
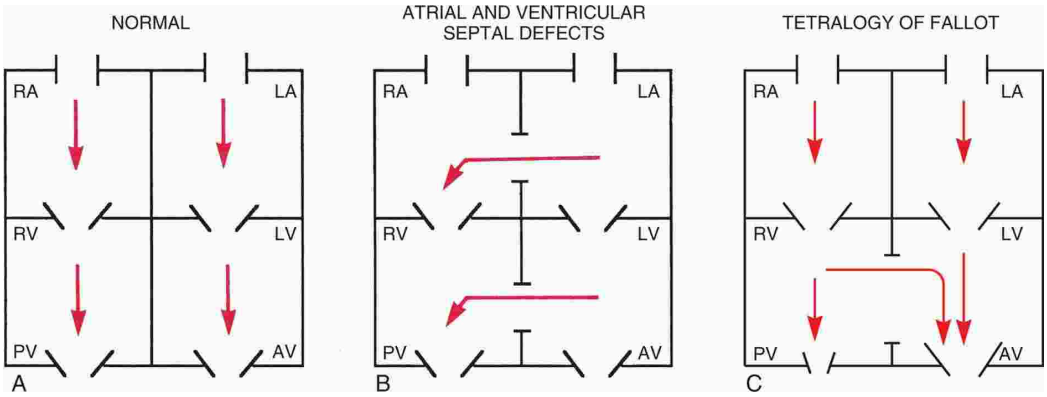

FIG. 33.2 Shunting of Blood in Congenital Heart Disease.
(A) Normal. **(B)** Acyanotic defect. **(C)** Cyanotic defect. *AV*, Aortic valve; *LA*, left atrium; *LV*, left ventricle; *PV*, pulmonic valve; *RA*, right atrium; *RV*, right ventricle. (From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2016.)

Three diagrams A, B, and C depict the clinical and physiological sequelae of the type of congenital heart defect based on its category. Illustration A depicts a normal defect which shows the movement of blood through the right side of the heart and into the pulmonary system is separate from the blood flow through the left side of the heart into the systemic circulation. Illustration B depicts atrial and ventricular septal defects which shows the shunting of blood flow that occurs from the left heart into the right heart. Illustration C depicts the tetralogy of fallot which shows the shunting of blood occurs from

the right side of the heart directly into the left side of the heart.

Shunting of blood flow from the left heart into the right heart is called a **left-to-right shunt** and occurs in conditions such as atrial septal defect (ASD) and ventricular septal defect (VSD) (see Fig. 33.2B). This type of shunt occurs because the pressure is higher on the left side of the heart than it is in the right side of the heart. A left-to-right shunt increases the volume in the right side of the heart and results in increased blood flow into the pulmonary circulation. Depending on the degree of shunting, this increase in pulmonary blood flow may cause affected children to develop symptoms of heart failure. Because blood continues to flow through the lungs before passing into the systemic circulation, there is no decrease in tissue oxygenation or cyanosis. Thus, defects that cause left-to-right shunt are termed **acyanotic heart defects**. There are other types of acyanotic heart defects where blood flow is obstructed as it leaves the ventricles, but there is no hole or defect to cause shunting. These lesions can result from partial or complete obstructions in either the right side of the heart, the left side of the heart, or both.

Cyanotic heart defects frequently cause shunting of blood from the right side of the heart directly into the left side of the heart (**right-to-left shunt**). A right-to-left shunt decreases blood flow through the pulmonary system, causing less-than-normal oxygen delivery to the tissues and resulting in a bluish discoloration of the skin called **cyanosis** (see Chapter 35). Tetralogy of Fallot is the most common cyanotic heart defect.[3] In this condition, narrowing of the pulmonary outflow tract increases right heart pressures, thus forcing blood through a defect in the ventricular septum into the left heart (see Fig. 33.2C). Other types of heart defects result in cyanosis due to the mixing of venous and arterial blood that enters the systemic circulation.

Most congenital heart defects are named to describe the underlying defect (e.g., valvular abnormalities, abnormal openings

in the septa, and malformation or abnormal placement of the great vessels). Descriptions of the most common defects follow.

Defects With Increased Pulmonary Blood Flow

Patent Ductus Arteriosus

Patent ductus arteriosus (PDA) is failure of the fetal ductus arteriosus (DA) to close within hours after birth (Fig. 33.3). The most important risk factor for PDA is premature birth. Other risk factors include congenital rubella, perinatal asphyxia, and birth in high altitude places. Genetic risks are associated with inherited syndromes such as 22q11.2 deletion syndrome.[7]

FIG. 33.3 Patent Ductus Arteriosus (PDA). **(A)** PDA with left-to-right shunt. **(B)** PDA *(asterisk)* in an adult with pulmonary hypertension. *Ao*, Aorta; *LPA*, left pulmonary artery; *RPA*, right pulmonary artery; *SCV*, subclavian vein. (A, From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2016. B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Top panel, A. An illustration of the heart shows the patent ductus arteriosus. The flow of blood is traced through the left and right atriums and ventricles. Bottom panel, B. A photo of the superior view of the patent ductus arteriosus identifies the following structures, clockwise from the top: aorta, P D A, left pulmonary artery, right pulmonary artery, and subclavian vein.

Pathophysiology

The DA connects the aorta and pulmonary artery (PA) during fetal development and functions to bypass the lungs, which are still a fluid filled organ in utero. Between 10 and 15 hours after birth, higher oxygen concentrations in the blood cause the DA to undergo muscle contraction and functionally close. Normally by the third week after birth, fibrous proliferation of the intimal layer causes permanent closure of the DA. Premature infants, neonates who suffer asphyxia, and infants born at higher altitudes have lower blood oxygen concentrations and therefore are more susceptible to PDA.

In PDA, the persistent patency of the DA allows blood to flow from the higher pressure aorta to the lower pressure PA, causing the blood to flood the lungs (left-to-right shunt). The amount of shunting determines the clinical manifestations. PDA can be classified into five different types (A-E), dependent on anatomical characteristics of the defect and the associated degree of obstruction. This is important in determining the urgency and type of management.[7]

Clinical Manifestations

Infants may be asymptomatic or show signs of pulmonary distress, such as dyspnea and tachypnea, fatigue, poor feeding or diaphoresis with feeding, and failure to thrive (FTT). There is a characteristic continuous, machinery-like murmur in both systole and diastole, heard best at the left upper sternal border. There can be a thrill to palpation. Aortic flow (run-off) into the lower pressure pulmonary circulation produces low diastolic blood pressure, widened pulse pressure, and bounding pulses. In preterm infants, PDA is associated with an increased risk for bronchopulmonary dysplasia, especially if they require prolonged intubation and mechanical ventilation (see Chapter 36).[8] Children are at risk for bacterial endocarditis and may develop chronic lung disease and pulmonary hypertension in later life from chronic excessive pulmonary blood flow.

Evaluation and Treatment

The diagnosis of PDA is confirmed by echocardiography. Administration of intravenous indomethacin or ibuprofen (nonsteroidal anti-inflammatory drugs [NSAIDs]) has proved successful in closing a PDA in premature infants and some newborns. Surgical closure of the PDA is indicated only when pharmacologic therapy has failed. There is evidence that successful surgical closure in children at about 6 months of age is associated with a decreased risk for the development of chronic lung disease.[9] Closure of the PDA with an occlusion device during cardiac

catheterization is performed in select children older than 6 months of age.[7] Both surgical and transcatheter procedures are considered low risk.[3] Transcatheter closure has also been performed successfully in premature infants, although more studies are needed.[10]

Atrial Septal Defect

Anatrial septal defect (ASD) is an opening in the septal wall between the two atria. This opening allows blood to shunt from the left atrium (LA) to the right atrium (RA) (Fig. 33.4). It is a common form of CHD and carries significant mortality and morbidity if not treated early.

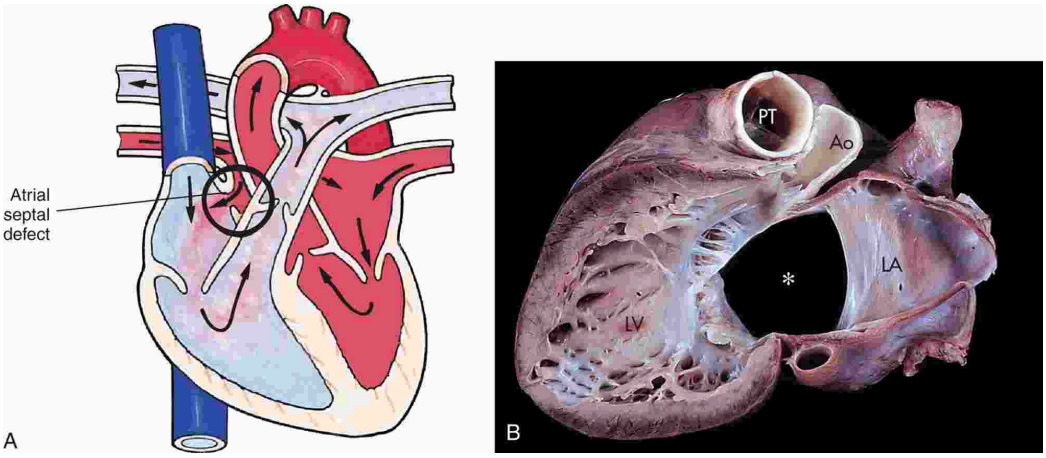

FIG. 33.4 Atrial Septal Defect.
(A) Abnormal opening between the atria causing blood from the higher-pressure left atrium to flow into the lower-pressure right atrium. **(B)** Complete ASD *(asterisk)* form in children. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PT*, pulmonary artery trunk. (A, From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 9th edition. St. Louis: Mosby; 2011. B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Left panel, A. An illustration of the heart shows the atrial septal defect. The flow of blood is traced through the left and right atriums and ventricles. Right panel, B. A photo of the superior view of the atrial septal defect identifies the following structures, clockwise from the top: pulmonary artery trunk, aorta, left atrium, and complete A S D.

Pathophysiology

There are three types of ASDs:

- **Ostium primum atrial septal defect** is an opening low in the atrial septum and may be associated with abnormalities of the mitral valve or atrioventricular canal (AVC).
- **Ostium secundum atrial septal defect** is an opening in the middle of the atrial septum and is the most common type.
- **Sinus venosus atrial septal defect** is an opening usually high in the atrial wall near the junction of the superior vena cava. In rare cases, the sinus venosus ASD opening may be located in the atrial wall near the junction of the inferior vena cava.

Another type of abnormal opening in the atrial septal wall is called a **patent foramen ovale (PFO)**. Like the DA, the **foramen ovale** is part of normal fetal circulation and serves to bypass the pulmonary circulation in utero, usually closing after birth. When the lungs become functional, the pulmonary pressure decreases and the LA pressure exceeds that of the RA. This pressure change forces the septum to functionally close the foramen ovale. If it does not close, PFO results, and shunting from the LA to RA persists. In many types of CHD, the foramen ovale remains open as a component of more complex cardiac defects.[3]

Clinical Manifestations

Infants and children with an ASD are usually asymptomatic. If the ASD is not too large, nearly half will close spontaneously.[11] Infants with a large ASD may develop pulmonary overcirculation. In these infants, excessive pulmonary blood flow from left-to-right shunting causes dyspnea and tachypnea symptoms, commonly referred to as heart failure (HF). A systolic ejection murmur and a widely split-second heart sound (reflecting RV volume overload) are the expected findings on physical examination. Some older children and adults will experience shortness of breath with activity as the RV becomes less compliant with age. About 24% of adults have an asymptomatic PFO that does not require treatment, although clot formation and embolization to the brain may occur (cryptogenic stroke).

Evaluation and Treatment

The diagnosis of ASD is confirmed by echocardiography. Surgical closure requires open heart surgery and involves a pericardial patch or suture closure of the defect. Transcatheter device closure offers a less invasive alternative for children with an ASD that meets anatomic and size criteria.[12] Perioperative complications are common but are usually minor. Arrhythmias or complete heart block may occur.

Ventricular Septal Defect

A **ventricular septal defect (VSD)** is an opening of the septal wall between the ventricles (Fig. 33.5). VSDs are one of the most common types of congenital heart defects and account for 10% to 40% of all CHDs.[13]

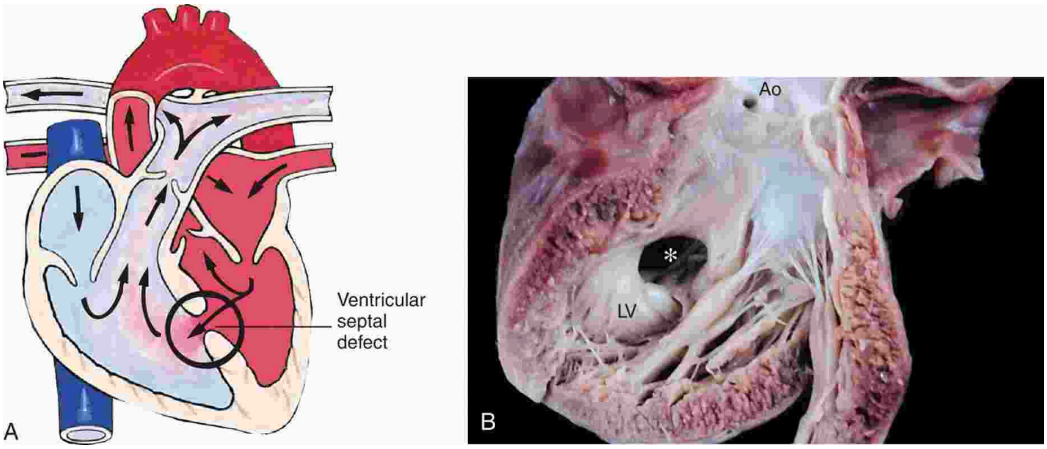

FIG. 33.5 Ventricular Septal Defect (VSD).
(A) VSD with left-to-right shunt. **(B)** Muscular *(asterisk)* defect (opened left ventricle). *Ao*, Aorta; *LV*, left ventricle. (A, From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 9th edition. St. Louis: Mosby; 2011. B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Left panel, A. An illustration of the heart shows the ventricular sepal defect. The flow of blood is traced through the left and right atriums and ventricles. Right panel, B. A photo of the superior view of the ventricular septal defect identifies the following structures, from the top to the bottom: aorta, muscular defect, and left ventricle.

Pathophysiology

VSDs are classified by location. **Perimem-branous ventricular septal defects** are located high in the ventricular septal wall underneath the atrioventricular (AV) valves. **Muscular ventricular septal defects** are located low in the septal wall. VSDs also can be located in the inlet

(AV canal type) or the outlet (also called subpulmonary or supracristal) portion of the ventricle. VSDs are similar to ASDs in that blood will shunt from left to right. The amount of shunting depends on the size of the defect. Depending on the size and location, many VSDs close spontaneously, most often within the first 2 years of life.[3]

Clinical Manifestations

Depending on the size, location, and degree of shunting and pulmonary vascular resistance (PVR), children may have no symptoms, or they may have clinical evidence of excessive pulmonary blood flow. In the infant, excessive pulmonary blood flow from left-to-right shunting causes heart failure (HF), even though the heart muscle functions well with a VSD. In addition to dyspnea and tachypnea, these infants can have poor feeding, diaphoresis with feeding, and FTT. A loud, harsh, holosystolic (pansystolic) murmur and systolic thrill (a palpable tremor) is a classic finding on physical examination.

If the degree of shunting is significant and not corrected, the child is at risk for developing pulmonary hypertension. This condition develops over decades of life in response to the excessive pulmonary blood flow. Irreversible pulmonary hypertension can result in **Eisenmenger syndrome**, in which shunting of blood is reversed because of high pulmonary pressure and resistance; it results in a right-to-left shunt with cyanosis.

Evaluation and Treatment

The diagnosis of VSD is confirmed by echocardiogram and auscultatory findings. Cardiac catheterization may be needed to determine the hemodynamics and, in some instances, the location of other defects. Smaller VSDs require minimal treatment and may close completely or become small enough that surgical closure is not required. If the infant has severe HF or FTT that is unmanageable with medical therapy, early surgical repair is performed. Surgical repair involves open-heart surgery with cardiopulmonary bypass.

The opening is either sutured closed or covered with a patch of pericardium or artificial material. Minimally invasive surgical closure techniques are proving effective and with a low incidence of adverse events.[14] Nonsurgical device closure in the catheterization laboratory is available, but only under restricted conditions, depending on the size and location of the defect.[15]

Atrioventricular Canal Defect

Atrioventricular canal (AVC) defect (atrioventricular septal defect, endocardial cushion defect) is the result of incomplete fusion of endocardial cushions (Fig. 33.6). Endocardial cushions fuse to form the septa that divide the four heart chambers and the mitral and tricuspid valves. When they do not develop properly, several types of AVC defects may occur. AVC is associated with extracardiac defects in about 75% of cases and is a common cardiac defect in children with trisomy 21 (Down syndrome).[16]

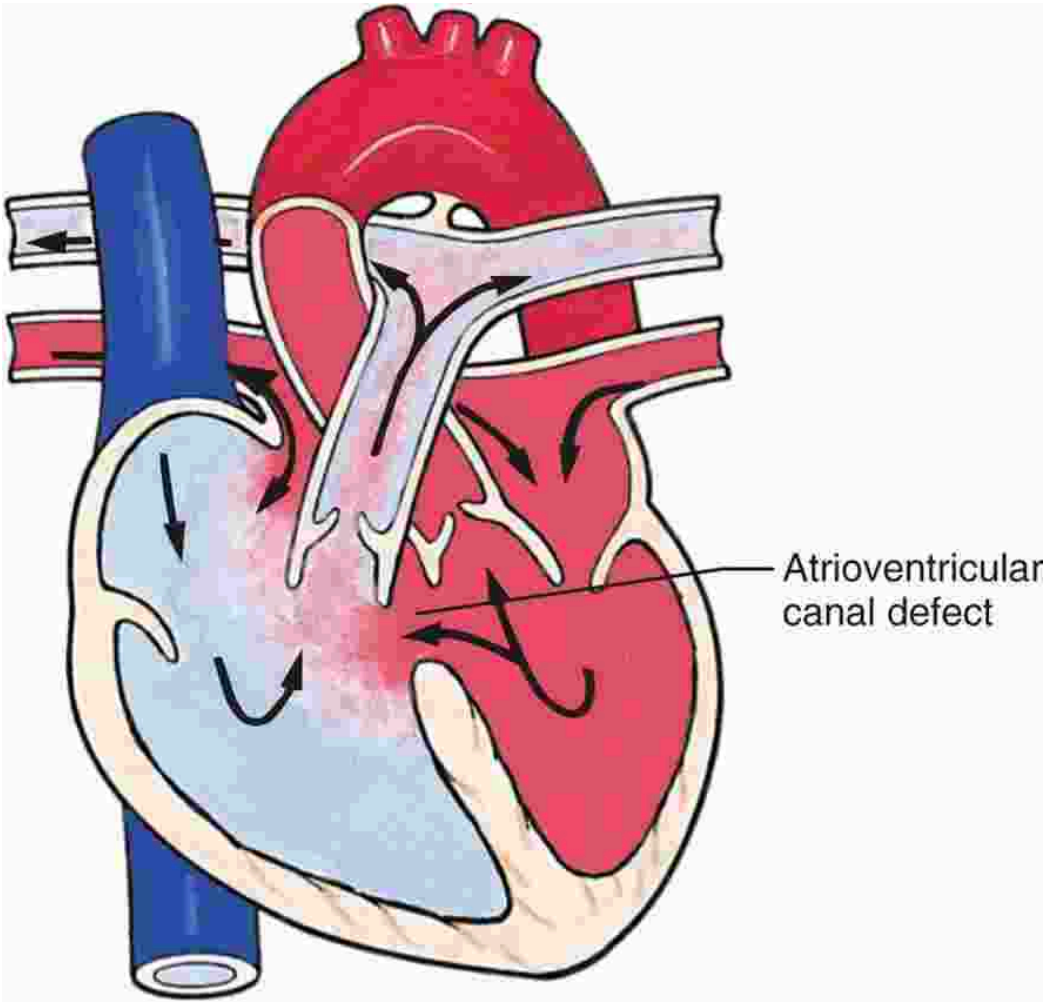

FIG. 33.6 Atrioventricular Canal (AVC) Defect.
(From Hockenberry MJ, Wilson, D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016.)

An illustration of the heart identifies the region of atrioventricular canal defect, between the left and right ventricles. Arrows indicate the flow as follows: from lungs to the ventricles and to the pulmonary artery.

Pathophysiology

Complete AVC (CAVC) defect consists of an ostium primum ASD, an inlet VSD, and a single common five leaflet mitral and tricuspid valve. Partial AVC (PAVC) defect consists of an ostium primum ASD and a cleft in the mitral valve. The direction and pathways of flow are determined by pulmonary and systemic resistance, LV and RV pressures, the type of AVC defect, and the compliance of each chamber. Shunting is generally from left to right.

Clinical Manifestations

Infants and children with PAVC may have minimal symptoms. Infants with CAVC often display moderate to severe HF symptoms attributable to left-to-right shunting and pulmonary overcirculation. These include tachypnea and tachycardia, poor feeding, diaphoresis with feeding, and FTT. Those with a large left-to-right shunt will have a holosystolic murmur. Children with CAVC are at risk for developing irreversible pulmonary hypertension if the condition is left untreated.[3] Children with Down syndrome and CAVC are at a higher risk for developing pulmonary hypertension at a younger age.[17] Therefore, surgical correction of CAVC in these children is recommended by 4 months.[18]

Evaluation and Treatment

AVC is diagnosed with fetal echocardiography. Cardiac catheterization is rarely indicated but may be performed to evaluate the reversibility of pulmonary vascular disease. Initial treatment goals include aggressive medical management of HF and nutritional supplementation. Infants are followed closely for signs or symptoms of FTT. Complete surgical repair is indicated in most cases and typically is performed between 3 and 6 months of age to prevent irreversible pulmonary hypertension. This procedure consists of patch closure of the septal defects and reconstruction of the AV valve tissue (either repair of the mitral valve cleft or fashioning of two AV valves). Postoperative complications include heart block, dysrhythmias, mitral regurgitation and/or stenosis, or left

ventricular outflow tract obstruction (LVOTO) requiring further surgical intervention or valve replacement.

Obstructive Defects

Coarctation of the Aorta

Coarctation of the aorta (COA) is an abnormal localized narrowing of the aorta just proximal to the insertion of the ductus arteriosus (Fig. 33.7). It is one of the most common types of CHD and commonly occurs along with other congenital valvular or septal defects.[19]

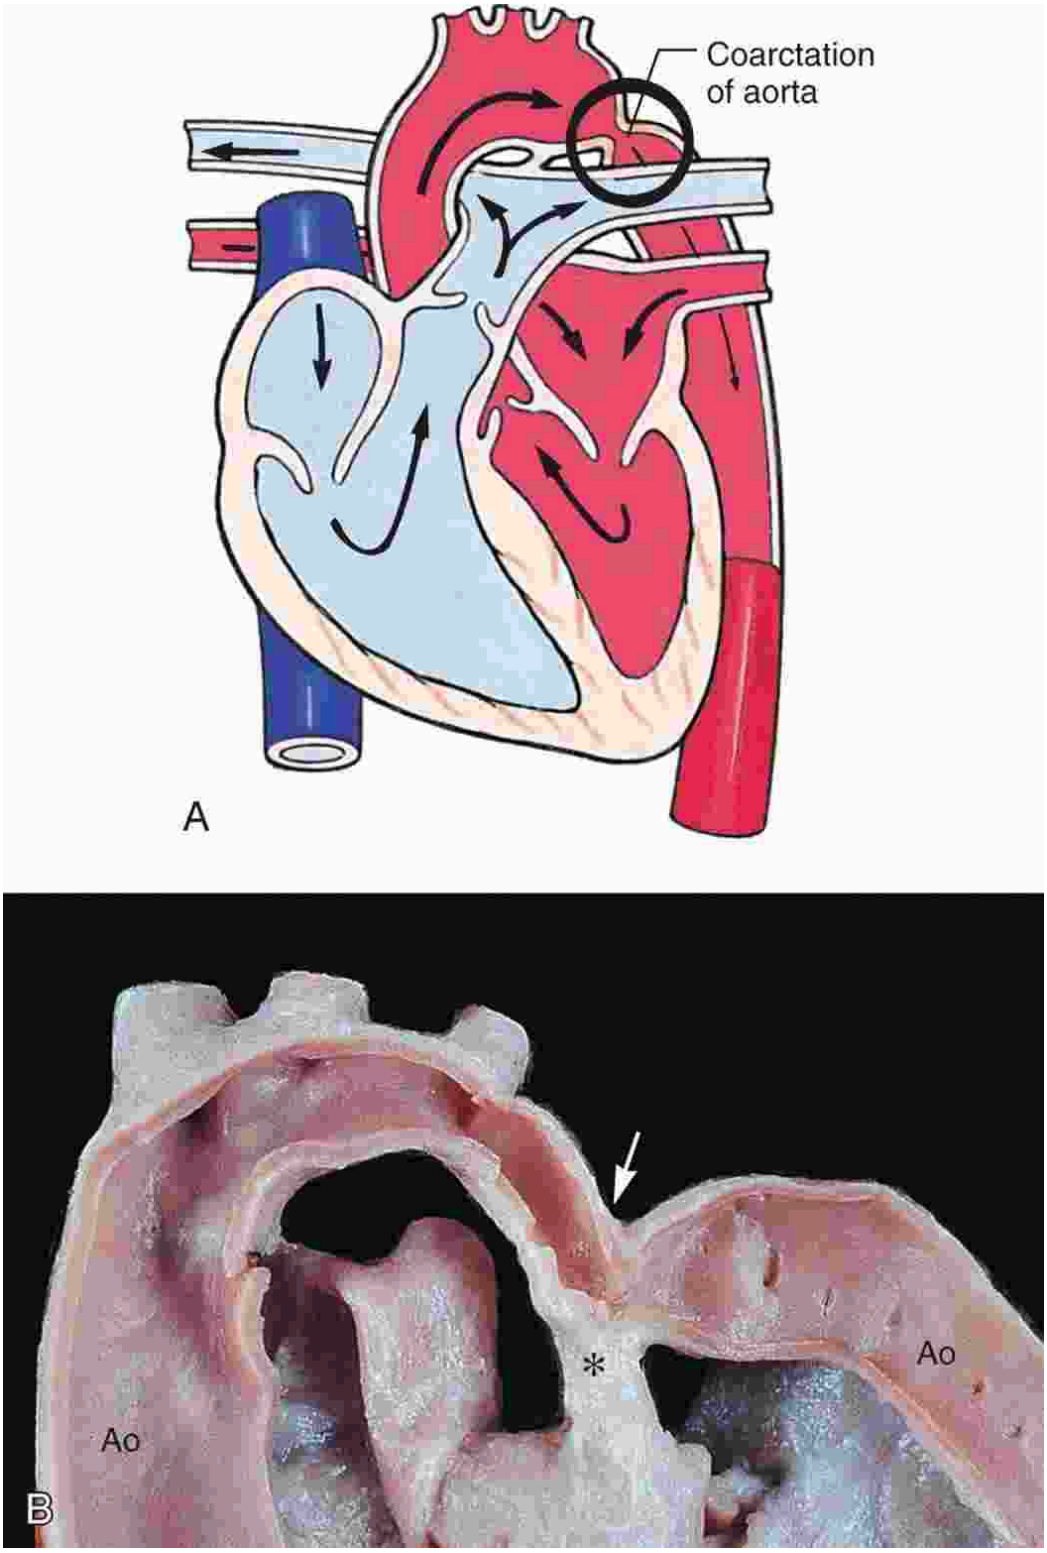

FIG. 33.7 Postductal and Preductal Coarctation of the Aorta (COA).
(A) Postductal coarctation occurs distal to

("after") the insertion of the closed ductus arteriosus into the aortic arch. Preductal coarctation occurs proximal to ("before") the insertion of the patent ductus arteriosus. The coarctation consists of a flap of tissue that protrudes from the tunica media of the aortic wall. **(B)** Coarctation of the aorta with typical indentation of the aortic wall *(arrow)* opposite the ductal arterial ligament *(asterisk)*. *Ao*, Aorta. (A, From Hockenberry MJ, Wilson, D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016. B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Top panel, A. An illustration of the heart identifies the region of coarctation of aorta at the top right. Bottom panel, B. A closeup of the cross-section of aorta shows an arrow pointing at the inward protrusion of the aortic wall.

Pathophysiology

Before birth, the ductus arteriosus bypasses the obstruction caused by COA and allows for blood to flow from the PA into the distal aorta. However, once the ductus functionally closes within hours after birth, blood flow is restricted by the coarctation, preventing adequate perfusion of the systemic circulation including the lower extremities and organs. The left ventricle experiences increased resistance to systolic ejection (afterload) and undergoes hypertrophy that may lead to eventual heart failure. Clinically, there is increased blood pressure proximal to the defect (head and upper extremities, right greater than left) and decreased blood pressure distal to the obstruction (torso and lower extremities). If the COA goes

undiagnosed, the child will develop collateral circulation in order to bypass the obstruction. These are small vessels arising from the subclavian arteries that join the intercostal arteries and flow into the descending aorta. Because of this, some cases of coarctation are not diagnosed until school age, adolescence, or adulthood and result in hypertension.

Clinical Manifestations

The location and severity of the COA determine whether an infant will become symptomatic after the ductus arteriosus closes. If the COA is severe, infants will present with low cardiac output, poor tissue perfusion, acidosis, and hypotension. Physical examination of the infant will reveal weak or absent femoral pulses. Some infants with COA will remain asymptomatic after the closure of the ductus arteriosus and will present later in childhood with unexplained upper extremity hypertension. Although rare, they also may experience dizziness, headaches, fainting, or epistaxis from hypertension. Children may complain of leg pain or cramping with exercise. Physical examination and measurement of upper and lower extremity blood pressures will often suggest the diagnosis. Children with COA have decreased or absent pulses in the lower extremities and a delay between the brachial and femoral pulses. In addition, they may have a systolic ejection murmur at the left interscapular area caused by turbulent blood flow through the narrowed portion of the aorta.

Evaluation and Treatment

Echocardiography is used to confirm the diagnosis. Magnetic resonance imaging (MRI) and computed tomography (CT) are used for surgical planning. In children with severe COA and shock, immediate initiation of continuous intravenous infusion of prostaglandin E_1 is imperative to maintain patency of the ductus arteriosus. These infants may require mechanical ventilation and vasoactive support pre-operatively. Once the symptomatic newborn is stabilized, emergent surgical correction is indicated. In an older

child who has developed collateral circulation, symptoms of cardiogenic shock or end-organ dysfunction are absent and prostaglandin is not indicated. Surgical timing is urgent but not emergent.

Surgical correction consists of either resection of the narrowed portion of the aorta with an end-to-end anastomosis (a surgical connection between vessels), aortic arch augmentation, or enlargement of the constricted section using a portion of the left subclavian artery (commonly named the "subclavian flap"). Because this defect is outside the heart and pericardium, cardiopulmonary bypass is usually not required, and the operation is performed via a thoracotomy incision. However, COA repair may be part of a more complex operation, which would require a sternotomy incision and cardiopulmonary bypass. Postoperative hypertension is treated with an intravenous, short-acting β-blocker, followed by oral medications, such as an angiotensin-converting enzyme (ACE) inhibitor. Residual hypertension after the repair of COA seems to be related to increased age prior to repair; therefore, surgical intervention is recommended at the time of diagnosis.

Percutaneous balloon angioplasty to dilate the aorta, with or without stent implantation, may be a less invasive option for treating COA in selected individuals (infants older than 6 months of age) or for reducing residual postoperative COA. However, aortic aneurysm formation and blood vessel injury from arterial access can be complications of the procedure and may require surgical correction.[19]

Aortic Stenosis

Aortic stenosis (AS) is a narrowing or stricture of the outlet of the LV, causing resistance of blood flow from the LV into the aorta (Fig. 33.8). It commonly is the result of a bicuspid aortic valve. AS is a common form of congenital heart disease found in approximately 0.5% to 0.8% of the population.[20]

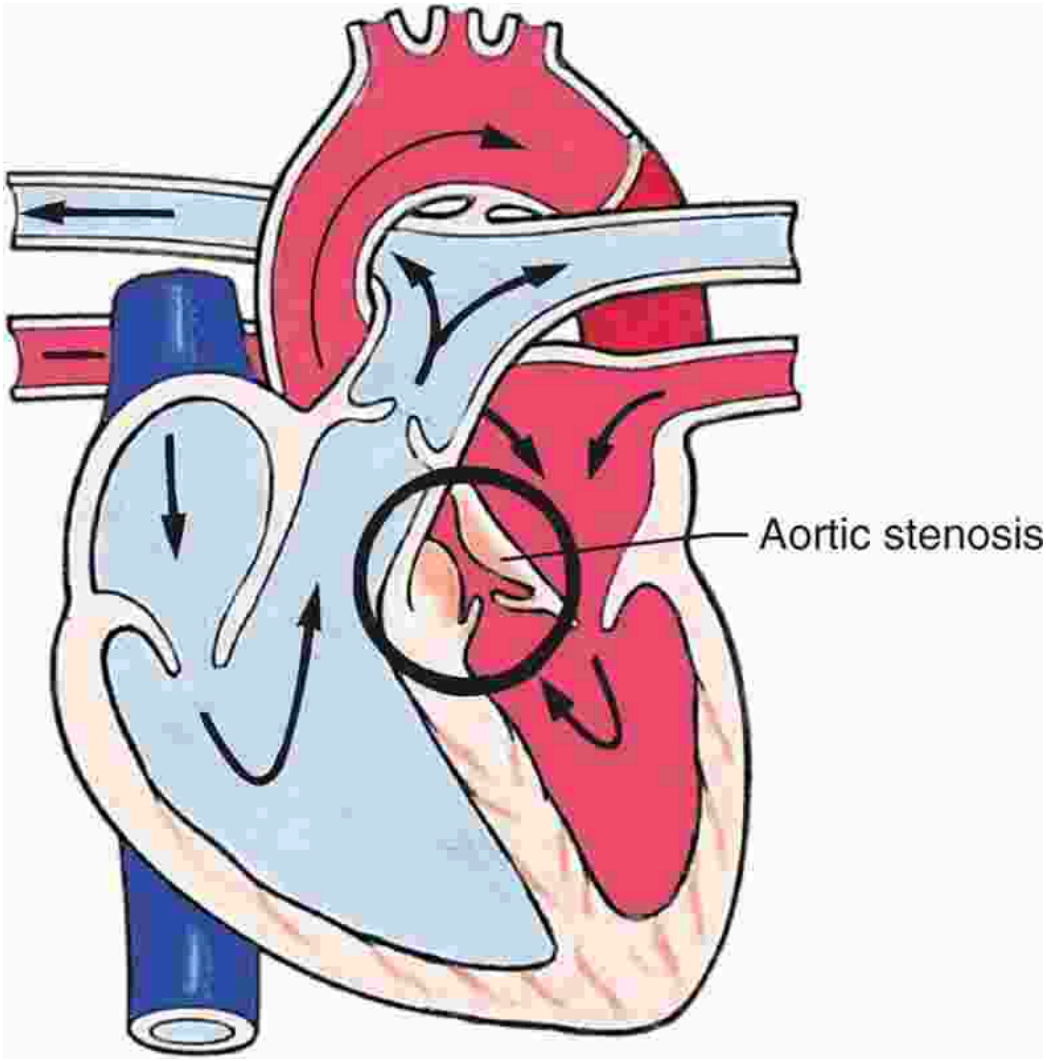

FIG. 33.8 Aortic Stenosis (AS).
Narrowing of the aortic valve causes resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary congestion. (From Hockenberry MJ, Wilson, D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016.)

An illustration of the heart identifies the region of aortic stenosis between the left and right atriums. Aortic stenosis is present in the aortic valve. Arrows

indicate the flow from the lungs to the ventricles and through the pulmonary artery.

Pathophysiology

The pathophysiologic consequence of severe AS is hypertrophy of the LV wall, which eventually leads to increased LV end-diastolic pressure. Pressure backs up from the LV into the LA, causing pulmonary hypertension and pulmonary edema. If severe, there may be decreased cardiac output and poor perfusion of the systemic arterial circulation. Left ventricular hypertrophy impedes coronary artery perfusion and may result in myocardial ischemia and associated papillary muscle dysfunction leading to mitral insufficiency.

There are three types of AS:

- **Valvular aortic stenosis** occurs because of malformed or fused cusps, resulting in a unicuspid or bicuspid valve. Valvular AS is a serious defect because the obstruction tends to be progressive. There may be sudden episodes of myocardial ischemia or low cardiac output that result in sudden death in late childhood or adolescence.
- **Subvalvular aortic stenosis** is a stricture caused by a fibrous ring below a normal valve or by a narrowed LV outflow tract in combination with a small aortic valve annulus (diameter at the base of the aortic root).
- **Supravalvular aortic stenosis**, a narrowing of the aorta just above the valve, occurs infrequently. It can occur as a single defect or as a part of Williams-Beuren syndrome, which also is characterized by an unusual elfin facial appearance and intellectual disability.[21]

Clinical Manifestations

Infants with severe AS demonstrate signs of decreased cardiac output, with faint pulses, hypotension, tachycardia, and poor feeding. These infants may progress to cardiogenic shock and evidence of end-organ hypoperfusion. A loud, harsh systolic ejection murmur is expected. In valvular AS, there may be an audible click during LV ejection as the stenosed valve partially opens. Many children with mild or moderate AS do not have symptoms. Older children may have complaints of epigastric pain and exercise intolerance. In rare cases, exertional chest pain, syncope, or sudden death may occur.

Evaluation and Treatment

A diagnosis of AS is confirmed by echocardiography. Treatment for subvalvular AS and supravalvular AS usually involves surgical excision of the area causing the constriction. Management of valvular AS depends on its severity. Mild to moderate valvular AS does not usually require intervention or restriction of activity, whereas more severe AS requires restriction of strenuous physical activity until correction of the stenosis is accomplished. The treatment of severe valvular AS varies. Dilation of the stenotic valve with balloon valvuloplasty is performed in the cardiac catheterization laboratory. This procedure avoids initial surgical intervention, but more than one-third of cases will require surgery for valve replacement within the next 6 years.[22] Surgical treatment for valvular AS depends on the severity of the stenosis, previous interventions, and the age of the child. Aortic valve commissurotomy (incision at the edges of the commissure, or joining point) or valvotomy may be used as an early intervention.[23] Both balloon valvuloplasty and valvotomy may result in significant aortic regurgitation (insufficiency) requiring valve replacement.[24] Aortic valve replacement may be done using a Ross procedure. This procedure involves replacing the aortic valve with the child's own pulmonary valve, then replacing the pulmonary valve with a cadaver allograft.[25] Mechanical valve replacement may be required if the valve is severely abnormal. If possible, mechanical valve

replacement is usually deferred to minimize the number of valve replacements over a child's life related to growth. Aortic stenosis requires lifelong evaluation and treatment. Multiple surgical or catheterization interventions are expected.[3]

Pulmonic Stenosis

Pulmonic stenosis (PS) is a narrowing or stricture of the pulmonary valve that causes resistance to blood flow from the RV into the PA (Fig. 33.9). It is commonly associated with other congenital cardiac defects.

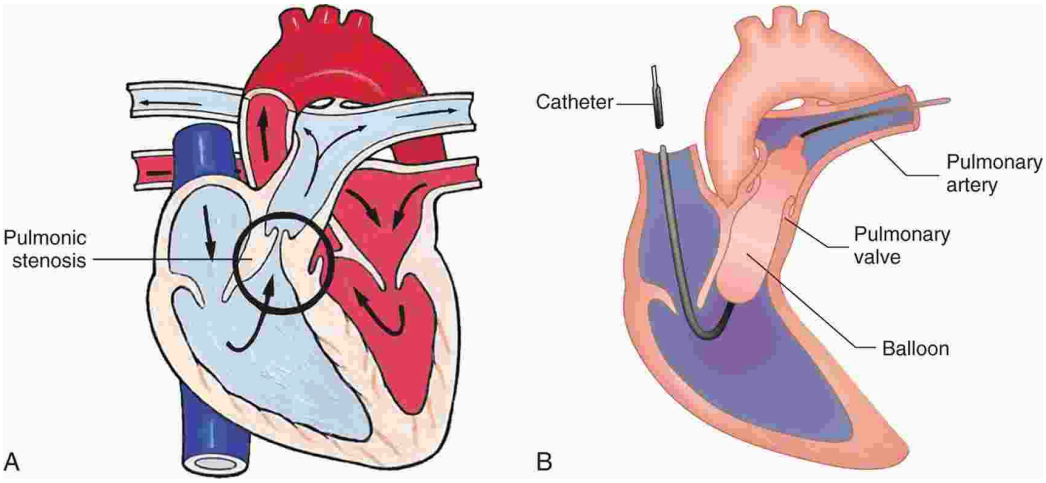

FIG. 33.9 Pulmonic Stenosis (PS).
(A) The pulmonary valve narrows at the entrance of the pulmonary artery. **(B)** Balloon angioplasty is used to dilate the valve. A catheter is inserted across the stenotic pulmonic valve into the pulmonary artery, and a balloon at the end of the catheter is inflated while it is positioned across the narrowed valve opening. (A, From Hockenberry MJ, Wilson, D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016.)

Left panel, A. An illustration of the heart identifies the region of pulmonic stenosis to the right of the right atrium. Pulmonic stenosis is present in the pulmonary valve. Arrows indicate the flow from the lungs to the ventricles and through the pulmonary artery. Right panel, B. An illustration of the right atrium and ventricle of the heart.

Pathophysiology

Similar to AS, the PS can be valvular, subvalvular, or supravalvular. In PS, the narrowed valve orifice increases the RV afterload and the

RV myocardium hypertrophies. If the obstruction is severe, pressure may back up into the RA, causing atrial dilation. If there is a PFO or ASD, a right-to-left shunt may develop (cyanotic heart defect). **Pulmonary atresia** is an extreme form of PS, with total fusion of the valve leaflets (blood cannot flow to the lungs). Pulmonary atresia is usually associated with a hypoplastic RV and, sometimes, a VSD. In infants with severe pulmonary stenosis or pulmonary atresia without PFO or VSD, pulmonary blood flow and therefore oxygenation is dependent upon a PDA.[26]

Clinical Manifestations

Most infants are asymptomatic if the PS is mild to moderate. Newborns with severe PS or pulmonary atresia will be cyanotic (from a right-to-left shunt through an ASD) and may have signs of decreased cardiac output. A harsh systolic murmur, ejection click, and a thrill at the upper left sternal border is expected with PS.

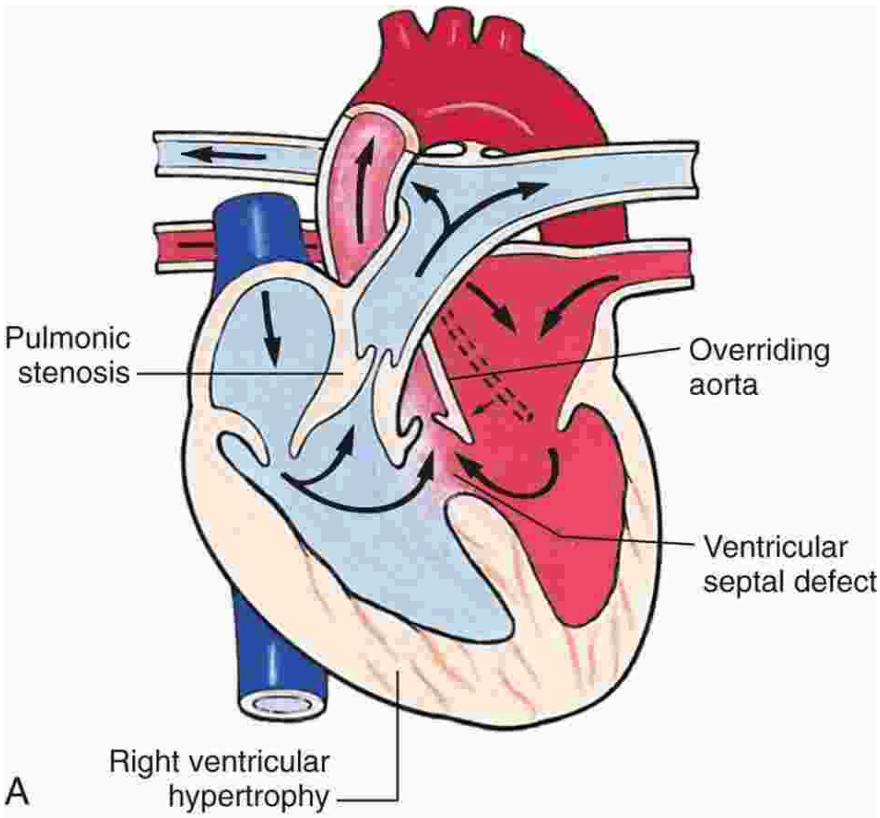
Evaluation and Treatment

Echocardiography confirms the diagnosis and determines the severity of the PS. Mild PS is usually not progressive and often does not require intervention. Critical PS must be addressed immediately. Infants with severe PS or pulmonary atresia require continuous intravenous infusion of prostaglandin E_1 to keep the DA open and to maintain pulmonary blood flow and oxygenation. The treatment of choice for infants with moderate to severe PS is balloon angioplasty (see Fig. 33.9B).[27] This procedure is considered highly effective in reducing the pressure gradient across the pulmonic valve. In rare cases, surgical valvotomy may be required. Both valvotomy and balloon angioplasty may result in pulmonary valve incompetence, and long-term follow-up may reveal the need for pulmonary valve replacement. Treatment for pulmonary atresia depends on the size of the pulmonary arteries, the size of the right ventricle, and whether there are associated cardiac defects. Initial treatment may consist of an aortopulmonary shunt to supply stable blood flow to the lungs and, later, a second procedure to connect the RV to the PA.

Defects With Decreased Pulmonary Blood Flow

Tetralogy of Fallot

Tetralogy of Fallot (TOF) occurs in 5% to 10% of all CHD and is the most common cyanotic heart defect. The classic form of TOF consists of four defects: (1) a large VSD, (2) PS, (3) an overriding aorta that straddles the VSD, and (4) RV hypertrophy (Fig. 33.10).



Pulmonic stenosis

(A, From Hockenberry MJ, Wilson, D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016. B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Top panel, A. An illustration of the heart identifies the overriding aorta, the ventricular septal defect, the right ventricular hypertrophy, and the pulmonic stenosis. Arrows depicting the flow of blood from atrium to ventricle and later through overriding aorta. Bottom panel, B. A closeup of the heart shows right ventricle, the left ventricle, the aorta (highlighted by an arrow), and the pulmonary trunk.

Pathophysiology

The pathophysiology associated with TOF varies widely, depending primarily on the degree of PS, the size of the VSD, and the pulmonary and systemic resistance to flow. In cases with a large VSD, pressures are equal in the RV and LV. Therefore, the major determinant of shunt direction through the VSD is the difference between pulmonary vascular resistance and systemic vascular resistance. If systemic resistance is more than pulmonary resistance, the shunt is from left to right (acyanotic; known as "pink tets"). If resistance to pulmonary flow is greater than systemic resistance, the shunt is from right to left, causing decreased pulmonary blood flow, decreased oxygen in the blood, and cyanosis. Physiologic

compensation for low oxygen saturation (hypoxemia) in the systemic circulation is the production of more red blood cells (polycythemia), the development of collateral bronchial vessels, and enlargement of the nail beds (clubbing).

Clinical Manifestations

Some infants may be acutely cyanotic at birth. In others, the progression of hypoxia and cyanosis may be more gradual over the first year of life as the pulmonary stenosis worsens. The typical heart murmur of TOF is a pulmonary systolic ejection murmur caused by the obstruction in the outflow tract of the RV, which creates turbulence during systole. The enlarged RV may cause the left side of the chest to be more prominent, and a "heave" also may be palpated. Acute episodes of cyanosis and hypoxia can occur, called *hypercyanotic spells* or *"tet" spells*. Hypercyanotic spells (increased right-to-left shunt) may occur during crying, exertion, or after feeding.

Evaluation and Treatment

The diagnosis is confirmed with echocardiography. Additionally, chest radiograph shows the heart to be shaped like a boot (upturned apex because of small PA). Diagnostic cardiac catheterization is rarely indicated, except to define unusual coronary artery anatomy crossing the RV outflow tract that may complicate surgical palliation.

Management of hypercyanotic spells is aimed at decreasing the pulmonary vascular resistance and increasing the systemic vascular resistance to help promote left-to-right shunting. Therefore, placing the infant in a knee-chest position and administering oxygen and morphine sulfate are most commonly used to treat hypercyanotic spells. Older children with unrepaired TOF will use squatting to help with cyanosis because it increases peripheral vascular resistance (e.g., the knee-chest position). If prolonged or frequent, these spells are an indication for prompt evaluation and surgical treatment.

Elective pulmonary balloon valvuloplasty performed before 6 months of age in those with acyanotic TOF can delay surgical repair.[28] Indications for earlier surgical repair include increasing cyanosis or the development of hypercyanotic spells. Complete repair involves closure of the VSD, resection of the infundibular stenosis, and application of a pericardial patch to enlarge the RV outflow tract that can extend across the PV annulus (transannular patch). This repair may be done by full primary repair, which is associated with fewer reinterventions, or by staged repair, which is associated with less early mortality and morbidity.[29] Despite the greater risk for surgical mortality, early complete surgical repair is associated with survival rates to age 5 as high as 92%.[30] In a staged approach, the first stage is the placement of a palliative shunt from the subclavian or innominate artery to the PA, known as the *modified Blalock-Taussig* (using a prosthetic graft) or *classic Blalock-Taussig* (using the native subclavian artery) in order to increase pulmonary blood flow. This is done within the first few days of life and is followed at 2 to 6 months of age by the next surgical phase to achieve complete repair. Depending on the size of the pulmonary outflow tract, transcatheter pulmonary valve replacement can be a less invasive treatment for severe pulmonary insufficiency in selected individuals, and transcatheter techniques for total repair are being studied.[31] Children with tetralogy of Fallot remain at risk for lethal cardiac arrhythmias and right ventricular dysfunction even decades after the initial repair; therefore, continued monitoring of these individuals is indicated.[32]

Tricuspid Atresia

Tricuspid atresia is failure of the tricuspid valve to develop; consequently, there is no communication from the RA to the RV (Fig. 33.11). It accounts for approximately 1% of all new cases of CHD, and incidence is similar in both males and females. Risk factors for tricuspid atresia include trisomy 21, poorly controlled diabetes and excess alcohol consumption during pregnancy, and a family history of CHD.[33] Tricuspid atresia is associated with other defects

including septal defects, hypoplastic or absent RV, enlarged MV and LV, and/or varying degrees of pulmonic stenosis.

FIG. 33.11 Tricuspid Atresia.
(A) Tricuspid atresia hemodynamics. **(B)** Small right ventricle *(RV)* slit of ventricular septal defect; left ventricle *(LV)* is enlarged. *LA*, Left atrium; *RA*, right atrium. (A, From Hockenberry MJ, *Wilson D. Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016. B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Top panel, A. An illustration of the heart identifies the region of tricuspid atresia, between the right atrium and the right ventricle. Arrows indicate flow from the lung to the ventricles and through the pulmonary artery. Bottom panel, B. A closeup of the cross-section of the heart with tricuspid atresia highlights the region between the right atrium and the right ventricle.

Pathophysiology

In tricuspid atresia, deoxygenated blood returning to the RA flows through an ASD or a PFO to the LA. From there, the blood enters the LV and either goes into the systemic circulation through the aorta or through a VSD into the hypoplastic RV and into the lungs.[33] There is mixing of deoxygenated and oxygenated blood in the left side of the heart, resulting in systemic hypoxemia and mild cyanosis. Depending on the degree of PS and the size of the RV, a PDA is necessary to ensure blood flow into the pulmonary circulation. A PFO is required to maintain cardiac output due to lack of communication between the RA and RV.

Clinical Manifestations

Approximately half of affected children with tricuspid atresia will present with symptoms within the first day of life, and 80% by 1 month of age.[33] A murmur and cyanosis often are present in the newborn period. Tachycardia, dyspnea, fatigue, and poor feeding may be noted with excessive pulmonary blood flow and the development of HF. Older children may have signs of chronic hypoxemia with polycythemia and clubbing. Depending on the other defects associated with tricuspid atresia, the abnormal heart sounds heard on auscultation will have several components. The VSD causes a systolic regurgitant murmur which will be softer and shorter as the VSD enlarges. The second heart sound may be narrowly split due to decreased pulmonary blood, or only a single heart sound heard if PS or pulmonary atresia is present.

Evaluation and Treatment

Echocardiogram confirms the diagnosis of tricuspid atresia and may reveal the presence of associated defects. Pulse oximetry reveals hypoxemia. The neonate with PDA is treated with a continuous infusion of prostaglandin E_1 to maintain adequate pulmonary blood flow.[33] If the ASD is restrictive, a balloon atrial septostomy (creation of a hole between the atria) is performed during cardiac catheterization or under echocardiographic guidance at the bedside. Treatment is accomplished in staged procedures. First, the newborn gets a modified Blalock-Taussig shunt (subclavian or innominate artery to the PA) to supply blood flow to the lungs. Conversely, if the child is experiencing increased pulmonary blood flow, a PA band may be required.[33] Further surgery occurs between 4 to 8 months of age using the bidirectional Glenn shunt, in which the superior vena cava is anastomosed to the PA, the PA is tied off, and the shunt or PA band from the first procedure is removed. Finally, at 2 to 4 years of age, the pulmonary circulation is fully separated from the systemic circulation via a Fontan procedure, which is the routing of the inferior vena cava blood flow to the PA through a grafted or artificial tube called a conduit. Postoperative complications that prolong a

hospital stay include pleural effusions, elevated pulmonary vascular resistance, and ventricular dysfunction. Exercise tolerance is limited in many children, and careful monitoring is needed throughout childhood.[34]

Mixing Defects

Transposition of the Great Arteries

In **dextro-transposition of the great arteries** (dTGA), the great vessels arise from the incorrect ventricles: the PA leaves the LV and the aorta exits the RV (Fig. 33.12). This is called ventriculoarterial discordance. dTGA is a cyanotic heart defect that accounts for 5% to 7% of all CHD.[35]

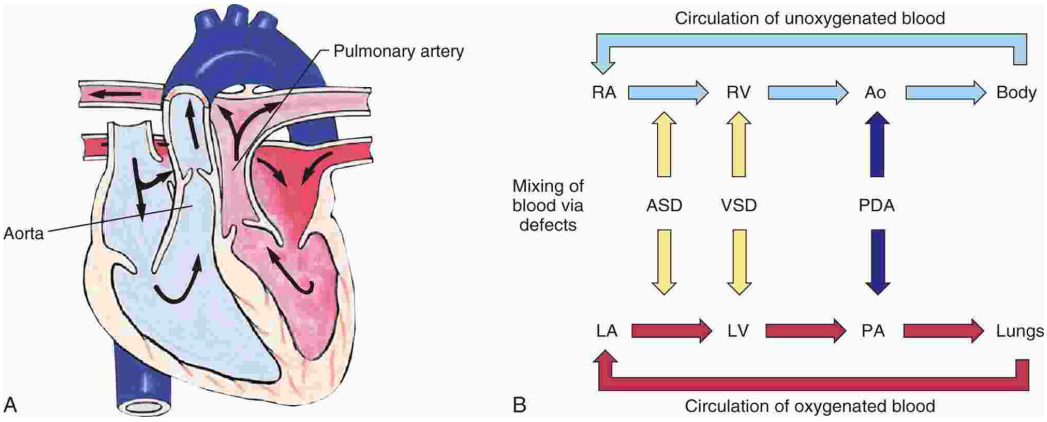

FIG. 33.12 Hemodynamics in Dextro-Transposition of the Great Arteries (dTGA). **(A)** Complete transposition of the great arteries with an intact interventricular septum. The aorta arises from the right ventricle and the pulmonary artery from the left ventricle. **(B)** Oxygen saturation in the separate, parallel circuits with transposition of the great vessels (TGV). Mixing of blood occurs only with the defects associated with TGV. *Ao*, Aorta; *ASD*, atrial septal defect; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *PDA*, patent ductus arteriosus; *RA*, right atrium; *RV*, right ventricle; *VSD*, ventricular septal defect. (A, From Hockenberry MJ, Wilson D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016.)

Left panel, A. An illustration of the heart identifies the aorta (on the right) and the pulmonary artery (on the left). Right panel, B. A flow diagram represents the circulation of oxygenated and unoxygenated blood. • Circulation of unoxygenated blood: right atrium to right ventricle to aorta to body to right atrium. • Circulation of oxygenated blood: left

atrium to left ventricle to pulmonary artery to lungs.
• Mixing of blood via defects: between circulation of oxygenated and unoxygenated blood through atrial septal defect, ventricular septal defect, and patent ductus arteriosus.

Pathophysiology

Because of the transposition of the PA onto the LV and the aorta onto the RV, there are two separate, parallel circuits in which deoxygenated blood circulates continuously through the systemic circulation and oxygenated blood circulates repeatedly through the pulmonary circulation. Associated defects, such as ASD, VSD, or PDA, permit mixing of saturated and desaturated blood, which is necessary to survive after birth and helps maintain adequate tissue oxygenation for a limited time.[36]

Clinical Manifestations

The degree of mixing permitted by the associated defects determines the type and severity of clinical manifestations. Children with limited communication between cardiac chambers are severely cyanotic, acidotic, and critically ill at birth. Those with large septal defects or a PDA may be less cyanotic but will develop heart failure if left untreated. Classically, no murmur is heard unless there is an associated VSD.[3]

Evaluation and Treatment

On chest radiograph, the heart has a characteristic shape, like an "egg on a string," with increased pulmonary vascular markings. Typically, the diagnosis is suspected from the physical examination and chest radiograph findings before confirming with echocardiography. Administration of intravenous prostaglandin E_1 to maintain the patency of the PDA is needed to increase oxygen

delivery until the presence and size of associated defects can be determined. Enlargement of the PFO by balloon atrial septostomy may be performed during cardiac catheterization or under echocardiographic guidance at the bedside to increase mixing at the atrial level if a VSD is not present.

The preferred type of surgical repair for dTGA performed in the first days of life is the *arterial switch operation*, which involves

- transecting the great arteries and anastomosing the main PA to the native proximal aorta (just above the aortic valve) and anastomosing the ascending aorta to the native proximal PA, and,
- moving and reimplanting the coronary arteries with a *button* of tissue onto the new aortic outflow.

Reimplantation of the coronary arteries is critical to survival. The arterial switch procedure reestablishes normal circulation in series, with the LV acting as the systemic pump. Potential complications of the arterial switch include narrowing at the great artery surgical anastomosis sites, aortic valve regurgitation, or coronary artery insufficiency resulting in myocardial ischemia. Long-term results for the arterial switch operation are usually good, with overall long-term survival as high as 80%.[37] However, persistent LV myocardial stiffening and fibrosis can be detected in adolescents and adults.[38] Depending on the anatomy and severity of dTGA, other procedures, such as atrial switch surgery, may be chosen with similar positive outcomes.[39]

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC), or *total anomalous pulmonary venous return (TAPVR)*, is characterized by failure of the pulmonary veins to join the LA during cardiac development (Fig. 33.13). It is a rare form of CHD.

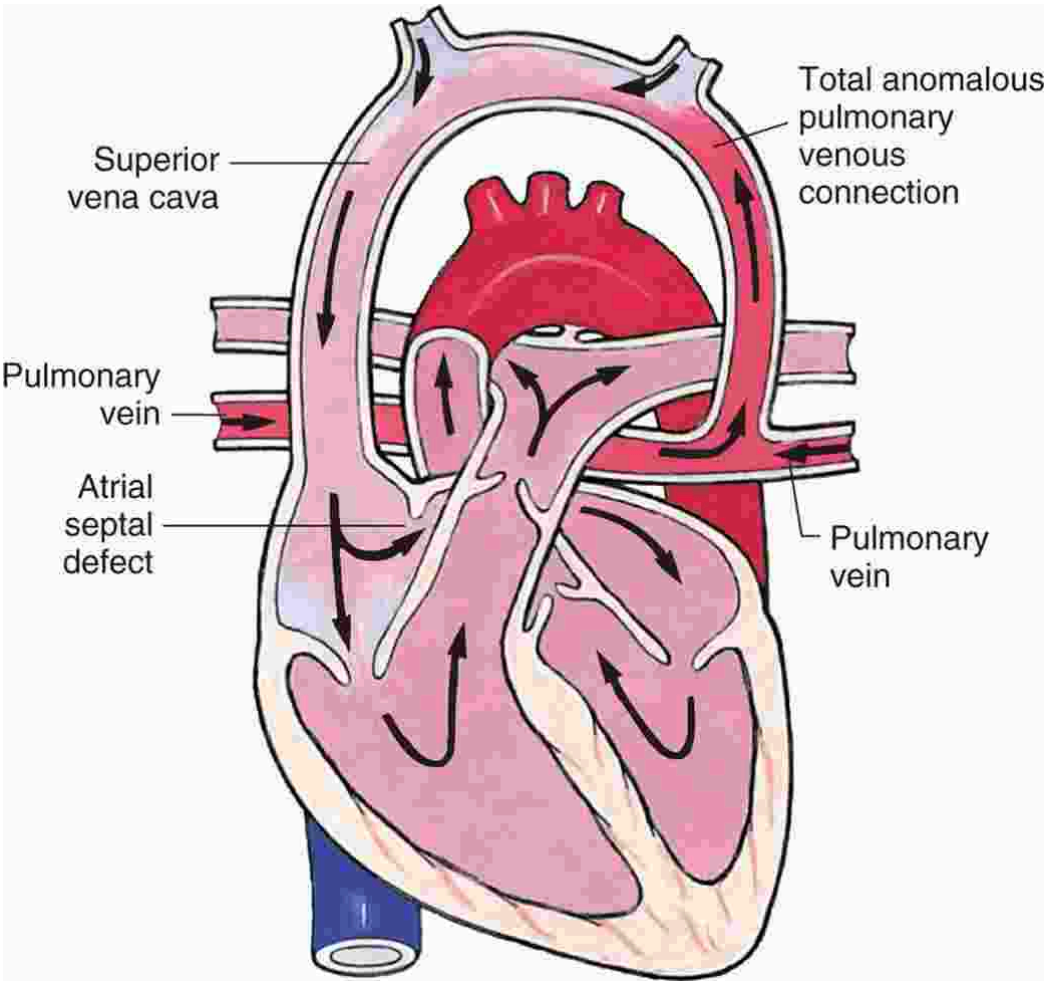

FIG. 33.13 Total Anomalous Pulmonary Venous Connection (TAPVC).

An illustration of the heart traces the flow through the following structures, counterclockwise from the right: pulmonary vein, total anomalous pulmonary venous connection, superior vena cava, and atrial septal defect.

Pathophysiology

In TAPVC, the pulmonary venous return is connected to the right side of the circulation rather than to the LA. The type of TAPVC is

classified according to the location of pulmonary venous return connection:

- *Supracardiac:* Attachment above the diaphragm, usually to the superior vena cava via vertical or innominate vein (most common form)
- *Cardiac:* Direct attachment to the heart, usually to the RA or coronary sinus
- *Infracardiac:* Attachment below the diaphragm, such as to the inferior vena cava or portal or hepatic vein (most severe and least common form)
- *Mixed:* A combination of the various types[40]

Physiologically, TAPVC can be differentiated into two groups: nonobstructive and obstructive, depending on the absence or presence of obstruction to the pulmonary venous drainage. In nonobstructive TAPVC, the RA receives all the blood that normally would flow into the LA. The presence and size of an associated ASD or PFO will determine the amount of blood that will shunt from the RA to the left side of the heart. If there is little communication between the atria, more blood will go to the RV than the LA, and there will be increased pulmonary blood flow, resulting in pulmonary edema as well as right heart enlargement. In the obstructive form of TAPVC, obstruction to pulmonary venous drainage decreases blood flow into the pulmonary circulation and leads to severe cyanosis and low cardiac output. Infracardiac TAPVC often is associated with obstruction of pulmonary venous drainage and has a higher mortality than the unobstructed types.

Clinical Manifestations

Cyanosis is the predominant clinical manifestation. The degree of cyanosis is inversely related to the amount of pulmonary blood flow. Children with unobstructed TAPVC may be asymptomatic until pulmonary vascular resistance decreases during infancy, causing increased pulmonary blood flow and signs and symptoms of

pulmonary overcirculation. In obstructed TAPVC, cyanosis is severe and the infant's condition deteriorates rapidly, necessitating immediate surgical intervention, or death will occur. Murmur is not a common feature of TAPVC.

Evaluation and Treatment

Chest radiograph will reveal cardiomegaly and increased pulmonary vascular markings. In supracardiac TAPVC, the heart may have a snowman appearance. The diagnosis is typically confirmed with echocardiography but may require confirmative angiography. Timing of corrective repair depends on whether there is obstruction to pulmonary venous return. In nonobstructive types of TAPVC, repair can be delayed until early infancy. If there is obstruction, surgical repair is emergent. In general, the surgical approach consists of anastomoses of the common pulmonary vein to the LA, the ASD is partially closed, and the vertical vein (if present) may be ligated.[40] Potential complications include re-obstruction at the anastomosis site, atrial dysrhythmias, PA hypertension, and LV dysfunction. Long term survival is generally above 90% for those without significant postoperative pulmonary venous obstruction.[41]

Truncus Arteriosus

Truncus arteriosus (TA) is failure of normal septation and division of the embryonic outflow tract into a PA and an aorta, resulting in a single vessel that exits the heart, providing both pulmonary and systemic blood flow (Fig. 33.14). It is a rare form of cyanotic CHD and often is associated with 22q11.2 deletion syndrome.[42]

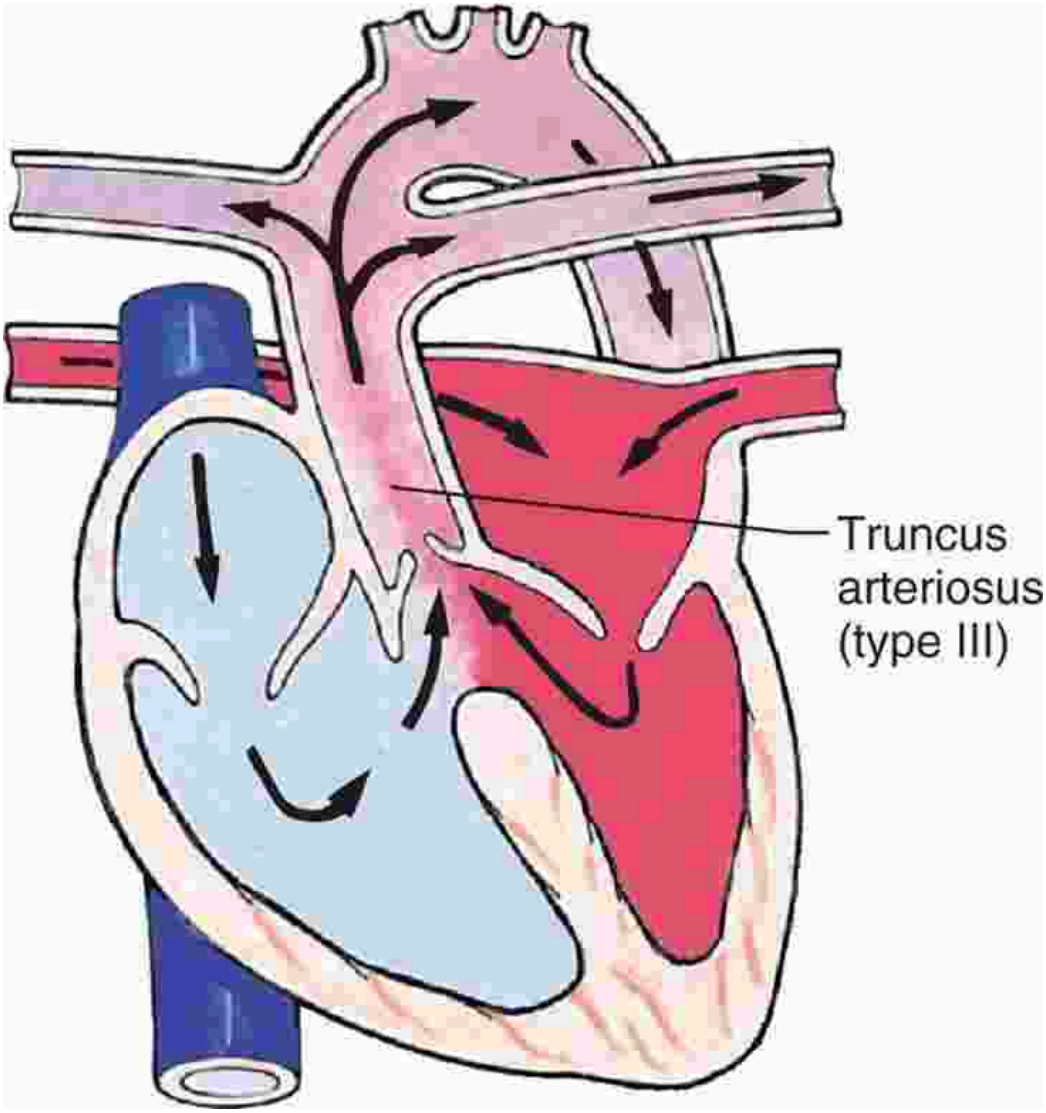

FIG. 33.14 Truncus Arteriosus (TA).
The TA fails to divide into the pulmonary artery and aorta, and the interventricular septum fails to close at the top. Blood from both ventricles mixes in the TA and then enters the pulmonary and systemic circuits. (From Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing*. 10th ed. St Louis: Mosby; 2016.)

An illustration of the heart identifies the region of truncus arteriosus (type 3) at the base of the aorta,

between the right ventricle and the left ventricle. Arrows indicate the flow of blood from the lungs to the ventricles and through the pulmonary artery.

Pathophysiology

In TA, the common vascular trunk created by the lack of division between the PA and aorta has a single valve with either three or four leaflets. This valve may exhibit regurgitation, stenosis, or both. A VSD is always present and allows for mixing of the systemic and arterial circulations causing some degree of cyanosis. Once ejected from the heart, blood flows preferentially to the lower pressure PAs, causing increased pulmonary blood flow, although this can be altered due to the presence of other defects such as PS. The four types of TA are:

- *Type I:* A single pulmonary trunk arises near the base of the truncus and divides into the left and right PAs
- *Type II:* The left and right PAs arise separately from the posterior aspect of the truncus
- *Type III:* The PAs arise independently and from the lateral aspect of the truncus
- *Type IV:* The bronchial arteries arise from the descending aorta, also known as pseudotruncus

Types I and II constitute 85% of cases, with types III and IV comprising the remainder of cases.

Clinical Manifestations

Physical findings depend on the amount of pulmonary blood flow and the presence of other cardiac anomalies. If PS is present, a newborn will present with cyanosis. Conversely, if PS is not present, the newborn initially will have mild cyanosis and moderate HF. A harsh systolic regurgitant murmur is usually present along the left

sternal border as a result of the VSD, and a systolic click at the apex and left upper sternal border indicating opening of the truncal valve.

Evaluation and Treatment

Chest radiograph will reveal cardiomegaly with biventricular and LA enlargement as well as increased pulmonary vascular markings. Conversely, if PS is present, heart size will be normal with decreased pulmonary vascular markings. The diagnosis is made by echocardiography. Corrective repair is performed in the first few days or weeks of life. It involves closing the VSD so that the blood flow from the LV outflow tract goes into the truncus, and excising the PAs from the aorta and attaching them to the RV through a tissue homograft (cadaver conduit).[42] Initial postoperative complications include dysrhythmias, truncal valve stenosis or insufficiency, and pulmonary hypertension.[43] Despite these potential complications, the overall uncomplicated 20-year survival after successful repair is over 75%.[44]

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) is abnormal development of the left side of the heart resulting in anatomic and functional inadequacy of the left ventricle to perform systemic perfusion.[45] Features include underdevelopment of the LV, aorta, and aortic arch, as well as small or absent mitral and aortic valves (Fig. 33.15).

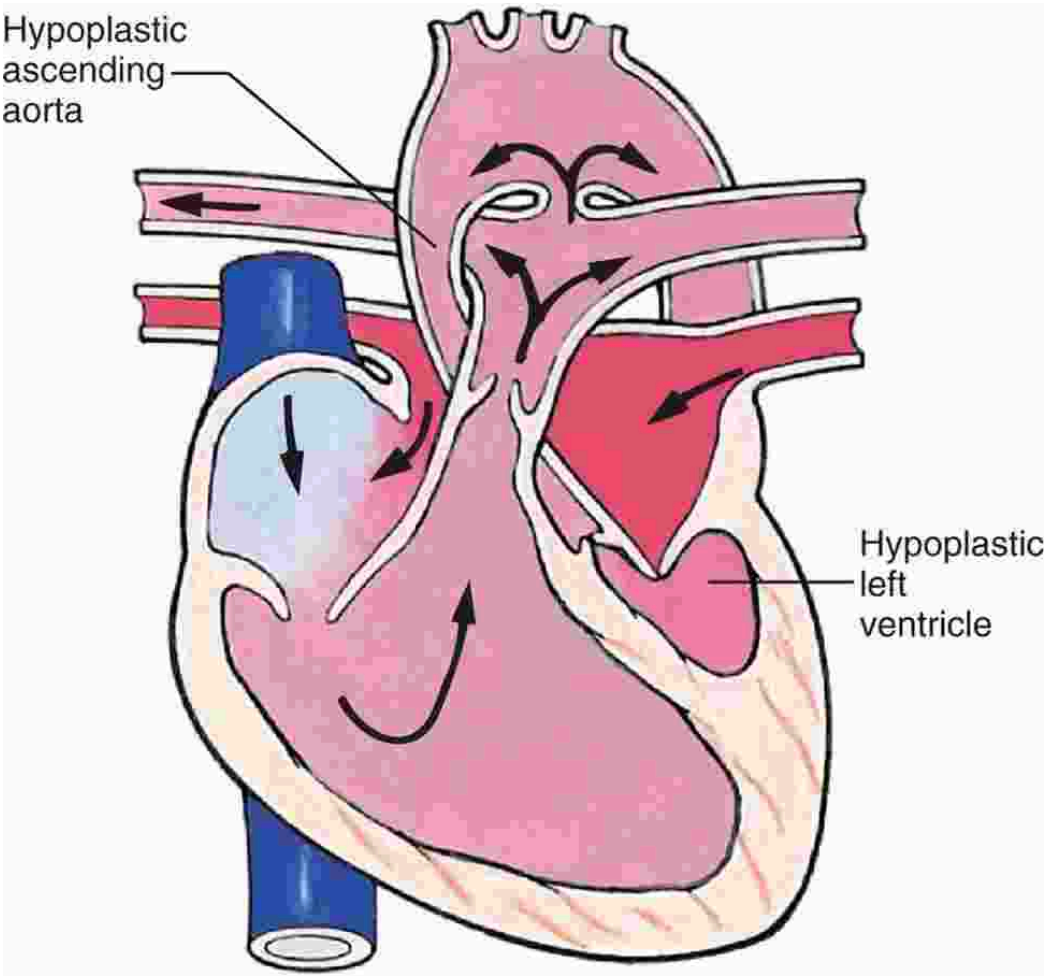

FIG. 33.15 Hypoplastic Left Heart Syndrome (HLHS). (From Hockenberry MJ, Wilson D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2016.)

Pathophysiology

In HLHS, most blood from the LA flows across the PFO to the RA, to the RV, and out the PA. A PDA then allows for blood to go to the descending aorta. The amount of blood that travels to the pulmonary and systemic circulation depends on the vascular resistance in each circuit. Retrograde blood flow from the PDA into the hypoplastic ascending aorta provides coronary and cerebral blood flow. Based on this, the presence of both an ASD or PFO and a PDA is critical for survival after birth.

Clinical Manifestations

HLHS may be detected by fetal echocardiogram. It presents in the early newborn period as mild cyanosis, tachypnea, and low cardiac output. Support of the systemic circulation is accomplished with prostaglandin E_1infusion to maintain flow through the DA. If there is not an adequate ASD or PFO, immediate interventional cardiac catheterization or echocardiography-guided balloon atrial septostomy is needed. If HLHS is not suspected and the DA closes, there is progressive deterioration with cyanosis and decreased cardiac output, leading to cardiovascular collapse. If left untreated, HLHS is usually fatal in the first days of life due to shock and organ failure secondary to inadequate cardiac output and oxygen delivery.

Evaluation and Treatment

Echocardiography shows all the features of HLHS. Chest radiography shows cardiomegaly and increased pulmonary vascular congestion. Surgical intervention is a staged approach to provide pulmonary blood flow and relieve the work of the RV.[45] This includes:

- *Norwood procedure:* Anastomosis of the main PA to the aorta to create a new aorta (or neo-aorta), construction of shunt to provide pulmonary blood flow (either *modified Blalock-Taussig* shunt or RV-PA conduit), and creation of a large ASD. This is performed in the first few days of life.
- *Bidirectional Glenn procedure:* Anastomosis of the superior vena cava to the PA and ligation of previously placed shunt. This is completed around 4 months of life.
- *Fontan procedure:* Routing of the inferior vena cava blood flow to the PA with a grafted or artificial tube. This occurs at approximately 3 years of age.

Another option for high-risk infants with HLHS and other comorbidities, such as prematurity, is the Hybrid Stage I palliation. This involves placement of bilateral PA bands to restrict pulmonary

blood flow and stenting of the PDA to provide stable systemic blood flow. The individual then undergoes the second and third stage of surgical interventions listed previously. Postoperative complications are different for each surgical intervention, although the development of heart failure is a risk at any point. Infants who are not candidates for staged procedures are offered palliative care. Heart transplantation may be possible for some individuals. While there are improved survival rates because of advances in surgical and medical technology, many infants and children with this complex CHD have long-term liver fibrosis, osteoporosis, and neurodevelopmental disabilities.[45] Research into stem-cell and gene therapies are showing promise (see Emerging Science Box: Stem Cell Therapies for Congenital Heart Disease).[46]

Emerging Science Box Stem Cell Therapies for Congenital Heart Disease

Complex congenital heart defects such as COA, TGA, TOF, and HLHS are often termed "Critical Congenital Heart Defects." In the United States, approximately 25% of congenital heart defects fall into this category annually. These conditions have a shorter life expectancy than many other forms of CHD and/or have more long-term complications in survivors. In an effort to improve outcomes for these disorders, stem cell therapies are being studied. Most clinical trials have used mesenchymal stem cells (MSCs), autologous umbilical cord blood cells, or tissue-engineered stem cell grafts. MSCs have the ability to transform into functional cardiomyocytes and can contribute to myocardial repair and the growth of new blood vessels. Autologous umbilical cord blood cells have been used less often, but results from recent research trials look promising. Stem cells are introduced via intracoronary perfusion, or more commonly, by direct injection or implantation into the myocardium. Most successful studies have involved the use of stem cells for treatment of HLHS. For example, a recent study injected autologous umbilical cord blood-derived

mononuclear cells directly into the right ventricular myocardium during the second stage of surgery for HLHS. Results show the procedure is safe, and continuing research into efficacy is ongoing. The current goal of cell-based therapies is to serve as an adjunct to surgery by maintaining right ventricular function and contributing to improved morbidity and mortality.

Acquired Cardiovascular Disorders

Acquired heart diseases refer to disease processes or abnormalities that occur after birth. They result from various causes, such as congenital heart disease, infection, genetic disorders, autoimmune processes in response to infection, environmental factors, or autoimmune diseases. Examples of acquired heart diseases include heart failure, Kawasaki disease, systemic hypertension, myocarditis, rheumatic heart disease, and cardiomyopathy. This chapter discusses heart failure, Kawasaki disease, and systemic hypertension in children. Myocarditis, rheumatic heart disease, and cardiomyopathy are discussed in Chapter 32.

