25,26]

Adiponectin, which is produced primarily by visceral adipose tissue but also by cardiomyocytes and skeletal muscle, increases

energy expenditure. It also has insulin-sensitizing and anti-inflammatory properties. Plasma levels of adiponectin decrease with visceral obesity, and resistance to adiponectin action develops. Decreased adiponectin levels are associated with increased hepatic gluconeogenesis, insulin resistance, decreased skeletal muscle glucose uptake, and increased levels of inflammatory mediators, such as interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-α). Adiponectin serves as an anti-inflammatory and antiatherogenic plasma protein; it also has an important role in vascular remodeling, and it is cardioprotective. Decreased levels of adiponectin are associated with type 2 diabetes mellitus and an increased risk for coronary artery disease resulting from hyperlipidemia, hypertension, and factors that promote thrombosis and inflammation.[27]

Decreased beta cell function and insulin resistance are associated with obesity. The mechanisms are not clear, but an association exists between hyperlipidemia and increased fat storage, macrophages and inflammation, and alterations in adipokines. Leptin resistance and decreased adiponectin also contribute to insulin resistance. Insulin resistance results in hyperinsulinemia, hyperglycemia, and a predisposition to type 2 diabetes mellitus. Retinol-binding protein 4 (binds vitamin A) is an adipokine produced both in the liver and by adipocytes. It is increased in visceral adiposity and contributes to inflammation and insulin resistance in the liver and muscles; it also is associated with cardiovascular disease and may contribute to hepatic steatosis (fatty liver).[28]

Endocannabinoids (i.e., anandamide) are arachidonic acid derivatives (unsaturated, essential fatty acids) expressed in both the brain and peripheral nerve tissues. They have effects on endocannabinoid (CB) receptors in orexigenic pathways. They increase appetite, enhance nutrient absorption, stimulate lipogenesis, and increase WAT accumulation by acting at both central (CB1 receptor) and peripheral sites (CB2 receptor). They also inhibit energy expenditure and thermogenesis. An increase in endocannabinoids is proposed to be associated with visceral

obesity.[29] Angiotensinogen (AGT) is produced in the liver and by adipocytes and is increased in obesity. AGT is the precursor to angiotensin 1 (AGTI), which is then converted to angiotensin 2 (AGTII). The effects of AGTII include vasoconstriction, renal retention of sodium and water, and release of aldosterone. Increased AGTII from adipose tissue also promotes lipogenesis, oxidative stress, inflammation, and insulin resistance. All of these effects contribute to the complications associated with obesity.[30] Gastrointestinal hormones also play a role in the complex pathophysiology of obesity (see Box 23.2). The most significant ones are reviewed next.

Ghrelin is produced by the stomach gastric mucosa. Ghrelin stimulates food intake and fat storage and prevents life-threatening hypoglycemia by inhibiting insulin secretion and stimulating glucagon secretion. It increases in response to fasting and chronic caloric restriction and decreases after food intake. Ghrelin is thought to have antilipolytic effects and stimulates lipogenesis in visceral WAT, leading to an increase in body weight and body fat mass. Ghrelin also stimulates the release of GH from anterior pituitary cells, the release of gastric acid, gastrointestinal motility, and pancreatic secretion of insulin. It has satiety, vasodilatory, and cardioprotective effects. An elevation in FFAs and GH after eating normally decreases the release of ghrelin. However, obesity is associated with a decreased plasma level of ghrelin, and plasma ghrelin levels do not fall after eating. This is known as *ghrelin resistance*. The mechanisms for this response are not clear, and the role of ghrelin in obesity has yet to be clearly defined.[31]

Glucagon-like peptide 1 (GLP-1) is an anorexigenic hormone secreted by intestinal endocrine cells when nutrients enter the small intestine. GLP-1 stimulates pancreatic glucose-dependent insulin secretion, decreases blood glucose levels, delays gastric emptying, suppresses appetite, increases satiety, and increases energy expenditure. GLP-1 levels may be decreased in obese individuals, and a GLP-1 receptor analogue has been approved to treat both obesity and type 2 diabetes mellitus.[32]

Peptide YY (PYY) is released from intestinal endocrine cells in response to nutrients entering the intestine. PPY inhibits gastric motility and mucosal secretion and increases satiety and decreases appetite by acting on the medullary brain stem. PYY decreases with obesity.[33]

Cholecystokinin (CCK) is secreted by proximal small intestinal cells after food intake. Its actions include gallbladder contraction, release of pancreatic enzymes and insulin, satiation, and reduced food intake. Work is in progress to develop type 1 CCK receptor (CCK1R) agonists for the treatment of obesity.[34]

Lipotoxicity

Chronic positive energy balance and obesity can overwhelm fat storage by adipocytes, resulting in altered lipid metabolism and insulin resistance. Normally, insulin can inhibit lipolysis by activation of insulin receptors in adipocytes. With obesity, adipocytes are resistant to insulin inhibition of lipolysis. With a chronic increased energy intake, the increase in adipocyte size and number in visceral WAT exceeds the supporting vascular supply, resulting in hypoxia and inflamed and fibrotic adipose tissues. Excess lipolysis and FFAs are distributed to nonadipose cells (e.g., kidney, liver, heart, skeletal muscle). When their utilization capacity is exceeded, cellular dysfunction or death occurs, and this is known as *lipotoxicity*.[35]

Obesity and Inflammation

Obesity produces a state of chronic, low-grade inflammation in WAT. The enlarged adipose cell size results in apoptosis, local hypoxia, cell and mechanical stress, and promotes inflammation. Proinflammatory macrophages, lymphocytes, neutrophils, and mast cells infiltrate enlarged adipocytes and release inflammatory cytokines (e.g., TNF-α, and IL-6) (see Box 23.1).[36] The inflammatory state is supported by increased leptin, decreased adiponectin, and increased resistin (a hormone released by macrophages that promotes insulin resistance and inflammation). The inflammatory

state, immune dysregulation, accelerated lipolysis, and lipotoxicity contribute to the development of insulin resistance, metabolic syndrome (see Chapter 22 and Box 22.2), and the complications of obesity, including type 2 diabetes mellitus, cardiovascular disease, kidney disease, NASH, and cancer.[2]

Obesity and the Gut Microbiome

Changes in the intestinal microbiome also are associated with and are a contributing cause of obesity, although the mechanisms are not clear. Microbes (mostly bacteria) are found in high concentration in the lower gastrointestinal tract, and the bacterial composition is affected by genetics, diet, geographical location, use of antibiotics and other medications, and energy balance. These bacteria have considerable variability among individuals and participate in the breakdown of complex carbohydrates, nutrient absorption, vitamin synthesis, inflammatory responses, gut permeability, and bile acid metabolism. Gut microbial fermentation of dietary fiber produces short chain fatty acids (acetate, butyrate, and propionate), which function as energy sources and signaling molecules that affect the host's energy metabolism and inflammation.

More studies are needed to determine how changes in microbiota contribute to body weight regulation, metabolism, low-grade inflammation, and increased adiposity and how manipulation of the gut microbiota can assist in preventing or treating obesity.[37]

.

Clinical Manifestations

Obesity usually presents with different forms or phenotypes of adipose tissue distribution and/or extent of metabolic abnormalities.[38] Visceral obesity (also known as intra-abdominal, central, or masculine obesity) occurs when the distribution of body fat is localized around the abdomen and upper body, resulting in an apple shape. Visceral obesity is associated with accelerated lipolysis and has an increased risk for chronic systemic inflammation,

metabolic syndrome, obstructive sleep apnea syndrome, type 2 diabetes mellitus, cardiovascular complications, osteoarthritis, and cancer. Visceral venous blood drains into the portal vein, contributing to higher liver synthesis of plasma lipids and increasing the risk of nonalcoholic fatty liver disease (NAFLD) and NASH.[39]

Peripheral obesity (also known as subcutaneous, gluteal-femoral, or feminine obesity) occurs when the distribution of body fat is extraperitoneal and distributed around the thighs and buttocks and through the muscle, resulting in a pear shape. It is more common in premenopausal women. Peripheral and subcutaneous fat is less metabolically active and lipolytic and releases fewer adipokines (particularly adiponectin) than visceral fat. Risk factors are still present for the complications of obesity, but they are less severe than for visceral obesity.[40]

Obesity has been described in relation to the extent of metabolic abnormalities that are present. However, there is no universally accepted definition or guidelines to describe metabolic health for the phenotypes or the potentially transient nature of a metabolically healthy status. Depending on the phenotype, there are associated differences in adipose tissue distribution, metabolism, lipid profiles, and gut microbiota. There are modifiable lifestyle factors (diet, exercise, smoking, alcohol use, psychological stress, geographical location), and unmodifiable factors (age, sex, ethnicity, and genetics) that also play a role, all of which add to the complexity of a uniform definition. Continued development of clarity and consensus regarding criteria and parameter guidelines will facilitate research designs and personalized treatment decisions. Box 23.3 presents a summary of the proposed phenotype characteristics.

Box 23.3

Obesity Metabolic Phenotypes

Metabolically unhealthy normal-weight obesity (MUHNW)

Individuals with a normal body weight and BMI (18.5–25 kg/m^2) but a body fat percentage greater than 30%, ectopic fat distribution (fat in liver, skeletal muscle, heart, and pancreatic tissues) with increased subcutaneous abdominal fat.

Increases in inflammatory adipokines, insulin resistance, and increased risk for metabolic syndrome, type 2 diabetes mellitus (T2DM), cardiovascular disease (CVD), and a higher mortality than a normal weight healthy population.

Metabolically healthy obesity (MHO)—{benign or uncomplicated obesity} Individuals with an elevated BMI (>30 kg/m^2) and less visceral adiposity without metabolic abnormalities (i.e., normal insulin sensitivity—fasting glucose concentrations), normal lipid values and C-reactive protein and absence of hypertension. Increased risk for insulin resistance, metabolic syndrome, T2DM and cardiovascular disease after many years of obesity.

Metabolically unhealthy obesity (MUO).

BMI over 30 kg/m^2 and body fat percentage over 30% with excess visceral fat. Waist circumferences greater than 40 inches (102 cm) in men and 35 inches (88 cm) in women. Elevated fasting glucose, dyslipidemia, and hypertension. At high risk to develop metabolic syndrome progression, T2DM, and CVD and consequently, higher mortality.

Evaluation and Treatment

All children and adults should be screened for obesity. Several methods are available for estimating or measuring the amount of adipose tissue: anthropometric measurements, including weight, height, and circumferences or various body diameters (i.e., waist-to-hip ratios and waist circumference); skinfold thickness (measured with skinfold calipers); ultrasound to measure peripheral body fat; and bioelectric impedance and underwater hydrostatic weighing to calculate total body fat. The only method for directly measuring total body fat is by dual-energy x-ray absorptiometry (DXA) scanning, an enhanced type of x-ray imaging.

In clinical practice, anthropometric and body diameter measures are most commonly used to calculate the BMI because they are the easiest to measure and most cost-effective. Body mass indices have been established based on height, weight, age, sex, and ethnicity. Overweight is defined as a BMI greater than 25 kg/m^2, and obesity is a BMI greater than 30 kg/m^2. BMI charts are available for children ages 2 to 20 years; these can be used for comparison during adulthood, because obese children generally become obese adults.

However, the BMI does not measure the amount and location of body fat. The waist circumference (more than 40 inches [102 cm] for men and more than 35 inches [88 cm] for women) adds information to assist with disease risk assessment in general practice. Obesity risk assessment is available from the American Association of Clinical Endocrinologists and the American College of Endocrinology.[41] No specific diagnostic criteria for obesity have been established.

Obesity is a chronic disease for which various treatment approaches have been used, including correction of metabolic abnormalities and individually tailored lifestyle interventions, such as weight reduction diets and exercise programs. Additional treatments include psychotherapy, behavioral modification, self-motivation, and support systems.[42,43] Several drugs have been approved for the pharmacologic management of obesity.[44]

Currently, bariatric surgical procedures (i.e., the Roux-en-Y gastric bypass, adjustable gastric banding, and sleeve gastrectomy) offer the

most significant reduction in weight, reduction in comorbidities, and decrease in insulin resistance for the treatment of obesity.[45] Efforts are continuing to identify the molecular and neuroendocrine causes of obesity. This will lead to more specific and personalized prevention and treatment strategies (see Emerging Science Box: SGLT-2 Use for the Treatment of Obesity).

Starvation

Malnutrition is lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals and is caused by an improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors. Starvation is a reduction in energy intake related to inadequate food sources that leads to weight loss. Short-term starvation and long-term starvation have different effects. Therapeutic short-term starvation is part of many weight reduction programs because it causes an initial rapid weight loss that reinforces the individual's motivation to diet (see Emerging Science Box: Weight Loss for more information). Therapeutic long-term starvation is used in medically controlled environments to facilitate rapid weight loss in morbidly obese individuals. Pathologic long-term starvation can be caused by poverty; food shortages; chronic diseases of the cardiovascular, pulmonary, hepatic, and digestive systems; malabsorption syndromes; human immunodeficiency virus (HIV) infection; cancer; and anorexia nervosa.[46]

Short-term starvation, or extended fasting, consists of several days of total dietary abstinence or deprivation. The body responds with mechanisms to protect protein mass. For 4 to 6 hours after the last meal, the body is in a well-fed state and its energy requirements are supplied by glucose from recently ingested carbohydrates. Once all available energy has been absorbed from the intestine, glycogen in the liver is converted to glucose through glycogenolysis—the splitting of glycogen into glucose. This process peaks within 4 to 8 hours, and gluconeogenesis begins. Gluconeogenesis is the formation of glucose from noncarbohydrate molecules: lactate, pyruvate, amino acids, and the glycerol portion of fats from

lipolysis. Like glycogenolysis, gluconeogenesis takes place within the liver. Both of these processes deplete stored nutrients and, thus, cannot meet the body's energy needs indefinitely. Lipolysis and proteins continue to be catabolized to a minimal degree, providing carbon for the synthesis of glucose.[47]

Long-term starvation begins after several days of dietary abstinence and eventually causes death from proteolysis. Absolute deprivation of food (e.g., that associated with famine) causes marasmus, or protein-energy malnutrition (loss of muscle mass, body fat depletion, and absence of edema). Protein deprivation in the presence of carbohydrate intake is called kwashiorkor (loss of muscle mass with sustained body fat and peripheral edema). Marasmic kwashiorkor (edematous, severe childhood malnutrition) is a combination of chronic energy deficiency and chronic or acute protein deficiency and inadequate micronutrients.[48,49] These conditions are described in Chapter 42.

Anorexia is loss of appetite. Anorexia nervosa is a psychological cause of long-term starvation (Box 23.4). Cachexia (also known as cytokine-induced malnutrition) is skeletal muscle wasting, causing muscle atrophy with involuntary loss of weight leading to, fatigue, and weakness. Muscle atrophy is a result of negative protein and energy balance secondary to reduced food intake and abnormal metabolism.[50] Systemic inflammation caused by inflammatory mediators (e.g., TNF-α, interferon-γ, IL-1, IL-6, and IL-8), an increased catabolic response, and metabolic abnormalities are associated with the cachexia.[51] Cancer, congestive heart failure, chronic obstructive pulmonary disease, acquired immunodeficiency syndrome (AIDS), rheumatoid arthritis, tuberculosis, and other major chronic progressive proinflammatory diseases are contributable pathophysiological processes. While individuals may experience one or the other, anorexia and cachexia often occur together.[51] (Fig. 23.3).

Box 23.4

Diagnostic Criteria for Eating Disorders

Anorexia Nervosa

Persistent restriction of energy intake leading to significantly low body weight (in context of what is minimally expected for age, sex, developmental trajectory, and physical health).
Either an intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain (even though significantly low weight).
Disturbance in the way one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.
Subtypes:

- Restricting type
- Binge-eating/purging type

Bulimia Nervosa

Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:

- Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
- A sense of lack of control overeating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.

The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
Self-evaluation is unduly influenced by body shape and weight.
The disturbance does not occur exclusively during episodes of anorexia nervosa.

Binge Eating Disorder[a]

Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
- Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
- A sense of lack of control overeating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

The binge eating episodes are associated with three or more of the following:
- Eating much more rapidly than normal.
- Eating until feeling uncomfortably full.
- Eating large amounts of food when not feeling physically hungry.
- Eating alone because of feeling embarrassed by how much one is eating.
- Feeling disgusted with oneself, depressed, or very guilty afterward.
- Marked distress regarding binge eating is present.
- Binge eating occurs, on average, at least once a week for 3 months.
- Binge eating is not associated with the recurrent use of inappropriate compensatory behaviors as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa methods

to compensate for overeating, such as self-induced vomiting.