Heart Failure

Heart failure (HF) occurs when the heart is unable to maintain sufficient cardiac output to meet the metabolic demands of the body. It is a common complication of many congenital heart defects.[47] The likely etiology of new-onset HF is determined by the age of diagnosis. For example, HF that results from CHD with pulmonary

overcirculation from a large left-to-right shunt is common in newborns and infants (Table 33.3), whereas HF in older children is most often due to acquired disorders such as viral myocarditis, rheumatic heart disease, autoimmune disorders, anemia, Kawasaki disease, and hypothyroidism.[48]

Table 33.3

Congenital Heart Defects Causing Heart Failure

Age	Congenital Heart Defect
Time of birth	HLHS Volume overload caused by tricuspid regurgitation (rare) AV fistula
Birth to 1 week	HLHS Aortic atresia TGA with VSD COA TAPVC with obstruction PDA in small premature infants
First 4 weeks	COA TAPVC Large left-to-right shunt caused by VSD, PDA in premature infants Tricuspid atresia Persistent TA with large left-to-right shunt

Age	Congenital Heart Defect
	All previously mentioned defects
4–6 weeks	TGA with VSD Large left-to-right shunt caused by endocardial cushion defect
6 weeks to 6 months	VSD
6 months	Endocardial fibroelastosis

Modified from Park MK. *Pediatric cardiology for practitioners*, 6th edition. St. Louis: Mosby; 2014.

Pathophysiology

HF in children is most often a result of pulmonary venous hypertension and pulmonary venous congestion either from pulmonary overcirculation or LV dysfunction. RV failure is rare in childhood. The pathophysiology of HF due to pulmonary overcirculation that results from CHD is discussed earlier in this chapter. In LV dysfunction, the pathophysiologic mechanisms of HF in infants and children are similar to those in adults (see Chapter 32). Compensatory mechanisms, including the sympathetic nervous system and the renin-angiotensin-aldosterone system, are activated in the face of inadequate cardiac output. These hormones result in myocardial remodeling, LV hypertrophy, interstitial fibrosis, and changes in calcium handling in the sarcoplasmic reticulum and contractile proteins, resulting in direct cardiotoxicity.[47]

Clinical Manifestations

HF in infants is manifested as poor feeding and growth, often leading to FTT. Dyspnea, tachypnea, and diaphoresis may be accompanied by retractions, grunting, and nasal flaring. On physical exam, crackles and wheezing can be auscultated within the lungs, and a gallop is present when assessing heart sounds. Common skin changes, such as pallor or mottling, are often present (Box 33.1). Signs of systemic venous congestion, such as hepatomegaly, weight gain without caloric intake increase, and ascites, can be present but could be suggestive of other medical conditions such as renal or nutritional deficiencies.

Box 33.1

Clinical Manifestations of Heart Failure

Impaired Myocardial Function

- Tachycardia
- Sweating (inappropriate)
- Decreased urinary output
- Fatigue
- Weakness
- Restlessness
- Anorexia
- Pale, cool extremities
- Weak peripheral pulses
- Decreased blood pressure
- Gallop
- Cardiomegaly

Pulmonary Congestion

- Tachypnea
- Dyspnea
- Retractions (infants)
- Flaring nares
- Exercise intolerance
- Orthopnea
- Cough, hoarseness
- Cyanosis
- Wheezing (rare)
- Grunting

Systemic Venous Congestion

- Weight gain
- Hepatomegaly
- Ascites
- Neck vein distention (rare in children)
- Peripheral edema (rare)

(From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

Evaluation and Treatment

A thorough physical examination with emphasis on cardiac and pulmonary findings will often reveal the degree of HF. Plotting a child's growth (height, weight, head circumference) is an important method of assessing a child's health. Echocardiography is the gold standard for definitive diagnosis of structural and functional cardiac disease. A chest radiograph is useful in assessing the presence of cardiomegaly and signs of increased pulmonary circulation or pulmonary edema. An electrocardiogram (ECG) also should be performed to determine the presence of dysrhythmia or hypertrophy.

HF in infants and children is classified on the basis of cardiac function and structure, which helps to determine treatment choices.[47] Management in pediatrics is extrapolated from adult guidelines as described by a pediatric cardiology taskforce in 2014.[49] Treatment is aimed at decreasing cardiac workload and increasing the efficiency of heart function. ACE inhibitors are the first-line treatment of HF. Aldosterone receptor antagonists improve mortality in children with HF. Digoxin may be used for selected children with left-to-right shunting lesions. In young children with acute HF, there is evidence that epinephrine is more effective than dobutamine in improving cardiac output, and milrinone provides improved contractility while reducing vascular resistance.[50] Diuretics are recommended in those with fluid overload. In severe cases of HF, angiotensin receptor neprilysin inhibitors and ivabradine may be considered.[47] End-stage HF requires anticoagulation, and mechanical circulatory support may be indicated to support the failing myocardium while awaiting cardiac transplantation.[51]

Kawasaki Disease

Kawasaki disease (KD), formerly known as mucocutaneous lymph node syndrome, is an acute systemic vasculitis that may result in myocarditis and coronary artery aneurysms. KD is a leading cause of acquired heart disease among children in the United States, although it remains far more prevalent in Asian countries such as Japan and Korea.[52] KD is primarily a condition of young children, with 80% of cases seen in children younger than 5 years of age, peaking in the toddler age group. Approximately 5% of cases are diagnosed in children 10 years or older whose disease often goes unrecognized until cardiac complications develop. Males are affected slightly more than females. In the United States, black individuals are affected twice as often as white individuals.

Pathophysiology

The etiology of KD remains unknown.[52] Current etiologic theories center on a normal immunologic response to an infectious, toxic, or antigenic substance, or an abnormal immune response to a common stimulus. The predominant theory is a genetic predisposition to the development of autoimmune response to inhaled viruses such as retroviruses, coronaviruses, or Epstein-Barr virus.[53] Dysbiosis of the intestinal microbiome and intestinal permeability may also play a role.

The innate and adaptive immune system responses in KD include the release of multiple inflammatory cytokines, increased serum levels of antibodies, and infiltration of vessel walls by neutrophils, macrophages, and lymphocytes. Additional immune changes include elevated activity of T helper 17 cells (Th17), a decrease in T regulatory cells, and a proliferation of T cytotoxic and B cells (see Chapter 8).[54] A necrotizing arteritis develops with the risk of aneurysm development, especially affecting the coronary arteries. An acute myocarditis also occurs in many individuals. Kawasaki disease progresses pathologically and clinically in these stages:

Stage I (days 1 through 12): Small capillaries, arterioles, and venules become inflamed, as does the heart itself (acute

myocarditis).

Stage II (days 13 through 25): Inflammation spreads to larger vessels and aneurysms of the coronary arteries may develop (acute necrotizing vasculitis).

Stage III (days 26 through 40): Medium-sized arteries begin the granulation process which contributes to coronary artery thickening with increased risk for thrombosis.

Stage IV (day 41 and beyond): Myofibroblasts are activated, and vessels develop scarring, intimal thickening, calcification, and stenosis.

The acute myocarditis of KD may progress to left ventricular dysfunction. Fortunately, these pathophysiologic changes are usually self-limiting and respond well to anti-inflammatory treatment.[53] However, some children present with Kawasaki shock syndrome, which is characterized by hypotension, poor perfusion, hyponatremia, coagulopathy, and anemia.[52] KD myocarditis is similar to that being seen in association with pediatric coronavirus disease 2019 (COVID-19) infection (see Emerging Science Box: COVID-19 Post-Infective Myocarditis in Children). Coronary artery aneurysms resulting from the necrotizing vasculitis occur in up to 25% to 30% of untreated children with Kawasaki disease, and early treatment is crucial to preventing this complication.[52] These aneurysms occur most frequently in males and those who either receive treatment late (after 10 days) or who are resistant to treatment.[55]

Emerging Science BoxCOVID-19 Post-Infective Myocarditis in Children

SARS-CoV-2 infection and resulting COVID-19 is associated with the development of Multisystem Inflammatory Syndrome in Children (MIS-C) (see Chapter 36). In addition to the pulmonary complications associated with MIS-C, injury to the cardiovascular system is common. Post-infective myocarditis can occur in the wake of many viral infections, including those caused by

Coxsackievirus B virus, enteroviruses, influenza, rubella, and adenoviruses. However, children with COVID 19 post-infective myocarditis have a clinical picture that generally is more severe. Similar to Kawasaki disease, COVID-19 related MIS-C is recognized as a systemic vasculitis affecting not only the lung but all organs, including the myocardium. While some investigators have postulated that SARS-CoV-2 initiates Kawasaki disease itself, others consider COVID-19 post-infective myocarditis to be a separate entity and point to characteristics that differentiate the two. For example, while the two diseases share fever, rash, cheilitis, and adenopathy, children with COVID 19 are older (mean age 7 years vs. 3 years), have more digestive symptoms, and are more likely to develop shock and severe myocarditis. Similar to Kawasaki disease, children with COVID-19 post-infective myocarditis may develop coronary artery aneurysms. Management of COVID-19 post-infective myocarditis includes supportive therapy with oxygen and diuretics plus ionotropic medications and mechanical hemodynamic support if needed. Intravenous immunoglobulin (IVIG) and antiviral administration is associated with improved outcomes in affected children. The majority of children recover with few if any long term sequelae, including the resolution of coronary aneurysms. However, there is still the possibility of persistent or progressive cardiovascular complications, some of which may go undiagnosed and may result in serious morbidity and mortality later in life (e.g., coronary aneurysms). This has led to emerging recommendations that children who recover from COVID-19 MIS-C should undergo a cardiac evaluation before participating in sports and should be followed for potential cardiac complications into adulthood.

Data from Barach P, et al. Rethinking COVID-19 in children: Lessons learned from pediatric viral and inflammatory cardiovascular diseases. *Progress in Pediatric Cardiology*, 2020;22:101233. Clinical Manifestations

KD progresses in three stages (acute, subacute, and convalescent):

- *Acute phase*: The child with classic or typical KD has fever, conjunctivitis, oral changes ("strawberry" tongue), rash, erythema of the palms and soles, and lymphadenopathy, and is often irritable. During this phase, myocarditis in addition to vasculitis may develop.
- *Subacute phase*: Begins when the fever ends and continues until the clinical signs have resolved. It is at this time that the child is most at risk for coronary artery aneurysm development. Desquamation (skin peeling) of the palms and soles occurs at this time, as well as marked thrombocytosis.
- *Convalescent phase*: This phase is marked by the elevation of the erythrocyte sedimentation rate and C-reactive protein level, as well as by an increased platelet count. Arthritis or arthralgia of the joints may be present. This phase continues until all laboratory values return to normal—usually about 6 to 8 weeks after onset.

Evaluation and Treatment

The diagnosis and management of KD is based on guidelines published by the American Heart Association in 2017.[56] Initial diagnosis is made on the basis of clinical features, and the child must exhibit 5 days of fever along with four of five criteria presented in Box 33.2. Other supportive diagnostic findings include leukocytosis, anemia, hypoalbuminemia, increased c-reactive protein, thrombocytosis, and elevated liver enzymes. An echocardiogram is

obtained at the time of diagnosis as a baseline measurement to assess for coronary aneurysms or inflammation. Serial echocardiograms are obtained after treatment to assess for the development of coronary aneurysms or regression of those present early in the course of the disease.

Box 33.2

Diagnostic Criteria for Kawasaki Disease

Classic KD is diagnosed in the presence of fever for at least 5 days together with at least 4 of the 5 following principal clinical features:

1. Bilateral conjunctival infection without exudation
2. Inflammation of the oral mucous membranes, such as erythema, dryness, and fissuring of the lips; oropharyngeal reddening; or "strawberry tongue"
3. Changes in the extremities, such as peripheral edema, peripheral erythema, and desquamation of the palms and soles, particularly periungual peeling
4. Polymorphous rash, often accentuated in the perineal area
5. Cervical lymphadenopathy (one lymph node >1.5 cm)

Modified from McCrindle BW, Rowley AH, Newburger JW, et al. Diagnosis, treatment, and long-term management of Kawasaki disease: A scientific statement for health professionals from the American Heart Association. *Circulation*, 2017;135:e927–e999.

Treatment with aspirin and intravenous immunoglobulin during the acute phase significantly decreases the incidence of coronary aneurysms.[52] In severe cases, children may also receive corticosteroids or other anti-inflammatory agents such as infliximab, etanercept, or cyclosporin.[52] Refractory KD is the recurrence or persistence of fever after immunoglobulin infusion and requires

retreatment and the use of high-dose anti-inflammatory agents.[52] Aspirin is continued until the manifestations of inflammation are resolved, but it may be used indefinitely in children with residual coronary artery abnormalities. Most children recover completely from KD, including regression of aneurysms. The most common cardiovascular complication is coronary thrombosis with myocardial infarction due to persistent coronary artery aneurysms.

Pediatric Hypertension

Pediatric hypertension (HTN) affects millions of children worldwide, and the prevalence is increasing, especially in developing countries.[57] Updated criteria for the diagnosis of HTN in children and adolescents was published in 2017 by the American Academy of Pediatrics.[58] Like in adults, blood pressure in children is categorized into Normal, Elevated, Stage 1, HTN, and Stage 2 HTN. For young children, these categories are determined by where the individual's blood pressure falls as a percentile of average readings for healthy children. For adolescents, the criteria for each of these categories is the same as those for adults (see Chapter 32). A summary of normative blood pressure levels for neonates and young children can be found in Table 33.4. Epidemiologic studies estimate that in the United States, up to 16% of children between the ages of 10 to 17 years have elevated blood pressure, and 2% to 4% have hypertension.[59]

Table 33.4

Normative Blood Pressure Levels (Systolic/Diastolic Pressure [Mean]) by Dinamap Monitor in Children 5 Years Old or Younger

Age	Mean BP Levels (mm Hg)	90th Percentile	95th Percentile
1–3 days	64/41 (50)	75/49 (50)	78/52 (62)
1 months to 2 years	95/58 (72)	106/68 (83)	110/71 (86)
2–5 years	101/57 (74)	112/66 (82)	115/68 (85)

Age	Mean BP Levels (mm Hg)	90th Percentile	95th Percentile
1–3 days	64/41 (50)	75/49 (50)	78/52 (62)
1 months to 2 years	95/58 (72)	106/68 (83)	110/71 (86)
2–5 years	101/57 (74)	112/66 (82)	115/68 (85)

BP, Blood pressure.

Data from Park MK. *Pediatric cardiology for practitioners*, 6th edition. St. Louis: Mosby; 1989; modified from Park MK, Menard SM. Normative oscillometric blood pressure values in the first 5 years in an office setting. *American Journal of Diseases of Children*, 1989;143:860.

Hypertension is classified into two categories:

- *primary (or essential) hypertension*, in which a specific cause cannot be identified
- *secondary hypertension*, in which a cause can be identified (Box 33.3)

Box 33.3

Conditions Associated With Secondary

Hypertension in Children

Renal Disorders

- Congenital defects
  - Polycystic kidney, ectopic kidney, horseshoe kidney, etc.
  - Obstructive anomalies
  - Hydronephrosis
- Renal tumor
  - Wilms tumor
  - Retrovascular tumor
- Abnormalities of renal arteries
- Renal vein thrombosis
- Acquired disorders
  - Glomerulonephritis, acute or chronic
  - Pyelonephritis
  - Nephritis associated with collagen disease

Cardiovascular Disease

- Coarctation of the aorta
- Arteriovenous fistulae
- Patent ductus arteriosus
- Aortic or mitral insufficiency

Metabolic and Endocrine Diseases

- Adrenal tumors
  - Adenoma
  - Pheochromocytoma
  - Neuroblastoma
  - Cushing syndrome
  - Adrenogenital syndrome
  - Hyperthyroidism
  - Aldosteronism

Hypercalcemia
Diabetes mellitus

Neurologic Disorders

Space-occupying lesions of cranium (increased intracranial pressure)
Tumors, cysts, hematoma
Cerebral edema
Encephalitis (including Guillain-Barré and Reye syndromes)

Miscellaneous Causes

Drugs (corticosteroids, oral contraceptives, pressor agents, amphetamines)
Burns
Genitourinary surgery
Trauma (e.g., stretching of femoral nerve with leg traction)
Insect bites (e.g., scorpion)
Intravascular overload (blood, fluid)
Hypernatremia
Toxemia of pregnancy
Heavy metal poisoning

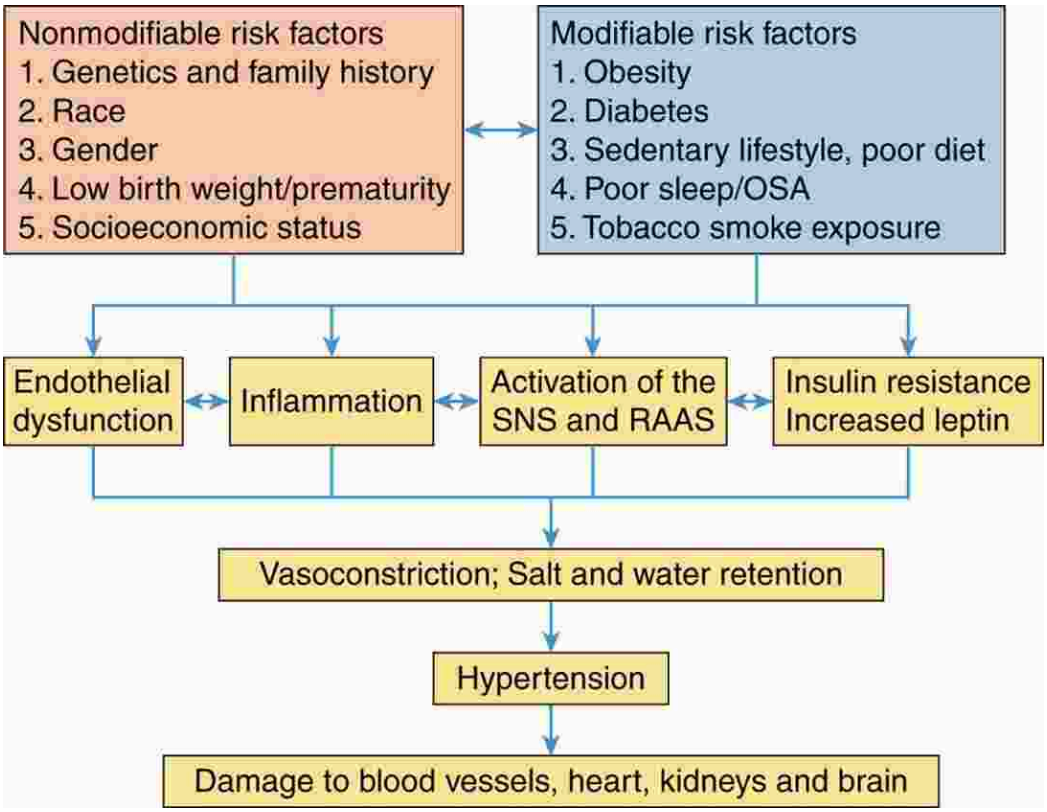
From Hockenberry MJ, Wilson D. *Wong's essentials of pediatric nursing*, 10th edition. St. Louis: Mosby; 2015.

HTN in children differs from adult HTN in etiology and presentation. Low birth weight and an adverse intrauterine environment are linked to epigenetic modifications and alterations in renal, vascular, and autonomic functions.[60] Young children, when diagnosed with HTN, are often found to have secondary HTN caused by some underlying disease, such as renal disease or COA (see Box 33.3). An increased prevalence of primary HTN has been linked to the increasing prevalence of obesity and diabetes in

children and adolescents. Primary HTN in children has been shown to cause subclinical organ damage, such as increased ventricular mass, carotid artery disease, and microalbuminuria.[61] Emerging data suggests that pediatric hypertension may also result in impaired cognition later in life.[62]

Pathophysiology

Primary hypertension is now the most common form of hypertension in children and adolescents. The pathophysiology of pediatric primary HTN has not been fully elucidated but is believed to result from a combination of modifiable and nonmodifiable risk factors (Algorithm 33.1). Similar to primary HTN in adults, the pathophysiology of pediatric HTN consists of a complex interaction between inflammatory processes, activation of the sympathetic nervous systems, upregulation of the renin-angiotensin-aldosterone system, increased sodium absorption, and increased vascular reactivity with the end result leading to hypertension. Additionally, obesity-linked increases in serum leptin, a hormone produced by adipose tissue, is associated with HTN in obese children.



ALGORITHM 33.1 Proposed Mechanisms of Primary Hypertension in Children. *OSA*, Obstructive sleep apnea; *SNS*, sympathetic nervous system; *RAAS*, renin-angiotensin-aldosterone system.

A flowchart shows the proposed mechanisms of primary hypertension in children. Nonmodifiable risk factors include the following: 1. Genetics and family history. 2. Race. 3. Gender. 4. Low birth weight or prematurity. 5. Socioeconomic status. Modifiable risk factors include the following: 1. Obesity. 2. Diabetes. 3. Sedentary lifestyle, poor diet. 4. Poor sleep or O S A. 5. Tobacco smoke exposure. The structure of the flowchart is as follows. 1.

Nonmodifiable risk factors. Interrelated with 2. Leads to 3, 4, 5, and 6. 2. Modifiable risk factors. Leads to 3, 4, 5, and 6. 3. Endothelial dysfunction. Leads to 7. 4. Inflammation. Leads to 7. 5. Activation of the S N S and R A A S. Leads to 7. 6. Insulin resistance and increased leptin. Leads to 7. 7. Vasoconstriction; salt and water retention. Leads to 8. 8. Hypertension. Leads to 9. 9. Damage to blood vessels, heart, kidneys, and brain.

Clinical Manifestations

Most children with systemic HTN are asymptomatic. Although the United States Preventive Task Force does not recommend routine screening for high blood pressure in children and adolescents, those with high body mass index, family history, or history of potential secondary causes of hypertension are at increased risk.[63] If hypertension is suspected, it is necessary that a thorough history, including family history of HTN and heart disease, as well as physical examination be obtained. The examination should include an accurate blood pressure measurement obtained in the right arm with the arm supported at the level of the heart; three separate measurements using an appropriate-size cuff also are needed for an accurate blood pressure reading. In neonates, an oscillometric device (e.g., dynamap) should be used, and measurements should be obtained at least 90 minutes after feeding with the infant lying prone or supine.[57]

Evaluation and Treatment

The diagnosis and management of hypertension in children and adolescents is based on guidelines published by the American Academy of Pediatrics in 2017.[58] The history and physical

examination should be directed at determining the etiology of HTN, such as COA or renal disease (Table 33.5). For example, blood pressure differences between upper and lower extremities and echocardiogram can be used to identify COA. Table 33.6 includes routine and special laboratory tests for HTN. If HTN is determined to be essential, or primary, in nature, nonpharmacologic therapy is used initially. Moderate weight loss and exercise can decrease systolic and diastolic pressures in many children. Appropriate diet, regular physical activity, and avoidance of smoking have been shown to be effective in reducing blood pressure. Ambulatory blood pressure monitoring has been shown to be more precise in the assessment of blood pressure in children and is more predictive of end-organ damage.[64] Medication therapy is controversial in children with primary HTN; however, when nonpharmacologic therapy fails, the approach is similar to the treatment of HTN in adults with the use of ACE inhibitors, angiotensin receptor blockers, and calcium channel blockers.[58] The current emphasis on preventive cardiology, especially for children, is significant because many investigators believe signs of atherosclerosis are present during childhood.

Table 33.5

Most Common Causes of Chronic Sustained Hypertension in Children

Age Group	Causes
Newborn	Renal artery thrombosis, renal artery stenosis, congenital renal malformation, coarctation of the aorta (COA), bronchopulmonary dysplasia
<6 years	Renal parenchymal disease, COA, renal artery stenosis
6–10 years	Renal artery stenosis, renal parenchymal disease, primary hypertension
>10 years	Primary hypertension, renal parenchymal disease

From Park MK. *Pediatric cardiology for practitioners*, 6th edition. St. Louis: Mosby; 2014.

Table 33.6

Routine and Special Laboratory Tests for Hypertension

Laboratory Tests	Significance of Abnormal Results
Urinalysis, urine culture, blood urea nitrogen, and creatinine levels	Renal parenchymal disease
Serum electrolyte levels (hypokalemia)	Hyperaldosteronism, primary or secondary Adrenogenital syndrome Renin-producing tumors
ECG, chest x-ray studies	Cardiac cause of hypertension, also baseline function
Intravenous pyelography (or ultrasonography, radionuclide studies, computed tomography of kidneys)	Renal parenchymal diseases Renovascular hypertension Tumors (neuroblastoma, Wilms tumor)
Plasma renin activity, peripheral	High-renin hypertension Renovascular hypertension Renin-producing tumors

Laboratory Tests	Significance of Abnormal Results
	Some caused by Cushing syndrome Some caused by essential hypertension Low-renin hypertension Adrenogenital syndrome Primary hyperaldosteronism
24-hour urine collection for 17-ketosteroids and 17-hydroxycorticosteroids	Cushing syndrome Adrenogenital syndrome
24-hour urine collection for catecholamine levels and vanillylmandelic acid	Pheochromocytoma Neuroblastoma
Aldosterone	Hyperaldosteronism, primary or secondary Renovascular hypertension Renin-producing tumors
Renal vein plasma renin activity	Unilateral renal parenchymal disease

Laboratory Tests	**Significance of Abnormal Results**
	Renovascular hypertension
Abdominal aortogram	Renovascular hypertension Abdominal COA Unilateral renal parenchymal diseases Pheochromocytoma
Intra-arterial digit subtraction angiography	Renovascular hypertension

Laboratory Tests	Significance of Abnormal Results
Urinalysis, urine culture, blood urea nitrogen, and creatinine levels	Renal parenchymal disease
Serum electrolyte levels (hypokalemia)	Hyperaldosteronism, primary or secondary Adrenogenital syndrome Renin-producing tumors
ECG, chest x-ray studies	Cardiac cause of hypertension, also baseline function
Intravenous pyelography (or ultrasonography, radionuclide studies, computed tomography of kidneys)	Renal parenchymal diseases Renovascular hypertension Tumors (neuroblastoma, Wilms tumor)
Plasma renin activity, peripheral	High-renin hypertension Renovascular hypertension Renin-producing tumors Some caused by Cushing syndrome Some caused by essential hypertension Low-renin hypertension Adrenogenital syndrome Primary hyperaldosteronism
24-hour urine collection for 17-ketosteroids and 17-hydroxycorticosteroids	Cushing syndrome Adrenogenital syndrome
24-hour urine collection for catecholamine levels and vanillylmandelic acid	Pheochromocytoma Neuroblastoma
Aldosterone	Hyperaldosteronism, primary or secondary Renovascular hypertension Renin-producing tumors
Renal vein plasma renin activity	Unilateral renal parenchymal disease Renovascular hypertension
Abdominal aortogram	Renovascular hypertension Abdominal COA Unilateral renal parenchymal diseases Pheochromocytoma
Intra-arterial digit subtraction angiography	Renovascular hypertension

COA, Coarctation of the aorta; *ECG*, electrocardiogram.

Summary Review

Congenital Heart Disease

1. Congenital heart defects are heart defects present since birth, and some have associated causes, both environmental and genetic.
2. Environmental risk factors associated with the incidence of CHDs typically are maternal conditions and include infections, radiation, metabolic disorders, alcohol or drug intake, and perinatal conditions.
3. Genetic factors associated with congenital heart defects include, but are not limited to, Down syndrome, trisomy 13, trisomy 18, cri du chat syndrome, 22q11 deletion syndrome, and Turner syndrome.
4. Classification of congenital heart defects is based on whether they cause (1) increased pulmonary blood flow, (2) obstruction to flow, (3) decreased pulmonary blood flow, or (4) mixed desaturated and saturated blood within the chambers or great arteries of the heart.
5. Cyanosis, a bluish discoloration of the skin, indicates that the tissues are not receiving normal amounts of oxygenated blood. Cyanosis can be caused by defects that (1) restrict blood flow into the pulmonary circulation, (2) overload the pulmonary circulation, causing pulmonary overcirculation, pulmonary edema, and respiratory difficulty, or (3) cause large amounts of unoxygenated blood to shunt from the pulmonary to the systemic circulation.
6. Congenital defects that maintain or create direct communication between the pulmonary and systemic circulatory systems cause blood to shunt from one system to another, mixing oxygenated and unoxygenated blood and increasing blood volume and, occasionally, pressure on the receiving side of the shunt.
7. The direction of shunting through an abnormal communication depends on differences in pressure and resistance between the two systems. Direction of shunt blood flow is always from an area of high pressure to an area of low pressure.

8. If the abnormal communication between the left and right circuits is large, volume and pressure overload in the pulmonary circulation can lead to left-sided HF.
9. Acyanotic congenital defects that increase pulmonary blood flow consist of abnormal openings (ASD, VSD, PDA, or AVC) that permit blood to shunt from left (systemic circulation) to right (pulmonary circulation). Cyanosis does not occur because the left-to-right shunt does not interfere with the flow of oxygenated blood through the systemic circulation.
10. An acyanotic defect caused by obstruction of ventricular outflow is commonly caused by PS or AS. In less severe obstruction, ventricular outflow remains normal because of compensatory ventricular hypertrophy stimulated by increased afterload and, in postductal COA, development of collateral circulation around the coarctation.
11. Cyanotic congenital defects in which saturated and desaturated blood mix within the heart or great arteries include TGA, TAPVC, TA, and HLHS.
12. In cyanotic heart defects that decrease pulmonary blood flow (TOF and tricuspid atresia), myocardial hypertrophy cannot compensate for restricted RV outflow. Flow to the lungs decreases, and cyanosis is caused by an insufficient volume of oxygenated blood and right-to-left shunt.
13. The initial treatment for CHD, depending on the defect, is aimed at controlling the level of HF symptoms or cyanosis. Interventional procedures in the cardiac catheterization laboratory and surgical palliation or repair are performed to establish a source of pulmonary blood flow or restore normal circulation.

Acquired Cardiovascular Disorders

1. Heart failure occurs when the heart is unable to maintain sufficient cardiac output to meet the metabolic demands of

the body. HF in infants and young children is usually the result of congenital heart defects that increase blood volume in the pulmonary circulation. HF in older children is more often due to LV dysfunction that results from viral myocarditis, rheumatic heart disease, autoimmune disorders, anemia, Kawasaki disease, and hypothyroidism. A clinical manifestation of HF unique to children is FTT.

2. Acquired heart diseases are those that develop after birth. They may result from infection, genetic disorders, autoimmune processes or diseases, or environmental factors.
3. Kawasaki disease (KD) is an acute systemic vasculitis, or inflammation of the blood vessels, that also may result in the development of coronary artery aneurysms and thrombosis if untreated.
4. Systemic hypertension in children differs from HTN in adults in etiology and presentation. When significant HTN is found in young children, they should be evaluated for the presence of secondary HTN, most commonly renal disease or COA.

Chapter Outline

OUTLINE

Structures of the Pulmonary System 1131
- Conducting Airways 1131
- Gas-Exchange Airways 1133
- Pulmonary and Bronchial Circulation 1135
- Chest Wall and Pleura 1137

Function of the Pulmonary System 1137
- Ventilation 1137
- Gas Transport 1143

Tests of Pulmonary Function 1148

The primary function of the pulmonary system is the exchange of gases between the environmental air and the blood. The three steps in this process are (1) ventilation, the movement of air into and out of the lungs; (2) diffusion, the movement of gases between air spaces in the lungs and the bloodstream; and (3) perfusion, the movement of blood into the capillary beds of the lungs and out to body organs and tissues. The first two functions are carried out by the pulmonary system, and the third by the cardiovascular system (see Chapter 31). Normally the pulmonary system functions efficiently under a variety of conditions and with little energy expenditure.

Structures of the Pulmonary System

The pulmonary system includes two lungs, the upper and lower airways, the blood vessels that serve these structures (Fig. 34.1), the diaphragm, and the chest wall (thoracic cage). The lungs are divided into lobes: three in the right lung (upper, middle, lower) and two in

the left lung (upper, lower). Each lobe is further divided into segments and lobules. The mediastinum is the space between the lungs and contains the heart, great vessels, and esophagus. A set of conducting airways, or bronchi, delivers air to each section of the lung. The lung tissue that surrounds the airways supports them, preventing distortion or collapse of the airways as gas moves in and out during ventilation. The diaphragm is a dome-shaped muscle that separates the thoracic and abdominal cavities and is involved in ventilation.

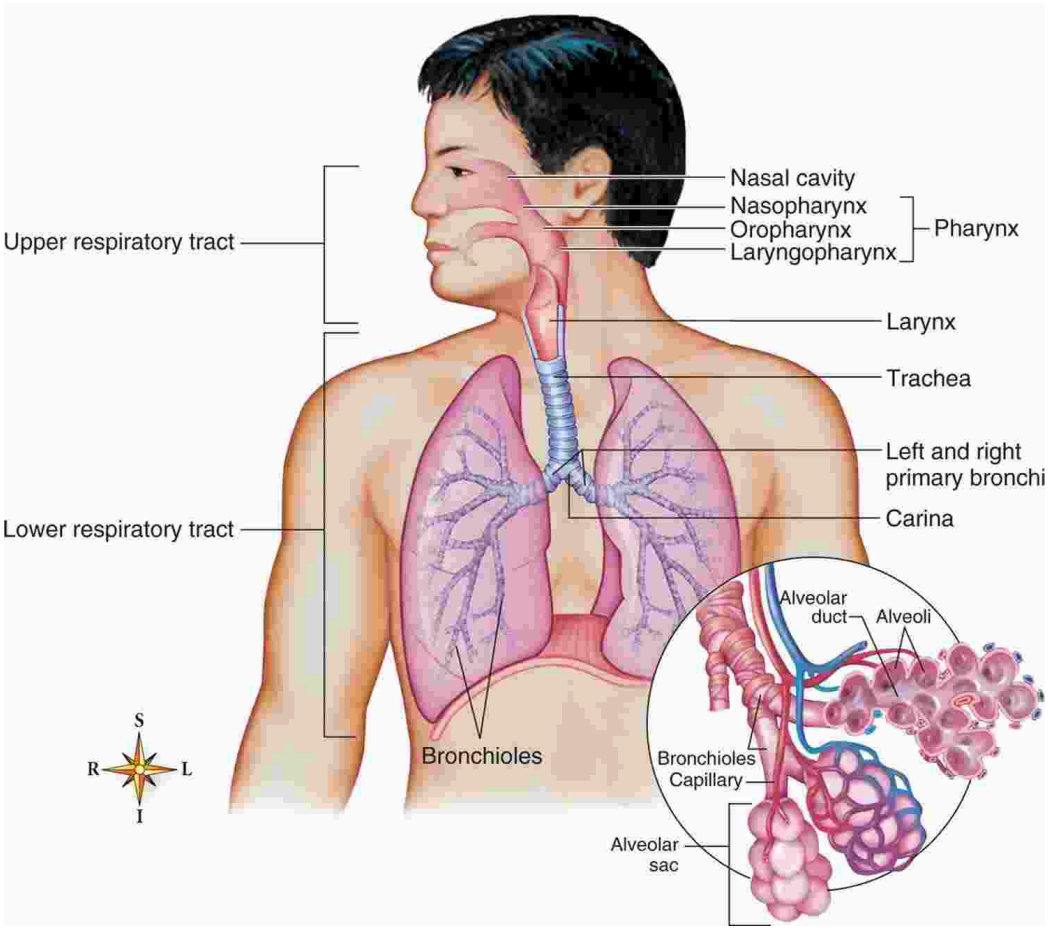

FIG. 34.1 Structure of the Pulmonary System. The upper and lower respiratory tracts (airways) are illustrated. The enlargement in the circle depicts the acinus, where oxygen and carbon dioxide are exchanged. (From Patton KT, Thibodeau GA. *Structure & function of the body*, 15th edition. St. Louis: Mosby; 2016.)

An illustration of a person's torso shows and labels the different parts of the upper and lower respiratory tracts. The upper respiratory tract comprises the pharynx and includes the following structures from the top to the bottom: nasal cavity, nasopharynx, oropharynx, and laryngopharynx. The lower

respiratory system comprises the larynx, trachea, left and right primary bronchi, carina, and bronchioles. An accompanying illustration shows a magnified view of the bronchioles and identifies the following parts: alveolar duct, alveoli, bronchioles capillary, and alveolar sac.

The lungs are protected from a variety of exogenous contaminants in inspired air by a series of mechanical and cellular defenses (Table 34.1). These defense mechanisms are so effective that, in the healthy individual, contamination of the lung tissue itself, particularly by infectious agents, is relatively uncommon.

Table 34.1

Pulmonary Defense Mechanisms

Structure or Substance	Mechanism of Defense
Upper respiratory tract mucosa	Maintains constant temperature and humidification of gas entering the lungs; traps and removes foreign particles, some bacteria, and noxious gases from inspired air
Nasal hairs and turbinates	Trap and remove foreign particles, some bacteria, and noxious gases from inspired air
Branching airways	Disrupt laminar flow and enhance deposition of particles and pathogens on ciliated mucosa
Mucous blanket	Protects trachea and bronchi from injury; traps most foreign particles and bacteria that reach the lower airways
Innate immune proteins	Lysozyme, lactoferrin, defensins, surfactant protein (A [SP-A] and surfactant protein D [SP-D]), and immunoglobulin A (IgA); recognize and promote killing of pathogens
Cilia	Propel mucous blanket and entrapped particles toward the oropharynx, where they can be swallowed or expectorated
Alveolar macrophages	Ingest and remove bacteria and other foreign material from alveoli by phagocytosis (see Chapter 7)

Structure or Substance	Mechanism of Defense
Surfactant	Enhances phagocytosis of pathogens and allergens in alveoli; down-regulates inflammatory responses
Irritant receptors in nares (nostrils)	Stimulation by chemical or mechanical irritants triggers sneeze reflex, which results in rapid removal of irritants from nasal passages
Irritant receptors in trachea and large airways	Stimulation by chemical or mechanical irritants triggers cough reflex, which results in removal of irritants from the trachea and large airways

Conducting Airways

The conducting airways allow air into and out of the gas-exchange structures of the lung. The nasopharynx, oropharynx, and related structures are often called the *upper airway* (Fig. 34.2). These structures are lined with a ciliated mucosa with a rich vascular supply that warms and humidifies inspired air and removes foreign particles from it before it passes into the lungs. The mouth and oropharynx are used for ventilation when the nose is obstructed or when increased flow is required (e.g., during exercise). Filtering and humidifying are not as efficient with mouth breathing.

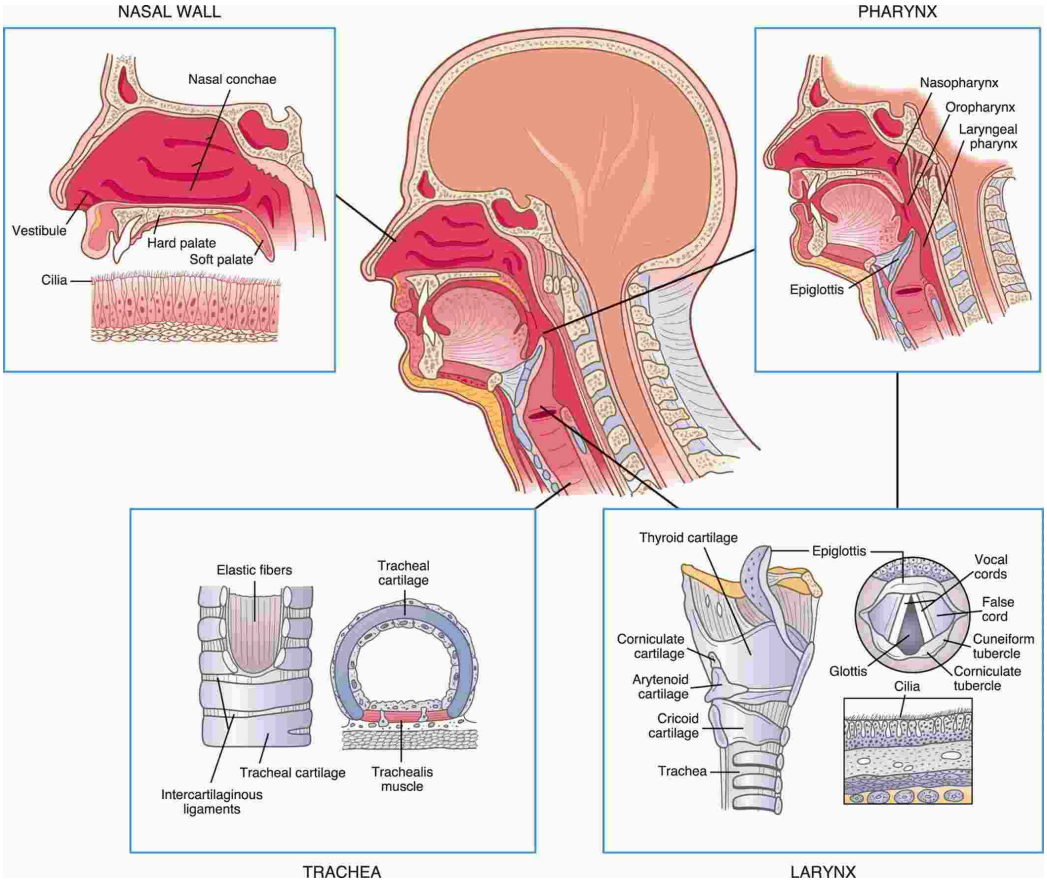

FIG. 34.2 Structures of the Upper Airway.
(Redrawn from Thompson JM, McFarland GK, Hirsch JE, et al. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002.)

An illustration of the left lateral view of a persons head is accompanied by magnified views of the different structures of the upper airway. The illustration of a magnified view of the nasal wall identifies the following structures: vestibule, cilia, hard palate, nasal conchae, and soft palate. The illustration of a magnified view of the pharynx identifies the following structures: nasopharynx, oropharynx, laryngeal pharynx, and epiglottis. The

illustration of a magnified view of the larynx shows a cutaway view and a cross-sectional view, identifying the following structures: thyroid cartilage, corniculate cartilage, arytenoid cartilage, traches, epiglottis, vocal cords, false cord, cuneiform tubercle, corniculate tubercle, glottis, and cilia. The illustration of a magnified view of the trachea shows a cutaway view and a cross-sectional view, identifying the following structures: elastic fibers, intercartilaginous ligaments, tracheal cartilage, and tracheal muscle.

The larynx connects the upper and lower airways and consists of the endolarynx and its surrounding triangular-shaped bony and cartilaginous structures. The endolarynx is formed by two pairs of folds: the false vocal cords (supraglottis) and the true vocal cords. The slit-shaped space between the true cords forms the glottis (see Fig. 34.2). The vestibule is the space above the false vocal cords. The laryngeal box is formed of three large cartilages (epiglottis, thyroid, cricoid) and three smaller cartilages (arytenoid, corniculate, cuneiform) connected by ligaments. The supporting cartilages prevent the collapse of the larynx during inspiration and swallowing. The internal laryngeal muscles control vocal cord length and tension, and the external laryngeal muscles move the larynx as a whole. Both sets of muscles are important to swallowing, ventilation, and vocalization. The internal muscles contract during swallowing to prevent aspiration into the trachea. These muscles also contribute to voice pitch.

The trachea, which is supported by U-shaped cartilage, connects the larynx to the bronchi (sing., bronchus), the conducting airways of the lungs. The trachea branches into two bronchi at the carina (see Fig. 34.1). The carina is very sensitive and, when stimulated, can cause coughing and airway narrowing.[1] The left mainstem bronchus

branches from the trachea at about a 45-degree angle. The right mainstem bronchus is slightly larger and more vertical than the left. Aspirated fluids or foreign particles thus tend to enter the right lung rather than the left. The right and left main bronchi enter the lungs at the hila (sing., hilum), or "roots" of the lungs, along with the pulmonary blood and lymphatic vessels. From the hila, the main bronchi branch into lobar bronchi and then to segmental and subsegmental bronchi, and finally end in the smallest of the conducting airways, the terminal bronchioles (Fig. 34.3). With these multiple divisions, the cross-sectional area of the airways increases to 20 times that of the trachea. This results in a decreased velocity of airflow into the gas-exchange portion of the lung and allows for optimal gas diffusion.

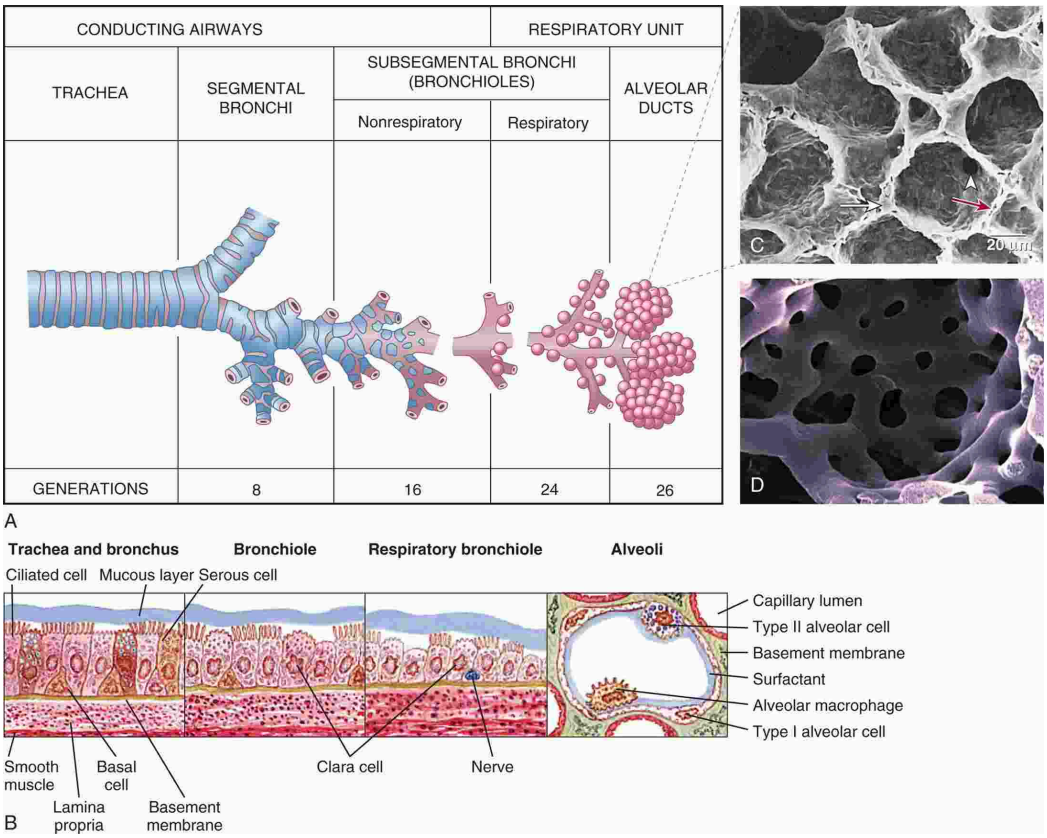

FIG. 34.3 Structures of the Lower Airway. (A) Structures of the lower respiratory airway. (B) Changes in the bronchial wall with progressive branching. Clara (club) cells secrete protective surfactant-type proteins. (C) Electron micrograph of alveoli: long white arrow identifies type II pneumocyte (secretes surfactant); white arrowhead identifies pores of Kohn; red arrow identifies alveolar capillary. (D) Plastic cast of pulmonary capillaries at high magnification. (A, Redrawn from Thompson JM, McFarland GK, Hirsch JE, et al. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002; B, From Wilson SF, Thompson JM. *Respiratory disorders*, St. Louis: Mosby; 1990; C, From Mason RJ, et al. *Murray and Nadel's textbook of respiratory medicine*, 5th edition. Philadelphia: Saunders; 2010; D, Courtesy A. Churg, MD, and J. Wright, MD, Vancouver, Canada. From Leslie, K. O., & Wick, M. R. *Practical pulmonary pathology:*

A diagnostic approach, 2nd ed. Philadelphia: Saunders; 2011.)

Table A shows the differentiation in the conducting airways and the respiratory units. The conducting airway begins with the trachea, branches into segmental bronchi (generation 8), and the nonrespiratory subsegmental bronchi (bronchioles, generation 16). The respiratory unit comprises the respiratory subsegmental bronchi (bronchioles, generation 24) and the alveolar ducts (generation 26). Illustration B shows the structure bronchial wall. • Trachea and bronchus: mucous layer, ciliated cell, serous cell, basement membrane, basal cell, lamina propria, and smooth muscle. • Bronchiole: Clara cell. • Respiratory bronchiole: Clara cell and nerve. • Alveoli: capillary lumen, type 2 alveolar cell, basement membrane, surfactant, alveolar macrophage, and type 1 alveolar cell. Photomicrograph C shows the porous structure of the alveoli. Photomicrograph D shows the network structure of capillaries.

The bronchial walls have three layers: an epithelial lining, a smooth muscle layer, and a connective tissue layer. In the large bronchi, the connective tissue layer contains cartilage. High columnar pseudostratified epithelium lines the larger airways and becomes progressively thinner, changing to columnar cuboidal epithelium in the bronchioles and squamous epithelium in the

alveoli. The epithelial lining of the bronchi contains single-celled mucous-secreting goblet cells and ciliated cells. The goblet cells produce a mucous blanket that protects the airway epithelium. The mucus blanket is composed of periciliary fluid and airway liquid surface layers. When goblet cells detect microbes invading the bronchial tree, they secrete enzymes that improve the ability of the mucus they produce to trap the microbes in the mucous blanket.[2] Ciliated epithelial cells rhythmically beat this mucous blanket toward the trachea and pharynx, where it can be swallowed or expectorated by coughing. Toward the terminal bronchioles, ciliated cells and goblet cells become sparser, and smooth muscle and connective tissue layers thin (see Fig. 34.3).

Gas-Exchange Airways

The conducting airways terminate in the gas-exchange airways, including the respiratory bronchioles, alveolar ducts, and alveoli (sing., alveolus). A cluster of these three structures distal to a single terminal bronchiole is called an acinus (see Figs. 34.1 and 34.3). The alveoli are the primary gas-exchange units of the lung, where oxygen (O_2) enters the blood and carbon dioxide (CO_2) is removed (Fig. 34.4). Tiny passages called *pores of Kohn* permit some air to pass through the septa from alveolus to alveolus, promoting collateral ventilation and even distribution of air among the alveoli. The lungs contain approximately 50 million alveoli at birth and 480 million by adulthood.

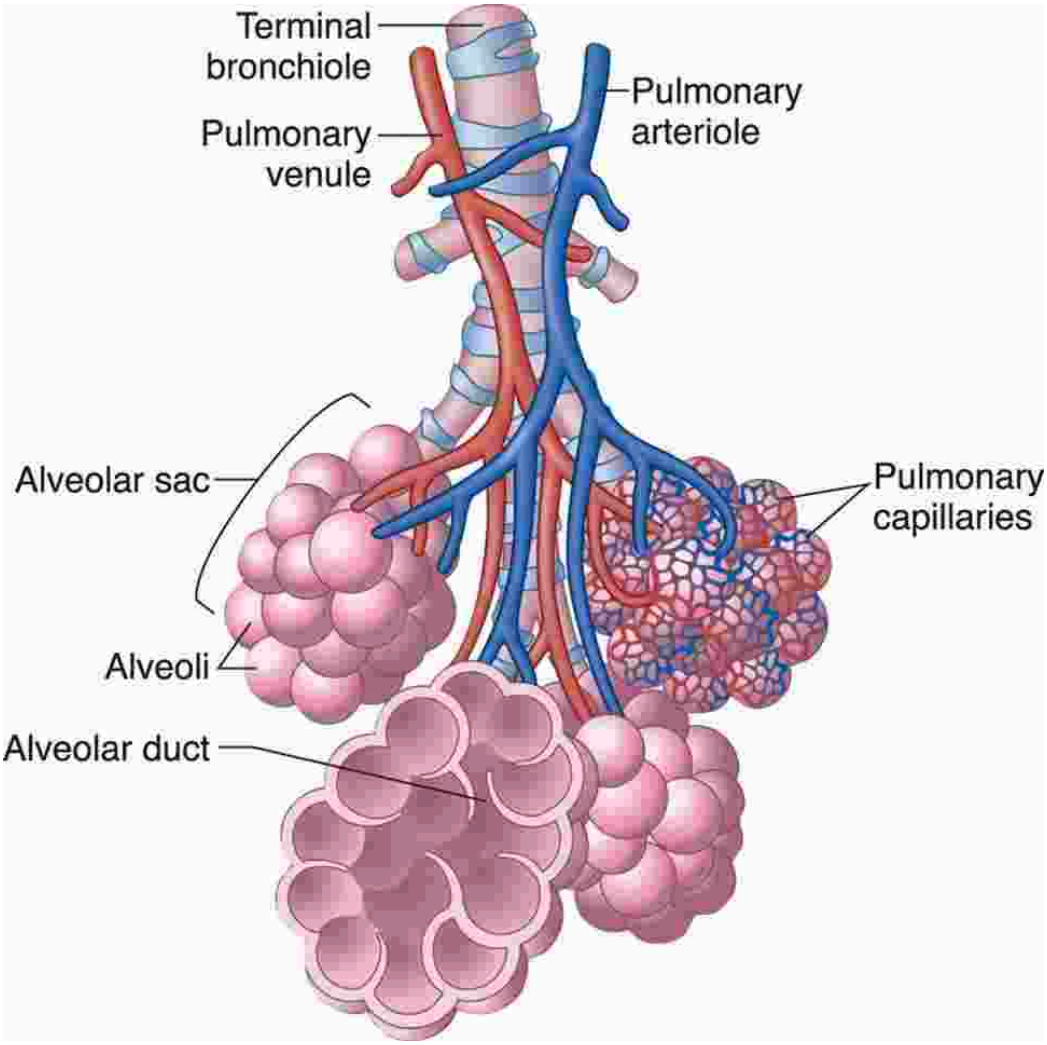

FIG. 34.4 Alveoli.
Bronchioles subdivide to form tiny tubes called alveolar ducts, which end in clusters of alveoli called alveolar sacs. (Modified from Patton KT, Thibodeau GA. *The human body in health & disease*, 6th edition. St. Louis: Mosby; 2014.)

An illustration of the alveoli shows and labels the following structures from the top: terminal bronchiole, pulmonary venule, pulmonary arteriole,

alveolar sac, alveoli, pulmonary capillaries, and alveolar duct.

Alveolar cells provide a protective interface with the environment and are essential for adequate gas exchange, preventing entry of foreign agents, regulating ion and water transport, and maintaining the mechanical stability of the alveoli. The alveolar septa consist of an epithelial layer and a thin, elastic basement membrane but no muscle layer. Two major types of epithelial cells appear in the alveolus. Type I alveolar cells provide structure and are large, thin cells that comprise 95% of the surface across which gas exchange occurs.[3] Type II alveolar cells secrete surfactant, a lipoprotein that coats the inner surface of the alveolus and facilitates its expansion during inspiration, which lowers alveolar surface tension at end-expiration, thereby preventing lung collapse (atelectasis). Surfactant also plays a role in defending against infection.

Macrophages are the most numerous immune cells present in the lung environment and provide defense of the airway from the bronchi to the alveoli. Humans breathe over 10,000 L of non-sterile air per day, and potentially pathogenic microorganisms must be removed in order to prevent infection. In the alveoli, *alveolar macrophages* move through the pores of Kohn and patrol the alveoli, where they detect and ingest inhaled microorganisms without activating neutrophils and other elements of innate immunity.[4] They also provide protection by clearing surfactant from the lung and ingesting foreign materials that reach the alveolus, preparing these substances for removal through the lymphatics.[5] Phagocytosis and the mononuclear phagocyte system are described in Chapters 7 and 8. Surfactant and alveolar macrophages work together with the normal pulmonary microbiota to prevent lower lung infection. Pathogens must overcome these defense mechanisms in order to cause lower respiratory tract infection. Changes in the pulmonary microbiome are associated with many pulmonary diseases (see Emerging Science Box: The Pulmonary Microbiome).

Pulmonary and Bronchial Circulation

The pulmonary circulation facilitates gas exchange, delivers nutrients to lung tissues, acts as a blood reservoir for the left ventricle, and serves as a filtering system that removes clots, air, and other debris from the circulation. The pulmonary vasculature is composed of three compartments connected in series: arteries, capillaries, and veins (Fig. 34.5).

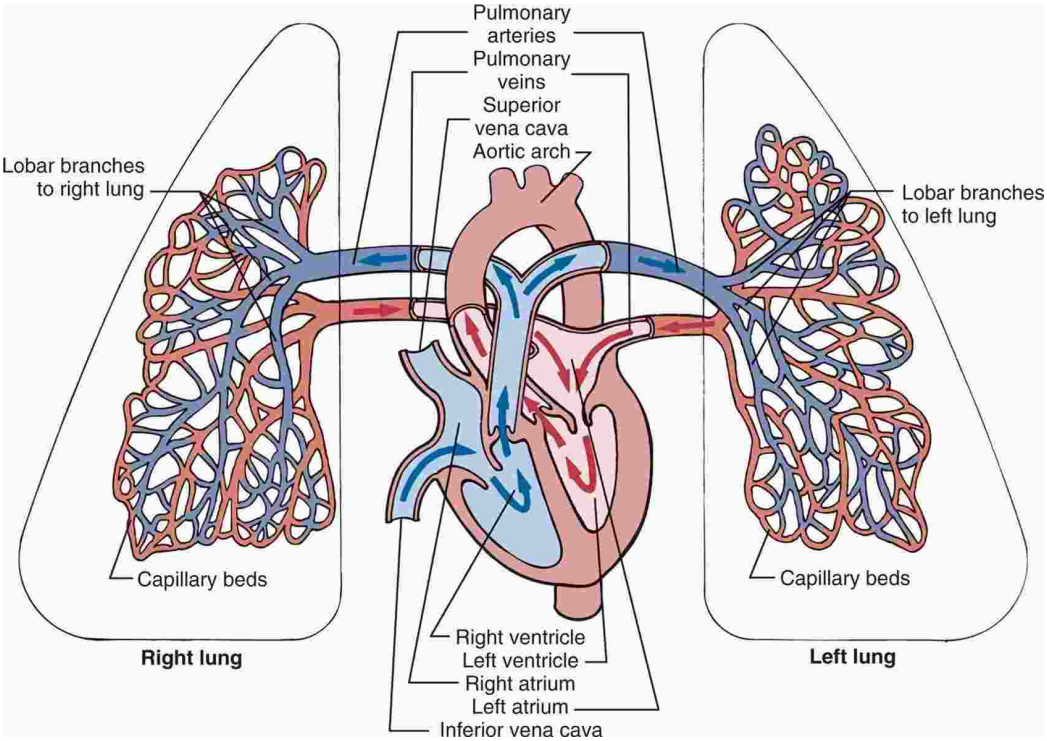

FIG. 34.5 The Pulmonary Circulation.
The right and left pulmonary veins and arteries and the branching capillaries are illustrated. Note the pulmonary artery carries venous blood, and the pulmonary vein carries arterial blood.

An illustration of the left lung, the heart, and the right lung shows the pulmonary circulation. The following structures on the right lung are identified: lobar branches to right lung and capillary beds. The followings structures on the left lung are identified: lobar branches to left lung and capillary beds. The following structures on the heart are identified: pulmonary arteries, pulmonary veins, superior vena cava, aortic arch, right ventricle, left ventricle, right atrium, left atrium, and inferior vena cava. Blood flows from the capillary beds of both lungs into the

heart and from the heart into the pulmonary arteries leading to the lungs.

Although the entire cardiac output from the right ventricle goes into the lungs, the pulmonary circulation has a lower pressure and resistance than the systemic circulation. Pulmonary arteries are exposed to about one-fifth the pressure of the systemic circulation and have a much thinner muscle layer. Pulmonary artery pressure is about 18 mm Hg, compared to 90 mm Hg in the aorta. Usually, about one-third of the pulmonary vessels are filled with blood (perfused) at any given time. More vessels become perfused when right ventricular cardiac output increases. Therefore, increased delivery of blood to the lungs does not normally increase the mean pulmonary artery pressure significantly. During intense exercise, pulmonary arterial pressure may increase as much as 30 to 50 mm Hg, although the threshold above which the diagnosis of exercise pulmonary hypertension has not been fully established.[6] The pulmonary artery divides and enters the lung at the hila, branching with each main bronchus and with all bronchi at every division. Thus, every bronchus and bronchiole has an accompanying artery or arteriole. The arterioles divide at the terminal bronchioles to form a network of pulmonary capillaries around the acinus (see Fig. 34.4). Capillary walls consist of an endothelial layer and a thin basement membrane. The capillary endothelium is composed of two cell types. One type is composed of aerocytes specialized for gas exchange and allows leukocytes to enter the alveolus during inflammation. The other type is termed gCap and is specialized to regulate vasomotor tone and as progenitor cells for capillary repair.[3] The shared alveolar and capillary walls compose the alveolocapillary membrane, a very thin membrane made up of the alveolar epithelium, the alveolar basement membrane, an interstitial space, the capillary basement membrane, and the capillary endothelium (Fig. 34.6). Gas exchange occurs across this membrane. The extremely thin alveolar walls are easily damaged and can leak plasma and blood into the alveolar

space. Any disorder that thickens the membrane impairs gas exchange.

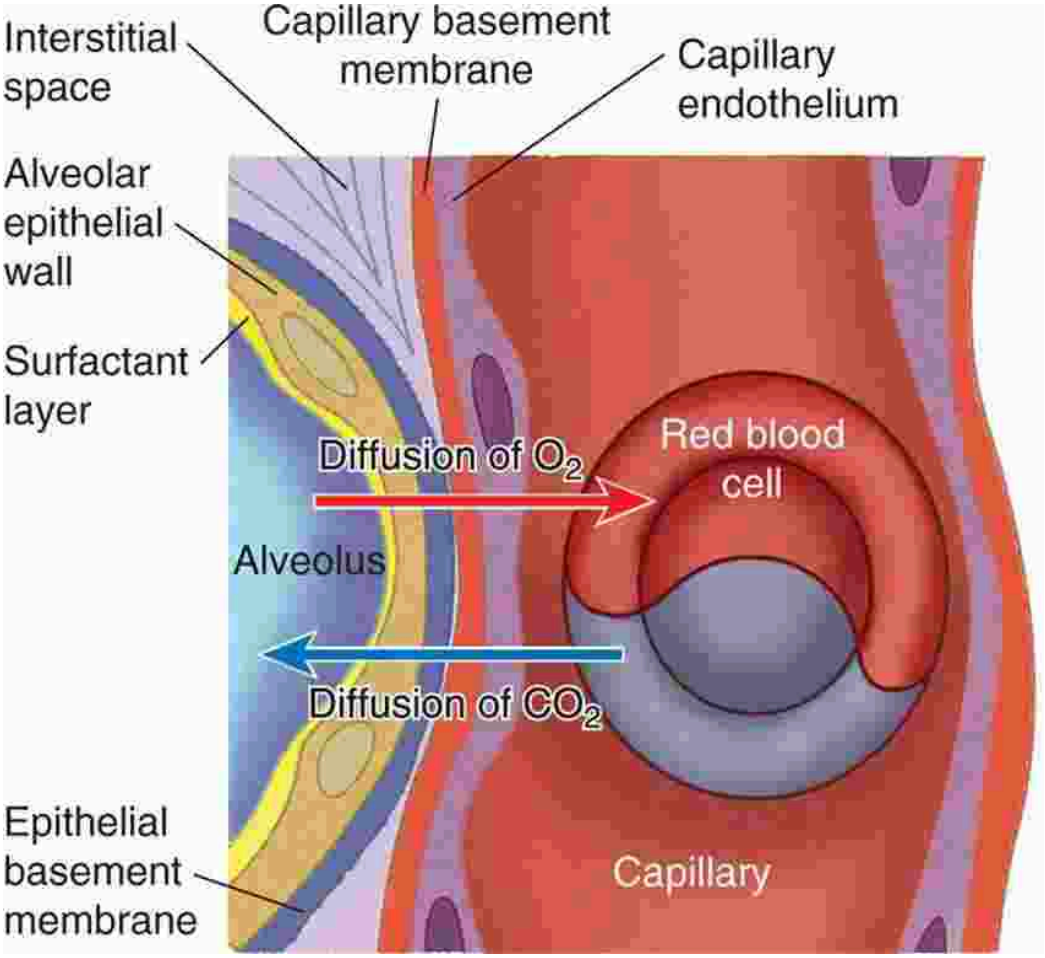

FIG. 34.6 Cross-Section Through an Alveolus Showing Histology of the Alveolar-Capillary Membrane (Respiratory Membrane).
The dense network of capillaries forms an almost continuous sheet of blood in the alveolar walls, providing a very efficient arrangement for gas exchange. CO_2, Carbon dioxide; O_2, oxygen.
(Adapted from Montague SE, Watson R, Herbert R. *Physiology for nursing practice*, 3rd edition. London: Elsevier; 2005.)

An illustration of the cross-section of the alveolus shows and labels the following structures: surfactant layer, alveolar epithelial wall, epithelial basement

membrane, interstitial space, capillary basement membrane, capillary endothelium, capillary, and red blood cell. Diffusion of oxygen is traced from the alveolus to the red blood cell. Diffusion of carbon dioxide is traced from the red blood cell to the alveolus.

Each pulmonary vein drains several pulmonary capillaries. Unlike the pulmonary arteries, which follow the branching bronchi, pulmonary veins are dispersed randomly throughout the lung and then leave the lung at the hila and enter the left atrium. They are similar to veins in the systemic circulation, but they have no valves.

The bronchial circulation is part of the systemic circulation, and it both moistens inspired air and supplies nutrients to the conducting airways, large pulmonary vessels, lymph nodes, and membranes (pleurae) that surround the lungs. The bronchial arteries supply blood to the trachea, bronchi and its branches, esophagus, visceral pleura, the vasa vasorum of the thoracic aorta, and the pulmonary arteries and to the nerves, pulmonary veins, and lymph nodes. The bronchial circulation does not participate in gas exchange.

The lung vasculature also includes deep and superficial pulmonary lymphatic capillaries through which fluid and alveolar macrophages can leave the alveoli to the terminal bronchioles, where they enter the lymphatic system. The superficial lymphatic capillaries drain the membrane that surrounds the lungs. Both deep and superficial lymphatic vessels leave the lung at the hilum through a series of mediastinal lymph nodes; thus many infectious or malignant processes in the lung also affect these nodes.[7] The lymphatic system plays an important role in both providing immune defense and keeping the lung free of fluid. (The lymphatic system is described in Chapter 31.)

Control of the Pulmonary Circulation

The caliber of pulmonary artery lumina decreases as smooth muscle in the arterial walls contracts. Contraction increases pulmonary artery pressure. Caliber increases as these muscles relax, decreasing blood pressure. Contraction (vasoconstriction) and relaxation (vasodilation) primarily occur in response to both local humoral conditions and the autonomic nervous system (ANS), as is the systemic circulation.

The most important cause of pulmonary artery constriction is a low alveolar partial pressure of oxygen (P_AO_2), often termed hypoxic pulmonary vasoconstriction. This results from an increase in intracellular calcium levels in vascular smooth muscle cells in response to a low O_2 concentration and the presence of charged O_2 molecules, called *oxygen radicals*.[8] It can affect only one segment of the lung (i.e., one lobe that is obstructed, decreasing its PAO_2) or the entire lung. If only one segment of the lung is involved, the arterioles to that segment constrict, shunting blood to other, well-ventilated portions of the lung. This reflex improves the lung's efficiency by better matching ventilation and perfusion. If all segments of the lung are affected, however, vasoconstriction occurs throughout the pulmonary vasculature, and pulmonary hypertension (elevated pulmonary artery pressure) can result. The pulmonary vasoconstriction caused by a low P_AO_2 values is reversible if the P_AO_2 level is corrected. Chronic alveolar hypoxia can result in inflammation and structural changes in pulmonary arterioles, causing permanent pulmonary artery hypertension, which eventually leads to right heart failure (cor pulmonale) (see Chapter 35).

Acidemia also causes pulmonary artery constriction. If the acidemia is corrected, the vasoconstriction is reversed. (Respiratory acidosis and metabolic acidosis are described in Chapter 3.) An elevated partial pressure of carbon dioxide (PaCO2) in the arterial blood value without a drop in pH does not cause pulmonary artery constriction. Other biochemical factors that affect the caliber of vessels in the pulmonary circulation are histamine, prostaglandins, endothelin, serotonin, nitric oxide, and bradykinin.

Chest Wall and Pleura

The chest wall (skin, ribs, intercostal muscles) protects the lungs from injury. The intercostal muscles of the chest wall, along with the diaphragm, accessory muscles, and abdominal muscles, perform the muscular work of breathing. The thoracic cavity is contained by the chest wall and encases the lungs (Fig. 34.7). A serous membrane called the pleura adheres firmly to the lungs and then folds over itself and attaches firmly to the chest wall. The membrane covering the lungs is the *visceral pleura;* that lining the thoracic cavity is the *parietal pleura*. The area between the two pleurae is called the pleural space, or pleural cavity. Normally, only a thin layer of fluid secreted by the pleura (pleural fluid) fills the pleural space, lubricating the pleural surfaces and allowing the two layers to slide over each other without separating. Pressure in the pleural space is usually negative or subatmospheric (−4 to −10 mm Hg).

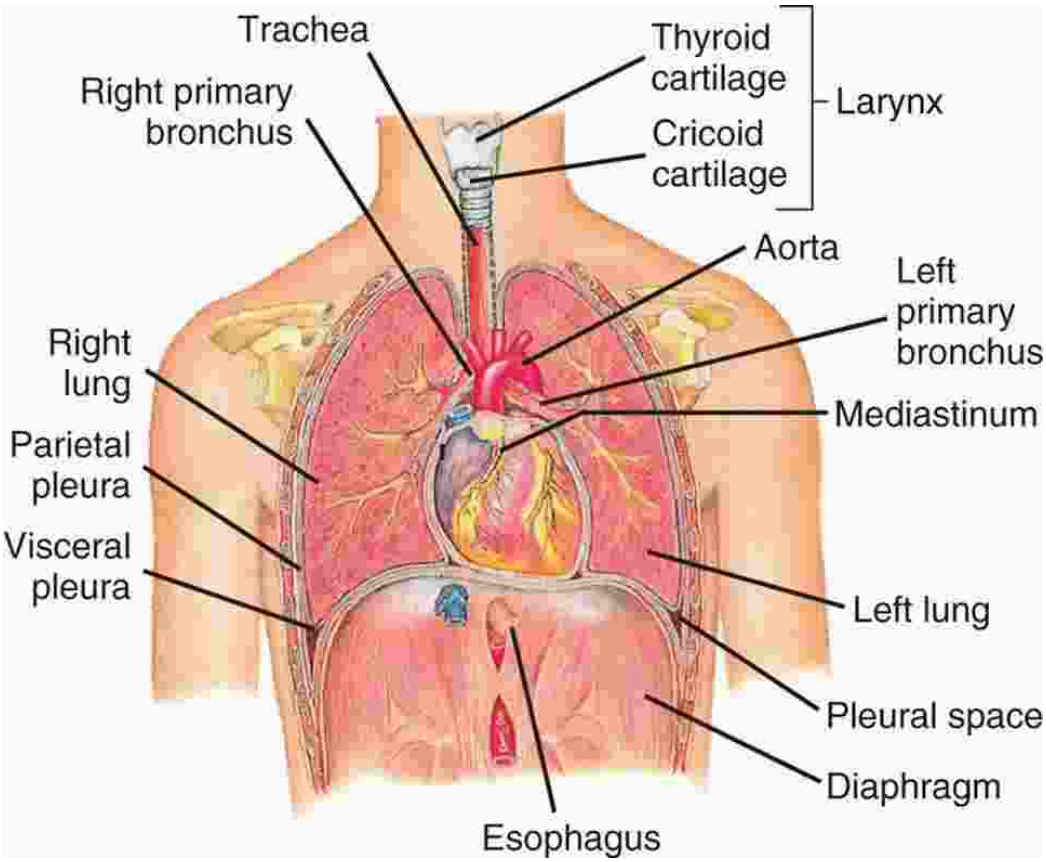

FIG. 34.7 Thoracic (Chest) Cavity and Related Structures.
The thoracic (chest) cavity is divided into three subdivisions (left and right pleural divisions and mediastinum) by a partition formed by a serous membrane called the pleura. (From Thibodeau GA, Patton KT. *Anatomy & physiology*, 3rd edition. St. Louis: Mosby; 1996.)

Function of the Pulmonary System

The pulmonary system (1) ventilates the alveoli, (2) diffuses gases into and out of the blood, and (3) perfuses the lungs so that the organs and tissues of the body receive blood that is rich in O_2 and deficient in CO_2. Each component of the pulmonary system contributes to one or more of these functions (Fig. 34.8).

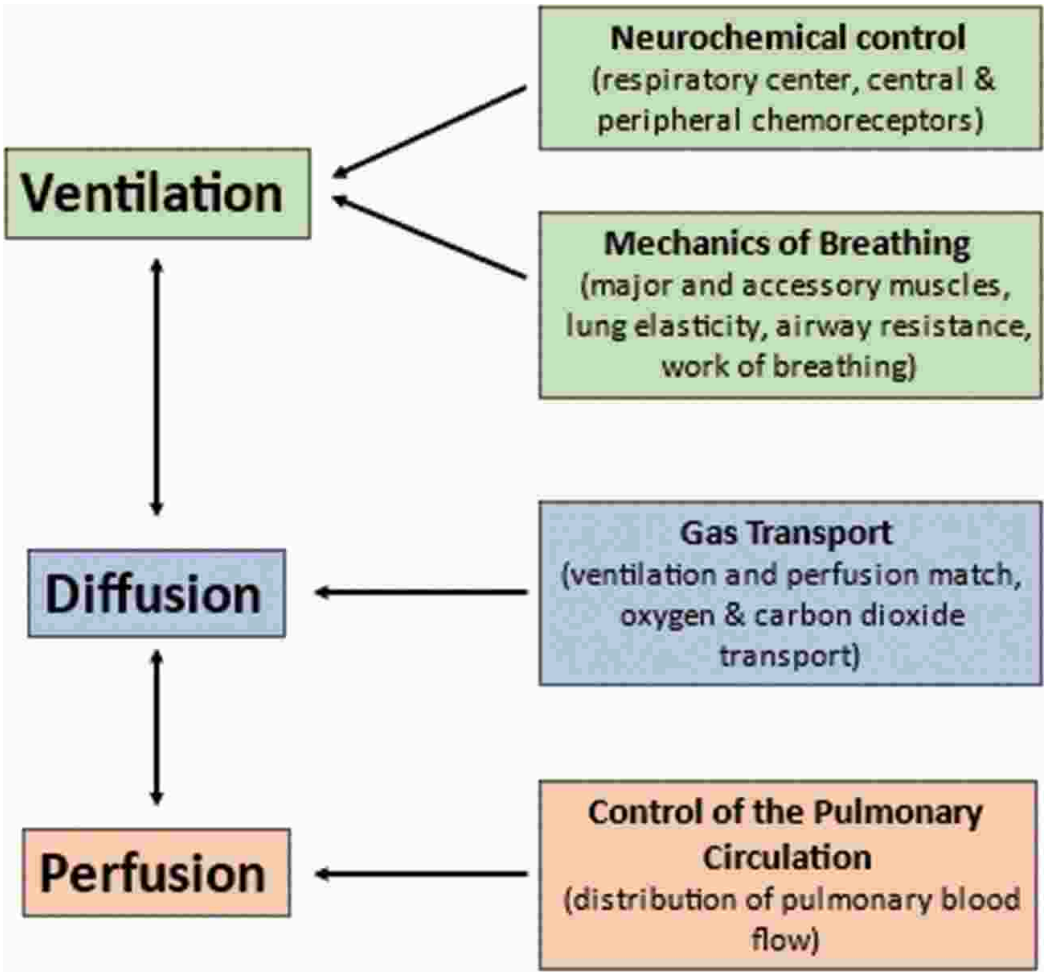

FIG. 34.8 Functional Components of the Respiratory System.

The central nervous system responds to neurochemical stimulation of ventilation and sends signals to the chest wall musculature. The response of the respiratory system to these impulses is influenced by several factors that affect the mechanisms of breathing and, therefore, the adequacy of ventilation. Gas transport between the alveoli and pulmonary capillary blood depends on a variety of physical and chemical activities. Finally, the control of the pulmonary circulation plays a role in the appropriate distribution of blood flow.

A flowchart shows the functional components of the respiratory system. 1. Ventilation (interrelated with 2): Neurochemical control (respiratory center, central and peripheral chemoreceptors) and mechanics of breathing (major and accessory muscles, lung elasticity, airway resistance, and work of breathing. 2. Diffusion (interrelated with 3): Gas transport (ventilation and perfusion match, oxygen and carbon dioxide transport). 3. Perfusion: Control of the pulmonary circulation (distribution of pulmonary blood flow).

Ventilation

Ventilation is the mechanical movement of gas or air into and out of the lungs. It is often misnamed *respiration*, which is actually the exchange of O_2 and CO_2 during cellular metabolism. The "respiratory rate" is actually the ventilatory rate, or the number of times gas is inspired and expired per minute. The volume of ventilation is calculated by multiplying the ventilatory rate (breaths per minute) by the volume or amount of air per breath (liters per breath, or tidal volume). This is called the minute volume (or minute ventilation [$\dot{V}$]) and is expressed in liters per minute. The effective ventilation is calculated by multiplying the ventilatory rate by the tidal volume minus the dead space. Dead-space ventilation (V_D) is the volume of air per breath that does not participate in gas exchange. It is ventilation without perfusion. *Anatomic dead-space* is the volume of air in the conducting airways. *Alveolar dead-space* is the volume of air in unperfused alveoli.

CO_2, the gaseous form of carbonic acid (H_2CO_3), is produced by cellular metabolism. The lung eliminates about 10,000

milliequivalents (mEq) of H_2CO_3 per day in the form of CO_2, which is produced at the rate of approximately 200 mL/min. CO_2 is eliminated to maintain a normal partial pressure of arterial CO_2 ($PaCO_2$) of 40 mm Hg and normal acid-base balance (see Chapter 3 for a discussion of acid-base regulation). Adequate ventilation is necessary to maintain normal $PaCO_2$ levels. Diseases that limit the ventilatory rate or tidal volume, or both, decrease ventilation and result in CO_2 retention. The adequacy of alveolar ventilation *cannot* be accurately determined by observation of the ventilatory rate, pattern, or effort. If a healthcare professional needs to determine the adequacy of ventilation, an arterial blood gas analysis or capnography must be performed to determine if there is CO_2 retention.

Neurochemical Control of Ventilation

Breathing is usually involuntary because homeostatic changes in the ventilatory rate and volume are adjusted automatically by the nervous system to maintain normal gas exchange. Voluntary breathing is necessary for talking, singing, laughing, and deliberately holding one's breath. The mechanisms that control respiration are complex (Fig. 34.9).