Data from American Psychiatric Association (APA). *DSM-5: Diagnostic and statistical manual of mental disorders*, 5th edition. Arlington, VA: Author; 2013:338–345.

[a]**NOTE:** Binge eating disorder is less common but much more severe than overeating. Binge eating disorder is associated with more subjective distress regarding the eating behavior, and commonly other co-occurring psychologic problems

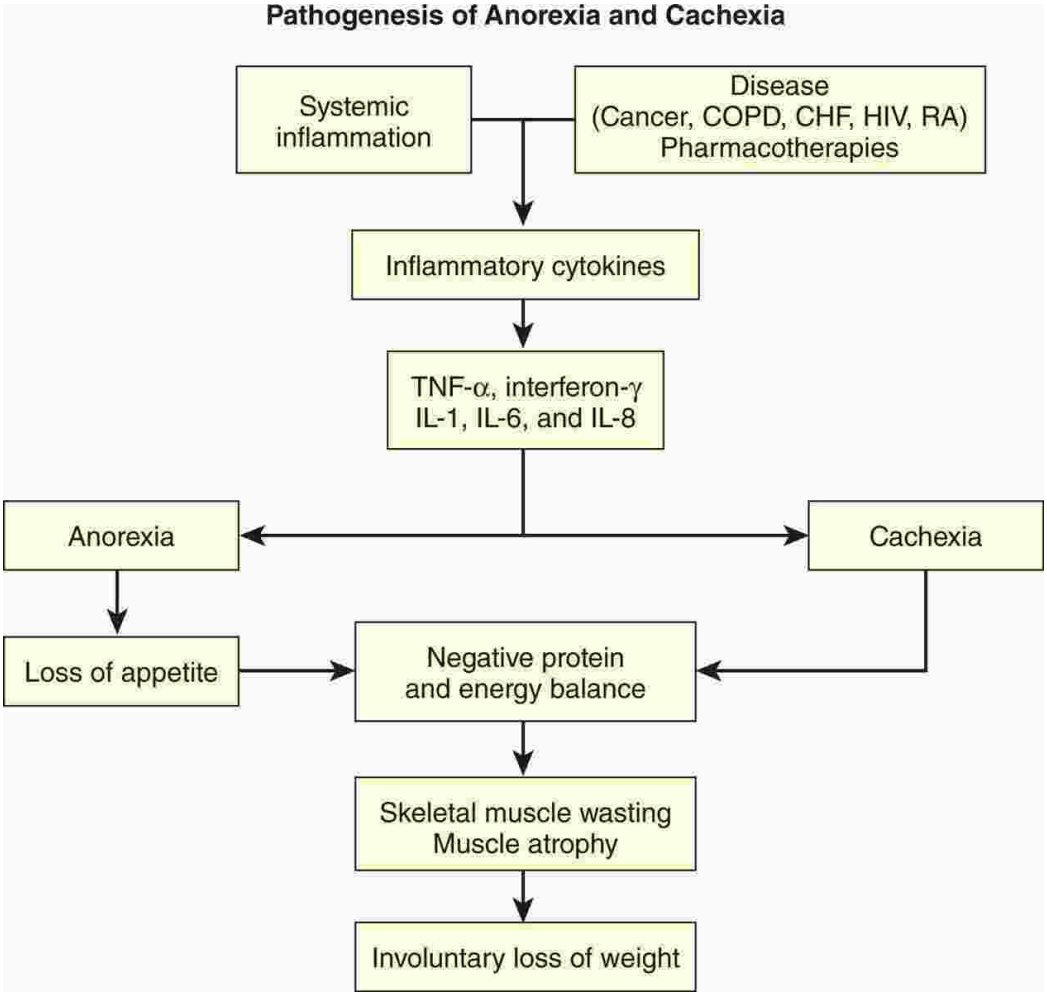

FIG. 23.3 Pathogenesis of Anorexia and Cachexia. ***COPD*****, Chronic obstructive pulmonary disease;** ***CHF*****, congestive heart failure;** ***HIV*****, human immunodeficiency virus;** ***RA*****, rheumatoid arthritis.**

“A flow chart represents the pathogenesis of anorexia and cachexia. 1. Systemic inflammation. Leads to 3. 2. Disease (cancer, C O P D, C H F, H I V, R A); pharmacotherapies. Leads to 3. 3. Inflammatory cytokines. Leads to 4. 4. T N Y-alpha, interferon-gamma, I L-1, I L-6, and I L-8. Leads to 5 and 6. 5.

Anorexia. Leads to 7. 6. Cachexia. Leads to 8. 7. Loss of appetite. Leads to 8. 8. Negative protein and energy balance. Leads to 9. 9. Skeletal muscle wasting; muscle atrophy. Leads to 10. 10. Involuntary loss of weight."

The major metabolic characteristic of long-term starvation is a decreased dependence on gluconeogenesis and an increased use of ketone bodies (products of lipid and pyruvate metabolism) as a cellular energy source. During long-term starvation, depressed insulin levels and increased levels of glucagon, cortisone, epinephrine, and GHs promote lipolysis in adipose tissue. Lipolysis liberates fatty acids—which supply energy to cardiac and skeletal muscle cells—and ketone bodies—which sustain brain tissue. Fatty acid, or ketone body, oxidation meets most of the energy needs of the cells. (Some glucose is still needed as fuel for brain tissue and red blood cells.) Once the supply of adipose tissue is depleted, proteolysis begins. The breakdown of muscle and visceral protein is the last process the body engages in to supply energy for life. Death results from severe alterations in electrolyte balance and loss of renal, pulmonary, and cardiac function.[52]

Adequate ingestion of appropriate nutrients is the obvious treatment for starvation. In medically induced starvation, the body is maintained in a ketotic state until the desired amount of adipose tissue has been lysed. Starvation imposed by chronic disease, long-term illness, malabsorption syndromes, and chronic eating disorders is treated with enteral or parenteral nutrition (Box 23.5). Perioperative or critical care management of nutrition is necessary to prevent unnecessary starvation.[53] Care must be taken to prevent refeeding syndrome (Box 23.6) during the treatment of long-term starvation.

Box 23.5

Complications of Anorexia Nervosa and Bulimia

Anorexia Nervosa Complications	
Cardiac	
	Bradycardia
	Dysrhythmia
	Left ventricular atrophy
	Mitral valve prolapse
	Pericardial effusion
	Sudden cardiac death
Dermatological	
	Acrocyanosis
	Hair thinning
	Xerosis
Endocrine	
	Amenorrhea
	Estrogen decreased in females and testosterone decreased in males
	Euthyroid sick syndrome
	Hypoglycemia
	Hypogonadal related to reduced pulsed hypothalamic gonadotropin releasing hormone secretion
	Hypothyroidism: cold intolerance
	Low libido
	Preterm birth
	Thermoregulation impaired

Anorexia Nervosa Complications	
Gastrointestinal	
	Abdominal bloating
	Abdominal pain
	Constipation related to slowed peristalsis
	Dysphagia related to weakened oropharyngeal muscles
	Early Satiety
	Gastroparesis
	Liver function test abnormalities related to malnutrition; elevated transaminases
	Pelvic floor dysfunction
	Postprandial fullness
Hematological	
	Anemia
	Leukopenia
	Thrombocytopenia
Metabolic	
	Electrolyte Imbalances (hypokalemia; hypophosphatemia; hypomagnesemia; hyponatremia)
Musculoskeletal	
	Osteoporosis: decreased bone mineral density
	Stress fracture risk from decreased bone formation and increased bone resorption
Neurological	

Anorexia Nervosa Complications	
	Brain atrophy
	Cognitive function impairment
	Taste and smell abnormalities
Bulimia Complications	
Self-Induced Vomiting	
	Dyspepsia
	Dysphagia
	Electrolyte and acid base disorders (hypokalemia; metabolic alkalosis)
	Gastric reflux
	Hoarse voice
	Parotid gland enlargement
	Tooth erosion
	Vocal cord inflammation
Laxative Abuse	
	Diarrhea
	Electrolyte and acid base disorders (hypokalemia; hyperphosphatemia; metabolic alkalosis)
	Hemorrhoids
	Rectal Prolapse

Box 23.6

Refeeding Syndrome

Refeeding syndrome is a life-threatening condition that occurs in severely malnourished individuals when parenteral or enteral nutritional therapy is initiated. During starvation, loss of body minerals causes the movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma. When refeeding starts, an increase in insulin levels stimulates the movement of glucose and these ions back into the cells, and the plasma concentrations can decrease to dangerously low levels, causing hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency (particularly

thiamin). Alterations usually occur within 72 h after the start of nutritional therapy.

Hypophosphatemia contributes to alterations in red blood cell shape and function, contributing to tissue hypoxia and increased respiratory drive. Rapid expansion of the extracellular fluid volume also can occur with carbohydrate refeeding and may cause fluid overload. The consequences of these alterations include life-threatening dysrhythmias, congestive heart failure, muscle weakness (including respiratory muscles), and death. Individuals at greatest risk are those with starvation from any cause, including anorexia nervosa, chronic diseases, aging, morbid obesity with massive weight loss, and prolonged fasting. Refeeding syndrome is prevented by identifying at-risk individuals; slowly reinstituting feeding (about 20 kcal/kg/day for the first few days); and monitoring plasma levels of phosphate, potassium, magnesium, and calcium during the change from catabolic to anabolic metabolism.

Early or late feeding after ICU admission? *Nutrients*, 2017;9(12):E1278.

Anorexia of Aging

Anorexia of aging describes a decrease in appetite or food intake in older adults. It can occur in illness-free individuals and with an adequate food supply. The resulting undernutrition leads to adverse outcomes and may affect up to 30% of independently living elders with higher incidence occurring in hospital and extended care

nursing faciltities.[54] The anorexia of aging results from multiple age-related changes, including reduced energy needs, waning hunger, diminished senses of smell and taste, decreased production of saliva, altered gastrointestinal satiety control mechanisms, and the presence of comorbidities (Fig. 23.4). The neuroendocrine system physiologically regulates appetite with multiple hormones implicated as mediators of hunger and satiety.[54]

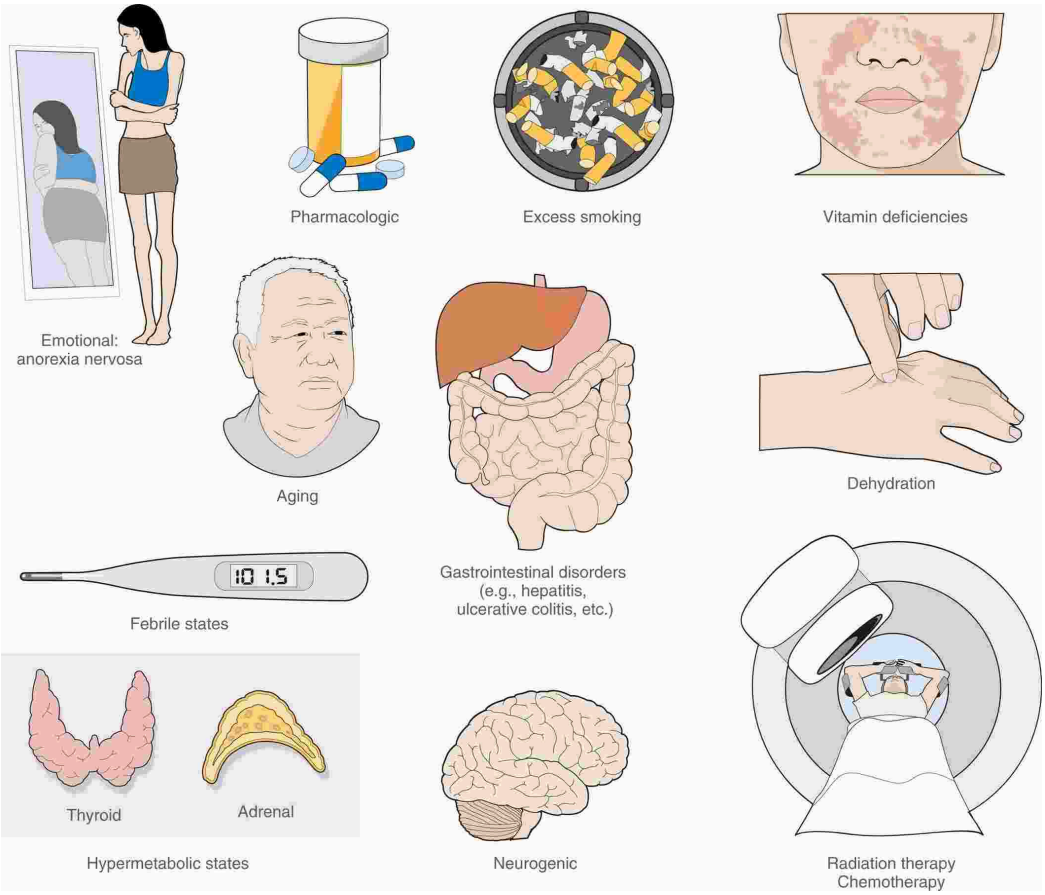

FIG. 23.4 Causes of Anorexia.

"A series of illustration shows the causes of anorexia. • Emotional: anorexia nervosa. The illustration shows a thin woman looking at a fat reflection of herself in the mirror. • Pharmacologic. The illustration shows a bottle of pills. • Excess smoking. The illustration shows a lot of cigarette buts in an ash tray. • Vitamin deficiencies. The illustration shows rashes on the jaws of a person. • Aging. The illustration shows the bust of an elderly person. • Febrile states. The illustration shows a thermometer registering a temperature of 101.5. • Gastrointestinal

disorders (example, hepatitis, ulcerative colitis, et cetera) The illustration shows the digestive system. • Dehydration. The illustration shows a hand pinching the back of another hand. • Hypermetabolic states. The illustration shows the thyroid and the adrenal glands. • Neurogenic. The illustration shows a lateral view of the brain. • Radiation therapy, chemotherapy. The illustration shows a person underdoing a radiation treatment."

Centrally, aging is associated with decreased orexigenic signals (e.g., levels of ghrelin or ghrelin resistance and reduced hypothalamic receptors, or both) and increased anorexigenic signals (e.g., decreased levels of leptin, insulin, PYY, and CCK), which lead to loss of appetite and diminished food intake (see Box 23.2). Chronic low-grade inflammation with elevated cytokines also can contribute to delayed gastric emptying and decreased motility of the small intestine. Risk factors for the anorexia of aging include functional impairments and deficiencies (e.g., loss of vision, poor dentition, dysphagia, inability to prepare foods); medical and psychiatric conditions (e.g., malabsorption syndromes, chronic disease, cancer, and depression); loneliness and grief; medications, including polypharmacy; social isolation; and abuse or neglect.[55] Progression of the underlying causes of anorexia (e.g., chronic obstructive pulmonary disease, congestive heart failure) increases the workload of breathing, which decreases energy reserves required to eat and digest food. The consequences of anorexia of aging include malnutrition, physical frailty, mitochondrial dysfunction, reduced regenerative capacity, increased oxidative stress, and imbalanced hormones. There are several tools available to screen for anorexia of aging in elderly individual. Early intervention improves the overall well-being of older individuals experiencing anorexia.

Currently, no specific treatments exist for the anorexia of aging, although exercise, nutrition, and other supportive strategies are used. Exercise is a key strategy in treating elderly individuals with anorexia. Exercise improves appetite and oral intake, but has other beneficial effects, such as elevating mood and building muscle and strength. Nutrition also plays a vital role. It is recommended that older adults aged 65 years and above maintain a dietary protein intake of 0.9 to 1.2 g/kg/day and individuals with acute or chronic diseases should intake 1.2 to 1.5 g/kg/day.[56] Other supportive interventions to help mitigate the effects of anorexia of the aging include improved food access and appearance, dental and eye care, and social stimulation. Pharmaceutical agents (e.g., megestrol acetate and dronabinol) are not recommended in elderly persons because the risk does not outweigh the benefit. Anorexia of aging is common; however, it should not be accepted as a normal consequence of aging. Mortality rates have been shown to be higher in those with anorexia of aging and unintentional weight loss.[57]

Summary Review

Adipose Tissue

1. Adipose tissue provides insulation and tissue support and is the body's major energy reserve, storing and releasing triglycerides and glycerol.
2. Adipose tissue is classified according to color: WAT, BAT, and bAT.
3. WAT contains macrophages, mast cells, neutrophils, fibroblasts, endothelial cells, blood vessels, nerves, and precursor adipocytes.
4. WAT is the largest fat depot and is located in visceral (central) and subcutaneous (peripheral) sites. It also is located in muscle and bone marrow.
5. White adipocytes store fat as a single lipid droplet or vacuole.