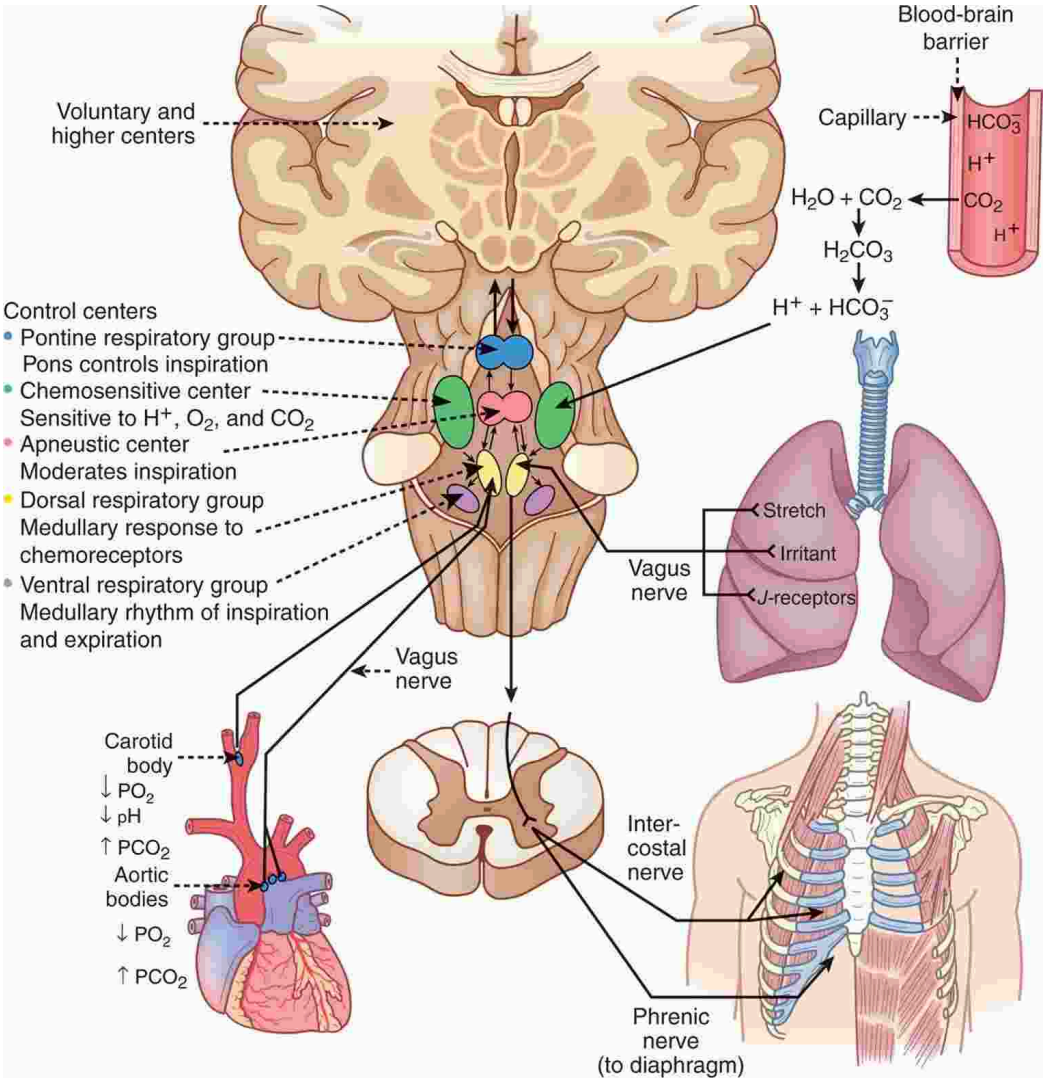

FIG. 34.9 Neurochemical Respiratory Control System. CO_2, Carbon dioxide; H^+, hydrogen; H_2CO_3, carbonic acid; HCO_3^-, bicarbonate; Po_2, partial pressure of oxygen.

An illustration of the brain, capillary, lung, torso, cartilage, and heart shows the neurochemical respiratory control system. The illustration of the capillary shows bicarbonate ions, hydrogen ions, and carbon dioxide. Carbon dioxide from the capillary

mixes with water to form carbonic acid, which breaks down into hydrogen ions and bicarbonate ions. Hydrogen ions acts on chemosensitive center. The illustration of the brain shows the voluntary and higher centers and the control centers. • Pontine respiratory group. Pons controls inspiration. • Chemosensitive center. Sensitive to hydrogen ions, oxygen, and carbon dioxide. • Apneustic center. Moderates inspiration. • Dorsal respiratory group. Medullary response to chemoreceptors. • Ventral respiratory group. Medullary rhythm of inspiration and expiration. An illustration of the lung shows the stretch, irritant, and J-receptors that connect through the vagus nerve to the brain stem. An illustration of the rib cage shows the intercostal nerve and the phrenic nerve (to diaphragm). An illustration of the heart shows the carotid body and the aortic bodies connected to the vagus nerve in the brain. The carotid body relates to decreased partial pressure of oxygen, decreased p H, and increased partial pressure of carbon dioxide. The aortic bodies represent decreased partial pressure of oxygen and increased partial pressure of carbon dioxide.

The respiratory center in the brainstem controls respiration by transmitting impulses to the respiratory muscles, causing them to contract and relax. The respiratory center is composed of several groups of neurons located bilaterally in the brainstem: the pontine

respiratory group (pneumotaxic and apneustic centers), the dorsal respiratory group (DRG), the ventral respiratory group (VRG), the pontine respiratory center, and the apneustic center.

The basic automatic rhythm of respiration is set by the VRG, a cluster of inspiratory nerve cells located in the medulla that sends efferent impulses to the diaphragm and inspiratory intercostal muscles. The DRG receives afferent input from peripheral chemoreceptors in the carotid and aortic bodies; from mechanical, neural, and chemical stimuli; and from receptors in the lungs, and it alters breathing patterns to restore normal blood gases. This is usually accompanied by a sensation of dyspnea (breathing discomfort) (see Emerging Science Box: Silent Hypoxemia in COVID-19). The pontine respiratory group does not generate primary rhythm but, rather, acts as a modifier of the rhythm established by the VRG. Breathing can be modified by input from the cortex, the limbic system, and the hypothalamus, and the pattern of breathing can be influenced by emotion, pain, and disease.

Chemoreceptors

Chemoreceptors monitor the pH, $PaCO_2$, and PaO_2 of arterial blood. Central chemoreceptors are located near the respiratory center and monitor arterial blood indirectly by sensing changes in the pH of cerebrospinal fluid (CSF) (see Fig. 34.9). As CO_2 accumulates in the blood because of decreased ventilation, it diffuses across the blood-brain barrier (the capillary wall separating the blood from the cells of the central nervous system) into the CSF until the partial pressure of CO_2 (PCO_2) is equal on both sides. CO_2 that has entered the CSF combines with water (H_2O) to form H_2CO_3, which subsequently dissociates into hydrogen ions (H^+) that are capable of stimulating acid-activated central chemoreceptors (the retrotrapezoid nucleus).[9]

As the central chemoreceptors sense the decrease in pH, they stimulate the respiratory center to increase the depth and rate of ventilation. Increased ventilation causes the partial pressure of carbon dioxide ($PaCO_2$) in the arterial blood to decrease below that of

the CSF, and CO_2 diffuses out of the CSF, returning its pH to normal. In this way, PaCO2 regulates ventilation through its effect on the pH (hydrogen ion content) of the CSF.

The central chemoreceptors are sensitive to very small changes in the pH of the CSF (equivalent to a 1 to 2 mm Hg change in PCO_2) and can maintain a normal $PaCO_2$ under many different conditions, including strenuous exercise. If inadequate ventilation, or hypoventilation, is long term (e.g., in chronic obstructive pulmonary disease [COPD]), these receptors become insensitive to small changes in $PaCO_2$ ("reset") and regulate ventilation poorly. In addition, prolonged increases in $PaCO_2$ result in renal compensation through bicarbonate (HCO_3^-) retention. This HCO_3^- gradually diffuses into the CSF, where it normalizes the pH and limits the effect on the ventilatory drive.

The peripheral chemoreceptors are located in aortic bodies, the aortic arch, and carotid bodies at the bifurcation of the carotids, near the baroreceptors. They are only somewhat sensitive to changes in pH and instead are sensitive primarily to PaO_2 levels. As the PaO_2 and pH decrease, peripheral chemoreceptors, particularly in the carotid bodies, send signals to the respiratory center to increase ventilation. However, the PaO_2 must drop well below normal (to approximately 60 mm Hg) before the peripheral chemoreceptors have much influence on ventilation. If the pH is decreased as well, ventilation increases much more than it would in response to either abnormality alone. The peripheral chemoreceptors become the major stimulus to ventilation when the central chemoreceptors are reset by chronic hypoventilation.

Lung receptors

Three types of lung sensory receptors send impulses from the lungs to the DRG:

1. Irritant receptors (rapidly adapting receptors) are found in the epithelium of all conducting airways. They are sensitive to

noxious aerosols (vapors), gases, and particulate matter (e.g., inhaled dust), which cause them to initiate the cough reflex. Transient receptor potential (TRP) channels respond to irritant receptor activation and inflammatory stimuli and induce cough via the vagus nerve.[10] When stimulated, irritant receptors also cause bronchoconstriction and increased ventilatory rate. These receptors are located primarily in the proximal larger airways and are nearly absent in the distal airways; thus, it is possible for secretions to accumulate in the distal respiratory tree without initiating cough.

2. Stretch receptors (slowly adapting receptors) are located in the smooth muscles of the airways and are sensitive to increases in the size or volume of the lungs. They decrease the ventilatory rate and volume when stimulated, an occurrence sometimes referred to as the *Hering-Breuer expiratory reflex*. This reflex is active in newborns and assists with ventilation. In adults, this reflex is active only at high tidal volumes (e.g., with exercise and mechanical ventilation) and may protect against excess lung inflation.
3. Pulmonary C-fiber receptors (also known as *J-receptors* [juxtapulmonary capillary receptors]) are located near the capillaries in the alveolar septa and in other airway locations as nociceptors. They are sensitive to increased pulmonary capillary pressure, which stimulates them to initiate rapid, shallow breathing; laryngeal constriction on expiration; and mucus secretion; hypotension; and bradycardia. They may be associated with the sensation of dyspnea.[11]

Autonomic nervous system

The lung is innervated by the ANS (The structures and function of the ANS are discussed in detail in Chapter 15). Fibers of the sympathetic division of the ANS in the lung branch out from the upper thoracic and cervical ganglia (stellate ganglia) of the spinal cord. The primary sympathetic neurotransmitter in the lung is

norepinephrine. Fibers of the parasympathetic division of the ANS travel in the vagus nerve to the lung, where they release acetylcholine. The parasympathetic and sympathetic divisions of the ANS control airway caliber (interior diameter of the airway lumen) by stimulating the bronchial smooth muscle to contract or relax. Bronchial smooth muscle tone depends on equilibrium, that is, equal stimulation of contraction and relaxation. The sympathetic nervous system's release of norepinephrine stimulates airway β-adrenergic receptors causing airway smooth muscle to relax (bronchodilation). The parasympathetic nervous system's release of acetylcholine stimulates two types of muscarinic receptors in the lung, M_2 and M_3. Stimulation of M_2 receptors limits the further release of acetylcholine, whereas stimulation of M_3 receptors causes airway smooth muscle to contract (bronchoconstriction) and increases mucous secretion. M_3 activation and associated bronchoconstriction occur if receptors in the airway epithelium are stimulated by irritants in inspired air, by inflammatory mediators (e.g., histamine, serotonin, prostaglandins, leukotrienes), by many drugs, and by humoral substances.[12] Muscarinic receptor antagonists are used to promote bronchodilation and reduce mucous secretion in conditions such as asthma and COPD (see Chapter 35).[13]

Mechanics of Breathing

The mechanical aspects of inspiration and expiration are known collectively as the *mechanics of breathing* and involve (1) major and accessory muscles of inspiration and expiration, (2) elastic properties of the lungs and chest wall, and (3) resistance to airflow through the conducting airways. Alterations in any of these properties increase the work of breathing or the metabolic energy needed to achieve adequate ventilation and oxygenation of the blood.

Major and accessory muscles

The major muscles of inspiration are the diaphragm and the external intercostal muscles (muscles between the ribs) (Fig. 34.10). The diaphragm is the primary muscle of ventilation and provides the

anatomic separation between the thorax and the abdomen. It is a dome-shaped muscle that separates the abdominal and thoracic cavities. It has multiple intrathoracic attachments and is innervated by the paired phrenic nerves. When it contracts and flattens downward, it increases the volume of the thoracic cavity, creating a negative pressure that draws gas into the lungs through the upper airways and trachea. The phrenic nerves have both sensory and motor functions. They originate from the C3 to C5 spinal nerves and descend through the thorax to innervate the right and left hemidiaphragms. They provide sensory input from the pleura and upper peritoneum. They provide the only motor innervation of the diaphragm and are essential for stimulating adequate ventilation. Trauma to the cervical spine above C4, central nervous system disorders, neuropathies, and neuromuscular diseases (see Chapter 18) may lead to diaphragmatic paralysis and respiratory failure.[14] The right and left phrenic nerves pass close to the right hilum and left hila of the lung, respectively, and may be impacted by diseases such as tumors or trauma that damage the hilar regions causing hemiparalysis of the diaphragm. Prolonged mechanical ventilation can inhibit the function of the phrenic nerve making it more difficult to return to normal ventilation.[15] Contraction of the external intercostal muscles elevates the anterior portion of the ribs and increases the volume of the thoracic cavity by increasing its front-to-back (anterior-posterior [AP]) diameter. Although the external intercostal muscles may contract during quiet breathing, inspiration at rest is usually assisted by the diaphragm only.

FIG. 34.10 Muscles of Ventilation.
(A) Anterior view. (B) Posterior view. (Modified from Thompson JM, McFarland GK, Hirsch JE, et al. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002.)

Illustration A is the anterior view of the muscles in the rib cage. The following structures are labeled: scalenus muscles, sternocleidomastoid, intercostal muscles, pectoralis minor, serratus anterior, and rectus abdominis. Illustration B is the posterior view of the muscles in the rib cage. The following structures are labeled: serratus posterior superior, intercostal muscles, diaphragm, serratus posterior inferior, and transversus thoracis.

The accessory muscles of inspiration are the sternocleidomastoid and scalene muscles. Like the external intercostal muscles, these muscles enlarge the thorax by increasing its AP diameter. The accessory muscles assist inspiration when the minute volume (volume of air inspired and expired per minute) is very high, such as during strenuous exercise or when the work of breathing is increased because of disease. The accessory muscles do not increase the volume of the thorax as efficiently as the diaphragm does.

There are no major muscles of expiration because normal, relaxed expiration is passive and requires no muscular effort. The accessory muscles of expiration, the abdominal and internal intercostal muscles, assist expiration when the minute volume is high, during coughing, or when airway obstruction is present. When the abdominal muscles contract, intra-abdominal pressure increases, pushing up the diaphragm and decreasing the volume of the thorax. The internal intercostal muscles pull down the anterior ribs, decreasing the AP diameter of the thorax.

Alveolar surface tension

Surface tension occurs at any gas-liquid interface and refers to the tendency for liquid molecules that are exposed to air to adhere to one another. This phenomenon can be seen in the way liquids "bead" when splashed on a waterproof surface.

Within a sphere, such as an alveolus, surface tension tends to make expansion difficult. According to the law of Laplace, the pressure *(P)* required to inflate a sphere is equal to two times the surface tension (2 *T*) divided by the radius *(r)* of the sphere, or $P = 2\ T/r$. As the radius of the sphere (or alveolus) becomes smaller, more and more pressure is required to inflate it. If the alveoli were lined with a water-like fluid, taking breaths would be extremely difficult.

Alveolar ventilation, or distention, is made possible by surfactant, which lowers the surface tension by coating the air-liquid interface in the alveoli. Surfactant, a lipoprotein (90% lipids and 10% protein) produced by type II alveolar cells, includes two groups of surfactant proteins. One group consists of small hydrophobic molecules called surfactant B and C that have a detergent-like effect that separates the liquid molecules, thereby decreasing alveolar surface tension. These surfactant proteins line the alveolar side of the alveolocapillary membrane and, in effect, reverse the law of Laplace. As the radius of a surfactant-lined sphere (alveolus) becomes smaller, the surface tension *decreases*, and as the radius grows larger, the surface tension *increases*. This occurs because the surfactant molecules have much weaker intermolecular attraction than do liquid molecules. The surfactant molecules occupy most of the air-fluid interface and disrupt the intermolecular forces that tend to collapse the alveoli. Therefore, the alveoli are much easier to inflate at low lung volumes (i.e., after expiration) than at high volumes (i.e., after inspiration). The decrease in surface tension caused by surfactant also is responsible for keeping the alveoli free of fluid. If surfactant is not produced in adequate quantities, alveolar surface tension increases, causing alveolar collapse, decreased lung expansion, increased work of breathing, and severe gas-exchange abnormalities. Surfactant

replacement therapy is used for a number of pulmonary diseases in which alveolar collapse (atelectasis) occurs.[16]

The other group of surfactant proteins is crucial in lung defense. Surfactant proteins A and D contribute to the control of lung inflammation by decreasing the release of proinflammatory mediators, preventing oxidative injury, and regulating the role of fibroblasts in airway remodeling.[17] These surfactant proteins have important antimicrobial effects, and defects in these proteins are linked to several lung disorders, including pneumonia, asthma, and COPD.[18]

Elastic properties of the lung and chest wall

The lung and chest walls have elastic properties that permit expansion during inspiration and return to resting volume during expiration. The elasticity of the lungs is caused both by elastin fibers in the alveolar walls surrounding the small airways and pulmonary capillaries and by surface tension at the alveolar air-liquid interface. The elasticity of the chest wall is the result of the configuration of its bones and musculature.

Elastic recoil is the tendency of the lungs to return to the resting state after inspiration. Normal elastic recoil permits passive expiration, eliminating the need for major muscles of expiration. Passive elastic recoil may be insufficient during labored breathing (high minute volume) when the accessory muscles of expiration may be needed. The accessory muscles are also used if disease compromises elastic recoil (e.g., in emphysema) or blocks the conducting airways.

Normal elastic recoil depends on an equilibrium between opposing forces of recoil in the lungs and chest wall. Under normal conditions, the chest wall tends to recoil by expanding outward. When the sternum is split to open the thoracic cavity, the chest wall moves outward laterally. The tendency of the chest wall to recoil by expanding is balanced by the tendency of the lungs to recoil or inward collapse around the hila. This reaction is caused by elastic

recoil and surface tension in the alveoli. The opposing forces of the chest wall and lungs create the small negative intrapleural pressure.

A balance between the outward recoil of the chest wall and the inward recoil of the lungs occurs at the resting level, at the end of expiration. During inspiration, the diaphragm and intercostal muscles contract, air flows into the lungs, and the chest wall expands. Muscular effort is needed to overcome the resistance of the lungs to expansion. During expiration, the muscles relax, and the elastic recoil of the lungs causes the thorax to decrease in volume until a balance between the chest wall and lung recoil forces is reached (Fig. 34.11).

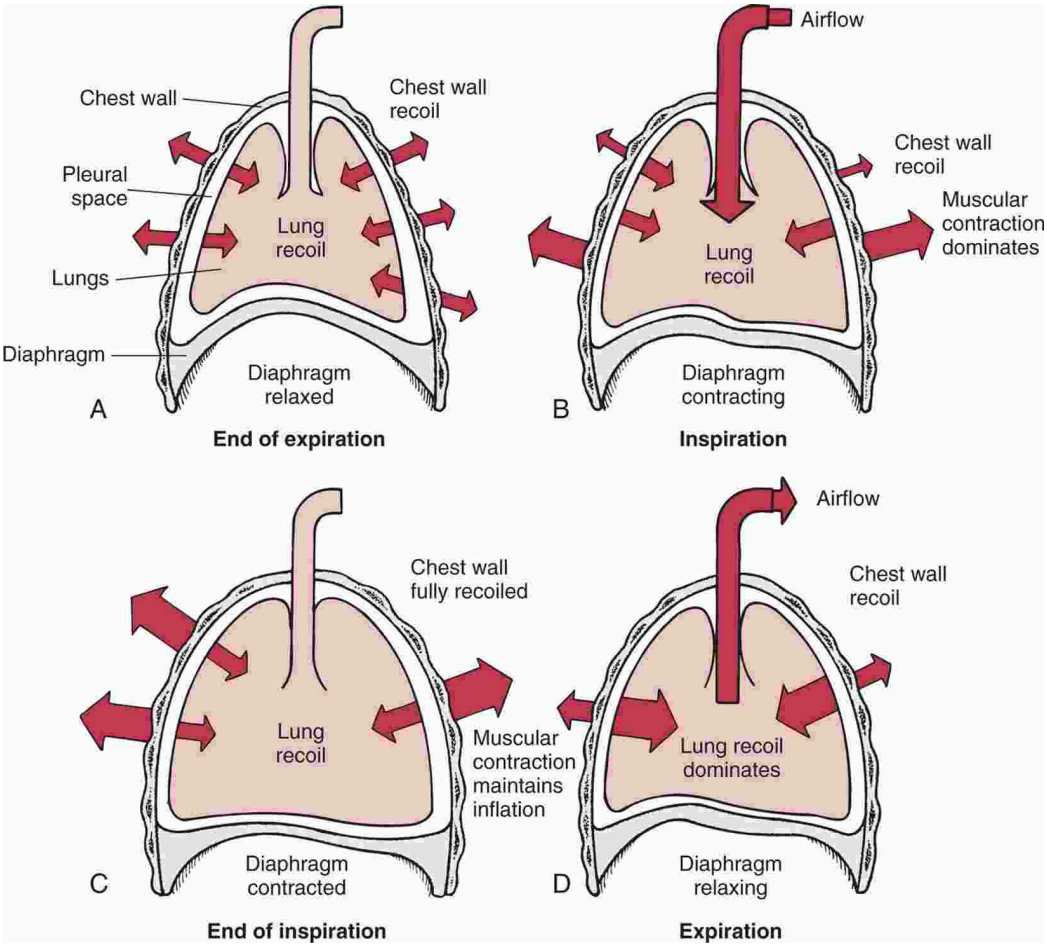

FIG. 34.11 Interaction of Forces During Inspiration and Expiration.
(A) Outward recoil of the chest wall equals inward recoil of the lungs at the end of expiration. (B) During inspiration, contraction of respiratory muscles, assisted by chest wall recoil, overcomes the tendency of lungs to recoil. (C) At the end of inspiration, respiratory muscle contraction maintains lung expansion. (D) During expiration, respiratory muscles relax, allowing elastic recoil of the lungs to deflate the lungs.

Four illustrations, A, B, C, and D, shoe interaction of forces during inspiration and expiration. Illustration A represents the end of expiration. The chest wall,

pleural space, lungs, and diaphragm are identified. The diaphragm is relaxed. Chest wall recoil is traced along the wall both inward and outward. Illustration B represents inspiration. The air flows into the lungs and expands the chest as the muscular contraction dominates. The diaphragm is contracting. Chest wall recoil is outward and minimal; muscular contraction dominates; and lung recoil is medium. Airflow is inward. Illustration C represents end of inspiration. The lung is fully inflated, the diaphragm is contracted, and the muscular contraction maintains inflation. Chest wall is fully recoiled. Illustration D represents expiration. The air flows out of the lung as the lung recoil dominates. Chest wall recoil is minial. Airflow is outward.

Compliance is the measure of lung and chest wall distensibility and is defined as volume change per unit of pressure change. It represents the relative ease with which these structures can be stretched and is, therefore, the opposite of elasticity. Compliance is determined by the alveolar surface tension and the elastic recoil of the lung and chest wall.

Increased compliance indicates that the lungs or chest wall is abnormally easy to inflate and has lost some elastic recoil. A decrease in compliance indicates that the lungs or chest wall is abnormally stiff or difficult to inflate. Compliance increases with normal aging and with disorders such as emphysema; it decreases in individuals with acute respiratory distress syndrome, pneumonia, pulmonary edema, and fibrosis. (These disorders are described in Chapter 35.)

Airway resistance

Airway resistance, which is similar to resistance to blood flow (described in Chapter 31), is determined by the length, radius, and cross-sectional area of the airways and by the density, viscosity, and velocity of the gas (Poiseuille's law). Resistance is computed by dividing the change in pressure (P) by the rate of flow (F), or $R = P/F$ (Ohm's law), and can easily be measured in the pulmonary function laboratory. Airway resistance is normally very low. One-half to two-thirds of total airway resistance occurs in the nose. The next highest resistance is in the oropharynx and larynx. Airway resistance also is affected by the diameter of the airways, and there is very little resistance in the conducting airways of the lungs because of their large cross-sectional area. Bronchodilation, which decreases resistance to airflow, is caused by β_2-adrenergic receptor stimulation. Bronchoconstriction, which increases airway resistance, can be caused by the stimulation of parasympathetic receptors in the bronchial smooth muscle and by numerous irritants and inflammatory mediators. Airway resistance can also be increased by edema of the bronchial mucosa and by airway obstructions, such as mucus, tumors, or foreign bodies. Pulmonary function tests (PFTs) measure lung volumes and flow rates and can be used to measure airway resistance and help diagnose certain lung diseases (see Tests of Pulmonary Function section).

Work of breathing

The work of breathing is determined by the muscular effort (and therefore oxygen and energy) required for ventilation. Normally very low, the work of breathing may increase considerably in diseases that disrupt the equilibrium between forces exerted by the lung and chest wall. More muscular effort is required when lung compliance decreases (e.g., in pulmonary edema), chest wall compliance decreases (e.g., in spinal deformity or obesity), or airways are obstructed by bronchospasm or mucous plugging (e.g., in asthma or bronchitis). An increase in the work of breathing can

result in a marked increase in O_2 consumption and an inability to maintain adequate ventilation.

Gas Transport

Gas transport is the delivery of O_2 to the cells of the body and the removal of CO_2. Delivery of O_2 has four steps: (1) ventilation of the lungs, (2) diffusion of O_2 from the alveoli into the capillary blood, (3) perfusion of systemic capillaries with oxygenated blood, and (4) diffusion of O_2 from systemic capillaries into the cells. Steps in the transport of CO_2 occur in reverse order: (1) diffusion of CO_2 from the cells into the systemic capillaries, (2) perfusion of the pulmonary capillary bed by venous blood, (3) diffusion of CO_2 into the alveoli, and (4) removal of CO_2 from the lung by ventilation. If any step in gas transport is impaired by a respiratory or cardiovascular disorder, gas exchange at the cellular level is compromised.

Measurement of Gas Pressure

The properties of air, once it enters the body, are determined by interactions among gas molecules at a given temperature. The millions of gas molecules are moving randomly, colliding with each other and with the wall of the space in which they are contained. These collisions exert pressure. If the same number of gas molecules is contained in a small and a large container, the pressure is greater in the small container because more collisions occur in the smaller space (Fig. 34.12). Heat increases the speed of the molecules, which increases the number of collisions and, therefore, the pressure.

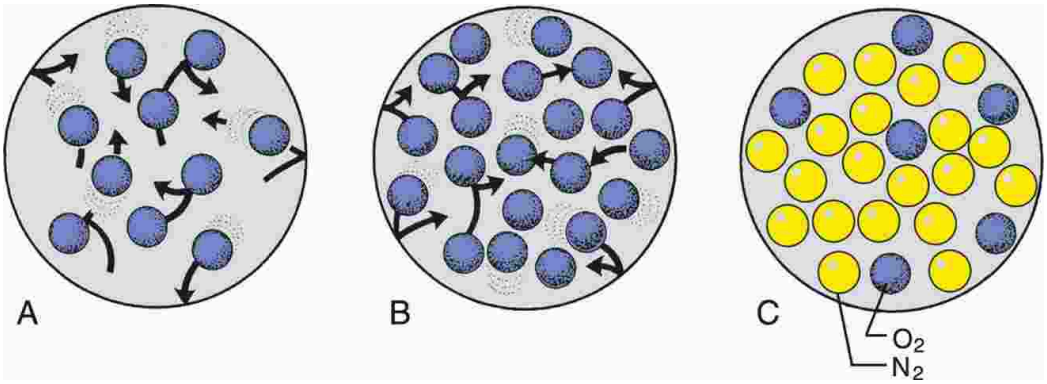

FIG. 34.12 Relationship Between Number of Gas Molecules and Pressure Exerted by the Gas in an Enclosed Space.
(A) Theoretically, 10 molecules of the same gas exert a total pressure of 10 mm Hg within the space. (B) If the number of molecules is increased to 20, the total pressure is 20 mm Hg. (C) If there are different gases in the space, each gas exerts a partial pressure: here, the partial pressure of nitrogen *(yellow)* is 18, the partial pressure of oxygen *(blue)* is 6, and the total pressure is 24 mm Hg.

Illustration A shows ten oxygen molecules in an enclosed space moving in different directions. Illustration B shows twenty oxygen molecules in an enclosed space moving in different directions. Illustration C shows six oxygen molecules and nineteen nitrogen molecules packed in an enclosed space.

Barometric pressure (P_B) (atmospheric pressure) is the pressure exerted by gas molecules in air at specific altitudes. At sea level, barometric pressure is 760 mm Hg, which is the sum of the pressures

exerted by each gas in the air at sea level. The portion of the total pressure exerted by any individual gas is its partial pressure. At sea level, the air consists of O_2 (20.9%), nitrogen (78.1%), and a few other trace gases. The partial pressure of oxygen (PO_2) is equal to the percentage of O_2 in the air (20.9%) times the total P_B (760 mm Hg at sea level), or 159 mm Hg. At higher elevations, the P_B falls, and the amount of gases in the air decreases.

The amount of water vapor contained in a gas mixture is determined by the temperature of the gas and is unrelated to the barometric pressure. Gas that enters the lungs becomes saturated with water vapor (humidified) as it passes through the upper airway. At body temperature (37°C [98.6°F]), water vapor exerts a pressure of 47 mm Hg regardless of the total P_B. The partial pressure of water vapor (PH2O) must be subtracted from the P_B before the partial pressure of other gases in the mixture can be determined. In air saturated with water at sea level, the partial pressure of oxygen is (760 − 47) × 0.209 = 149 mm Hg. All pressure and volume measurements made in pulmonary function laboratories specify the temperature and humidity of a gas at the time of measurement.

The percentage of O_2 in the inspired air is equal to the PO_2 (20.9%) and is called the fraction of inspired oxygen (FiO_2) in room air. The adequacy of ventilation to deliver O_2 to the alveoli cannot be measured directly but can be estimated by measuring the removal of CO_2 from the blood, as calculated by dividing the $PaCO_2$ by the respiratory quotient. The respiratory quotient describes the relationship between ventilation and perfusion of the lung and is considered to be 0.8.

The amount of oxygen in the alveoli (PAO2) depends on the barometric pressure, the water vapor pressure, the amount of oxygen in the inspired air, the adequacy of ventilation as measured by the PaCO2, and the respiratory quotient. The calculation of PAO2 using these parameters is called the alveolar gas equation:PAO2 = (PB − PH2O) × FiO2 − (PaCO2/respiratory quotient). For example, at sea level in an individual with normal ventilation, the amount of

oxygen in the alveoli available for gas diffusion into the blood is calculated as $PAO_2 = (760 - 47) \times 0.209 - (40/0.8) = 99$ mm Hg (Fig. 34.13). Different values for PAO_2 can be calculated if there are changes in the inspired oxygen content or the $PaCO_2$, which are common occurrences in clinical settings. All pressure and volume measurements made in pulmonary function laboratories specify the temperature and humidity of a gas at the time of measurement. Symbols used in the measurement of gas pressures and pulmonary ventilation are defined in Table 34.2.

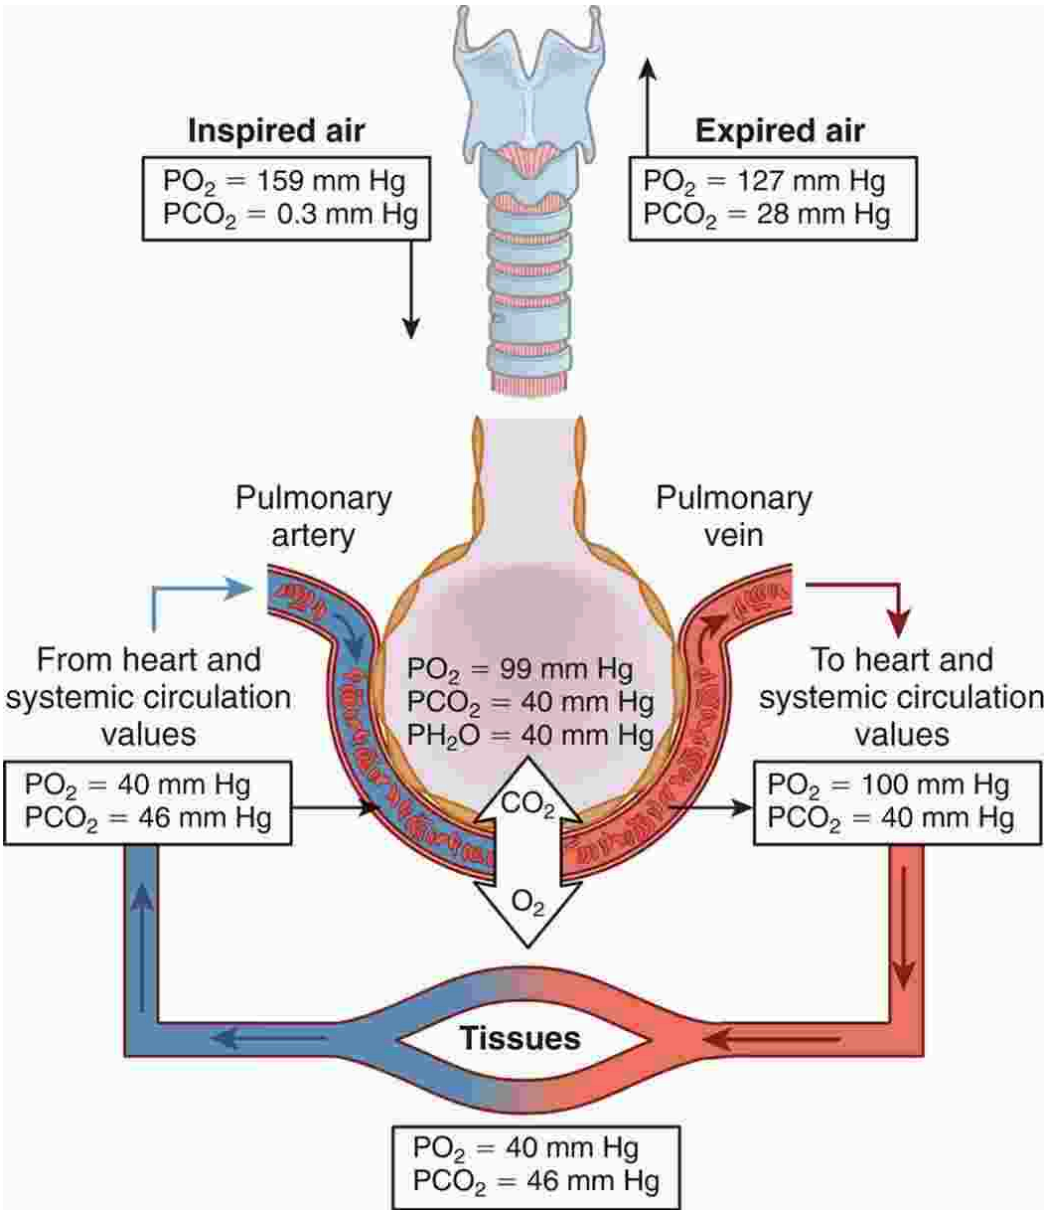

FIG. 34.13 Partial Pressure of Respiratory Gases in Normal Respiration. The numbers shown are average values near sea level. (Modified from Thompson JM, McFarland GK, Hirsch JE, et al. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002.)

An illustration shows the partial pressure of respiratory gasses in normal respiration. Alveoli pressure quantities are as follows: partial pressure of

oxygen at 99 millimeters of mercury, partial pressure of carbon dioxide at 40 millimeters of mercury, and partial pressure of water at 40 millimeters of mercury. Inspired air (partial pressure of oxygen equals 159 millimeters of mercury and partial pressure of carbon dioxide equals 0.3 millimeters of mercury) flows into the respiratory system. Expired air (partial pressure of oxygen equals 127 millimeters of mercury and partial pressure of carbon dioxide equals 28 millimeters of mercury) flows out of the respiratory system. Blood flows from heart (systemic circulation values: partial pressure of oxygen equals 40 millimeters of mercury and partial pressure of carbon dioxide equals 46 millimeters of mercury) through the pulmonary vein to the heart (partial pressure of oxygen equals 100 millimeters of mercury and partial pressure of carbon dioxide equals 40 millimeters of mercury) to the tissues (partial pressure of oxygen equals 40 millimeters of mercury and partial pressure of carbon dioxide equals 46 millimeters of mercury) and back to the heart.

Table 34.2

Common Pulmonary Abbreviations

Symbol[a]	Definition
V	Volume or amount of gas
Q	Perfusion or blood flow
P	Pressure (usually partial pressure) of a gas
PiO_2	Partial pressure of inspired oxygen (varies with altitude)
PaO_2	Partial pressure of oxygen in arterial blood
PAO_2	Partial pressure of oxygen in alveolar blood
$PaCO_2$	Partial pressure of carbon dioxide in arterial blood
PH_2O	Partial pressure of water vapor
PN_2	Partial pressure of nitrogen
PvO_2	Partial pressure of oxygen in mixed venous or pulmonary artery blood
$P(A–a)O_2$	Difference between alveolar and arterial partial pressure of oxygen (A–a gradient)
P_B	Barometric or atmospheric pressure
SaO_2	Saturation of hemoglobin (in arterial blood) with oxygen
$S\bar{v}0_2$	Saturation of hemoglobin (in mixed venous blood)
V_A	Alveolar ventilation—effective total lung capacity
V_D	Dead-space ventilation
V_E	Minute capacity

Symbol[a]	Definition
V_T	Tidal volume or average breath
$\dot{V}/\dot{Q}$	Ratio of ventilation to perfusion
FiO_2	Fraction (percent) of inspired oxygen (0.21)
FRC	Functional residual capacity
FVC	Forced vital capacity
FEV_1	Forced expiratory volume in 1 second
ERV	Expiratory reserve volume
IRV	Inspiratory reserve volume
IC	Inspiratory capacity

Symbol[a]	Definition
V	Volume or amount of gas
Q	Perfusion or blood flow
P	Pressure (usually partial pressure) of a gas
P_{IO_2}	Partial pressure of inspired oxygen (varies with altitude)
P_{aO_2}	Partial pressure of oxygen in arterial blood
P_{AO_2}	Partial pressure of oxygen in alveolar blood
P_{aCO_2}	Partial pressure of carbon dioxide in arterial blood
P_{H_2O}	Partial pressure of water vapor
P_{N_2}	Partial pressure of nitrogen
$P_{\bar{v}O_2}$	Partial pressure of oxygen in mixed venous or pulmonary artery blood
$P(A–a)O_2$	Difference between alveolar and arterial partial pressure of oxygen (A–a gradient)
P_B	Barometric or atmospheric pressure
Sa_{O_2}	Saturation of hemoglobin (in arterial blood) with oxygen
$S\bar{v}0_2$	Saturation of hemoglobin (in mixed venous blood)
V_A	Alveolar ventilation—effective total lung capacity
V_D	Dead-space ventilation
V_E	Minute capacity
V_T	Tidal volume or average breath
$\dot{V}/\dot{Q}$	Ratio of ventilation to perfusion
F_{IO_2}	Fraction (percent) of inspired oxygen (0.21)
FRC	Functional residual capacity
FVC	Forced vital capacity
FEV_1	Forced expiratory volume in 1 second
ERV	Expiratory reserve volume
IRV	Inspiratory reserve volume
IC	Inspiratory capacity

[a]Subscripts identify the particular gas, volume, or pressure being discussed. An overhead dot, such as in $\dot{V}/\dot{Q}$, means measurement over time, usually 1 minute.

Distribution of Ventilation and Perfusion

Effective gas exchange depends on an approximately even distribution of gas (ventilation) and blood (perfusion) in all portions of the lungs. The lungs are suspended from the hila in the thoracic cavity. When an individual is in an upright position (sitting or standing), gravity pulls the lungs down toward the diaphragm and compresses their lower portions, or bases. The alveoli in the upper portions, or apices, of the lungs contain a greater residual volume of gas and are larger and less numerous than those in the lower portions. Because surface tension increases as the alveoli become larger, the larger alveoli in the upper portions of the lung are more

difficult to inflate (less compliant or less distensible) than the smaller alveoli in the lower portions of the lung. Therefore, during ventilation, most of the tidal volume is distributed to the bases of the lungs, where compliance is greater.

The heart pumps against gravity to perfuse the pulmonary circulation. As blood is pumped into the lung apices of a sitting or standing individual, some blood pressure is dissipated in overcoming gravity. As a result, blood pressure at the apices is lower than that at the bases. Because greater pressure causes greater perfusion, the bases of the lungs are better perfused than the apices (Fig. 34.14). Thus, ventilation and perfusion are greatest in the same lung portions—the lower lobesin the upright position. If a standing individual assumes a supine or side-lying position, the areas of the lungs that are then most dependent become the best ventilated and perfused.

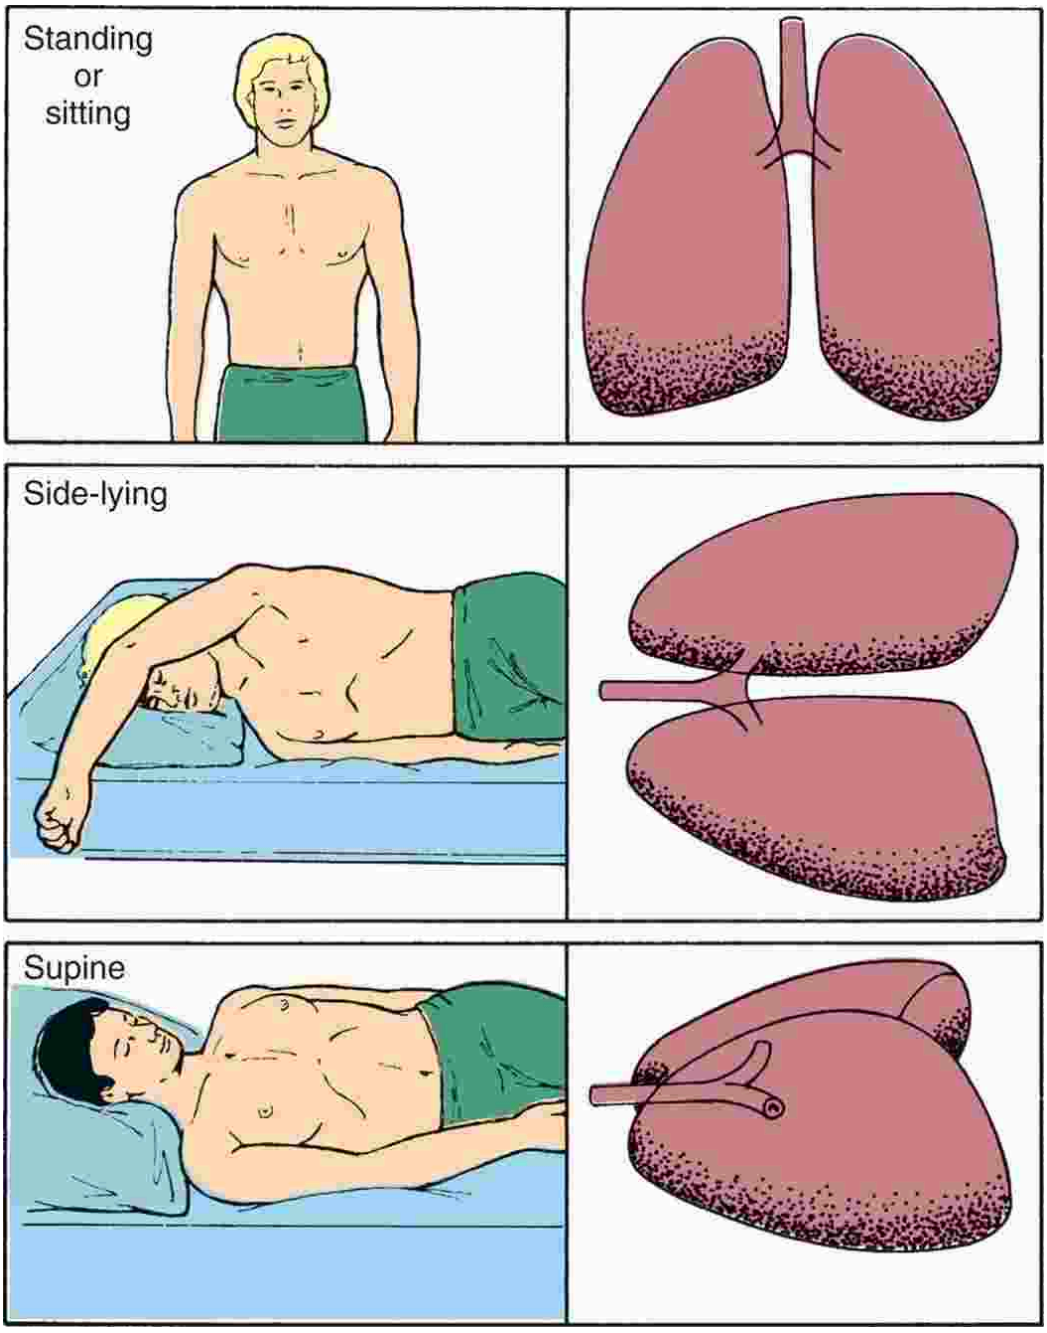

FIG. 34.14 Pulmonary Blood Flow and Gravity. The greatest volume of pulmonary blood flow normally will occur in the gravity-dependent areas of the lung. Body position has a significant effect on the distribution of pulmonary blood flow. The shaded areas represent gravity-dependent pulmonary blood flow.

Three pairs of illustrations show the upper body and lungs of a person, respectively. Top panel. The illustration on the left shows the anterior view of a person standing (or sitting). The illustration on the right shows the anterior view of the lungs. Middle panel. The illustration on the left shows a person lying on their side (side-lying). The illustration on the right shows the anterior view of the lungs on the side. Bottom panel. The illustration on the left shows a person in supine position. The illustration on the right shows a lateral view of the lungs on the side.

The distribution of perfusion in the pulmonary circulation also is affected by the alveolar pressure (gas pressure in the alveoli). The pulmonary capillary bed differs from the systemic capillary bed in that it is surrounded by gas-containing alveoli. If the gas pressure in the alveoli exceeds the blood pressure in the capillary, the capillary collapses, and flow ceases. This is most likely to occur in portions of the lung where blood pressure is lowest and alveolar gas pressure is greatest—that is, at the apex of the lung.

The lungs are divided into three zones on the basis of relationships among all the factors affecting pulmonary blood flow. Alveolar pressure and the forces of gravity, arterial blood pressure, and venous blood pressure affect the distribution of perfusion, as shown in Fig. 34.15.

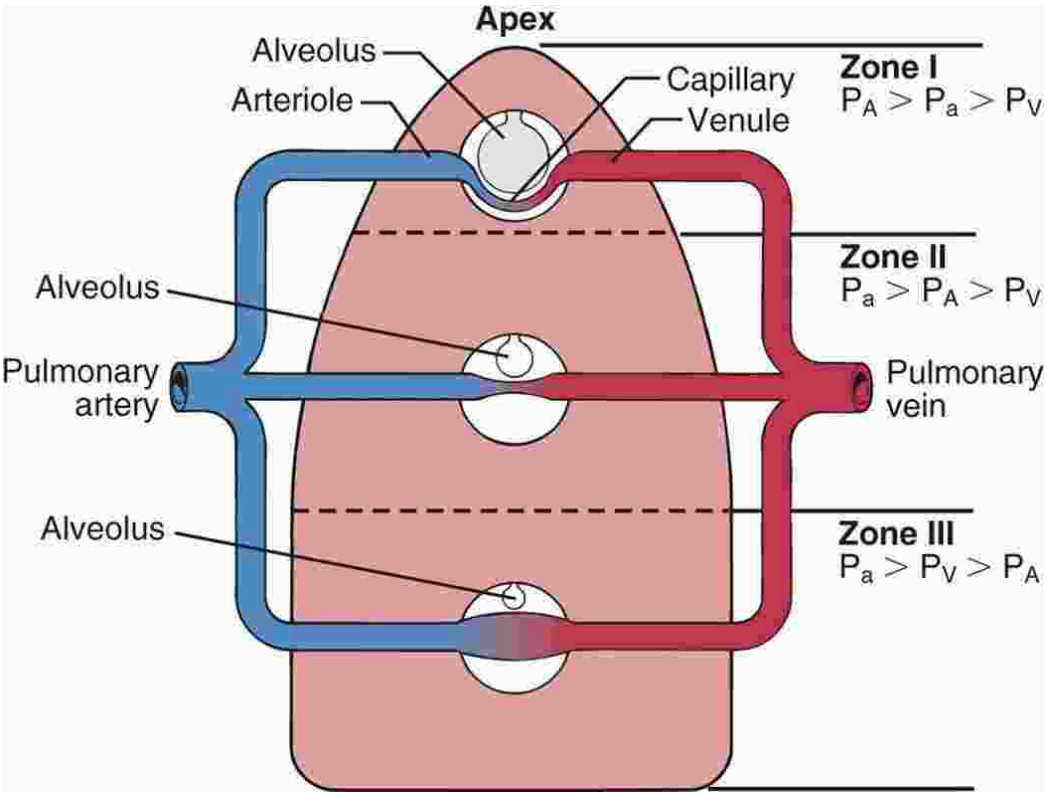

FIG. 34.15 Gravity and Alveolar Pressure. Effects of gravity and alveolar pressure on pulmonary blood flow in the three lung zones. In zone I, the alveolar pressure (P_A) is greater than the arterial pressure (P_a) and the venous pressure (P_V), and no blood flow occurs. In zone II, the P_a exceeds the P_A, but the P_A exceeds the P_V. Blood flow occurs in this zone, but the P_A compresses the venules (venous ends of the capillaries). In zone III, both the P_a and P_V are greater than the P_A, and blood flow fluctuates, depending on the difference between the P_A arterial pressure and the P_V.

An illustration shows gravity and alveolar pressure. The following structures are labeled from the top to

the bottom: apex, alveolus (zone one), arteriole, capillary, venule, alveolus (zone two), pulmonary artery, pulmonary vein, alveolus (zone three). • Zone one: Alveolar pressure is greater than arterial pressure, which is greater than venous pressure. • Zone two: Arterial pressure is greater than alveolar pressure, which is greater than venous pressure. • Zone three: Arterial pressure is greater than venous pressure, which is greater than alveolar pressure.

In zone I, the alveolar pressure exceeds the pulmonary arterial and venous pressures. The capillary bed collapses, and normal blood flow ceases. Normally zone I is a very small part of the lung at the apex. In zone II, the alveolar pressure is greater than the venous pressure but not the arterial pressure. Blood flows through zone II, but it is impeded to a certain extent by the alveolar pressure. Zone II is normally above the level of the left atrium. In zone III, both the arterial and venous pressures are greater than the alveolar pressure, and blood flow is not affected by the alveolar pressure. Zone III is in the base of the lung. Blood flow through the pulmonary capillary bed increases in regular increments from the apex to the base.

Although both blood flow and ventilation are greater at the base of the lungs than at the apices, they are not perfectly matched in any zone. Perfusion exceeds ventilation in the bases, and ventilation exceeds perfusion in the apices of the lung. The relationship between ventilation and perfusion is expressed as a ratio called the ventilation-perfusion ratio ($\dot{V}/\dot{Q}$). The normal $\dot{V}/\dot{Q}$ is called the respiratory quotient and is 0.8. This is the amount by which perfusion exceeds ventilation under normal conditions.

As described previously in this chapter, a low alveolar partial pressure of oxygen causes a reflex called hypoxic pulmonary vasoconstriction. Increases in carbon dioxide also contribute to

pulmonary vasoconstriction.[19] If a segment of the lung experiences decreased alveolar oxygen and increased carbon dioxide, arterioles to that segment constrict, so that appropriate matching of ventilation and perfusion is restored.

Oxygen Transport

Approximately 1000 mL (1 L) of O_2 is transported to the cells of the body each minute. O_2 is transported in the blood in two forms: a small amount dissolves in plasma, and the remainder binds to hemoglobin molecules. Without hemoglobin, O_2 would not reach the cells in amounts sufficient to maintain normal metabolic function. (Hemoglobin is discussed in detail in Chapter 28, and cellular metabolism is explored in Chapter 1.)

Diffusion across the alveolocapillary membrane

The alveolocapillary membrane is ideal for O_2 diffusion because it has a large total surface area (70 to 100 m^2) and is very thin (0.5 μm). In addition, the P_AO_2 (approximately 99 mm Hg at sea level) is much greater than that in capillary blood (approximately 40 mm Hg), a condition that promotes rapid diffusion down the concentration gradient from the alveolus into the capillary. Therefore, a pressure gradient of nearly 60 mm Hg facilitates the diffusion of O_2 from the alveolus into the capillary (see Fig. 34.13).

Blood remains in the pulmonary capillary for about 0.75 seconds, but only 0.25 seconds is required for the O_2 concentration to equilibrate (equalize) across the alveolocapillary membrane. Therefore, O_2 has ample time to diffuse into the blood, even during increased cardiac output, which speeds blood flow and shortens the time the blood remains in the capillary.

Determinants of arterial oxygenation

As O_2 diffuses across the alveolocapillary membrane, it dissolves in the plasma, where it exerts pressure (PaO_2). As the PaO_2 increases, O_2 moves from the plasma into the red blood cells (erythrocytes) and

binds with hemoglobin molecules. O_2 continues to bind with hemoglobin until the hemoglobin-binding sites are filled, or *saturated*. O_2 then continues to diffuse across the alveolocapillary membrane until the PaO_2 (oxygen dissolved in plasma) and P_AO_2 (oxygen in the alveolus) equilibrate, eliminating the pressure gradient across the alveolocapillary membrane. At this point, diffusion ceases (see Fig. 34.13).

The majority (97%) of the O_2 that enters the blood is bound to hemoglobin. The remaining 3% stays in the plasma and creates the PaO_2. The PaO_2 can be measured in the blood by obtaining an arterial blood gas measurement. The oxygen saturation (Sao_2) is the percentage of the available hemoglobin that is bound to O_2 and can be measured using a device called an *oximeter*. The total amount of oxygen carried in the blood is the oxygen content and is measured in milliliters per deciliter (1 dL = 100 mL) of blood. It is the combined value of the O_2 in oxygen-saturated hemoglobin and the O_2 dissolved in the blood.

To calculate the total arterial O_2 content, one must know (1) the hemoglobin concentration, or the amount of hemoglobin that is available to bind with oxygen (hemoglobin [Hb] in grams per deciliter); (2) the oxygen saturation, or the percentage of available hemoglobin that is bound to oxygen (SaO_2); and (3) the partial pressure of oxygen (PaO_2). The maximum amount of oxygen that can be transported by hemoglobin is 1.34 mL/g. The amount of oxygen that can be physically dissolved in blood is 0.003 mL/dL per mm Hg. With the specific values known, the oxygen content of arterial blood can be calculated. To calculate the oxygen content of venous blood, the partial pressure of mixed venous blood (Pvo_2) and venous oxygen saturation (Svo_2) are substituted for the arterial values in the basic formula. Normal venous oxygen content is 15 to 16 mL/dL.

Because hemoglobin transports all but a small fraction of the O_2 carried in arterial blood, changes in the hemoglobin concentration affect the O_2 content of the blood. Decreases in the hemoglobin concentration below the normal value of approximately 15 g/dL of

blood reduce the O_2 content, and increases in the hemoglobin concentration may increase O_2 content. An increased hemoglobin concentration is a major compensatory mechanism in pulmonary diseases that impair gas exchange. For this reason, measurement of the hemoglobin concentration is important in assessing individuals with pulmonary disease. If cardiovascular function is normal, the body's initial response to low O_2 content is to accelerate cardiac output. In individuals who also have cardiovascular disease, this compensatory mechanism is ineffective. An elevated hemoglobin level can compensate for an inability to accelerate cardiac output, making an increased hemoglobin concentration an even more important compensatory mechanism.

Oxyhemoglobin association and dissociation

When hemoglobin molecules bind with O_2, oxyhemoglobin (HbO_2) forms. Binding occurs in the lungs and is called *oxyhemoglobin association* or *hemoglobin saturation with oxygen* (SaO_2). The reverse process, in which O_2 is released from hemoglobin, occurs in the body tissues at the cellular level and is called *hemoglobin desaturation*. When hemoglobin saturation and desaturation are plotted on a graph, the result is a distinctive S-shaped curve known as the oxyhemoglobin dissociation curve (Fig. 34.16). For PaO_2 values less than 60 mm Hg, oxygen is readily unloaded to peripheral tissues, and hemoglobin's affinity for oxygen diminishes, reflecting the steep part of the curve. For PaO_2 values greater than 60 mm Hg, the curve becomes relatively flat, reflecting the maximum saturation of hemoglobin with oxygen in the lungs.

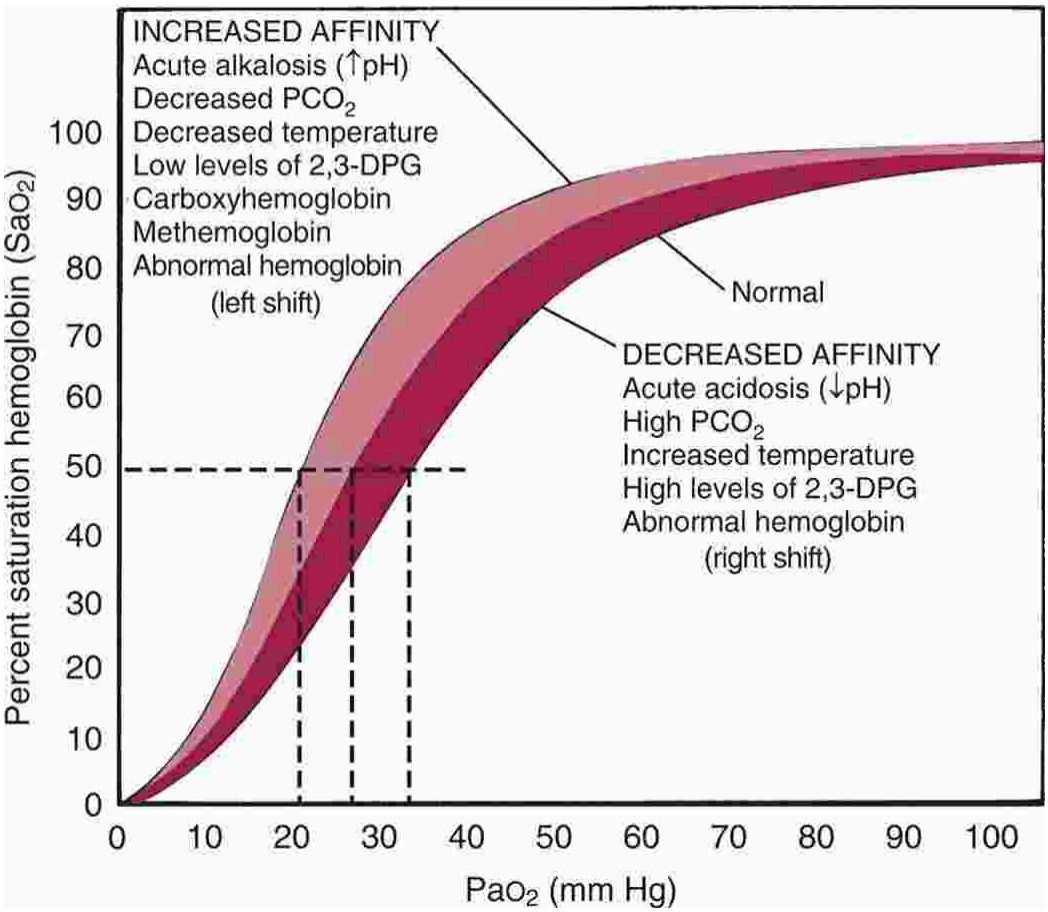

FIG. 34.16 Oxyhemoglobin Dissociation Curve. The horizontal or flat segment of the curve at the top of the graph is the arterial or association portion, or that part of the curve where oxygen (O_2) is bound to hemoglobin and occurs in the lungs. This portion of the curve is flat because partial pressure changes of O_2 between 60 and 100 mm Hg do not significantly alter the percentage saturation of hemoglobin with O_2 and allow adequate hemoglobin saturation at a variety of altitudes. If the relationship between the oxygen saturation of hemoglobin in arterial blood (SaO_2) and the partial pressure of oxygen in the arterial blood (PaO_2) were linear (in a downward sloping straight line) instead of flat between 60

and 100 mm Hg, there would be inadequate saturation of hemoglobin with O_2. The steep part of the oxyhemoglobin dissociation curve represents the rapid dissociation of O_2 from hemoglobin that occurs in the tissues. During this phase, there is rapid diffusion of O_2 from the blood into tissue cells. The P50 is the Pa_{O_2} at which hemoglobin is 50% saturated, normally 26.6 mm Hg. A lower than normal P50 represents increased affinity of hemoglobin for O_2; a high P50 is seen with decreased affinity. Note that variation from the normal is associated with decreased (low P50) or increased (high P50) availability of O_2 to tissues (dashed lines). The shaded area shows the entire oxyhemoglobin dissociation curve under the same circumstances. 2,3-DPG, 2,3-Diphosphoglycerate; Pa_{O_2}, arterial pressure of oxygen; P_{CO_2}, partial pressure of carbon dioxide.

(From Lane EE, Walker JF. *Clinical arterial blood gas analysis*. St. Louis: Mosby; 1987.)

A graph plots the oxyhemoglobin dissociation curve. The vertical axis, representing percent saturation hemoglobin (saturation of hemoglobin in arterial blood), ranges from 0 to 100 in increments of 10. The horizontal axis, representing partial pressure of oxygen (millimeters of mercury), ranges from 0 to 100 in increments of 10. Two thick concave-down curves are plotted on the graph rise from (0, 0), curve at about (50, 70) and (50, 80), and flatline through

(100, 90). The lower curve is normal and represents decreased affinity: acute acidosis (decreased p H), high partial pressure of carbon dioxide, increased temperature, high levels of 2, 3-D P G, and abnormal hemoglobin (right shift). The upper curve represents increased affinity: acute alkalosis (decreased p H), decreased partial pressure of carbon dioxide, decreased temperature, low levels of 2, 3-D P G, carboxyhemoglobin, methemoglobin, and abnormal hemoglobin (left shift).

Several factors can change the relationship between the PaO_2 and the SaO_2, causing the oxyhemoglobin dissociation curve to shift to the right or left (see Fig. 34.16). At a PaO_2 of 26.6 mm Hg, hemoglobin is 50% saturated, known as P_{50}. An increase in the P_{50} value shifts the curve to the right, indicating hemoglobin's decreased affinity for O_2 or an increase in the ease with which oxyhemoglobin dissociates and O_2 moves into the cells. A larger partial pressure is necessary to maintain 50% oxygen saturation. A shift to the left depicts hemoglobin's increased affinity for O_2, which promotes association in the lungs and inhibits dissociation in the tissues. Lower partial pressure is necessary to maintain 50% oxygen saturation.

The oxyhemoglobin dissociation curve is shifted to the right by acidosis (low pH) and hypercapnia (increased $PaCO_2$). In the tissues, the increased levels of CO_2 and H^+ produced by metabolic activity decrease the affinity of hemoglobin for O_2, and O_2 is released into the tissues. The curve is shifted to the left by alkalosis (high pH) and hypocapnia (decreased $PaCO_2$). In the lungs, as CO_2 diffuses from the blood into the alveoli, the blood CO_2 level is reduced, and the

affinity of hemoglobin for O_2 is increased so that more O_2 can be transported from the lungs into the tissues. The shift in the oxyhemoglobin dissociation curve caused by changes in the CO_2 and hydrogen ion concentrations in the blood is called the Bohr effect.

The oxyhemoglobin curve is also shifted by changes in body temperature and increased or decreased levels of 2,3-diphosphoglycerate (2,3-DPG), a substance normally present in erythrocytes. Hyperthermia and increased 2,3-DPG levels shift the curve to the right so that more O_2 is released into the tissues. Hypothermia and decreased 2,3-DPG levels shift the curve to the left.

Carbon Dioxide Transport

Approximately 200 mL of CO_2 is produced by the tissues per minute at rest as a byproduct of cellular metabolism. This CO_2 equilibrates with carbonic acid (H_2CO_3) and must be eliminated continuously to prevent acidosis. The elimination of CO_2 by the lungs plays an important role in the regulation of acid-base balance (see Chapter 3).

CO_2 is carried in the blood in three ways: (1) dissolved in plasma, (2) transported as bicarbonate, and (3) combined with blood proteins to form carbamino compounds. As CO_2 diffuses out of the cells into the blood, it dissolves in the plasma. Approximately 10% of the total CO_2 in venous blood and 5% of the CO_2 in arterial blood are carried dissolved in the plasma. As CO_2 moves into the blood, it diffuses into the red blood cells. Within the red blood cells, CO_2, with the help of the enzyme carbonic anhydrase, combines with water to form carbonic acid and then quickly dissociates into H^+ and HCO_3^-. As carbonic acid dissociates, the H^+ binds to hemoglobin, where it is buffered, and the HCO_3^- moves out of the red blood cell into the plasma. Approximately 60% of the CO_2 in venous blood and 90% of the CO_2 in arterial blood are carried in the form of bicarbonate. The remainder combines with blood proteins, hemoglobin, in particular, to form carbamino compounds.

CO_2 is 20 times more soluble than O_2 and diffuses quickly from the tissue cells into the blood. The amount of CO_2 able to enter the blood is enhanced by the diffusion of O_2 out of the blood and into the cells. Reduced hemoglobin (hemoglobin that is dissociated from O_2) can carry more CO_2 than can hemoglobin saturated with O_2. Therefore, the drop in O_2 saturation at the tissue level increases the ability of hemoglobin to carry CO_2 back to the lung.

The diffusion gradient for CO_2 in the lung is only approximately 6 mm Hg (P_vCO_2 = 46 mm Hg; P_ACO_2 = 40 mm Hg) (see Fig. 34.13). Yet CO_2 is so soluble in the alveolocapillary membrane that the CO_2 in the blood quickly diffuses into the alveoli, where it is removed from the lung with each expiration. Diffusion of CO_2 in the lung is so efficient that diffusion defects that cause hypoxemia (low O_2 content of the blood) do not as readily cause hypercapnia (excessive CO_2 in the blood).

The diffusion of CO_2 out of the blood and into the lungs also is enhanced by O_2 binding with hemoglobin. As hemoglobin binds with O_2, the amount of CO_2 carried by the blood decreases, and it is released into the alveoli. Thus, in the tissue capillaries, O_2 dissociation from hemoglobin facilitates the pickup of CO_2, and the binding of O_2 to hemoglobin in the lungs facilitates the release of CO_2 from the blood. This effect of O_2 on CO_2 transport is called the Haldane effect.

Tests of Pulmonary Function

Several laboratory tests aid in the diagnosis and evaluation of pulmonary system abnormalities. Most of them are easy to perform at hospitals and clinics. They provide valuable information about the possible cause of a respiratory abnormality and evaluate the progression or resolution of disease.[20]

Pulmonary function testing includes spirometry, which measures the volume and flow of air inhaled and exhaled and is plotted

against time (flow rate) during different breathing maneuvers. Several different types of spirometers are available. It is essential that these devices meet current standards and that they are used properly in order to achieve accurate results.[21] The procedure produces a spirogram, which is a record of the individual's ventilation in relation to time (Fig. 34.17). Clinically the most important spirometric tests are the forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV_1). (These tests and other important measurements are described in Table 34.3.) Spirometry enables clinicians to detect restrictive or obstructive deficits early in the course of disease. *Restrictive lung diseases* restrict the lungs' volume; the lungs are unable to expand normally, diminishing the amount of gas that can be inspired and reducing the FVC. *Obstructive lung diseases* affect gas flow; airflow into and out of the lungs is obstructed, reducing the FEV_1 (see Chapter 35).

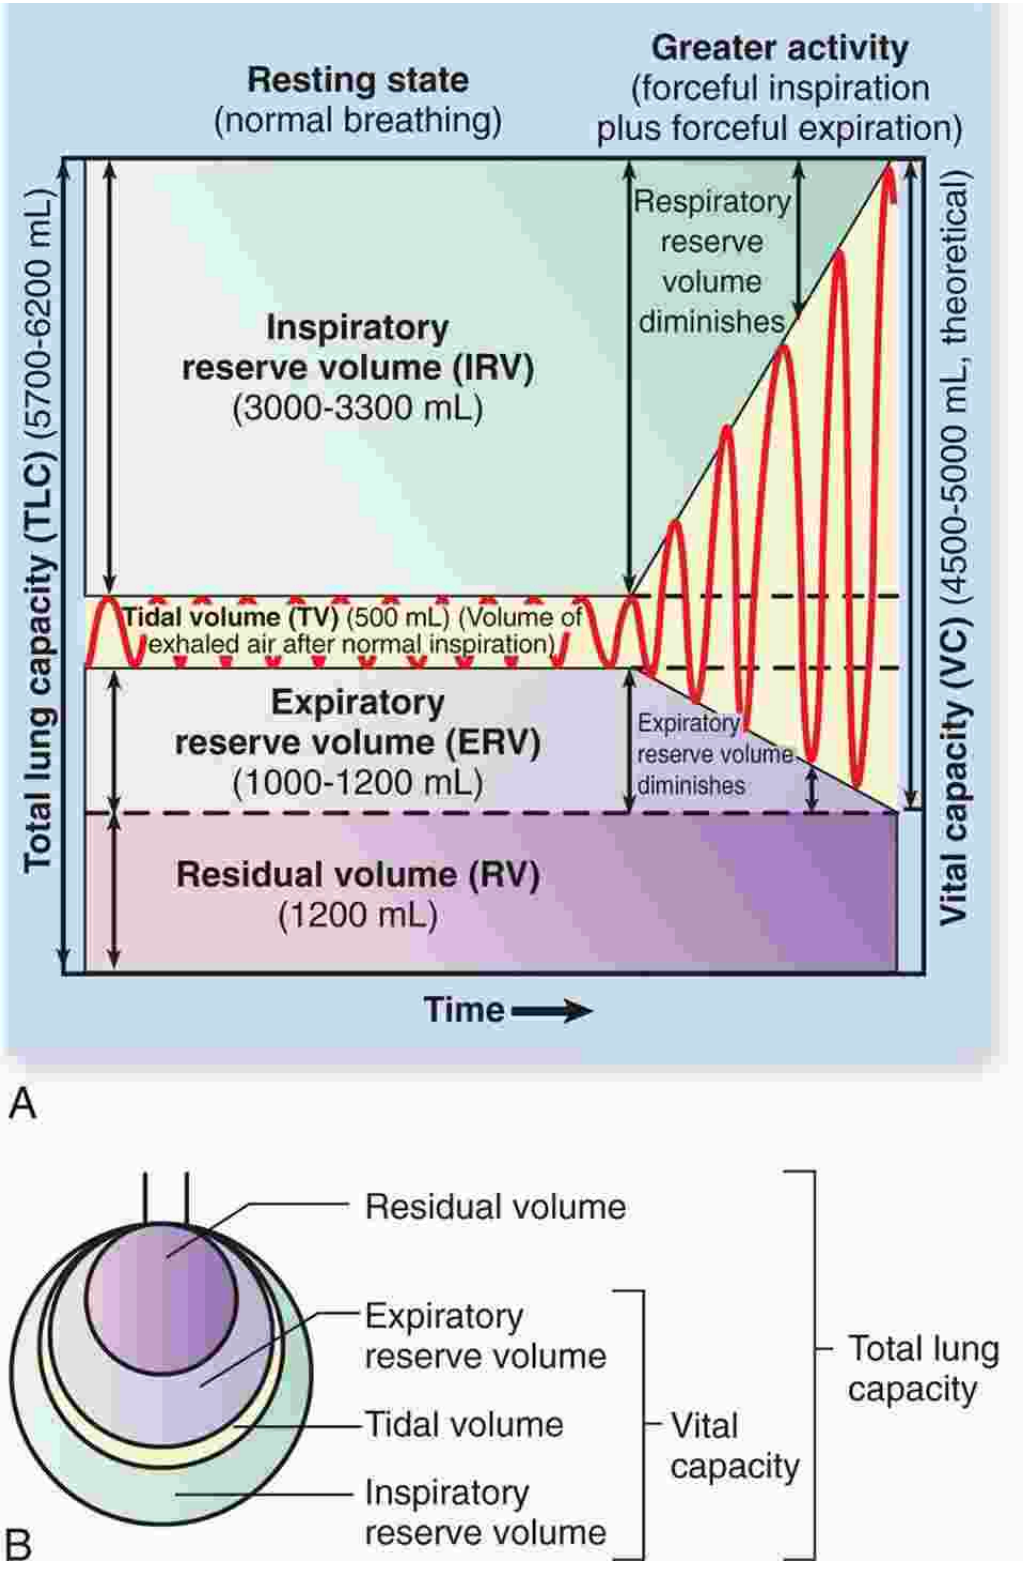

FIG. 34.17 Pulmonary Ventilation and Lung Capacities.

(A) Spirogram. During normal, quiet respiration,

the atmosphere and lungs exchange about 500 mL of air (VT). With a forcible inspiration, about 3300 mL more air can be inhaled (*IRV*). After a normal inspiration and normal expiration, approximately 1000 mL more air can be forcibly expired (*ERV*). Vital capacity is the amount of air that can be forcibly expired after a maximal inspiration and indicates, therefore, the largest amount of air that can enter and leave the lungs during respiration. Residual volume (*RV*) is the air that remains trapped in the alveoli. (B) Lung capacities. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

Illustration A shows a spirogram indicating changes in lung volume under different conditions of breathing. Illustration B depicts total lung capacity with the labels of vital capacity and total lung capacity. The labels with the volumes in decreasing order are as follows. Residual volume, expiratory reserve volume, inspiratory reserve volume, and tidal volume.

Table 34.3

Values Measured by Spirometry

Symbol	Ventilatory Property Measured
FVC	Forced vital capacity; maximum amount of gas that can be displaced from the lung during a forced expiration
FEV_1	Forced expiratory volume in 1 second; maximum amount of air that can be expired from the lung in 1 second
FEV_1/FVC	Percentage of maximum inspiration that is expired in 1 second; usually 80% of FVC
FEV_3	Forced expiratory volume in 3 seconds; maximum amount of gas that can be expired in 3 seconds
FEV_3/FVC	Percentage of FVC that is expired in 3 seconds; usually 95% of FVC
$FEF_{25–75\%}$	Forced expiratory flow rate during the middle 50% of expiration; sometimes reported as maximum mid expiratory flow rate (MMFR)
MVV	Maximum voluntary ventilation
PEF	Peak expiratory flow

Lung capacities, such as vital capacity (sum of inspiratory reserve volume, tidal volume, and expiratory reserve volume) and total lung capacity (sum of the vital capacity and the residual capacity), are always the sum of two or more volumes. Norms for volumes and capacities are based on age, sex, and height and are referred to as *predicted values*. Differences from predicted or changes from baseline values are taken into account in diagnosing and assessing respiratory disorders.

Pulmonary diffusing capacity (transfer factor) is a measure of the rate of gas diffusion across the alveolocapillary membrane. O_2, or more commonly carbon monoxide (CO), is used to measure diffusing capacity. CO has a high affinity for hemoglobin and is not limited by pulmonary blood flow and therefore is an excellent measure of diffusion. The measurement is made by determining how much CO is taken up by the blood and dividing this amount by the pressure gradient across the alveolocapillary membrane. Helium (an inert gas poorly soluble in alveolar blood and lung tissue) often is added to the gas mixture to obtain a simultaneous measurement of residual volume (RV), functional residual capacity (FRC), and total lung capacity (TLC). Individuals are asked to perform ventilatory maneuvers similar to those used in spirometry testing. A decreased diffusing capacity can be the result of an abnormal ventilation-perfusion ratio or an actual diffusion defect. For example, diffusing capacity is decreased in individuals with emphysema, where there is a decrease in the surface area of pulmonary capillaries available for gas exchange.

Oximetry is commonly performed for individuals with suggested or diagnosed pulmonary disease. It indirectly measures hemoglobin oxygen saturation and can suggest that the PaO_2 is low. However, it is prone to inaccurate measurements, particularly in individuals with poor peripheral circulation, and does not measure the $PaCO_2$ or pH of the blood. Capnography measures the amount of CO_2 in expired air and thus estimates $PaCO_2$, but this test is also prone to inaccuracy. Arterial blood gas analysis is the direct measurement of the pH and gas concentrations in arterial blood and provides more accurate and complete information about an individual's gas exchange and acid-base status. Acidosis (low pH), alkalosis (high pH), ventilatory alterations, and decreased PaO_2 can be diagnosed accurately only by arterial blood gas analysis. A blood gas report may be divided into an acid-base/ventilation portion and an oxygenation portion. (Normal values for arterial blood gases are given in Table 34.4; acid-base alterations are described in Chapter 3.)

Table 34.4

Normal Ranges for Arterial and Mixed Venous Blood Gases

Measurement	Arterial Blood	Mixed Venous Blood[a]	Clinical Notes
Acid-base status (pH)	7.35–7.45	7.33–7.43	Most important acid-base value; detects acidosis or alkalosis
Partial pressure of carbon dioxide (P_{CO_2})	35–45 mm Hg	41–57 mm Hg	Measures adequacy of ventilation and respiratory contribution of acid-base abnormality (respiratory acidosis)
Bicarbonate concentration (HCO_3^-)	22–26 mEq/L	24–28 mEq/L	Measures metabolic contribution to acid-base abnormality (metabolic acidosis); calculated from pH and P_{CO_2}
Base excess (BE)	−2 to +2	0 to +4	Reflects deviation of bicarbonate concentration from normal
Partial pressure of oxygen	80–100 mm Hg	35–40 mm Hg	Indicates driving pressure that

Measurement	Arterial Blood	Mixed Venous Blood[a]	Clinical Notes
(P_{O_2}) (sea level)			causes oxyhemoglobin binding; varies with age and barometric pressure
Saturation of hemoglobin with oxygen (S_{O_2})	96%–98%	70%–75%	Indicates abnormalities of oxyhemoglobin association and dissociation; may be measured directly or calculated from P_{CO_2}, pH, and body temperature
Concentration of hemoglobin in the blood	15 g/dL	15 g/dL	Detects alterations of gas transport caused by anemia

Measurement	Arterial Blood	Mixed Venous Blood[a]	Clinical Notes
Acid-base status (pH)	7.35–7.45	7.33–7.43	Most important acid-base value; detects acidosis or alkalosis
Partial pressure of carbon dioxide (P_{CO_2})	35–45 mm Hg	41–57 mm Hg	Measures adequacy of ventilation and respiratory contribution of acid-base abnormality (respiratory acidosis)
Bicarbonate concentration (HCO_3^-)	22–26 mEq/L	24–28 mEq/L	Measures metabolic contribution to acid-base abnormality (metabolic acidosis); calculated from pH and P_{CO_2}
Base excess (BE)	−2 to +2	0 to +4	Reflects deviation of bicarbonate concentration from normal
Partial pressure of oxygen (P_{O_2}) (sea level)	80–100 mm Hg	35–40 mm Hg	Indicates driving pressure that causes oxyhemoglobin binding; varies with age and barometric pressure
Saturation of hemoglobin with oxygen (S_{O_2})	96%–98%	70%–75%	Indicates abnormalities of oxyhemoglobin association and dissociation; may be measured directly or calculated from P_{CO_2}, pH, and body temperature
Concentration of hemoglobin in the blood	15 g/dL	15 g/dL	Detects alterations of gas transport caused by anemia

[a]Mixed venous (pulmonary artery) blood is analyzed for critically ill individuals and those undergoing cardiac catheterization (it is not practical to withdraw samples except from a pulmonary artery catheter). Mixed venous blood gas analysis, in conjunction with arterial analysis, provides important information about the adequacy of cardiac output and tissue oxygenation.

Signs and symptoms of most respiratory abnormalities first appear when the system is stressed during exercise. Therefore, if pulmonary disease is suspected, the individual is evaluated at rest and during exercise. Evaluation during exercise usually entails spirometry and oximetry to monitor hemoglobin saturation. The exercise usually consists of riding a stationary bicycle or walking on a treadmill. Exercise testing enables clinicians to detect early changes in respiratory function and thus begin treatment. Exercise tests also are used in planning and evaluating exercise and rehabilitation programs.

Thoracic imaging techniques are among the most common examinations for diagnosis and detection of pulmonary disease and tumors and for evaluation of disease progression. Numerous techniques are available and include chest radiography, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography, and ultrasonography. Pulmonary angiography is used for the detection of pulmonary embolism and pulmonary arteriovenous malformations. Techniques may be combined for the best evaluation of pulmonary structure and function.

Geriatric Considerations

Aging and the Pulmonary System

Most knowledge about pulmonary structure and function is based on norms for the middle-age years. Less is known about structure and function in the very young (see Chapter 36) and in older adults, but a few normal physiologic (developmental and degenerative) changes are known to occur from birth to old age. An understanding of these changes is needed to provide

appropriate care and to differentiate between age-associated alterations and disease. Normal alterations in the pulmonary system that occur with aging include (1) loss of elastic recoil, (2) stiffening of the chest wall, (3) changes in gas exchange, and (4) increases in flow resistance. These changes, which affect lung volumes, are gradual and usually without adverse consequences in healthy individuals (Fig. 34.18). They are influenced by genetics, sociocultural factors, nutritional status, exercise, decreased immune function, respiratory disease, body size, sex, and race. Exposure to environmental toxins, such as some respiratory tract infections, tobacco smoke, air pollution, and occupational dusts, also contributes to decreased lung function with aging. These changes contribute to increased lung disease morbidity and mortality in older adults, including chronic obstructive lung disease, lung cancer, pulmonary fibrosis, and infection.