6. With a positive energy balance, WAT storage increases by adipocyte hypertrophy (more common in visceral fat) and adipogenesis (hyperplasia, more common in subcutaneous fat).
7. Estrogen enhances the deposition of subcutaneous fat compared to visceral fat.
8. BAT has multiple lipid droplets that are rich in mitochondria containing iron, which gives them a brown color. Exposure to cold, sympathetic activation and release of catecholamines, and activation of T_3 generates heat through free fatty acid oxidation (nonshivering thermogenesis).
9. Both neonates and adults have BAT, but not in the amounts of WAT.
10. bAT emerges within WAT with exposure to cold and exercise. This is known as the beiging of WAT.
11. BAT and bAT both protect against obesity and metabolic syndrome.
12. MAT is found in all bones. With obesity, MAT releases adipokines that affect osteoblast and osteoclast function. Excessive MAT is associated with osteoporosis and fractures.
13. Adipose tissue is an endocrine organ that secretes hormones, called *adipokines*, with autocrine, paracrine, and endocrine actions necessary for metabolic function and immune responses.
14. Regulation of food intake and energy balance are accomplished by balancing opposing sets of neurons in the arcuate nucleus: orexigenic neurons (promote appetite, stimulate eating, and decrease metabolism) and anorexigenic neurons (suppress appetite, inhibit eating, and increase metabolism). Peripherally, gastrointestinal hormones and adipokines also control food intake and energy expenditure.
15. Brain centers related to reward, pleasure, memory, and addictive behavior can override hypothalamic control of food intake and satiety, causing increased fat stores by increasing consumption of highly palatable foods.

Obesity

1. Obesity is an increase in body adipose tissue and an endocrine and metabolic disorder that develops when caloric intake exceeds energy expenditure. Obesity is defined as a BMI greater than 30 kg/m^2 in adults and a BMI greater than or equal to the age- and sex-specific 95th percentile of the 2000 CDC growth charts in children.
2. Obesity is an epidemic that has occurred worldwide in both adults and children. It is the fifth leading cause of death globally. Three leading causes of death in the United States are associated with obesity: cardiovascular disease, type 2 diabetes mellitus, and certain cancers. Obesity also increases the risk for numerous other systemic disorders.
3. Single-gene (rare) and polygenic disorders and metabolic disorders are associated with obesity, as are gene–environment interactions.
4. Adipokines and gastrointestinal hormones are altered with obesity and contribute to associated complications.
5. Leptin resistance occurs when leptin levels increase with obesity and promote overeating and excessive weight gain, hyperglycemia, hyperinsulinemia, and hyperlipidemia. It also stimulates macrophages and endothelial cells to produce proinflammatory mediators.
6. Adiponectin levels decrease with obesity, contributing to insulin resistance, inflammation, and hyperlipidemia.
7. Retinol-binding protein 4 levels are increased in visceral adiposity and promote insulin resistance and hepatic steatosis.
8. Endocannabinoids are increased in obesity and promote appetite, enhance nutrient absorption, stimulate lipogenesis, and inhibit energy expenditure.
9. Angiotensinogen and angiotensin 2 increase in obesity, promoting vasoconstriction, inflammation, lipogenesis, oxidative stress, and insulin resistance.

10. Gastrointestinal hormones (ghrelin, GLP-1, PYY, and CCK) also provide signals that control food intake and energy expenditure and are involved in the pathophysiology of obesity.
11. Ghrelin increases with obesity and stimulates food intake, promotes the release of growth hormone, and stimulates lipogenesis. It also has satiety, vasodilatory, cardioprotective, and antiproliferative effects; its role in obesity is not clear.
12. GLP-1 promotes insulin secretion, delays gastric emptying, suppresses appetite, increases satiety, increases energy expenditure, and is decreased with obesity.
13. PYY inhibits gastric motility, decreases appetite, and is decreased with obesity.
14. CCK is released after food intake and stimulates insulin secretion and satiation, decreases food intake, and is reduced in obesity.
15. Lipotoxicity occurs with excess adipocyte fat storage and lipolysis with distribution of free fatty acids to peripheral organs, resulting in cellular dysfunction and death.
16. Obesity is a state of chronic low-grade inflammation caused by expansion of adipocyte macrophages, neutrophils, lymphocytes, and mast cells, which release inflammatory mediators.
17. The chronic inflammation, alterations in adipokine action, and accelerated lipolysis related to excessive fat contribute to the complications of obesity, particularly insulin resistance, type 2 diabetes mellitus, cardiovascular disease, and cancer.
18. Changes in the intestinal microbiome also are associated with and are a contributing cause of obesity, although the mechanisms are not clear.
19. Obesity has two major phenotypes: visceral obesity (also known as intra-abdominal, central, or masculine obesity) and peripheral obesity (also known as subcutaneous, gluteal-femoral, or feminine obesity). Visceral obesity has the greatest risk for accelerated lipolysis, chronic inflammation, insulin resistance, and associated complications.

20. Normal-weight obesity describes individuals with a normal body weight and BMI but with greater than 30% body fat. These individuals are at risk for metabolic dysregulation, increases in inflammatory cytokines, insulin resistance, increased risk for cardiovascular disease, and higher mortality.
21. Treatment of obesity may include correction of metabolic abnormalities and individually tailored lifestyle interventions (diets, exercise, behavioral modifications, self-motivation) and psychotherapy. The current most effective treatment for extreme obesity is bariatric surgery.
22. New drugs are being developed that target specific molecules and will provide a personalized approach to treatment.

Starvation

1. The body responds to short-term starvation (several days of total dietary abstinence or deprivation) with mechanisms to protect protein mass, using the processes of glycogenolysis and gluconeogenesis. Neither of these processes can meet the body's energy needs indefinitely because they deplete stored nutrients.
2. Long-term starvation (begins after several days of dietary abstinence) results in an initial decreased dependence on gluconeogenesis and an increased use of ketone bodies as a cellular energy source, followed by lipolysis in adipose tissue. In the absence of adequate nutrition, long-term starvation results in proteolysis, with death resulting from severe alterations in electrolyte balance and loss of renal, pulmonary, and cardiac function.
3. Anorexia is a loss of appetite, whereas anorexia nervosa is a psychological cause of long-term starvation.
4. Cachexia is involuntary weight loss with associated muscle wasting and atrophy. The atrophy is due to negative protein

and energy balance. Cachexia can be caused by chronic progressive proinflammatory disease processes.
5. The major metabolic characteristic of long-term starvation is a decreased dependence on gluconeogenesis and an increased use of ketone bodies (products of lipid and pyruvate metabolism) as a cellular energy source.
6. Treatment is management of nutrition through parenteral nutrition; however, it is important to prevent refeeding syndrome.

Anorexia of Aging

1. Anorexia of aging is a decrease in appetite or food intake in older adults that leads to undernutrition, resulting in a decline in function and an increased risk for morbidity and mortality.
2. Contributing factors related to aging include diminished sensory functions, poor dentition, decreased gastric emptying, decreased hunger and satiety, effects of medications, and social isolation and neglect.
3. Consequences of anorexia of aging include malnutrition, physical frailty, mitochondrial dysfunction, reduced regenerative capacity, increased oxidative stress, and imbalanced hormones.
4. No specific treatments exist for the anorexia of aging, although exercise, nutrition, and other supportive strategies are used.

Emerging Science Box Weight Loss

Intermittent fasting has become a growing trend for weight loss with the increase in obesity. Intermittent fasting refers to regular periods with no or very limited caloric intake. For example, an individual may fast daily for 16 h or fast for 24 h on alternate days, or fast for 2 days per week on non-consecutive days. Caloric consumption during fasting can range from 0% to 25% of the individual's caloric needs. Current studies suggest that not only

does intermittent fasting cause a reduction in weight (0.8% to 13.0% of baseline weight), but this type of diet could reduce the risk of cardiovascular disease. Recent evidence indicates that meal timing may influence circadian rhythm, and as a result, may directly or indirectly affect cardiometabolic risk. Researchers continue to study the effects of intermittent fasting on hypertension, dyslipidemia, and diabetes. Intermittent fasting may exert its effects through multiple pathways, including reducing oxidative stress, optimization of circadian rhythms, and ketogenesis. Currently, the evidence shows that intermittent fasting can trigger a metabolic switch from glucose-based to ketone-based energy. This switch can increase resistance to stress and overall improvement of longevity with an inverse relationship on the incidence of diseases, including cancer and obesity.

Emerging Science Box SGLT-2 Use for the Treatment of Obesity

Efficacy and safety of sodium-glucose co-transporter 2 (SGLT-2) inhibitors have been well studied for the treatment of diabetes mellitus type 2. Beyond its ability to lower blood glucose, SGLT-2

inhibitors have also exhibited beneficial effects on body weight and systolic blood pressure and have shown to decrease risk for major cardiovascular and renal events. SGLT-2 inhibitors cause body weight loss by way of glucose excretion, or calorie loss, in the kidneys. Weight loss with use of SGLT-2 inhibitors has been consistent in multiple studies related to individuals with diabetes mellitus type 2, whether the SGLT-2 is prescribed as a mono or combination therapy. Exhibited weight loss appears to be dose dependent and often minimal on its own; however, in combination with glucagon-like peptide 1 receptor agonists (GLP1-RAs)—which naturally suppresses appetite—greater weight loss and maintenance of weight loss was observed versus SGLT-2 monotherapy alone. The majority of studies completed have only included individuals with the diagnoses of obesity *and* diabetes mellitus type 2, but there are ongoing trials studying the effects of SGLT-2 inhibitors in obesity *without* the diagnosis of diabetes. While lifestyle modification remains the mainstay for treatment of obesity, pharmacological modalities are an attractive and less invasive alternative to surgical intervention. Medication management options increase the ability to provide person-centered care to patients, especially if one medication can improve multiple conditions, overall health quality, and longevity.

Tests of Reproductive Function 759

Aging and Reproductive Function 759
- Aging and the Female Reproductive System 759
- Aging and the Male Reproductive System 763

The male and female reproductive systems have several anatomic and physiologic features in common. Most obvious is their major function—reproduction—through which a 23-chromosome female gamete, the ovum (pl., ova), and a 23-chromosome male gamete, the spermatozoon

(sperm cell), unite to form a 46-chromosome zygote that is capable of developing into a new individual. The male reproductive system produces sperm that can be transferred to the female reproductive tract. The female reproductive system produces the ovum; if the ovum is fertilized, it is then called the embryo and developing fetus. These functions are determined not only by anatomic structures but also by complex hormonal, neurologic, and psychogenic factors.

Development of the Reproductive Systems

The structure and function of both male and female reproductive systems depend on steroid hormones called sex hormones and their precursors. Cholesterol is the precursor for steroid hormones, including sex hormones (e.g., estrogen and testosterone). Other hormones that are not steroid hormones (e.g., gonadotropins) also support reproduction. The actions of both sex and reproductive hormones are summarized in Table 24.1. Sex and reproductive hormones act on target tissues by binding with cellular receptors (see Chapter 21 hormonal regulation). Hormonal effects on the reproductive systems begin during embryonic development and continue in varying degrees throughout life.

Table 24.1

Summary of Female and Male Sex and Reproductive Hormones

Hormone (Source)	Action in Females	Action in Males
Dehydroepiandrosterone (DHEA) (adrenal gland, ovary, other tissues)	Converted to androstenedione and then to estrogens, testosterone, or both	Converted to androstenedione and then to estrogens, testosterone, or both
Estrogens (estrone, estradiol, estriol) (ovary and placenta, small amounts in other tissues)	Stimulates development of female sexual characteristics: maturation of breast, uterus, and vagina; promotes proliferative development of endometrium during menstrual cycle; during pregnancy promotes mammary gland development, fetal adrenal gland function, and uteroplacental blood flow (see Box 24.1)	Growth at puberty, growth plate fusion in bone, prevention of apoptosis of germ cells

Hormone (Source)	Action in Females	Action in Males
Testosterone (adrenal glands from DHEA, testes)	Libido, learning, sleep, protein anabolism, growth of muscle and bone; growth of pubic and axillary hair; activation of sebaceous glands, accounting for some cases of acne during puberty	Stimulates spermatogenesis, stimulates development of primary and secondary sexual characteristics, promotes growth of muscle and bone (anabolic effect); growth of pubic and axillary hair; activates sebaceous glands, accounting for some cases of acne during puberty; maintains libido
Gonadotropin-releasing hormone (GnRH) (hypothalamus-neuroendocrine cells)	Stimulates secretion of gonadotropins (FSH and LH) from anterior pituitary	Stimulates secretion of gonadotropins (FSH and LH) from anterior pituitary
Follicle-stimulating hormone (FSH) (anterior pituitary, gonadotroph cells)	Gonadotropin; promotes development of ovarian follicles; stimulates estrogen secretion	Gonadotropin; promotes development and growth of testes and stimulates spermatogenesis by Sertoli cells

Hormone (Source)	Action in Females	Action in Males
Luteinizing hormone (LH) (anterior pituitary, gonadotroph cells)	Gonadotropin; triggers ovulation; promotes development of corpus luteum	Gonadotropin; stimulates testosterone production by Leydig cells of testis
Inhibin (ovary and testes)	Inhibits FSH production in anterior pituitary (perhaps by limiting GnRH)	Inhibits FSH production in anterior pituitary
Human chorionic gonadotropin (hCG) (placenta)	Supports corpus luteum, which secretes estrogen and progesterone during first 7 weeks of pregnancy	
Activin (ovary)	Stimulates secretion of FSH and pituitary response to GnRH and FSH binding in dominant granulosa cells	
Progesterone (ovary and placenta)	Promotes secretory changes in endometrium during luteal phase of menstrual cycle; quiets uterine	

Hormone (Source)	Action in Females	Action in Males
	myometrium (muscle) activity and prevents lactogenesis during pregnancy	
Relaxin (corpus luteum, myometrium, and placenta)	Inhibits uterine contractions during pregnancy and softens pelvic joints and cervix to facilitate childbirth	

Sexual Differentiation and Hormone Production in Utero

Initially, in embryonic development, the reproductive structures of male and female embryos are homologous (the same) or undifferentiated. They consist of one pair of primary sex organs, or gonads, and two pairs of ducts—the wolffian ducts and the müllerian ducts (Fig. 24.1). The müllerian ducts are the precursor of the internal female sex organs (oviducts, uterus, cervix, and upper vagina). Müllerian ducts are initially formed regardless of genotypic sex and require no sex-determining region on the Y chromosome *(SRY)* signaling for development. *SRY* signaling is required in males to cause regression of the müllerian ducts, which in turn prevents the development of the female reproductive tract. The wolffian ducts are the precursor of male internal sex organs (secrete testosterone and promote the development of the male sex organs). Both pairs of ducts empty into an opening called the *urogenital sinus*.

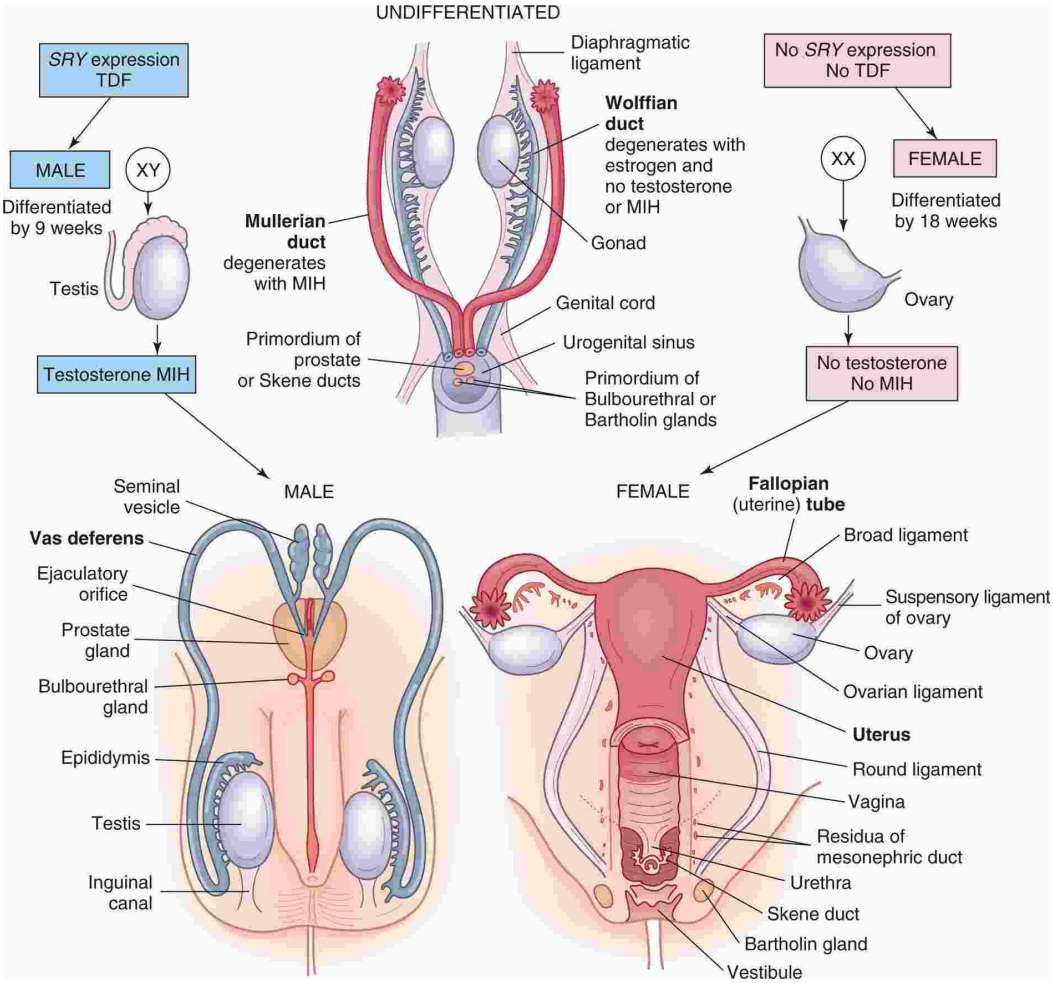

FIG. 24.1 Embryonic Sexual Differentiation. Embryonic and fetal development of the internal genitalia. *MIH*, Müllerian inhibitory hormone; *SRY*, gene that produces TDF; *TDF*, testosterone development factor; see text for additional details.

"A series of illustrations show and label the structures in an undifferentiated, the male, and the female sexual organs. Top panel, undifferentiated. The following parts in the structure are labeled from the top to the bottom: diaphragmatic ligament, wolffian duct (degenerates with estrogen and no testosterone or M I H), gonad, Mullerian duct (degenerates with M I H),

genital cord, urogenital sinus, primordium of prostate or Skene ducts, and primordium of bulbourethral or Bartholin glands. S R Y expression and T D F result in male organs (X Y), differentiated by nine weeks, as a result of testosterone and M I H. No S R Y expression and no T D F result in female orans (X X), differentiated by eighteen weeks, as a result of no testosterone and no M I H. Bottom-left panel, male. The following structures in the illustration are labeled from the top to the bottom: seminal vesicle, vas deferens, ejaculatory orifice, prostate gland, bulbourethral gland, epididymis, testis, inguinal canal. Bottom-right panel, female. The following structures in the illustration are labeled from the top to the bottom: fallopian (uterine) tube, broad ligament, suspensory ligament of ovary, ovarian ligament, uterus, round ligament, vagina, residua of mesonephric duct, urethra, Skene duct, Bartholin gland, and vestibule."

The first sign of development of reproductive organs (male or female) occurs during the fifth week of gestation. Between 6 and 7 weeks' gestation, the male embryo differentiates under the influence of testes-determining factor (TDF), a protein expressed by the *SRY* gene. When the *SRY* gene is expressed, male gonadal development prevails. TDF stimulates the male gonads to develop into the two testes, and by 8 weeks' gestation, testosterone secretion begins. Müllerian inhibitory hormone (MIH), secreted by Sertoli cells in the testes, promotes degeneration of the müllerian ducts. Without MIH, the müllerian ducts would develop, and the wolffian ducts would degenerate with

loss of male sex organ development. The Leydig cells secrete testosterone and promote Wolffian duct development, which differentiates into the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts. By 9 months' gestation, the male gonads (testes) have descended into the scrotum. The testes produce sperm after puberty.

Female gonadal development occurs in the absence of *SRY* expression and with the expression of other genes. The presence of *estrogen* and the absence of *testosterone* and MIH cause degeneration in the wolffian ducts and maintenance of the müllerian ducts. At 6 to 8 weeks' gestation, the two female gonads develop into ovaries, which will produce ova. By the tenth week, the wolffian ducts deteriorate, and the upper ends of the müllerian ducts become the fallopian tubules, whereas the lower ends join to become the uterus, cervix, and upper two-thirds of the vagina (see Fig. 24.1). The fallopian tubes will carry ova from the ovaries to the uterus during a female's reproductive years. Lack of testosterone and the presence of estrogen promote the development of external genitalia (lower end of vagina, labia, and clitoris).

Like the internal reproductive structures, the external structures develop from homologous embryonic tissues. During the first 7 to 8 weeks' gestation, both male and female embryos develop an elevated structure called the *genital tubercle* (Fig. 24.2). Testosterone is necessary for the genital tubercle to differentiate into external male genitalia; otherwise, female genitalia develop, which may occur even in the absence of ovaries, possibly because of the presence of placental estrogens.

FIG. 24.2 External Genitalia Development.
Embryonic and fetal development of the external genitalia.

"A series of illustrations show and label the structures in an undifferentiated, the male, and the female external genitalia. Top panel, undifferentiated, seven weeks. The following structures on the illustration are labeled, from the top to the bottom: genital tubercle, glans area, urethral groove, anus, and genital tubercle. Middle panel, male and female, ten weeks. The following structures on the illustration are labeled, from the top to the bottom: glans, future prepuce, urethral fold, urogenital groove, labioscrotal area, and anus. Bottom panel, male and female, forty weeks. The following structures on the male genitalia are labeled, from the top to the bottom: urethral meatus, prepuce, glans penis, shaft of penis, scrotum, and anus. The following structures on the female genitalia are labeled, from the top to the bottom: prepuce, glans clitoris, urethral meatus, labium minus, vagina, labium majus, and anus."

Anterior pituitary development begins between the fourth and fifth weeks of fetal life, and the vascular connection between the hypothalamus and the pituitary is established by the 12th week. Gonadotropin-releasing hormone (GnRH) is produced in the hypothalamus by 10 weeks' gestation and controls the production of two gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), by the anterior pituitary gland. In the female fetus, high levels of FSH and LH are excreted. FSH and LH stimulate the

production of estrogen and progesterone by the ovary. The production of FSH and LH increases until about 28 weeks' gestation when the production of estrogen and progesterone by the ovaries and placenta is high enough to result in the decline of gonadotropin production. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that, millions are produced daily, usually for life.

By the end of pregnancy, a sensitive negative-feedback system, which includes the gonadostat, is operative in the human fetus. The gonadostat responds to high placental estrogen levels by releasing low levels of GnRH. Soon after birth, steroid hormones levels drop because of the withdrawal of maternal placental hormones. Hypothalamic pulsatile GnRH is secreted, and gonadotropins LH and FSH are released. Their levels peak at 3 to 6 months for boys and at 12 to 18 months for girls, and then fall steadily. The gonadotropins will be suppressed until the onset of puberty.

Puberty and Reproductive Maturation

Adolescence is the stage of human development between childhood and adulthood and includes social, psychological, and biologic changes. Puberty is the onset of sexual maturation and differs from adolescence. Genetics, environment, ethnicity, general health, and nutrition can influence the timing of puberty. In females, puberty begins at about age 8 to 9 years with thelarche (breast development). In males, it begins later, at about age 11 years.

Reproductive maturation involves the hypothalamic-pituitary-gonadal axis, the central nervous system, and the endocrine system (Fig. 24.3). There is a sequential series of hormonal events that promote sexual maturation as puberty approaches. Nocturnal gonadotropin secretion (i.e., LH and FSH) and an increased response in the pituitary to GnRH occur about 1 year before puberty. This, in turn, stimulates gonadal maturation (gonadarche) with estradiol secretion in females and testosterone secretion in males. Estradiol causes thelarche, maturation of the reproductive organs (vagina, uterus, ovaries), and deposition of fat in the female's hips. Estrogen

and increased production of growth factors cause rapid skeletal growth in both males and females. Testosterone causes the growth of the testes, scrotum, and penis. A positive feedback loop is created with gonadotropins stimulating the gonads to produce more sex hormones. The most important hormonal effects occur in the gonads. In males, the testes begin to produce mature sperm that are capable of fertilizing an ovum. Male puberty is complete with the first ejaculation that contains mature sperm. In females, the ovaries begin to release mature ova. Female puberty is complete at the time of the first ovulatory menstrual period. Before puberty, there also is an increase in adrenal androgen in both sexes, known as adrenarche. Adrenal androgens are converted to testosterone and estradiol and contribute to the growth of axillary and pubic hair and activation of sweat and sebaceous glands during puberty. Puberty is complete when an individual is capable of reproduction.

"A flowchart represents the hormonal stimulation of the gonads. 1. Age and health, environment, and stress. Impacts 2. 2. Extrahypothalamic central nervous system. Triggers 5. 3. Hypothalamus. Secretes 6. 4. G n R H. Triggers 7. 5. Anterior pituitary. Releases 8. 6. Gonadotropins: F S H and L H. Affects 9. 7. Gonads (ovaries or testes). Releases 10. 8. Sex hormones: estrogen, testosterone. Provides feedback mechanisms to 3 and 5."

Puberty is a time during which some individuals begin to experience gender dysphoria.Gender dysphoria refers to the discomfort, distress, disharmony, and conflict caused by the discrepancy between a person's gender identity and their personal sense of self as a man or woman, their associated primary or secondary sexual characteristics, and their expected social gender roles. Transgender is a term used to describe individuals whose gender identity or expression differs from their sex assigned at birth. Many transgender individuals choose hormonal or surgical interventions to reduce gender dysphoria (see Emerging Science Box: Gender Reassignment and Gender Affirming Hormone Therapy).

The Female Reproductive System

The function of the female reproductive system is to produce mature ova; then, if fertilization occurs, the female reproductive system provides protection and nourishment to the fetus until it is expelled at birth.

External Genitalia

The external genitalia protect body openings and play an important role in sexual functioning. Fig. 24.4 shows the external female genitalia, known collectively as the vulva or pudendum. The major structures are as follows:

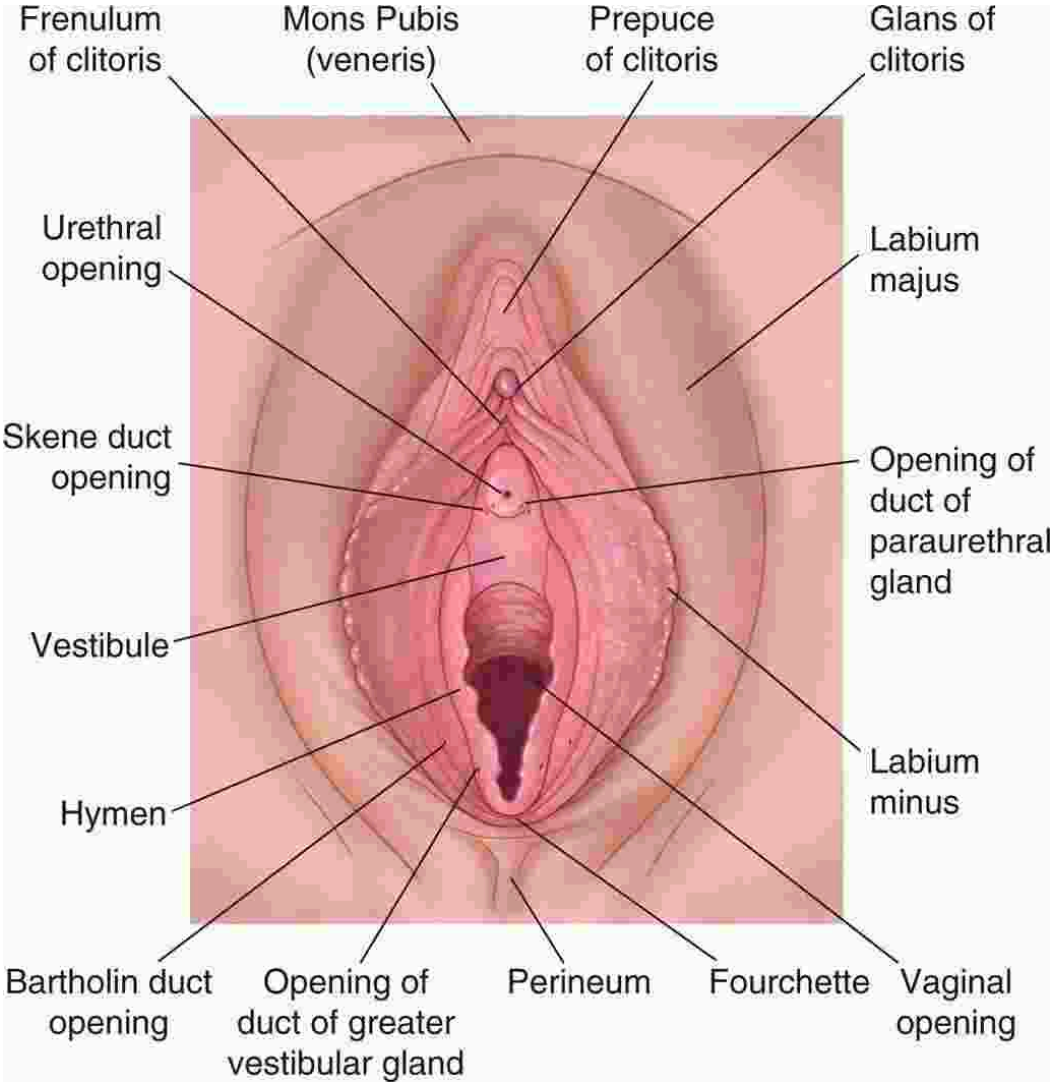

FIG. 24.4 **External Female Genitalia.** (Modified from Drake R, Vogl AW, Mitchell A, et al. *Gray's atlas of anatomy*, 3rd edition. Philadelphia: Churchill Livingstone; 2020.)

An illustration of the external female genitalia shows and labels the following structures, clockwise from the top: mons pubis (veneris), prepuce of clitoris, glans of clitoris, labium majus, opening of duct of paraurethral gland, labium minus, vaginal opening, fourchette, perineum, opening of duct of greater vestibular gland,

Bartholin duct opening, hymen, vestibule, Skene duct opening, urethral opening, and frenulum of clitoris.

Mons Pubis

The mons pubis is a fatty layer of tissue over the pubic symphysis (joint formed by the union of the pubic bones) that protects the joint during sexual intercourse. During puberty, it becomes covered with pubic hair, and sebaceous and sweat glands become more active. Estrogen causes the fat to be deposited under the skin giving it a mound-like shape.

Labia Majora and Minora

The labia majora (sing., labium majus) is composed of two folds of skin arising at the mons pubis and extending back to the fourchette, forming a cleft. During puberty, the amount of fatty tissue increases, pubic hair grows on lateral surfaces, and sebaceous glands on hairless medial surfaces secrete lubricants. This structure is highly sensitive to temperature, touch, pressure, and pain and protects the inner structures of the vulva. It is homologous to the male scrotum (see Fig. 24.2).

The labia minora (sing., labium minus) is composed of two smaller, thinner, asymmetric folds of skin within the labia majora that form the clitoral hood (prepuce) and frenulum, then split to enclose the vestibule, and converge near the anus to form the fourchette. The labia minora are hairless, pink, and moist; they are well supplied by nerves, blood vessels, and sebaceous glands that secrete bactericidal fluid with a distinctive odor that lubricates and waterproofs vulvar skin. The labia swell with blood during sexual arousal.