Residual volume
Total lung capacity
Vital capacity

FIGURE 34.18 Changes in Lung Volumes with Aging.
In aging, vital capacity decreases, and residual volume increases.

An illustration of the lung depicts the relative changes in lung volume associated with aging and normal lung showing the inspiratory reserve volume, tidal volume, and expiratory reserve volume decreases and residual volume increases in aging lung.

During adulthood and as age advances, the alveoli tend to lose alveoli wall tissue and capillaries. This process increases alveolar size, diminishes the alveolar surface area available for gas diffusion, and decreases airway support provided by normal lung tissues. These changes are similar to those seen in emphysema and diminish the elasticity of the lungs. Chest wall compliance decreases with age because the ribs become ossified (less flexible), and the joints become stiffer. As a result, the chest wall loses some of its ability to expand. In addition, respiratory muscle strength and endurance decrease by up to 20% by age 70. These mechanical changes in the lung and chest wall, along with structural changes in the alveoli, reduce the ventilatory capacity in older adults. Vital capacity decreases and residual volume increases; however, total lung capacity remains unchanged. These changes decrease ventilatory reserves and lead to decreased ventilation-perfusion ratios. With advancing age, there is also increased immune dysregulation, asymptomatic low-grade inflammation ("inflamm-aging"), and increased risk of infection.

Alterations in gas exchange are reflected by blood gas analysis. With advancing age, pH and $PaCO_2$ levels do not change much, even though it has been documented that the chemoreceptors

become less sensitive to gas partial pressures with age. Older adults have a decreased compensatory response to hypercapnia and hypoxemia; however, the perception of dyspnea remains intact and is even enhanced. PaO_2 declines with age as a result of structural and mechanical changes, such as loss of alveolar surface area, thickening of plural septa, loss of lung elasticity, and increase in ventilation-perfusion mismatch. The maximum PaO_2 value in an older adult at sea level can be estimated by multiplying the person's age by 0.3 and subtracting the product from 100. For example, an 80-year-old individual would have an estimated maximum PaO_2 of 76 mm Hg (0.3 × 80 = 24; 100 − 24 = 76).

The decrease in PaO_2 and the diminished ventilatory reserve in an older adult lead to a decrease in exercise tolerance. Respiratory muscle strength and endurance decrease with age. Furthermore, older adults are at greater risk for respiratory depression caused by medications. Changes in respiratory structure and function can vary considerably from person to person, however. Changes also are affected by activity and fitness earlier in life.

Summary Review

Structures of the Pulmonary System

1. The pulmonary system consists of the lungs, upper and lower airways, chest wall, and pulmonary and bronchial circulation.

2. Air is inspired and expired through the conducting airways: nasopharynx, oropharynx, trachea, bronchi, and bronchioles.
3. Gas exchange occurs in structures beyond the respiratory bronchioles: in the alveolar ducts and the alveoli. Together these structures compose the acinus.
4. The chief gas exchange units of the lungs are the alveoli. The membrane that surrounds each alveolus and contains the pulmonary capillaries is called the alveolocapillary membrane.
5. The gas-exchange airways are perfused by the pulmonary circulation, a separate division of the circulatory system. The bronchi and other lung structures are perfused by a branch of the systemic circulation called the bronchial circulation.
6. The pulmonary circulation is innervated by the autonomic nervous system (ANS), but vasodilation and vasoconstriction are controlled mainly by local and humoral factors, particularly arterial oxygenation and acid-base status.
7. The chest wall, which contains and protects the contents of the thoracic cavity, consists of the skin, ribs, and intercostal muscles, which lie between the ribs.
8. The chest wall is lined by a serous membrane called the parietal pleura; the lungs are encased in a separate membrane called the visceral pleura. The pleural space is the area where these two pleurae contact and slide over one another.

Function of the Pulmonary System

1. The pulmonary system (1) ventilates the alveoli, (2) diffuses gases into and out of the blood, and (3) perfuses the lungs so that the organs and tissues of the body receive blood that is rich in oxygen and deficient in carbon dioxide.
2. Ventilation is the process by which air flows into and out of the gas-exchange airways.

3. Most of the time, ventilation is involuntary. It is controlled by the sympathetic and parasympathetic divisions of the autonomic nervous system, which adjust airway caliber (by causing the bronchial smooth muscle to contract or relax) and control the rate and depth of ventilation.
4. Neuroreceptors in the lungs (lung receptors) monitor the mechanical aspects of ventilation. Irritant receptors sense the need to expel unwanted substances, stretch receptors sense lung volume (lung expansion), and J-receptors sense pulmonary capillary pressure.
5. Chemoreceptors in the circulatory system and brainstem sense the effectiveness of ventilation by monitoring the pH status of cerebrospinal fluid and the oxygen content (PO_2) of arterial blood.
6. Successful ventilation involves the mechanics of breathing: the interaction of forces and counterforces involving the muscles of inspiration and expiration, alveolar surface tension, elastic properties of the lungs and chest wall, and resistance to airflow.
7. The major muscle of inspiration is the diaphragm. When the diaphragm contracts, it moves downward in the thoracic cavity, creating a vacuum that causes air to flow into the lungs.
8. The type II alveolar cells produce surfactant, a lipoprotein that lines the alveoli. Surfactant reduces alveolar surface tension and permits the alveoli to expand as air enters.
9. Elastic recoil is the tendency of the lungs and chest wall to return to their resting state after inspiration. The elastic recoil forces of the lungs and chest wall are in opposition and pull on each other, creating the normally negative pressure of the pleural space.
10. Compliance is the ease with which the lungs and chest wall expand during inspiration. Lung compliance is ensured by an adequate production of surfactant, whereas chest wall expansion depends on elasticity.

11. The work of breathing is determined by the muscular effort required for ventilation and is normally very low. Work increases when lung or chest wall compliance decreases or airways are obstructed.
12. Gas transport depends on ventilation of the lungs, diffusion of oxygen across the alveolocapillary membrane, perfusion of systemic capillaries with oxygenated blood, and diffusion between systemic capillaries and tissue cells.
13. Efficient gas exchange depends on an even distribution of ventilation (gas) and perfusion (blood) within the lungs. Both ventilation and perfusion are greatest in the bases of the lungs because the alveoli in the bases are more compliant (their resting volume is low), and perfusion is greater in the bases as a result of gravity.
14. Almost all the oxygen that diffuses into pulmonary capillary blood is transported by hemoglobin, a protein contained within red blood cells. The remainder of the oxygen is transported dissolved in plasma.
15. Oxygen enters the body by diffusing down the concentration gradient, from high concentrations in the alveoli to lower concentrations in the capillaries. Diffusion ceases when alveolar and capillary oxygen pressures equilibrate.
16. Oxygen is loaded onto hemoglobin by the driving pressure exerted by Pao_2 in the plasma. As pressure decreases at the tissue level, oxygen dissociates from hemoglobin and enters tissue cells by diffusion, again down the concentration gradient.
17. Compared with oxygen, carbon dioxide is more soluble in plasma. Therefore carbon dioxide diffuses readily from tissue cells into plasma and from plasma into the alveoli. Carbon dioxide returns to the lungs dissolved in plasma, as bicarbonate, or in carbamino compounds (e.g., bound to hemoglobin).

Tests of Pulmonary Function

1. Spirometry measures the volume and flow rate of air during forced expiration.
2. The alveolar-arterial oxygen gradient is used to evaluate the cause of hypoxia.
3. Diffusing capacity is a measure of the gas diffusion rate at the alveolocapillary membrane.
4. Arterial blood gas analysis can be used to determine pH, oxygen, and CO_2 concentrations.
5. Thoracic imaging techniques are used to detect pulmonary disease and tumors and to evaluate disease progression.

Aging and the Pulmonary System

1. Aging affects the mechanical aspects of ventilation by decreasing chest wall compliance and elastic recoil of the lungs. Changes in these elastic properties reduce ventilatory reserve.
2. Aging causes loss of alveolar wall tissue and alveolar enlargement, thus diminishing the surface area available for gas diffusion.
3. Aging can cause the PaO_2 level to decrease but does not affect the $PaCO_2$ level.
4. Vital capacity decreases, and residual volume increases with age; however, total lung capacity remains unchanged.

Emerging Science Box The Pulmonary Microbiome

Until recently, it was believed that the lower lungs were sterile. The first report of a healthy lung microbiome was published in 2010, and many more confirmatory articles have been published since then. The pulmonary microbiome is dynamic and is constantly influenced by the movement of air, mucus, and microbes in and out of the lung. The lung's natural defense mechanisms, such as the presence of bacteriostatic surfactant and

active bronchial and alveolar macrophages, limit bacterial density along the mucosal surfaces, but those microorganisms that do survive provide important immunologic roles in preventing disease. There is an interaction between the oral and gut mucosa and the pulmonary microbiome (gut-lung axis), and these relationships are just beginning to be understood in terms of causing and treating lung disease.

A healthy pulmonary microbiome confers protection against many infectious and inflammatory conditions. Changes in lung microbiota (dysbiosis) have been associated with environmental impacts such as tobacco smoking, air pollution, and the use of corticosteroids and antibiotics. There is also increasing evidence that pulmonary dysbiosis is a contributing factor for a number of pulmonary disorders. For example, studies have found that Proteobacteria such as *Moraxella*, *Pseudomonas*, and *Enterobacteriaceae* are more prevalent in the airways of those with asthma. These microorganisms are postulated to accentuate the inflammatory processes that underlie asthma pathophysiology and may provide a link between diet, obesity, and asthma onset and severity. Similar links have been found between pulmonary and gut microbiota and the pathogenesis and clinical course of COPD, cystic fibrosis, idiopathic pulmonary fibrosis, and bronchiectasis. Recent studies suggest that pulmonary dysbiosis can have an adverse effect on the pathogenesis and clinical severity of coronavirus disease 2019 (COVID-19). Therapeutic interventions aimed at modifying the microbiome are undergoing intensive research, and early outcomes appear positive for several common pulmonary disorders.

Emerging Science BoxSilent Hypoxemia in COVID-19

Silent (apathetic) hypoxemia is defined as a lack of dyspnea despite significant decreases in oxygen saturation of the blood. In healthy individuals, changes in lung mechanics, arterial oxygen and carbon dioxide levels, and inflammatory cytokines stimulate afferent impulses from pulmonary mechano-chemoreceptors (irritant, stretch, pulmonary C-fiber receptors) and peripheral and central chemoreceptors to the respiratory center in the brainstem. In response, the respiratory center sends efferent signals to the respiratory system that appropriately alter the respiratory rate and tidal volume. These compensatory mechanisms are usually accompanied by the sensation of dyspnea (a subjective experience of breathing discomfort). It has been noted, however, that considerable variation exists between individuals with respect to the amount of dyspnea experienced with various levels of hypoxemia. Some individuals experience severe dyspnea and panic, whereas others will experience very little dyspnea even when oxygen saturations fall below 70%. These latter individuals are considered to have silent hypoxemia. Silent hypoxemia can be seen in diseases such as atelectasis and cardiac shunts; however, it appears to be quite common in coronavirus infection 2019 (COVID-19). Hypotheses for silent hypoxemia in COVID-19 include a relative lack of early changes in pulmonary mechanics, viral interactions with hemoglobin, inhibition of carotid body

responsiveness, and neuronal damage to the central nervous system. This is of particular concern because of the propensity of COVID-19 pneumonia to progress rapidly to severe respiratory failure despite a lack of dyspnea early in the course of infection. Careful monitoring of oxygen saturation and carbon dioxide levels is critical to identifying seriously ill individuals.

- Malignancies of the Respiratory Tract, 1182

Pulmonary disease is often classified as acute or chronic, obstructive or restrictive, infectious or noninfectious, and malignant or benign. Signs and symptoms of lung disease are common and associated not only with primary lung disorders, but also with diseases of other organ systems, particularly the heart.

Clinical Manifestations of Pulmonary Alterations

Signs and Symptoms of Pulmonary Disease

Pulmonary disease is associated with many signs and symptoms such as dyspnea and cough, and their specific characteristics often help identify underlying pulmonary disorder. Other signs and symptoms include abnormal sputum, hemoptysis, altered breathing patterns, cyanosis, nail clubbing, and chest pain.

Dyspnea

Dyspnea, a subjective experience of breathing discomfort, is one of the most common symptoms of pulmonary disease. It is often described as breathlessness, air hunger, shortness of breath, or labored breathing. Often a person becomes preoccupied with breathing. Even though dyspnea is a common pulmonary complaint, it can be due to other conditions, such as acute pain, heart disease, trauma, and anxiety.

Dyspnea originates from interactions among multiple physiological, psychological, social, and environmental factors. Stimulation of many receptors can contribute to the sensation of dyspnea, including afferent receptors in the brain and brainstem, mechanoreceptors in the chest wall and upper airway, and central and peripheral chemoreceptors that sense the effectiveness of gas exchange. These receptors communicate with the central nervous system respiratory control center, which then sends signals to the cerebral cortex and to the mechanical portions of the respiratory system to modulate breathing (see Chapter 34). In many individuals with dyspnea, neuromechanical dissociation exists between the inspiratory neural drive to breathe and the ability of the respiratory system to respond mechanically.[1] Damage to the lung parenchyma, diffuse or focal

disturbances of ventilation (e.g., pleural effusion, pneumothorax, asthma or muscle weakness), increased ventilatory demand (e.g., hypoxia, anemia, febrile states), alterations in gas exchange (e.g., pneumonia or pulmonary embolism [PE]), or decreases in compliance and ventilatory capacity (e.g., interstitial fibrosis or pulmonary edema) (see Chapter 34) can cause dyspnea.

Dyspnea may occur transiently or can become chronic. The magnitude of the experience of dyspnea may not directly correlate with the severity of the underlying disease. In fact, some individuals may not experience dyspnea even when they have very low blood oxygen levels (silent hypoxemia; see Chapter 34).[2] Dyspnea often first presents during exercise and is called dyspnea on exertion (DOE). DOE is common in individuals with underlying pulmonary disorders such as chronic obstructive pulmonary disease and asthma, and in those with heart failure. Orthopnea is dyspnea that occurs when an individual lies supine, which increases intrathoracic and intraabdominal pressure. This puts pressure on the diaphragm and the respiratory muscles and is usually relieved by standing. Paroxysmal nocturnal dyspnea (PND) occurs when individuals with pulmonary or cardiac disease awake at night with air hunger requiring the person to sit or stand to relieve the dyspnea.

More severe signs of dyspnea include nasal flaring and use of accessory muscles of respiration. Retractions (pulling inward of the intercostal or abdominal muscles during inspiration) can be seen in both children and in individuals with poorly developed thoracic musculature. Subjective complaints of dyspnea can be quantified by asking the individual to rate the level of dyspnea using an ordinal or visual analog scale. Dyspnea may be unrecognized in mechanically ventilated individuals and is often accompanied by pain and anxiety.

Cough

Cough is a protective reflex that helps clear the airways by an explosive expiration. Inhaled particles, accumulated mucus, inflammation, or the presence of a foreign body initiates the cough reflex by stimulating the irritant receptors in the epithelium of the airway. There are few such receptors in the most distal bronchi and the alveoli; thus, it is possible for significant amounts of secretions to accumulate in the distal respiratory tree without initiating the cough reflex. The cough reflex consists of inspiration, closure of the glottis and vocal cords, contraction of the expiratory muscles, and reopening of the glottis. These physiological changes cause a sudden, forceful movement of air through expiration that removes the offending substance. The effectiveness of the cough depends on the strength of the respiratory muscles and the depth of the inspiration. Those with an inability to cough effectively are at greater risk for pneumonia.

Acute cough is cough that resolves within 2 to 3 weeks of the onset of illness or resolves with treatment of the underlying condition. It can be caused by any upper or lower respiratory disease; but commonly is related to upper respiratory tract infections, allergic rhinitis, acute bronchitis, pneumonia, congestive heart failure, pulmonary embolus, or aspiration. *Chronic cough* is defined as cough that is persistent beyond 8 weeks.[3] In individuals who do not routinely inhale irritants such as tobacco smoke, the most common causes of chronic cough are postnasal drainage, asthma, bronchitis or bronchiectasis, and gastroesophageal reflux disease (GERD). Medications, such as angiotensin-converting enzyme (ACE) inhibitors, can also cause chronic cough. ACE inhibitor-related cough is believed to result from decreased breakdown in bradykinin and substance P, causing them to accumulate in the respiratory tract where they stimulate the cough reflex.[4] In persons who smoke or inhale toxins such as dust, sand, or chemicals, chronic bronchitis is the most common cause of chronic cough, although lung cancer must always be considered. Many cases may have no identifiable underlying cause.

Abnormal Sputum

Changes in the amount, color, and consistency of sputum provide information about the cause and progression of disease and the effectiveness of therapy. Expectorated sputum may look clear, foamy, purulent, or bloody. Purulent sputum can be yellow, green, or creamy in color. The gross

and microscopic appearances of sputum enable the clinician to identify cellular debris or microorganisms, which aids in diagnosis and choice of therapy.

Hemoptysis is the coughing up of bloody sputum originating from the tracheobronchial branches of the pulmonary system.[5] Hemoptysis is sometimes confused with hematemesis, which is the vomiting of blood. Bloody sputum is often frothy and is usually bright red with an alkaline pH. Hematemesis is usually dark with a coffee-ground appearance, has an acidic pH, and is often mixed with food particles. Hemoptysis usually indicates lung cancer, bronchiectasis, or infection (pneumonia, tuberculosis, lung abscess).[6] Other causes include cancer or PE. The amount and duration of bleeding provide important clues about its source. Chest imaging, often combined with bronchoscopy, is used to confirm the site of bleeding.

Abnormal Breathing Patterns

Normal breathing (eupnea) is involuntary, rhythmic, and effortless. The average adult has a resting ventilatory rate of 8 to 16 breaths/min and tidal volume of 400 to 800 mL with occasional deeper breaths or sighs. Sighs are voluntary deep breathing, help to maintain normal lung function, are usually 1.5 to 2 times the normal tidal volume, and occur approximately 10 to 12 times per hour. Anxiety can cause sighing respirations, which consist of irregular breathing characterized by frequent, deep sighing inspirations.

The rate, depth, regularity, and effort of breathing undergo characteristic alterations in response to physiologic and pathophysiologic conditions. Patterns of breathing automatically adjust to minimize the work of respiratory muscles. Strenuous exercise or metabolic acidosis induces Kussmaul respiration (hyperpnea), which is characterized by a slightly increased ventilatory rate and very large tidal volumes.

Labored breathing occurs whenever there is an increased work of breathing, especially if the airways are obstructed. In large airway obstruction, a slow ventilatory rate (bradypnea), large tidal volume, increased effort, prolonged inspiration and expiration, and stridor or audible wheezing are typical. In small airway obstruction, a rapid ventilatory rate, small tidal volume, increased effort, prolonged expiration, and wheezing are often present. *Restricted breathing* is commonly caused by disorders, such as pulmonary fibrosis, that stiffen the lungs or chest wall and decrease compliance. Restricted breathing often results in small tidal volumes and tachypnea.

Shock and severe cerebral hypoxia contribute to gasping respirations that consist of irregular, quick inspirations with an expiratory pause. Cheyne-Stokes respirations are characterized by alternating periods of deep, shallow breathing and apnea. Apnea lasting 15 seconds or more is often followed by ventilations that increase in volume until a peak is reached; then ventilation (tidal volume) decreases again to apnea. Cheyne-Stokes respirations result from any condition that reduces blood flow to the brainstem, which in turn slows impulses sending information to the respiratory centers of the brainstem. Neurologic impairment above the brainstem can also be a contributing factor (see Chapter 17).

Hypoventilation and Hyperventilation

Hypoventilation is inadequate alveolar ventilation in relation to metabolic demands. Hypoventilation occurs when minute ventilation (respiratory rate × tidal volume) is reduced. It is caused by alterations in the drive to breathe (neurologic control) or the ability to respond to that drive (pulmonary mechanics). When alveolar ventilation is normal, carbon dioxide (CO_2) is removed from the lungs at the same rate as it is produced by cellular metabolism, and the arterial CO_2 pressure ($PaCO_2$) and alveolar CO_2 pressure (P_ACO_2) remain at normal levels. With hypoventilation, CO_2 removal lags behind CO_2 production, and the $PaCO_2$ increases, causing hypercapnia ($PaCO_2$ greater than 44 mm Hg) (see Table 34.2 for a definition of gas partial pressures and other common pulmonary abbreviations). Hypercapnia results in an increase in hydrogen ion

concentration (i.e., an increase in carbonic acid) in the blood leading to a pH of less than 7.35 (respiratory acidosis) that can affect the function of many tissues throughout the body.

Hypoventilation is often overlooked until it is severe because the breathing pattern and ventilatory rate may appear to be normal, and changes in the tidal volume can be difficult to detect clinically. Measurement of the $PaCO_2$ (i.e., blood gas analysis) or the amount of CO2 in the inspired and expired air (capnography) reveals the hypoventilation. Severe hypoventilation can cause secondary hypoxemia, somnolence, and disorientation.

Hyperventilation is alveolar ventilation exceeding metabolic demands. The lungs remove CO_2 faster than it is produced by cellular metabolism, resulting in a decreased $PaCO_2$, or hypocapnia ($PaCO_2$ <36 mm Hg). Hypocapnia results in a decrease in the concentration of hydrogen ions in the blood (i.e., a decrease in carbonic acid), leading to a pH of greater than 7.45 (respiratory alkalosis) that can interfere with tissue function. Hyperventilation commonly occurs with severe anxiety, acute head injury, pain, and in response to conditions that affect the lung and chest wall, especially those that cause hypoxemia. Like hypoventilation, hyperventilation can be determined by arterial blood gas analysis.

Cyanosis

Cyanosis is a bluish discoloration of the skin and mucous membranes caused by increasing amounts of desaturated or reduced hemoglobin (which is bluish) in the blood. *Peripheral cyanosis* results from poor blood circulation in the fingers and toes. It is most often caused by heart disease, intense peripheral vasoconstriction (such as that observed in persons who have Raynaud disease), or cold environments. Peripheral cyanosis is best seen in the nail beds. *Central cyanosis* is caused by decreased arterial oxygenation (low PaO_2) from decreased inspired oxygen (e.g., at high altitudes), central nervous system disorders that affect respiration, pulmonary diseases, or cardiac diseases. Central cyanosis is best assessed in the buccal mucous membranes and lips.

Lack of cyanosis does not necessarily indicate that oxygenation is normal. In adults, cyanosis is not evident until severe hypoxemia is present and, therefore, is an insensitive indicator of respiratory failure. Severe anemia (inadequate hemoglobin concentration) and carbon monoxide poisoning (in which hemoglobin binds to carbon monoxide instead of to oxygen) can cause inadequate oxygenation of tissues without causing cyanosis. Individuals with polycythemia (an abnormal increase in the number of red blood cells), however, may have cyanosis when oxygenation is adequate. Therefore, cyanosis must be interpreted in relation to the underlying pathophysiologic condition. If cyanosis is suspected, blood gas analysis should be done.

Clubbing

Clubbing is the selective bulbous enlargement of the end of a digit (finger or toe) (Fig. 35.1). It is recognized by measuring the nail-fold angle and phalangeal depth.[7] Its severity can be graded from 1 to 5 based on the extent of nail bed hypertrophy and the number of changes in the nails themselves. Clubbing of the nails is usually painless and develops gradually over weeks or months. The most common cause of clubbing in the United States is lung cancer.[7] Clubbing also is commonly associated with diseases that cause chronic hypoxemia, such as bronchiectasis, cystic fibrosis, pulmonary fibrosis, lung abscess, and congenital heart disease. Clubbing without underlying cancer or lung disease can occur in association with a variety of conditions including gastrointestinal disorders, hepatobiliary diseases, and endocrine disorders. Clubbing may be congenital.

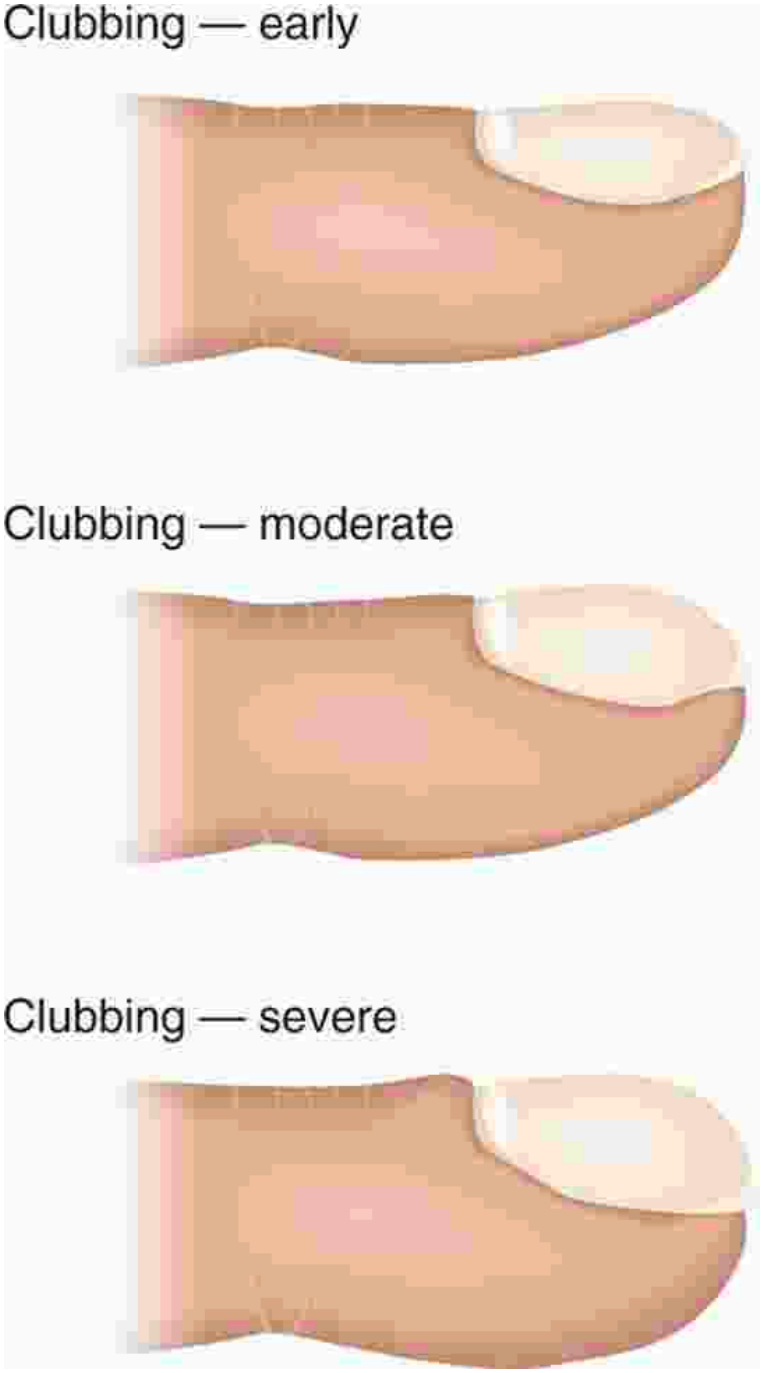

FIG. 35.1 Clubbing of Fingers Caused by Chronic Hypoxemia. (Modified from Seidel HM, et al. *Mosby's guide to physical examination*, 7th edition. St. Louis: Mosby; 2011.)

Three illustrations show the clubbing of fingers. Top panel, early clubbing. The illustration shows the right lateral profile of a finger with the floating nail sign. Middle panel, moderate clubbing. The illustration shows the right lateral profile of a finger with an increased convexity of the nail fold. Bottom

panel, sever clubbing. The illustration shows the right lateral profile of a finger with an enlarged end.

The exact cause of clubbing is unknown. In lung cancer, some propose that platelet clumps escape filtration by the pulmonary bed and enter the systemic circulation. These platelets then release platelet-derived growth factor (PDGF), causing periosteal changes near the nail bed. In individuals with chronic hypoxemia, some suggest that decreased oxygen causes the release of vascular endothelial growth factor, which promotes proliferation of the connective tissue between the nail matrix and the distal phalanx.[8] Clubbing is rarely reversible.

Pain

Pain caused by pulmonary disorders originates in the pleurae, airways, or chest wall. Infection and inflammation of the pleura (pleurisy or pleuritis) cause sharp or stabbing pain (pleurodynia) when the pleura stretches during inspiration. The pain is usually localized to a portion of the chest wall, where a unique breath sound called a *pleural friction rub* may be heard over the painful area during inspiration. Laughing or coughing makes pleural pain worse.

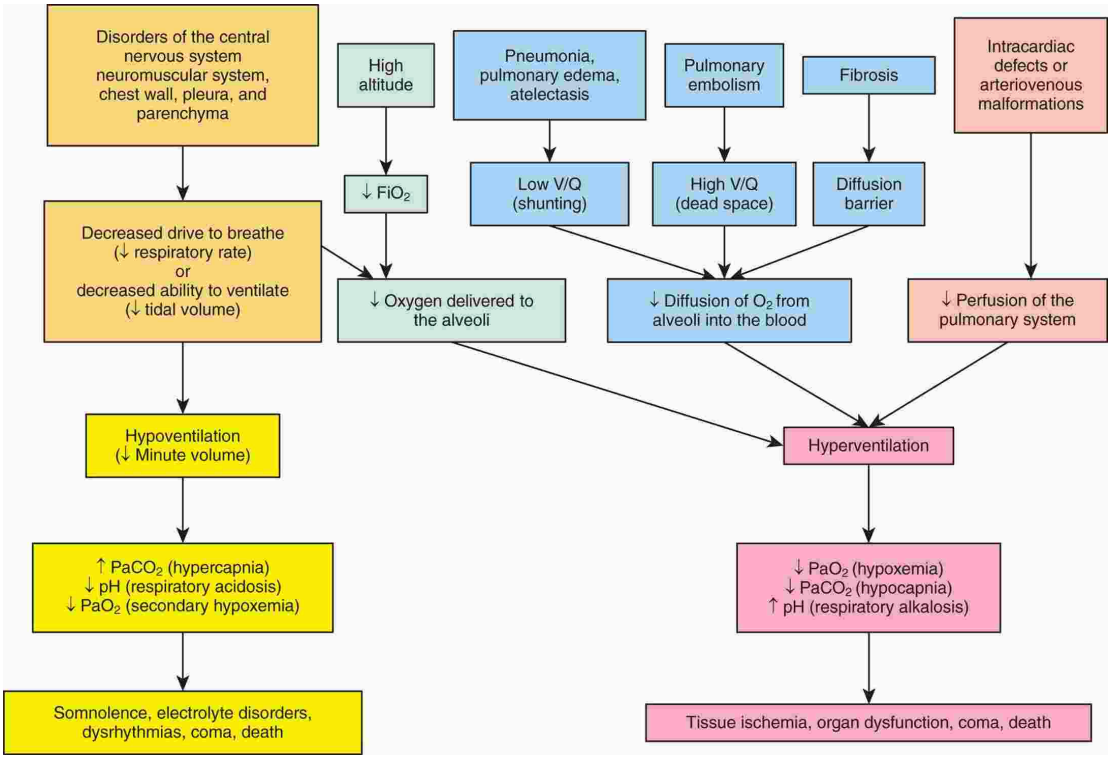
Infection and inflammation of the trachea or bronchi (tracheitis or tracheobronchitis, respectively) can cause central chest pain that is pronounced after coughing. High blood pressure in the pulmonary circulation (pulmonary hypertension [PH]) can cause pain during exercise that is often mistaken for angina-like cardiac pain.

Pain in the chest wall is muscle pain or rib pain. Excessive coughing (which makes the muscles sore) and rib fractures or thoracic surgery produce such pain. Inflammation of the costochondral junction (costochondritis) also can cause chest wall pain. Chest wall pain can often be reproduced by pressing on the sternum or ribs.

Conditions Caused by Pulmonary Disease or Injury

Hypercapnia

Hypercapnia, increased $PaCO_2$, is caused by hypoventilation of the alveoli (Algorithm 35.1). CO_2 is easily diffused from the blood into the alveolar space, but it must be removed from the alveoli by ventilation to maintain a normal $PaCO_2$. Thus, minute ventilation (respiratory rate × tidal volume) determines not only the alveolar ventilation, but also the $PaCO_2$. Although respiratory rate is measured routinely, tidal volume is difficult to assess at the bedside, and hypoventilation can be overlooked. Therefore, if hypoventilation is suspected, it is important to obtain blood gas analysis or capnography to determine the severity of the hypercapnia and resultant respiratory acidosis (acid-base balance is described in Chapter 3).



ALGORITHM 35.1 Hypercapnia and Hypoxemia.
Disorders that diminish the respiratory rate or tidal volume lead to hypoventilation, hypercapnia, and respiratory acidosis. Disorders that decrease the amount of oxygen delivered to the alveoli, the diffusion of oxygen from the alveoli into the blood, or perfusion of the pulmonary system are associated with hyperventilation, hypoxemia, and a respiratory alkalosis.

A flowchart shows the pathways to hypercapnia and hypoxemia. 1. Disorders of the central nervous system neuromuscular system, chest wall, pleura, and parenchyma. Leads to 2. 2. Decreased drive to breathe (decreased respiratory rate) or decreased ability to ventilate (decreased tidal volume). Leads to 3 and 8. 3. Hypoventilation (decreased minute volume). Leads to 4. 4. Increased partial pressure of carbon dioxide (hypercapnia), decreased p H (respiratory acidosis), and decreased partial pressure of oxygen (secondary hypoxemia). Leads to 5. 5. Somnolence, electrolyte disorders, dysrhythmias, coma, death. 6. High altitude. Leads to 7. 7. Decreased fraction of inspired oxygen. Leads to 8. 8. Decreased oxygen delivered to the alveoli. Leads to 18. 9. Pneumonia, pulmonary edema, atelectasis. Leads to 10. 10. Low V-Q ratio (shunting). Leads to 13. 11. Pulmonary embolism. Leads to 12. 12. High V-Q ratio (dead space). Leads to 13. 13. Decreased diffusion of oxygen from alveoli into the blood. Leads to 18. 14. Fibrosis. Leads to 15. 15. Diffusion barrier. Leads to 13. 16. Intracardiac defects or arteriovenous malformations. Leads to 17. 17. Decreased perfusion of the pulmonary system. Leads to 18.

18. Hypertension. Leads to 19. 19. Decreased partial pressure of oxygen (hypoxemia), decreased partial pressure of carbon dioxide (hypocapnia), and increased p H (respiratory alkalosis). Leads to 20.20. Tissue ischemia, organ dysfunction, coma, and death.

Hypercapnia has many causes. Most are a result of a decreased drive to breathe or an inadequate ability to respond to ventilatory stimulation. Some of these causes include (1) depression of the respiratory center by drugs; (2) diseases of the medulla, including infections of the central nervous system or trauma; (3) abnormalities of the spinal conducting pathways, as in spinal cord disruption or poliomyelitis; (4) diseases of the neuromuscular junction or of the respiratory muscles themselves, as in myasthenia gravis or muscular dystrophy; (5) thoracic cage abnormalities, as in chest injury or congenital deformity; (6) large airway obstruction, as in tumors or sleep apnea; and (7) increased work of breathing or physiologic dead space, as in emphysema.

Hypercapnia and the associated respiratory acidosis can cause dysrhythmias due to electrolyte abnormalities. High levels of arterial CO_2 cause cerebral vasodilation, resulting in somnolence and even coma. Alveolar hypoventilation with an increased alveolar CO_2 concentration limits the amount of oxygen available for diffusion into the blood, thereby leading to secondary hypoxemia.

Hypoxemia

Hypoxemia, or reduced oxygenation of arterial blood (reduced PaO_2), is caused by respiratory alterations, whereas hypoxia (or ischemia) is reduced oxygenation of cells in tissues. Hypoxemia results from problems with one or more of the major mechanisms of oxygenation Table 35.1 lists some of the common clinical causes of hypoxemia. Although hypoxemia can lead to tissue hypoxia, tissue hypoxia also can result from other abnormalities unrelated to alterations of pulmonary function, such as low cardiac output, anemia, or cyanide poisoning.

Table 35.1

Causes of Hypoxemia

MECHANISM	COMMON CLINICAL CAUSES
Decrease in inspired oxygen (decreased FiO_2)	High altitude Low oxygen content of gas mixture Enclosed breathing spaces (suffocation)
Hypoventilation of the alveoli (secondary hypoxemia)	Lack of neurologic stimulation of the respiratory center (oversedation, drug overdose, neurologic damage)
	Defects in chest wall mechanics (neuromuscular disease, trauma, chest deformity, air trapping)
	Large airway obstruction (laryngospasm, foreign body aspiration, neoplasm)
	Increased work of breathing (emphysema, severe asthma)
Ventilation-perfusion mismatch	Asthma Chronic bronchitis Pneumonia Acute respiratory distress syndrome Atelectasis Pulmonary embolism
Alveolocapillary diffusion abnormality	Edema Fibrosis Emphysema
Decreased pulmonary capillary perfusion	Intracardiac defects Intrapulmonary arteriovenous malformations

Decreased pulmonary capillary perfusion	Intracardiac defects Intrapulmonary arteriovenous malformations

Hypoxemia results from problems with one or more of the major mechanisms of oxygenation (see Algorithm 35.1):

1. Oxygen delivery to the alveoli
    a. Minute ventilation (secondary hypoxemia)
    b. Oxygen content of the inspired air (FiO_2)
2. Diffusion of oxygen from the alveoli into the blood
    a. Balance between alveolar ventilation and perfusion ($\dot{V}/\dot{Q}$ match)
    b. Diffusion of oxygen across the alveolar capillary barrier
3. Perfusion of the pulmonary system

The amount of oxygen in the alveoli is the P_AO_2 and is dependent on two factors. The first factor is the amount of alveolar minute ventilation (tidal volume × respiratory rate), as discussed previously in the Hypoventilation section. Hypoventilation results in an increase in the P_ACO_2 and a decrease in the amount of oxygen available in the alveoli for diffusion into the blood. This type of secondary hypoxemia is associated with hypercapnia and respiratory acidosis and can be corrected if alveolar ventilation is improved by increases in the rate and depth of breathing. The second factor is the presence of inadequate oxygen content of the inspired air. The amount of oxygen in inspired air is expressed as the percentage or fraction of air that is composed of oxygen, the FiO_2. The FiO_2 of air at sea level is 20.9%. Anything that decreases the FiO_2 (e.g., high altitude) decreases the P_AO_2.

Diffusion of oxygen from the alveoli into the blood also is dependent on two factors. The first is the balance between the amount of air that enters alveoli ($\dot{V}$) and the amount of blood perfusing the capillaries around the alveoli ($\dot{Q}$). An abnormal ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) is the most common cause of hypoxemia (Fig. 35.2). The normal $\dot{V}/\dot{Q}$ is 0.8 (also called the respiratory quotient) because some blood is normally shunted to the bronchial circulation so that ventilation is somewhat greater than perfusion. $\dot{V}/\dot{Q}$ mismatch refers to an abnormal distribution of ventilation

and perfusion. Hypoxemia can be caused by inadequate ventilation of well-perfused areas of the lung (low V· /Q·), resulting in wasted perfusion. Mismatching of this type, called shunting, occurs in atelectasis, in asthma because of bronchoconstriction, and in pulmonary edema and pneumonia when alveoli are filled with fluid. A compensatory mechanism called hypoxic pulmonary vasoconstriction causes arterioles that perfuse localized areas of shunting to constrict and reduce blood flow to the damaged lung tissue (see Chapter 34). This prevents wasted perfusion and sends the shunted blood to better functioning parts of the lung. This improves overall V· /Q· matching and raises the PaO_2. However, in lung diseases that affect large portions of the lung, diffuse hypoxic pulmonary vasoconstriction can lead to elevated pulmonary artery pressures (PH) and lead to right heart failure, or *cor pulmonale* (see Cor Pulmonale under Pulmonary Vascular Disease section).

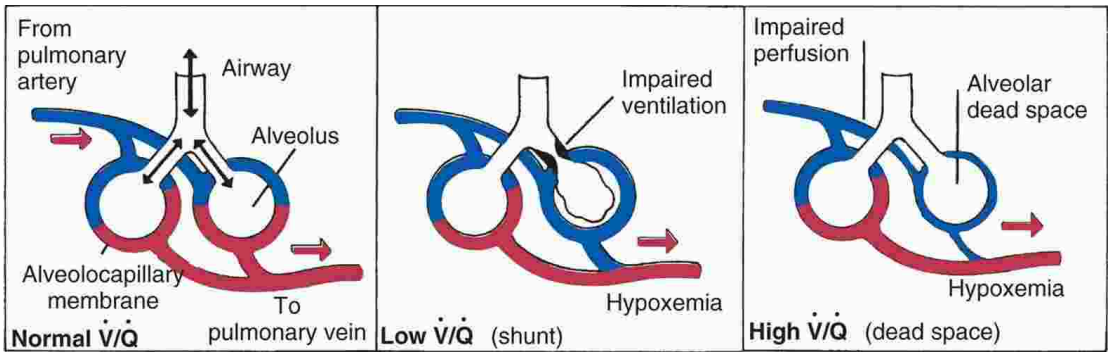

FIG. 35.2 Ventilation-Perfusion (V· /Q·) Abnormalities.

Three illustrations show ventilation-perfusion abnormalities. Left panel, normal V-Q ratio. The flow is traced from pulmonary artery through the alveolocapillary membrane of the alveolus and to the pulmonary vein. Middle panel, low V-Q ratio (shunt). 1 of the 2 alveoli is deformed, resulting in an impaired ventilation leading to hypoxemia. Bottom panel, high V-Q ratio (dead space). 1 of the 2 alveoli has alveolar dead space. The impaired perfusion leads to hypoxemia.

Hypoxemia also can be caused by poor perfusion of well-ventilated portions of the lung (high V· /Q·), resulting in wasted ventilation. The most common cause of high V· /Q· is a pulmonary embolus that impairs blood flow to a segment of the lung. An area where alveoli are ventilated but not perfused is termed alveolar dead space. Increases in alveolar dead space also occur in diseases, such as emphysema, that destroy lung tissue.

The second factor affecting diffusion of oxygen from the alveoli into the blood is the alveolocapillary membrane. Diffusion of oxygen through the alveolocapillary membrane is impaired if the membrane is thickened, or the surface area available for diffusion is decreased. Thickened alveolocapillary membranes, as occur with edema and fibrosis, increase the time required for oxygen to diffuse from the alveoli into the capillaries. If diffusion is slowed enough, the oxygenation levels (PO_2) of alveolar gas and capillary blood do not have time to equilibrate during the fraction of a second that blood remains in the capillary. Hypercapnia is seldom produced by impaired diffusion because CO_2 diffuses so easily from capillary to alveolus.

Hypoxemia can also result when blood flow bypasses the lungs, allowing deoxygenated venous blood to return to the systemic circulation. This can occur when there are intracardiac defects that

cause right-to-left shunting (see Chapter 33) or because of intrapulmonary arteriovenous malformations.

Hypoxemia is most often associated with a compensatory hyperventilation and the resultant respiratory alkalosis (i.e., decreased $PaCO_2$ and increased pH). However, in individuals with associated ventilatory difficulties, hypoxemia may be complicated by hypercapnia and respiratory acidosis. Hypoxemia results in widespread tissue dysfunction and, when severe, can lead to organ infarction. Clinical manifestations of acute hypoxemia may include cyanosis, confusion, tachycardia, edema, and decreased renal output.

Acute Respiratory Failure

Respiratory failure is defined as inadequate gas exchange, which is characterized as PaO_2 ≤60 mm Hg (hypoxemic respiratory failure) and/or $PaCO_2$ ≥50 mm Hg, pH ≤7.25 (hypercapnic respiratory failure). Respiratory failure can result from direct injury to the lungs, airways, or chest wall or indirectly because of disease or injury involving another body system, such as the brain, spinal cord, or heart. If the respiratory failure is primarily hypercapnic, it is the result of inadequate alveolar minute ventilation and the individual requires ventilatory support, such as with a bag-valve mask, noninvasive positive pressure ventilation, or intubation and the use of mechanical ventilation. If the respiratory failure is primarily hypoxemic, it is the result of inadequate exchange of oxygen between the alveoli and the capillaries and the individual must receive supplemental oxygen. Many people will have combined hypercapnic and hypoxemic respiratory failure and will require both kinds of support.

Of the many possible causes of respiratory failure, it is especially important to recognize that it is a potential complication of any major surgical procedure, especially those that involve the central nervous system, thorax, or upper abdomen. The most common postoperative pulmonary problems are atelectasis, pneumonia, pulmonary edema, and pulmonary emboli, each of which may cause respiratory failure. People who smoke or are obese are at particular risk, especially if they have preexisting lung disease. Limited cardiac reserve, neurologic disease, chronic renal failure, chronic hepatic disease, and infection also increase the tendency to develop postoperative respiratory failure.

Prevention of respiratory failure includes the recognition of at-risk individuals and the initiation of deep-breathing exercises and early ambulation to prevent atelectasis and the accumulation of secretions. Incentive spirometry provides individuals immediate feedback about tidal volumes, which encourages them to breathe more deeply. Humidification of inspired air can help loosen secretions. Antibiotics may be prescribed to treat infection. If severe respiratory failure develops, the individual may require mechanical ventilation or extracorporeal membrane oxygenation.

Disorders of the Chest wall and Pleura

Many conditions can affect the chest wall, pleura, or both, and compromise the function of the respiratory system. Chest wall disorders primarily affect tidal volume, resulting in hypoventilation and hypercapnia. Pleural diseases impact both ventilation and oxygenation.

Chest Wall Restriction

If the chest wall is deformed, traumatized, immobilized, or heavy from the accumulation of fat, the work of breathing increases, and ventilation may be compromised because of a decrease in tidal volume. The degree of ventilatory impairment depends on the severity of the chest wall restriction. Grossly obese individuals are often dyspneic on exertion or when recumbent. Individuals with severe kyphoscoliosis (bending and rotation of the spinal column, with distortion of the thoracic cage) often present with dyspnea on exertion that can progress to respiratory failure. Other musculoskeletal abnormalities that can impair ventilation are ankylosing spondylitis (see Chapter 44) and pectus excavatum (a deformity characterized by depression of the sternum).

Impairment of respiratory muscle function caused by neuromuscular diseases, such as poliomyelitis, muscular dystrophy, myasthenia gravis, and Guillain-Barré syndrome (see Chapters 18 and 45), also can restrict the chest wall and impair pulmonary function. Muscle weakness can result in hypoventilation, hypercapnia, inability to remove secretions, and hypoxemia.

Pain from chest wall injury, surgery, or disease can restrict the movement of the chest wall, causing significant hypoventilation. Trauma to the thorax not only can restrict chest expansion because of pain but also can cause structural and mechanical changes that impair the ability of the chest to expand normally. Flail chest complicates up to 15% of chest trauma cases.[9] It results from the fracture of several consecutive ribs with or without fracture of the sternum. These multiple fractures result in instability of a portion of the chest wall, causing paradoxical movement of the chest with breathing. During inspiration, the negative intrathoracic pressure causes the unstable portion of the chest wall to move inward and during expiration it moves outward, impairing movement of gas.

In chest wall restriction, an increase in the respiratory rate can compensate for small decreases in tidal volume. However, as tidal volume decreases further, hypercapnic respiratory failure develops. Although alveolar function is usually preserved, hypoxemia occurs secondary to the hypoventilation. A diagnosis of chest wall restriction is made by pulmonary function testing (reduction in forced vital capacity [FVC]), arterial blood gas measurement and capnography (hypercapnia), and radiographs. Treatment is aimed at any reversible underlying cause, and supportive measures such as physiotherapy, pain management, and incentive spirometry are indicated. In severe cases, noninvasive or invasive mechanical ventilation may be indicated. Flail chest is managed with positive-pressure ventilation and surgical stabilization.[9]

Pleural Abnormalities

Pneumothorax

Pneumothorax is the presence of air or gas in the pleural space. It is caused by a rupture in either the visceral pleura (surrounds the lungs) or the parietal pleura (lines the inner surface of the chest wall) or both. As air separates the visceral and parietal pleurae, it destroys the negative pressure of the pleural space and disrupts the equilibrium between the elastic recoil forces of the lung and chest wall. This disequilibrium causes the affected part of the lung to collapse toward the hilum (Fig. 35.3), resulting in impaired oxygenation and ventilation.

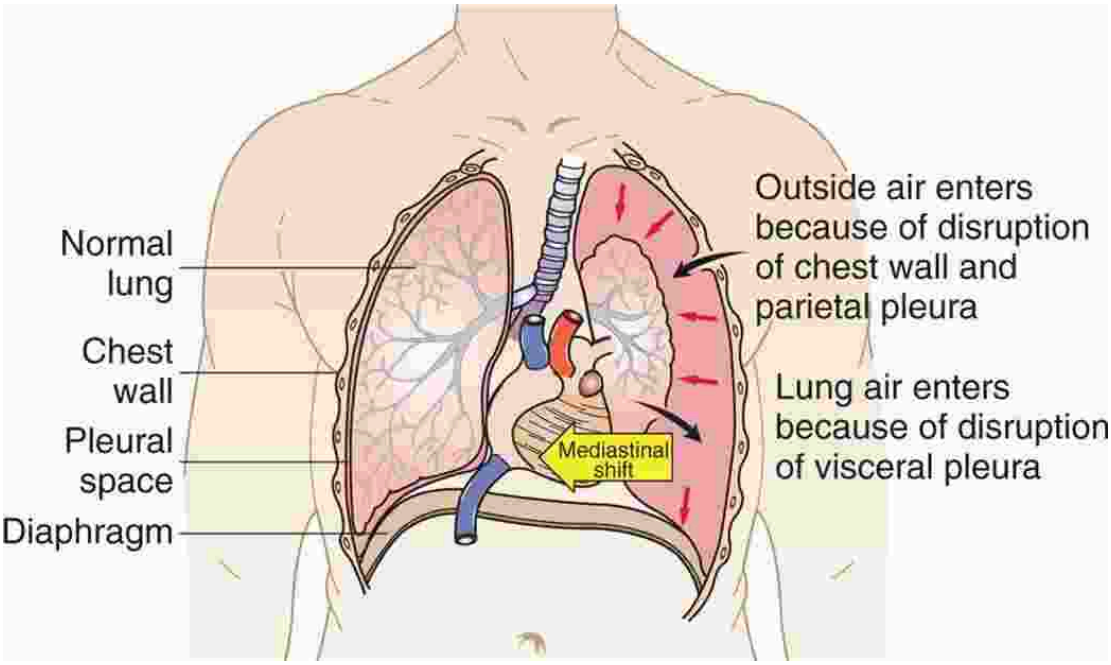

FIG. 35.3 Pneumothorax.
Air in the pleural space causes the lung to collapse around the hilus and may push the mediastinal contents (heart and great vessels) toward the other lung.

An illustration of the pneumothorax in a person's torso shows and labels the following structures: normal lung, chest wall, pleural space, and diaphragm. The following characteristics are described as well. • Outside air enters because of disruption of chest wall and parietal pleura. • Lung air enters because of disruption of visceral pleura. • Mediastinal shift is traced from the right to the left along the bottom of the left lung. • Arrows show the wall compressing and the diaphragm expanding.

Pneumothorax can be categorized as spontaneous or traumatic, and spontaneous pneumothorax can be categorized as primary or secondary.[10] *Primary spontaneous pneumothorax* occurs unexpectedly in healthy individuals (usually men) between 20 and 40 years of age and is caused by the spontaneous rupture of blebs (blister-like formations) on the visceral pleura. Bleb rupture, usually in the apices of the lungs, can occur during sleep, rest, or exercise. The cause of bleb formation is not known, but there appears to be a genetic component, and more than 80% of these individuals have been found to have emphysema-like changes in their lungs despite no history of smoking. *Secondary spontaneous pneumothorax* occurs in individuals with underlying respiratory disorders such as emphysema, cystic fibrosis, tuberculosis, lung cancer, and pneumonia in which the integrity of the visceral pleura is compromised. *Traumatic pneumothorax* may be due to punctures by a fractured rib or knife and bullet wounds. It also may result from complications of medical interventions *(iatrogenic pneumothorax)*, such as transthoracic needle aspiration or mechanical ventilation (barotrauma). Traumatic pneumothorax frequently involves both the visceral and parietal pleura.

Spontaneous or traumatic pneumothorax can present as either open or tension. In open (communicating) pneumothorax, air that is drawn into the pleural space during inspiration through

the injured area is forced back out during expiration. Open pneumothorax usually results in partial lung collapse. In tension pneumothorax, the site of pleural rupture acts as a one-way valve, permitting air to enter the pleural space on inspiration but preventing its escape during expiration. As more air enters the pleural space, air pressure in the pleural space increases. Air pressure in the pleural space pushes against the lung, causing compression atelectasis. Both oxygenation and ventilation are severely impacted. As the pleural pressure continues to increase, it may press on the mediastinum, compressing and displacing the heart, great vessels, and trachea *(mediastinal shift)* (see Fig. 35.3). The pathophysiologic effects of tension pneumothorax are life-threatening.

Clinical manifestations of pneumothorax begin with sudden pleural pain, tachypnea, and dyspnea. Depending on the size of the pneumothorax, physical examination may reveal absent or decreased breath sounds and hyperresonance to percussion on the affected side. Tension pneumothorax may be complicated by severe hypoxemia, tracheal deviation away from the affected lung, and hypotension. The diagnosis of pneumothorax is confirmed with chest radiographs, ultrasound, and computed tomography (CT). Management of primary spontaneous pneumothorax is often possible in an ambulatory setting with placement of a small catheter into the pleural space equipped with one-way valve, although some individuals may require follow-up thoracic surgery to prevent recurrences.[11] In contrast, individuals with tension pneumothorax deteriorate rapidly, and immediate hospitalization and treatment are required. Pneumothorax is treated by aspiration, usually with insertion of a thoracostomy (chest) tube that is attached to a water-seal drainage system with suction. After the pneumothorax is evacuated and the pleural rupture has healed, the chest tube is removed. For individuals with persistent air leaks, other interventions may be needed, including pleurodesis (the instillation of substances such as talc into the pleural space) or surgery.[12]

Pleural Effusion

Pleural effusion is the presence of fluid in the pleural space. The source of the fluid is usually blood vessels or lymphatic vessels lying beneath the pleural space. Pleural effusions can be divided into five categories based on their mechanisms: transudative, exudative, empyema, hemothorax, and chylothorax (Table 35.2).

Table 35.2

Mechanism of Pleural Effusion

Type of Fluid/Effusion	Source of Accumulation	Primary or Associated Disorder
Transudate (hydrothorax)	Watery fluid that diffuses out of capillaries beneath pleura (i.e., capillaries in lung or chest wall)	Cardiovascular disease that causes high pulmonary capillary pressures; liver or kidney disease that disrupts plasma protein production, causing hypoproteinemia (decreased oncotic pressure in blood vessels)
Exudate	Fluid rich in cells and proteins (leukocytes, plasma proteins of all kinds; see Chapter 5) that migrates out of capillaries	Infection, inflammation, or malignancy of pleura that stimulates mast cells to release biochemical mediators that increase capillary permeability
Pus (empyema)	Microorganisms and debris of infection (leukocytes, cellular debris) accumulate in pleural space	Pulmonary infections, such as pneumonia; lung abscesses; infected wounds
Blood (hemothorax)	Hemorrhage into pleural space	Traumatic injury, surgery, rupture, or malignancy that damages blood vessels
Chyle (chylothorax)	Chyle (milky fluid containing lymph and fat droplets) that moves from lymphatic vessels into pleural space instead of passing from gastrointestinal tract to thoracic duct	Traumatic injury, surgical procedure, infection, or disorder that disrupts lymphatic transport

The principles of diffusion are described in Chapter 1; mechanisms that increase capillary permeability and cause exudation of cells, proteins, and fluid are discussed in Chapter 5.

Transudative pleural effusions are often clear or slightly discolored and contain few cells and little protein. Transudation of fluid into the pleural space occurs because of changes in hemodynamic or oncotic pressures within the pulmonary vessels (see Chapter 3). Common examples include congestive heart failure, in which venous and left atrial pressures are increased pushing fluid into the pleural space, and hypoproteinemia (such as is seen with liver and kidney disorders), which decreases capillary oncotic pressure and promotes diffusion of water out of the capillaries. Exudative effusion occurs in response to inflammation, infection, or malignancy and involves inflammatory processes that increase capillary permeability. When stimulated by biochemical mediators of inflammation, tight junctions between capillary endothelial cells open, enabling leukocytes and plasma proteins to migrate out into affected tissues (see Chapter 7). Exudative effusions that occur in association with pneumonia are called *parapneumonic effusions*.[13] These often resolve with treatment of the underlying infection but can progress to empyema. Empyema is pleural effusion containing infectious microorganisms. It develops when the pulmonary lymphatics become blocked, leading to an outpouring of contaminated lymphatic fluid into the pleural space.[13] Empyema occurs most commonly in older adults and children as a complication of pneumonia, surgery, trauma, or bronchial obstruction from a tumor. Commonly documented infectious organisms include *Staphylococcus aureus, Escherichia coli, Klebsiella*

pneumoniae, and anaerobic bacteria. Hemothorax is the presence of blood in the pleural space usually due to trauma, surgery, cancer, PE, or tuberculosis. Chylothorax results from a tear in the thoracic duct leading to the leakage of chyle into the pleural space. It is a rare complication of surgery and some malignancies. Most malignant pleural effusions are related to lung cancer, breast cancer, and lymphoma, occurring in an estimated one-third of individuals with lung cancer.[13]

Small collections of fluid may not affect lung function and remain undetected. Most will be removed by the lymphatic system once the underlying condition is resolved. Dyspnea, compression of the lung with impaired ventilation, and pleural pain are common in larger effusions. Mediastinal shift and cardiovascular complications occur in a large, rapidly developing effusions. Physical examination shows decreased breath sounds and dullness to percussion on the affected side. A pleural friction rub may be heard over areas of inflamed pleura.

The diagnosis is confirmed by chest imaging and thoracentesis. Chest radiographs may show large amounts of pleural fluid (Fig. 35.4). Thoracic ultrasound, CT, or MRI may be needed for smaller or more localized fluid collections. Thoracentesis can provide symptomatic relief, and examination of the fluid can assist in determining the type of effusion. The number and type of cells, the pH, and the presence or absence of microorganisms in the pleural fluid are determined.[13,14] In some cases, medical pleuroscopy and pleural biopsies may be needed to evaluate unexplained effusions.

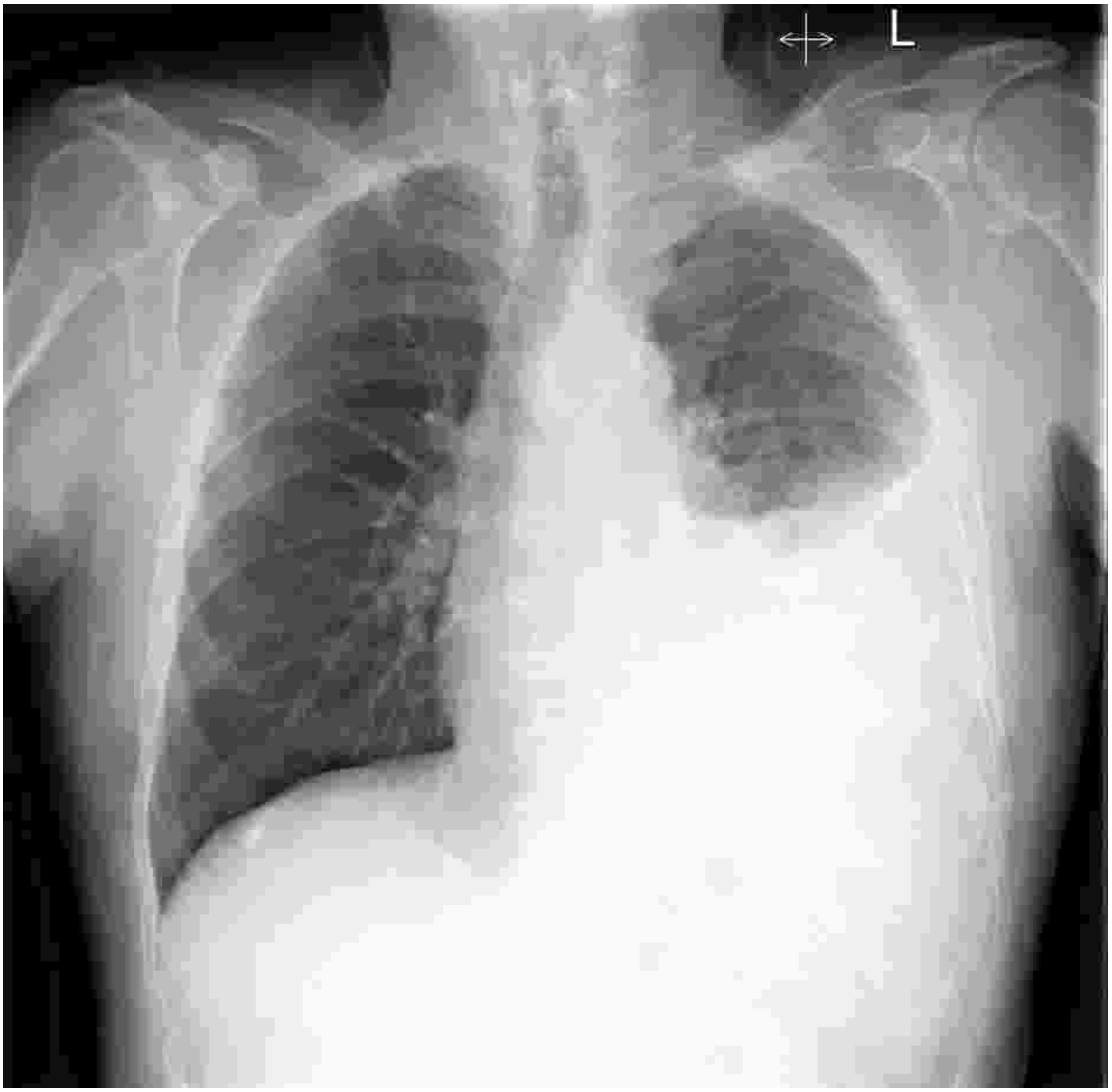

FIG. 35.4 Pleural Effusion. (From Tsitsias T, Santhirakumaran G, Jenkins M. Management of pleural effusions. *Surgery (Oxford)*, 2020;38(5), 244–248. https://doi.org/10.1016/j.mpsur.2020.03.004.)

Management depends on the type and cause of the pleural effusion.[15] Transudative effusions are managed by treating the underlying condition. Exudative effusions are also managed by treating the underlying condition; however, if the effusion is large, drainage is achieved through the placement of a chest tube. Management of empyema includes the administration of appropriate antimicrobials and drainage of the pleural space with a chest tube, often combined with the use of intrapleural enzyme therapy, such as deoxyribonuclease (stimulates pleural fluid formation, reduces pleural fluid viscosity, and promotes resolution of systemic inflammation) to achieve adequate drainage. Malignant exudative effusions may require placement of an indwelling pleural catheter and pleurodesis.[13] Hemothorax is managed surgically. Chylothorax may improve spontaneously or may require radiation (in the case of malignancy) or surgical management.

Pulmonary Disorders

Restrictive Lung Diseases

Restrictive lung diseases are characterized by decreased compliance (stiffness) of the lung tissue. This means that more effort is needed to expand the lungs during inspiration, which increases the work of breathing. Individuals with lung restriction have dyspnea, an increased respiratory rate, and a decreased tidal volume. Pulmonary function testing reveals a decrease in the FVC. Restrictive lung diseases also can cause V· /Q· mismatch and affect the alveolocapillary membrane, which reduces the diffusion of oxygen from the alveoli into the blood and results in hypoxemia. Some of the most common restrictive lung diseases in adults are aspiration, atelectasis, bronchiectasis, bronchiolitis, pulmonary fibrosis, inhalation disorders, pneumoconiosis, allergic alveolitis, pulmonary edema, and acute respiratory distress syndrome.

Aspiration

Aspiration is the passage of fluid and solid particles into the lung. It accounts for 5% to 15% of community-acquired pneumonia cases, especially in older individuals.[16] An estimated 45% of the population aspirates while sleeping without causing disease.[17] Predisposing factors for clinically significant aspiration and aspiration pneumonia include dysphagia; absent cough reflex; altered level of consciousness caused by substance use, sedation, or anesthesia; endotracheal intubation; being bedridden; neurologic disorders such as dementia, stroke, and seizure disorders; home oxygen therapy; use of proton pump inhibitor medications; and feeding through a nasogastric tube.[17] In the upright individual, the right lung, particularly the right lower lobe, is more susceptible to aspiration than the left lung because the branching angle of the right mainstem bronchus is straighter than the branching angle of the left mainstem bronchus. In recumbent individuals, the superior segments of the lower lobes and the posterior segments of the upper lobes are most commonly affected.[18]

The characteristics of the aspirated material interact with host defenses leading to several possible pulmonary complications, including aspiration pneumonia, pneumonitis, pulmonary abscess, and airway obstruction. Aspiration of oral or pharyngeal secretions, including acidic gastric fluid, results in bronchial and alveolar inflammation and aspiration pneumonitis. Bronchial damage includes loss of ciliary function and bronchospasm. In the alveoli, acidic fluid damages the alveolocapillary membrane and diminishes surfactant production. Consequently, plasma and blood cells move from capillaries into the alveoli, and the lung becomes stiff and noncompliant. Aspiration of oral contents may lead to infection of the lung parenchyma resulting in aspiration pneumonia.[18] The type and number of microorganisms present in the oropharynx (oral microbiome) along with host defense mechanisms interact to determine the likelihood and severity of aspiration pneumonia. In recent years, the most common causative microorganisms have changed such that gram-negative aerobic bacteria are now more common than anaerobes.[16,17] Aspiration of large food particles has serious consequences. Solid food particles can obstruct a bronchus, resulting in bronchial inflammation and collapse of airways distal to the obstruction. If the aspirated solid is not identified and removed by bronchoscopy, a chronic, local inflammation develops that may lead to recurrent infection, abscess formation, and bronchiectasis.

Clinical manifestations of acute aspiration include the sudden onset of choking or intractable cough with or without vomiting. The development of aspiration pneumonitis is characterized by dyspnea, tachypnea, and tachycardia. Auscultation reveals both crackles and wheezes. Hypoxemia develops rapidly. Fever and purulent sputum production are common if aspiration pneumonia develops. Chronic aspiration is characterized by recurrent lung infections, chronic cough, or persistent wheezing over months and even years. Diagnosis is made by assessing risk factors, symptoms, and chest radiographs. In some individuals, bronchoscopy with bronchoalveolar lavage is indicated.

Preventive measures for individuals at risk include use of a semirecumbent position, surveillance of enteral feeding, use of promotility drugs, and avoidance of excessive sedation. Fasting for a minimum of 8 hours before surgery reduces the incidence of aspiration associated with general

anesthesia. The use of nasogastric tubes to reduce stomach contents is controversial and has not been shown to reduce the incidence of aspiration.[16]Oral hygiene may reduce the incidence of aspiration pneumonia. Speech-language pathologists employ a variety of feeding and swallowing techniques that can significantly reduce the risk of aspiration in selected individuals.

Treatment of aspiration pneumonitis includes use of supplemental oxygen and suctioning. Mechanical ventilation may be needed in severe cases. Routine administration of corticosteroids or antibiotics is not recommended for mild to moderate aspiration pneumonitis.[16] If aspiration pneumonia develops, the administration of antibiotics is indicated.[17]

Atelectasis

Atelectasis is the collapse of lung tissue. Atelectasis causes V· /Q· mismatch, leading to hypoxemia. There are three types of atelectasis:

1. Obstructive (absorption) atelectasis results from obstructed or hypoventilated alveoli as the air is gradually absorbed out of the alveoli and into the blood. Mucous plugging or bronchogenic lung carcinoma are common causes of airway obstruction causing atelectasis.[19] Aspiration of a foreign body may also result in airway obstruction and atelectasis. A subset of obstructive atelectasis occurs due to hypoventilation of alveoli, especially in individuals who have undergone surgery or who have severe chest or abdominal pain. After surgery, individuals are often in pain, breathe shallowly, are reluctant to change position, and produce viscous secretions that tend to pool in dependent portions of the lung, causing obstruction of small airways. This type of atelectasis occurs in subsegmental portions of the lung forming 'platelike' lesions.
2. Compression atelectasis is caused by external pressure exerted by tumor, fluid, or air in the pleural space or by abdominal distention pressing on a portion of lung, causing alveoli to collapse.
3. Surfactant impairment (adhesive) atelectasis results from decreased production or inactivation of surfactant. Surfactant is necessary to reduce surface tension in the alveoli and thus prevent lung collapse during expiration. Surfactant impairment can occur because of premature birth and from any serious lung injury, such as aspiration, acute respiratory distress syndrome, anesthesia induction, or mechanical ventilation.

Clinical manifestations of atelectasis include dyspnea, cough, fever, and leukocytosis and therefore may be mistaken for infection. Prevention and treatment of atelectasis usually include deep-breathing exercises (often with the aid of an incentive spirometer), frequent position changes, and early ambulation. Deep breathing promotes ciliary clearance of secretions, stabilizes the alveoli by redistributing surfactant, and promotes collateral ventilation through the *pores of Kohn*, promoting expansion of collapsed alveoli (Fig. 35.5). Bronchoscopy may be needed to remove foreign bodies, or when complete or near-complete lung atelectasis has occurred.

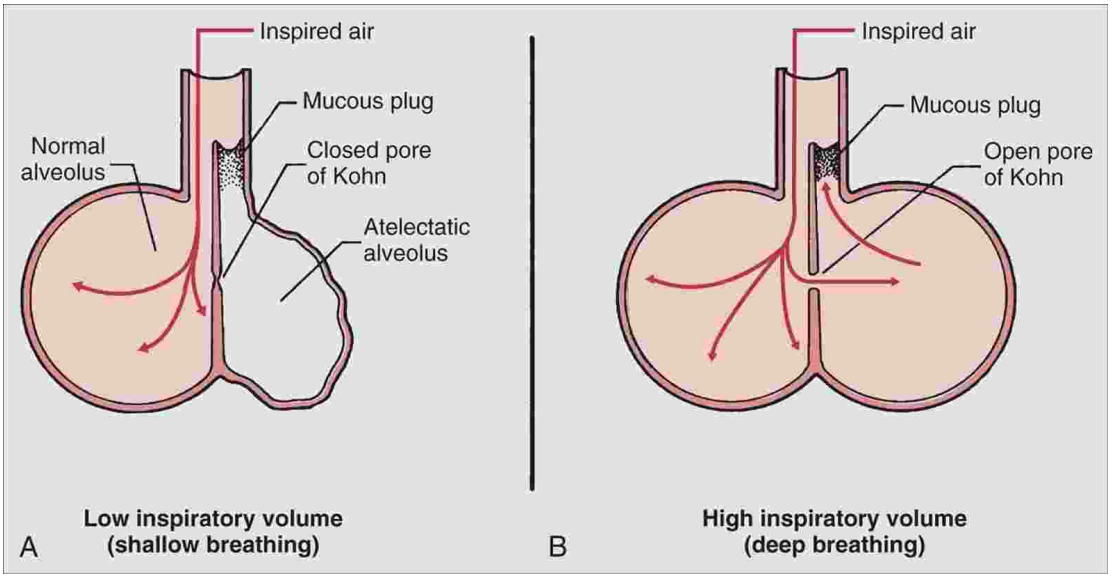

FIG. 35.5 **Pores of Kohn.**
(A) Absorption atelectasis caused by a lack of collateral ventilation through the pores of Kohn. **(B)** Restoration of collateral ventilation during deep breathing.

Two illustrations show the pores of Kohn. Left panel, A, low inspiratory volume (shallow breathing). The illustration on the left shows a normal alveolus, while that on the right is atelectatic, with a mucous plug and a closed pore of Kohn. Inspired air flows into the normal alveolus. Right panel, B, high inspiratory volume (deep breathing). The illustration on the right shows two normal alveolus. The alveolus on the right shows a mucous plug and an open pore of Kohn. Inspired air flows into the normal alveolus on the left, from where it flows to the alveolus on the right.

Bronchiectasis

Bronchiectasis is persistent abnormal dilation of the bronchi. It usually occurs in conjunction with other respiratory conditions that are associated with chronic bronchial inflammation, such as cystic fibrosis. It also can occur due to prolonged atelectasis, aspiration of a foreign body, recurrent pulmonary infections (e.g., mycoplasma, viruses), tuberculosis, or congenital weakness of the bronchial wall. Bronchiectasis also is associated with a number of systemic disorders, such as rheumatologic disease, inflammatory bowel disease, and immunodeficiency syndromes (e.g., acquired immunodeficiency syndrome [AIDS]). There may be no known cause (idiopathic). Several classification schemes for bronchiectasis have been proposed based on underlying cause, pathologic features (e.g., cylindrical, saccular, varicose), microbiologic phenotypes, or clinical presentation. However, the heterogeneity of the disease process and associated clinical features has limited the clinical utility of these classification groupings.[20]

In most cases, the bronchiectasis results from recurrent inflammatory and infectious insults to the bronchial epithelium leading to the infiltration of neutrophils and the release of neutrophil-derived proteases that destroy the elastic and muscular components of the bronchial walls.[21] This is followed by obstruction of the bronchial lumen, fibrosis, and permanent dilation. Chronic infection

by *Pseudomonas aeruginosa* is common and is associated with more rapid lung function decline, more sputum production, and increased mortality.[22]

The primary symptom of bronchiectasis is a chronic productive cough. Dyspnea and fatigue are common. Recurrent lower respiratory tract infections lead to expectoration of copious amounts of foul-smelling, purulent sputum. Common signs include clubbing of the fingers (from chronic hypoxemia) and hemoptysis. Hypoxemia occurs due to V· /Q· mismatch. Pulmonary function studies show decreases in the FVC and expiratory flow rates. The diagnosis is usually confirmed using high-resolution CT. Bronchiectasis is treated with antibiotics (inhaled or systemic), anti-inflammatory drugs, bronchodilators, mucolytic agents, chest physiotherapy, and supplemental oxygen.[21] Removal of the affected portion of the lung may be necessary. A lung transplant may be needed in advanced disease that is unresponsive to conventional treatment.[23]

Bronchiolitis

Bronchiolitis is a diffuse injury of the bronchioles (small airways with a diameter of 2 mm or less) resulting in inflammation and fibrosis. Primary bronchiolitis occurs most commonly in children due to viral infection. In adults, it most often results from smoking and chronic bronchitis but can occur in otherwise healthy individuals in association with an upper or lower respiratory tract infection. Bronchiolitis also occurs in association with interstitial lung diseases such as inhalational lung injury, hypersensitivity pneumonia, and pulmonary fibrosis. This type of bronchiolitis includes a fibrotic process that causes scarring of the lungs and is referred to as organizing pneumonia.[24] In severe lung injury, like that which may occur as a complication of lung or hematopoietic stem cell transplantation, the development of scarring and occlusion of the airways causes severe respiratory compromise and is referred to as bronchiolitis obliterans.[25]

Clinical manifestations of bronchiolitis include a rapid ventilatory rate, use of accessory muscles, low-grade fever, and a nonproductive cough. Wheezing may be heard. A V· /Q· mismatch results in hypoxemia. The diagnosis of bronchiolitis is made by bronchoscopy with biopsy. Bronchiolitis is treated with chest physical therapy that includes humidified air administration, deep-breathing exercises, and postural drainage. Pharmacologic management includes antibiotics, corticosteroids, and immunosuppressive drugs. Careful handling of the lung tissue prior to surgery, tailored management of antirejection drugs, and the use of other medications (e.g., azithromycin and montelukast) can improve bronchiolitis obliterans outcomes after lung transplantation.[26]

Pulmonary Fibrosis

Pulmonary fibrosis is an excessive amount of fibrous or connective tissue in the lung. Pulmonary fibrosis can be idiopathic or caused by formation of scar tissue after active pulmonary disease (e.g., acute respiratory distress syndrome, pneumonia, inhalational injury). It may also be associated with autoimmune disorders (e.g., rheumatoid arthritis, progressive systemic sclerosis, sarcoidosis), inhalation of harmful substances (e.g., coal dust, asbestos), or chest irradiation. Fibrosis of the interstitial lung tissue around the alveoli causes decreased oxygen diffusion across the alveolocapillary membrane and hypoxemia. As the disease progresses, decreased lung compliance leads to an increased work of breathing, a decreased tidal volume, and resultant hypoventilation with hypercapnia. Diffuse pulmonary fibrosis has a poor prognosis.

Idiopathic pulmonary fibrosis (IPF) is a chronic progressive disease of unknown etiology. IPF is the most common of the fibrosing interstitial lung diseases, although its true prevalence is difficult to determine because of inconsistent diagnostic criteria.[27] It typically affects older individuals, and men are affected more often than women. Environmental factors such as smoking, viral infections, gastroesophageal reflux, inhalational injuries, and associated aberrant DNA methylation patterns are felt to be a critical component of the risk for IPF.[28] Many gene polymorphisms for inflammatory, immune, and fibrotic responses have been linked to the development of IPF. Mutations in the MUC5b gene are linked to airway mucociliary dysfunction and microbiome dysbiosis.

Desmoplakin (DSP) variants contribute to changes in tissue architecture. Polymorphisms near the *AKAP13*, *ITGB6*, and *ELK1*genes have been identified that increase the risk of developing idiopathic pulmonary fibrosis (IPF) through increased growth factor and profibrotic cytokine production.[29]

The pathogenesis of IPF is felt to be multifactorial. Epithelial damage along with innate and adaptive immune responses involving neutrophils, macrophages, fibrocytes, and T lymphocytes result in the release of inflammatory cytokines and growth factors (e.g., transforming growth factor-β [TGF-β] and connective tissue growth factor [CTGF]).[30] Oxidative stress associated with activation of inflammatory and epithelial cells contributes to DNA damage, alveolar epithelial cell apoptosis, and the release of pro-fibrotic cytokines.[31] This initiates a fibrotic process that leads to interstitial and alveolar fibrin deposition, scarring, and "honeycombing" of the lung parenchyma. Dysfunctional surfactant production and alveolar collapse also occur.[32] Disease progression is highly variable, with some individuals demonstrating a slow decline, while others progress to death within a few years. Acute exacerbations may occur without clear provocation and accelerate decline.

IPF presents with dyspnea on exertion and dry cough. Auscultation reveals fine crackles. Many individuals also may present with symptoms and signs of comorbid conditions such as coronary artery disease, emphysema, and lung cancer. The diagnosis of IPF rests on the use of high-resolution CT scans and biopsies. Histological hallmarks include dense fibrosis and micro-honeycombing in the sub-pleural areas. Treatment includes pulmonary rehabilitation and symptom management along with psychosocial support, management of comorbidities, and palliative care. Two pharmacologic therapies aimed at decreasing the fibrotic process, nintedanib and pirfenidone, have been shown to slow disease progression in IPF.[33]Lung transplant is indicated in selected individuals. New approaches to therapy are in development (Emerging Science Box: Future Treatments for Idiopathic Pulmonary Fibrosis).[29]

Inhalation Disorders

Exposure to toxic gases

Inhalation of gaseous irritants can cause significant respiratory dysfunction. Commonly encountered toxic gases include smoke, ammonia, hydrogen chloride, sulfur dioxide, chlorine, phosgene, and nitrogen dioxide. Inhalation injuries in burns can include heat, smoke particles, and toxic gases from household or industrial combustants. Inhaled toxins cause damage to the airway epithelium and promote mucus secretion, inflammation, mucosal edema, ciliary damage, pulmonary edema, and surfactant inactivation. The cellular effects of exposure to toxic gases are described in Chapter 2. Acute toxic inhalation frequently is complicated by acute respiratory distress syndrome and pneumonia. Initial symptoms include burning of the eyes, nose, and throat; coughing; chest tightness; and dyspnea. Hypoxemia is common. Treatment includes supplemental oxygen, mechanical ventilation, bronchodilators, corticosteroids, and support of the cardiovascular system. Most individuals respond quickly to therapy. Some, however, may improve initially and then deteriorate as a result of bronchiectasis or bronchiolitis.