Clitoris

The clitoris is a richly innervated erectile organ between the labia minora. It is a small, cylindric structure having a visible glans and a shaft that lies beneath the skin; the clitoris is homologous to the penis. It secretes smegma, which has a unique odor that may be sexually

arousing. Like the penis, the clitoris is a major site of sexual stimulation and orgasm. With sexual arousal, erectile tissue fills with blood, causing the clitoris to enlarge slightly.

Vestibule

The vestibule is an area protected by the labia minora that contains the external opening of the vagina, called the *introitus* or vaginal orifice. A thin, perforated membrane, the *hymen*, may cover the introitus. The vestibule also contains the opening of the urethra, or *urinary meatus* (orifice). These structures are lubricated by two pairs of glands: Skene glands and Bartholin glands. The ducts of the Skene glands (also called the *lesser vestibular* or *paraurethral glands*) open on both sides of the urinary meatus. The ducts of the Bartholin glands *(greater vestibular* or *vulvovaginal glands)* open on either side of the introitus. In response to sexual stimulation, Bartholin glands secrete mucus that lubricates the inner labial surfaces, as well as enhances the viability and motility of sperm. Skene glands help lubricate the urinary meatus and the vestibule. In response to sexual excitement, the highly vascular tissue just beneath the vestibule also fills with blood and becomes engorged.

Perineum

The perineum is an area with less hair, skin, and subcutaneous tissue lying between the vaginal orifice and anus. Unlike the rest of the vulva, this area has little subcutaneous fat, so the skin is close to the underlying muscles. The perineum covers the muscular *perineal body*, a fibrous structure that consists of elastic fibers and connective tissue and serves as the common attachment for the bulbocavernosus, external anal sphincter, and levator ani muscles. The perineum varies in length from 2 to 5 cm or more and has elastic properties. The length of the perineum and the elasticity of the perineal body influence tissue resistance and injury during childbirth.

Internal Genitalia

Vagina

The vagina is an elastic, fibromuscular canal that is 9 to 10 cm long in a reproductive-age female. It extends up and back from the introitus to

the lower portion of the uterus. As Fig. 24.5 shows, the vagina lies between the urethra (and part of the bladder) and the rectum. Mucosal secretions from the upper genital organs, menstrual fluids, and products of conception leave the body through the vagina. During coitus, the penis enters the vagina. During sexual arousal, the vagina lengthens and widens, and the vaginal wall becomes engorged with blood, much like the labia minora and clitoris. Engorgement pushes some fluid to the surface of the mucosa, enhancing lubrication. The vaginal wall does not contain mucus-secreting glands; rather, secretions drain into the vagina from the endocervical glands or from the Bartholin and Skene glands of the vestibule. The vagina also functions as the birth canal during childbirth. Its elasticity and relatively sparse nerve supply enhance the vagina's function in this role. During childbirth, the pelvic floor muscles and rugae of the vagina stretch to facilitate the passage of the infant.

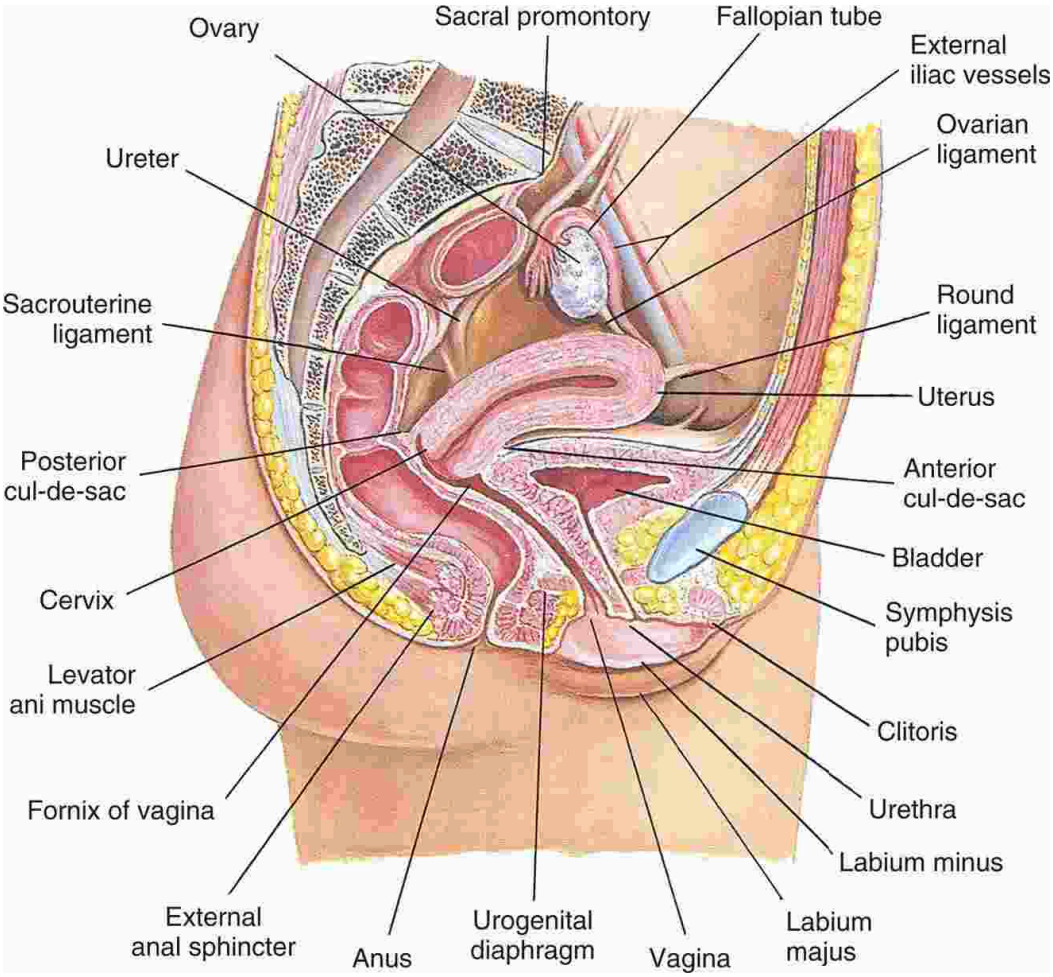

FIG. 24.5 Internal Female Genitalia and Other Pelvic Organs. (From Ball JW, et al. Seidel's *Guide to Physical Examination*. 8th ed. St Louis: Mosby; 2015.)

An illustration of the internal female genitalia and other pelvic organs shows and labels the following structures, clockwise from the top: sacral promontory, fallopian tube, external iliac vessels, ovarian ligament, round ligament, uterus, anterior cul-de-sac, bladder, symphysis pubis, clitoris, urethra, labium minus, labium majus, vagina, urogenital diaphragm, anus, external anus sphincter, fornix of vagina, levator ani

muscle, cervix, posterior cul-de-sac, sacrouterine ligament, ureter, and ovary.

The vaginal wall is lined with a mucous membrane of squamous epithelial cells that thickens and thins in response to hormones, particularly estrogen. The squamous epithelial membrane is continuous with the membrane that covers the lower part of the uterus. In females of reproductive age, the mucosal layer is arranged in transverse wrinkles, or folds, called rugae (sing., ruga), that permit stretching during coitus and childbirth. Below the mucosal layer are three more layers: fibrous connective tissue containing numerous blood and lymphatic vessels, smooth muscle and connective tissue, and a rich network of blood vessels.

The upper part of the vagina surrounds the cervix, the lower end of the uterus (see Fig. 24.5). The recessed space around the cervix is called the fornix of the vagina. The posterior fornix is "deeper" than the anterior fornix because of the angle at which the cervix meets the vaginal canal. In most females, this angle is about 90 degrees. A pouch called the cul-de-sac separates the posterior fornix and the rectum.

Two factors help maintain the self-cleansing action of the vagina and defend it from infection, particularly during the reproductive years. They are (1) an acid-base balance that discourages the proliferation of most pathogenic bacteria and (2) the thickness of the vaginal epithelium. Before puberty, vaginal pH is about 7.0 (neutral), and the vaginal epithelium is thin. At puberty, the pH becomes more acidic (4.0 to 5.0), and the squamous epithelial lining thickens. These changes are maintained until menopause (cessation of menstruation) when the pH rises again to more alkaline levels and the epithelium thins. Therefore, protection from infection is greatest during the years when a female is most likely to be sexually active. Both defense factors are greatest when estrogen levels are high, and the vagina contains a normal population of *Lactobacillus acidophilus*, a harmless resident bacterium that helps maintain pH at acidic levels. Any condition that causes vaginal pH to rise—such as douching or use of vaginal sprays

or deodorants, the presence of low estrogen levels, or destruction of *L. acidophilus* by antibiotics—lowers vaginal defenses against infection.

Uterus

The uterus is a hollow, pear-shaped organ whose lower end opens into the vagina. It anchors and protects a fertilized ovum, provides an optimal environment while the ovum develops, and pushes the fetus out at birth. In addition, the uterus plays an important role in sexual response and conception. During sexual excitement, the opening of the lower uterus (the cervix) dilates slightly. At the same time, the uterus increases in size and moves upward and backward, creating a tenting effect in the midvagina that results in the cervix "sitting" in a pool of semen. During orgasm, rhythmic contractions facilitate the movement of sperm through the cervical os while also enhancing physical pleasure.

At puberty, the uterus attains its adult size and proportions and descends from the abdomen to the lower pelvis, between the bladder and the rectum (see Fig. 24.5). The uterus of a mature, nonpregnant female is approximately 7 to 9 cm long and 6.5 cm wide, with muscular walls 3.5 cm thick, enlarging by about 1 cm in all dimensions after pregnancy.[1] It is loosely held in position by ligaments, peritoneal tissue folds, and the pressure of adjacent organs, especially the urinary bladder, sigmoid colon, and rectum. In most females, the uterus is tipped forward (anteverted) so that it rests on the urinary bladder. However, it may be tipped backward (retroverted), and various degrees of forward or backward flexion are normal (Fig. 24.6).

FIG. 24.6 Variations in Uterine Positions.

"An illustration of the lateral view of the pelvis, showing the uterus, bladder, vagina, and rectum, highlights the variations in uterine positions. Top panel, midline. The uterus is vertical. Middle-left panel, anteverted. The uterus is bent toward to the bladder. Middle-right panel, anteflexed. The uterus is curled toward the bladder. Bottom-left panel, retroverted. The uterus is bent away from the bladder. Bottom-right panel, retroflexed. The uterus is pressing at the rectal wall."

The uterus has two major parts: the corpus (body of the uterus) and the cervix (Fig. 24.7). The top of the corpus, above the insertion of the fallopian tubes, is called the fundus. The diameter of the uterine cavity is widest at the fundus and narrowest at the isthmus, just above the cervix (see Fig. 24.5). The cervix, or "neck of the uterus," extends from the isthmus to the vagina. The passageway between the upper opening (the internal os) and the lower opening (the external os) of the cervix is called the endocervical canal (see Fig. 24.7). The entire uterus, like the upper vagina, is innervated exclusively by motor and sensory fibers of the autonomic nervous system.

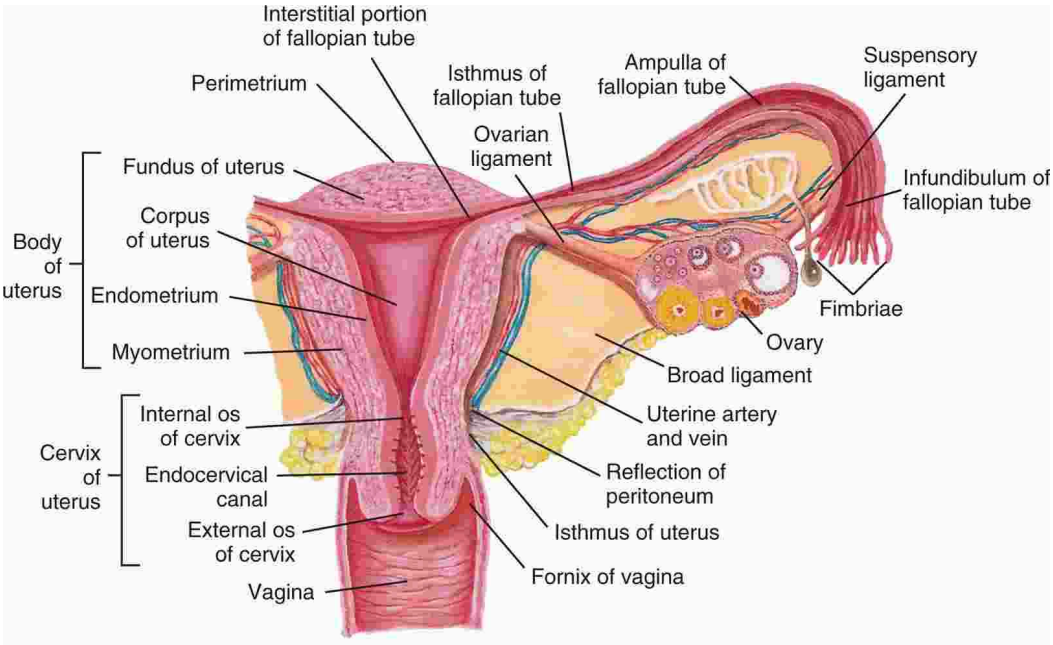

FIG. 24.7 Cross Section of Uterus, Fallopian Tube, and Ovary. (From Solomon B, et al. *Seidel's guide to physical examination*, 9th edition. Elsevier; 2019.)

An illustration of the cross-section of the uterus, fallopian tube, and ovary, shows and labels the following structures, clockwise from the top: perimetrium, interstitial portion of fallopian tube, ovarian ligament, isthmus of fallopian tube, ampulla of fallopian tube, suspensory ligament, infundibulum of fallopian tube, fimbriae, ovary, broad ligament, uterine artery and vein, reflection of peritoneum, isthmus of uterus, fornix of vagina, vagina, cervix of uterus, and body of uterus. The cervix of uterus includes the following parts, from the top: internal o s of cervix, endocervical canal, and external o s of cervix. The body of uterus includes the following

parts, from the top: fundus of uterus, corpus of uterus, endometrium, and myometrium.

The uterine wall is composed of three layers (see Fig. 24.7). The perimetrium (parietal peritoneum) is the outer serous membrane that covers the uterus. The myometrium is the thick, muscular middle layer. It is thickest at the fundus, apparently to facilitate birth. The endometrium, or uterine lining, is composed of a functional layer (superficial compact layer and spongy middle layer) and a basal layer. The functional layer of the endometrium responds to the sex hormones estrogen and progesterone. Between puberty and menopause, this layer proliferates and is shed monthly. The basal layer, which is attached to the myometrium, regenerates the functional layer after shedding (menstruation).

The endocervical canal does not have an endometrial layer but is lined with columnar epithelial cells. It is continuous with the lining of the outer cervix and vagina, which are lined with squamous epithelial cells. The point where the two types of cells meet is called the *transformation zone*, or squamous-columnar junction (see Fig. 25.20). The transformation zone is vulnerable to the human papillomavirus (HPV), especially HPV types 16 and 18, which can lead to cervical dysplasia or carcinoma in situ. Cells of the transformation zone are removed for examination during a Papanicolaou (Pap test) smear.

The cervix acts as a mechanical barrier, protecting the uterus from infectious microorganisms from the vagina. The external cervical os is a very small opening that contains thick, sticky mucus (the mucous "plug") during the luteal phase of the menstrual cycle and throughout pregnancy. During ovulation, the mucus changes under the influence of estrogen and forms watery strands, or spinnbarkeit mucus, to facilitate the transport of sperm into the uterus. In addition, the downward flow of cervical secretions moves microorganisms away from the cervix and uterus. In females of reproductive age, the pH of these secretions is inhospitable to many bacteria. Further, mucosal secretions contain enzymes and antibodies (mostly immunoglobulin A [IgA]) of the secretory immune system. Uterine pathophysiologic

disorders include infection, displacement of the uterus within the pelvis, benign growths (fibroids) of the uterine wall, hyperplasia of the endometrium, endometriosis, and cancer (see Chapter 25).

Fallopian Tubes

The two fallopian tubes (oviducts, uterine tubes) enter the uterus bilaterally just beneath the fundus (see Fig. 24.7). They direct the ova from the spaces around the ovaries to the uterus. From the uterus, the fallopian tubes curve up and over the two ovaries. Each tube is 8 to 12 cm long and about 1 cm in diameter, except at its ovarian end, which resembles the bell of a trumpet and is fringed or fimbriated (infundibulum). The fimbriae (fringes) move, creating a current that draws the ovum into the infundibulum. Once the ovum enters the fallopian tube, cilia (hairlike structures) and peristalsis (muscle contractions) keep it moving toward the uterus.

The ampulla, or distal third, of the fallopian tube is the usual site of fertilization (see Fig. 24.7). Sperm released into the vagina travel upward through the endocervical canal and uterine cavity and enter the fallopian tubes. If an ovum is present in either tube, fertilization can occur. Whether or not the ovum encounters sperm, it continues to travel through the fallopian tube to the uterus. If fertilized, the ovum (then called a *blastocyst*) implants itself in the endometrial layer of the uterine wall. If not fertilized, the ovum fragments and leaves the uterus with menstrual fluids. Disorders that affect the fallopian tubes (e.g., congenital malformations, infection, and inflammation) can block the path of both sperm and the ovum and may cause infertility or ectopic (tubal) pregnancy.

Ovaries

The ovaries, the female gonads, are the primary female reproductive organs (Fig. 24.8). Their two main functions are secretion of female sex hormones and development and release of female gametes, or ova.

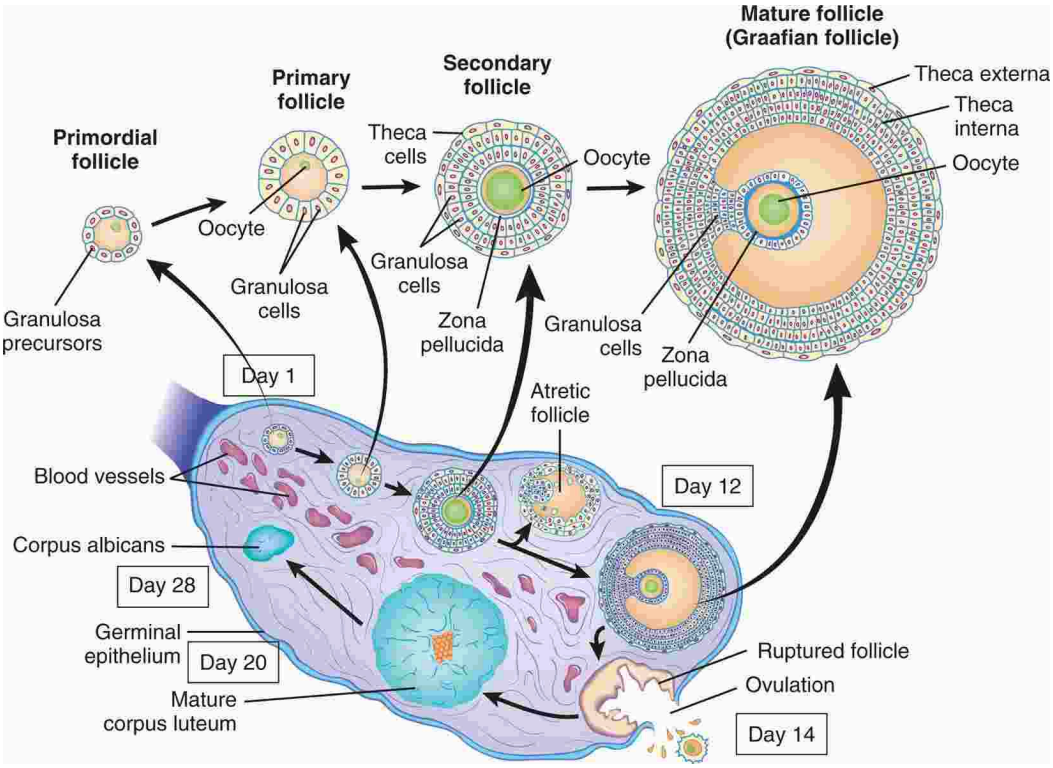

FIG. 24.8 Cross Section of Ovary and Development of an Ovarian Follicle. Schematic representation (not to scale) of the structure of the ovary, showing the various stages in the development of the follicle and its successor structure, the corpus luteum. (Adapted from Berne RM, Levy MN, eds. *Physiology*, 5th edition. St. Louis: Mosby; 2003.)

"A series of illustration of the cross-section of the ovary tracks the development of ovarian follicle. Day 1. The primordial follicle is an oocyte surrounded by a layer of granulosa precursors. The follicle undergoes the following changes until Day 12. • The primary follicle has a larger oocyte surrounded by a layer of granulosa cells. • The secondary follicle is filled with oocyte and is surrounded by a zona pellucida,

multiple layers of granulosa cells, and an outer layer of theca cells. • The atretic follicle develops. Day 12. The mature follicle (Graafian follicle) shows an oocyte surrounded by a thicker zona pellucida, proliferated granulosa cells, theca interna, and theca externa. Day 14. The follicle ruptures and results in ovulation. A mature corpus luteum develops. Day 20. Geminal epithelium. Mature corpus luteum develops. Day 28. Corpus albicans."

The almond-shaped ovaries are located on both sides of the uterus and are suspended and supported by a portion of the broad ligament (the mesovarium component), ovarian ligaments, and suspensory ligaments (see Fig. 24.7). The ovaries are smaller than their male homologs, the testes. In females of reproductive age, each ovary is about 3 to 5 cm long, 2.5 cm wide, and 2 cm thick, weighing 4 to 8 g. Size and weight vary slightly during each phase of the menstrual cycle (see the Menstrual (Ovarian) Cycle section).

The central part of the ovary, or medulla, is composed of connective tissue and contains many small arteries, veins, and lymphatics that enter at the hilum. Surrounding the medulla is the cortex. At birth, the cortex of each ovary contains approximately 1 to 2 million ova within primordial (immature) ovarian follicles. By puberty, the number ranges between 300,000 and 500,000, and some of the follicles and the ova within them begin to mature. Follicles grow and undergo atresia continuously and irrevocably throughout a woman's life. Between puberty and menopause, the ovarian cortex always contains follicles and ova in various stages of development (primary and secondary follicles). Once every menstrual cycle (about every 28 days), one of the follicles reaches maturation and discharges its ovum through the ovary's outer covering, the germinal epithelium. During the reproductive years, 400 to 500 ovarian follicles mature completely and release an ovum (ovulation). The remaining follicles either fail to

develop at all or degenerate without maturing completely and are known as atretic follicles (see Fig. 24.8).

After the release of the mature ovum (ovulation), the follicle develops into another structure, the corpus luteum (see Fig. 24.8). If fertilization occurs, the corpus luteum enlarges and begins to secrete hormones that maintain and support pregnancy. If fertilization does not occur, the corpus luteum secretes these hormones for approximately 14 days and then degenerates, which triggers the maturation of another follicle. The ovarian cycle—the process of follicular maturation, ovulation, corpus luteum development, and corpus luteum degeneration—is continuous from puberty to menopause, except during pregnancy or hormonal contraceptive use. At menopause, this process ceases, and the ovaries atrophy to the point that they cannot be felt during a pelvic examination.

Sex hormones are secreted by cells present within the ovarian cortex, including two types of cells in the ovarian follicle—theca cells (produce androgens that migrate to granulosa cells) and granulosa cells (convert androgens to estradiol)—and cells of the corpus luteum (secrete primarily progesterone, estrogen, and inhibin) (see Fig. 24.8). These cells all contain receptors for gonadotropins (LH, FSH) or for sex hormones, which are discussed in the next section.

Female Sex Hormones

The sex hormones are all steroid hormones and are synthesized from cholesterol (see Chapter 21). The dominant female sex hormones, estrogen and progesterone, are produced primarily by the ovaries (see Table 24.1). During fetal development, infancy, and childhood, sex hormone production is low. At puberty, hormone production surges, triggering sexual maturation and the development of secondary sex characteristics. From puberty to menopause, the sex hormones are produced cyclically; production surges and diminishes monthly, creating the ovarian and uterine changes associated with the menstrual cycle. These hormones also are produced in higher levels during pregnancy by the placenta, inhibiting ovulation. Individual effects of sex hormones depend on the amount and concentration in the blood.

Both male and female sex hormones are present in all adults. However, the female body contains low levels of testosterone and other androgens, and the male body contains low levels of estrogen.

Estrogens and Androgens

Estrogen is a generic term for any of three similar hormones derived from cholesterol: estradiol, estrone, and estriol. Estradiol (E2) is the most potent and plentiful of the three and is principally produced (95%) by the ovaries (ovarian follicle and corpus luteum). Limited amounts are secreted by the cortices of the adrenal glands and the placenta during pregnancy. Androgens are converted to estrone in ovarian and adipose tissue; estriol is the peripheral metabolite of estrone and estradiol.

Estrogen has numerous biologic effects, many of which involve interactions with other hormones. It is needed for the maturation of reproductive organs, development of secondary sex characteristics, growth, and maintenance of pregnancy. It also is needed for many nonreproductive effects, including closure of long bones after the pubertal growth spurt (in both males and females), maintenance of bone and skin, and systemic organ function (see Table 24.1 and Box 24.1). After menopause, the ovaries dramatically reduce the production of estradiol, and secretion of estrone is markedly diminished (see the Aging and the Female Reproductive System section). At this time, the majority of estradiol is derived from intracellular synthesis in peripheral tissues. Estradiol acts locally to meet physiologic needs according to cell type and is then inactivated without systemic effects.[2]

Box 24.1

Summary of Nonreproductive Effects of Estrogen

- Estrogens (including estrone, estradiol, estriol) function through estrogen receptors alpha and beta, have different roles in

different cells and tissues and have paracrine or intracrine function.

- Maintains bone density by antagonizing effects of parathyroid hormone.
- Acts in the liver to decrease cholesterol level, increase high-density lipoprotein (HDL) level, and decrease low-density lipoprotein (LDL) level (antiatherosclerotic); promotes fat deposition.
- Maintains nervous system (neurotrophic and neuroprotective); facilitates memory and cognition.
- Increases collagen content, dermal thickness, elasticity, water content, and healing ability of the skin.
- Protects against chronic kidney disease in individuals without diabetes.
- Prevents vascular injury and early atheroma formation through endothelial mechanisms.
- Inhibits platelet adhesiveness.
- Can promote inflammation and have variable effects on immunity.
- Promotes clotting; increased risk of thromboembolism (only estrogen associated with pregnancy or use in contraceptive pills or hormone replacement therapy).

Like other steroid hormones, estrogens are derived from cholesterol in a complex, enzyme-mediated series of reactions. The hypothalamus secretes GnRH in a pulsatile manner that stimulates gonadotropin (LH and FSH) release from the anterior pituitary. Gonadotropins trigger the ovarian production of estrogen. The primary function of LH is to stimulate theca cells of the ovarian follicle to produce androgens, mainly androstenedione. (Androgens are discussed further under the section titled Male Sex and Reproductive Hormones.) Some of these androgens are converted to estrogen by the theca cells themselves, and others diffuse into the granulosa cells. Within the granulosa layer, FSH induces conversion (aromatization) of androgens to estrogens. Estrogens are then released into the bloodstream.

Although androgens are primarily male sex hormones produced in the testes, small amounts are produced in the adrenal cortex in both males and females and in the ovaries in females. Some androgens (dehydroepiandrosterone and its metabolite androstenedione) are precursors of estrogens (estrone, estradiol) (see Table 24.1). At puberty, androgens contribute to the skeletal growth spurt and cause the growth of pubic and axillary hair. Androgens also activate sebaceous glands, accounting for some cases of acne during puberty, and play a role in libido.

Progesterone

Luteinizing hormone from the anterior pituitary stimulates the corpus luteum to secrete progesterone, the second major female sex hormone. With estrogen, progesterone controls the ovarian menstrual cycle. LH surge occurs when there is a peak level of estrogen, about 24 to 36 hours before ovulation. LH promotes luteinization of the granulosa in the dominant follicle, resulting in progesterone production and the development of blood vessels and connective tissue. During the follicular phase, the ovary and adrenal glands each contribute approximately 50% of progesterone production. Conversely, large amounts are cyclically secreted from the ovary while the corpus luteum is active for about 9 to 13 days after ovulation. (The complementary and opposing effects of progesterone and estrogen are listed in Table 24.2.) Progesterone secreted by the corpus luteum stimulates the thickened endometrium to become more complex in preparation for implantation of a blastocyte. If conception and implantation do occur, the corpus luteum persists and secretes progesterone (and estrogen) until the placenta is well established at approximately 8 to 10 weeks' gestation and undertakes progesterone production.

Table 24.2

Complementary and Opposing Effects of Estrogen and Progesterone

Structure	Effect of Estrogen	Effect of Progesterone
Vaginal mucosa	Proliferation of squamous epithelium; increase in glycogen content of cells; layering (cornification) of cells	Thinning of squamous epithelium; decornification
Cervical mucosa	Production of abundant fluid secretions that favor survival and enhance motility of sperm	Production of thick, sticky secretions that tend to plug cervical os
Fallopian tube	Increase of motility and ciliary action	Decrease of motility and ciliary action
Uterine muscle	Increase of blood flow; increase of contractile proteins; increase of uterine muscle and myometrial excitability to action potential; increase of sensitization to oxytocin	Relaxation of myometrium; decrease of sensitization to oxytocin
Endometrium	Stimulation of growth; increase in number of progesterone receptors	Activation of glands and blood vessels; accumulation of glycogen and enzymes; decrease in number of estrogen receptors

Structure	Effect of Estrogen	Effect of Progesterone
Breasts	Growth of ducts; promotion of prolactin effects	Growth of lobules and alveoli; inhibition of prolactin effects

Progesterone is sometimes called the *hormone of pregnancy*. Progesterone's effects in pregnancy include:

- maintaining the thickened endometrium;
- relaxing the smooth muscle in the myometrium, which prevents premature contractions and helps the uterus to expand;
- thickening (hypertrophy) the myometrium, which prepares it for the muscular work of labor;
- promoting the growth of lobules and alveoli in the breast in preparation for lactation, but preventing lactation until the fetus is born and then promoting lactation in collaboration with prolactin after birth;
- preventing additional maturation of ova by suppressing FSH and LH, thereby stopping the menstrual cycle;
- providing immune modulation, allowing tolerance against fetal antigens (the mother's immune system does not attack the fetus); and
- preventing preterm birth.