Emerging Science BoxFuture Treatments for Idiopathic Pulmonary Fibrosis

While the use of nintedanib and pirfenidone has been shown to slow the fibrotic process in idiopathic pulmonary fibrosis (IPF), long-term outcomes remain poor, and new therapies are needed. The pathophysiologic processes that contribute to the onset and progression of idiopathic pulmonary fibrosis are complex. Environmental factors interact with genetic and epigenetic factors to activate innate and adaptive immune responses culminating in interstitial fibrin deposition and alveolar collapse. Many new discoveries about these processes have been made. For example, the interaction between changes in the microorganisms that colonize the

pulmonary system (microbiome) and genetic mutations is being elucidated. Pulmonary microbiome dysbiosis with the presence of bacteria such as *Escherichia* is felt to contribute to epithelial cell dysfunction and initiation of fibrosis. The gene Mucin-5B is important to innate immune responses to microorganisms. It is believed that polymorphisms of the Mucin-5B gene and associated alterations of MUC5B protein gene are linked to the risk of developing IPF through their impact on immune responses to pulmonary dysbiosis. Another exciting area of research focuses on the role of autotaxins, which are a group of enzymes involved in fibroblast recruitment and epithelial damage. Discoveries such as these have led to numerous studies toward new approaches to the treatment of IPF, such as modulation of the lung microbiome and autotaxin inhibitors. Pamrevlumab, which is an anti- connective tissue growth factor antibody, has shown promising efficacy in IPF in phase III trials. Other treatments being researched include pentraxin-2 analogues, which inhibit fibroblast maturation; leukotriene antagonists, which reduce inflammation; monoclonal antibodies to interleukins and growth factors; and medications that block the adaptive immune system.

Prolonged exposure to high concentrations of supplemental oxygen can result in a relatively rare condition in adults known as oxygen toxicity. The basic underlying mechanism of injury is a severe inflammatory response mediated by oxygen free radicals and lipid peroxidation of cell membranes. Damage to alveolocapillary membranes results in disruption of surfactant production, production of interstitial and alveolar edema, fibrosis, and a reduction in lung compliance. In infants, this can lead to a condition known as *bronchopulmonary dysplasia*, in which there is severe scarring of the lung. Treatment involves a reduction of the inspired oxygen concentration as soon as tolerated.

Pneumoconiosis

Pneumoconiosis represents any change in the lung caused by inhalation of inorganic dust particles. Pneumoconiosis often occurs after years of exposure to the offending particles, with progressive fibrosis of lung tissue. The dusts of silica and coal inhaled in the workplace are the most common causes of pneumoconiosis. These exposures result in disorders called silicosis and coal workers' lung. Asbestosis is another form of pneumoconiosis. Other causes include talc, fiberglass, clays, mica, slate, cement, and metals (cadmium, beryllium, tungsten, cobalt, aluminum, iron, indium, and titanium).

Deposition of these materials in the lungs causes chronic inflammation with scarring of the alveolocapillary membrane, resulting in pulmonary fibrosis and progressive pulmonary deterioration. Silica and coal particles create pulmonary nodules as well as fibrotic interstitial infiltrates. Smoking-related emphysema and tuberculosis infection are serious comorbidities in many individuals with silicosis and coal workers' lung. Asbestos is composed of long thin particles which cause not only interstitial fibrotic changes but also pleural disease and cancer (bronchogenic cancer and malignant mesothelioma).[34]

Clinical manifestations of pneumoconiosis include cough, chronic sputum production, dyspnea, decreased lung volumes (restriction), and hypoxemia. Bronchospasm with wheezing is often present. In most cases, diagnosis is made by obtaining a complete exposure and occupational

history along with chest radiography. Lung biopsy is sometimes required to confirm the diagnosis. Treatment is usually palliative and focuses on preventing further exposure, management of associated hypoxemia and bronchospasm, and pulmonary rehabilitation.

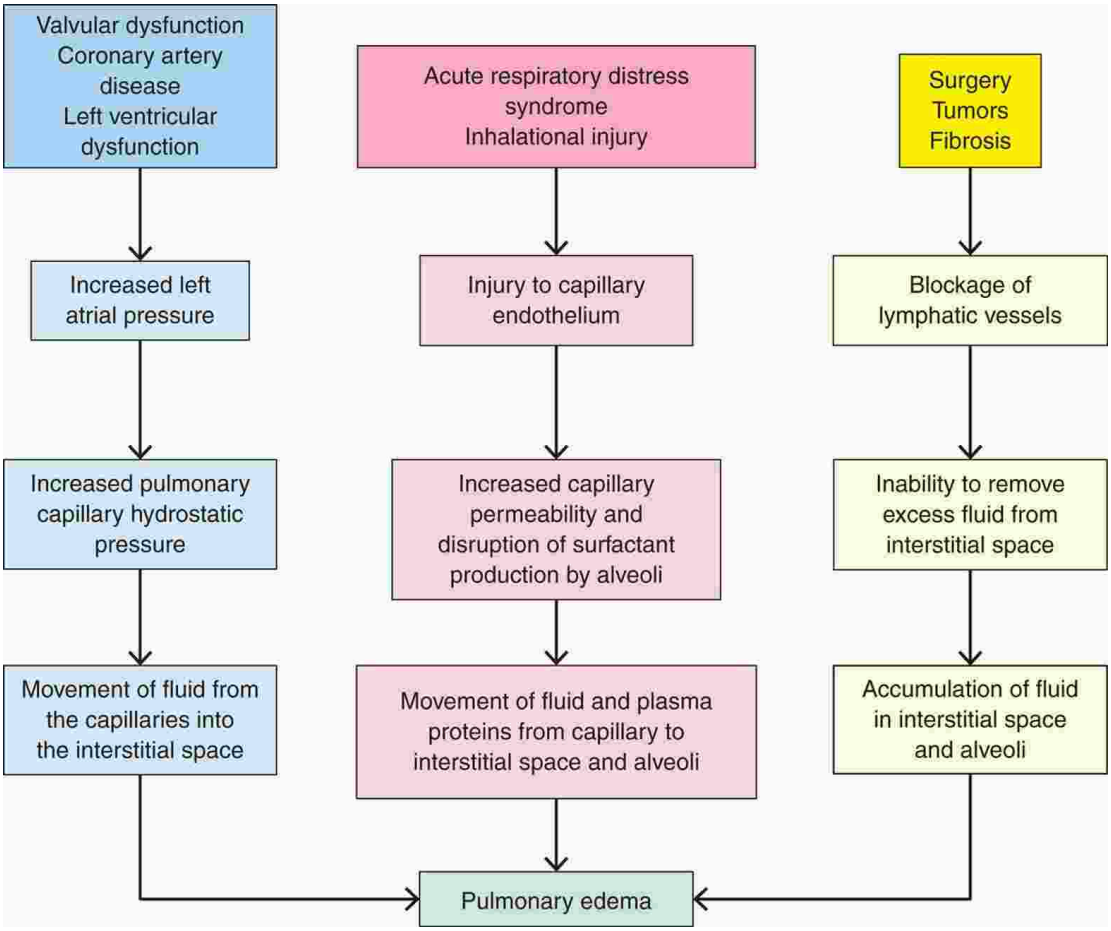
Hypersensitivity pneumonitis

Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an inflammatory disease of the lungs caused by inhalation of organic particles. Many organic substances can cause this disorder, including grains, silage, bird droppings or feathers, wood and cork dust, animal pelts, coffee beans, fish meal, mushroom compost, and molds that grow on sugarcane, barley, and straw. Although it is often described as an allergic disease, it is not immunoglobulin E (IgE)-mediated. Rather the pathophysiology is of type III and type IV hypersensitivity with infiltration of T cytotoxic lymphocytes, inflammatory cells, autoantibodies, and resultant tissue damage (see Chapter 9).[35]

Hypersensitivity pneumonitis can be classified into acute, chronic non-fibrotic, or chronic fibrotic forms.[36] The acute form results from high-level exposure, causes fever, cough, and chills a few hours after exposure. Tachypnea and inspiratory crackles over the lower lung lobes are found on physical examination. Chronic hypersensitivity pneumonitis results from long-term, low-level exposure and may occur within weeks, months, or even years of exposure.[36] With continued exposure, pulmonary fibrosis develops with progressive dyspnea, fatigue, and weight loss. The diagnosis is made by obtaining a history of exposure and by performing serum antibody testing, chest radiography, high resolution CT, bronchoscopy with lavage, and, in some cases, lung biopsy.[37] Treatment consists of removal of the offending agent and administration of corticosteroids. New antifibrotic medications are being explored.[36]

Pulmonary Edema

Pulmonary edema is excess fluid in the lung. The normal lung maintains minimal fluid in interstitial tissues by lymphatic drainage and a balance among capillary hydrostatic pressure, capillary oncotic pressure, and capillary permeability. Chapter 3 provides further discussion on osmotic forces (hydrostatic and oncotic pressures). In addition, surfactant lining the alveoli repels water, keeping fluid from entering the alveoli. Pulmonary edema develops when these protective mechanisms are disrupted. Predisposing factors for pulmonary edema include heart disease, lung capillary injury, and processes that block the lymphatic vessels. The pathogenesis of pulmonary edema is shown in Algorithm 35.2.



ALGORITHM 35.2 **Pathogenesis of Pulmonary Edema.**

A flowchart shows three pathways leading to pulmonary edema. The sequence of the pathway on the left is as follows. • Valvular dysfunction, coronary artery disease, and left ventricular dysfunction. • Increased left atrial pressure. • Increased pulmonary capillary hydrostatic pressure. • Movement of fluid from the capillaries into the interstitial space. The sequence of the pathway in the middle is as follows. • Acute respiratory distress syndrome inhalation injury. • Injury to capillary endothelium. • Increased capillary permeability and disruption of surfactant production by alveoli. • Movement of fluid and plasma proteins from capillary to interstitial space and alveoli. The sequence of the pathway on the right is as follows. • Surgery, tumors, fibrosis. • Blockage of lymphatic vessels. • Inability to remove excess fluid from interstitial space. • Accumulation of fluid in interstitial space and alveoli.

The most common cause of pulmonary edema is left-sided heart disease. When the left ventricle fails, filling pressures on the left side of the heart increase and cause a concomitant increase in the pulmonary capillary hydrostatic pressure (see Chapter 32). When the hydrostatic pressure exceeds

the oncotic pressure, fluid moves from the capillary into the interstitial space and alveoli. When the flow of fluid out of the capillaries exceeds the lymphatic system's ability to remove it, pulmonary edema develops.

Another cause of pulmonary edema is pulmonary or systemic injury that increases capillary permeability, as in cases of acute respiratory distress syndrome or inhalation of toxic gases. Damage to the alveolocapillary membrane and inflammation allow water, cells, and plasma proteins to leak out of the capillary and move into the interstitial space and alveoli. Pulmonary edema also can result from obstruction of the lymphatic system. This may occur during surgical procedures or because of the presence of tumors and fibrotic tissue. Fluid in the alveoli results in low a $\dot{V}/\dot{Q}$ ratio and hypoxemia.

Clinical manifestations of pulmonary edema include dyspnea, tissue hypoxia, and increased work of breathing. Physical examination may reveal inspiratory crackles (rales) and dullness to percussion over the lung bases. In severe cases, pink, frothy sputum is expectorated, hypoxemia worsens, and hypoventilation with hypercapnia may develop.

The treatment of pulmonary edema depends on its cause. If the edema is caused by increased hydrostatic pressure resulting from heart failure, therapy is directed toward improving cardiac output with diuretics, vasodilators, and drugs that improve the contraction of the heart muscle (see Chapter 32). If the edema is the result of increased capillary permeability resulting from injury, the treatment is focused on removing the offending agent and implementing supportive therapy to maintain adequate ventilation and circulation. Individuals with either type of pulmonary edema require supplemental oxygen. Lymphatic blockage is managed by treating the underlying condition but may not be reversible. Mechanical ventilation may be needed if edema significantly impairs ventilation and oxygenation.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a form of acute lung inflammation and diffuse alveolocapillary injury that results from direct pulmonary injury or from severe systemic inflammation. Although rare in the general population, it is estimated that 10% of individuals admitted to the ICU and 23% of all individuals requiring mechanical ventilation carry the diagnosis of ARDS.[38] Individuals with ARDS have an acute onset of bilateral infiltrates on a chest radiograph (i.e., pulmonary edema) and a persistent hypoxemia despite supplemental oxygen (low ration of PaO_2 to FiO_2). The most common predisposing factors are sepsis and multiple trauma. There are many other causes, including pneumonia, burns, aspiration, cardiopulmonary bypass surgery, pancreatitis, blood transfusions, drug overdose, inhalation of smoke or noxious gases, fat emboli, radiation therapy, and disseminated intravascular coagulation. The emergence of Coronavirus Disease-2019 (COVID-19) has resulted in a dramatic increase in the number of ARDS cases worldwide (Emerging Science Box: The Pathogenesis of the Acute Respiratory Distress Syndrome (ARDS) in COVID-19).[39] Several genetic and epigenetic factors have been identified that confer susceptibility to developing ARDS.[40] Several subphenotypes and endotypes of ARDS have been proposed (e.g., uninflamed versus hyperinflammatory forms), but to date, there is no clear clinical application of these classifications.[41] Despite advances in diagnosis and therapy, mortality remains at approximately 30% to 40%.[39]

Pathophysiology

All disorders causing ARDS result in an acute inflammatory lung injury characterized by diffuse alveolar damage and triggered by direct injury to the lung epithelium and/or by indirect biochemical injury to the endothelium.[38] Within 72 hours, damage to both pulmonary capillary endothelial cells and alveolar epithelial cells develops. Endothelial damage activates neutrophils, macrophages, and platelets with the

Emerging Science BoxThe Pathogenesis of the Acute Respiratory Distress Syndrome in COVID-19 Infection

As described in Chapter 10, the pathogenesis of COVID-19 infection begins when SARS-CoV-2 binds its viral S spike protein with angiotensin-converting enzyme (ACE)-2 receptors on host respiratory epithelial cells. SARS-CoV-2 infection in the respiratory system can be divided into three clinical stages: viral infection, pulmonary involvement with inflammation, and fibrosis. The virus first enters and replicates in the epithelial cells of the upper respiratory tract, making it transmissible from person to person through speech-related aerosolization of viral particles. The virus is then tropic for ciliated lower airway epithelial cells and alveolar type II pneumocytes, both of which express the ACE-2 receptor. There follows an inflammatory response involving infiltration of large numbers of macrophages and neutrophils and the release of cytokines including interleukins, tumor necrosis factor alpha, and interferons, along with the activation of complement and clotting systems. This has been called a "cytokine storm" and results in diffuse alveolar and microvascular damage and thrombosis. Fluid leaks into the pulmonary interstitium resulting in V· /Q· mismatch and hypoxemia. As the disease progresses, interstitial fibrosis and formation of hyaline membranes develop. In many individuals with COVID-19, these pathologic changes cause hypoxic pulmonary vasoconstriction, right-to-left shunting, and decreased pulmonary compliance like that seen in other forms of acute respiratory distress syndrome (ARDS). These individuals are severely dyspneic due to the increased work of breathing and frequently require mechanical ventilation with high levels of positive end-expiratory pressure (PEEP). However, in a significant proportion of those with ARDS associated with the COVID-19, there is little hypoxic pulmonary vasoconstriction and little reduction in lung compliance. These individuals are less likely to be severely dyspneic and may appear to be in much less overall respiratory distress. Mechanical ventilation with PEEP in these individuals may actually increase lung damage. Instead, a gradual escalation of oxygen therapy is indicated, including continuous positive airway pressure by means of noninvasive ventilation. Intubation with mechanical ventilation or extracorporeal membrane oxygenation (ECMO) are used only if these methods prove insufficient to maintain adequate gas exchange. Pharmacologic interventions that can be considered for COVID-19 associated ARDS include antivirals, monoclonal antibodies, corticosteroids, anticoagulants, inhaled vasodilators, bronchodilators, surfactant, and anti-immune therapies (see Chapter 10).

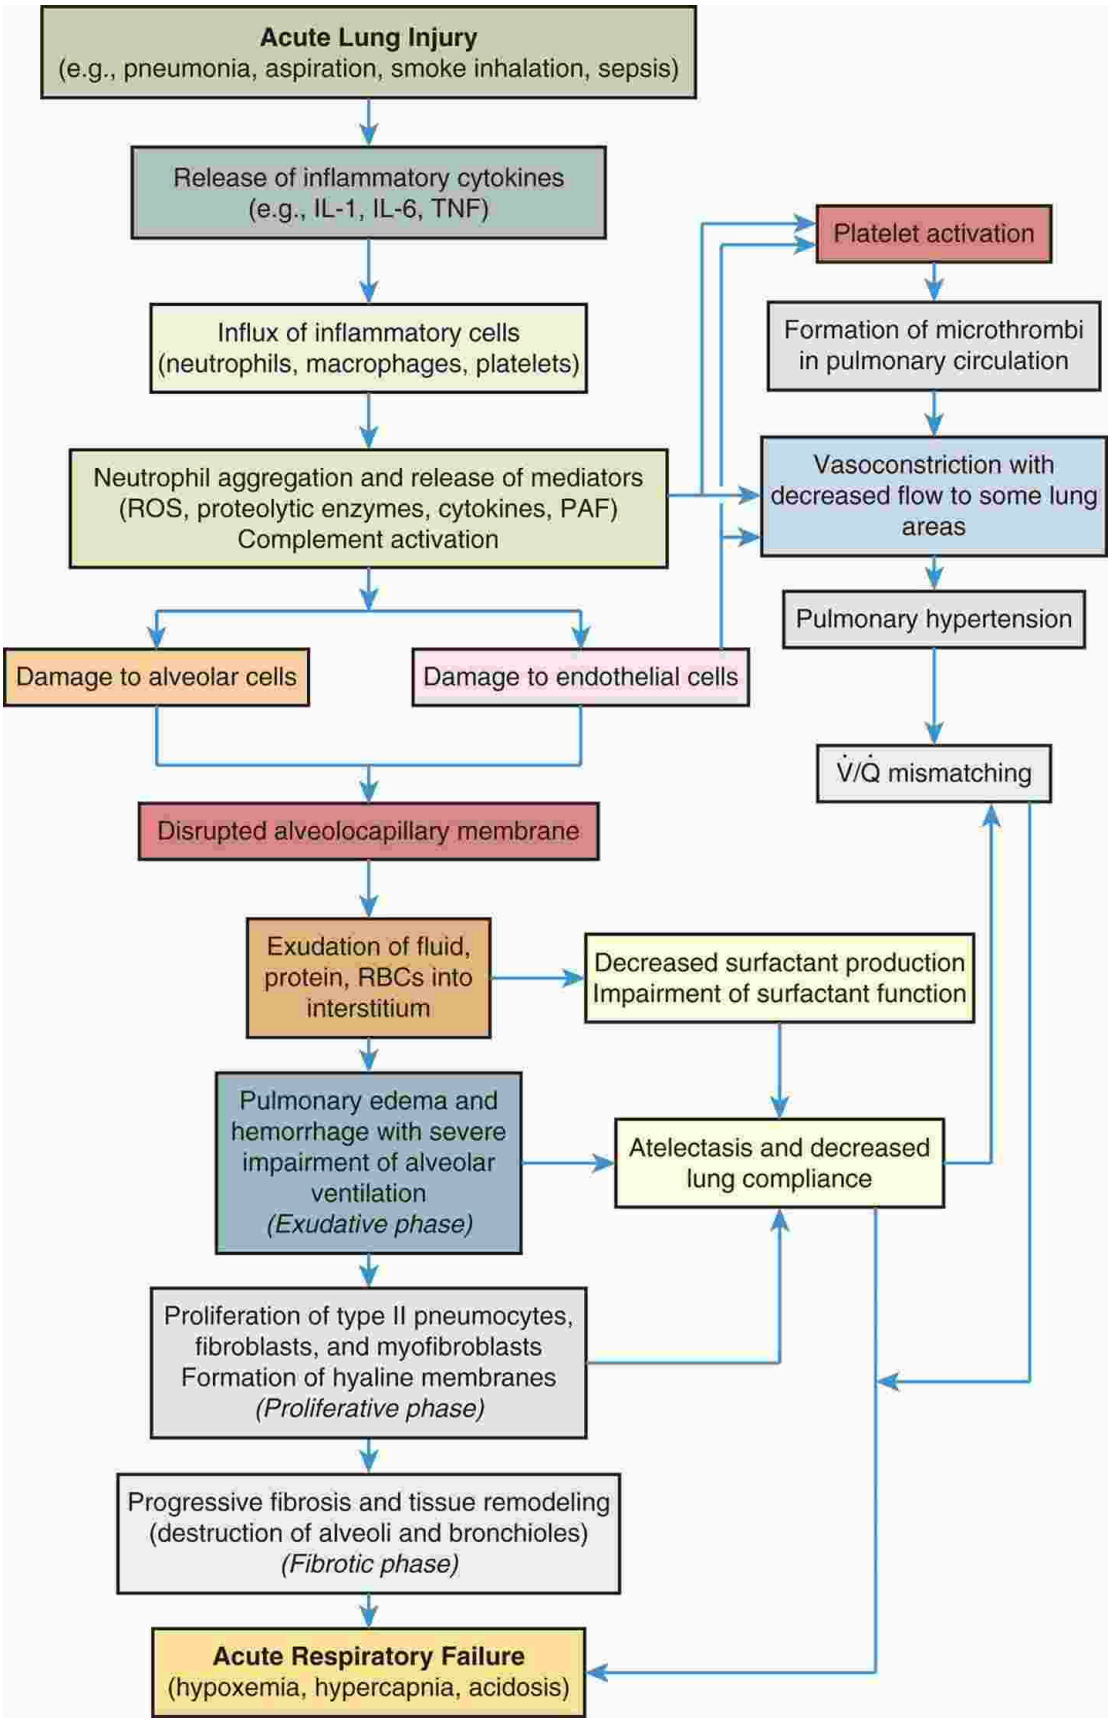
release of inflammatory cytokines, resulting in greatly increased capillary membrane permeability, hypercoagulability, and pulmonary arteriolar vasoconstriction. Fluids, proteins, and blood cells leak from the capillary bed into the pulmonary interstitium and flood the alveoli (exudative phase). Alveolar ventilation is severely reduced, resulting in V· /Q· mismatch and severe hypoxemia. Increasing respiratory rate results in an initial hypocapnia and respiratory alkalosis. Epithelial cell damage causes a reduction in surfactant production, resulting in atelectasis. Lung compliance

declines, with associated decreases in tidal volume and the development of hypercapnia. The result of this overwhelming inflammatory response by the lungs is acute hypoxemic and hypercapnic respiratory failure. Within 4 to 14 days, there is resolution of the pulmonary edema, and the proliferative phase of ARDS begins. The intra-alveolar exudate becomes cellular granulation tissue, appearing as hyaline membranes that form a diffusion barrier for oxygen exchange and resulting in continued hypoxemia. The final stage (fibrotic stage) occurs within 14 to 21 days and consists of remodeling and fibrosis of the lung tissue. In severe cases, the fibrosis progressively obliterates the alveoli, respiratory bronchioles, and interstitium, leading to long-term respiratory compromise. Algorithm 35.3 summarizes the pathogenesis of ARDS.



Acute Lung Injury
(e.g., pneumonia, aspiration, smoke inhalation, sepsis)
Release of inflammatory cytokines
(e.g., IL-1, IL-6, TNF)
Influx of inflammatory cells
(neutrophils, macrophages, platelets)
Neutrophil aggregation and release of mediators
(ROS, proteolytic enzymes, cytokines, PAF)
Complement activation
Damage to alveolar cells
Damage to endothelial cells
Disrupted alveolocapillary membrane
Exudation of fluid, protein, RBCs into interstitium
Pulmonary edema and hemorrhage with severe impairment of alveolar ventilation
(Exudative phase)
Proliferation of type II pneumocytes, fibroblasts, and myofibroblasts
Formation of hyaline membranes
(Proliferative phase)
Progressive fibrosis and tissue remodeling
(destruction of alveoli and bronchioles)
(Fibrotic phase)
Acute Respiratory Failure
(hypoxemia, hypercapnia, acidosis)
Platelet activation
Formation of microthrombi in pulmonary circulation
Vasoconstriction with decreased flow to some lung areas
Pulmonary hypertension
V̇/Q̇ mismatching
Decreased surfactant production
Impairment of surfactant function
Atelectasis and decreased lung compliance

Atelectasis and decreased lung compliance. Leads to 12 and 17.

Clinical Manifestations

The clinical manifestations of ARDS are progressive and include

1. Dyspnea and hypoxemia with poor response to oxygen supplementation
2. Initial hyperventilation and respiratory alkalosis
3. Decreased tissue perfusion, metabolic acidosis, and organ dysfunction
4. Increased work of breathing, decreased tidal volume, and hypoventilation
5. Hypercapnia, respiratory acidosis, and worsening hypoxemia
6. Respiratory failure, decreased cardiac output, hypotension, multiple organ dysfunction syndrome (MODS) and death

Evaluation and Treatment

The diagnosis is based on a history of the lung injury, physical examination, blood gas analysis, and chest radiographs. In 2012, a consensus definition described three major criteria for the diagnosis of ARDS: (1) onset within 1 week of known clinical insult or new or worsening respiratory symptoms;

(2) bilateral opacities not fully explained by effusions, lobar/lung collapse, or nodules on chest x-ray or CT; and (3) respiratory failure not fully explained by cardiac failure or fluid to exclude hydrostatic edema if no ARDS risk factor is present.[42] Measurement of serum biomarkers (i.e., surfactant proteins, B-type natriuretic peptide [BNP], C-reactive protein [CRP], and interleukins) may aid in the diagnosis and prognosis of ARDS. Treatment is based on early detection, supportive therapy, and prevention of complications. Supportive therapy is focused on maintaining adequate oxygenation and ventilation while preventing further lung injury and infection. This often requires high flow nasal oxygen and various modes of mechanical ventilation, prone positioning, or extracorporeal oxygenation.[43] The risk of barotrauma increases as lung compliance decreases, making lung-protective strategies of ventilation (e.g., lowering tidal volume and driving pressure) essential in severe disease.[44] To date, no pharmacologic interventions have been consistently shown to improve morbidity or mortality, although corticosteroids continue to be recommended for moderate to severe ARDS.[39] New treatment strategies such as mesenchymal stem cell and exosome-based therapies are showing early promise.[45] COVID-19 related ARDS is treated with antivirals, monoclonal antibodies, corticosteroids, anticoagulants, inhaled vasodilators, bronchodilators, surfactant, and anti-immune therapies (see Emerging Science Box: The Pathogenesis of the Acute Respiratory Distress Syndrome (ARDS) in COVID-19).[39]

Obstructive Lung Diseases

Obstructive lung disease is characterized by narrowing of the airways, resulting in airway obstruction that is worse with expiration. More force is required to expire a given volume of air; thus, individuals have an increased work of breathing and must use their accessory muscles of expiration. Emptying of the lungs is slowed, as measured by a decreased forced expiratory volume in 1 second (FEV_1). Air is trapped in the lungs resulting in decreased tidal volume eventually leading to hypoventilation and hypercapnia. Changes in alveolar ventilation result in $\dot{V}/\dot{Q}$ mismatching and hypoxemia. The unifying symptom of obstructive lung diseases is dyspnea, and the unifying sign is wheezing. The most common obstructive diseases are asthma, chronic bronchitis, and emphysema. Because many individuals have chronic bronchitis with emphysema, these diseases together are often called *chronic obstructive pulmonary disease (COPD)*.

Asthma

Asthma, as defined by the Global Initiative for Asthma (GINA) 2021 report, is a "…heterogenous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms, such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation."[46] The chronic inflammation causes bronchial hyperresponsiveness, constriction of the airways, and variable airflow obstruction that is reversible, although airflow limitation may become persistent with disease progression. Asthma occurs at all ages, affecting 7% of children (see Chapter 36) and 8% (approx. 20 million) adults in the United States.[47] It is more prevalent in women and in individuals who live below the poverty level.

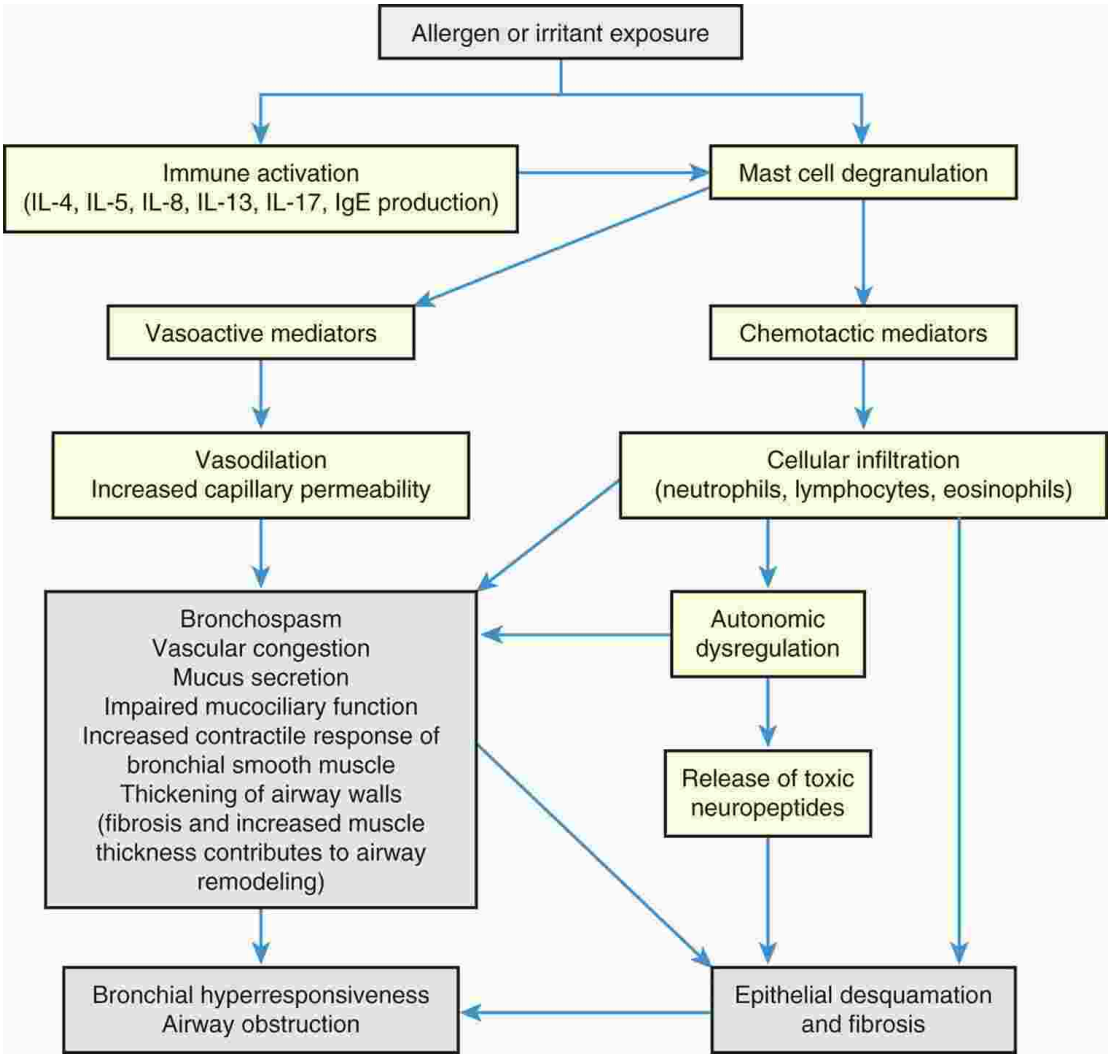
Asthma is a familial disorder, and more than 120 genes have been identified that play a role in the susceptibility, pathogenesis, and treatment response of asthma.[48] Specific gene expressions may impart associated *phenotypes*, the most common of which are allergic asthma, non-allergic asthma, adult-onset asthma, asthma with persistent airflow limitation, and asthma with obesity. Classifying individuals with asthma into these phenotypes can guide therapies that target specific pathophysiologic pathways.[49] Allergic asthma (type I hypersensitivity; see Chapter 9) is the most common phenotype and is the primary focus of the information in this chapter, although overlap with other phenotypes is common. Asthma also can be classified into various *endotypes*, such as

clinical characteristics, biomarkers, lung physiology, histopathology, epidemiology, and treatment response.

Allergen exposure, urban residence, exposure to indoor and outdoor air pollution, tobacco smoke, recurrent respiratory tract viral infections, obesity, use of acetaminophen-containing medications, and GERD impact gene expression (epigenetics) and therefore the risk of developing asthma.[50] Exposure to high levels of certain allergens increases the risk for allergic asthma in sensitized individuals by promoting more type 1 hypersensitivity (see Chapter 9). The effect of infections is more complicated. Decreased exposure to certain infectious microorganisms appears to create an immunologic imbalance that favors the development of allergy and asthma (hygiene hypothesis). In contrast, exposure to several common respiratory viruses (e.g., respiratory syncytial virus) increases the risk of asthma. Furthermore, diet, immunization and antibiotic use, and indoor/outdoor activity patterns have been linked to asthma development.[51] The relationship between the microbiome and asthma risk is shedding light on these complex interactions. There is accumulating evidence of a cross-talk between gut and lung. Upper gastrointestinal microorganisms influence the airway microbiota primarily through aspiration. Dysbiosis of the gut can lead to dysbiosis in the lung via microorganisms traveling through the bloodstream. Airway dysbiosis is linked to allergen sensitization and the development of asthma.[52,53] Exposure to inhaled irritants can cause neutrophil activation, inflammation, and damage to airways independent of allergen sensitivity and may contribute to the onset of symptoms in both allergic and non-allergic asthma phenotypes. Obesity is associated with a chronic inflammatory state that sensitizes the bronchial mucosa to allergen and irritant exposure. Acetaminophen depletes glutathione levels in the respiratory tract, leading to oxidative stress, airway inflammation, and bronchoconstriction. GERD causes stimulation of the vagus nerve with the release of acetylcholine (ACh), which causes bronchoconstriction.

Pathophysiology

In allergic asthma, airway epithelial exposure to antigen initiates both an innate and an adaptive immune response in sensitized individuals (type I hypersensitivity; see Chapter 9). A concise overview of the pathophysiology of asthma is depicted in Algorithm 35.4. The immune response to epithelial antigen exposures includes many cells and cellular elements contributing to persistent inflammation of the bronchial mucosa and hyperresponsiveness of the airways.[54] These cells include dendritic cells (antigen-presenting macrophages), T-helper 2 (Th2) lymphocytes, B lymphocytes, mast cells, neutrophils, eosinophils, and basophils (see Chapter 8). There is both an early (immediate) asthmatic response and a late (delayed) response.



ALGORITHM 35.4 Overview of the Pathophysiology of Asthma.
Allergen or irritant exposure results in a cascade of inflammatory events, leading to acute and chronic airway dysfunction. *IgE*, Immunoglobulin E; *IL*, interleukin.

A flowchart shows the overview of the pathophysiology of asthma. 1. Allergen or irritant exposure. Leads to 2 and 3. 2. Immune activation (I L-4, I L-5, I L-8, I L-13, I L-17, I g E production). Leads to 3. 3. Mast cell degranulation. Leads to 4 and 5. 4. Vasoactive mediators. Leads to 6. 5. Chemotactic mediators. Leads to 7. 6. Vasodilation; increased capillary permeability. Leads to 11. 7. Cellular infiltration (neutrophils, lymphocytes, eosinophils). Leads to 10, 11, and 12. 8. Autonomic dysregulation. Leads to 9 and 11. 9. Release of toxic neuropeptides. Leads to 10. 10. Epithelial desquamation and fibrosis. 11. Bronchospasm, vascular congestion, mucus secretion, impaired mucociliary function, increased contractile response of bronchial smooth muscle, thickening of airway walls (fibrosis and increased

muscle thickness contributes to airway remodeling). Leads to 10. 12. Bronchial hyperresponsiveness; airway obstruction. Leads to 12.

During the *early asthmatic response*, antigen exposure to the bronchial epithelium activates dendritic cells, which present antigen to T-helper cells. T-helper cells differentiate into Th2 cells, which release numerous cytokines. Of these, the most important in the pathogenesis of asthma include IL-4, which activates B lymphocytes (plasma cells), IL-5, which activates eosinophils, IL-13, which contributes to airway injury, and IL-33, which promotes the maturation of Th2 cells and the activation of mast cells, basophils, and eosinophils.[55] Plasma cells produce antigen-specific IgE, which binds to the surface of mast cells. Subsequent cross-linking of IgE molecules with the antigen causes mast cell degranulation and the release of inflammatory mediators, including histamine, bradykinins, leukotrienes, prostaglandins, platelet-activating factor, and interleukins. Together these inflammatory mediators cause vasodilation, increased capillary permeability, mucosal edema, bronchial smooth muscle contraction (bronchospasm), and mucus secretion with narrowing of the airways and obstruction to airflow. Inflammation also leads to increased ACh release by the pulmonary parasympathetic nervous system. ACh binds to the muscarinic 3 (M_3) receptor, further contributing to bronchospasm and mucus secretion.[56] Eosinophils release toxic neuropeptides that contribute to increased bronchial hyperresponsiveness (Figs. 35.6 and 35.7).

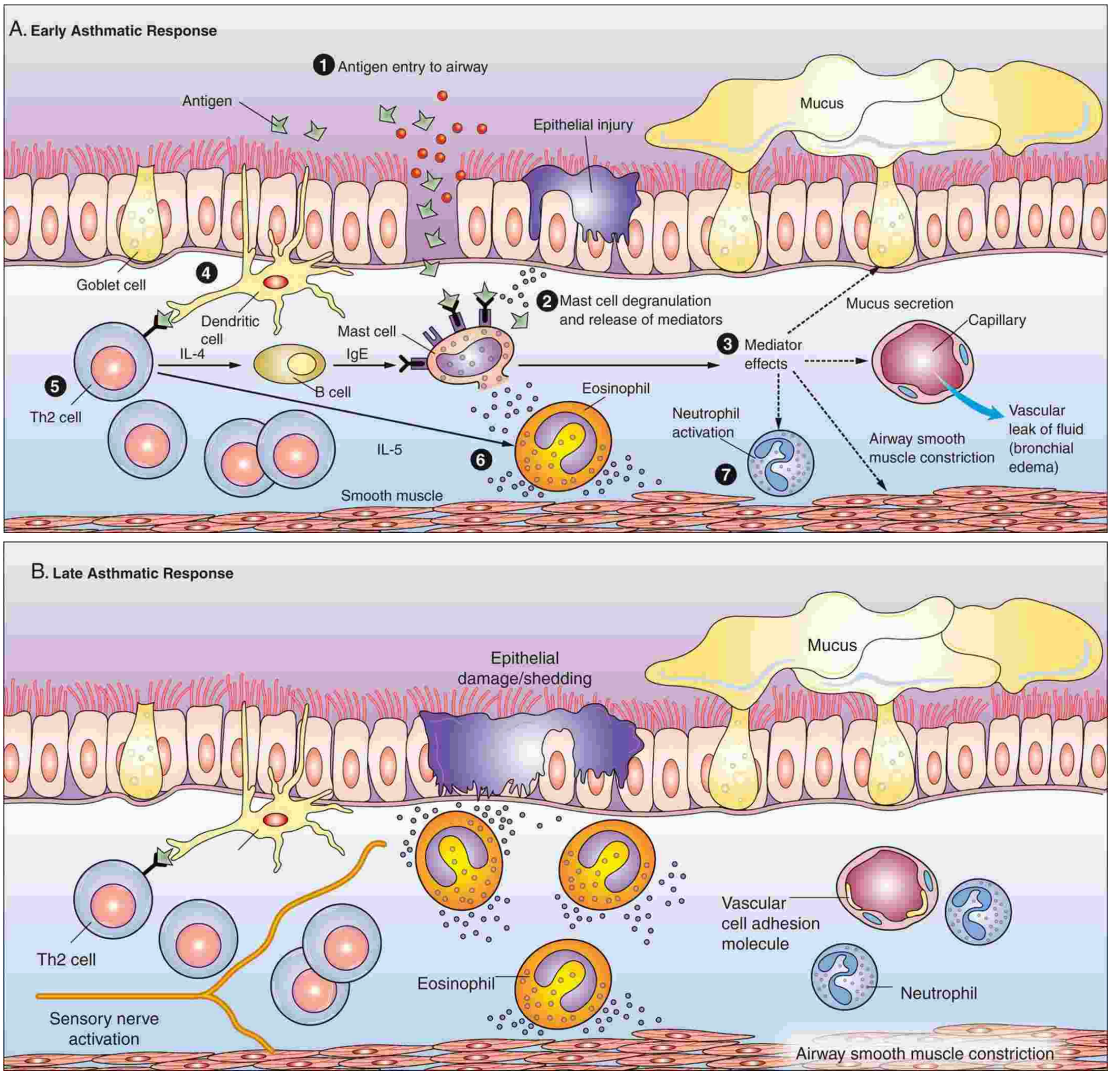


FIG. 35.6 Early and Late Asthmatic Response.
(A) *Early response:* Inhaled antigen *(1)* binds to mast cells covered with preformed immunoglobulin E (IgE). Mast cells degranulate *(2)* and release inflammatory mediators, such as histamine, bradykinins, leukotrienes, prostaglandins, platelet-activating factor, and interleukins. Secreted mediators *(3)* induce active bronchospasm (airway smooth muscle constriction), edema from increased capillary permeability, and airway mucus secretion from goblet cells. At the same time, antigen is detected by *(4)* dendritic cells that process and present it to T-helper 2 *(Th2)* cells *(5)*, which produce interleukin-4 *(IL-4)* and many other interleukins (see text). IL-4 promotes switching of B cells to favor IgE production. Th2 cells also produce IL-5 *(6)*, which activates eosinophils. Many inflammatory cells, including neutrophils *(7)*, also contribute to the inflammatory process. **(B)** *Late response:* Areas of epithelial damage and shedding caused, at least in part, by toxicity of eosinophil products (major basic protein, eosinophilic cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase). Many inflammatory cells are recruited by chemokines and upregulation of vascular cell adhesion molecules. Local T lymphocytes display a predominant Th2 cytokine profile. They produce IL-4 and IL-13, which promote switching of B cells to favor IgE production; and IL-3, IL-5, and

granulocyte-macrophage colony–stimulating factor, which encourage eosinophil differentiation and survival. Inflammatory mediators also activate sensory nerves, further stimulating bronchoconstriction.

Two illustrations show early and late asthmatic response. Top panel, A, early asthmatic response. The illustration shows a layer of epithelial cells. There is a gap in the layer. Goblet cells and secretions from the mucus are also identified over some of the cells. There is also a region of epithelial injury. 1. Antigen entry to airway is traced through the gap in the epithelial layer. 2. Mast cell degranulation and release of mediators. 3. Mediator effects: mucus secretion, capillary (vascular leak of fluid or bronchial edema), airway smooth muscle constriction, and neutrophil activation. 4. Dendritic cell. 5. T h 2 cell. 6. Eosinophil. 7. Neutrophil. Bottom panel, B, late asthmatic response. The illustration shows a layer of epithelial cells with goblet cells, secretions from the mucus, and a region of epithelial damage or shedding. Other structures identified on the illustration include dendritic cell, T h 2 cell, sensory nerve activation, eosinophil, vascular cell adhesion molecule, and neutrophil.

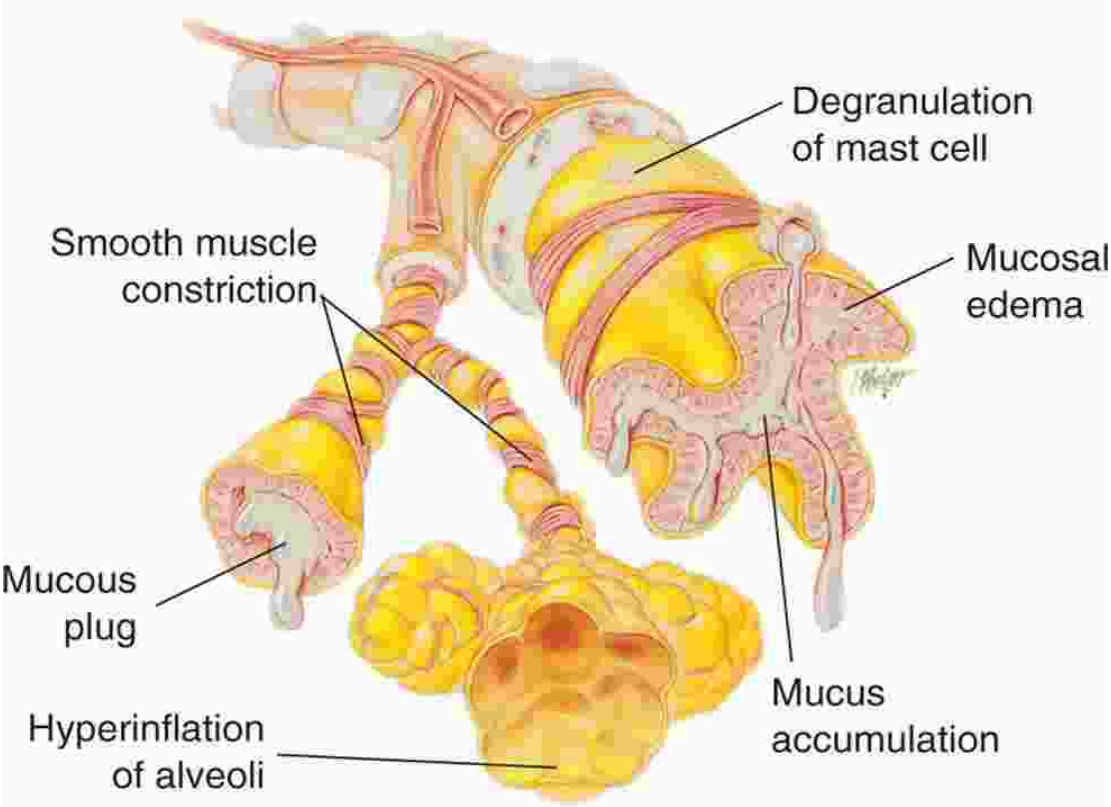

FIG. 35.7 Asthma.
Thick mucus, mucosal edema, and smooth muscle spasm cause obstruction of small airways; breathing becomes labored and expiration is difficult. (Modified from Des Jardins T, Burton GG. *Clinical manifestations and assessment of respiratory disease*, 3rd edition. St. Louis: Mosby; 1955.)

An illustration of the bronchus shows and labels the following conditions of bronchial asthma: degranulation of mast cell, mucosal edema, mucus accumulation, smooth muscle constriction, mucous plug, and hyperinflation of alveoli.

The *late asthmatic response* begins 4 to 8 hours after the early response. Chemotactic recruitment of eosinophils, neutrophils, and lymphocytes during the acute response causes a release of inflammatory mediators, again inciting bronchospasm, edema, and mucus secretion with obstruction to airflow. Synthesis of leukotrienes contributes to prolonged smooth muscle contraction. Eosinophils cause direct tissue injury with fibroblast proliferation and airway scarring. Damage to ciliated epithelial cells contributes to the accumulation of mucus and cellular debris, forming plugs in the airways. Untreated inflammation can lead to long-term airway damage resulting in subepithelial fibrosis and smooth muscle hypertrophy (airway remodeling) and may become irreversible.[57]

Airway obstruction increases resistance to airflow and expiratory flow rates. Decreased expiratory flow causes air trapping, hyperinflation of the lungs, and an increased work of breathing. Changes in resistance to airflow are not uniform throughout the lungs, and the distribution of inspired air is uneven, resulting in $\dot{V}/\dot{Q}$ mismatch and hypoxemia. Hyperventilation is triggered by lung receptors responding to airway obstruction and increased

lung volume. The result is early hypoxemia with decreased $PaCO_2$ and increased pH (respiratory alkalosis). With progressive obstruction of expiratory airflow, air trapping becomes more severe, and the lungs and thorax become hyperexpanded, positioning the respiratory muscles at a mechanical disadvantage. This leads to a decrease in tidal volume, hypoventilation, increased $PaCO_2$, and respiratory acidosis. Respiratory acidosis signals respiratory failure.

Clinical Manifestations

Individuals are usually asymptomatic between attacks, and pulmonary function tests are normal. At the beginning of an asthmatic attack, the individual experiences chest constriction, expiratory wheezing, dyspnea, nonproductive cough, prolonged expiration, use of accessory muscles of respiration, tachycardia, and tachypnea. A pulsus paradoxus (decrease in systolic blood pressure during inspiration of more than 10 mm Hg) may be noted. Peak flow measurements should be obtained. Because the severity of blood–gas alterations is difficult to evaluate by clinical signs alone, arterial blood gas tensions should be measured if oxygen saturation falls below 90%.

If bronchospasm is not reversed by usual treatment measures, the individual is considered to have status asthmaticus (acute severe bronchospasm), and the situation becomes life-threatening. If status asthmaticus continues, hypoxemia worsens, expiratory flows and volumes decrease further, and effective ventilation decreases. Acidosis develops as the $PaCO_2$ level begins to rise. Ventilation may cease altogether, and a silent chest (no audible air movement) and a $PaCO_2$ greater than 70 mm Hg are ominous signs of impending death.

Evaluation and Treatment

The diagnosis of asthma is based on the history of symptom patterns and evidence of variable and reversible airflow limitation.[46] It is supported by a history of allergies and recurrent episodes of wheezing, dyspnea, and cough or exercise intolerance. These symptoms often are worse at night, vary over time and in intensity, and are triggered by exposure to allergens, irritants, changes in weather, and viral infections, Physical examination findings are often normal between episodes. Spirometry is used to document reversible decreases in FEV_1 during an induced attack. Careful assessment is critical to making the correct diagnosis since many other conditions may be mistaken for asthma, including heart disease, cystic fibrosis, vocal cord dysfunction, and medication-related cough. Allergy testing may be performed. Once the diagnosis is established, asthma is classified by severity.[46]

The evaluation of an acute asthma attack requires the rapid assessment of arterial blood gases and expiratory flow rates (using a peak flow meter) and a search for underlying triggers, such as infection. Hypoxemia and respiratory alkalosis are expected early during an acute attack. The development of hypercapnia with respiratory acidosis signals the need for mechanical ventilation. Management of the acute asthma attack is based on severity as determined by peak flow measurements. In those with severe exacerbation, immediate administration of oxygen, inhaled short-acting β-agonist bronchodilators, and systemic corticosteroids are indicated.[58] Careful monitoring of gas exchange and airway patency in response to therapy provides information necessary to determine whether hospitalization and noninvasive ventilation are necessary. Exhaled nitric oxide (FeNO) levels increasingly are used to follow response to therapy and can be used when other diagnostic modalities are inconclusive.[59] Antibiotics are not indicated for acute asthma unless there is a documented bacterial infection.

The goals of asthma management are to control symptoms and prevent exacerbation. Management decisions are guided by the GINA working group.[46] In addition, a 2020 Focused Updates to the Asthma Management Guidelines from the National Asthma Education and Prevention Program Coordinating Committee is available.[59] Management of chronic asthma begins with avoidance of allergens and irritants. Individuals with asthma tend to underestimate the severity of their asthma, and extensive education is important, including the use of a peak flow

meter and adherence to an action plan. A stepwise approach for persistent asthma treatment is recommended. The use of continuous low-dose inhaled corticosteroids with or without long-acting beta-agonist (LABA) for even the mildest forms of asthma is most effective in managing symptoms. The use of short-acting beta-agonists (SABAs) is associated with an increased risk for severe exacerbations and should be reserved for those individuals with intermittent asthma symptoms[59] and those with persistent asthma who are well controlled and do not want to alter their current regimen or are unlikely to be adherent to low-dose inhaled corticosteroids alone.[46] Because of these adherence concerns, new recommendations also include the use of as-needed low dose inhaled corticosteroids combined with formoterol as an option for adults and adolescents with mild asthma.[46,60] For all categories of more severe asthma, continuous administration of inhaled corticosteroids is the mainstay of therapy. In individuals who fail to respond to initial management, it is essential to assess and correct problems such as incorrect inhaler technique, poor adherence, persistent exposure to allergens and irritants, comorbidities, and incorrect diagnosis before stepping up treatment. If these problems are addressed, and the individual is still not adequately controlled, LABAs, long-acting muscarinic antagonists (LAMAs), or leukotriene antagonists can be added.[46] Leukotrienes are products of arachidonate metabolism (see Chapter 7) which contribute to airway hypersensitivity, bronchospasm, and inflammatory injury. Blockage of these cytokines can decrease airway inflammation and bronchospasm in selected individuals with asthma.[61] In adults with severe asthma that is unresponsive to treatment with these medications, the anti-inflammatory antibiotic azithromycin may be considered.[46] Biologic therapies with monoclonal antibodies to IgE, IL-5, and IL-13 (e.g., omalizumab, mepolizumab, reslizumab, and benralizumab) have been found to be helpful as adjunctive therapy to inhaled steroids, and many new biologics are being developed (Emerging Science Box: Biological Treatments for Uncontrolled Asthma). Immunotherapy (allergy shots) has been shown to be an important tool in reducing asthma exacerbations, reducing the need for both long and short-acting asthma medications, and improving quality of life and FEV_1. Immunotherapy also can be given sublingually, although current recommendations state that sublingual immunotherapy should not be substituted for subcutaneous immunotherapy in those individuals with persistent asthma despite treatment.[59] In individuals in whom long-term control of symptoms has been achieved, careful step down in medications may be attempted.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is defined by the Global Initiative for Chronic Obstructive Lung Disease

Emerging Science Box Biological Treatments for Uncontrolled Asthma

Approximately 10% of individuals with asthma suffer from severe disease that remains poorly controlled despite appropriate use of bronchodilators and high-dose inhaled corticosteroids. Many of these individuals have large numbers of activated lymphocytes and eosinophils that release high levels of inflammatory cytokines resulting in persistent disease, resistance to treatment, and progressive remodeling of airways. Among the most important of these cytokines are interleukin (IL)-4, IL-5, and IL-13. Other injurious cytokines include IL-17, IL-25, IL-33, and thymic stromal lymphopoietin. The recognition of these pathophysiologic changes in uncontrolled severe asthma has led to the development of tailored therapies that target specific pathways of airway inflammation. The first biologic developed to treat uncontrolled asthma was omalizumab. It is a monoclonal antibody that prevents the binding of IgE to mast cells and basophils. More recently, the role of eosinophils in the pathophysiology of severe asthma and airway remodeling is being targeted using monoclonal antibodies that block IL-5. Three drugs

targeting IL-5 currently are approved for use and include mepolizumab, reslizumab, and benralizumab. Dopilumab is a monoclonal antibody that blocks both the IL-4 and the IL-13 receptors and has recently been approved for home use. All five of these monoclonal antibody drugs have been shown to improve symptoms, decrease the number and severity of exacerbations, and reduce the use of systemic corticosteroids in selected individuals with severe asthma. Emerging therapies aimed at other inflammatory and immune cytokines are being explored. Examples include the potential use of monoclonal antibodies that block receptors for thymic stromal lymphopoietin (tezpelumab), leukotrienes, IL-25, and IL-33.

(GOLD) 2022 report as "…a common, preventable and treatable disease characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases and influenced by host factors including abnormal lung development.[62] COPD is the most common chronic lung disease in the world, and the sixth leading cause of death in the United States, affecting as many as 10% of individuals in states where cigarette smoking is prevalent.[63] Risk factors for COPD include tobacco smoke (cigarette, pipe, cigar, and environmental tobacco smoke), occupational dusts and chemicals (vapors, irritants, and fumes), indoor air pollution from biomass fuel used for cooking and heating (in poorly vented dwellings), outdoor air pollution, factors that affect lung growth during gestation, certain infections such as tuberculosis, low socioeconomic status, and genetic abnormalities.[62] Evidence is emerging that the use of e-cigarettes (vaping) leads to an increased risk for COPD (Emerging Science Box: E-Cigarettes and Respiratory Disease).[64] Changes in the lung microbiome also have been linked to the development of COPD.[65] At least 22 gene polymorphisms, as well as epigenetic susceptibilities, have been identified in association with COPD.[66] An inherited homozygous mutation in the gene responsible for α_1-antitrypsin synthesis occurs in 1 in 2000 persons of European descent and results in the development of COPD at an early age, even in individuals who never smoked.[67]

The two most common phenotypes of COPD are chronic bronchitis and emphysema. Chronic bronchitis is defined as hypersecretion of mucus and chronic productive cough that continues for at least 3 months of the year (usually the winter months) for at least 2 consecutive years. Emphysema is abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis. Both phenotypes are associated with an enhanced chronic inflammatory response in the airways to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity of disease. The asthma-COPD overlap (ACO) is a phenotype of chronic respiratory disease where there is an overlap of the clinical symptoms of asthma and COPD.[68]

Pathophysiology

The pathologic changes of COPD occur in large central airways, small peripheral airways, and the lung parenchyma. In both chronic bronchitis and emphysema, chronic irritant exposure recruits neutrophils, macrophages, and lymphocytes to the lung, resulting in progressive damage from inflammation, oxidative stress, extracellular matrix proteolysis, and apoptotic and autophagic cell

death.[62,66] Frequent infectious exacerbations and lung senescence with aging contribute to the progression of disease.

In chronic bronchitis, inspired irritants result in airway inflammation with infiltration of neutrophils, macrophages, and lymphocytes into the bronchial wall. Continual bronchial inflammation causes bronchial edema, an increase in the size and number of mucous glands and goblet cells in the airway epithelium, smooth muscle hypertrophy with fibrosis, and narrowing of airways. Thick, tenacious mucus is produced and cannot be cleared because of impaired ciliary function (Fig. 35.8), compromising the lung's defense mechanisms. These pathophysiological changes increase susceptibility to pulmonary infection, which contributes to injury and ineffective repair. Frequent infectious exacerbations from bacterial colonization of damaged airways are complicated by bronchospasm with dyspnea and productive cough. Exacerbations contribute to the overall severity and progression of disease. This process initially affects only the larger bronchi, but eventually, all airways are involved. The thick mucus and hypertrophied bronchial smooth muscle constrict the airways and lead to obstruction, particularly during expiration when the airways are narrowed. This expiratory obstruction traps air in the distal portions of the lung (hyperinflation), which expands the thorax and positions the respiratory muscles at a mechanical disadvantage. This leads to decreased tidal volume, hypoventilation, and hypercapnia. Airway obstruction also leads to $\dot{V}/\dot{Q}$ mismatch with hypoxemia.

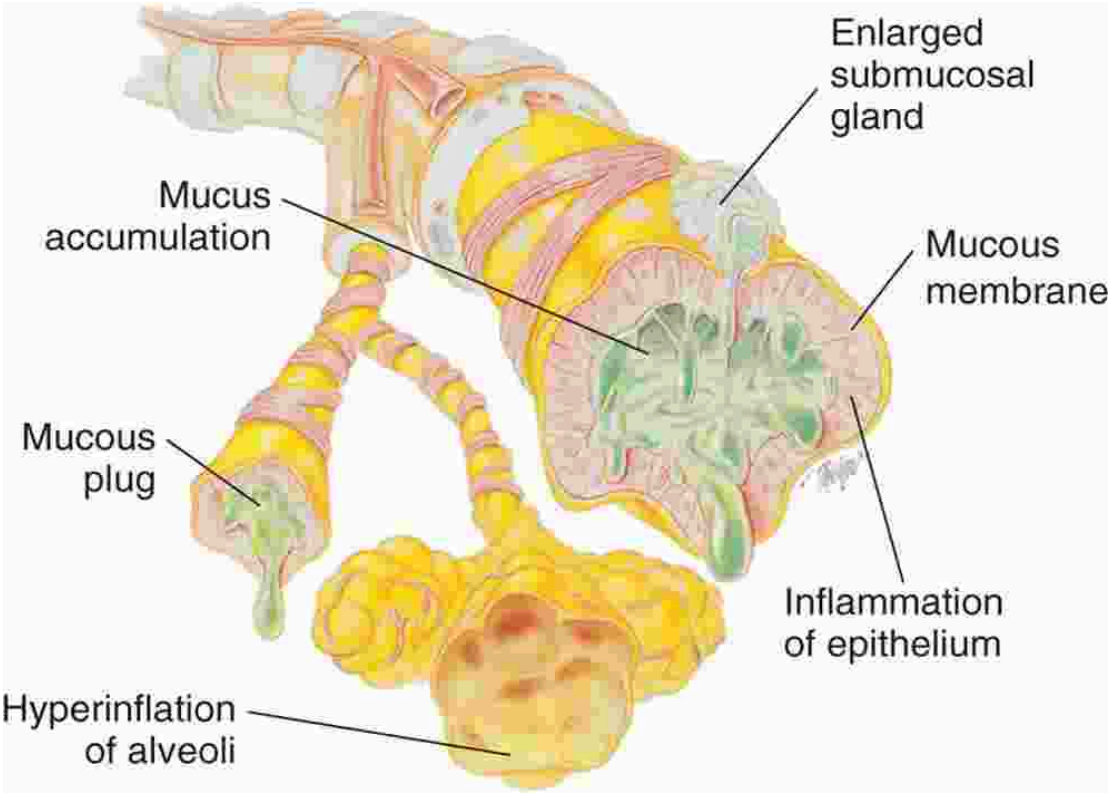

FIG. 35.8 Chronic Bronchitis.
Inflammation and thickening of the mucous membrane, with accumulation of mucus and pus, leading to obstruction characterized by a productive cough.
(Modified from Des Jardins T, Burton GG. *Clinical manifestations and assessment of respiratory disease*, 3rd edition. St. Louis: Mosby; 1995.)

An illustration of the bronchus shows and labels the following conditions of chronic bronchitis: enlarged submucosal gland, mucous membrane, inflammation of epithelium, mucus accumulation, mucous plug, and hyperinflation of alveoli.

In emphysema, there is destruction of alveolar walls resulting in abnormal permanent enlargement of gas-exchange airways. Obstruction results from inflammatory and destructive

Emerging Science BoxE-Cigarettes and Respiratory Disease

Electronic cigarette (e-cigarette) use has increased in the 10 years since they were introduced, especially among adolescents and young adults for which e-cigarette use has increased by over 1500% to an estimated 10.5% of middle school students and 27.5% of high school students. E-cigarettes include any nicotine delivery products, commonly known as "vapes." Although some previous studies suggests that e-cigarettes are more effective than nicotine replacement therapy with respect to 1-year smoking abstinence rates, more recent data are less conclusive and they are not benign in their effects on lung tissue. The use of e-cigarettes, especially those with multiple ingredients, exposes users to high levels of inhaled cytotoxic toxins including propylene glycol and vegetable glycerin. E-cigarettes also emit aldehydes (such as formaldehyde), as well as aerosolized particles, diacetyl, and volatile organic compounds. Exposure to these toxins results

in airway inflammation (macrophage and neutrophil activation and cytokine release), capillary dysfunction, and alveolar injury along with increased susceptibility to respiratory infections. E-cigarette use is linked to both acute and chronic respiratory disease. In December 2019, an outbreak of e-cigarette product use-associated lung injury (EVALI) resulted in over 2500 hospitalizations and 54 deaths. In addition, emerging data demonstrates up to a 75% increase in risk for COPD in individuals who use e-cigarettes, especially those who use them daily. Many e-cigarette users also use combustible tobacco products, especially among the adolescents and young adults. Combined use of both e-cigarettes and combustible tobacco products confers up to a 3-fold increase in risk for COPD and asthma. Continued research on the impact of e-cigarette use on the prevalence of lung disorders, such as COPD and cancer is needed.

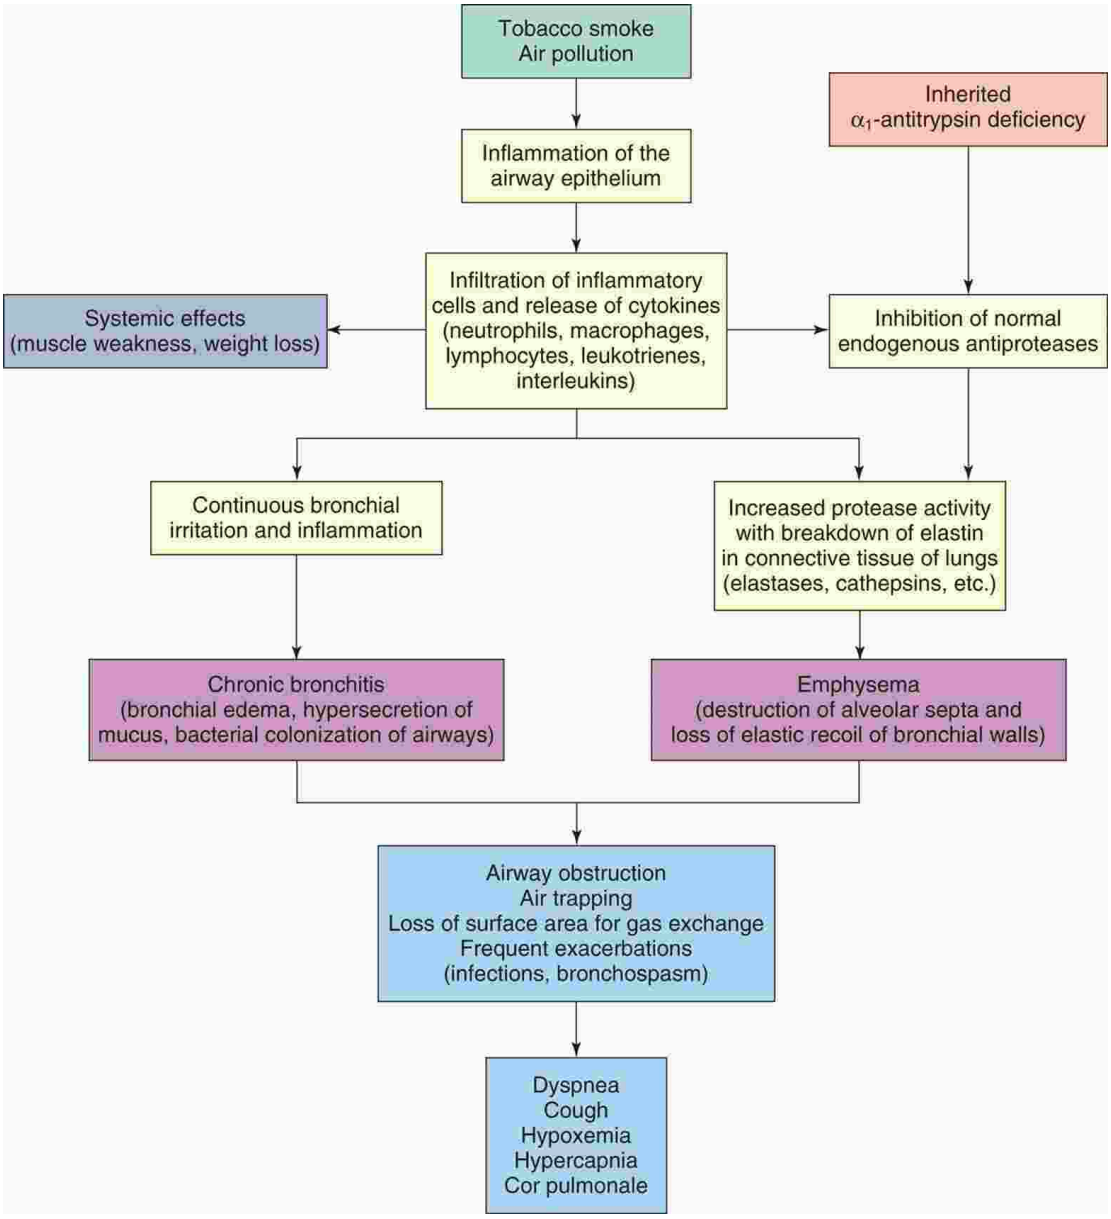
changes in lung tissues rather than mucus production as in chronic bronchitis. It most often is the result of inhalation of toxic gases such as cigarette smoke. Emphysema is characterized by inflammation and an imbalance between proteases and antiproteases, oxidative stress, and apoptosis of lung structural cells. An autoimmune response is triggered by infiltration of lymphocytes and the release of toxic immune cytokines.[62] These processes lead to the destruction of alveoli through the breakdown of elastin within the septa (Algorithm. 35.5). Alveolar destruction produces large air spaces within the lung parenchyma (bullae) and air spaces adjacent to pleurae (blebs) (Fig. 35.9). Bullae and blebs are not effective in gas exchange and contribute to V· /Q· mismatching and hypoxemia. The main mechanism of airflow limitation is loss of elastic recoil with collapse of the airways during expiration (Fig. 35.10). Air trapping causes hyperexpansion of the chest, placing the muscles of respiration at a mechanical disadvantage and increasing workload of breathing. This gradually progresses, leading to reduced tidal volumes so that many individuals will develop hypoventilation and hypercapnia. Persistent inflammation results in hyperreactivity of the bronchi causing bronchoconstriction. Acute bronchoconstriction may be partially reversible with bronchodilators. Continued destruction of alveolar walls and pulmonary capillaries causes pulmonary hypertension (PH) and *cor pulmonale* (see the Pulmonary Hypertension section). Approximately one-third of individuals with emphysema have significant eosinophilic inflammation, which contributes to airway injury and may predict lack of responsiveness to treatment.[66] Chronic inflammation also can have significant systemic effects. including weight loss, muscle weakness, and increased susceptibility to comorbidities.



ALGORITHM 35.5 Pathogenesis of Chronic Bronchitis and Emphysema (Chronic Obstructive Pulmonary Disease).

A flowchart represents the pathogenesis of chronic bronchitis and emphysema. 1. Tobacco smoke; air pollution. Leads to 2. 2. Inflammation of the airway epithelium. Leads to 3. 3. Infiltration of inflammatory cells and release of cytokines (neutrophils, macrophages, lymphocytes, leukotrienes, interleukins). Leads to 5, 6, 7, and 8. 4. Inherited alpha-antitrypsin deficiency. Leads to 6. 5. Systemic effects (muscle weakness, weight loss). 6. Inhibition of normal endogenous antiproteases. Leads to 8. 7. Continuous bronchial irritation and inflammation. Leads to 9. 8. Increased protease activity with breakdown of elastin in connective tissue of lungs (elastases, cathepsins,

etc.). Leads to 10. 9. Chronic bronchitis (bronchial edema, hypersecretion of mucus, bacterial colonization of airways). Leads to 11. 10. Emphysema (destruction of alveolar septa and loss of elastic recoil of bronchial walls). Leads to 11. 11. Airway obstruction, air trapping, loss of surface area for gas exchange, frequent exacerbations (infections, bronchospasm). Leads to 12. 12. Dyspnea, cough, hypoxemia, hypercapnia, and cor pulmonale.

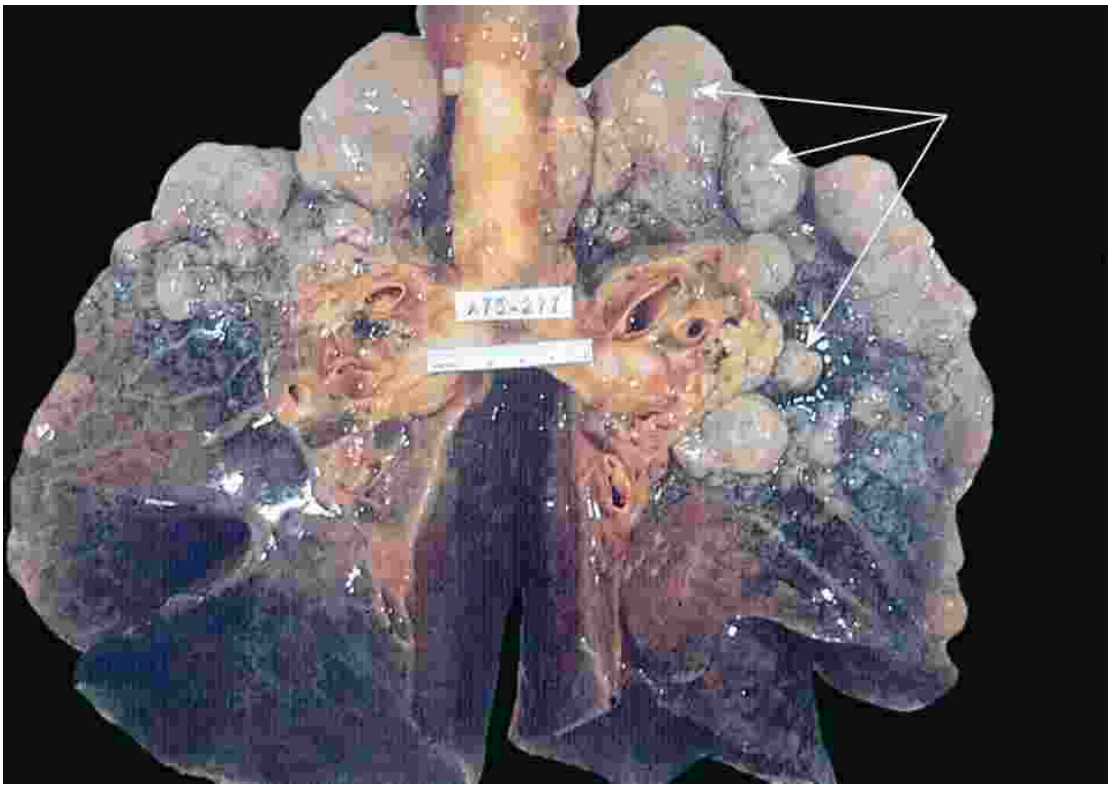


FIG. 35.9 Bullous emphysema with large apical and subpleural bullae (arrows). (From Kumar V, et al., eds. *Robbins basic pathology*, 8th edition. Philadelphia: Saunders/Elsevier; 2007.)

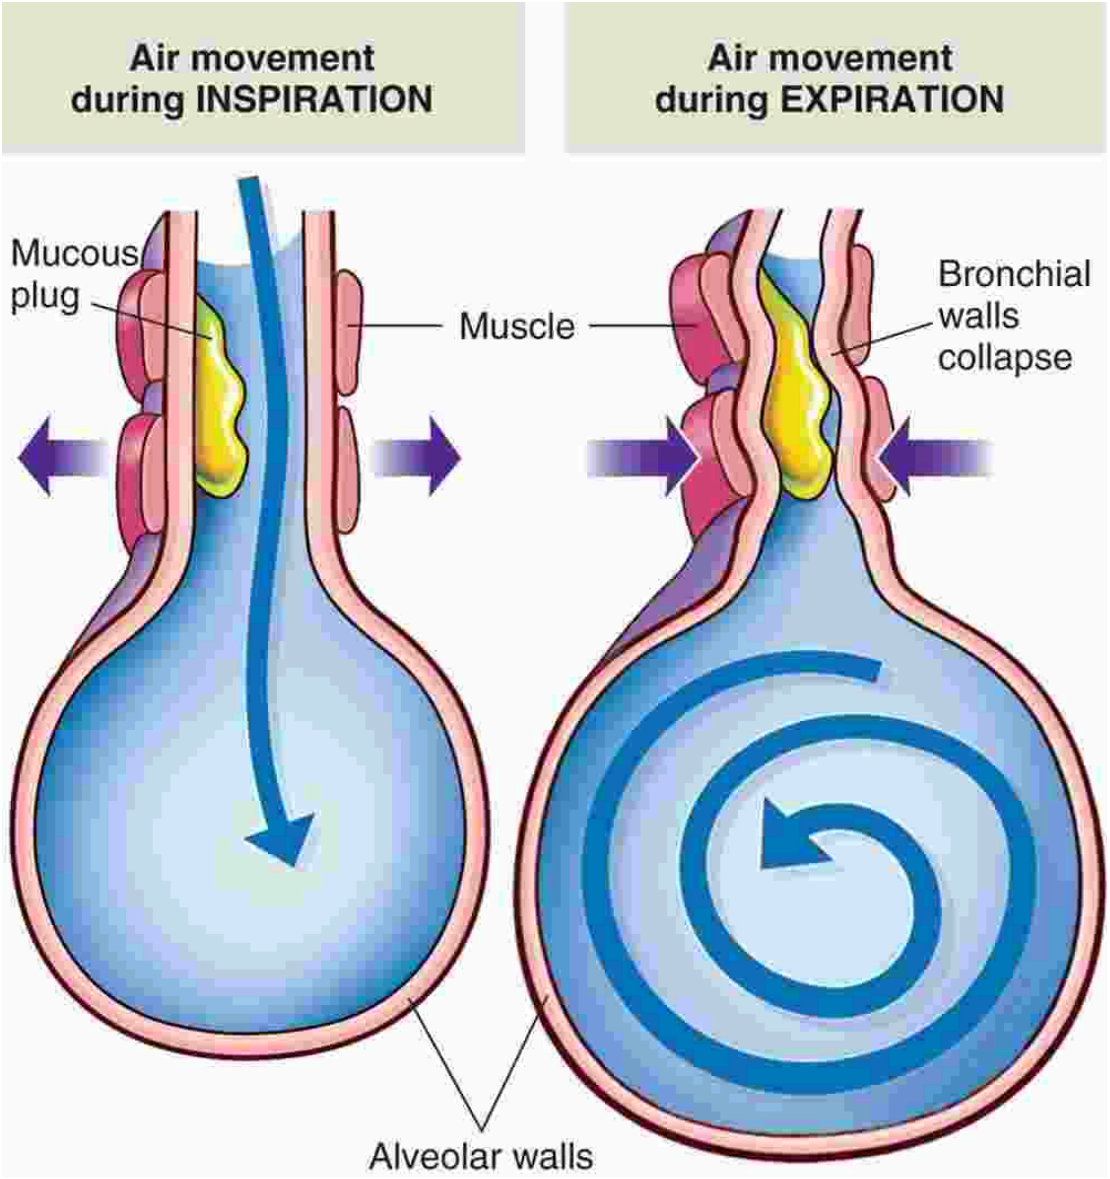

FIG. 35.10 Mechanisms of Air Trapping in Chronic Obstructive Pulmonary Disease.
Mucous plugs and narrowed airways cause air trapping and hyperinflation of alveoli on expiration. During inspiration, the airways are pulled open, allowing gas to flow past the obstruction. During expiration, decreased elastic recoil of the bronchial walls results in collapse of the airways and prevents normal expiratory airflow.

Two illustrations of the alveolus show air movement during inspiration and expiration. Left panel, air movement during inspiration. The mucous plug along the bronchial wall is identified. The muscles pull outward creating space for the air to move into the alveolus. Right panel, air movement during expiration. The mucous plug along the bronchial wall is identified. The

muscles contract inward, reducing the space and filling the bronchus with mucous. The alveolus is enlarged with air circulating within its walls.

Inherited α1-antitrypsin deficiency (primary emphysema) accounts for 1% to 3% of all cases of emphysema. Normally, α1-antitrypsin inhibits the action of proteolytic enzymes (e.g., elastases released by neutrophils) that serve to break down lung tissue. Without this inhibitory activity, neutrophils are recruited into the lung, protease activity is unopposed, and structural damage develops.[67] Deficiency of α1-antitrypsin is suggested in individuals who develop emphysema before 40 years of age and in individuals who never smoked but still develop the disease. Nonsmoking individuals with α1-antitrypsin deficiency develop COPD at an older age than those with the deficiency who also smoke. Hepatic fibrosis also may occur. Because there are emerging effective treatments, some experts now recommend that all individuals with diagnosed COPD be screened for alpha-1 antitrypsin deficiency. Family screening is indicated for those who test positive.[69] Supportive treatment for the lung disease associated with α1-antitrypsin deficiency is the same as treatment for COPD. Specific treatment with intravenous augmentation therapy using plasma-purified α1-antitrypsin slows disease progression.[69] New treatments, including gene therapy and stem cell technologies, are being explored.[70]

Clinical Manifestations

Dyspnea on exertion that progresses to marked dyspnea, even at rest, is the most common symptom of COPD.[71] In chronic bronchitis, individuals have a persistent productive cough, whereas in emphysema, cough is usually productive only during acute exacerbations. Table 35.3 provides a comparative list of the common clinical manifestations between chronic bronchitis and emphysema. The individual with COPD is often thin, has tachypnea with prolonged expiration, and must use accessory muscles for ventilation. The anteroposterior diameter of the chest is increased (barrel chest), and the chest has a hyperresonant sound with percussion. The individual often leans forward with arms extended and braced on knees when sitting and exhales through pursed lips (helps prevent expiratory airway collapse). As the disease progresses. marked hypoxemia leads to polycythemia (overproduction of erythrocytes) and cyanosis. If not reversed, respiratory failure leads to PH and eventually results in *cor pulmonale* with right heart failure and peripheral edema.