Menstrual (Ovarian) Cycle

In addition to pregnancy, the obvious manifestation of female reproductive functioning is menstrual bleeding (the menses), which starts with menarche (first menstruation) and ends with menopause (cessation of menstrual flow for 1 year). In the United States, the age of first menstruation is about 12 years.[3]

The onset of menarche appears to be related to body weight, especially a high percentage of body fat (a high ratio of fat to lean tissue), which many trigger a change in the metabolic rate and lead to hormonal changes associated with early menarche. The hormone

leptin increases before the onset of menarche. Leptin (a regulatory hormone of appetite and energy metabolism) promotes the secretion of kisspeptin from the hypothalamus and leads to the release of GnRH, which in turn enhances the release of FSH and LH and estradiol, triggering ovulation and the onset of puberty. A high percentage of body fat is associated with higher levels of leptin. Childhood obesity is associated with an increase in leptin and with early menarche (age 11 years or younger).[4]

Cycles are not ovulatory at first and may vary in length from 10 to 60 days or more. As adolescence proceeds, regular patterns of menstruation and ovulation are established at intervals ranging between 21 and 45 days.[5] Menstruation continues to recur in a recognizable and characteristic pattern during adulthood, with the length of the menstrual cycle varying considerably among individuals. The commonly accepted cycle average is 28 (25 to 30) days, with rhythmic intervals of 21 to 35 days considered normal (Fig. 24.9). Approximately 4 to 10 years before menopause, cycles begin to lengthen again with variation related to changing hormone levels.[6]

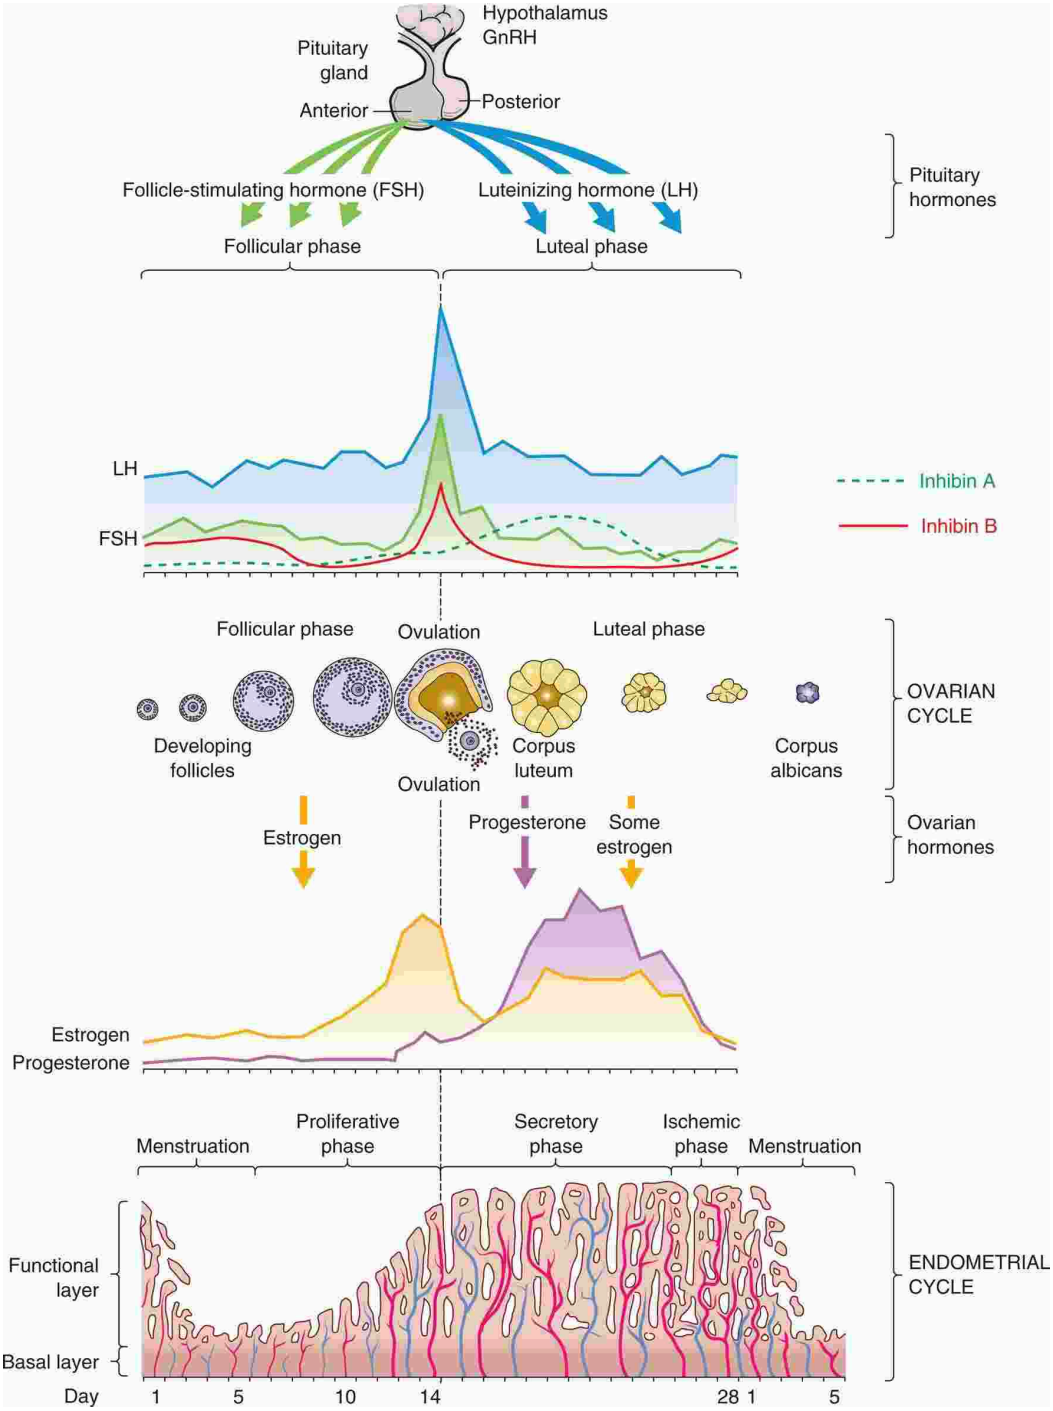

FIG. 24.9 The Menstrual Cycle.

GnRH, Gonadotropin-releasing hormone. (Adapted from Lowdermilk DL, et al. *Maternity and women's health care*, 10th edition. St. Louis: Mosby; 2012.)

Four illustrations show the four phases of the menstrual cycle. The cycle consists of follicular or proliferative phases, luteal or secretory phases, follicular or luteal phases, and proliferative, secretory, or ischemic phases.

Phases of the Menstrual Cycle

The menstrual (ovarian) cycle (see Fig. 24.9) is the process of menstruation (menses) in the uterine endometrium and ovulation in the ovary. The cycle consists of the follicular/proliferative phase (postmenstrual) followed by the luteal/secretory phase (premenstrual) and then the ischemic/menstrual phase if conception does not occur. These are named for processes that occur in the ovary (follicular and luteal phases) and the uterine endometrium (proliferative, secretory, and ischemic phases) during the menstrual cycle.

During menstruation (menses), the functional layer of the endometrium disintegrates and is discharged through the vagina. Menstruation is followed by the follicular/proliferative phase. This phase is named for two simultaneous processes: maturation of an ovarian follicle and proliferation of the uterine endometrium (see Fig. 24.9). During this phase, GnRH and a balance between activin and inhibin levels from the granulosa cells contribute to the increase of FSH level, which stimulates a number of follicles. The result is a rescue of a dominant ovarian follicle from normal dissolution by days 5 to 7 of the cycle. Together, estrogen and FSH make the granulosa cells of the primary follicle more sensitive to FSH and promote LH stimulation, which causes a more rapid secretion of follicular estrogen. A surge in the levels of both LH and FSH is then required for final follicular growth and ovulation. Estrogen levels increase, and inhibin B inhibits the secretion of FSH level by the granulosa cells in the dominant follicle. This drop in FSH concentration decreases the growth of less developed follicles (see Fig. 24.8). Estrogen causes cells of the endometrium to proliferate.

Ovulation is the release of an ovum from a mature follicle and marks the beginning of the luteal/secretory phase of the menstrual cycle. The ovarian follicle begins its transformation into a corpus luteum (see Fig. 24.8), hence the name *luteal phase*. Pulsatile secretion of LH from the anterior pituitary stimulates the corpus luteum to secrete progesterone, estrogen, and inhibin A (suppresses FSH secretion), which in turn initiates the secretory phase of endometrial development. Estrogen maintains the thickness of the endometrium, and progesterone stimulates the growth of glands and blood vessels in the endometrium. The glands begin to secrete a thin, glycogen-containing fluid, hence the name *secretory phase*. At this point, one of the following two paths occurs:

- If conception and implantation do not occur, the corpus luteum degenerates and ceases its production of progesterone and estrogen. Without progesterone or estrogen to maintain it, the endometrium enters the ischemic ("blood-starved") phase and disintegrates, hence the name ischemic/menstrual phase. Menstruation then occurs, marking the beginning of another cycle.
- If conception occurs, the nutrient-laden endometrium is ready for implantation. Human chorionic gonadotropin (hCG) is secreted 3 days after fertilization by the blastocytes and maintains the corpus luteum once implantation occurs at about day 6 or 7. Levels of hCG can be detected in maternal blood and urine 8 to 10 days after ovulation. The production of estrogen and progesterone will continue until the placenta can adequately maintain hormonal production.

Ovulatory cycles appear to have a minimum length of 24 to 26.5 days: the ovarian follicle requires 10 to 12.5 days to develop, and the luteal phase appears fixed at 14 days (±3 days). Menstrual blood flow usually lasts 3 to 7 days but may be between 2 and 8 days and still be considered within normal limits. Bleeding is consistently scant to heavy and varies from 30 to 80 ml, with most blood loss occurring during the first 3 days of menses. Menstrual discharge consists of

blood, mucus, and desquamated endometrial tissue and does not clot under normal circumstances. It is usually dark and produces a characteristic musty odor on oxidation. Environmental factors such as severe emotional stress, illness, malnutrition, obesity, extreme exercise, and seasonal variation may affect the length of the menstrual cycle.[7,8]

Cervical mucus also undergoes cyclic changes during the menstrual cycle. During the proliferative phase, the cervical mucus is thin and watery. Peak estrogen levels occur just before ovulation and maximally stimulate the cervical glands to produce mucus. Cervical mucus becomes abundant and more elastic (spinnbarkeit). In the presence of estrogen, tiny channels develop in the mucus, which allows sperm access to the interior of the uterus. Changes in the consistency of cervical mucus can be used to identify fertile intervals. After ovulation, the ovary begins to secrete progesterone under the influence of the corpus luteum. The amount of cervical mucus is reduced, becomes thicker and stickier, and blocks sperm migration.

The vaginal epithelium also responds to the cyclic hormonal changes of the menstrual cycle. Under the influence of estrogen, cells of the vaginal epithelium become thicker during the follicular/proliferative phase. After ovulation, layers of keratinized cells overgrow the basal epithelium (cells become larger and flatter), a process known as cornification. Near the end of the luteal phase, leukocytes invade the vaginal epithelium, removing the outer layers in a process termed decornification with thinning of the epithelium.

Basal body temperature (BBT) undergoes characteristic biphasic changes during menstrual cycles in which ovulation occurs. During the follicular phase, the BBT fluctuates around 98°F (37°C). During the luteal phase, the average temperature increases by 0.4°F to 1.0°F (0.2°C to 0.5°C). At the end of the luteal phase, 1 to 3 days before the onset of menstruation, BBT declines to follicular-phase levels. The shift in temperature is related to ovulation, corpus luteum formation, and increased serum progesterone levels. Progesterone acts on the thermoregulatory center of the hypothalamus to increase body temperature. Changes in BBT are used to estimate ovulatory cycles but when used alone may not be the best method to support fertility awareness.[9]

Hormonal Control

Hormonal control of the menstrual cycle depends on complex interactions among the hypothalamus, the anterior pituitary, and the ovaries (or hypothalamic-pituitary-ovarian [HPO] axis) (Table 24.3). Hormonal control is dependent on negative and positive ovarian feedback mechanisms. In the hypothalamus, kisspeptin activates the release of GnRH to stimulate the gonadotropin production of FSH and LH. The constant and pulsatile release of GnRH is critical to the timing of the menstrual cycle. GnRH is secreted into the hypophyseal portal system and travels to the anterior pituitary, where it stimulates the secretion of LH and FSH. FSH and LH are released from the anterior pituitary in pulses that correspond to the pulsatile secretion of GnRH.

Table 24.3

Hormonal Feedback Mechanism in the Menstrual Cycle

Phase of Cycle and Ovarian Hormone Levels	Feedback to Hypothalamus and Anterior Pituitary	Resultant GnRH, FSH, and LH Levels	Ovarian and Menstrual Events
Early follicular phase: estrogen levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	Ovarian follicle develops; endometrium proliferates
Late follicular (preovulatory) phase: estrogen levels high; progesterone increases with small surge before ovulation	Positive and stimulatory	All surge; LH dominates	Process of ovulation begins; endometrial proliferation complete
Ovulatory phase: estrogen levels dip; progesterone levels begin to rise	Negative and inhibitory	All fall sharply	Corpus luteum begins to develop; endometrium enters secretory phase

Phase of Cycle and Ovarian Hormone Levels	**Feedback to Hypothalamus and Anterior Pituitary**	**Resultant GnRH, FSH, and LH Levels**	**Ovarian and Menstrual Events**
Early luteal phase: estrogen and progesterone levels high; progesterone dominates	Negative and inhibitory	All continue to decline, but gradually	Corpus luteum fully developed; endometrium ready for implantation
Late luteal phase: estrogen and progesterone levels fall sharply	Negative and inhibitory; feedback lessens slightly	All rise slightly	Corpus luteum regresses; endometrium breaks down; menstruation begins
Menstrual phase: estrogens levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	More ovarian follicles begin to develop; functional layer of endometrium is shed

Phase of Cycle and Ovarian Hormone Levels	Feedback to Hypothalamus and Anterior Pituitary	Resultant GnRH, FSH, and LH Levels	Ovarian and Menstrual Events
Early follicular phase: estrogen levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	Ovarian follicle develops; endometrium proliferates
Late follicular (preovulatory) phase: estrogen levels high; progesterone increases with small surge before ovulation	Positive and stimulatory	All surge; LH dominates	Process of ovulation begins; endometrial proliferation complete
Ovulatory phase: estrogen levels dip; progesterone levels begin to rise	Negative and inhibitory	All fall sharply	Corpus luteum begins to develop; endometrium enters secretory phase
Early luteal phase: estrogen and progesterone levels high; progesterone dominates	Negative and inhibitory	All continue to decline, but gradually	Corpus luteum fully developed; endometrium ready for implantation
Late luteal phase: estrogen and progesterone levels fall sharply	Negative and inhibitory; feedback lessens slightly	All rise slightly	Corpus luteum regresses; endometrium breaks down; menstruation begins
Menstrual phase: estrogens levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	More ovarian follicles begin to develop; functional layer of endometrium is shed

FSH, Follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone.

During the early follicular phase, estrogen levels rise steadily and, through negative feedback, suppress FSH and positively increase the production of LH. During the late follicular phase, the preovulatory rise in progesterone concentration facilitates the positive feedback of estrogen; estrogen levels begin to increase, stimulating a surge of LH secretion from the anterior pituitary. The midcycle surge of LH and FSH induces ovulation. A nonsteroidal ovarian factor, gonadotropin surge–attenuating factor (GnSAF), may antagonize the effect of estrogen on the pituitary and regulate the surge of LH at midcycle.[10] Rising estrogen and progesterone levels during the luteal phase may inhibit the anterior pituitary and thus reduce LH and FSH secretion. Just before the onset of menstruation, FSH and LH levels begin to increase slightly, probably because of declining estrogen and progesterone levels (see Fig. 24.9).

A variety of growth factors and autocrine/paracrine peptides influence hormonal control and follicular response. During the early follicular stage, FSH stimulates FSH receptors and LH receptors and the release of insulin-like growth factor one, as well as the production of inhibin and activin in the ovary. Activin from granulosa cells stimulates the secretion of FSH and increases the pituitary response to GnRH, and increases FSH binding in the granulosa cells in the dominant follicle. FSH stimulates inhibin secretion from granulosa

cells, and it, in turn, suppresses FSH synthesis. Inhibin B is primarily secreted in the follicular phase of the cycle but sharply spikes when ovulation occurs. Inhibin A is secreted in the luteal phase and further suppresses FSH. Inhibin also restrains prolactin and growth hormone release, interferes with GnRH receptors, and promotes the breakdown of intracellular gonadotropins. In summary, the balance between activin and inhibin regulates FSH secretion. Follistatin inhibits activin and boosts inhibin activity. Inhibin and activin also regulate LH stimulation of androgen synthesis (required for ovarian estrogen biosynthesis) in theca cells.[11] Fig. 24.9 depicts fluctuating estrogen, progesterone, gonadotropin, and inhibin levels. Research continues to advance understanding of the function and structural complexity of these polypeptides and their interaction with GnRH, gonadotropins, and sex hormones.[12]

Structure and Function of the Breast

The breasts are modified sebaceous glands that lie on the ventral surface of the thorax, within the superficial fascia of the chest wall. They extend vertically from the second rib to the sixth or seventh intercostal space and laterally from the side of the sternum to the midaxillary line. Breast tissue also may extend into the axilla; this tissue is known as the *tail of Spence*.

Female Breast

The adult female breast is composed of 15 to 20 pyramid-shaped lobes that are separated and supported by suspensory (Cooper) ligaments (Fig. 24.10). Each lobe contains 20 to 40 lobules, which subdivide further into many functional units called acini (sing., acinus). Each acinus is lined with a layer of epithelial cells capable of secreting milk during lactation and a layer of subepithelial cells capable of contracting to squeeze milk from the acinus. The acini empty into a network of lobular collecting ducts, which empty into interlobular collecting and ejecting ducts. Ductal elongation and organized branching are achieved with collagen fiber alignment. The ducts reach the skin through openings (pores) in the nipple. The lobes and lobules

are surrounded and separated by muscle strands and fatty connective tissue. The amount of fatty connective tissue varies among individuals depending on weight, genetic, and endocrine factors; this contributes to the diversity of breast size and shape and the function of the mammary epithelium. Fat increases in the breast after menopause and is a local source of estrogen and other steroid hormones.[13]

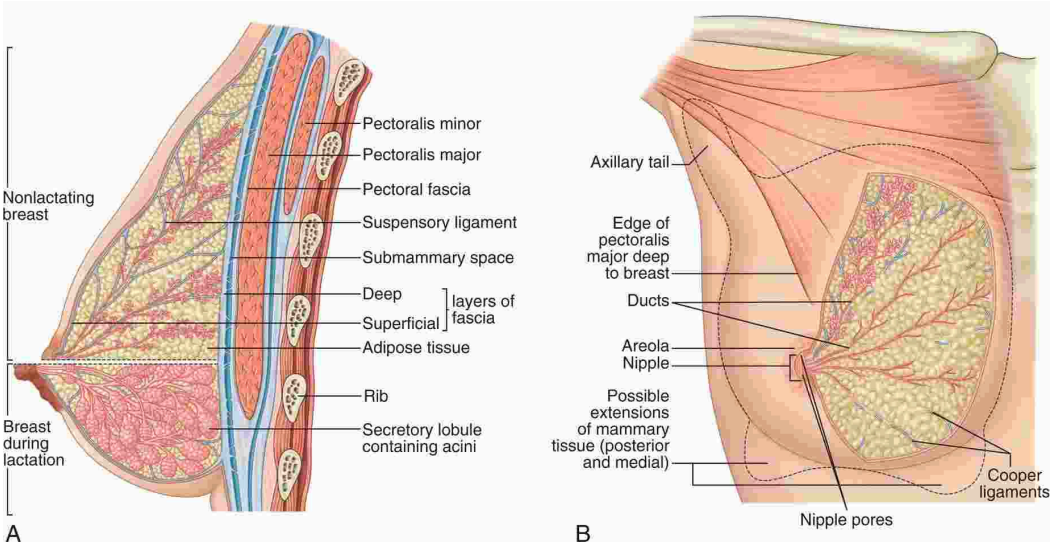

FIG. 24.10 Schematic Diagram of the Breast.
(A) Lactating breast. **(B)** Structure of the breast.
(From Standring S. *Gray's anatomy*, 42nd edition. London: Elsevier; 2021.)

"Illustration A shows a lateral, cross-sectional view of a breast. The following structures of the breast are labeled, from the top to the bottom: pectoralis minor, pectoralis major, pectoral fascia, suspensory ligament, submammary space, layers of fascia (deep, superficial), adipose tissue, rib, and secretory lobule. The upper part of the breast, above the nipple, represents a nonlactating breast, and shows tiny secretory lobules. The lower part of the breast, below the nipple, represents a lactating breast, and shows larger secretory lobules containing acini. Illustration B is an anterior view of a breast. The following structures of the breast are labeled, from the top to the bottom: axillary tail, edge of pectoralis major deep to breast, ducts, areola, nipple, cooper ligaments, and

possible extensions of mammary tissue (posterior and medial)."

An extensive capillary network surrounds the acini and is supplied by branches of the internal mammary, thoracoacromial, internal and lateral thoracic, and intercostal arteries. Venous return follows arterial supply, with relatively rapid emptying into the superior vena cava. The breasts receive sensory innervation from branches of the second through sixth intercostal nerves and the cervical plexus. This accounts for the fact that breast pain may be referred to the chest, back, scapula, medial arm, and neck. Lymphatic drainage of the breast occurs largely through axillary nodes, but there may be a predominance of superficial mammary routes with resultant asymmetry between a person's breasts. Lymphatic drainage from one breast may drain to the opposite side and is a factor in cancer metastasis (Fig. 24.11).

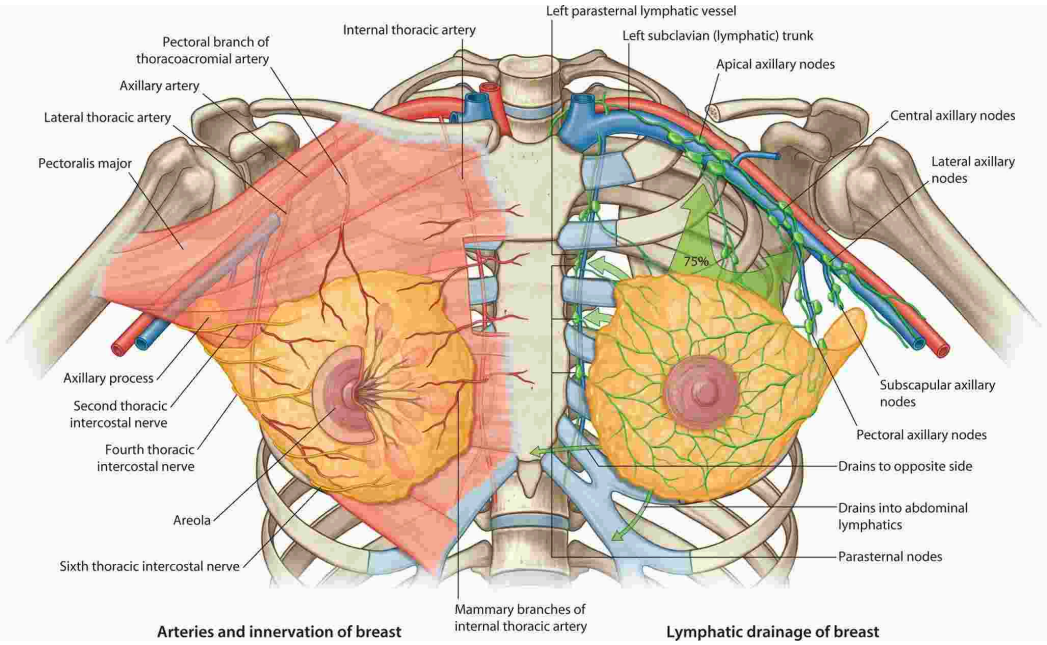

FIG. 24.11 Vasculature, Innervation, and Lymphatic Drainage of the Female Breast. (From Standring S. *Gray's atlas of anatomy*, 42nd edition. London: Elsevier; 2021.)

"An illustration shows the vasculature, innervation, and lymphatic drainage of the female breast. The left side of the illustration shows the arteries and innervation of breast, labeling the following structures from the top to the bottom: internal thoracic artery, pectoral branch of thoracoacromial artery, axillary artery, pectoralis major, axillary process, second thoracic intercostal nerve, fourth thoracic intercostal nerve, mammary branches of internal thoracic artery, areola, and sixth thoracic intercostal nerve. The right side of the illustration shows the lymphatic draining of breast, labeling the following structures from the top to the bottom: left parasternal lymphatic vessel, left

subclavian (lymphatic) trunk, apical axillary nodes, central axillary nodes, lateral axillary nodes, subscapular axillary nodes, pectoral axillary nodes, drains to opposite side, drains into abdominal lymphatics, and parasternal nodes."

The nipple is a pigmented cylindric structure usually located in the fourth or fifth intercostal space. It measures 0.5 to 1.3 cm in diameter and is approximately 10 to 12 mm in height when erect. On its surface lie multiple pores, one from each lobe. The areola is the pigmented circular area around the nipple. It may be 15 to 60 mm in diameter. A number of sebaceous glands, the glands of Montgomery, are located within the areola and aid in the lubrication of the nipple during lactation. The nipple and areola contain smooth muscles, which receive motor innervation from the sympathetic nervous system. Breast-feeding, sexual stimulation, and exposure to cold cause the nipple to become erect.

The fetal and early postnatal development of breast tissue does not depend on hormones, although fetal breast tissue does become progressively responsive to hormonal stimulation. The neonatal breasts are rudimentary, containing 10 to 12 branching ducts. During childhood, breast growth is latent, and growth of the nipple and areola keeps pace with body surface growth. (Male breast development normally does not progress any further.) At the onset of puberty in the female, growth hormone, insulin-like growth factor 1 (IGF1), and estrogen stimulate mammary growth. Thelarche is usually the first sign of puberty in the female. Full differentiation and development of breast tissue occur over approximately four years and are mediated by the levels of several hormones, including estrogen, progesterone, prolactin, growth hormone, thyroid and parathyroid hormones, insulin, and cortisol. Estrogen promotes the increase in the size of the breast by the formation of a mass of tissue under the areola, increases the size and pigmentation of the areola, and promotes the development of the lobular ducts. The breast cells of *parous* females (those who have given birth) are different than those of females who

never become pregnant, as the expansion of acini only occurs with pregnancy when the mammary gland prepares for lactation. During menopause, the lobules of the parous breast involute to prepregnancy composition and become identical to the nulliparous breast.[14]

During the reproductive years, the breast undergoes cyclic changes in response to changes in the levels of estrogen and progesterone associated with the menstrual cycle. Estrogen promotes the development of the lobular ducts; progesterone stimulates the development of cells lining the acini. During the follicular/proliferative phase of the menstrual cycle, high estradiol levels increase the vascularity of breast tissue and stimulate the proliferation of ductal and acinar tissue. This effect is sustained into the luteal/secretory phase of the cycle. During this phase, progesterone levels increase and contribute to the breast changes induced by estradiol. Specific effects of progesterone include dilation of the ducts and conversion of the acinar cells into secretory cells. Most females experience some degree of premenstrual breast fullness, tenderness, and increased breast nodularity. Breast volume may increase as much as 10 to 30 ml. Because the length of the menstrual cycle does not allow for complete regression of new cell growth, breast growth continues at a slow rate until approximately 35 years of age. Because of the cyclic changes that occur in breast tissue, breast examination should be conducted at the conclusion of or a few days after the menstrual cycle, when hormonal effects are minimal and breasts are at their smallest and least tender.

The function of the female breast is primarily to provide a source of nourishment for the newborn. During pregnancy, the breast remodels into a milk-secreting organ and reaches its ultimate mature developmental stage. With increased levels of estrogen, the lobules further differentiate. Progesterone stimulates the development of cells lining the alveoli to produce milk. Lactation (milk production) occurs after childbirth in response to increased levels of prolactin. Prolactin secretion, in turn, increases by continued breastfeeding. Oxytocin, another hormone released during and after delivery, controls milk ejection from alveolar cells. Milk is continuously secreted into the alveolar lumen and is stored there until suckling by the infant stimulates oxytocin, which triggers the let-down reflex. The alveoli

empty into a network of lactiferous ducts. These ducts reach the skin through 9 or 10 pores in the nipple.

Physiologically, breast milk is the most appropriate nourishment for newborns. Colostrum, produced in low quantities in the first few days postpartum, is rich in immunologic components, including secretory IgA, lactoferrin, leukocytes, and developmental factors, such as epidermal growth factor. The nutrient composition changes over time to meet the changing digestive capabilities and nutritional requirements of the infant. Secretory IgA and nonspecific antimicrobial factors, such as lysosomes and lactoferrin, protect the infant against infection. During lactation, high prolactin levels interfere with hypothalamic-pituitary hormones that stimulate ovulation. This mechanism suppresses the menstrual cycle and can prevent ovulation.

Male Breast

Until puberty, the development of the male breast is similar to that of the female breast. In the absence of sufficiently high levels of estrogen and progesterone, and with antagonistic effects of androgens, the male breast does not develop any further. The normal male breast consists mostly of fat with a small, underdeveloped nipple and a few ductlike structures in the subareolar area. The male breast may appear enlarged in obese males because of the accumulation of fatty tissue. During puberty, some males experience benign gynecomastia (benign proliferation of male breast glandular tissue), a condition in which the breasts enlarge temporarily as a result of hormonal fluctuations and which should be differentiated from any underlying systemic disorders.

The Male Reproductive System

The external genitalia in males perform the major functions of reproduction. Sperm are produced in the male gonads (testes) and delivered by the penis to the female vagina. The internal male genitalia consist of conducting tubes and fluid-producing glands, all of which aid in the transport of sperm from the testes to the urethral opening of

the penis. The male reproductive and urinary structures are shown in Fig. 24.12.

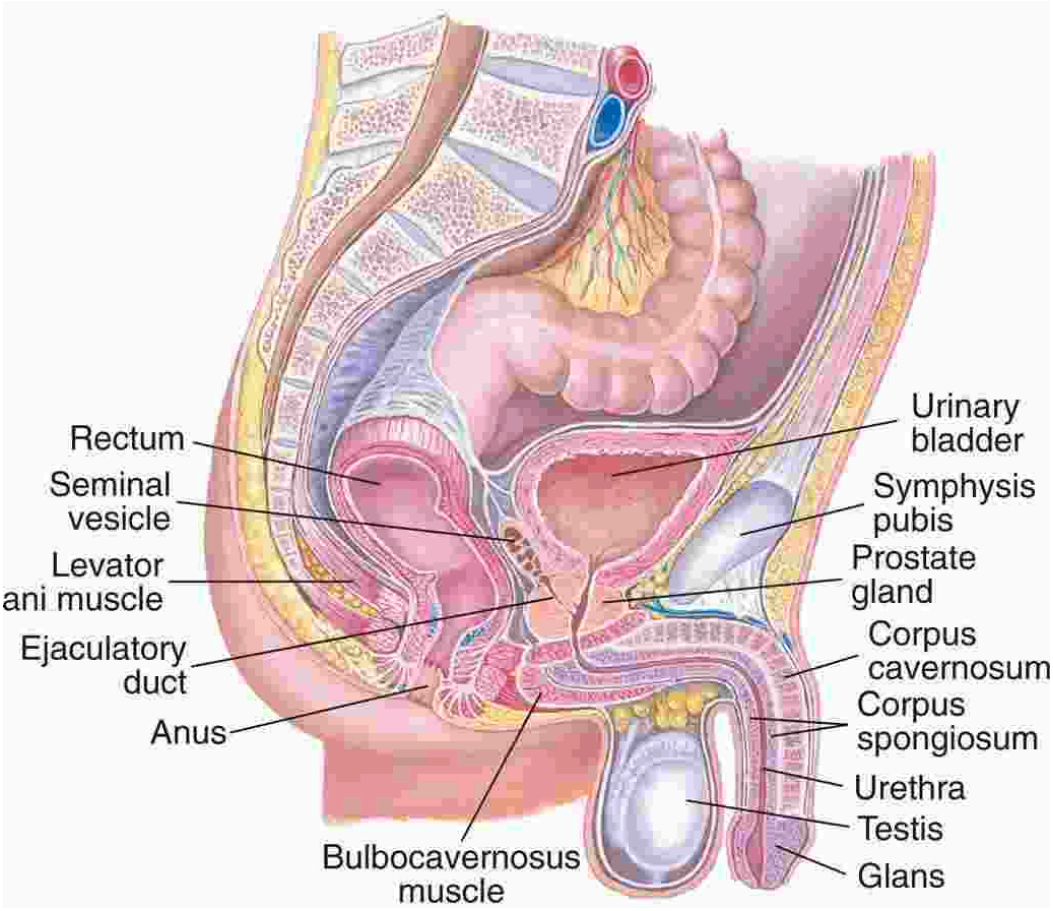

FIG. 24.12 Structure of the Male Reproductive Organs. (From Ball JW, et al. *Seidel's guide to physical examination*, 9th edition. St. Louis: Mosby; 2019.)

An illustration of the right lateral view of the male reproductive organs shows and labels the followings structures, clockwise from the top: urinary bladder, symphysis pubis, prostate gland, corpus cavernosum, corpus spongiosum, urethra, testis, glans, bulbocavernosus muscle, anus, ejaculatory duct, levator ani muscle, seminal vesicle, and rectum.

External Genitalia

Testes

The testes (sing., testis) are the essential organs of male reproduction. Like the ovaries, the testes have two functions: (1) production of gametes (i.e., sperm) and (2) production of sex hormones (i.e., androgens and testosterone).

During embryonic and fetal life, the testes develop within the abdomen (see Fig. 24.1). About 3 months before birth, the testes start to descend toward the developing scrotum (Fig. 24.13). About 1 month before birth, they enter twin passageways called inguinal canals. Vaginal processes created by outpouchings of the peritoneum (lining of the abdominal cavity) also descend through the inguinal canals. When descent is complete, the abdominal end of each vaginal process closes, and the scrotal end of each process becomes the outer covering of the testis, the tunica vaginalis. (See Fig. 24.16, A for the inguinal canal in a mature adult.) Failure of the testes to descend through the inguinal canal is known as cryptorchidism.