Table 35.3

Clinical Manifestations of Chronic Obstructive Lung Disease

Clinical Manifestations	Bronchitis	Emphysema
Productive cough	Classic sign	With infection
Dyspnea	Late in course	Common
Wheezing	Intermittent	Common
History of smoking	Common	Common
Barrel chest	Occasionally	Classic
Prolonged expiration	Always present	Always present
Cyanosis	Common	Uncommon
Chronic hypoventilation	Common	Late in course
Polycythemia	Common	Late in course
Cor pulmonale	Common	Late in course

Evaluation and Treatment

Diagnosis of COPD is based on history of exposures, family history, respiratory symptoms, physical examination, chest imaging, and pulmonary function tests. Pulmonary function testing reveals airway obstruction (decreased FEV_1) that is progressive and unresponsive to bronchodilators. Chest x-ray may reveal changes in thoracic diameter, distended lung fields, and flattening of the diaphragm. High-resolution CT scanning provides detailed information about the underlying COPD phenotype which may help to guide management.[72] Oximetry should be obtained, and arterial blood gas analysis should be performed in those with significant hypoxemia. Hypoxemia may first occur with exercise but gradually progresses to hypoxemia at rest. Hypercapnia develops as air trapping worsens and the work of breathing increases. Serum eosinophil counts should also be obtained.

Prevention of COPD is the best treatment because pathologic changes are not reversible. By the time an individual seeks medical care for symptoms, considerable airway damage is present. If the individual stops smoking and receives optimal pharmacotherapy, disease progression can be slowed. Influenza, COVID-19, and pneumococcal vaccination should be kept up to date. Pharmacologic management is based on clinical severity as described by the GOLD classification for COPD (mild, moderate, severe, or very severe).[62] Initial treatment most often begins with a LAMA (e.g., tiotropium or revefenacin).[72] Additional medications that can be considered include LABA and inhaled glucocorticoids, and combinations of these may be beneficial for severe COPD (triple combination).[62] Inhaled corticosteroids are associated with an increased risk of pneumonia and should not be used alone. The addition of a phosphodiesterase E4 (PDE4) inhibitor (e.g., roflumilast) and a macrolide antibiotic (azithromycin) can be considered for those with moderate to severe COPD.[62]

Acute exacerbations of COPD are characterized by an increased dyspnea, cough, or sputum purulence. They most often are caused by bacterial or viral infection but may also occur due to changes in air quality or medication use. These exacerbations may be life-threatening and contribute to overall disease progression. Therapy includes bronchodilators (often given via

nebulizer), systemic corticosteroids, and antibiotics.[72] If respiratory failure develops, high-flow nasal cannula or noninvasive ventilation are indicated.[73]

Pulmonary rehabilitation improves symptoms and quality of life in individuals with moderate to severe COPD, and efforts at creating effective programs using telehealth modalities are being developed.[62,74] Progressive pulmonary dysfunction with hypoxemia and hypercapnia may require long-term oxygen therapy and ventilation. Oxygen is titrated with care to individuals with severe hypoxemia and CO2 retention. Lung volume reduction surgery improves symptoms in selected individuals with severe COPD but is associated with significant postoperative complications and new safer bronchoscopic techniques are emerging.[75] Lung transplantation can be considered, especially in younger individuals with inherited α1-antitrypsin deficiency. In addition, many comorbidities, such as bronchiectasis, cardiovascular disorders, metabolic diseases, bone disease, stroke, lung cancer, cachexia and muscle weakness, anemia, depression, and cognitive decline accompany COPD and require monitoring and therapy.

Respiratory Tract Infections

Respiratory tract infections are the most common cause of short-term disability in the United States. Most of these infections—the common cold, pharyngitis, and laryngitis—involve only the upper airways and are not discussed in this chapter. Infections of the lower respiratory tract occur most often in the very young and very old, smokers, or those with impaired immunity. However, viral pneumonias can occur in healthy individuals of any age.

Acute Bronchitis

Acute bronchitis is an acute infection or inflammation of the airways or bronchi and is usually self-limiting. Most cases of acute bronchitis are caused by viruses. Many of the clinical manifestations are similar to those of pneumonia (i.e., fever, cough, chills, malaise), but the physical examination does not reveal signs of pulmonary consolidation (i.e., dullness to percussion, crackles, egophony), and chest radiographs do not show infiltrates. Individuals with viral bronchitis usually have a nonproductive cough that occurs in paroxysms and is aggravated by cold, dry, or dusty air. Purulent sputum may be produced in bacterial bronchitis. Chest pain often develops from the effort of coughing. Treatment consists of rest, hydration, humidity, analgesics, and a cough suppressant, such as codeine. Antibiotics are indicated for bacterial bronchitis.

Pneumonia

Pneumonia is an infection of the lower respiratory tract caused by bacteria, viruses, fungi, protozoa, or parasites. It is estimated that lower respiratory tract infections affected nearly 500 million people and resulted in 1.23 million deaths globally in 2019.[76] Pneumonia accounts for over 45,000 deaths per year in the United States.[77]

Pneumonia can be categorized as community-acquired (CAP) or hospital-acquired (HAP).[76] CAP is defined as pneumonia that is acquired outside of the hospital setting. It is one of the most common reasons for hospitalization in the United States. Risk factors for pneumonia include age below 5 or above 70 years, compromised immunity, underlying lung disease, alcoholism, altered consciousness, impaired swallowing, smoking, malnutrition, immobilization, underlying cardiac or liver disease, and residence in a nursing home or other extended care facility. Other risk factors include the use of gastric acid suppressive agents or benzodiazepines.[78]

HAP denotes an episode of pneumonia that develops during hospitalization. It is the second most common nosocomial infection (urinary tract infection [UTI] is the most common) and has the greatest mortality. Ventilator-associated pneumonia (VAP) is a subset of HAP and is a nosocomial infection that occurs in many individuals who require intubation and mechanical ventilation. VAP affects nearly a third of all individuals in ICUs and has a higher mortality than HAP in

nonventilated individuals. Risk factors for HAP include oropharyngeal colonization with resistant pathogens, presence of an endotracheal tube (intubation), impaired swallowing and cough reflex, and decreased level of consciousness.[76]

The causative microorganisms for pneumonia influence the clinical presentation of the individual, the treatment plan, and the prognosis. The mechanisms of viral and bacterial infection are reviewed in Chapter 10. The microorganisms that commonly cause CAP have changed in the past decade due to increasing numbers of individuals in the community who are immunocompromised, live in chronic care institutions, or have chronic underlying conditions. Viruses are now believed to be the most common cause of CAP. The most common cause of viral CAP is influenza, which occurs most often during the winter season. While usually a mild and self-limiting infection, influenza causes over 50,000 deaths annually in the United States.[79] Respiratory syncytial virus is another common cause of CAP. Pneumonias caused by Epstein Barr virus, herpes simplex virus, and cytomegalovirus primarily occur in immunocompromised individuals such as those with human immunodeficiency virus (HIV) infection (see Chapter 10). Viral pneumonia also can be a complication of another viral illness, such as chickenpox or measles (spread to the lungs from the blood). New or atypical forms of viral infection such as COVID-19 have affected previously healthy populations and pose a considerable threat for pandemics (see Chapter 10, Emerging Science Box: Severe Acute Respiratory Syndrome Coronavirus -2 and Coronavirus Disease 2019). The most common cause of bacterial CAP is *Streptococcus pneumoniae*, also known as the pneumococcus. Other common etiologic bacteria include *Legionella pneumophila, Moraxella catarrhalis*, and *Hemophilus influenzae*.[76] Atypical microorganisms such as *Chlamydophila pneumoniae* and *Mycoplasma pneumoniae* also cause CAP. Fungi are a less common cause of CAP except in the case of severe immunocompromise like that seen in individuals with HIV infection when *Pneumocystis jirovecii, Aspergillus*, and *Cryptococcus* infections may occur.[80] Unfortunately, there is increasing incidences of CAP caused by antibiotic-resistant organisms such as methicillin-resistant *S. aureus* (MRSA), *P. aeruginosa*, and *Enterobacteriaceae*.[81] The most common etiologic microorganisms in HAP are *S. aureus* and MRSA, *Enterobacteriaceae, P. aeruginosa, Acinetobacter* species, *K. pneumoniae*, and *Enterococcus coli*.[76,82] These microorganisms also cause pneumonia in individuals who recently have been discharged from the hospital or who live in long-term care facilities.

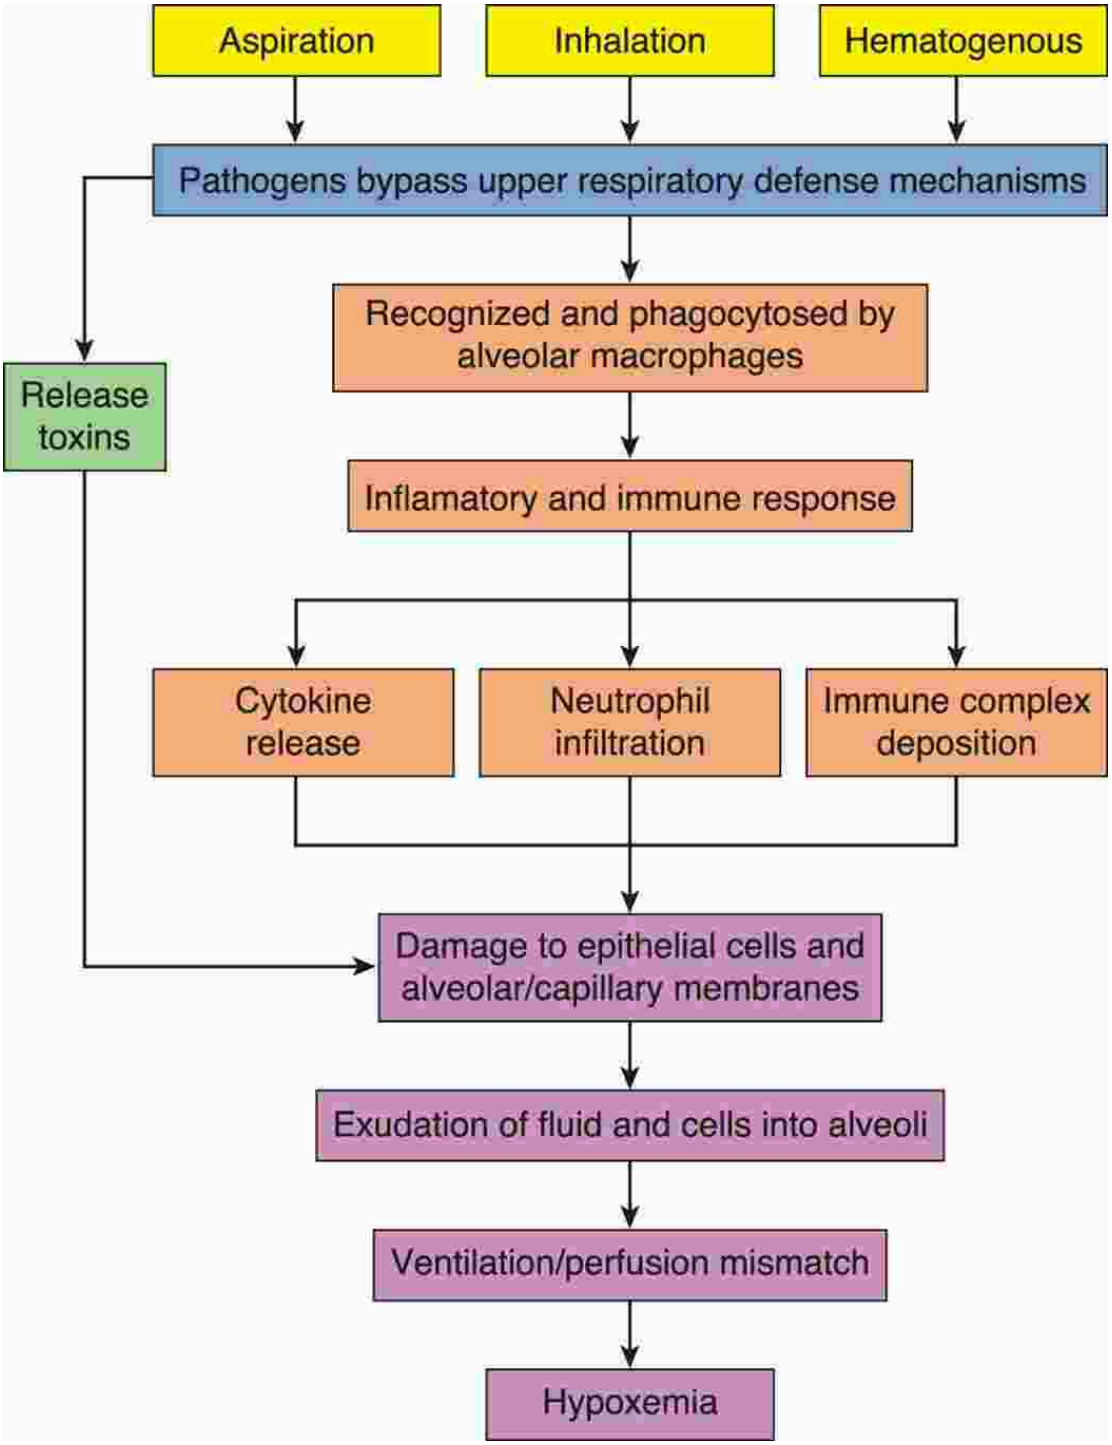
Pathophysiology

Viruses can enter the lower respiratory tract through direct inoculation or inhalation, spread from viral infections near the upper respiratory tract, or hematogenously. They target the airway and alveolar epithelial cells, especially pneumocytes. For example, in influenza, viral hemagglutinin (HA) binds to sialic acid residues expressed on epithelial cells, leading to viral entry into these cells.[83] Viral replication ensues, along with activation of both innate and adaptive immune responses. In severe viral pneumonias that can occur with influenza and COVID-19, a cytokine storm ensues which causes epithelial and endothelial damage, hypercoagulability, and increased vascular permeability leading to alveolar edema and ARDS (see Emerging Science Box: The Pathogenesis of the Acute Respiratory Distress Syndrome (ARDS) in COVID-19). Influenza and other respiratory viruses can set the stage for a secondary bacterial infection by damaging ciliated epithelial cells, which normally prevent pathogens from reaching the lower airways. Sloughing of destroyed bronchial ciliated epithelium occurs throughout the respiratory tract, preventing mucociliary clearance. Viral pneumonia is usually self-limiting and alveolar regeneration results in complete resolution of lung injury. However, bronchiectasis, irreversible atelectasis, long-term morbidity, and mortality occur in some individuals, especially the very young and very old.

In bacterial pneumonia, colonization of the upper respiratory tract followed by aspiration of oropharyngeal secretions is the most common route of lower respiratory tract infection.[76] Another route of infection is through the inhalation of certain microorganisms (e.g., *M. pneumoniae, C.*

pneumoniae, Legionella pneumoniae) that have been released into the air when an infected individual coughs, sneezes, or talks, or from aerosolized water, such as that from contaminated respiratory therapy equipment. The pathogens then adhere to the upper airway epithelium where they escape from mucociliary clearance and evade host clearance through expression of host-mimicking or antigenically varying molecules.[76] They then enter the lower airways through inhalation. In VAP, bacteria form biofilms on the endotracheal tube, allowing bacteria to bypass protective mechanisms and directly invade the lung. Bacterial pneumonia also can occur when pathogens are spread to the lung hematogenously from infection elsewhere in the body or from intravenous (IV) drug use.

The most important guardian cell of the lower respiratory tract is the alveolar macrophage, which recognizes pathogens through its pattern-recognition receptors (e.g., Toll-like receptors) and phagocytoses them (see Chapters 7 and 8). Some bacteria (e.g., pneumococci) have capsules that make phagocytosis by alveolar macrophages more difficult, and opsonization with complement and antibodies is required (see Chapter 7). Macrophages present infectious antigens to the adaptive immune system, activating T cells and B cells with the induction of both cellular and humoral immunity (see Chapters 8). The release of TNF-α and interleukin-1 (IL-1) from macrophages, along with chemokines and chemotactic factors from mast cells and fibroblasts contributes to widespread inflammation and the recruitment of neutrophils from the capillaries into the alveoli. Neutrophils release neutrophil extracellular traps (NETs), which are essential to removing the invading microorganism but cause bystander damage to host lung tissue.[84] Adaptive immune activation leads to the production of antibodies and immune cytokines that activate lymphocytes. IL-17 and IL-22 activate epithelial cells to secrete antimicrobial proteins and stimulate epithelial repair mechanisms.[76] Inflammatory mediators, immune complexes, and toxins damage bronchial mucous membranes and alveolocapillary membranes, causing the alveoli and terminal bronchioles to fill with infectious debris and exudate causing V· /Q· mismatching and hypoxemia. Some microorganisms cause further damage to lung tissue through the release of toxins. For example, pneumococci release pneumolysin, which is a pore-forming toxin that damages airway and alveolar cells and induces inflammatory cytokine release.[76] *Staphylococcus aeruginosa* organisms release alpha-hemolysin which damages epithelial cells.[85] The pathogenesis of bacterial pneumonia is outlined in Algorithm 35.6.



ALGORITHM 35.6 **Pathophysiologic Course of Bacterial Pneumonia.**

A flowchart shows the pathophysiologic course of bacterial pneumonia. 1. Aspiration. Leads to 4. 2. Inhalation. Leads to 4. 3. Hematogenous. Leads to 4. 4. Pathogens bypass upper respiratory defense mechanisms. Leads to 5 and 6. 5. Recognized and phagocytosed by alveolar macrophages. Leads to 7.

6. Release toxins. Leads to 11. 7. Inflammatory and immune response. Leads to 8, 9, and 10. 8. Cytokine release. Leads to 11. 9. Neutrophil infiltration. Leads to 11. 10. Immune complex deposition. Leads to 11. 11. Damage to epithelial cells and alveolar or capillary membranes. Leads to 12. 12. Exudation of fluid and cells into alveoli. Leads to 13. 13. Ventilation or perfusion mismatch. Leads to 14. 14. Hypoxemia.

Clinical Manifestations

Most cases of pneumonia are preceded by a viral upper respiratory tract infection. Individuals then develop fever, chills, a cough (productive or dry), malaise, pleural pain, and sometimes dyspnea and hemoptysis. The physical examination may show signs of pulmonary consolidation, such as dullness to percussion, inspiratory crackles, increased tactile fremitus (palpable chest vibrations when a person speaks), and egophony ("E" to "A" change). A pleural effusion may develop. Individuals also may demonstrate symptoms and signs of underlying systemic disease or sepsis. Pneumonia may contribute to decreased left ventricular function, arrhythmias, ischemia, and infarction (see Chapter 32). Individuals hospitalized for pneumonia have an increased risk for cardiovascular disease whose symptoms may be erroneously attributed to pneumonia persistence or recurrence.

Evaluation and Treatment

The initial diagnosis of pneumonia is made based on the history of exposures and symptoms, followed by a careful physical examination (tachypnea, tachycardia, crackles, bronchial breath sounds, findings of pleural effusion). The white blood cell count is usually elevated, although it may be low if the individual is immunocompromised or has significant comorbidities. Chest radiographs show infiltrates that may involve a single lobe of the lung or may be more diffuse. No further evaluation is indicated for outpatients with mild to moderate CAP.[76] In the case of severe CAP requiring hospitalization, in those suspected of having MRSA or *P. aeruginosa*, or in HAP, the pathogen is identified by means of sputum characteristics (Gram stain and culture).[86] If sputum studies fail to identify the pathogen, further diagnostic studies may include blood cultures, thoracentesis, bronchoscopy, or lung biopsy. Serum procalcitonin can be used to assess severity of disease but should not be used to guide initial antibiotic therapy.[86] Urine and serum antigen rapid testing for pneumococcus or *Legionella* may be obtained for selected individuals.

Prevention of pneumonia includes avoidance of aspiration, respiratory isolation of infected individuals, and vaccination. Measures to prevent VAP include head of bed elevation, oral hygiene, hand hygiene, and the use of specialized endotracheal tubes.[87]

The first step in the management of pneumonia is establishing adequate ventilation and oxygenation. Hydration and good pulmonary hygiene (e.g., deep breathing, coughing, chest physical therapy) also are important. Viral pneumonia is treated with supportive therapy. Antivirals are indicated for hospitalized individuals.[86] Antibiotics should be given promptly for bacterial pneumonia. Empiric treatment with macrolide antibiotics is recommended for outpatients with CAP who are not suspected of having resistant infections. In severe CAP, HAP, and VAP, broad-spectrum antibiotics that cover resistant organisms are recommended.[86] New antibiotics with improved outcomes in resistant infections are being developed.[88] Opportunistic infections in immunocompromised individuals may be the result of several different microorganisms and often require multiple drugs, including antifungals.

Tuberculosis

Tuberculosis (TB) is an infection caused by *Mycobacterium tuberculosis*, a bacillus that usually affects the lungs but may invade other body systems. TB affects an estimated 10 million people worldwide, resulting in 1.6 million deaths and is the leading cause of death in the world from a curable infectious disease.[89] TB cases increased greatly during the mid-1990s because of AIDS, but both have decreased since 2000. Unfortunately, emerging multidrug-resistant strains are becoming more common. Emigration of infected individuals from high-prevalence countries, transmission in crowded institutional settings, homelessness, substance abuse, and lack of access to screening and medical care have contributed to the spread of TB.

Pathophysiology

TB is highly contagious and is transmitted from person to person in airborne droplets. In immunocompetent individuals, the *M. tuberculosis* is usually contained by the person's inflammatory and immune response systems. This results in latent TB infection (LTBI) and is associated with no clinical evidence of disease. Once the bacilli are inspired, they lodge in the lung, usually in the upper lobe, and cause localized nonspecific inflammation to the lung tissue. Some bacilli migrate through the lymphatics and become lodged in the lymph nodes, initiating an immune response. Alveolar macrophages and neutrophils engulf and isolate the bacilli, preventing them from spreading.[90] However, the bacterium can evade the person's defense mechanism within macrophages and resist lysosomal killing, forming a granulomatous lesion called a *tubercle*(see Chapter 7). Infected tissues within the tubercle die, forming cheeselike material called *caseation necrosis*. Collagenous scar tissue then grows around the tubercle, completing the isolation of bacilli. The immune response is complete after about 10 days, preventing further multiplication of bacilli.

Once bacilli are isolated in tubercles, tuberculosis may remain latent (LTBI) for life. If the immune system is impaired, reactivation with progressive disease can occur and may spread throughout the lung and through the blood and lymphatics to other organs, causing active pneumonia and extrapulmonary disease. Cancer, immunosuppressive medications (e.g., corticosteroids), poor nutritional status, renal failure, and HIV can reactivate the disease.

Clinical Manifestations

LTBI is asymptomatic. Symptoms of active disease often develop gradually and are not diagnosed until the disease has advanced. Common clinical manifestations include night sweats, fatigue, weight loss, lethargy, anorexia (loss of appetite), and a low-grade fever that usually occurs in the afternoon. A cough that produces purulent sputum develops slowly and becomes more frequent over several weeks or months. Dyspnea, chest pain, and hemoptysis may occur as the disease progresses. Extrapulmonary TB disease is common in HIV-infected individuals and may cause neurologic deficits, meningitis symptoms, bone pain, and urinary symptoms.

Evaluation and Treatment

Screening for tuberculosis is usually conducted using the tuberculin skin test (TST; purified protein derivative [PPD]). A positive PPD is not sensitive nor specific for TB infection. For example, a person who previously received a bacilli Calmette-Guérin (BCG) vaccine can have a false positive TB skin test, while immunocompromised individuals may be unable to react to the protein and therefore have a false negative test. High-risk individuals instead should be screened with the interferon-gamma release assay (IGRA). The diagnosis is confirmed through sputum stain and culture and chest radiographs. However, a positive result from a sputum culture can take up to 6 weeks.

Currently, the only tuberculosis vaccine licensed for use globally is BCG, although new advances in TB vaccine development are encouraging.[91] Prevention of reactivation of LTBI through the use of antituberculous medications is recommended for at-risk individuals, such as those with HIV and those initiating immunosuppressive therapy for other conditions.[92] Individuals with active TB must

be kept in respiratory isolation until their sputum is negative for bacilli. In drug-susceptible TB, four antibiotics are given together for the first two months of treatment, followed by an additional four months of a two-drug combination.[93] Monitoring for adherence is important to prevent the development of resistant strains. Assessing individuals for toxicities and drug-to-drugs interactions is essential. Multidrug-resistant TB requires genotypic and phenotypic drug susceptibility testing, and new drugs are emerging that can improve treatment outcomes.[94,95]

Abscess Formation and Cavitation

An abscess (liquefactive necrosis) is a circumscribed area of suppuration and destruction of lung parenchyma. Abscesses often occur because of aspiration associated with alcohol abuse, seizure disorders, general anesthesia, and swallowing disorders. Abscess formation follows consolidation of lung tissue, in which inflammation causes alveoli to fill with fluid, pus, and microorganisms. Necrosis of consolidated tissue may lead to cavitation in which the abscess empties into a bronchus, forming a cavity. Abscess communication with a bronchus causes production of copious amounts of malodorous sputum and occasionally hemoptysis. Other clinical manifestations include fever, cough, chills, and pleural pain. The diagnosis is made by chest radiography and sputum analysis. Treatment includes appropriate antibiotics and chest physical therapy. Bronchoscopy may be needed to drain the abscess.

Pulmonary Vascular Disease

Blood flow through the lungs can be disrupted by disorders that occlude the vessels, increase pulmonary vascular resistance, or destroy the vascular bed. The consequences of altered pulmonary blood flow can result in severe and life-threatening changes in V· /Q·. Significant disorders include PE, PH, and cor pulmonale.

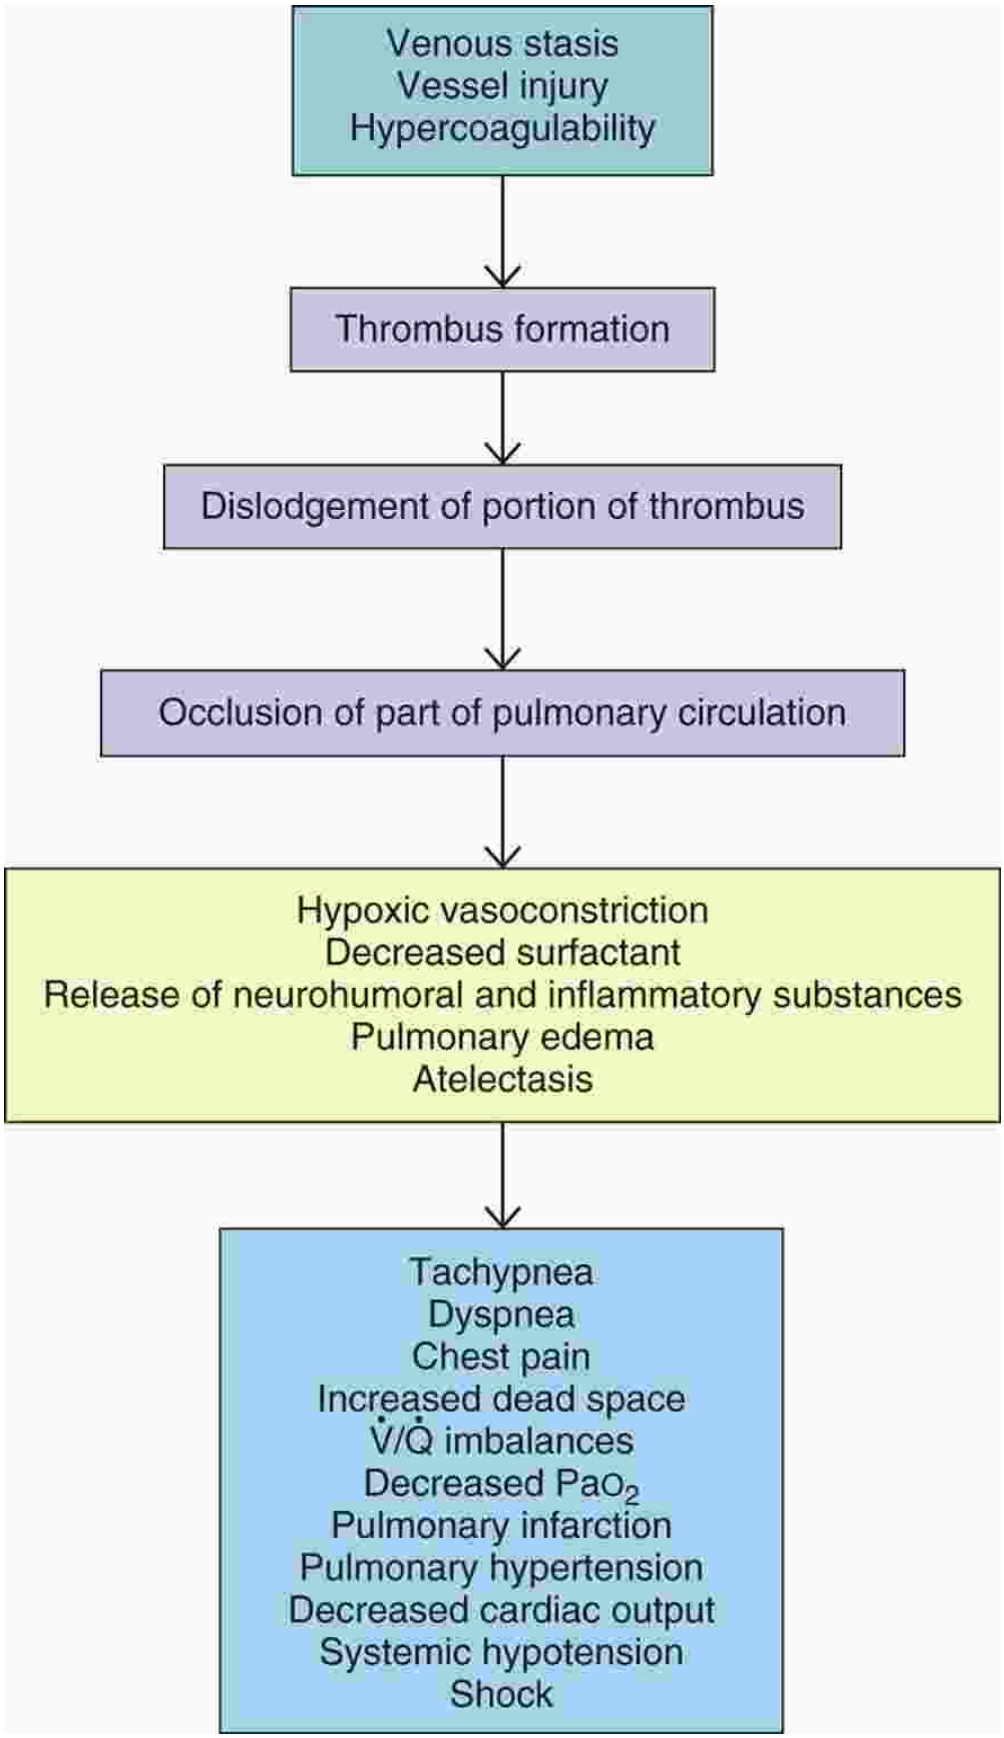
Pulmonary Embolism

Pulmonary embolism (PE) is occlusion of a portion of the pulmonary vasculature by an embolus. An estimated 900,000 people in the United States develop deep venous thrombosis (DVT)/PE, and sudden death is the first symptom in 25% of people who have a PE.[96] PE most commonly results from embolization of a clot from DVT involving the lower leg (see Chapter 32); this form of PE is often called venous thromboembolism (VTE). Other, less common types of emboli include tissue fragments, lipids, a foreign body, an air bubble, or amniotic fluid.

Risk factors for VTE include conditions and disorders that promote blood clotting because of venous stasis (immobilization, heart failure), injuries to the endothelial cells that line the vessels (trauma, infection, caustic IV infusions), and hypercoagulability (inherited coagulation disorders, malignancy, hormone replacement therapy, pregnancy, oral contraceptives). Increased risk for thrombosis associated with hemodynamic stasis, hypercoagulability, and endothelial injury is known as *triad of Virchow* (see Chapter 32). Individuals with cancer are at particular risk for VTE due to stasis of blood flow due to pressure of tumor on vessels, thrombogenic medications, chronic inflammation, and procoagulant molecules secreted by some cancer cells.[97] COVID-19 also is associated with a significantly increased risk for VTE.[98] Approximately 5% to 8% of the U.S. population has an inherited thrombophilia.[96] Inherited coagulation disorders include factor V Leiden mutation, prothrombin gene mutations, and deficiencies of antithrombin II, protein S, and protein C. It is now well recognized that systemic or localized bacterial and viral infections markedly increase the risk of both arterial thromboemboli and VTE in both inpatients and outpatients. For example, the incidence of VTE in individuals hospitalized for COVID-19 is estimated at 15% to 18% and arterial thromboemboli (acute coronary syndrome, stroke and other arterial emboli) at 4%.[99]

Pathophysiology

The effect of the embolus depends on the extent of pulmonary blood flow obstruction, the size of the affected vessels, and the nature of the embolus. As a result of the thrombus lodging in the pulmonary circulation, there is a release both of neurohumoral substances, such as serotonin, histamine, catecholamines, and angiotensin II, and of inflammatory mediators, such as endothelin, leukotrienes, thromboxanes, and toxic oxygen-free radicals. This causes widespread vasoconstriction that further impedes blood flow to the lung. Small pulmonary emboli typically cause V· /Q· mismatch and associated hypoxemia without damaging the lung itself. More significant obstruction of the pulmonary vasculature leads to pulmonary artery vasoconstriction, PH, and an increased workload for the right ventricle (RV). Large emboli can cause pulmonary infarction, dysrhythmias, decreased cardiac output, shock, and death. If the embolus does not cause infarction, the clot is dissolved by the fibrinolytic system, and pulmonary function returns to normal. If pulmonary infarction occurs, shrinking and scarring develop in the affected area of the lung. The pathogenesis of PE caused by DVT is summarized in Algorithm 35.7.



Venous stasis
Vessel injury
Hypercoagulability
Thrombus formation
Dislodgement of portion of thrombus
Occlusion of part of pulmonary circulation
Hypoxic vasoconstriction
Decreased surfactant
Release of neurohumoral and inflammatory substances
Pulmonary edema
Atelectasis
Tachypnea
Dyspnea
Chest pain
Increased dead space
V̇/Q̇ imbalances
Decreased Pa_{O_2}
Pulmonary infarction
Pulmonary hypertension
Decreased cardiac output
Systemic hypotension
Shock

ALGORITHM 35.7 Pathogenesis of Pulmonary Embolism Caused by a Thrombus (Venous Thromboembolism).
PaO_2, Arterial oxygen pressure; V· /Q·, ventilation-perfusion.

A flowchart represents the pathogenesis of pulmonary embolism. 1. Venous stasis; vessel injury; hypercoagulation. Leads to 2. 2. Thrombus formation. Leads to 3. 3. Dislodgement of portion of thrombus. Leads to 4. 4. Occlusion of part of pulmonary circulation. Leads to 5. 5. Hypoxic vasoconstriction; decreased surfactant; release of neurohumoral and inflammatory substances; pulmonary edema; atelectasis. Leads to 6. 6. Tachypnea; dyspnea; chest pain; increased dead space; V-Q ratio imbalances; decreased partial pressure of oxygen; pulmonary infarction; pulmonary hypertension; decreased cardiac output; systemic hypotension; shock.

Clinical Manifestations

In most cases, the clinical manifestations of PE are nonspecific and may be confused with many other pulmonary or cardiac conditions. Although most emboli originate from clots in the lower extremities, DVT is often asymptomatic, and clinical examination may not indicate the presence of clot. Therefore, evaluation of risk factors and predisposing factors is an important aspect of diagnosis.

The classic clinical presentation of PE is the sudden onset of pleuritic chest pain, dyspnea, tachypnea, tachycardia, and unexplained anxiety. Occasionally syncope or hemoptysis occurs. With large emboli, a pleural friction rub, pleural effusion, fever, and leukocytosis may be noted. Recurrent small emboli may not be detected until progressive incapacitation, precordial pain, anxiety, dyspnea, and right ventricular enlargement are exhibited. Massive occlusion causes severe PH and shock.

Evaluation and Treatment

The diagnosis of PE is made by assessing the clinical probability followed by measuring D-dimer levels in the blood (a product of thrombus degradation). Although these clinical predictive models are not completely accurate, in general if clinical probability is low and D-dimer levels are normal, the diagnosis of PE is excluded. If clinical probability is high or D-dimer is elevated, CT arteriography or magnetic resonance arteriography (MRA) is used to confirm the diagnosis.[100,101] Arterial blood gas analysis usually demonstrates hypoxemia and respiratory alkalosis. Measurement of the levels of BNP and troponin is useful in evaluating PE associated with right ventricular dysfunction. Testing for inherited hypercoagulability is recommended in those with unprovoked or recurrent DVT.

Prevention of PE includes elimination of predisposing factors for individuals at risk. Venous stasis in hospitalized persons is minimized by leg elevation, bed exercises, position changes, early postoperative ambulation, and pneumatic calf compression. Clot formation is also prevented by prophylactic anticoagulant therapy, most often with direct oral anticoagulant medications (DOACs; e.g., apixaban, dabigatran, rivaroxaban).[102]

Anticoagulant therapy is the primary treatment for PE. DOACs are now the treatment of choice for most individuals with stable oxygenation and hemodynamics who can be treated as outpatients.[100,103,104] Acute PE with significant symptoms and hypoxemia requires hospitalization and supportive care. Initial anticoagulant therapy usually includes factor Xa inhibitors (e.g.,

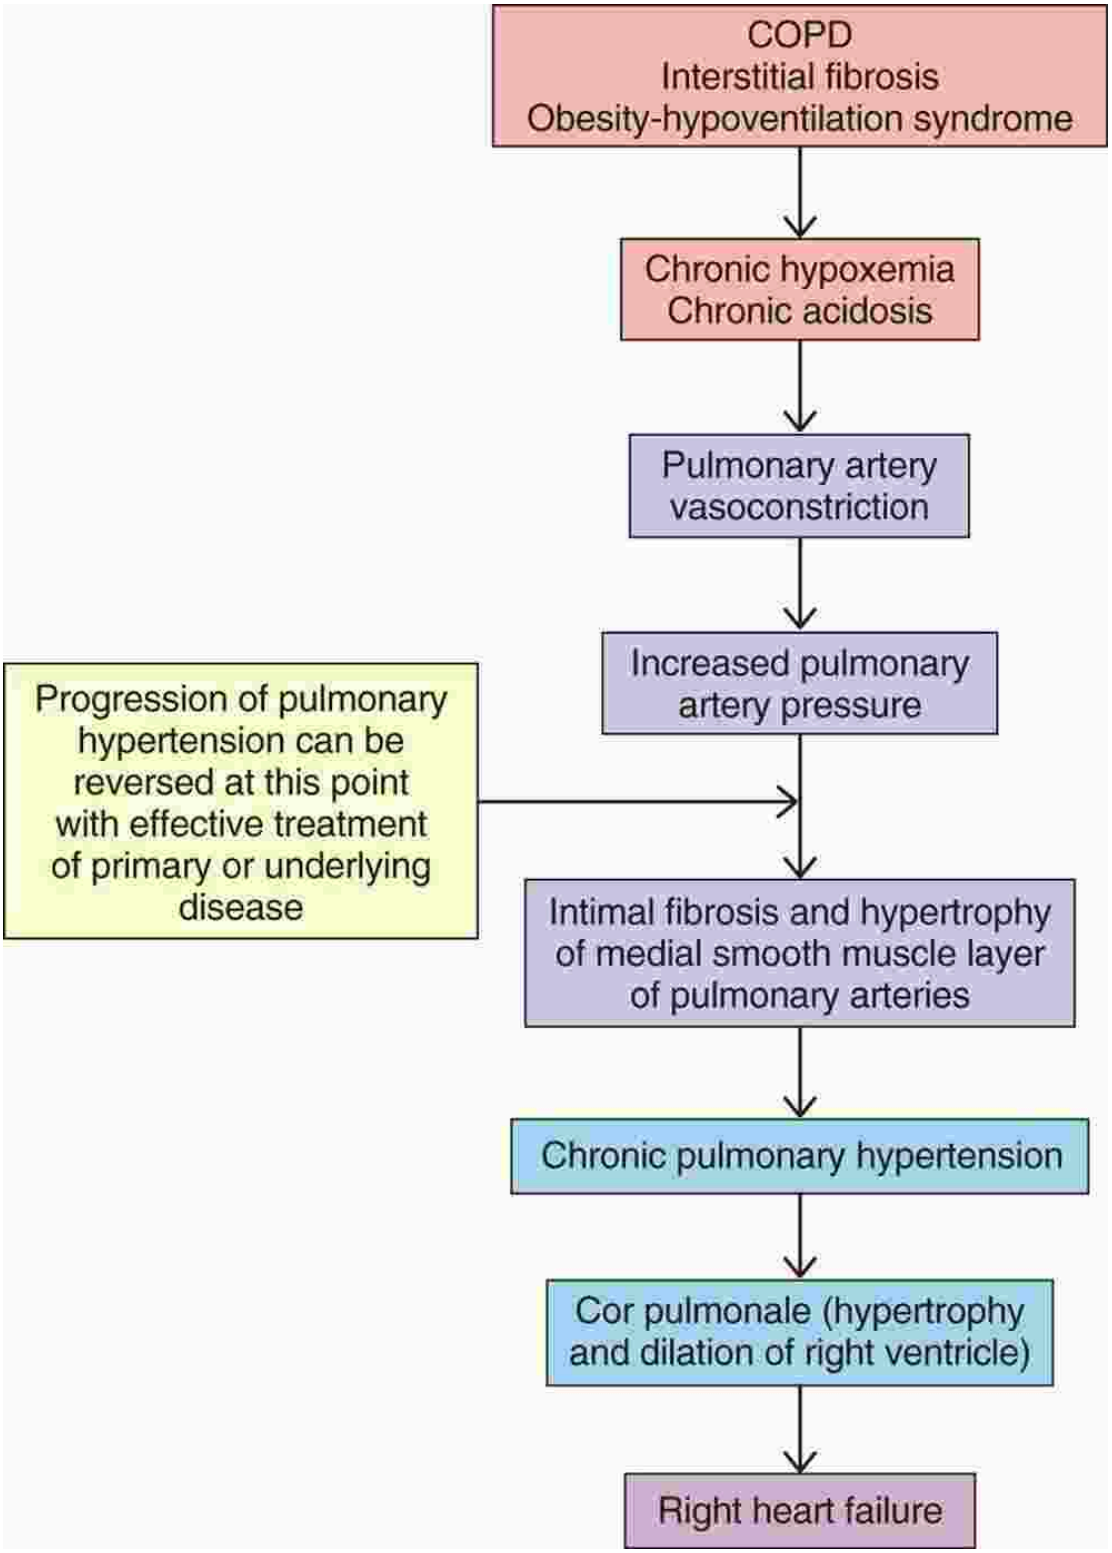
fondaparinux) or low-molecular-weight heparins (e.g., enoxaparin). The risk of recurrent VTE is high, especially in individuals with persistent risk factors. Therefore, long-term treatment with DOACs usually is indicated after discharge from the hospital. If the PE is associated with hemodynamic instability, an intravenous fibrinolytic agent, such as streptokinase, is indicated, and some individuals will require catheter-directed therapies or surgical thrombectomy.[103,105] In individuals who have contraindications to anticoagulation therapy, the placement of a filter in the inferior vena cava can prevent emboli from reaching the lungs. In some cases, these filters can be used during high-risk situations such as acute trauma, with retrieval after recovery.[106]

Pulmonary Hypertension

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure greater than 25 mm Hg at rest (normal is 15 to 18 mm Hg). PH is classified by the WHO into five groups and multiple subgroups based on the cause. One major category of PH is termed pulmonary artery hypertension (PAH) and includes subcategories of idiopathic, heritable, drug and toxin-induced, and disorders associated with PAH (e.g., connective tissue disease). The other major categories of PH include PH caused by left-sided heart disease, PH caused by lung diseases and/or hypoxia, chronic thromboembolic PH, and PH with unclear multifactorial mechanisms (e.g., tumors, metabolic disorders, chronic renal failure). Left heart disease is the most common cause of PH, and COPD and interstitial fibrosis are the most common lung diseases associated with PH.

Pathophysiology

PAH is characterized by endothelial dysfunction with overproduction of vasoconstrictors, such as thromboxane and endothelin, and decreased production of vasodilators, such as prostacyclin and nitric oxide. Inflammation with infiltration of macrophages, neutrophils and lymphocytes, and the release of enzymes and vascular growth factors lead to fibrosis and vascular *remodeling* with permanent arteriolar narrowing and superimposed abnormal vasoconstriction.[107] Vasoconstriction causes resistance to pulmonary artery blood flow, thus increasing the pressure in the pulmonary arteries and RV. As resistance and pressure increase, the workload of the RV increases with subsequent right ventricular hypertrophy. Right heart failure may occur. PH from left heart disease is caused by increased filling pressures into the left heart (see Chapter 32). In PH caused by lung disease, damage to the lung parenchyma combined with hypoxic pulmonary vasoconstriction leads to increased pressures in the right heart and *cor pulmonale*. The pathogenesis of PH resulting from disease of the respiratory system is shown in Algorithm 35.8.



ALGORITHM 35.8 Pathogenesis of Pulmonary Hypertension and Cor Pulmonale Resulting from Respiratory Disease.
COPD, Chronic obstructive pulmonary disease.

A flowchart represents the pathogenesis of pulmonary hypertension. 1. C O P D; interstitial fibrosis; obesity-hypoventilation syndrome. Leads to 2. 2. Chronic hypoxemia; chronic acidosis. Leads to 3. 3. Pulmonary artery vasoconstriction. Leads to 4. 4. Increased pulmonary artery pressure. Leads to 6. 5. Progression of pulmonary hypertension can be reversed at this point with effective treatment of primary or underlying disease. Leads to 6. 6. Intimal fibrosis and hypertrophy of medial smooth muscle layer of pulmonary arteries. Leads to 7. 7. Chronic pulmonary hypertension. Leads to 8. 8. Cor pulmonale (hypertrophy and dilation of right ventricle). Leads to 9. 9. Right heart failure.

Clinical Manifestations

Symptoms of PH may not develop until late in the disease process. Manifestations of fatigue, chest discomfort, tachypnea, and dyspnea (particularly with exercise) are common. The physical examination may reveal peripheral edema, jugular venous distention, a precordial heave, and accentuation of the pulmonary component of the second heart sound.

Evaluation and Treatment

The first indication of PH may be an abnormality seen on a chest radiograph (enlarged right heart) or an electrocardiogram that shows right ventricular hypertrophy. Identification of underlying cardiac or pulmonary conditions is essential. Common diagnostic modalities used to determine the cause include a chest x-ray, echocardiography, and CT.

General therapies for PAH include administration of oxygen, diuretics, and anticoagulants; and avoidance of contributing factors, such as air travel, decongestants, nonsteroidal antiinflammatories, pregnancy, and tobacco use. Pharmacologic interventions for PAH may include vasodilators such as calcium channel blockers, prostacyclin and its analogs, inhaled nitric oxide, endothelin receptor antagonists, phosphodiesterase-5 inhibitors, and soluble guanylate cyclase activators.[108] Selexipag, an oral, long-acting agonist of the prostacyclin receptor (IP receptor), recently has been shown to reduce morbidity and mortality in adults with PAH.[109] None of these drugs are curative, but they may improve morbidity and mortality. Individuals who do not achieve adequate clinical remission may require lung transplantation. Stem cell therapies are being explored.[110] The most effective treatments for PH associated with cardiac and pulmonary disorders are supplemental oxygen and treatment of the underlying disease.

Cor Pulmonale

Cor pulmonale is right ventricular enlargement (hypertrophy, dilation, or both) due to pulmonary disorders that cause PH.

Pathophysiology

Chronic pulmonary disease associated with hypoxemia and hypercapnia cause pulmonary vasoconstriction and increased pressures in the pulmonary system. Cor pulmonale develops as PH exerts chronic pressure overload in the RV (see Algorithm 35.8). Pressure overload increases the work of the RV, resulting in hypertrophy of the normally thin-walled heart muscle. RV compliance decreases causing increasing pressures in the LV that are reflected to the RA and systemic venous circulation. This eventually progresses to dilation and failure of the ventricle.

Clinical Manifestations

The clinical manifestations of cor pulmonale may be obscured by underlying respiratory or cardiac disease and may appear only during exercise testing. The heart may appear normal at rest, but with exercise, cardiac output decreases due to decreased diastolic filling time for the RV. The electrocardiogram may show right ventricular hypertrophy. The pulmonary component of the second heart sound (i.e., closure of the pulmonic valve) may be accentuated, and a pulmonic valve murmur may be present. A tricuspid valve murmur may accompany the development of RV failure. Increased pressures in the systemic venous circulation cause jugular venous distention, hepatosplenomegaly, and peripheral edema.

Evaluation and Treatment

The diagnosis is based on the physical examination, thoracic imaging, and electrocardiography or echocardiography, or both. The treatment goal for cor pulmonale is to decrease the workload of the RV by lowering the pulmonary artery pressure. Treatment is the same as that for PH, and its success depends on reversal of the underlying lung disease.

Malignancies of the Respiratory Tract

Laryngeal Cancer

Cancer of the larynx (laryngeal cancer) represents less than 1% of all cancers in the United States. In 2021 it is estimated that there were 12,620 new cases and 3770 deaths due to laryngeal cancer, with a 5-year survival rate of 60.7%.[111] Laryngeal cancer is much more common in men than women, and the primary risk factor is tobacco smoking. The risk is heightened by the combination of smoking and alcohol consumption. The human papillomavirus (HPV types 6 and 11) also has been linked to both benign and malignant tumors of the larynx. There is evidence that GERD may also increase the risk for laryngeal cancer.[112]

Pathophysiology

Carcinoma of the true vocal cords (glottis) is more common than that of the supraglottic structures (structures above the glottis) (Fig. 35.11). Tumors of the subglottic area are rare. Squamous cell carcinoma is the most common cell type, although neuroendocrine carcinomas also occur. Metastasis develops by cells spreading into the draining lymph nodes, but distant metastasis is rare.

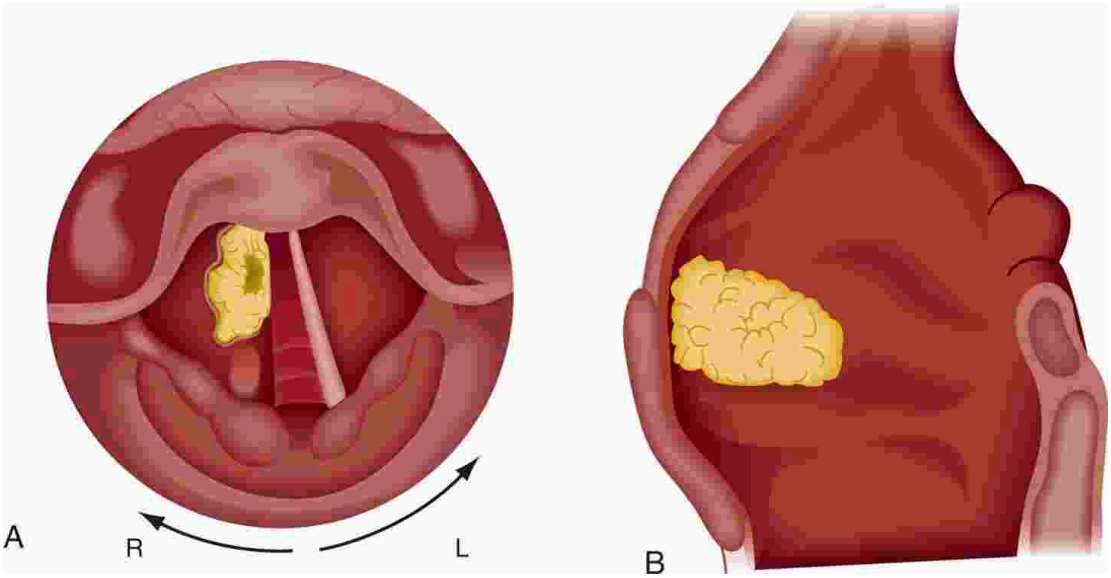


FIG. 35.11 Laryngeal Cancer.
(A) Mirror view of carcinoma of the right false cord partially hiding the true cord.
(B) Lateral view. (Redrawn from del Regato JA, et al. *Ackerman and del Regato's cancer*, 2nd edition. St. Louis: Mosby; 1985.)

Clinical Manifestations

The presenting symptoms of laryngeal cancer include dysphagia, hoarseness (dysphonia), dyspnea, and cough. Progressive hoarseness can result in voice loss. Dyspnea is rare with supraglottic tumors but can be severe in subglottic tumors. Swallowing may initiate a cough reflex. Laryngeal pain is likely with supraglottic lesions.

Evaluation and Treatment

Early evaluation for dysphonia improves subsequent survival after the diagnosis and treatment of laryngeal cancer, while delay in evaluation is associated with greater mortality.[113] This makes education of at-risk individuals important. Evaluation for laryngeal cancer includes external inspection and palpation of the larynx and the lymph nodes of the neck. Indirect or direct laryngoscopy with biopsy provides a definitive diagnosis. Imaging procedures facilitate the identification of tumor boundaries and the degree of extension to surrounding tissue.

Combined treatment with surgery (transoral laser microsurgery and partial or total laryngectomy), chemotherapy, immunotherapy, and irradiation can result in cure in selected cases.[114] Larynx-preservation strategies are being used to preserve swallowing and speech whenever possible. Swallowing and speech therapy after treatment can significantly improve recovery. Voice restoration after total laryngectomy includes using esophageal speech, electrolarynx, or voice prosthesis, among others.

Lung Cancer

Lung cancer is the second most common cancer in the United States and the leading cause of cancer death. In 2021, it is estimated that there were 235,760 new cases (12.4% of all new cancer cases) and 131,880 deaths (21.7% of all cancer deaths).[115] Despite emerging new therapies, the overall 5-year survival remains low, at about 22%.

Cigarette smoking accounts for 80% to 90% of primary lung cancers, however only 15% of smokers develop lung cancer, suggesting a genetic susceptibility.[116] The reduction in smoking

prevalence over the past 3 decades has led to a gradual decline in incidence, but many new cases of lung cancer occur in individuals who have already quit smoking. Smokers with COPD are at even greater risk. Other risk factors for lung cancer include aging, secondhand (environmental) smoke, radon gas exposure, occupational exposures to certain workplace toxins (e.g., asbestos), radiation, and both indoor and outdoor air pollution. Environmental risk factors for cancer are discussed in Chapter 12. Genetic risks include polymorphisms of the genes responsible for growth factor receptors, angiogenesis, apoptosis, deoxyribonucleic acid (DNA) repair, and detoxification of inhaled smoke.

Types of lung cancer

Most primary lung cancers arise from cells that line the bronchi within the lungs and are therefore called *bronchogenic carcinomas*. Lung cancers are classified by cell type and molecular profiling. Although there are many types of lung cancer, they can be divided into two main categories: non–small cell lung carcinoma (NSCLC) and neuroendocrine tumors of the lung. The category of NSCLC accounts for 80% to 85% of all lung cancers and can be subdivided into three types of lung cancer: squamous cell carcinoma, adenocarcinoma, and large cell undifferentiated carcinoma. Neuroendocrine tumors of the lung also arise from the bronchial mucosa and include small cell carcinoma, large cell neuroendocrine carcinoma, and typical and atypical carcinoid tumors. Small cell carcinoma is the most common of these neuroendocrine tumors, accounting for approximately 15% to 20% of all lung cancers.

Other pulmonary tumors, such as mesotheliomas (associated with asbestos exposure), occur less commonly. Many cancers that arise in other organs of the body metastasize to the lungs; however, these are not considered primary lung cancers and are categorized by their site of origin. Characteristics of primary lung tumors, including clinical manifestations, are listed in Table 35.4.

Table 35.4

Characteristics of Lung Cancers

Tumor Type	Growth Rate	Metastasis	Means of Diagnosis	Clinical Manifestations and Treatment
Non–Small Cell Carcinoma				
Squamous cell carcinoma	Slow	Late, mostly to hilar lymph nodes	Biopsy, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, hemoptysis, sputum production, airway obstruction, hypercalcemia; treated surgically, chemotherapy, radiation, and immunotherapy as adjunctive therapy
Adenocarcinoma	Moderate	Early, to lymph nodes, pleura, bone, adrenal glands, and brain	Radiography, fiberoptic bronchoscopy, electron microscopy	Pleural effusion; treated surgically, chemotherapy, and immunotherapy as adjunctive therapy
Large cell carcinoma	Rapid	Early and widespread	Sputum analysis, bronchoscopy, electron microscopy (by exclusion of other cell types)	Chest wall pain, pleural effusion, cough, sputum production, hemoptysis, airway obstruction resulting in pneumonia; treated surgically
Neuroendocrine Tumors of the Lung				
Small cell carcinoma	Very rapid	Very early; to mediastinum, lymph nodes, brain, bone marrow	Radiography, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, chest pain, dyspnea, hemoptysis, localized wheezing,

Tumor Type	Growth Rate	Metastasis	Means of Diagnosis	Clinical Manifestations and Treatment
				airway obstruction, signs and symptoms of excessive hormone secretion; treated by chemotherapy and ionizing radiation to thorax and central nervous system
Other Pulmonary Tumors				
Malignant pleural mesothelioma (MPM)	Rapid	Early, to lymph nodes, lungs, heart, bone	Radiography, thoracentesis	Chest pain, chronic cough, signs of pleural effusion; treated by surgery, chemotherapy, radiation, and immunotherapy

Tumor Type	Growth Rate	Metastasis	Means of Diagnosis	Clinical Manifestations and Treatment
Non–Small Cell Carcinoma				
Squamous cell carcinoma	Slow	Late, mostly to hilar lymph nodes	Biopsy, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, hemoptysis, sputum production, airway obstruction, hypercalcemia; treated surgically, chemotherapy, radiation, and immunotherapy as adjunctive therapy
Adenocarcinoma	Moderate	Early, to lymph nodes, pleura, bone, adrenal glands, and brain	Radiography, fiberoptic bronchoscopy, electron microscopy	Pleural effusion; treated surgically, chemotherapy, and immunotherapy as adjunctive therapy
Large cell carcinoma	Rapid	Early and widespread	Sputum analysis, bronchoscopy, electron microscopy (by exclusion of other cell types)	Chest wall pain, pleural effusion, cough, sputum production, hemoptysis, airway obstruction resulting in pneumonia; treated surgically
Neuroendocrine Tumors of the Lung				
Small cell carcinoma	Very rapid	Very early; to mediastinum, lymph nodes, brain, bone marrow	Radiography, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, chest pain, dyspnea, hemoptysis, localized wheezing, airway obstruction, signs and symptoms of excessive hormone secretion; treated by chemotherapy and ionizing radiation to thorax and central nervous system
Other Pulmonary Tumors				
Malignant pleural mesothelioma (MPM)	Rapid	Early, to lymph nodes, lungs, heart, bone	Radiography, thoracentesis	Chest pain, chronic cough, signs of pleural effusion; treated by surgery, chemotherapy, radiation, and immunotherapy

Non–small cell lung cancer

Squamous cell carcinoma accounts for about 30% of bronchogenic carcinomas. These tumors are typically located near the hila and project into bronchi (Fig. 35.12A). Because of this central location, symptoms of a nonproductive cough or hemoptysis are common. Pneumonia and atelectasis are often associated with squamous cell carcinoma. Chest pain is a late symptom associated with large tumors. These tumors are often well localized and tend not to metastasize until late in the course of the disease.

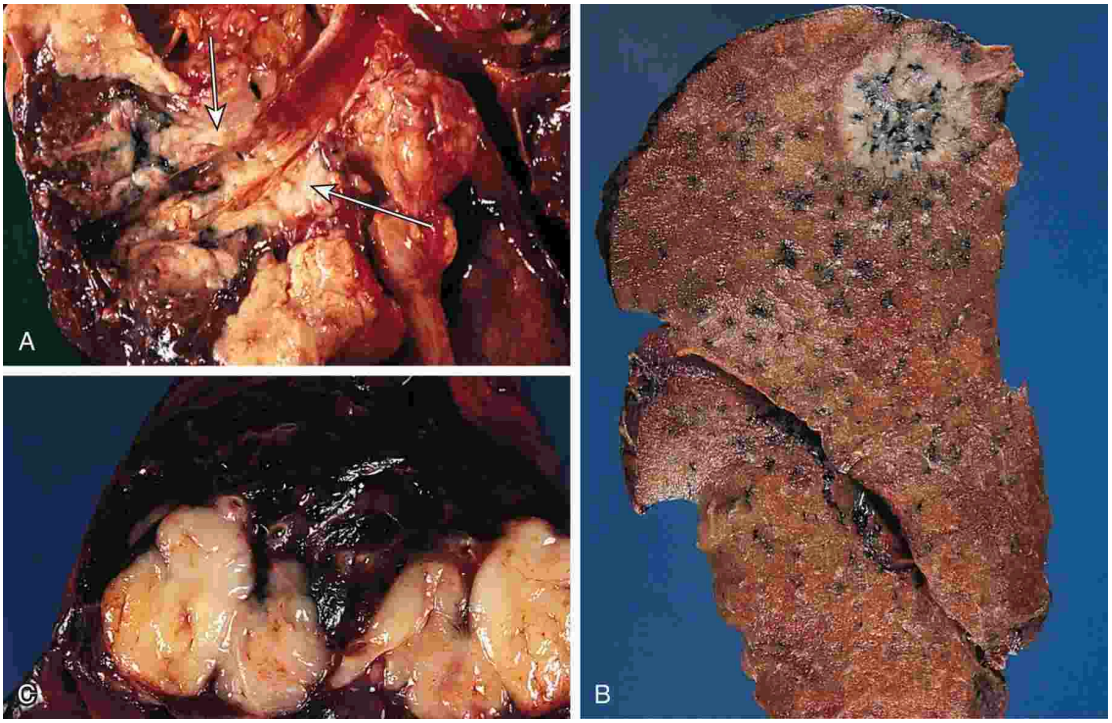

FIG. 35.12 Lung Cancer.
(A) Squamous cell carcinoma. This hilar tumor originates from the main bronchus. **(B)** Peripheral adenocarcinoma. The tumor shows prominent black pigmentation, suggestive of having evolved in an anthracotic scar. **(C)** Small cell carcinoma. The tumor forms confluent nodules. On cross section, the nodules have an encephaloid appearance. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Three closeups, A, B, and C, shows cancerous cells in the lungs. Top-left panel, A. The closeup shows abnormal growth of squamous cells on the lung. Right panel, B. The closeup shows a lung covered with scattered dark needle-like scars. Bottom-left panel, C. The closeup shows nodules of white mass.

Adenocarcinoma (tumor arising from glands) of the lung constitutes 35% to 40% of all bronchogenic carcinomas (Fig. 35.12B). Environmental tobacco smoke, occupational carcinogens, viruses, hormones, and positive family history are associated with this tumor type. Epidermal growth factor receptor (EGFR) mutations and anaplastic lymphoma kinase (ALK) gene rearrangements, as well as other tyrosine kinase inhibitors, are common in this type of lung cancer and are targets for therapy.[117,118] Pulmonary adenocarcinoma develops in a stepwise fashion through atypical adenomatous hyperplasia, adenocarcinoma in situ, and minimally invasive adenocarcinoma to invasive carcinoma. These tumors, which are usually smaller than 4 cm, more commonly arise in the peripheral regions of the pulmonary parenchyma. Individuals may be asymptomatic, and the tumors may be discovered by routine chest imaging in the early stages, or the individual may present with pleuritic chest pain and shortness of breath from pleural involvement by the tumor.

Included in the category of adenocarcinoma is bronchioloalveolar cell carcinoma. These tumors arise from terminal bronchioles and alveoli and are now being referred to as *adenocarcinoma in situ*

or *minimally invasive adenocarcinoma*. They are slow-growing tumors with an unpredictable pattern of metastasis through the pulmonary arterial system and mediastinal lymph nodes.

Large cell carcinomas constitute approximately 10% of bronchogenic carcinomas. These transformed epithelial cells have lost clear evidence of maturation and are considered an undifferentiated non–small cell carcinoma. These tumors arise from squamous, glandular, or neuroendocrine precursor cells, commonly arise centrally, and can grow to distort the trachea and cause widening of the carina.

Neuroendocrine tumors

Neuroendocrine tumors include small cell carcinoma, large cell neuroendocrine carcinoma, and bronchial carcinoids. Large cell neuroendocrine and bronchial carcinoids are rare.[119]

Small cell lung carcinoma (SCLC) is the most common type of neuroendocrine lung tumor and causes 25% of lung cancer deaths with an overall 5-year survival of less than 10%. Small cell carcinoma arises from neuroendocrine cells that contain neurosecretory granules. Most of these tumors are central in origin (hilar and mediastinal) (see Fig. 35.12C), have a rapid rate of growth, and tend to metastasize early and widely. Because these cells arise from neuroendocrine cells, they are often associated with ectopic hormone production. Ectopic hormone production is important to the clinician because resulting signs and symptoms, called *paraneoplastic syndromes* (see Chapter 12), may be the first manifestation of the underlying cancer. Examples include hyponatremia (antidiuretic hormone), Cushing syndrome (adrenocorticotropic hormone), hypocalcemia (calcitonin), gynecomastia (gonadotropins), carcinoid syndrome (serotonin), and Lambert-Eaton myasthenic syndrome (paneoplastic cerebellar degeneration).

Bronchial carcinoid tumors represent about 1% of all lung tumors. They are not related to smoking, may begin in childhood, and grow very slowly. Carcinoid tumors contain neuroendocrine-like hormones, but rarely produce hormone related symptoms. The tumors are usually discovered by chest imaging undertaken for an unrelated condition and can be cured by local surgical or bronchoscopic resection.

Other lung cancers

Malignant mesotheliomas arise from the mesothelial cells that line the pleura. Nearly 80% have been linked to asbestos exposure, although it may take up to 40 years after exposure for the tumor to be diagnosed. They are classified as epithelioid, sarcomatoid, and biphasic, although new classification categories are being proposed.[120] Clinical manifestations include dyspnea and chest pain. Chest imaging may reveal a pleural effusion, with the diagnosis confirmed by CT scanning, thoracentesis, thoracoscopy, and cytology. Management includes surgery, chemotherapy, radiation, and immunotherapy, although toxicities are high and outcomes poor in those with advanced disease.[121,122]

Pathophysiology

Tobacco smoke contains more than 7000 chemicals, 69 of which are classified as carcinogens.[123] Air pollution and other inhaled toxins also contain numerous carcinogens. These chemicals, along with an inherited genetic predisposition to cancers, result in tumor development. Once lung cancer is initiated by these carcinogen-induced mutations, tumor development is promoted by additional mutations that alter the production and response to growth factors that alter cell growth and differentiation and by the production of inflammatory mediators. The bronchial mucosa suffers multiple carcinogenic "hits" because of repetitive exposure to tobacco smoke, and, eventually, epithelial cell changes begin progressing from metaplasia to carcinoma in situ and finally to invasive carcinoma. Further tumor progression includes invasion of surrounding tissues and finally metastasis to distant sites, including the brain, bone marrow, and liver (see Chapter 12 for the details of cancer biology).

Clinical Manifestations

Table 35.4 summarizes the characteristic clinical manifestations according to tumor type. Approximately half of individuals eventually diagnosed with lung cancer develop a new cough, a third develop dyspnea, and a quarter develop hemoptysis.[116] Recurrent infections are also common. These symptoms are nonspecific and often attributed to smoking;, and when they are severe enough to motivate the individual to seek medical advice, the disease is often advanced. Symptoms of advanced disease such as dysphagia, weight loss, fatigue, bone pain, and paraneoplastic syndromes may be the first indication of underlying lung cancer.

Evaluation and Treatment

Annual screening for lung cancer with low-dose CT (LDCT) scans is recommended for adults age 50 to 80 who have 20 pack years or more of smoking history and either continue to smoke or have quit within the past 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery.[124] Most studies suggest that concerns about the high false-positive rate and considerable radiation exposure are outweighed by the estimated 20% reduction in lung cancer mortality as compared to plain radiographs.[116] Diagnostic tests for the evaluation of lung cancer include sputum cytologic studies, chest CT, bronchoscopy, PET scanning, and endobronchial ultrasound (EBUS)-guided bronchoscopic biopsy. Biopsy determines the cell type. The evaluation of lymph nodes and other organ systems, usually by FDG-PET scanning, is used to determine the stage of the cancer. The currently accepted system for the staging of non–small cell cancer is the TNM classification (*T* denotes the extent of the primary tumor, *N* indicates the nodal involvement, *M* describes the extent of metastasis) (see Chapter 12). This system,as applied to primary lung cancers, was updated in 2016 and includes a detailed description of each category with the aim of improving both clinical and research approaches toward management.[125] Long delays between diagnosis and staging may occur and can lead to progression of disease and poorer outcomes in individuals with NSCLC.[126] In contrast to NCSLC, small cell lung cancers are only staged as either limited (confined to the area of origin in the lung) or extensive.

The histologic cell type, the genotype, and the stage of the disease are major factors that influence the choice of therapy. For all types of early-stage NSLC, the preferred treatment is surgical resection.[127] Once metastasis has occurred, total surgical resection is more difficult, and survival rates dramatically decrease. Other treatment modalities include chemotherapy, dose-intensified irradiation, radiofrequency ablation, microwave ablation, cryotherapy, and brachytherapy. Molecular and immunotherapies have been approved that can increase the survival time for selected individuals (Emerging Science Box: Molecular and Immune Therapies for Lung Cancer).[117,128,129] Only 5% of individuals with SCLC can be treated surgically. Systemic chemotherapy and radiation are indicated in most cases.

Emerging Science BoxMolecular and Immune Therapies for Lung Cancer

A better understanding of the genetic and immunologic features of lung cancer cells has led to new treatment options. Molecular therapies are now available for both non–small cell carcinoma (NSCLC) and, to a lesser degree, for small cell carcinoma (SCLC). These therapies target specific cancer cell mutations and require molecular analysis of tumor cells to determine if an individual is likely to benefit from their use. Among the most effective molecular therapies for NSCLC are drugs that block the action of epidermoid growth factor receptor (EGFR) and include erlotinib, gefitinib, afatinib, osimertinib, dacomitinib, and necitumumab. These drugs have increased overall response rates to treatment and survival time in individuals whose cancer cells are positive for EGFR mutations. Other targets either approved or awaiting approval include drugs

that block the effects of ALK and tyrosine-protein kinase ROS-1 mutations (crizotinib, ceritinib, entrectinib, lorlatinib). Drugs that block angiogenesis (bevacizumab and ramucirumab) are also used in selected individuals. Cancer cells have the capacity to prevent effective adaptive immune responses by activating molecules called immune checkpoint inhibitors, such as PDL-1 and CTLA-4, on the surface of T cells, thus shutting these cells off. Monoclonal antibodies can be used to block these immune checkpoint inhibitors and thus restore the immune response to the cancer. Immunotherapies currently approved by the U.S. Food and Drug Administration (FDA) for NSCLC that block PDL-1 or CTLA-4 include nivolumab, pembrolizumab, atezolizumab, durvalumab, avelumab, ipilimumab, and tremelimumab. Nivolumab can be considered for treatment of SCLC. These therapies can shrink tumors and prolong life but are rarely curative, and many have considerable side effects. New combinations of immunotherapy drugs used as first-line treatment for advanced lung cancer are being explored.

Summary Review

Clinical Manifestations of Pulmonary Alterations

1. Dyspnea is the feeling of breathlessness or shortness of breath, requiring the individual to become preoccupied with breathing.
2. Orthopnea is dyspnea that occurs when an individual lies flat, which causes the abdominal contents to exert pressure on the diaphragm.
3. Paroxysmal nocturnal dyspnea is dyspnea that occurs with pulmonary or cardiac disease, waking the individual while sleeping, gasping for air.
4. Coughing is a protective reflex that expels secretions and irritants from the airways. It can be acute or chronic.
5. Changes in the volume, consistency, or color of sputum may indicate underlying pulmonary disease.
6. Hemoptysis is expectoration of bloody mucus, usually due to infection or inflammation that damages the bronchi or lung parenchyma.
7. Abnormal breathing patterns are adjustments made by the body to minimize the work of respiratory muscles. They include Kussmaul, labored, restricted, gasping, Cheyne-Stokes respirations, and sighing.
8. Hypoventilation is decreased alveolar ventilation caused by altered pulmonary mechanics or neurologic control of breathing and results in increased $PaCO_2$ (hypercapnia).
9. Hyperventilation is increased alveolar ventilation produced by anxiety, head injury, pain, or severe hypoxemia and causes decreased $PaCO_2$ (hypocapnia).

10. Cyanosis is a bluish discoloration of the skin caused by desaturation of hemoglobin, polycythemia, or peripheral vasoconstriction.
11. Clubbing of the fingertips is associated with diseases that cause chronic hypoxemia, and it is rarely reversible.
12. Pain to the chest wall can result from infection and inflammation of the pleurae, trachea, bronchi, ribs, or respiratory muscles.
13. Hypercapnia is an increased $PaCO_2$ due to hypoventilation of the alveoli and is associated with respiratory acidosis. There are many causes of hypoventilation
14. Hypoxemia is a reduced PaO_2 caused by respiratory alterations, resulting in $\dot{V}/\dot{Q}$ mismatch.
15. Hypoxia is reduced oxygenation of cells, usually due to hypoxemia.
16. $\dot{V}/\dot{Q}$ match is the balance between the amount of air that enters the alveoli and amount of blood that is perfusing. An alteration in this balance can cause a $\dot{V}/\dot{Q}$ mismatch resulting in hypoxemia.
17. Respiratory failure is inadequate gas exchange that can result from direct injury to the lungs, airways, or chest wall or indirectly because of disease or injury involving another body system. It is classified as either hypoxemic or hypercapnic.

Disorders of the Chest Wall and Pleura

1. Restricted movement of the chest wall can occur by obesity and kyphoscoliosis, which compress the lungs, and by neuromuscular diseases that impair chest wall muscle function.
2. Flail chest results from rib or sternal fractures that disrupt the mechanics of breathing.
3. Pneumothorax is the accumulation of air in the pleural space caused by rupture of weakened areas of the pleura.
4. Tension pneumothorax is a life-threatening condition caused by trapping of air in the pleural space, producing displacement of the trachea, great vessels, and heart.
5. Pleural effusion is the accumulation of fluid in the pleural space resulting from disorders from capillaries underlying the pleura or from blockage or injury to lymphatic vessels that drain into the pleural space.
6. Empyema is the presence of pus in the pleural space (infected pleural effusion); it usually occurs because of lymphatic drainage from sites of bacterial pneumonia.

Pulmonary Disorders

1. Pulmonary disorders can be restrictive (limiting lung volumes) or obstructive (limiting airflow) or both.
2. Restrictive lung diseases are characterized by decreased lung compliance, requiring more effort to expand the lungs during inspiration, which increases the work of breathing. Individuals with lung restriction have dyspnea, an increased respiratory rate, and a decreased tidal volume.
3. Aspiration of food particles or pharyngeal or gastric secretions into the airways can cause obstruction, inflammation, or pneumonia.
4. Atelectasis is the collapse of alveoli resulting from compression of lung tissue, absorption of gas from obstructed alveoli, or decreased production of surfactant.
5. Bronchiectasis is abnormal dilation of the bronchi secondary to another pulmonary disorder, usually infection or inflammation.
6. Bronchiolitis is the inflammatory obstruction of small airways. It is most common in children.
7. Pulmonary fibrosis is excessive connective tissue in the lung that diminishes lung compliance; it may be idiopathic or caused by disease and is associated with chronic

inflammation.

8. Inhalation of noxious gases or prolonged exposure to high concentrations of oxygen can damage the bronchial mucosa or alveolocapillary membrane and cause inflammation or acute respiratory failure.
9. Pneumoconiosis, which is caused by inhalation of dust particles in the workplace, can cause pulmonary fibrosis and progressive pulmonary deterioration.
10. Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an allergic or hypersensitivity reaction to many allergens causing lung inflammation.
11. Pulmonary edema is excess fluid in the lung caused by increased capillary hydrostatic pressure, decreased capillary oncotic pressure, or increased capillary permeability. Causes include left heart failure that increases capillary hydrostatic pressure in the pulmonary circulation, inflammation of alveoli, or lymphatic obstruction.
12. Acute respiratory distress syndrome (ARDS) is a form of acute lung inflammation and diffuse alveolocapillary injury that results from direct pulmonary injury or from severe systemic inflammation. Endothelial damage results in increased capillary membrane permeability causing hypoxemia and remodeling of the tissue causes fibrosis.
13. Obstructive lung disease is characterized by airway obstruction that causes difficult expiration. Accessory muscles of expiration must be used, which increases the work of breathing. The unifying symptom of obstructive lung diseases is dyspnea, and the unifying sign is wheezing.
14. Asthma is a chronic inflammation that causes bronchial hyperresponsiveness, constriction of the airways, mucosal edema, increased mucus production, and variable airflow obstruction that can be reversible.
15. Chronic obstructive pulmonary disease (COPD) is a group of lung disorders with persistent airflow limitation due to chronic inflammatory response in the airways. COPD is usually progressive and includes asthma, bronchitis, and emphysema.
16. Chronic bronchitis causes airway obstruction resulting from inflammation, bronchial smooth muscle hypertrophy, and production of thick, tenacious mucus.
17. In emphysema, destruction of the alveolar septa and loss of passive elastic recoil lead to alveolar enlargement, airway collapse, obstruction of gas flow, and air trapping during expiration.
18. Respiratory tract infections are common and usually involve only the upper airways.
19. Acute bronchitis is usually a self-limiting inflammation or viral infection of the airways.
20. Pneumonia is infection of the lower respiratory tract caused by bacteria, viruses, fungi, protozoa, or parasites.
21. Pneumococcal *(Streptococcus pneumoniae)* is the most common cause of community acquired pneumonia.
22. Viral pneumonia can be severe, but is more often an acute, self-limiting lung infection usually caused by the influenza virus.
23. Tuberculosis (TB) is a lung infection caused by *Mycobacterium tuberculosis* (tubercle bacillus). In tuberculosis, the inflammatory response proceeds to isolate colonies of bacilli by enclosing them in tubercles and surrounding the tubercles with scar tissue. TB bacilli escape immune defenses by surviving within macrophages.
24. An abscess is a circumscribed area of suppuration and destruction of lung parenchyma, often caused by aspiration. Necrosis of consolidated tissue may lead to cavitation in which the abscess empties into a bronchus and cavity formation.
25. Pulmonary vascular diseases are caused by embolism, hypertension, or cor pulmonale in the pulmonary circulation.
26. Pulmonary embolism is a clot most often originating from deep venous thrombosis and causes vascular obstruction, $\dot{V}/\dot{Q}$ mismatch, hypoxemia, and pulmonary hypertension; it may or may not cause infarction.

27. Pulmonary artery hypertension (pulmonary artery pressure >25 mm Hg) can be caused by heritable defects, drugs, veno-occlusive disease, lung or heart disease, systemic disorders, and chronic pulmonary embolism.
28. Cor pulmonale is secondary to pulmonary artery hypertension and results in right ventricular enlargement or failure.
29. Laryngeal cancer occurs primarily in men, represents less than 1% of all cancers, and presents with a clinical symptom of progressive hoarseness.
30. Lung cancer, the most common cause of cancer death in the United States, is usually caused by tobacco smoking.
31. Lung cancer (bronchogenic carcinomas) cell types include non–small cell carcinoma (squamous cell, adenocarcinoma, and large cell) and neuroendocrine tumors (small cell lung carcinoma and bronchial carcinoid tumors). Each type arises in a characteristic site or type of tissue, causes distinctive clinical manifestations, and differs in likelihood of metastasis and prognosis.

Chapter Outline

OUTLINE

Disorders of the Upper Airways 1191
- Infections of the Upper Airways 1191
- Aspiration of Foreign Bodies 1194
- Obstructive Sleep Apnea 1194

Disorders of the Lower Airways 1195
- Disorders of Prematurity 1195
- Respiratory Tract Infections 1199
- Asthma 1203
- Pediatric Acute Respiratory Distress Syndrome 1204
- Cystic Fibrosis 1205

Sudden Infant Death Syndrome 1207

Alterations of respiratory function in children are influenced by physiologic development, which is determined by age, genetics, and environmental conditions. Infants, especially premature infants, are particularly vulnerable to a variety of respiratory disorders because of incomplete development of the airways, circulation, chest wall, and immune system. A variety of upper and lower airway infections can cause respiratory compromise or play a role in the pathogenesis of more chronic pulmonary disease. Pulmonary dysfunction can be categorized into disorders of either the upper or the lower airways.

http://evolve.elsevier.com/Rogers/pathophysiology/

Disorders of the Upper Airways

Disorders of the upper airways can cause significant obstruction to airflow. Common causes of upper airway obstruction (UAO) in children are infections, foreign body aspiration, and obstructive sleep apnea. Congenital malformations, such as laryngomalacia and subglottic stenosis, may occur but are a less common cause of UAO.

Infections of the Upper Airways

Table 36.1 compares some of the more common upper airway infections.

Table 36.1

Comparison of Upper Airway Infections

Condition	Age	Onset	Etiology	Pathophysiology
Viral Croup (acute laryngotracheobronchitis)	6 months to 3 years	Usually gradual following a viral prodrome	Viral (e.g., parainfluenza, respiratory syncytial virus)	Inflammation from larynx to bronchi
Spasmodic Croup	6 months to 5 years	Abrupt with absence of prodrome	Airway narrowing, gastroesophageal reflux, allergies	Noninflammatory edema of the larynx
Bacterial tracheitis	1–12 years	Abrupt or after viral illness	*Staphylococcus aureus*/methicillin resistant *S. aureus* (MRSA) *Haemophilus influenzae* type B Group A streptococci	Inflammation and edema of upper trachea, pseudomembrane formation
Acute epiglottitis	2–6 years; also in adults with a mean age of 45 years	Abrupt	*Streptococcus pneumoniae, Staphylococcus aureus, Moraxella*	Inflammation of supraglottic structures
Peritonsillar abscess	>9 years	May be abrupt	S. pyogenes S. aureus/MRSA	Abscess within or around tonsil

Condition	Age	Onset	Etiology	Pathophysiology	Symptoms
Viral Croup (acute laryngotracheobronchitis)	6 months to 3 years	Usually gradual following a viral prodrome	Viral (e.g., parainfluenza, respiratory syncytial virus)	Inflammation from larynx to bronchi	Harsh cough; stridor; low-grade fever; may have nasal discharge, conjunctivitis; symptoms last 2–7 days
Spasmodic Croup	6 months to 5 years	Abrupt with absence of prodrome	Airway narrowing, gastroesophageal reflux, allergies	Noninflammatory edema of the larynx	Abrupt onset of cough and stridor without fever or viral symptoms; symptoms last 2–4 h then recur.
Bacterial tracheitis	1–12 years	Abrupt or after viral illness	*Staphylococcus aureus*/methicillin resistant *S. aureus* (MRSA) *Haemophilus influenzae* type B Group A streptococci	Inflammation and edema of upper trachea, pseudomembrane formation	High fever; tachypnea, toxic appearance; harsh cough; purulent secretions
Acute epiglottitis	2–6 years; also in adults with a mean age of 45 years	Abrupt	*Streptococcus pneumoniae, Staphylococcus aureus, Moraxella*	Inflammation of supraglottic structures	Severe sore throat; high fever; stridor, toxic appearance; muffled voice; may drool; sits erect or leans forward
Peritonsillar abscess	>9 years	May be abrupt	S. pyogenes S. aureus/MRSA	Abscess within or around tonsil	Fever, malaise trismus (locked jaw), drooling, muffled voice

Croup

Croup illnesses are all characterized by obstruction of the upper airways. The two most common croup illnesses are viral croup and recurrent croup (spasmodic croup). Diphtheria can be considered a croup illness but is now rare because of vaccinations.

Viral croup is an acute *laryngotracheobronchitis* and almost always occurs in children between 6 months and 3 years of age with a peak incidence at 2 years of age.[1] It most commonly is caused by parainfluenza. Other causes include respiratory syncytial virus (RSV), rhinovirus, adenovirus, rubella virus, or atypical bacteria. SARS-CoV-2 infection has been diagnosed in several children with croup.[2] The incidence of croup is higher in males, with higher incidence during the winter months. Recurrent (spasmodic) croup is two or more episodes of symptoms similar to viral croup, except without symptoms of respiratory tract infection. It usually occurs in older children. The etiology is unknown, but it can be associated with underlying congenital obstruction or airway narrowing, gastroesophageal reflux, and allergies.

Pathophysiology

The pathophysiology of viral croup is the result of subglottic (the area containing the vocal cords) inflammation and edema from the infection. The mucous membranes of the larynx are tightly adherent to the underlying cartilage, whereas those of the subglottic space are looser and thus allow accumulation of mucosal and submucosal edema (Fig. 36.1). The cricoid cartilage is structurally the narrowest point of the airway, making edema in this area critical to the development of airway obstruction. Recurrent croup also causes obstruction but with less inflammation and edema. As illustrated in Algorithm 36.1, increased resistance to airflow leads to increased work of breathing, which generates more negative intrathoracic pressure that, in turn, may exacerbate dynamic collapse of the upper airway.

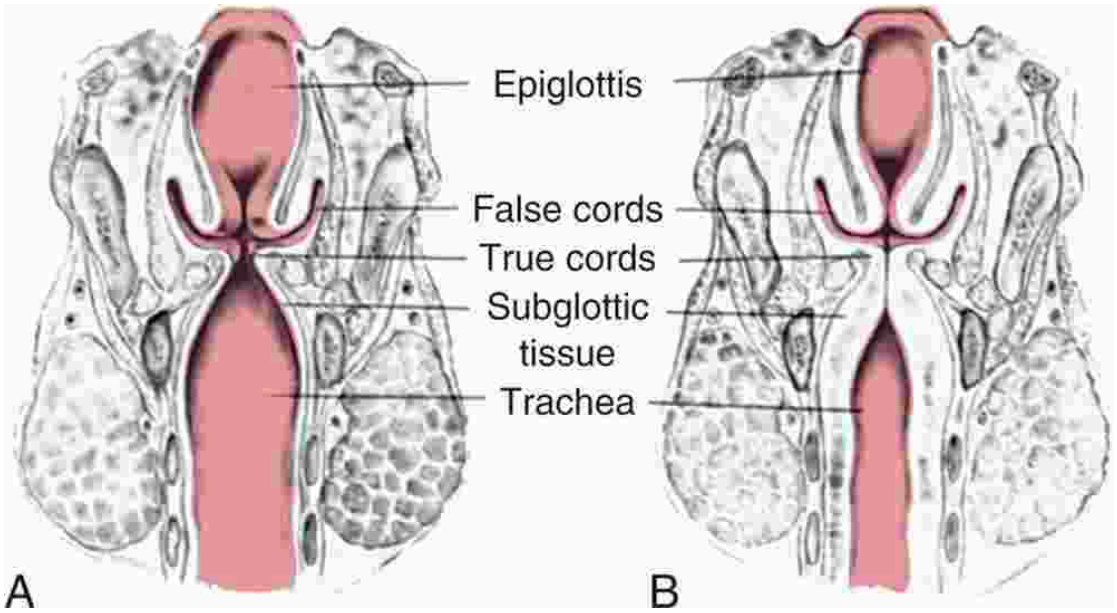

FIG. 36.1 The Larynx and Subglottic Trachea.
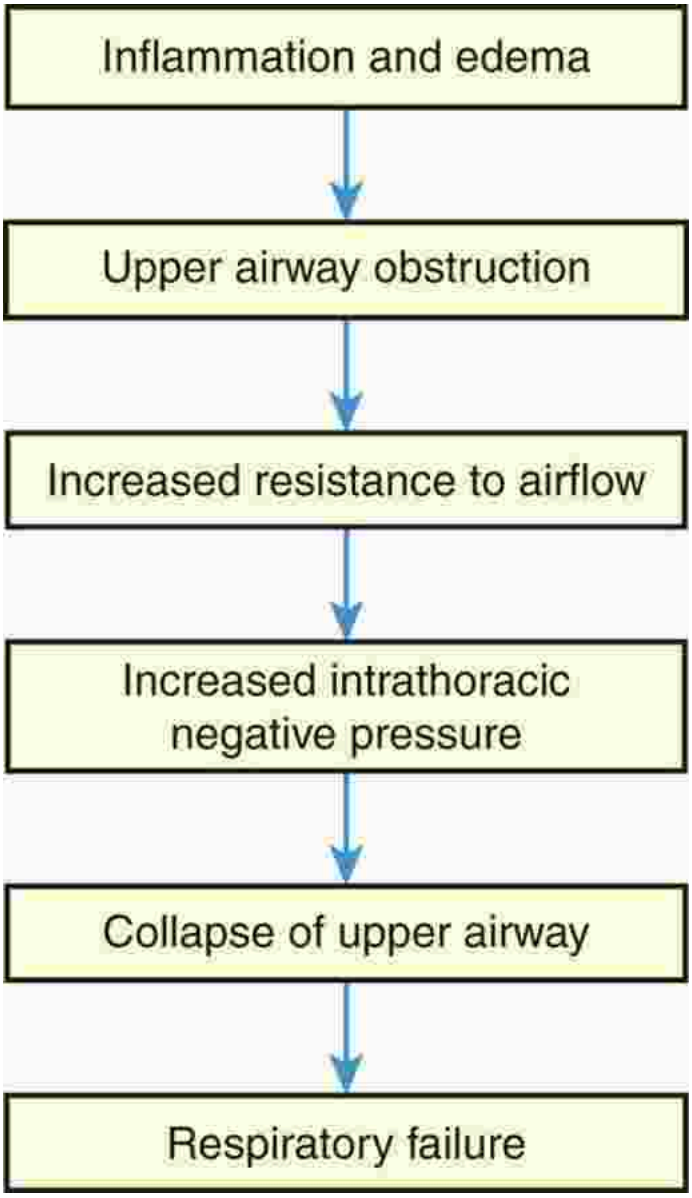
(A) Normal epiglottis, laryngeal vocal cords, and trachea. **(B)** Narrowing and obstruction of laryngeal tissue around false and true vocal cords from edema caused by croup. (From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*. 10th edition, St. Louis: Mosby; 2015.)



ALGORITHM 36.1 Upper Airway Obstruction With Croup.

A flowchart shows the upper airway obstruction with croup. The sequence of the pathway is as follows. • Inflammation and edema. • Upper airway obstruction. • Increased resistance to airflow. • Increased intrathoracic negative pressure. • Collapse of upper airway. • Respiratory failure.

Clinical Manifestations

Typically, a child with viral croup experiences rhinorrhea (runny nose), sore throat, and low-grade fever for a few days and then develops a harsh (seal-like), barking cough, a hoarse voice, and inspiratory stridor (a harsh, vibratory sound). The quality of the voice, cough, and stridor may suggest the location of the obstruction (Fig. 36.2). Most cases resolve spontaneously within 24 to 48 hours. A young child

with severe croup usually displays deep retractions (Fig. 36.3), agitation, tachycardia, and sometimes pallor or cyanosis.

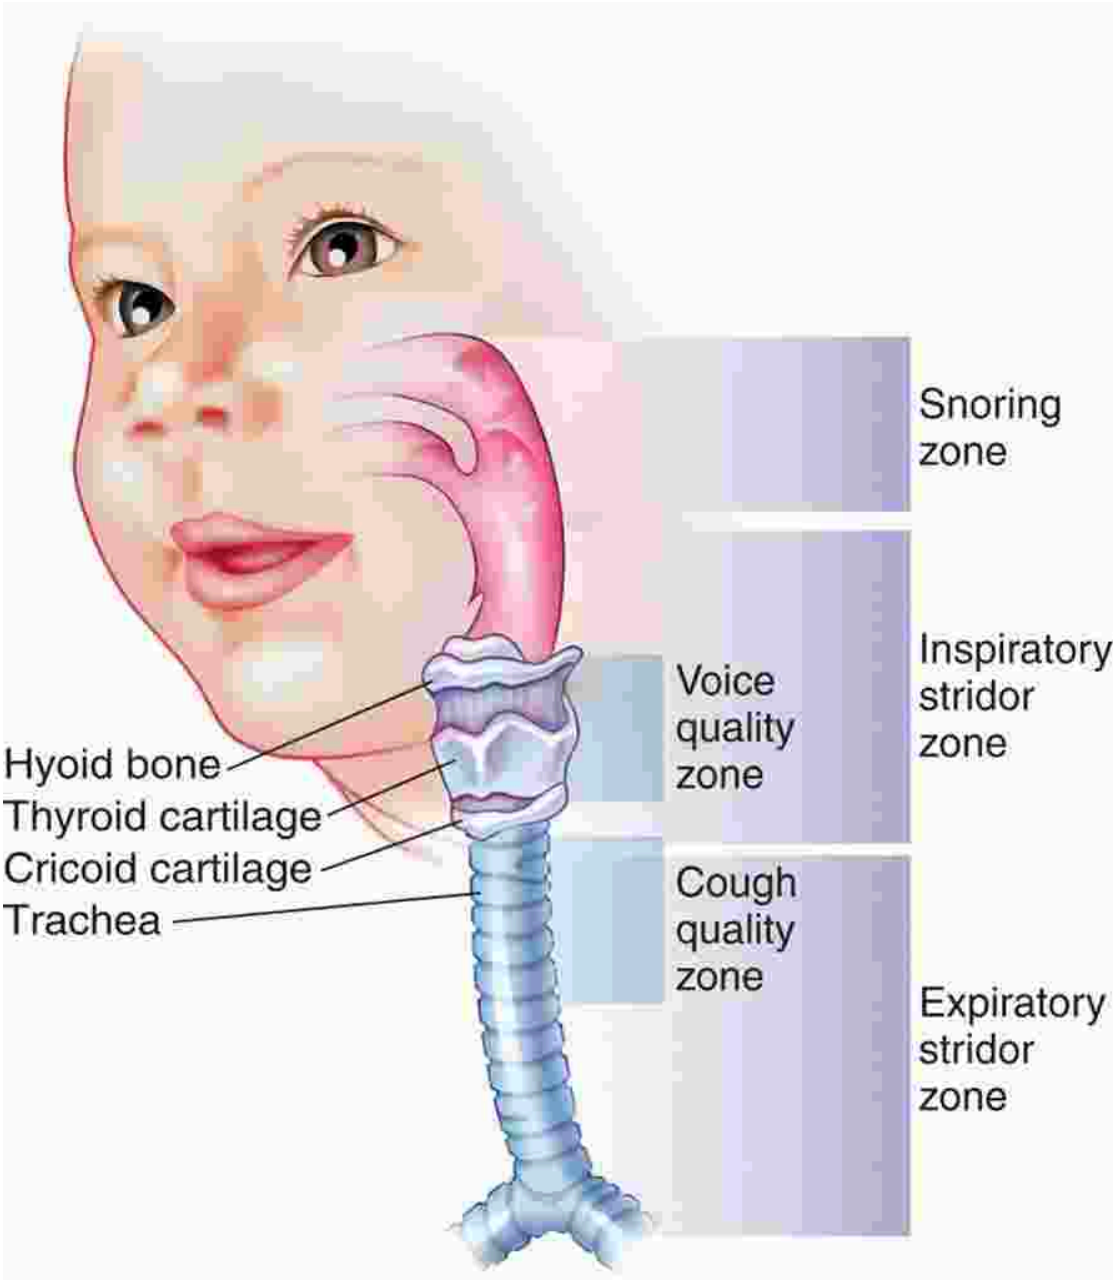


FIG. 36.2 Listening Can Help Locate the Site of Airway Obstruction.
A loud, gasping snore suggests enlarged tonsils or adenoids. In inspiratory stridor, the airway is compromised at the level of the supraglottic larynx, subglottic region and vocal cords which are behind the thyroid cartilage, or upper trachea. Expiratory stridor results from a narrowing or collapse in the trachea or bronchi. Airway noise during both inspiration and expiration often represents a fixed obstruction of the vocal cords or subglottic space. Hoarseness or a weak cry is a by-product of obstruction at the vocal cords. If a cough is croupy, suspect constriction below the vocal cords. (Redrawn from Eavey RD. *Contemporary pediatrics*, 1986;3(6):79; original illustration by Paul Singh-Roy.)

An illustration showing the left lateral view of the airway in a child identifies the following zones, from the top to the bottom: snoring zone, inspiratory stridor zone, and expiratory stridor zone. The voice quality zone (hyoid bone and thyroid cartilage) is within the inspiratory stridor zone. The cough quality zone (trachea) spans from the bottom of the inspiratory stridor zone to the upper part of the expiratory stridor zone. The cricoid cartilage is identified between the thyroid cartilage and the trachea.

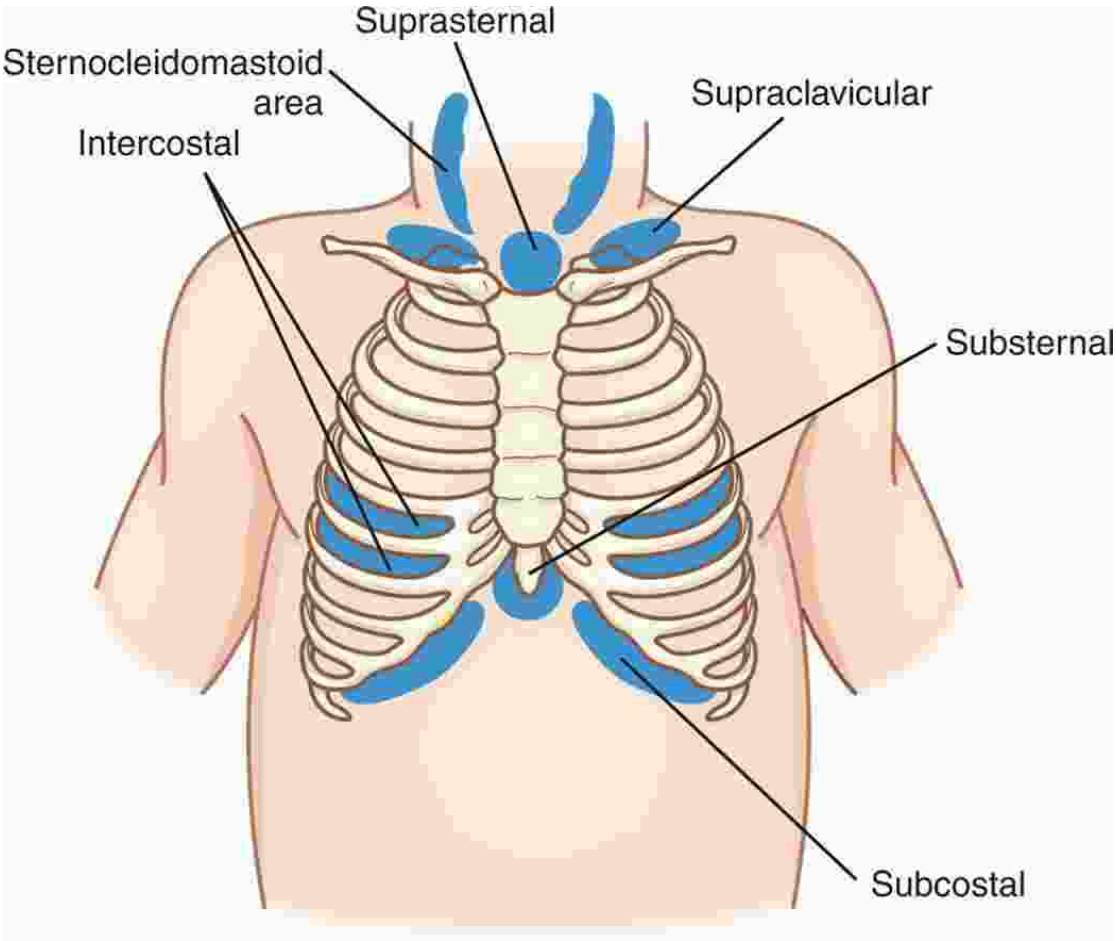

FIG. 36.3 Areas of Chest Muscle Retraction.

An illustration of the ribcage in a childs chest highlights the areas of chest muscle retraction, from the top to the bottom: sternocleidomastoid area, suprasternal, supraclavicular, intercostal, substernal, and subcostal.

Recurrent croup is characterized by a similar hoarseness, barking cough, and stridor. It is of sudden onset and usually occurs at night and without prodromal symptoms. It usually resolves quickly.

Evaluation and Treatment

The degree of symptoms determines the level of treatment. The most common tool for estimating croup severity is the Westley Croup Score.[3] Few cases require hospitalization, and most children with croup receive outpatient evaluation and management. These children usually have only mild stridor and appear alert, playful, and able to eat.

The mainstay of treatment for croup is oral or inhaled glucocorticoids which have been shown to reduce symptoms and shorten hospital stays.[4] The presence of stridor at rest, moderate or severe retractions of the chest, or agitation suggests severe disease and requires inpatient observation and treatment. For acute respiratory distress, nebulized epinephrine stimulates α- and β-adrenergic receptors promoting vasoconstriction, bronchodilation, and decreasing mucosal edema and airway secretions. Heliox (a helium-oxygen mixture) can be used in severe cases. This works by minimizing air flow resistance in the narrowed airway and decreases the work of breathing. In rare cases, croup may require placement of an endotracheal tube.

Bacterial Tracheitis

Bacterial tracheitis (pseudomembranous croup) is a relatively rare but potentially life-threatening condition with an estimated incidence of 0.1 cases per 100,000 children.[5] Most cases occur in children 6 years old or younger and follow a viral respiratory illness (influenza or parainfluenza). Bacterial tracheitis is caused most often by *Staphylococcus aureus* (including methicillin-resistant *S. aureus* [MRSA] strains), *Streptococcus pyogenes, Moraxella catarrhalis, Haemophilus influenzae*, or group A beta-hemolytic *Streptococcus* (GABHS).[5] Bacterial infection causes airway edema and copious purulent secretions which lead to airway obstruction that can be worsened by the formation of a tracheal pseudomembrane and mucosal sloughing. The acute clinical presentation usually includes tachypnea, stridor, hoarse voice, fever, cough, and/or increased secretions from the nose or mouth. Bacterial tracheitis is treated with immediate administration of antibiotics and may require emergent endotracheal intubation to prevent total UAO.

Acute Epiglottitis

Historically, acute epiglottitis was a disease mostly affecting children between the ages of 2 and 6 years of age and caused by *H. influenzae* type B (HiB). Since the advent of the *H. influenzae* vaccine, the overall incidence of acute epiglottitis has decreased significantly and it is increasingly an infectious disease of adults. Most cases are now caused by S*treptococcus pneumoniae, S. aureus*, and *Moraxella lacunata*.[6]

Pathophysiology

The epiglottis arises from the posterior tongue base and covers the laryngeal inlet during swallowing (see Fig. 36.1). Bacterial invasion of the mucosa with associated inflammation leads to the rapid development of edema, causing severe, life-threatening obstruction of the upper airway.

Clinical Manifestations

In the classic form of the disease, there is the sudden development of high fever, irritability, sore throat, inspiratory stridor, and severe respiratory distress. The affected individual appears anxious and has a voice that sounds muffled ("hot potato voice"). Drooling, absence of cough, a preference to sit, and dysphagia (inability to swallow) are common. In addition to appearing ill, the individual may adopt a position of leaning forward (tripoding) to try to improve breathing. Death can occur in a few hours. Pneumonia, cervical lymph node inflammation, otitis, and, rarely, meningitis or septic arthritis may occur during the course of epiglottitis.

Evaluation and Treatment

Acute epiglottitis is a life-threatening emergency. Efforts should be made to keep the individual calm and undisturbed. Physical examination of the throat should not be attempted because it may trigger laryngospasm and cause respiratory collapse. Soft tissue x-rays of the neck may reveal a widening of the epiglottis, although direct laryngoscopy is the gold standard for diagnosis.[6] With severe airway obstruction, the airway may be secured with intubation or emergency tracheotomy. The prompt

administration of broad-spectrum antibiotics is indicated, and corticosteroids may be considered, although this remains controversial. Resolution with treatment is usually rapid.

Tonsillar Infections

Tonsillar infections (tonsillitis) are occasionally severe enough to cause UAO. Viral infections, such as infectious mononucleosis, are the most common cause of tonsillitis, although there continue to be significant numbers of cases of tonsillitis secondary to group A beta-hemolytic streptococcal and MRSA infection. Inflammation of the tonsils is associated with the release of numerous inflammatory cytokines, T lymphocyte activation, and tonsillar hypertrophy.[7] Significant swelling of the tonsils and pharynx occurs, and a tenacious membrane may cover the mucosa. The development of significant airway obstruction in tonsillar infections may require the use of corticosteroids, especially in the case of mononucleosis. The management of severe bacterial tonsillitis requires the use of antibiotics. Some children with recurrent tonsillitis benefit from tonsillectomy or adenotonsillectomy. Guidelines published in 2019 provide detailed information about indications for surgery and appropriate pre, intra, and postoperative care.[8] Recurrent and chronic tonsillitis along with persistent tonsillar hypertrophy may occur and may be related to changes in the tonsillar microbiome.[9]

Peritonsillar abscess is a collection of pus between the tonsillar capsule and the pharyngeal constrictor muscle (Fig. 36.4). It is usually unilateral and is most often a complication of acute tonsillitis that occurs when bacteria spread to the peritonsillar space via the salivary duct system.[10] These infections are often polymicrobial.[6] The mean age of onset is 12 years of age.[11] Abscesses can contribute to UAO, and descending mediastinitis, necrotizing fasciitis, and jugular vein obstruction may occur (see Table 36.1).[10] Symptoms in children include fever, sore throat, dysphagia, trismus, pooling of saliva, and muffled voice. Peritonsillar bulging and cervical adenopathy on the same side are usually visible. Intraoral ultrasound or computed tomography (CT) is used to confirm the diagnosis.[12] Surgical management is usually indicated and may include incision and drainage of the abscess, tonsillectomy, or needle aspiration followed by empiric antibiotics and corticosteroids.[6] Death can occur from spontaneous abscess rupture with aspiration or airway obstruction.

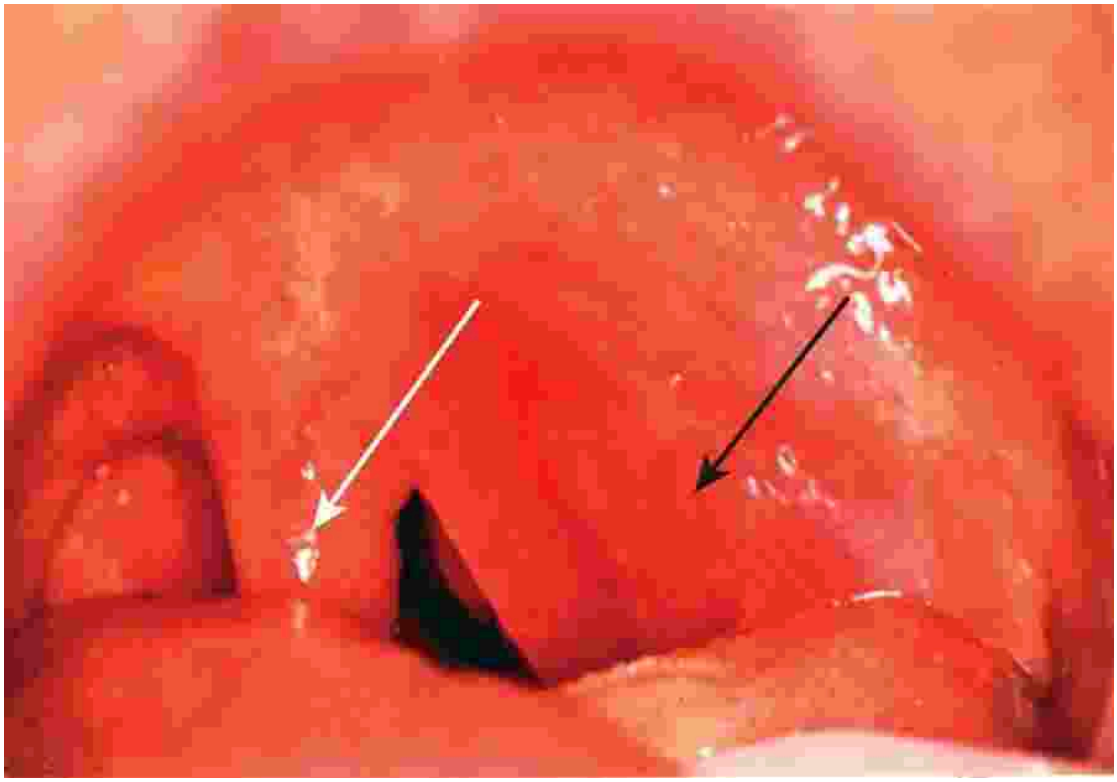

FIG. 36.4 Peritonsillar Abscess.
If the tonsils are inflamed and appear asymmetrical with unilateral palatal swelling *(black arrow)* and uvular deviation *(white arrow)*, a peritonsillar abscess should be suspected. (From Goldman L, Schafer AI. *Goldman's Cecil medicine*, 24th edition. Philadelphia: Saunders; 2012.)

Aspiration of Foreign Bodies

Aspiration of foreign bodies into the airways is most common in children 1 to 4 years of age. More than 100,000 cases and 100 deaths occur each year.[13] Risk factors include age, sex, tracheobronchial anatomy, and external setting (e.g., age and type of guardian, urban vs rural residence, presence of other children in the household).[14] Most objects are expelled by the cough reflex, but some objects may lodge in the larynx, trachea, or bronchi. Large objects (e.g., hard candy, a bite of hot dog, nuts, seeds, popcorn, grapes, beans, toy pieces, fragments of popped balloons, or coins) may occlude the airway and become life-threatening (Fig. 36.5). Foreign bodies lodged in the larynx or upper trachea cause cough, stridor, hoarseness or inability to speak, respiratory distress, and agitation or panic.[15] With smaller objects, the aspiration event often is not witnessed or is not recognized when it happens because the coughing, choking, or gagging symptoms may resolve quickly.

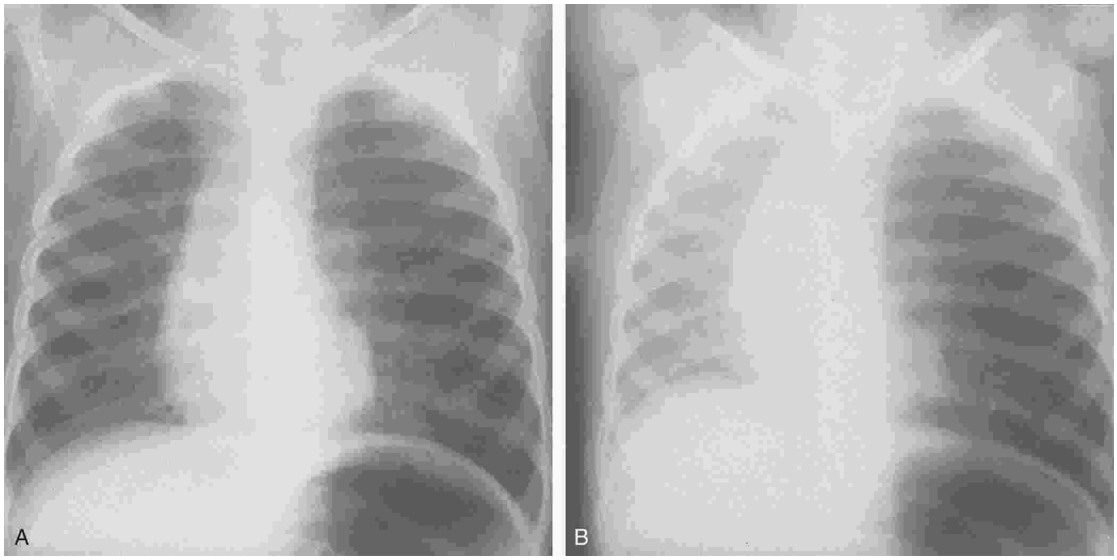

FIG. 36.5 Foreign Body Aspiration.
Anteroposterior inspiratory **(A)** and expiratory **(B)** chest radiographs. Air trapping in the left lung is caused by a peanut in the left mainstem bronchus. (From Taussig LM, Landau LI. *Pediatric respiratory medicine*, 2nd edition. St. Louis: Mosby; 2008.)

Two radiographs, A and B, show foreign body aspiration. Left panel, A. The radiograph does not highlight the lower part of the right lung. Right panel, B. The radiograph not highlight the lower par of the right lung, and the upper part is only partially highlighted.

If the child is acutely hypoxic and unable to move air, immediate action, such as sweeping the oral airway or performing abdominal thrusts (formerly called the *Heimlich maneuver*), may be required to prevent death. Otherwise, bronchoscopic removal should be performed urgently. If an aspirated foreign body is small enough, it will be transferred to a bronchus before becoming lodged. If the foreign body is lodged in the airway for a longer period of time, local irritation, granulation, obstruction, and infection will ensue. Thus, children may present with cough or wheezing, atelectasis, pneumonia, lung abscess, or blood-streaked sputum. Occult foreign body aspiration should be considered in children with chronic or recurrent respiratory diseases that are poorly explained, even in the absence of a previous history of aspiration.[16] These children are treated by prompt bronchoscopic removal of the object and administration of antibiotics as necessary.

Obstructive Sleep Apnea

Pediatric obstructive sleep apnea syndrome (OSAS) (also called obstructive sleep apnea or sleep-disordered breathing) results from partial or complete UAO obstruction that occurs during sleep with associated snoring, labored or obstructed breathing, and disrupted sleep patterns. Pediatric OSAS has an estimated prevalence of 1% to 5% and can occur at any age.[17] The prevalence is higher in obese children, as well as in vulnerable populations (Blacks, Hispanics, and preterm infants), and there may be a family history of OSAS. Other risk factors include adenotonsillar hypertrophy, allergic rhinitis, craniofacial abnormalities, and genetic disorders such as Down Syndrome. Possible influences early in life may include environmental smoke inhalation and socioeconomic status, together with genetic modifiers that promote airway inflammation.

Pathophysiology

Airway narrowing (adenotonsillar hypertrophy, craniofacial anomalies), increased upper airway collapsibility (obesity, neurologic disorders, Down syndrome), and airway inflammation (gastroesophageal reflux, asthma, allergy) are the common causes of OSAS. Airway obstruction can be partial or complete and is associated with atypical sleep patterns.[18] Obstruction of the upper airway during sleep results in cyclic episodes of increasing respiratory effort and changes in intrathoracic pressures with oxygen desaturation, hypercapnia, and arousal. The child goes back to sleep, and the cycle repeats. Infants are at risk because they have both anatomic and physiologic predispositions toward airway obstruction and gas exchange abnormalities.

Clinical Manifestations

Common manifestations of OSAS include snoring and labored breathing, sweating, and restlessness during sleep, which may be continuous or intermittent. There may be episodes of increased respiratory effort but no audible airflow, often terminated by snorting, gasping, repositioning, or arousal. Daytime sleepiness/napping is occasionally reported, as well as nocturnal enuresis. Cognitive and neurobehavioral impairment, excessive daytime sleepiness, impaired school performance, and poor quality of life are consequences of OSAS.

Evaluation and Treatment

The American Academy of Pediatrics guidelines for the diagnosis and treatment of OSAS recommend that all children should be screened for snoring.[19] Definitive evaluation is conducted using a polysomnographic sleep study. Imaging of the upper airway, including neck x-ray, CT, and magnetic resonance imaging (MRI), may be used to rule out tonsillar enlargement or upper airway narrowing.[20] If obstructive sleep apnea is caused by tonsillar enlargement, children most often are referred for tonsillectomy and adenoidectomy (T&A). For severely affected children who do not respond to T&A or who have different problems (e.g., obesity), the use of positive airway pressure (PAP) can improve symptoms and help prevent complications.[21] Anti-inflammatories, dental treatments, and weight loss can be considered.[19] Treatment is important to minimize associated morbidities such as hypertension, cardiovascular disease, learning difficulties, and behavioral issues.[18,22]

Disorders of the Lower Airways

Lower airway disease is one of the leading causes of morbidity in the first year of life and continues to be an important component of other illnesses progressing into childhood. Pulmonary disorders commonly observed include disorders of prematurity, infections, aspiration pneumonitis, asthma, acute respiratory distress syndrome (ARDS), and cystic fibrosis.

Disorders of Prematurity

Surfactant Deficiency Disorder (Respiratory Distress Syndrome of the Newborn)

Surfactant deficiency disorder (SDD), also known as respiratory distress syndrome (RDS) of the newborn, is a significant cause of neonatal morbidity and mortality. It occurs almost exclusively in premature infants because the immature lung has not yet developed adequate surfactant production. SDD (RDS) occurs in most infants born before 28 weeks of pregnancy, and 50% to 60% of infants born at 29 weeks' gestation. Risk factors include prematurity, low birth weight, male sex, a sibling with SDD, cesarean delivery without labor, multiple pregnancy, diabetic mother, and perinatal asphyxia. The incidence has increased in the United States over the past two decades; however, death rates have declined since the introduction of antenatal steroid therapy and postnatal surfactant therapy.[23] In rare cases, SSD occurs in full-term neonates as the result of mutations in genes that control surfactant synthesis (*SFTPA1, SFTPA2, SFTPB, SFTPC, ABCA3, NKX2-1*).[24]

Risk Factors

Surfactant Deficiency Disorder (Respiratory Distress Syndrome of the Newborn)

- Premature birth/low birth weight
- Male sex
- Sibling with SDD (RDS)
- Cesarean delivery without labor
- Multiple pregnancy
- Diabetic mother
- Perinatal asphyxia

Pathophysiology

SDD (RDS) is caused by surfactant deficiency. Surfactant is a lipoprotein with a detergent-like effect that separates the liquid molecules inside the alveoli, thereby decreasing alveolar surface tension. Without surfactant, alveoli collapse at the end of each exhalation, decreasing the alveolar surface area available for gas exchange. Surfactant normally is not secreted by the alveolar cells until approximately 20 to 24 weeks' gestation (Fig. 36.6). Premature infants also are born with underdeveloped and small alveoli that are difficult to inflate and have thick walls and inadequate capillary blood supply such that gas exchange is significantly impaired. The net effect is *atelectasis* (collapsed alveoli), resulting in hypoxemia. Atelectasis is difficult for the neonate to overcome because it requires a significant amount of work to open the alveoli with each breath. The infant's chest wall is weak and highly compliant and, thus, the rib cage tends to collapse inward with increased respiratory effort (Fig. 36.7). Increased work of breathing may result in hypercapnia. Hypoxia and hypercapnia cause pulmonary vasoconstriction, which increases intrapulmonary resistance and pulmonary hypoperfusion. Increased pulmonary vascular resistance may cause a partial return to fetal circulation, with right-to-left shunting of blood through the ductus arteriosus and foramen ovale (see Chapter 33). Inadequate perfusion of tissues and hypoxemia contribute to metabolic acidosis.

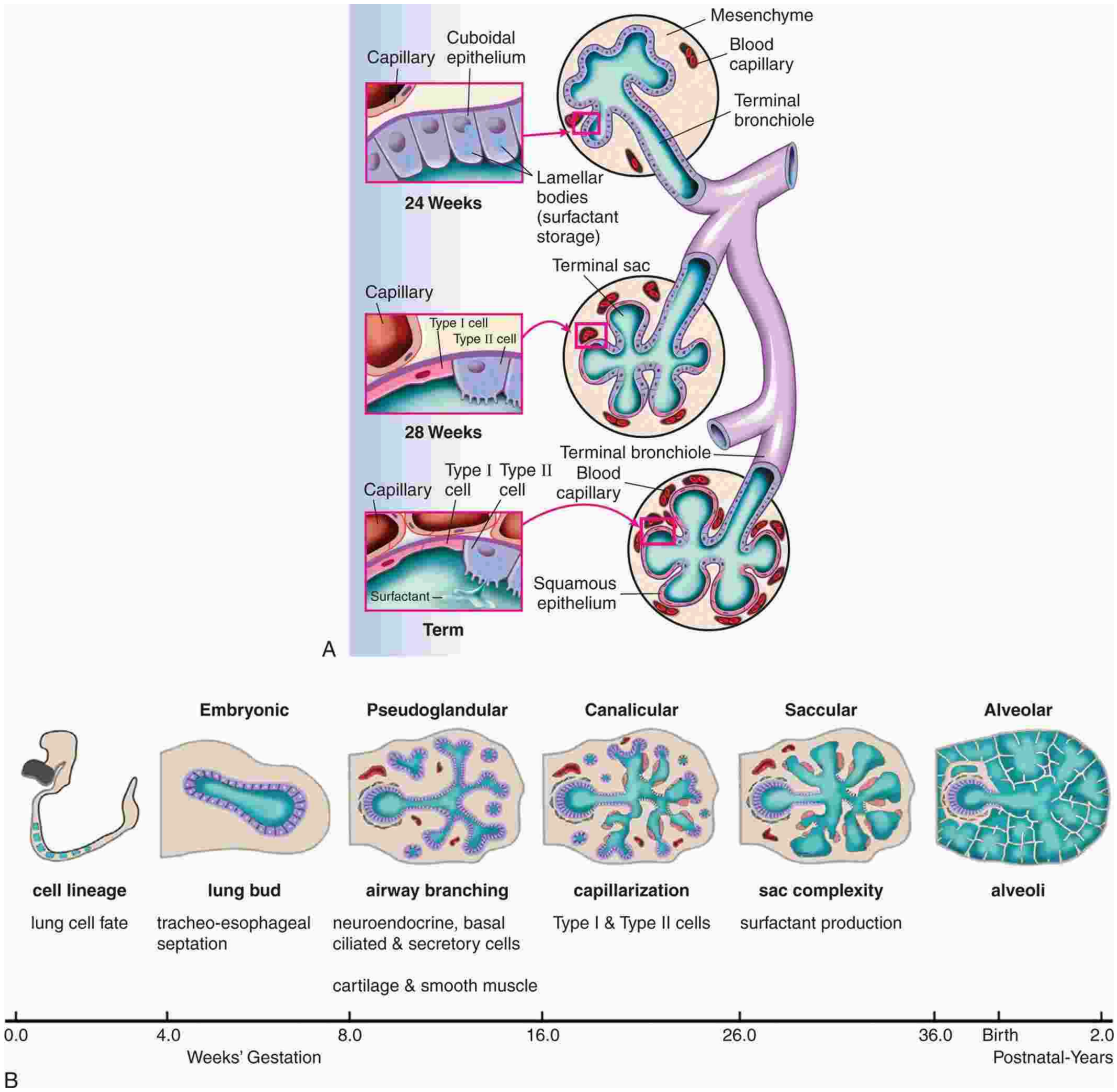

FIG. 36.6 Prenatal Development of the Alveolar Unit.
(A) Epithelial cells differentiate into type II and type I cells. Mature type II cells (type II pneumocytes) store and secrete surfactant. Type I cells are derived from type II cells and consist of flattened epithelium overlying capillaries, thus forming part of the thin air-blood gas exchange membrane of the alveoli. **(B)** Time line for gestational development of alveoli.

Two illustrations, A and B, show prenatal development of alveolar unit. Top panel, A. The bronchi and alveoli differentiation are illustrated as follows. • 24 weeks. The following structures in the alveolus are identified: mesenchyme, blood capillary, and terminal bronchiole. The capillary and the cuboidal epithelium are identified. The lamellar bodies (surfactant storage) are identified on the cuboidal epithelium. • 28 weeks. The terminal sac in the alveolus is better developed. The type 1 cell and type 2 cell are identified on the epithelial walls. • Term. The terminal bronchiole and the terminal sacs (with squamous epithelium) are fully developed. The capillary, type 1 cell, type 2 cell, and

surfactant are identified. Bottom panel, B. An illustrated timeline shows the development alveoli. The details from the timeline are as follows. 0.0 to 4.0 weeks gestation: The illustration shows the cell lineage (lung cell fate). • 4.0 to 8.0 weeks gestation (embryonic): The illustration shows a lung bud (trachea-esophageal septation). • 8.0 to 16.0 weeks gestation (pseudoglandular): The illustration shows the airway branching (neuroendocrine, basal ciliated, and secretory cells; cartilage and smooth muscle). • 16.0 to 26.0 weeks gestation (canalicular): The illustration shows capillarization (type 1 and type 2 cells). • 26.0 weeks gestation (saccular): The illustration shows sac complexity (surfactant production). • Postnatal years (birth to 2 years): The illustration shows the alveolar (alveoli).

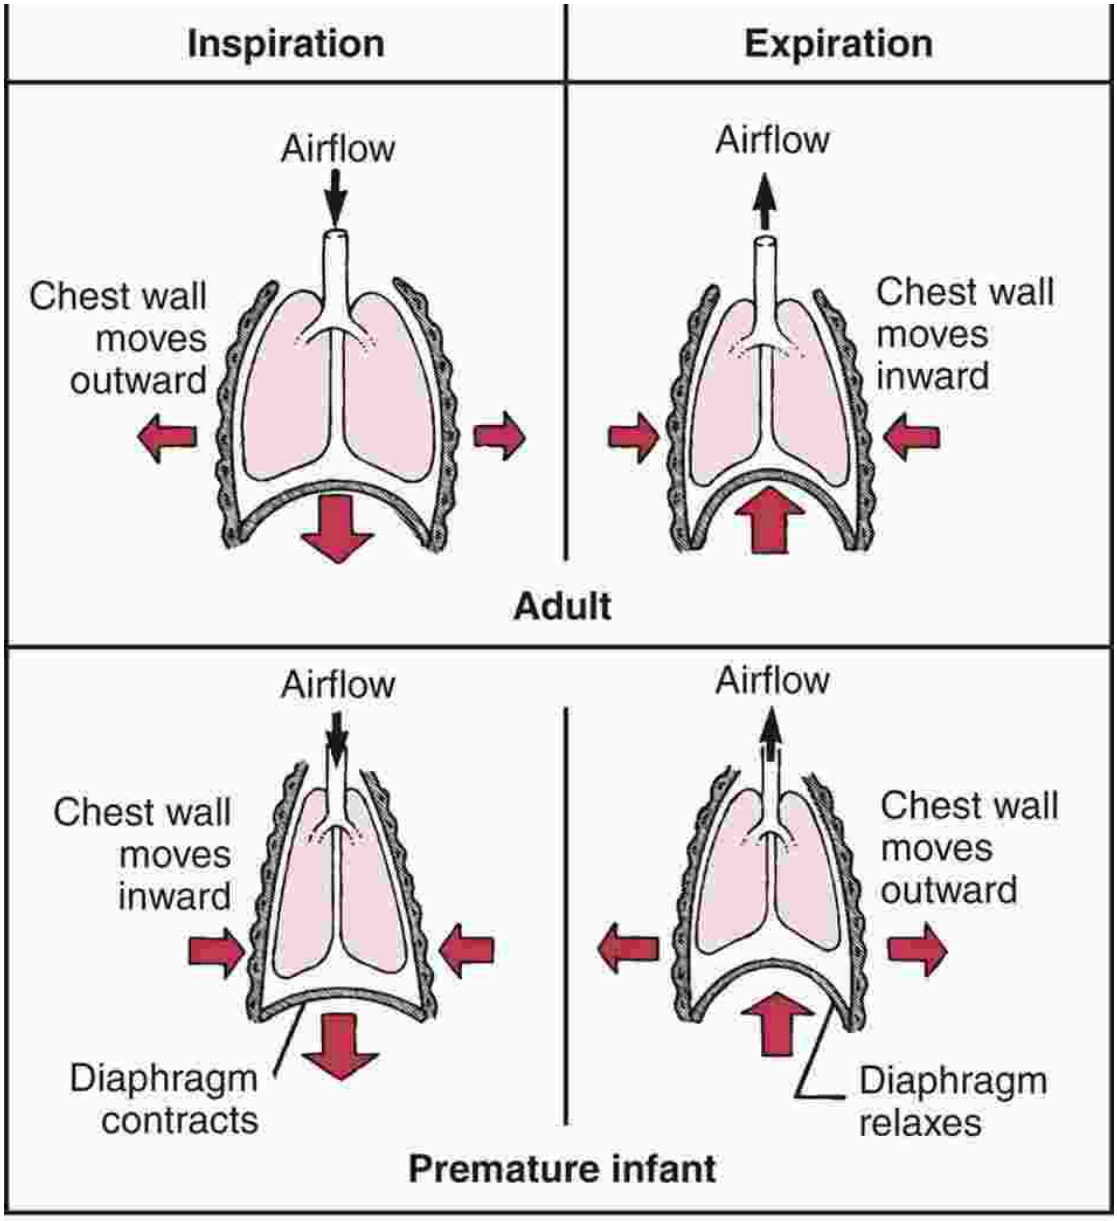

FIG. 36.7 Developmental Differences in the Chest Wall and Lung Mechanics. Differences in lung mechanics caused by differences in chest wall compliance (degree of rigidity) in premature infants and adults. (*Arrows* indicate direction of airflow, chest wall movement, and diaphragm movement.)

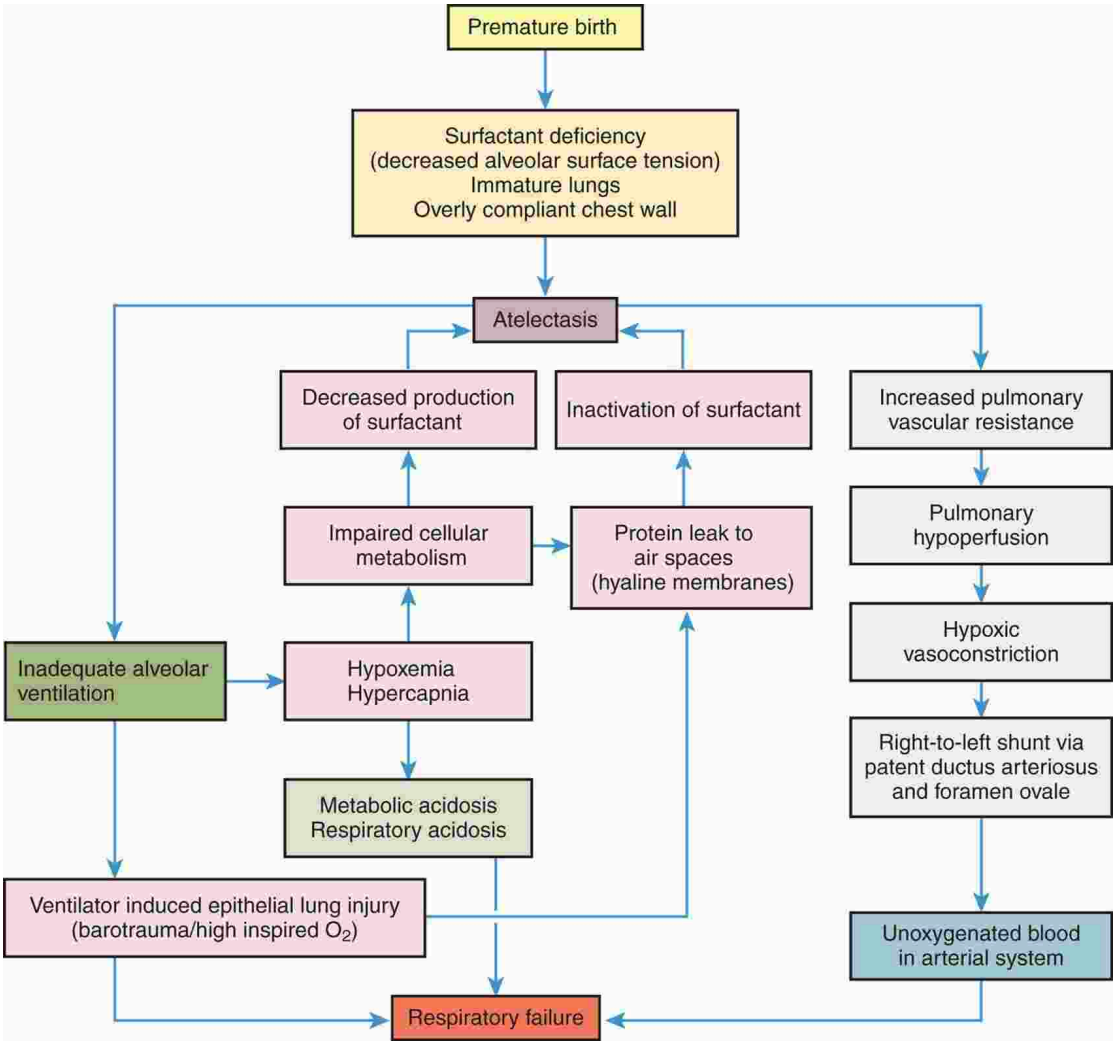
Top panel, A. The illustration of multiple radial structures demonstrates the lateral diameter of the chest wall. From the inside to the outside, the sizes increase in the following timeline: fetus to seven months, newborn, three months, 3.5 years, and adult. Bottom panel, B. An illustrated table shows inspiration and expiration in adults and premature infants. • Inspiration in adult: Air flows into the lungs, and the chest wall moves outward. • Expiration in adult: Chest wall moved inward, and the air flows out of the lungs. •

Inspiration in premature infant: Air flows into the lungs, chest wall moves inward, and diaphragm contracts. • Expiration in premature infant: Diaphragm relaxes, chest wall moves outward, and air flows out of the lungs.

Many premature infants with SDD (RDS) will require mechanical ventilation, which is lifesaving, but damages the alveolar epithelium, leading to leakage of plasma proteins into the alveoli. These proteins result in fibrin deposits in the air spaces, which create the appearance of *hyaline membranes* (transparent or glassy appearance on microscopic examination) and contribute to the inactivation of any surfactant that may be present. The pathogenesis of SDD (RDS) is summarized in Algorithm 36.2.



ALGORITHM 36.2 Pathogenesis of Surfactant Deficiency Disorder (Respiratory Distress Syndrome of the Newborn).
O_2, Oxygen.

A flowchart shows the pathogenesis of surfactant deficiency disorder. 1. Premature birth. Leads to 2. 2. Surfactant deficiency (decreased alveolar surface tension); immature lungs; overly compliant chest wall. Leads to 3. 3. Atelectasis. Leads to 10 and 16. 4. Decreased production of surfactant. Leads to 3. 5. Inactivation of surfactant. Leads to 3. 6. Impaired cellular metabolism. Leads to 4 and 7. 7. Protein leak to air spaces (hyaline membranes). Leads to 5. 8. Hypoxemia; hypercapnia. Leads to 6 and 9. 9. Lactic acidosis; respiratory acidosis. Leads to 18. 10. Increased pulmonary vascular resistance. Leads to 11. 11. Pulmonary hypoperfusion. Leads to 12. 12. Hypoxic vasoconstriction. Leads to 13. 13. Right-to-left shunt. Leads to 14. 14. Patent ductus arteriosus and foramen ovale. Leads to 15. 15. Metabolic acidosis. Leads to 18. 16. Inadequate

alveolar ventilation. Leads to 17. 17. Ventilator induced epithelial lung injury (barotrauma or high inspired oxygen). Leads to 18. 18. Respiratory failure.

Clinical Manifestations

Signs of SDD (RDS) appear within minutes of birth and include tachypnea (respiratory rate greater than 60 breaths/min), expiratory grunting, intercostal and subcostal, nasal flaring, and cyanosis. A characteristic chest x-ray appearance and hypoxemia that is refractory to the administration of supplemental oxygen are hallmarks of the condition. The severity tends to increase over the first hours of life. Apnea and irregular respirations occur as the infant tires. Clinical manifestations reach a peak within 3 days.

Evaluation and Treatment

The diagnosis is made on the basis of premature birth or other risk factors, chest radiographs, pulse oximetry measurements, and, if needed, analysis of amniotic fluid or tracheal aspirates to estimate lung maturity. For women at risk of preterm birth, antenatal treatment with glucocorticoids induces a significant and rapid acceleration of lung maturation and stimulation of surfactant production in the fetus and significantly reduces the incidence of SDD (RDS) and death.[23] The ultimate prevention for SDD (RDS) would be the prevention of premature birth.

Administration of exogenous surfactant (either synthetic or natural) within 15 to 30 minutes of birth is recommended as a prophylactic or preventive treatment for infants weighing between 500 g (1 lbs 1.65 oz) and 2000 g (4 lbs 6.5 oz). A thin catheter, nebulizer, or continuous positive airway pressure (CPAP) ventilation is used for administration. There is usually a dramatic improvement in oxygenation, as well as a decreased incidence of death, pneumothorax, and pulmonary interstitial emphysema from SDD (RDS).[25,26]

Supportive care includes oxygen administration and often such measures as mechanical ventilation. Mechanical ventilation can result in a proinflammatory state that may contribute to the development of chronic lung disease, such as bronchopulmonary dysplasia. Strategies that are lung protective include greater reliance on nasal CPAP, permissive hypercapnia, lower oxygen saturation targets, modulation of tidal volume (V_t) settings, and use of high-frequency oscillation.[27] Most infants survive SDD (RDS), and, in many cases, recovery may be complete within 10 to 14 days. However, the incidence of subsequent bronchopulmonary dysplasia is significant among very low birth weight infants.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD), also known as *chronic lung disease of prematurity*, is a chronic, inflammatory lung disease associated with arrested pulmonary development and a need for supplemental oxygen. A National Institutes of Health (NIH) consensus definition published in 2001 described BPD as occurring in infants born at less than 32 weeks with the requirement of supplemental oxygen for at least 28 days and at 36 weeks postmenstrual age (PMA).[28] The definition also includes a graded severity determination that is dependent on required respiratory support at term (mild, moderate, and severe, based on oxygen requirements and ventilatory needs). A new consensus definition is being developed that includes the following criteria: (1) less than 32 weeks' gestational age, (2) persistent parenchymal lung disease, (3) radiographic confirmation of parenchymal lung disease, and (4) at 36 weeks PMA requires supplemental oxygen for at least 3 consecutive days to maintain arterial oxygen saturation in the 90% to 95% range.[29]

BPD is the major cause of chronic pulmonary disease associated with premature birth.[30] It occurs most commonly in infants with severe SDD (RDS) who require prolonged perinatal supplemental oxygen (at least 28 days) and positive pressure ventilation. Each year in the United States, BPD affects about 45% of infants born extremely preterm.[31]

The widespread use of antenatal glucocorticoids and postnatal surfactant has lessened the incidence and severity of SDD (RDS) and BPD. BPD now is occurring primarily in the smallest premature infants

(23 to 28 weeks' gestation) who have received mechanical ventilation or those with other complicating risks. Maternal factors such as preeclampsia, placental dysfunction, and smoking are associated with a higher incidence of BPD.[32] Risk factors for BPD are summarized in *Risk Factors:* Bronchopulmonary Dysplasia.

Risk Factors

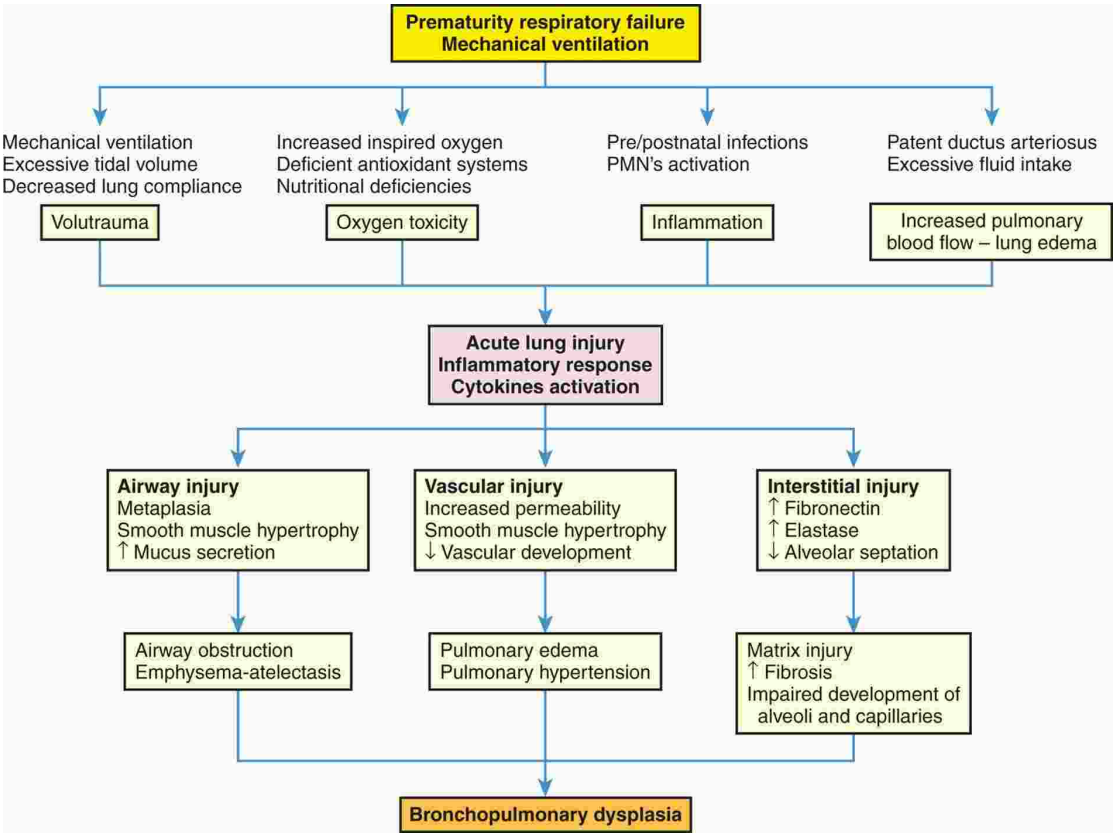
Bronchopulmonary Dysplasia

- Maternal Factors
  - Placental insufficiency
  - Lack of antenatal steroids
  - Infection
  - Smoking
- Infant Predisposition
  - Premature birth (especially ≤28 weeks)
  - Genetic susceptibility
  - Male sex
  - Race
  - Altered microbiome
  - Sepsis
- Mechanical Ventilation
  - Volutrauma
  - Barotrauma
  - Atelectotrauma
- Supplemental oxygen administration
  - DNA damage
  - Lipid peroxidation
  - Protein oxidation

Data fromSahni and Bhandari.[33]

Pathophysiology

Lung immaturity and inflammation contribute to the development of BPD. *Classic BPD* is characterized by airway injury, inflammation, and parenchymal fibrosis. With the initiation of surfactant therapy, what is called the *new BPD* is a form of arrested lung development that results from an aberrant repair response to antenatal and postnatal lung injury.[31] There is poor formation of the airway epithelium, alveolar structure, and a decreased surface area for gas exchange. Abnormal bronchoalveolar attachments, imbalances in neural pathways, changes in smooth muscle mass, and airway hyperreactivity contribute to the pathogenesis of BPD.[34] Levels of proinflammatory cytokines, such as tumor necrosis factor-alpha (TNF-α), interleukin-1β (IL-1β), interleukin 6 (IL-6), and interleukin 8 (IL-8), are all elevated in the amniotic fluid or tracheal aspirates, or both, of preterm infants who later develop BPD. Inflammation invites neutrophils and macrophages to release reactive oxygen species and proteolytic enzymes, initiating oxidative and immune injury.[30] Other important mediators include growth factors such as insulin-like growth factor-1 and vascular endothelial growth factor, along with other profibrotic and angiogenic cytokines which contribute to lung damage and pulmonary hypertension.[30]Algorithm 36.3 illustrates the pathophysiology of BPD. Persistent inflammation contributes to airway epithelial injury, pulmonary capillary fibrosis, perfusion mismatch, pulmonary hypertension, and decreased exercise capacity.[35]



ALGORITHM 36.3 **Pathophysiology of Bronchopulmonary Dysplasia.**
PMN, Polymorphonuclear neutrophil.

A flowchart represents the pathophysiology of bronchopulmonary dysplasia. 1. Prematurity respiratory failure; mechanical ventilation. Leads to 2, 3, 4, and 5. 2. Volutrauma (mechanical ventilation; excessive tidal volume; decreased lung compliance). Leads to 6. 3. Oxygen toxicity (increased inspired oxygen; deficient antioxidant systems; nutritional deficiencies). Leads to 6. 4. Inflammation (pre or postnatal infections; P M Ns activation). Leads to 6. 5. Increased pulmonary blood flowlung edema (patent ductus arteriosus; excessive fluid intake). Leads to 6. 6. Acute lung injury; inflammatory response; cytokines activation. Leads to 7, 8, and 9. 7. Airway injury (metaplasia; smooth muscle hypertrophy; increased muscle secretion). Leads to 10. 8. Vascular injury (increased permeability; smooth muscle hypertrophy; decreased vascular development). Leads to 11. 9. Interstitial injury (increased fibronectin; increased elastase; decreased alveolar septation). Leads to 12. 10. Airway obstruction; emphysema-atelectasis. Leads to 13. 11. Pulmonary edema; pulmonary hypertension. Leads to 13. 12. Matrix injury; increased fibrosis; impaired development of alveoli and capillaries. Leads to 13. 13. Bronchopulmonary dysplasia.

Clinical Manifestations

Clinically, the infant exhibits hypoxemia and hypercapnia caused by ventilation-perfusion mismatch and diffusion defects. The work of breathing increases, and the ability to feed may be impaired. Intermittent bronchospasm, mucus plugging, and pulmonary hypertension characterize the clinical course. In the most severely affected infants, dusky spells may occur with agitation, feeding, or gastroesophageal reflux. Infants with mild BPD may demonstrate only mild tachypnea and difficulty handling respiratory tract infections.

Evaluation and Treatment

An online risk estimator for BPD development has been created to help with early identification and management.[36] Chest x-ray and echocardiography are used to rule out other causes of respiratory distress. Infants with severe BPD require prolonged assisted ventilation with nasal CPAP or nasal intermittent positive pressure ventilation (IPPV). Diuretics are used to control pulmonary edema. Bronchodilators reduce airway resistance. Low dose systemic or inhaled corticosteroids improve respiratory function and reduce mortality, but dexamethasone is associated with an increased risk for neurologic and infectious complications.[37] Caffeine citrate administration to premature neonates within 2 days of birth reduces the risk for BPD as well as some cardiac and neurodevelopmental disorders. Vitamin A supplementation (necessary for normal lung development), and careful fluid and nutritional support are routinely used and have resulted in improved outcomes. Stem cell-based therapies and administration of growth factors are in clinical trials.[33] Children with BPD should be monitored into adulthood for the development of chronic lung disease.

Respiratory Tract Infections

Respiratory tract infections are common in children and are a frequent cause for emergency department visits and hospitalizations. The clinical presentation, child's age, season of the year, and environmental exposures can often provide clues to the etiologic agent, even when the agent cannot be proved.

Bronchiolitis

Bronchiolitis is the most common viral respiratory tract infection of the small airways that occurs almost exclusively in children younger than 2 years. It is the leading cause of hospitalization for infants during the winter season. The most common pathogen is respiratory syncytial virus (RSV), but bronchiolitis also may be caused by rhinovirus, adenovirus, influenza, parainfluenza virus, human metapneumovirus, and human bocavirus. Air pollution and cigarette smoke are linked to an increased risk for bronchiolitis. Healthy infants usually make a full recovery from RSV bronchiolitis, but infants who were premature (birth weight less than 2500 g) or who have underlying BPD, heart disease, or immune deficiency have a higher risk for a more severe or even deadly course.[38] Bronchiolitis has been linked to an increased risk for asthma later in childhood, particularly in those with a family history of asthma. Children who develop severe bronchiolitis and are found to have persistent RSV infection weeks after hospitalization are at greatest risk for recurrent wheezing and asthma by age 3 years.[39]

Pathophysiology

Viral infection causes necrosis of the bronchial epithelium and destruction of ciliated epithelial cells. There is infiltration with lymphocytes around the bronchioles and a cell-mediated hypersensitivity to viral antigens with the release of lymphokines causing inflammation, as well as activation of eosinophils, neutrophils, and monocytes.[40] The submucosa becomes edematous, and cellular debris and fibrin form plugs within the bronchioles. Edema of the bronchiolar wall, accumulation of mucus and cellular debris, and bronchospasm narrow many peripheral airways. Atelectasis occurs in some areas of the lung and hyperinflation in others. Airways become partially or completely occluded. The mechanics of breathing are disrupted by bronchiolitis. Airway narrowing causes obstruction of airflow that is worse on expiration. This leads to air trapping, hyperinflation, and increased functional residual capacity. Airway resistance and hyperinflation result in increased work of breathing and the development of hypercapnia in severe cases.

In rare cases, airway occlusion becomes severe and irreversible. This condition is known as bronchiolitis obliterans. This complication can occur after viral bronchiolitis, or it may occur after lung or bone marrow transplantation.[41]

Clinical Manifestations

Symptoms usually begin with rhinorrhea and cough. Over the next several days, systemic signs of decreased appetite, lethargy, and fever may develop. Increasing respiratory distress is evidenced by tachypnea, wheezing, and chest retractions. Very young infants may present with severe apnea before lower respiratory tract symptoms appear, and these apneas frequently require mechanical ventilation. Many children also may present with conjunctivitis or otitis media.

Evaluation and Treatment

Guidelines published in 2014 and reaffirmed in 2019 by the American Academy of Pediatrics are available for the evaluation, treatment, and prevention of bronchiolitis.[40,42] The diagnosis of bronchiolitis is made by reviewing the history, signs, and symptoms (e.g., rhinitis, cough, wheezing, chest retractions, tachypnea). Laboratory and radiologic examinations are not routinely performed.

Treatment for bronchiolitis is determined by the severity of the disease and the age of the child. Most cases are mild and require no specific treatment, and the child may be monitored as an outpatient. When treatment is indicated, it is primarily supportive in nature and may include high-flow nasal oxygen or noninvasive ventilation.[43] Bronchodilators, corticosteroids, and antibiotics are not recommended. Preventive treatment with RSV-specific monoclonal antibody (palivizumab) can reduce morbidity in infants with RSV bronchiolitis.[38,42] The American Academy of Pediatrics guidelines recommend the use of palivizumab prophylaxis for all infants born on or before 32 weeks gestation.[42] The National Perinatal Association also recommends the use of palivizumab in older preterm infants (born at 32 to 35 weeks gestation) who have additional risk factors.[44] Other preventive measures include the use of hand washing and alcohol-based decontamination, prevention of exposure to tobacco smoke, and promotion of infant breast feeding until at least 6 months of age.

Pneumonia

Pneumonia is infection and inflammation in the terminal airways and alveoli. Community-acquired pneumonia (CAP) is a major cause of morbidity and mortality in children, particularly in developing countries, although pneumonia related deaths among children globally have declined as a result of vaccines against *S. pneumoniae* and *H. influenzae*, antibiotic therapy, and improvements in education, nutrition, water, sanitation, and hygiene.[45] In the United States, CAP is the cause for over 100,000 pediatric hospitalizations annually.[46] The most common agents are viruses, and then bacteria and atypical microorganisms (e.g., mycoplasma) (Table 36.2). Risk factors for developing CAP are age younger than 2 years, overcrowded living conditions, winter season, recent antibiotic treatment, daycare attendance, and passive smoke exposure. Nutritional status, age, and underlying disease process influence morbidity and mortality rates related to CAP. Hospital-acquired pneumonia (HAP) is a nosocomial infection that occurs most commonly in those who are immunocompromised or who experience prolonged hospitalization for treatment of malignancy, trauma, surgery, or underlying chronic illness (see Chapter 35).

Table 36.2

Common Types of Pneumonia in Children

Type	Causal Agent	Age	Onset	Signs/Symptoms
Viral pneumonia	Respiratory syncytial virus (RSV), rhinovirus, influenza, adenovirus, parainfluenza, coronavirus	Neonates to 5 years	Acute or gradual, winter and early spring	Mild to high fever, cough, rhinorrhea, malaise, rales, rhonchi, wheezing, or apnea; variable radiographic pattern, may be severe requiring hospitalization
Pneumococcal pneumonia	*Streptococcus pneumoniae*	Usually 1 month to 4 years	Acute, occurs after an upper respiratory tract infection, winter and early spring	High fever, productive cough, pleuritic pain, increased respiration rate, decreased breath sounds in area of consolidation; lobar infiltrate on radiograph
Staphylococcal pneumonia	*Staphylococcus aureus* (including methicillin-resistant strains)	1 week to 2 years	Acute, winter	High fever, cough, respiratory distress, toxic appearance, sepsis; empyema or pneumatoceles common
Streptococcal pneumonia	Group B *Streptococcus*	Neonates	Acute, any season	Fussy, listless, tachypnea and retractions, pain in extremities, fever, meningitis, sepsis
Listeria pneumonia	*Listeria monocytogenes*	Neonates	May develop within hours of birth (early onset) or after several weeks (late onset)	Listlessness, poor feeding, respiratory distress, meningitis, sepsis
Atypical pneumonia	*Mycoplasma pneumoniae, Chlamydophila pneumoniae*	3 months to adolescents	Gradual	Low-grade fever, cough

Type	Causal Agent	Age	Onset	Signs/Symptoms
Viral pneumonia	Respiratory syncytial virus (RSV), rhinovirus, influenza, adenovirus, parainfluenza, coronavirus	Neonates to 5 years	Acute or gradual, winter and early spring	Mild to high fever, cough, rhinorrhea, malaise, rales, rhonchi, wheezing, or apnea; variable radiographic pattern, may be severe requiring hospitalization
Pneumococcal pneumonia	*Streptococcus pneumoniae*	Usually 1 month to 4 years	Acute, occurs after an upper respiratory tract infection, winter and early spring	High fever, productive cough, pleuritic pain, increased respiration rate, decreased breath sounds in area of consolidation; lobar infiltrate on radiograph
Staphylococcal pneumonia	*Staphylococcus aureus* (including methicillin-resistant strains)	1 week to 2 years	Acute, winter	High fever, cough, respiratory distress, toxic appearance, sepsis; empyema or pneumatoceles common
Streptococcal pneumonia	Group B *Streptococcus*	Neonates	Acute, any season	Fussy, listless, tachypnea and retractions, pain in extremities, fever, meningitis, sepsis
Listeria pneumonia	*Listeria monocytogenes*	Neonates	May develop within hours of birth (early onset) or after several weeks (late onset)	Listlessness, poor feeding, respiratory distress, meningitis, sepsis

Data adapted from Popovsky EY, Florin TA. Community-acquired pneumonia in childhood. *Reference Module in Biomedical Sciences*, 2020;B978-0-08–102723-3.00013–5.

Pathophysiology

Viral pneumonia accounts for approximately 66% of childhood CAP requiring hospitalization.[47] RSV is the most common viral pneumonia in young children. A number of other viruses are important, including parainfluenza, influenza, human rhinovirus, human metapneumovirus, and adenoviruses. SARS-CoV-2 infection is most often asymptomatic or mild in children; however, a significant number of affected children do suffer serious complications such as multisystem inflammatory syndrome and require hospitalization (see Emerging Science Box: COVID-19 Infection in Children).[48] Acquisition of these viruses is by direct inoculation of the upper respiratory tract through inhalation of infectious secretions (droplet transmission), aerosol exposure, or from fomites in the child's environment (see Chapter 10). There is initial destruction of the ciliated epithelium of the distal airway with sloughing of cellular material and initiation of an inflammatory response. Alveolar injury results in loss of surfactant formation, hyaline membrane formation, and edema of the alveolar-capillary membrane.[46] Bacterial coinfections are common.

Emerging Science BoxCOVID-19 Infection in Children

Overall, children make up only 2%–8% of diagnosed Coronavirus Disease 19 (COVID-19) cases worldwide, although the number of asymptomatic infections is likely to be much higher. While most children have no or very mild symptoms during acute SARS-CoV-2 infection, a significant number develop a serious illness that occurs days to a few weeks after the initial infection. This condition is called multisystem inflammatory syndrome in children (MIS-C). As of late January 2022, 6,851 children with MIS-C were reported to state public health departments in the United States. The median age of patients with MIS-C was 9 years and 60% were male. The case definition for MIS-C according to the U.S. Centers for Disease Control and Prevention (CDC) includes the following:- Age <21 years- Temperature ≥38.0°C for ≥24 hours or subjective fever for ≥24 hours- Severe illness (hospitalized) and ≥2 organ systems involved- Laboratory evidence of inflammation - Current or recent findings of positive by PCR; positive by serology; positive by antigen test; or COVID-19 exposure within prior 4 weeks- No alternative diagnosisWhile the pathogenesis of MIS-C continues to be delineated, both humoral and cellular autoimmune responses are implicated. It is postulated that

SARS-CoV-2 serves as a superantigen eliciting an overwhelming immune response. Autoantibodies and T cell recognition of antigens expressed on infected cells, as well as the formation of antigen/antibody complexes, result in cellular damage and the release of numerous inflammatory cytokines such as interleukins 1 and 6, tumor necrosis factor alpha, and monocyte chemotactic factors. Neutrophils are activated and contribute to tissue damage. A hyperinflammatory condition results causing mucocutaneous, cardiac, pulmonary, renal, gastrointestinal, neurological injury as well as thrombotic complications and shock. Acute severe COVID-19 infection in children is considered distinct from MIS-C in that it occurs when viral titers are high, whereas the onset of MIS-C can be delayed for days or even weeks after the initial infection. Symptoms involving multiple organ systems including the gastrointestinal (abdominal pain and vomiting), mucocutaneous (rash), cardiac (chest pain), and neurocognitive (confusion, lethargy, somnolence) systems are common in those with MIS-C, whereas respiratory symptoms are not a prominent feature. Coronary artery aneurysms or arrhythmias affect approximately 10% of those with MIS-C, so once the diagnosis is made, additional testing should include echocardiogram, electrocardiogram, cardiac enzyme or troponin testing, and B-type natriuretic peptide. The CDC-recommended management includes fluid resuscitation, cardiac and respiratory support, corticosteroids, aspirin, and anticoagulants. Intravenous immunoglobulin and interleukin-1 or interleukin-6 antagonists may be used in severe cases. Approximately 60% of individuals require admission to intensive care, 40% require inotropic support, and 15% require mechanical ventilation. The overall mortality rate is around 2%. Close follow-up including cardiac reevaluation is indicated.

Bacterial pneumonia beyond the neonatal period most commonly is the result of infection with *S. pneumoniae*.[47] Other causative bacteria include *S. aureus* and atypical bacteria (see Table 36.2). Childhood immunization with the pneumococcal and *H. influenzae* vaccines has decreased the incidence of these two types of bacterial pneumonia in children younger than 2 years of age. Bacterial pneumonia usually begins with aspiration of bacteria that have colonized the nasopharynx.[45] A preceding viral infection sometimes sets the stage for bacterial infection by causing epithelial damage, reduced mucociliary clearance in the trachea and major bronchi, and a reduced immune response. Once in the alveolar region, bacteria encounter local host defenses, such as antibodies, complement, and cytokines, which prepare bacteria for ingestion by alveolar macrophages. Alveolar macrophages recognize bacteria with their surface receptors and phagocytose them. Macrophages release numerous inflammatory cytokines, and neutrophils are recruited into the lung. An intense, cytokine-mediated inflammation will ensue. Vascular engorgement, edema, and a fibrinopurulent exudate occur. Alveolar filling interferes with gas exchange and, if extensive, can lead to respiratory failure. If sepsis occurs at the same time, shock and end-organ hypoperfusion will cause metabolic acidosis. Staphylococcal pneumonia and group A streptococcal pneumonia can be particularly fulminant with a high incidence of accompanying empyema, pneumatocele (a lung lesion filled with air), and sepsis.

Pneumonia in neonates during the first 7 days of life (congenital or early onset pneumonia) is most often due to exposure to maternal pathogens during birth such as *Toxoplasma gondii, cytomegalovirus*, and *herpes simplex virus*.[46] Bacterial pathogens include group B *streptococcus* and *Listeria monocytogenes*.

Risk factors include prematurity, low birth weight, and prolonged rupture of membranes. Late-onset neonatal pneumonia (greater than 7 days) may be caused by *S. aureus, S. pneumoniae*, or lower respiratory tract viruses.Atypical pneumonia caused by Mycoplasma pneumoniae is a common cause of CAP for school-age children and young adults. It colonizes the respiratory tract in an estimated 21% of asymptomatic children and can cause symptomatic infections at any time of the year.[49]*Mycoplasma* can cause a wide spectrum of disease including rash, mucositis, upper airway infections, pneumonia, and autoimmune hemolytic anemia. Transmission occurs person to person, and there is a 2- to 3-week incubation period. *Mycoplasma* microorganisms lack cell walls but have a limiting membrane and a specialized receptor for attaching to ciliated respiratory epithelial cells. Local sloughing of cells occurs. Lymphocytic infiltration develops around the bronchi, along with neutrophil recruitment to the airway lumen. Complications, when they do occur, can include bronchopneumonia, parapneumonic pleural effusions, and necrotizing pneumonitis. Chlamydophila pneumoniae is clinically indistinguishable from *Mycoplasma* infection and is typically grouped with it as "atypical pneumonia."

Clinical Manifestations

Pneumonia in children has many overlapping features with other lower respiratory tract conditions such as asthma and bronchiolitis. Common clinical manifestations include dyspnea, fever, cough, crackles, wheezing, tachypnea, and tachycardia. Chest retractions, nasal flaring, emesis, and evidence of dehydration may develop. Bacterial pneumonia often is preceded by a viral illness followed by fever and increasingly productive cough. Occasionally, there is blood streaking of the sputum. In atypical pneumonia, the onset is usually gradual, resembling an upper respiratory tract infection but with low-grade fever, cough, and chest pain

Evaluation and Treatment

Guidelines have been developed to improve and aid assessment and management of pediatric pneumonia.[50] The diagnosis of pneumonia is based on clinical and laboratory findings. Identifying etiologic pathogens can be very difficult in children, especially because there is often overlap between bacterial and viral pathogens. The etiologic agent can sometimes be inferred from the age of the child and the clinical scenario. Chest x-rays and oximetry can assist in determining the extent of pulmonary involvement. The use of serum procalcitonin measurement as a biomarker for bacterial pediatric pneumonia is controversial. Measurement of serum surfactant protein D is an emerging clinical biomarker that may help predict pneumonia severity in children.[51] Several more specific microbiologic tests, such as sputum and blood cultures, and antigen detection assays (e.g., influenza, pneumococcus, *Mycoplasma, Chlamydophila*) are available.[46]

Many pneumonias may be treated on an outpatient basis; however, more severely ill children require oxygen supplementation and, occasionally, assisted ventilation. This is particularly true with infants who have a severe viral pneumonia that involves large portions of the lung, such as that seen with RSV. In addition, adequate hydration, proper nutrition, and supportive pulmonary therapy are required to reduce the duration and severity of illness. Many infected infants are markedly tachypneic and unable to coordinate their breathing with swallowing; they may require enteral feeding. Aspiration is always a risk with infants in respiratory distress.

Empiric antibiotic administration for bacterial pneumonias is dependent on age and severity assessment.[46] Local patterns of resistance must be considered when choosing appropriate antibiotics. Current guidelines recommend 10 days of antibiotic treatment; however, evidence is emerging that shorter courses (5 days) of antibiotics may be equally effective.[52] Pneumococcal pneumonias may require immune adjuvant therapies in addition to antibiotics. Prevention with vaccines against influenza and pneumococcal pneumonias is important in infants and young children.

Aspiration Pneumonitis

Aspiration pneumonitis is caused by a foreign substance, such as meconium, food, secretions (saliva or gastric), or environmental compounds, entering the lung and resulting in inflammation of the lung tissue. The aspiration of meconium from amniotic fluid can occur at birth. Children undergoing

sedation or anesthesia may aspirate oral secretions contaminated with anaerobic bacteria or acidic stomach contents. Neurologically compromised children or children with chronic lung disease may have chronic pulmonary aspiration (CPA), which can cause progressive lung disease, bronchiectasis (chronically enlarged and scarred bronchi), and respiratory failure. CPA is the leading cause of death in children who are neurologically compromised because of failure of protective reflexes and difficulty swallowing (dysphagia).

The severity of lung injury after an aspiration incident is determined by the volume and pH of the material aspirated and the presence of pathogenic bacteria. A very low or an extremely high pH will cause a significant inflammatory response leading to damage to the bronchial epithelium followed by atelectasis and pneumonia.[53] Fibrosis and bronchiectasis may occur. With hydrocarbon fluid ingestions, lung injury is determined by the volatility and viscosity of the aspirated substance. A low-viscosity substance, such as gasoline or lighter fluid, is the most toxic; high-viscosity hydrocarbons, such as petroleum jelly or mineral oil, are much less likely to cause a pneumonitis.

Acute aspiration may present with the sudden onset of cough, dyspnea, and respiratory distress. CPA is characterized by cough, wheezing, and recurrent pneumonias. Evaluation includes chest radiography and arterial blood gases. Individuals suspected of CPA should be evaluated for dysphagia. Treatment for aspiration pneumonitis depends on the material aspirated. In children who aspirate significant amounts of toxic chemicals or acidic gastric contents, hospitalization and management for respiratory failure may be needed. Secondary bacterial pneumonia requires the use of broad-spectrum antibiotics. Children with CPA benefit from feeding and swallowing therapy. For selected children with neurologic disorders who have a large amount of upper respiratory tract secretions, anticholinergic medications, salivary gland injection with botulinum toxin A, or tracheotomy may be indicated.[53]

Asthma

Asthma is a chronic inflammatory disease characterized by bronchial hyperreactivity and reversible airflow obstruction, usually in response to an allergen (see Chapter 35). It is the most prevalent chronic disease in childhood, affecting approximately 7% of US children between birth and 17 years of age. Populations most affected include black and Puerto Rican children and those of low socioeconomic status.[54] Although 50% to 75% of children and adolescents with asthma are classified as having mild asthma, approximately one-third of severe exacerbations occur in this group.[55]

Childhood asthma results from a complex interaction between *genetic* susceptibility and *environmental* factors. Over 120 gene polymorphisms have been linked to the development of asthma, including genes for leukocyte function, cell surface receptors, susceptibility to certain infections, and autonomic function.[56] Important environmental risk factors for asthma include early exposure to allergens (e.g., dust mites, molds, cockroaches, cats), tobacco smoke, and air pollution. Gastroesophageal reflux and preterm birth are also risk factors. Exposure to respiratory pathogens such as fungi, some bacteria, and viruses (e.g., RSV) is associated with an increased risk for asthma in genetically predisposed individuals. Dysbiosis of the lung and gut microbiome also plays a major role in influencing the development of asthma in children.[57] Childhood obesity is strongly linked to asthma risk and severity (see Emerging Science Box: Obesity and Childhood Asthma).

Emerging Science BoxObesity and Childhood Asthma

The association between childhood obesity and asthma risk and severity is well described. Obesity is linked to both allergic and nonallergic asthma phenotypes, including early-onset obese-asthma and late-onset obese-asthma. The pathophysiology that underlies this association is complex. There are genetic factors that are common to both obesity and asthma, as well as numerous epigenetic factors that are influenced by diet, sedentary lifestyle, and childhood exposures to environmental toxins. For example, low dietary fiber intake is linked with gut microbiome dysbiosis, systemic inflammation, and increased asthma risk. Obesity is a metabolically active state in which there are increased levels of inflammatory cytokines such as interleukin-1, interleukin-6, interferon gamma, and tumor necrosis factor alpha. The allergic immune cytokines interleukin-4, interleukin-5, and interleukin-13 are also

increased. Furthermore, obesity results in an increased level of leptin which can increase levels of IgE and airway hyperreactivity. Insulin resistance and metabolic perturbations in obesity are linked with airway dysfunction. In addition to an increased risk for the development of asthma, obese individuals also are more likely to experience severe symptoms of dyspnea and chest tightness. Obese children with asthma are at increased risk for hospitalization for asthma-related respiratory distress and have a worse quality of life. Response to asthma medications is also decreased as compared to non-obese individuals with asthma. Management of obesity-related asthma is the same as for other types of asthma, with the addition of aggressive attempts at weight reduction. In children who accomplish significant weight loss, significantly improved asthma control and quality of life can be achieved.

Pathophysiology

The pathophysiology of asthma in children is similar to that for adults and is described in Chapter 35 (see Algorithm 35.4 and Figs. 35.6 and 35.7). Allergic asthma is initiated by a type I hypersensitivity reaction primarily mediated by T-helper 2 (Th2) lymphocytes, whose cytokines activate mast cells, eosinophilia, leukocytosis, and enhanced B-cell IgE production (see Chapter 9). As in adults, inflammation, bronchospasm, and mucus production in the airways lead to ventilation and perfusion mismatch with hypoxemia and to expiratory airway obstruction with air trapping and increased work of breathing. In young children, airway obstruction can be more severe because of the smaller diameter of their airways.

Most acute wheezing episodes in children with asthma are associated with viral respiratory tract infection (e.g., RSV, human rhinoviruses, and parainfluenza viruses).[58] In infants and toddlers younger than 2 years old, RSV is the most common. In older children and adults, rhinovirus (the "common cold" virus) is the major viral trigger. Bacterial respiratory tract infections also can trigger an acute asthma attack.

Clinical Manifestations

Clinical manifestations of an acute asthma attack include coughing, expiratory wheezing, and shortness of breath. Breath sounds may become faint when air movement is poor. The child may speak in clipped sentences or not at all because of dyspnea. The respiratory rate and heart rate are elevated. Nasal flaring and the use of accessory muscles with retractions in the substernal, subcostal, intercostal, suprasternal, or sternocleidomastoid areas are evident (see Fig. 36.3). Infants may appear to be "head bobbing" because of sternocleidomastoid muscle use. Pulsus paradoxus (a decrease in the systolic blood pressure of more than 10 mm Hg during inspiration) may be present. The child may appear anxious or may be sweating heavily, important signs of respiratory compromise.

Findings in chronic asthma may include persistent cough (often at night), wheezing when exposed to cold air or other irritants, exercise intolerance, and hyperinflation of the thorax (barrel chest). Clubbing should not be seen with asthma and, if present, should trigger evaluation for other conditions, such as cystic fibrosis. Exercise intolerance may indicate underlying asthma.

Evaluation and Treatment

Asthma is often underdiagnosed and undertreated, especially in preschool-age children, because asthma symptoms overlap with other respiratory illnesses, such as bronchitis or upper respiratory tract infections. The diagnosis of asthma is based on recurrent episodes of wheezing as well as a variety of risk factors, including a parental history of asthma, atopic dermatitis, sensitization to aeroallergens or foods, blood eosinophilia, or wheezing not associated with upper respiratory tract illnesses. The modified Asthma Predictive Index (mAPI) can be used to help with asthma diagnosis and is

recommended by the NIH guidelines.[59] Confirmation of the diagnosis of asthma relies on pulmonary function testing using spirometry, which can be accomplished only after the child is 5 to 6 years of age. For younger children, an empirical trial of asthma medications is commonly initiated.

The goal of asthma therapy is to achieve long-term control by reduction in impairment and risk. Child and family education and appropriate allergen avoidance techniques should begin immediately. Care providers need to periodically assess asthma control in children. Key features for assessment include nighttime awakenings, interference with normal activities, use of short-acting β_2-agonists, pulmonary function testing, and exacerbations requiring steroids. Peak flow meters are often used to help guide treatment.

The pharmacologic treatment of asthma in children is essentially the same as that for adults and is initiated in a stepwise sequence based on asthma severity and the response to treatment (see Chapter 35). The Global Initiative for Asthma (GINA) provides recommendations for the use of inhaled corticosteroids and leukotriene receptor antagonists in children.[60] Management of asthma medications in children is often difficult because fluctuation in the severity of the symptoms is common. A Single Maintenance and Reliever (SMART) approach with an inhaled corticosteroid and a long-acting beta agonist is effective in reducing exacerbations and improving symptoms in most children 4 years and older.[55] Before therapy is augmented, care providers need to assess medication administration techniques, environmental controls, and comorbidities. For a reduction in therapy, the asthma needs to be under good control for a minimum of 3 months. Many children with less severe asthma outgrow the disease by adulthood.

Pediatric Acute Respiratory Distress Syndrome

Pediatric acute respiratory distress syndrome (PARDS) is a clinical syndrome in which there is pulmonary edema that is not the result of cardiac disease (noncardiogenic pulmonary edema). It is characterized by an acute onset of hypoxemia and pulmonary infiltrates. PARDS accounts for 1% to 10% of total admissions to pediatric intensive care units.[61] The risk for development of PARDS varies depending on age and the underlying cause. For example, children with underlying malignancies are at much higher risk for PARDS associated with infection with or without septic shock.[62] Mortality from PARDS in children remains high at about 24% and is higher in those who are immunocompromised, require vasopressors, or have multiple organ dysfunction.[63,64] Mortality in children with malignancy admitted to the ICU with PARDS may be as high as 80%.

Pathophysiology

PARDS results from a direct lung injury, such as pneumonia, aspiration, near-drowning, or smoke inhalation; or from a systemic insult, such as sepsis, pancreatitis, or multiple traumas. Some cases of adolescent PARDS have been linked to vaping.[65] Although less common than in adults, COVID-19 may cause of PARDS (see Emerging Science Box: COVID-19 Infection in Children). PARDS is characterized by an inflammatory response that causes alveolocapillary injury followed by leakage of fluid into the alveoli, coagulation, surfactant degradation, and fibrosis.[61] The steps in the pathophysiology of PARDS is the same as that described for ARDS in adults in Chapter 35 (see Algorithm 35.3).

Clinical Manifestations

Children with PARDS most commonly have suffered a known clinical insult, followed by increasing dyspnea, hypoxemia, and pulmonary infiltrates on chest x-ray. Initially, hyperventilation occurs, but carbon dioxide (CO_2) retention may ultimately develop because of inadequate functional air space and respiratory muscle fatigue. The severity of the overall picture is modified by comorbid factors, such as the presence of sepsis or multiorgan failure, and by the presence or absence of complications, such as nosocomial pneumonia.

Evaluation and Treatment

The evaluation of children with PARDS includes a physical examination, evaluation of blood gases, and imaging. The Pediatric Acute Lung Injury Consensus Conference has developed diagnostic criteria for PARDS which describe an onset within 7 days of clinical insult, new infiltrates on chest x-ray, edema not explained by fluid overload, or cardiac failure and hypoxemia. Perinatal causes of acute hypoxemia are excluded (i.e., lung disease related to prematurity, perinatal lung injury, congenital abnormalities, left ventricular failure, or fluid overload).[66] The degree of hypoxemia used to define the severity of PARDS uses the oxygenation index (OI), which is determined by the mean airway pressure and the ratio of supplemental oxygen to the PaO_2.

Treatment for PARDS remains supportive in nature, and the goals are to maintain adequate tissue oxygenation, minimize acute lung injury, and avoid iatrogenic pulmonary complications. Most children with PARDS require mechanical ventilation to promote alveolar ventilation and stabilization, and redistribution of alveolar edema fluid into the interstitium. Infants are at greater risk for ventilator-induced lung injury, and non-invasive ventilation, lung protective ventilation strategies, or extracorporeal membrane oxygenation (ECMO) should be considered. Prone positioning for severe PARDS improves oxygenation and reduces mortality.[61] Use of corticosteroids in PARDS is controversial but has been associated with improvements in lung function and survival in some studies.[67] Surfactant therapies appear promising in preclinical and clinical studies.[68] More research is needed regarding the long-term outcomes of PARDS.

Cystic Fibrosis

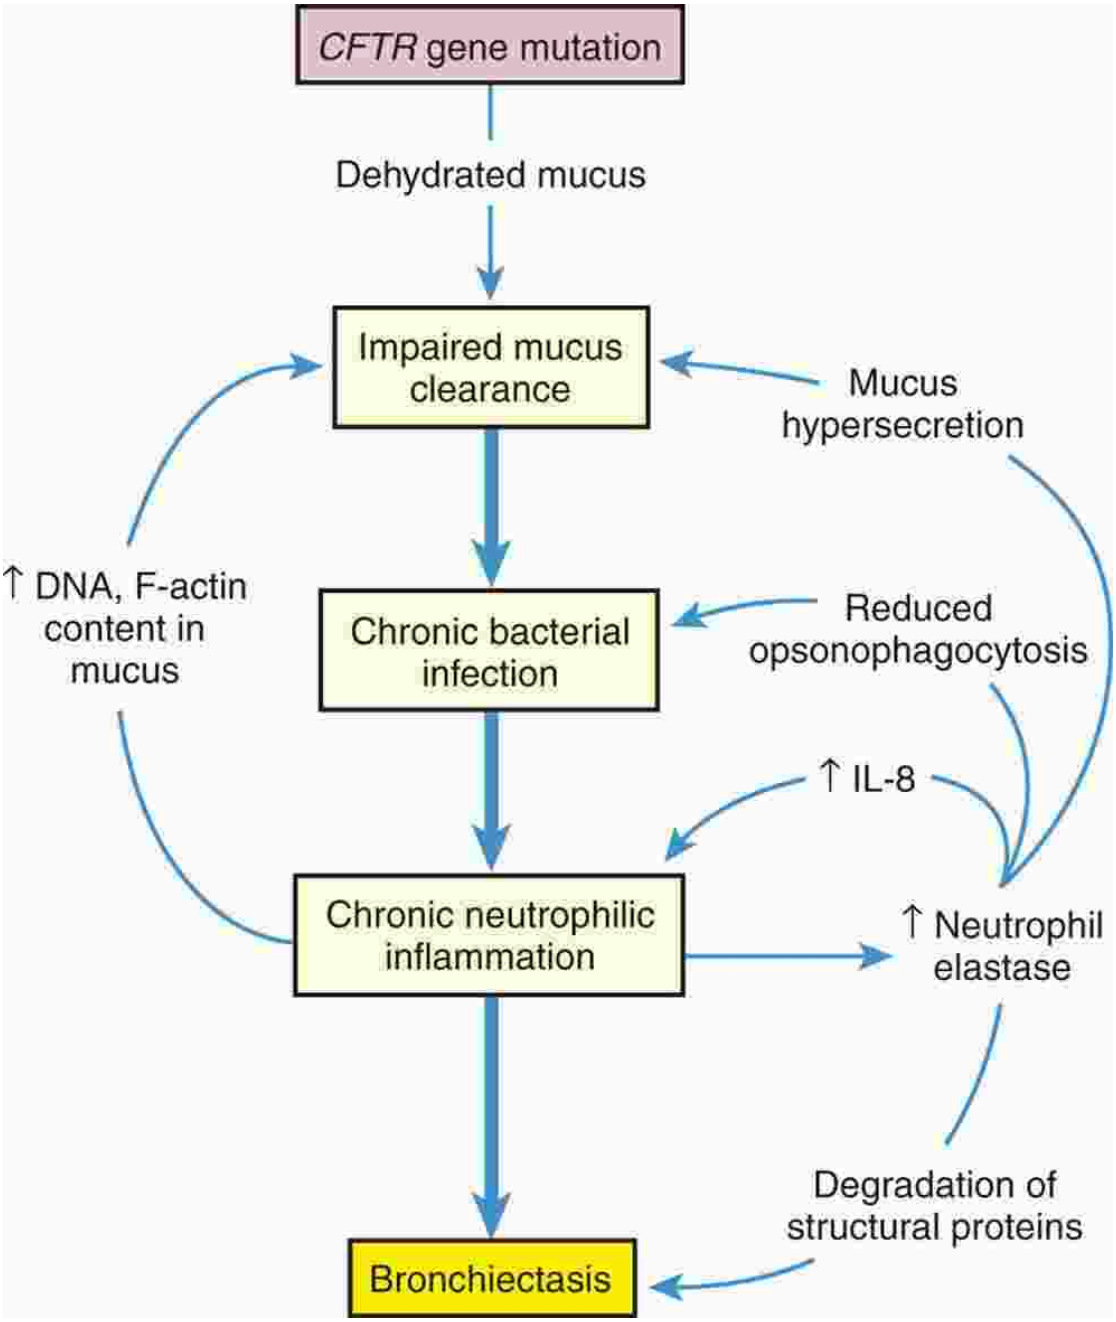
Cystic fibrosis (CF) is an autosomal recessive disease caused by inherited mutations in the *cystic fibrosis transmembrane conductance regulator (CFTR)* gene located on chromosome 7. These mutations result in defective epithelial chloride ion transport. There are over 2000 different variants of the CFTR gene. These mutations are divided into five classes with varying severity of disease expression: protein production mutations, protein processing mutations, gating mutations, conduction mutations, and insufficient protein mutations.[69]

In 2020 the Cystic Fibrosis Foundation Patient Registry reported 708 newly diagnosed individuals with CF in the U.S., and the median age at diagnosis was 3 months.[70] CF primarily affects Caucasians (approximately 95%). Due to improvement in treatment, median survival is 46.2 years and over half of people living with CF are 18 years or older.71 The overall estimated carrier frequency for people in the United States is 1 in 35, while the frequency in US Caucasians is 1 in 20. Carriers are not affected by the mutation.

Pathophysiology

CF is a multiorgan disease that affects the lungs, digestive tract (see Chapter 42), and reproductive organs. *CFTR* gene mutations result in the abnormal expression of cystic fibrosis transmembrane conductance regulator (CFTR) protein, which is an activated chloride channel present on the surface of many types of epithelial cells lining airways, bile ducts, the pancreas, sweat ducts, paranasal sinuses, and vas deferens.[72] Without adequate CFTR function, chloride and water are not transported appropriately across epithelial membranes, resulting in thick, dehydrated mucus secretions. The most important effects are on the lungs, and respiratory failure is almost always the cause of death.

The typical features of CF lung disease are mucous plugging, chronic inflammation, and chronic infection of the small airways (Algorithm 36.4).[73] The mucous plugging results from increased production of mucus from more numerous and larger goblet cells, altered physicochemical properties of the mucus, and impaired mucociliary clearance. The depleted fluid in the mucus and impaired mobility of the cilia allow mucus to adhere to the airway epithelium, along with bacteria and injurious by-products from neutrophils. Neutrophils are present in great excess in the airways and release oxidants and proteases (i.e., elastase) that cause direct damage to lung structural proteins.[74] Microorganisms also induce airway cells to produce inflammatory mediators that destroy immunoglobulin G (IgG) and complement components important for opsonization and phagocytosis of pathogens, thus contributing to chronic infection (see Algorithm 36.4).

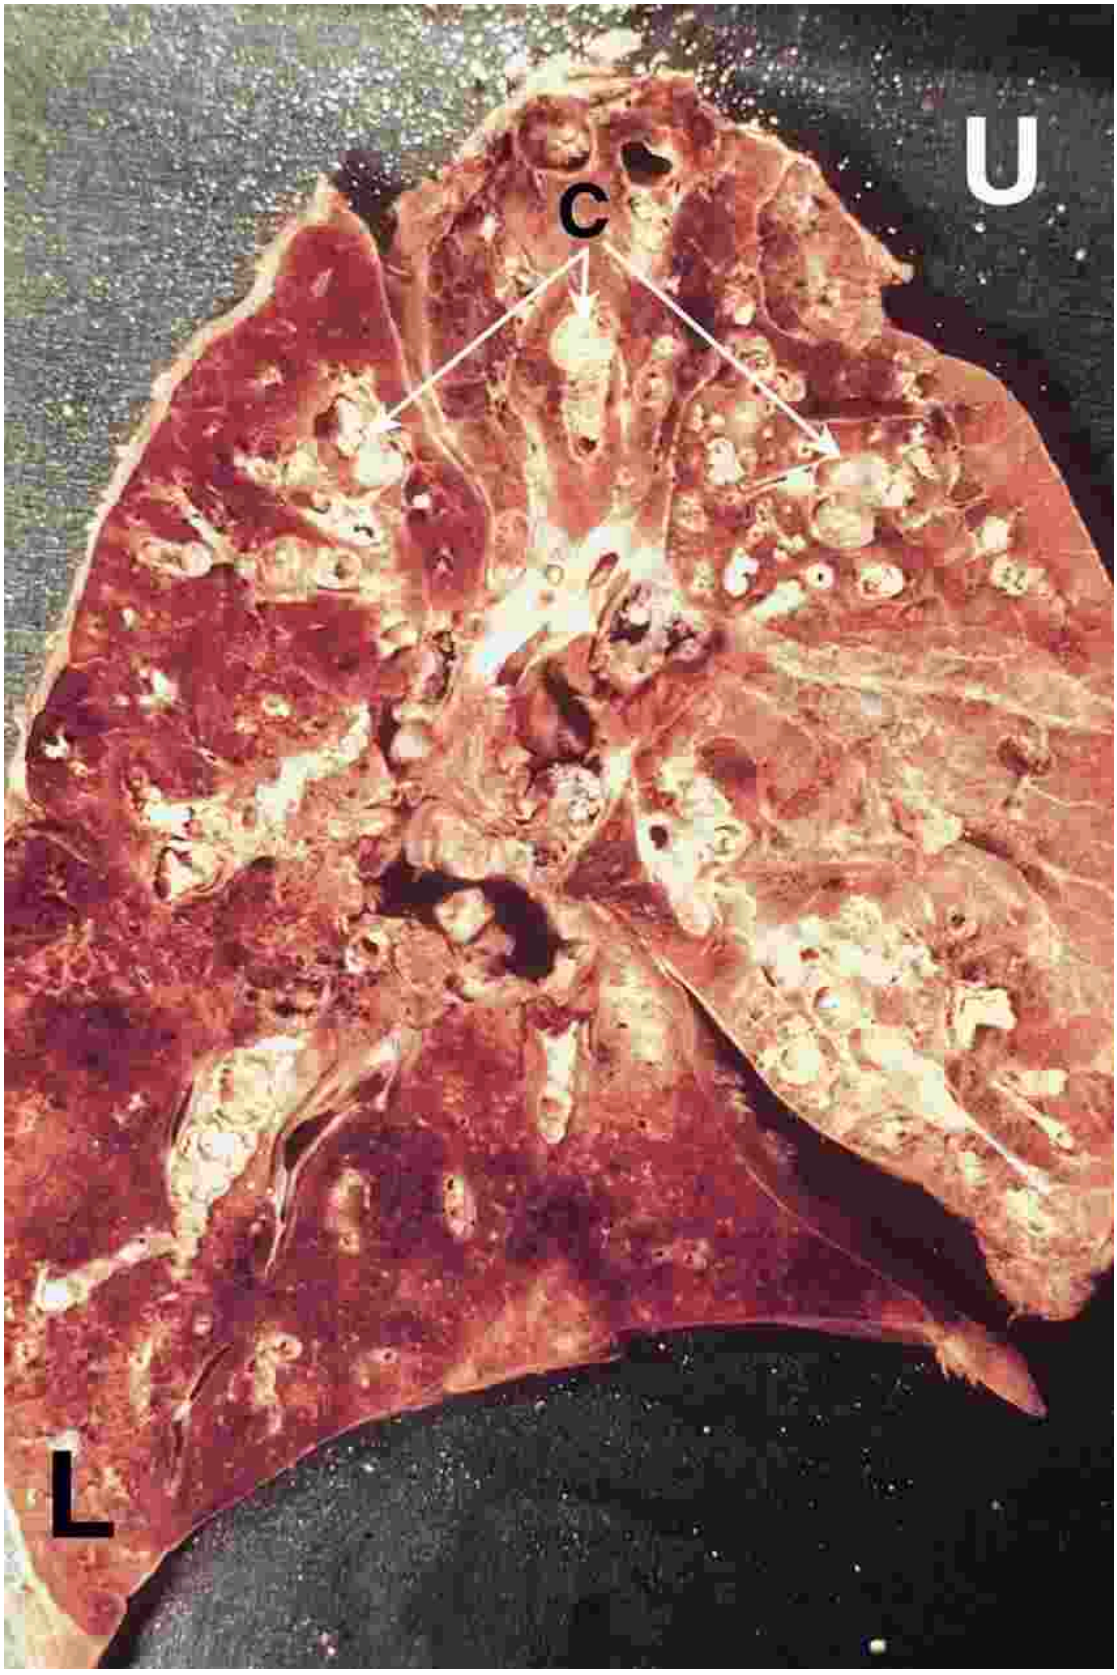


ALGORITHM 36.4 Pathogenesis of Cystic Fibrosis Lung Disease. *CFTR*, Cystic fibrosis transmembrane conductance regulator;*IL-8*, interleukin-8.

A flowchart represents the pathogenesis of cystic fibrosis lung disease. 1. C F T R gene mutation. Leads to 2. 2. Dehydrated mucus. Leads to 3. 3. Impaired mucus clearance. Leads to 4. 4. Chronic bacterial infection. Leads to 5. 5. Chronic neutrophilic inflammation. Leads to 6 and 11. 6. Bronchiectasis. 7. Increased D N A, F-actin content in mucus. Leads to 3. 8. Mucus hypersecretion. Leads to 3. 9. Reduced opsonophagocytosis. Leads to 4. 10. Increased I L-8. Leads to 9. Leads

to 5. 11. Increased neutrophil elastase. Leads to 8, 9, 10, and 12. 12. Degradation of structural proteins.

The CF airway microenvironment favors bacterial colonization, which leads to a bacterial biofilm that promotes chronic endobronchial infection. The biofilm resists beta-lactam antibiotics, and rapid mutation of the biofilm makes these children antibiotic resistant. Persistence of these microorganisms incites chronic local inflammation and airway damage, with microabscess formation, bronchiectasis, patchy consolidation and pneumonia, peribronchial fibrosis, and cyst formation (Fig. 36.8).[71] Peripheral bullae may develop, and pneumothorax may occur. Hemoptysis (coughing up blood) is sometimes life-threatening and may occur because of the erosion into enlarged bronchial arteries. Over time, pulmonary vascular remodeling occurs because of localized hypoxia and arteriolar vasoconstriction. Pulmonary hypertension and cor pulmonale may develop in the late stages of the disease (see Chapter 35).



U
C
L

FIG. 36.8 Pathology of the Lung in End-Stage Cystic Fibrosis.
Key features are widespread mucus impaction of the airways and bronchiectasis, especially from the upper lobe *(U; white arrows)*, with hemorrhagic pneumonia in the lower lobe *(L)*. Small cysts are present at the apex of the lung *(C)*. (From Kleinerman J, Vauthy P. *Pathology of the lung in cystic fibrosis*. Atlanta: Cystic Fibrosis Foundation; 1976.)

Clinical Manifestations

Clinical manifestations of CF can vary from mild to severe, depending on the degree of gene mutation. The most common presenting symptoms of CF involve the respiratory or gastrointestinal/digestive systems (Fig. 36.9). Respiratory symptoms include persistent cough or wheeze, excessive sputum production, and recurrent or severe pneumonia. Physical signs that develop over time include barrel chest and digital clubbing. More subtle presentations include chronic sinusitis and nasal polyps. Gastrointestinal affects include malnutrition and intestinal obstruction (see Chapter 42).

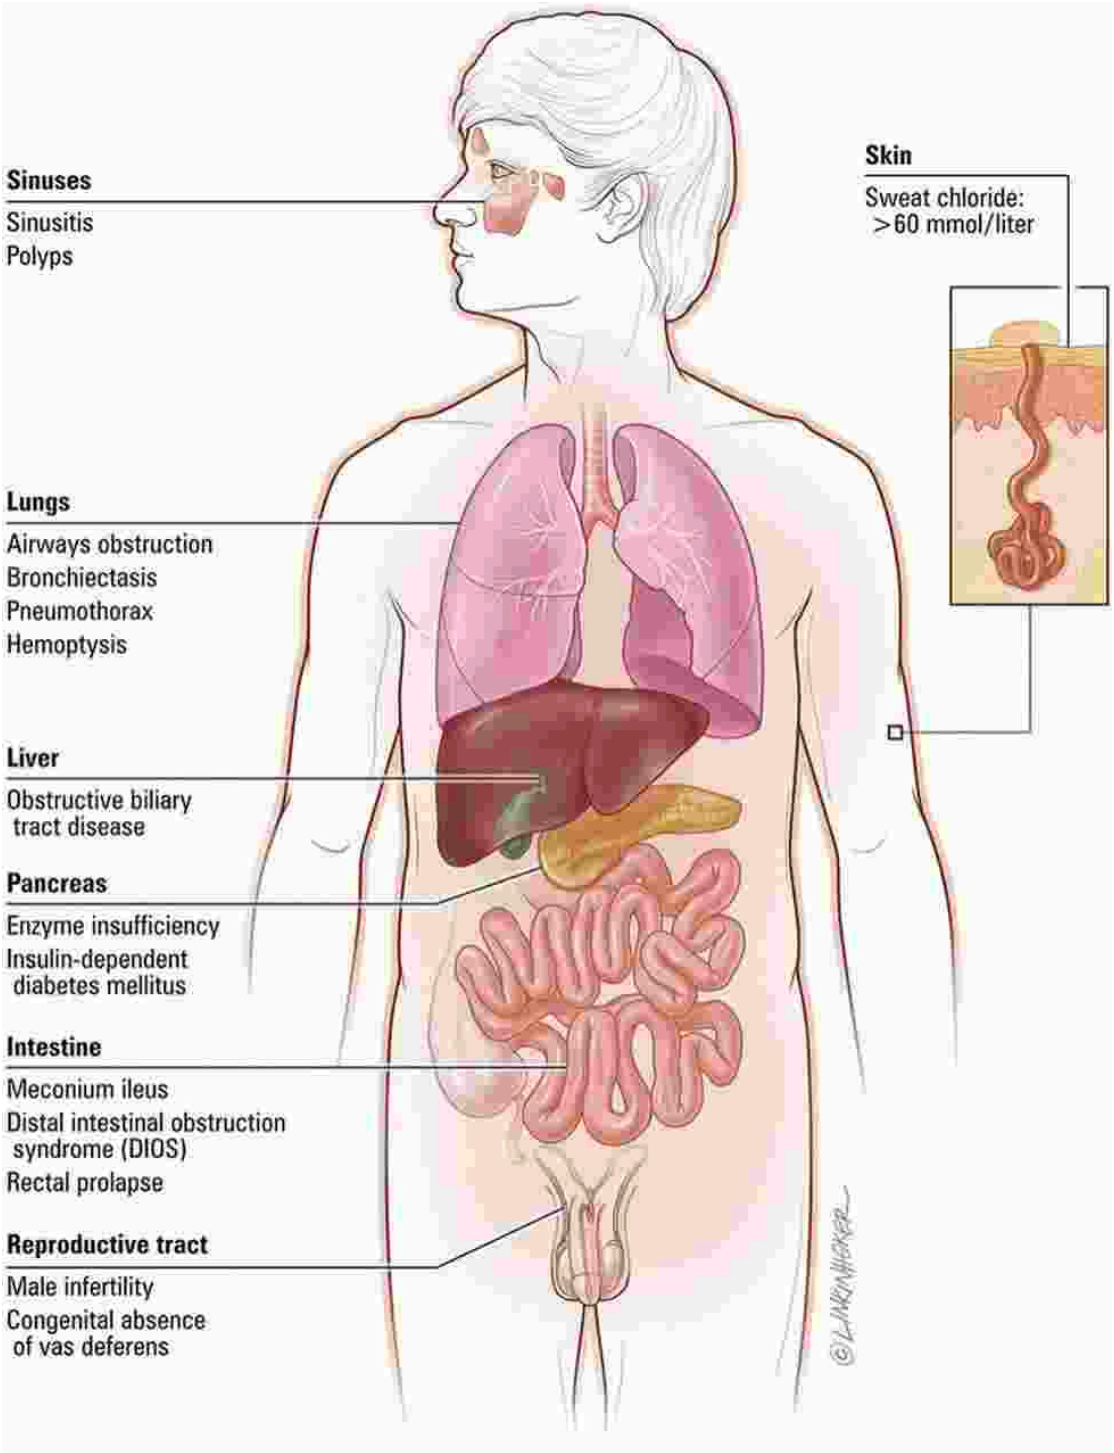


FIG. 36.9 Clinical Manifestations of Cystic Fibrosis.
Cystic fibrosis affects many organs in the body. (From Dickinson KM, Collaco JM. Cystic fibrosis. *Pediatrics in Review*, 2021;42(2):55–67. https://doi.org/10.1542/pir.2019-0212.)

An illustration showing the anterior view of a person with the integral organs highlighted shows the clinical manifestations of cystic fibrosis. • Sinuses: sinusitis and polyps. • Lungs: airways obstruction, bronchiectasis,

pneumothorax, hemoptysis. • Skin: sweat chloride (less than 60 millimoles per liter). • Liver: obstructive biliary and tract disease. • Pancreas: enzyme insufficiency and insulin-dependent diabetes mellitus. • Intestine: meconium ileus, distal intestinal obstruction syndrome (D I O S), rectal prolapse. • Reproductive tract: male infertility and congenital absence of vas deferens.

Evaluation and Treatment

According to the Cystic Fibrosis Foundation, guidelines for the diagnosis of CF include one or more clinical features, a history of CF in a sibling, or a positive newborn screen plus laboratory evidence of an abnormality in the *CFTR* gene or the CFTR protein. Newborn screening for CF is universal throughout the United States and is essential to providing early, pre-symptomatic diagnosis and treatment, including nutritional counseling, early digestive enzyme replacement, and provision of psychosocial support to families. The standard method of screening newborns in most states is the IRT, a blood test which measures immunoreactive trypsinogen (a chemical made by the pancreas) and identifies DNA changes.[75] If the IRT test is positive, then a sweat test is performed before 4 weeks of age. Carrier testing to detect adult heterozygotes is available and enables informed reproductive choices before the birth of the first child with CF (25% chance if both parents are carriers).[76]

Treatment is primarily focused on pulmonary health and nutrition and prevention of persistent cycles of lung infection and inflammation.[77] Pancreatic enzyme therapy is initiated when pancreatic insufficiency and malabsorption are documented, along with fat soluble vitamin replacement.[71] Common pulmonary therapies include airway clearance therapy (chest physical therapy and related mechanical devices), use of bronchodilators, and the administration of solutions which liquefy mucus (e.g., aerosolized dornase alfa [an enzyme] and hypertonic saline). Different classes of oral, inhaled, or intravenous antibiotics are used to treat different pathogens and to overcome antibiotic resistance. High-dose ibuprofen is indicated for children older than 6 years.[77] CFTR modulators can restore the function of the *CFTR* gene in 90% of individuals with CF (see Emerging Science Box: CFTR Modulators).[78]

Emerging Science BoxCFTR Modulators

An improved understanding of the cystic fibrosis transmembrane conductance regulator (CFTR) protein gene mutations led to the development CFTR modulating drugs. These modulator drugs have the ability to enhance the function of the CFTR gene and have been classified into five main groups depending on their effects: potentiators, correctors, stabilizers, read-through agents, and amplifiers. To date, four CFTR modulators have reached the market: ivacaftor(Kalydeco),lumacaftor/ivacaftor(Orkambi),tezacaftor/ivacaftor(Symdeko), andelexacaftor/tezacaftor/ivacaftor(Trikafta). These drug combinations have been found to be effective in achieving short- and long-term improvements in clinical outcomes for up to 90% of individuals with CF, transforming the disease into a treatable chronic condition. There is emerging evidence that starting these medications early in life before severe lung injury develops may halt disease progression. Unfortunately, it is as yet unclear if these treatments will prove safe and effective over decades of use, adherence issues need to be addressed, and these medications are very expensive. Furthermore, there remain rare CFTR mutations that are unresponsive to these treatments and will require additional innovative approaches such as gene and stem cell therapies.

Cell based therapies are under investigation.[79] Individuals with end-stage lung disease may consider lung transplantation.

Sudden Infant Death Syndrome

Sudden Infant Death Syndrome (SIDS) is the most common cause of sudden unexpected infant death. It remains a disease of unknown cause. It is defined as sudden death of an infant under 12 months of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.[80]

The incidence of SIDS is low during the first month of life, with the peak incidence at 2 to 4 months of age. It is unusual after 6 months of age. In 2019, there were approximately 1250 deaths due to SIDS.[81] SIDS almost always occurs during nighttime sleep, when infants are least likely to be observed. Clinical risk groups are summarized in *Risk Factors:* Sudden Infant Death Syndrome (SIDS). About 75% of all SIDS victims have no known predisposing clinical risk factor.

Risk Factors

Sudden Infant Death Syndrome

- Prone and side-lying sleeping positions
- Sleeping on soft bedding
- Overheated sleeping environment
- Lower socioeconomic status
- Mothers younger than 20
- Black or African American, Native Americans, Alaska Natives
- Low birth weight or growth-restricted infants
- Male infants
- Preterm delivery
- Multiple gestations
- Sibling who died of SIDS
- Smoking during pregnancy
- Exposure to tobacco smoke
- Lack of prenatal care
- Illicit drug use or binge-drinking
- Larger family size

Data from Moon RY; Task Force on Sudden Infant Death Syndrome. SIDS and other sleep-related infant deaths: Evidence base for 2016 updated recommendations for a safe infant sleeping environment. Pediatrics, 2016;138(5):e20162940.

The etiology of SIDS remains unknown but probably involves a combination of predisposing factors, including physiologic vulnerabilities and environmental stressors. A specific genetic cause for SIDS has not been identified; however, important risk factor genes include those involved in the regulation of the immune system and inflammation, cardiac abnormalities or arrhythmias, and brainstem function.[82] There is evidence for impaired autonomic regulation and failure of cardiovascular, ventilatory, and arousal responses. A prominent theory is that a subset of SIDS infants suffers from serotonergic

abnormalities due to a lesion in the medullary reticular formation that leads to a failure of protective brainstem responses during sleep.[83] Other theories involve immune dysregulation, airway inflammation, and responses to bacterial pathogens from the nasopharynx or viral respiratory tract infections. Findings on autopsy in over 90% of SIDS cases reveal intrathoracic petechiae, unclotted heart chamber blood, congested lungs, and enlarged brain and thymus, suggesting a heterogeneous pathogenesis.[84]

Currently, the best strategy for reducing SIDS and sudden unexpected infant death during sleep seems to be avoidance of risk factors such as placing the infant supine, use of a firm mattress with no soft or loose bedding, and avoidance of parental smoking before and after birth. Other recommendations include breast feeding, recommended immunizations, and use of a pacifier at sleep time.[85] Parents of infants with clinical risk should be taught cardiopulmonary resuscitation (CPR) as a precaution. Some infants at risk for episodes of apnea and bradycardia may warrant cardiorespiratory monitoring after careful consideration of the individual situation.

Summary Review

Disorders of the Upper Airways

1. Viral croup is an acute laryngotracheobronchitis, usually caused by the parainfluenza virus. This infection causes swelling of the upper trachea. The typical sign is a seal-like barking cough, which appears after a few days of rhinorrhea, sore throat, and low-grade fever.
2. Recurrent (spasmodic) croup is characterized by a similar barking cough but occurs in older children and has a sudden onset at night, without fever. The etiology is unknown.
3. Acute epiglottitis is a potentially life-threatening airway infection; its incidence in children has decreased dramatically since the advent of the Hib vaccine. Now other pathogens, such as GABHS, *Candida* species, *S. aureus*, MRSA, and viral pathogens are usually the causative agents.
4. Tonsillar infections are usually caused by viral infections, such as infectious mononucleosis, and can be complicated by tonsillar and peritonsillar abscesses.
5. Aspiration of foreign bodies that lodge in the airways may cause cough, hoarseness, stridor or wheezing, and dyspnea. The severity depends on the location of the foreign body within the airway and the degree of obstruction. Blockage of the larynx or trachea can be fatal, whereas bronchial obstruction may not be diagnosed immediately.
6. OSAS results from partial or complete upper airway obstruction during sleep with associated snoring, labored or obstructed breathing, and disrupted sleep patterns.

Disorders of the Lower Airways

1. SDD (RDS of the newborn) usually occurs in premature infants who are born before surfactant production and alveolocapillary development are complete. Atelectasis and hypoventilation cause shunting, hypoxemia, and hypercapnia. Prenatal steroids and postnatal surfactant are beneficial preventive therapies.
2. BPD is the result of tissue injury and repair and disrupted alveolar development in the lungs of infants who required ventilatory support during a time when their lungs were underdeveloped because of their prematurity. Surfactant therapy has improved outcomes. Infants with BPD may require oxygen and additional therapies for many months.
3. Bronchiolitis is a viral lower respiratory tract infection that presents with a runny nose, wheezing, cough, and tachypnea in infants and is usually caused by infection with RSV. Infants with risk factors of prematurity or underlying lung or heart disease are at high risk and may receive RSV-specific monoclonal antibody to prevent RSV disease.
4. Pneumonia is infection and inflammation in the terminal airways and alveoli. Viral, bacterial, and atypical pneumonia cause varying degrees of illness in children. Bacterial CAP is one of the leading causes of hospitalization and is prevented with a polyvariant pneumococcal conjugate vaccine.

5. Aspiration pneumonitis is caused by inhalation of a foreign substance, such as food, milk, secretions, or environmental compounds into the lung, resulting in inflammation.
6. Asthma is a chronic inflammatory disease characterized by bronchial hyperreactivity and reversible airflow obstruction, usually in response to an allergen. Its origins are multifactorial and include genetic, allergic, and viral-triggered mechanisms.
7. ARDS is a clinical syndrome in which there is pulmonary edema that is not the result of cardiac disease; it is often a life-threatening condition. ARDS results from direct lung injury. There is progressive respiratory distress with severe hypoxemia and respiratory failure.
8. Cystic fibrosis is an autosomal recessive genetic disease that affects the epithelial lining of many organ systems, especially the respiratory and gastrointestinal systems. Airway secretions are particularly thick and tenacious, and the airways develop a chronic bacterial infection. Chronic infection, plugged airways, and severe inflammation cause long-term lung damage and ultimately death. New CFTR modulators are improving outcomes.

Sudden Infant Death Syndrome

1. SIDS is the leading cause of postnatal death for infants outside of the hospital setting. It is associated with a low birth weight, a prone sleeping position, and other environmental factors. There has been a significant reduction in SIDS cases since the widespread adoption of recommendations for safe sleep techniques for infants.

Chapter Outline

OUTLINE

Structures of the Renal System 1211
- Structures of the Kidney 1211
- Urinary Structures 1216

Renal Blood Flow and Glomerular Filtration 1217
- Autoregulation of Intrarenal Blood Flow 1217
- Neural Regulation of Renal Blood Flow 1218
- Hormones and Other Factors Regulating Renal Blood Flow 1218

Kidney Function 1219
- Nephron Function 1219
- Hormones and Nephron Function 1225
- Renal Hormones 1225

Tests of Renal Function 1226
- Renal Clearance 1226
- Urinalysis 1227

The renal system consists of the kidneys. The primary function of the kidney is to maintain a stable internal environment for optimal cell and tissue metabolism. The kidneys accomplish these life-sustaining tasks by balancing solute and water transport, excreting metabolic waste products, conserving nutrients, and regulating acids and bases. The kidney also has an endocrine function and secretes the hormones renin for regulation of blood pressure, erythropoietin (Epo) for red blood cell production, and vitamin D_3 for calcium metabolism. The kidney also synthesizes glucose in a process called gluconeogenesis and releases it into the circulation when needed (Box 37.1). The formation of urine is achieved through the processes of glomerular filtration, tubular reabsorption, and secretion within the kidney. The bladder stores the urine received from the kidney by way of the ureters. Urine is then released from the bladder through the urethra.

Box 37.1

The Kidney and Glucose Regulation

The human kidney contributes to the regulation of glucose concentration by making glucose through gluconeogenesis, by taking up glucose from the circulation, and by reabsorbing glucose from the glomerular filtrate. The human liver and kidneys release approximately equal amounts of glucose through gluconeogenesis in the postabsorptive state (4–12 h after meal ingestion). Other tissues lack the enzyme necessary for gluconeogenesis (glucose-6-phosphatase) and cannot participate in gluconeogenesis. In the postprandial state (up to 4 h after meal ingestion), although overall endogenous glucose release decreases substantially, renal gluconeogenesis accounts for 40% of glucose formed by gluconeogenesis.

About 180 g of glucose are normally filtered each day by the kidneys. Almost all of this is actively reabsorbed by means of sodium-glucose cotransporter 2 (SGLT2), a transmembrane protein expressed in the luminal border of the proximal tubule. This ensures sufficient energy is available during fasting periods. When plasma glucose concentrations exceed a threshold, the SGLT2 becomes saturated, and glucose appears in the urine. Individuals with diabetes mellitus have an increased transport maximum (T_m) for glucose from enhanced expression of SGLT2 and this contributes to hyperglycemia when there is poor glucose control. SGLT2 inhibitors are used for reducing hyperglycemia associated with diabetes mellitus, and they also have beneficial effects by stabilizing cellular metabolic stress and reducing glucose-mediated toxicity and inflammation in the kidneys and the heart.

Renal glucose release is stimulated by epinephrine and is inhibited by insulin. Insulin suppresses glucose release in both the liver and the kidney. The kidneys do not synthesize glycogen and, therefore, do not release glucose through glycogenolysis. In the postabsorptive state, the kidneys utilize about 10% of all glucose used by the body. When there is hypoglycemia, the liver initially releases glucose through glycogenolysis and then increases gluconeogenesis. The kidney also counter-regulates hypoglycemia through gluconeogenesis, which may explain in part why individuals with renal failure tend to develop hypoglycemia.

Structures Of The Renal System

Structures of the Kidney

The **kidneys** are paired organs located in the posterior region of the abdominal cavity behind the peritoneum. They lie on either side of the vertebral column with their upper and lower poles extending from the twelfth thoracic vertebra to the third lumbar vertebra (Fig. 37.1). The right kidney is slightly lower than the left and is displaced downward by the overlying liver. Each kidney is approximately 11 cm long, 5 to 6 cm wide, and 3 to 4 cm thick. A tightly adhering **renal capsule** surrounds each kidney, which is embedded in a mass of perirenal fat. The capsule and fatty layer are covered with a double layer of **renal fascia**, which is composed of fibrous tissue and attaches the kidney to the posterior abdominal wall. A cushion of adipose tissue and the position of the kidney between the abdominal organs and muscles of the back protect it from trauma.

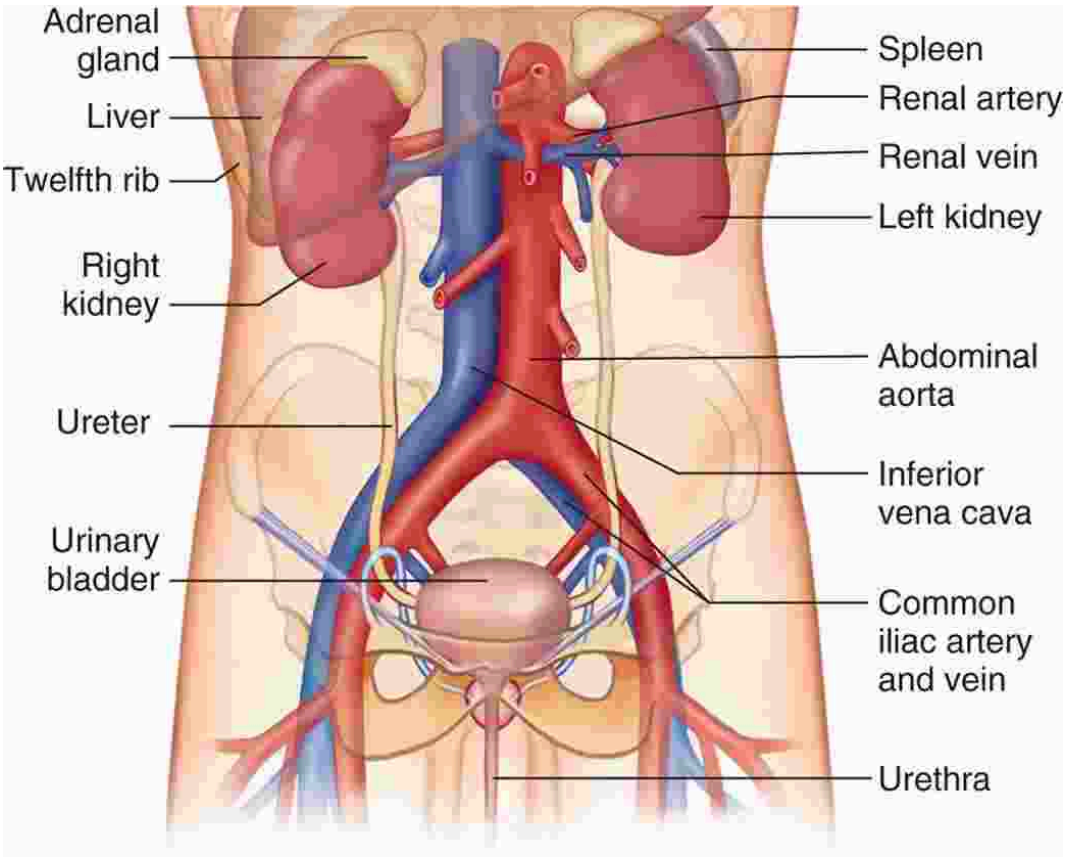

FIG. 37.1 Organs of the Urinary System. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

An illustration of the urinary system shows and labels the following structures, clockwise from the top-right: spleen, renal artery, renal vein, left kidney, abdominal aorta, inferior vena cava, common iliac artery and vein, urethra, urinary bladder, ureter, right kidney, twelfth rib, liver, and adrenal gland.

The internal structures of the kidney are summarized in Fig. 37.2. The **hilum** is a medial indentation in the kidney and is the location of the entry and exit for the renal blood vessels, nerves, lymphatic vessels, and ureter. The outer layer of the kidney is called the **cortex**. The **medulla** forms the inner part of the kidney and consists of regions called **pyramids. Renal columns** are an extension of the cortex and extend between the pyramids to

the renal pelvis. The apexes of the pyramids project into **minor calyces** (cup-shaped cavities) that unite to form **major calyces**. The minor and major calyces are chambers receiving urine from the collecting ducts and form the entry into the renal pelvis. The renal pelvis is an extension of the upper ureter. The walls of the calyces, pelvis, and ureter are lined with epithelial cells and contain smooth muscle cells that contract to move urine to the bladder. The **lobe** is the structural unit of the kidney. Each lobe is composed of a pyramid and the overlying cortex. There are about 14 to 18 lobes in each kidney.

Nephron

The **nephron** is the functional unit of the kidney. Each kidney contains approximately 1.2 million nephrons. The nephron is a tubular structure with subunits that include the renal corpuscle, proximal tubule (PT), loop of Henle, distal tubule, and collecting duct, all of which contribute to the formation of final urine (Fig. 37.3). The different structures of the epithelial cells lining various segments of the tubule facilitate the special functions of secretion and reabsorption (Fig. 37.4). The cortex contains the renal corpuscle, most of the PTs, and some segments of the distal tubule. The renal pyramids in the medulla contain the loops of Henle and collecting ducts. The kidney has three kinds of nephrons: (1) superficial **cortical nephrons** (85% of all nephrons), which originate close to the surface of the cortex or in the midcortex and extend partially into the medulla; (2) **midcortical nephrons** with short or long loops; and (3) **juxtamedullary nephrons** (about 12% of nephrons), which lie near and have long loops that extend deep into the medulla (about 40 mm) and are important for the concentration of urine (Fig. 37.5).

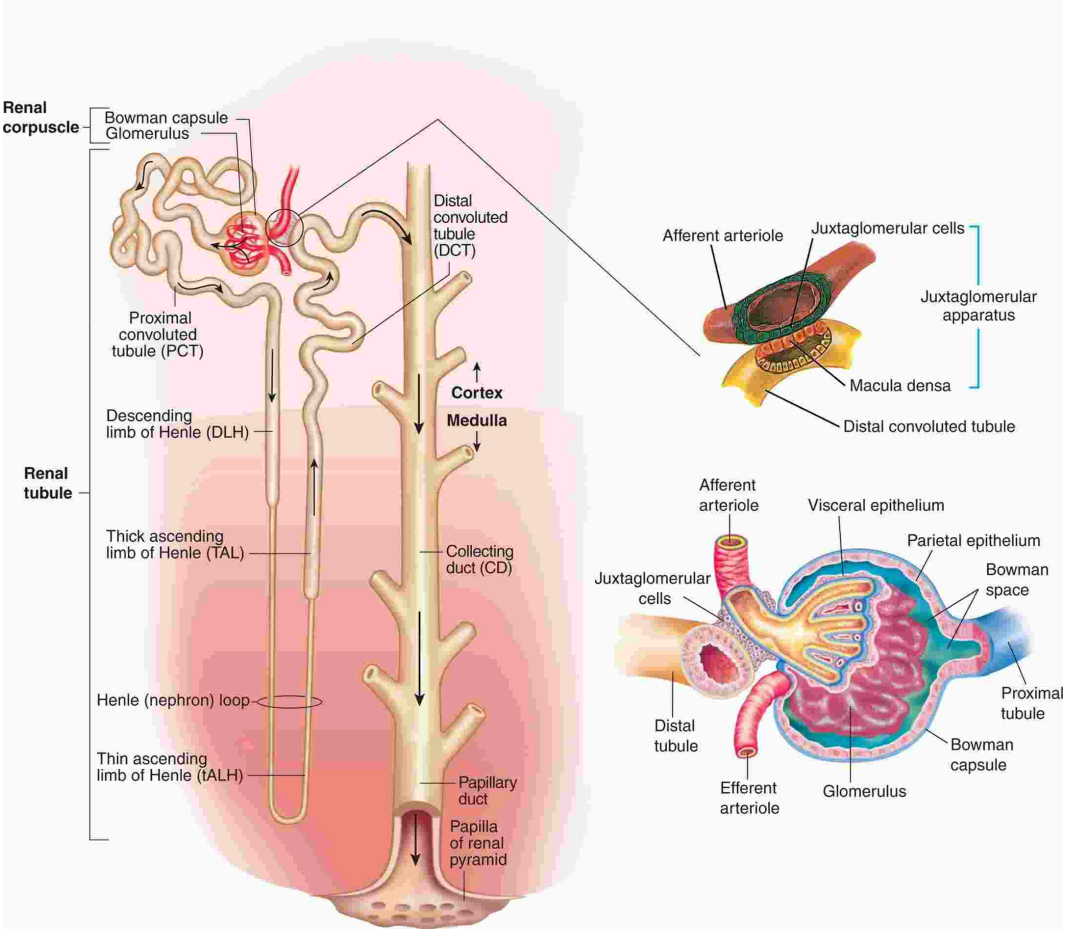

FIG. 37.3 Components of the Nephron. (From Patton, KT. *Anatomy and physiology*, 10th edition. St. Louis: Elsevier; 2019; Applegate EJ. *The anatomy and physiology learning system*, 4th edition. St. Louis: Saunders; 2011.)

An illustration shows the components of the nephron. The renal corpuscle comprises Bowman capsule and glomerulus. The renal tubule comprises the following structures: proximal convoluted tubule (P C T), descending limb of Henle (D L H), thick ascending limb of Henle (T A L), Henle (nephron) loop, and thin ascending limb of Henle (t A L H). Arrows indicate the flow. Additional structures identified include distal convoluted tubule (D C T), toward cortex, toward medulla, collecting

duct (C D), papillary duct, and papilla of renal pyramid. An accompanying illustration of the magnified view of the juxtaglomerular apparatus shows and labels the following structures: afferent arteriole, juxtaglomerular cells, macula densa, and distal convoluted tubule. An accompanying illustration of the cross-section of the juxtaglomerular apparatus shows and labels the following structures, clockwise from the top: visceral epithelium, parietal epithelium, Bowman space, proximal tubule, Bowman capsule, glomerulus, efferent arteriole, distal tubule, juxtaglomerular cells, and afferent arteriole.

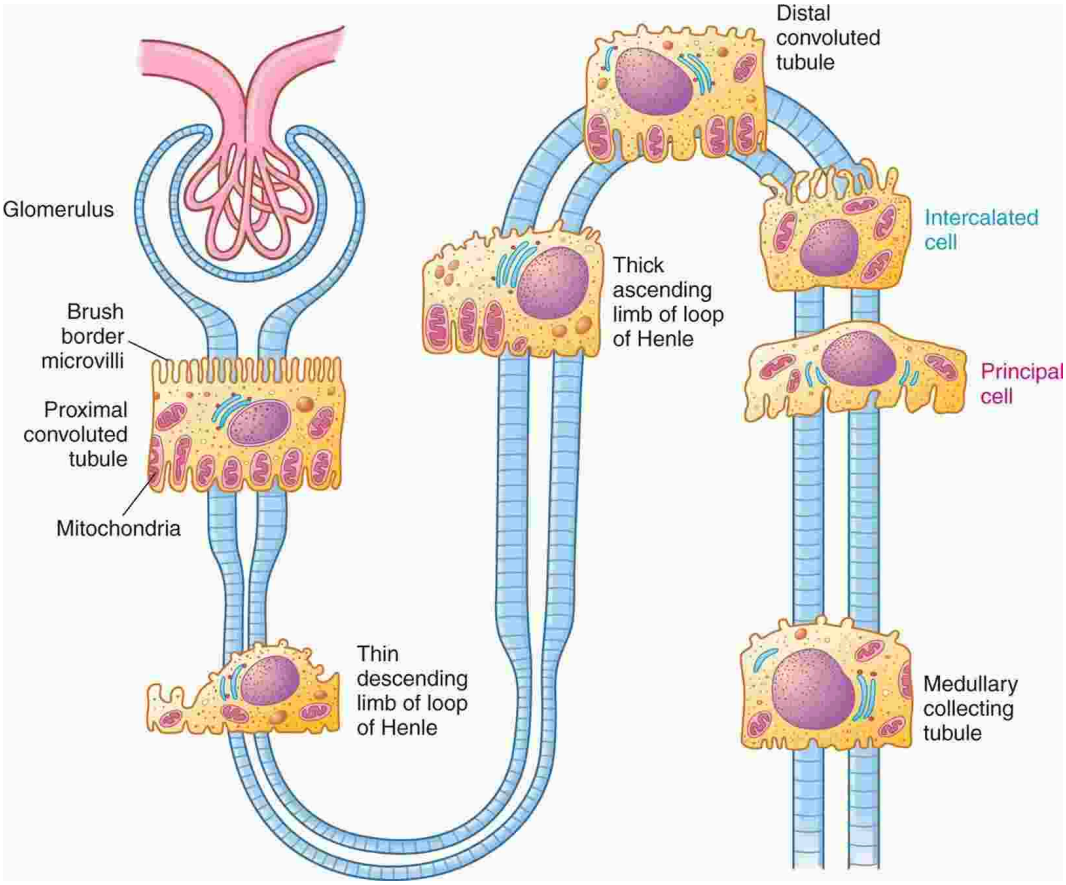

FIG. 37.4 Epithelial Cells of the Various Segments of Nephron Tubules.
The proximal tubule is the only segment of the nephron that has a brush border, and the increased surface area promotes reabsorption of 50% of the glomerular filtrate.

An illustration shows the epithelial cells of the various segments of nephron tubules. • Brush border microvilli; proximal convoluted tubule; mitochondria. • Thin descending limb of loop of Henle. • Thick ascending limb of loop of Henle. • Distal convoluted tubule. • Intercalated cell. • Principal cell. • Medullary collecting tubule.

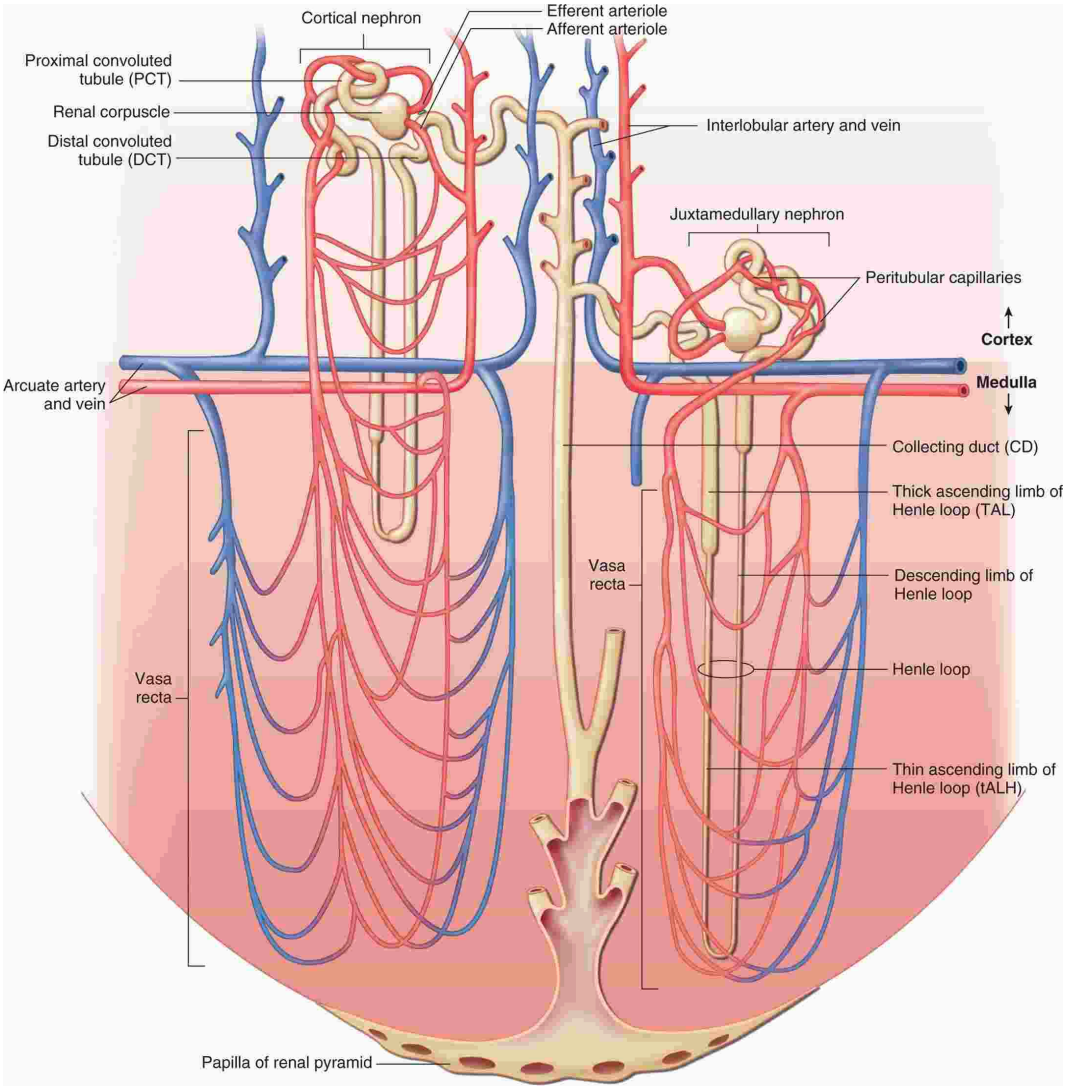

FIG. 37.5 Nephron Unit With Its Blood Vessels. Blood flows through nephron vessels as follows: interlobular artery, afferent arteriole, glomerulus, efferent arteriole, peritubular capillaries (around the tubules), venules, interlobular vein. (From Patton, KT. *Anatomy and physiology*, 10th edition. St. Louis: Elsevier; 2019:974.)

An illustration shows a nephron unit with its blood vessels. Toward cortex: cortical nephron (proximal convoluted tubule or P C T, renal corpuscle, distal convoluted tubule or D C T, efferent arteriole, and afferent arteriole), interlobular artery and vein, and juxtamedullary

nephron (peritubular capillaries). Toward medulla: collecting duct (C D), thick ascending limb of Henle loop (T A L), descending limb of Henle loop, Henle loop, and thin ascending limb of Henle loop (t A L H), all comprising the vasa recta. The arcuate artery and vein and papilla of renal pyramid are also labeled.

The **renal corpuscle** is composed of the glomerulus, Bowman (glomerular) capsule, and Bowman space. The **glomerulus** is a tuft of capillaries that loop into the **Bowman space**, like a fist pushed into bread dough. The Bowman space is continuous with the lumen of the renal tubules. **Mesangial cells** (shaped like smooth muscle cells) secrete the **mesangial matrix** (a type of connective tissue) and lie between and support the glomerular capillaries. Different mesangial cells contract like smooth muscle cells to regulate glomerular capillary blood flow. Mesangial cells also have phagocytic abilities similar to monocytes and release inflammatory cytokines and growth factors.

The **glomerular filtration membrane** filters blood components through three layers: (1) an inner capillary endothelium, (2) a middle basement membrane, and (3) an outer layer of capillary or visceral epithelium. The capillary endothelium is composed of cells in continuous contact with the basement membrane and contains pores. The pores are maintained by vascular epithelial growth factor (VEGF) produced by the visceral epithelium. The endothelial cells synthesize nitric oxide (a vasodilator) and endothelin-1 (a vasoconstrictor) that help regulate glomerular blood flow. The middle basement membrane is a selectively permeable membrane made up of a network of proteoglycans (type IV collagen) secreted and maintained by the epithelial cells. The epithelium has specialized cells called **podocytes** from which pedicles or projections radiate and adhere to the basement membrane. Pedicles from adjacent podocytes interlock, forming an elaborate network of intercellular clefts called **filtration slits**, or slit membranes (Fig. 37.6) that modulate filtration. Transcellular protein molecules ensure proper function of the filtration slits and, when altered, cause glomerular disease.[1]

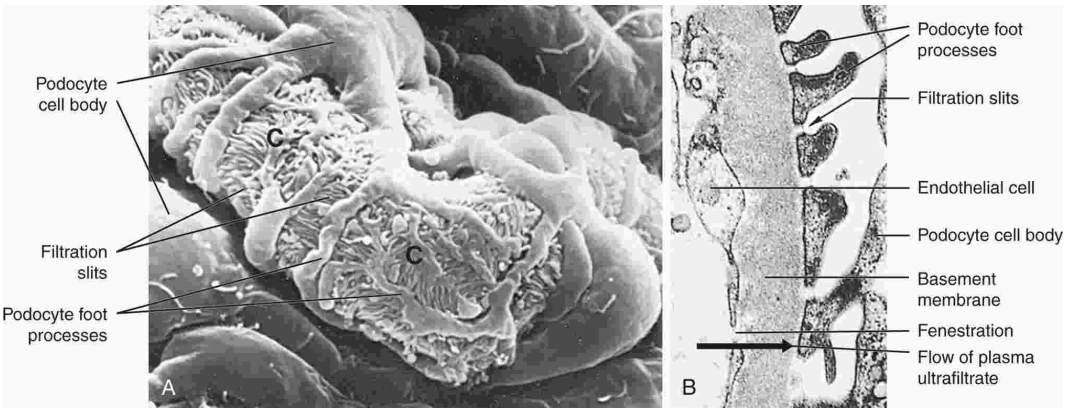

FIG. 37.6 Glomerular Capillary.
(A) Scanning electron micrograph of normal glomerular capillary *(C)*. **(B)** Glomerular capillary wall (filtration membrane) (×40,000). Black arrow indicates direction of urine flow. (From Kissane JM, ed. *Anderson's pathology*, 9th edition. St. Louis: Mosby; 1990.)

Left panel, A. A photomicrograph of a glomerular capillary shows and labels the following structures: podocyte cell body, filtration slits, and podocyte foot processes. C marks the capillaries. Right panel, B. A photomicrograph of the glomerular capillary wall shows and labels the following structures: podocyte foot processes, filtration slits, endothelial cell, podocyte cell body, basement membrane, fenestration, and flow of plasma ultrafiltrate. An arrow from the left to the right indicates the flow.

The endothelium, basement membrane, and podocytes are covered with protein molecules bearing negative (anionic) charges that retard the filtration of anionic proteins, preventing proteinuria. The glomerular filtration membrane separates the blood within the glomerular capillaries from the fluid (filtrate) in the Bowman space. The membrane allows all components of the blood to be filtered with the exception of blood cells and plasma proteins with a high molecular weight (most of the plasma

proteins). The glomerular filtrate passes through the three layers of the glomerular membrane and forms the primary urine.

The glomerulus is supplied by the afferent arteriole and drained by the efferent arteriole. A group of specialized cells known as **juxtaglomerular cells** (renin-releasing cells) are located around the afferent arteriole where it enters the glomerulus. Between the afferent and efferent arterioles is the **macula densa** (sodium-sensing cells) of the distal tubule. Together the juxtaglomerular cells, macula densa cells, and mesangial cells form the **juxtaglomerular apparatus (**JGA**)**. Control of renal blood flow (RBF), glomerular filtration, and renin secretion occurs at this site.

The **proximal tubule**, the first segment of the renal tubule, extends from the Bowman space. The PT has an initial convoluted segment that leads into a straight segment that descends toward the medulla (see Fig. 37.3). The wall of the proximal tubule consists of one layer of cuboidal epithelial cells with a surface layer of microvilli (a brush border) that increases the reabsorptive surface area. This is the only surface inside the nephron where the cells are covered with a brush border of microvilli (see Fig. 37.4). Sodium-coupled bicarbonate absorption from renal PTs provides a significant role in the maintenance of systemic acid/base balance (see Chapter 3). The early section of the PT also expresses a sodium glucose transporter (SGLT) known as SGLT2. SGLT2 belongs to a family of molecular carriers for transport of sugars, vitamins, amino acids, or smaller organic ions such as choline. SGLT2 reabsorbs approximately 90% of filtered glucose, and SGL2 inhibitors (gliflozins) have been developed as an oral medication for the treatment of type 2 diabetes mellitus (see Chapter 22).[2]

The PT joins the **loop of Henle**, which extends into the medulla. The loop is composed of a thin descending segment, a thin ascending segment, and a thick ascending segment. The thin descending segment is composed of squamous cells, has no active transport functions, and is highly permeable to water. The thin ascending segment is permeable to ions but not to water. The cells of the thick ascending segment are cuboidal and actively transport ions, particularly sodium, potassium, calcium, and magnesium into the interstitium, and pass urine into the distal convoluted tubule (see Fig. 37.14).

The **distal tubule** is shorter than the PT but also has straight and convoluted segments. It extends from the ascending loop of Henle to connecting tubules. An array of distal tubules joins into a **connecting tubule** and thus drains several nephrons. The connecting tubule then drains into a collecting duct. The **collecting duct** is a large tubule that descends down the

cortex and through the renal pyramids of the inner and outer medullae, draining urine into the minor calyx. In the distal tubule, **principal cells** reabsorb sodium and secrete potassium, and **intercalated cells** secrete hydrogen and reabsorb potassium and bicarbonate (see Fig. 37.4). These cells are important for maintaining fluid and electrolyte and acid-base balance.

Blood Vessels of the Kidney

The blood vessels of the kidney closely parallel the nephron's structure (see Fig. 37.5). The major vessels are as follows:

1. **Renal arteries** (see Fig. 37.2) arise as the fifth branches of the abdominal aorta, divide into anterior and posterior branches at the renal hilum, and then subdivide into lobar arteries supplying blood to the lower, middle, and upper thirds of the kidney.
2. **Interlobar arteries** are lobar subdivisions that travel down renal columns and between pyramids to form afferent glomerular arteries.
3. **Arcuate arteries** consist of branches of interlobar arteries at the cortical-medullary junction; they arch over the base of the pyramids and run parallel to the surface.
4. **Glomerular capillaries** consist of four to eight vessels and are arranged in a fistlike structure; they arise from the **afferent arteriole** and empty into the **efferent arteriole**, which carries blood to the peritubular capillaries. They are the major resistance vessels for regulating intrarenal blood flow (see Autoregulation of Intrarenal Blood Flow in the Renal Blood Flow section).
5. **Peritubular capillaries** surround convoluted portions of the proximal and distal tubules and the loop of Henle; they are adapted for cortical and juxtamedullary nephrons.
6. **Vasa recta** is a network of capillaries that forms loops and closely follows the loops of Henle; it is the only blood supply to the medulla (important for formation of concentrated urine).
7. **Renal veins** follow the arterial path in reverse direction and have the same names as the corresponding arteries; they eventually empty into the inferior vena cava. The lymphatic vessels also tend to follow the distribution of the blood vessels.

Urinary Structures

Ureters

The urine formed by the nephrons flows from the distal tubules and collecting ducts through the papillary ducts to the **renal papillae** (projections of the ducts) into the calyces, where it is collected in the renal pelvis (see Fig. 37.2). The urine is then funneled into the **ureters** (see Figs. 37.1 and 37.7). Each adult ureter is approximately 30 cm long and is composed of long, intertwining smooth muscle bundles. The lower ends pass through the posterior aspect of the bladder wall. The close approximation of smooth muscle cells in the ureter permits the direct transmission of electrical stimulation from one cell to another, resulting in downward peristaltic contraction, which propels urine into the bladder. Contraction of the bladder during **micturition** (urination) compresses the lower end of the ureter, preventing reflux. Peristalsis is maintained even when the ureter is denervated, so ureters can be transplanted.

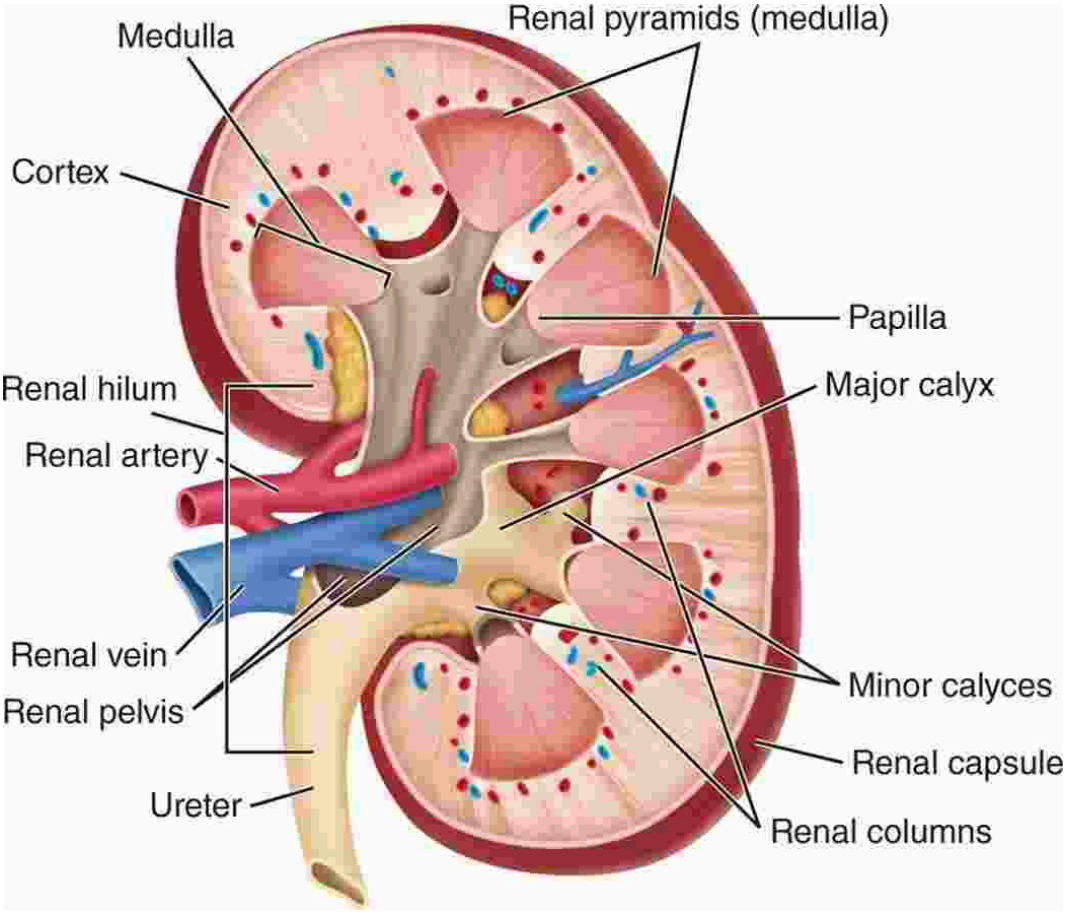

FIG. 37.2 Internal Structure of the Kidney. (From Solomon E. *Introduction to human anatomy and physiology*. 4th edition. St. Louis: Saunders; 2016.)

An illustration of the cross-section of the right kidney shows and labels the following structures, clockwise from the top-right: renal pyramids (medulla), papilla, major calyx, minor calyces, renal capsule, renal columns, ureter, renal pelvis, renal vein, renal artery, renal hilum, cortex, and medulla.

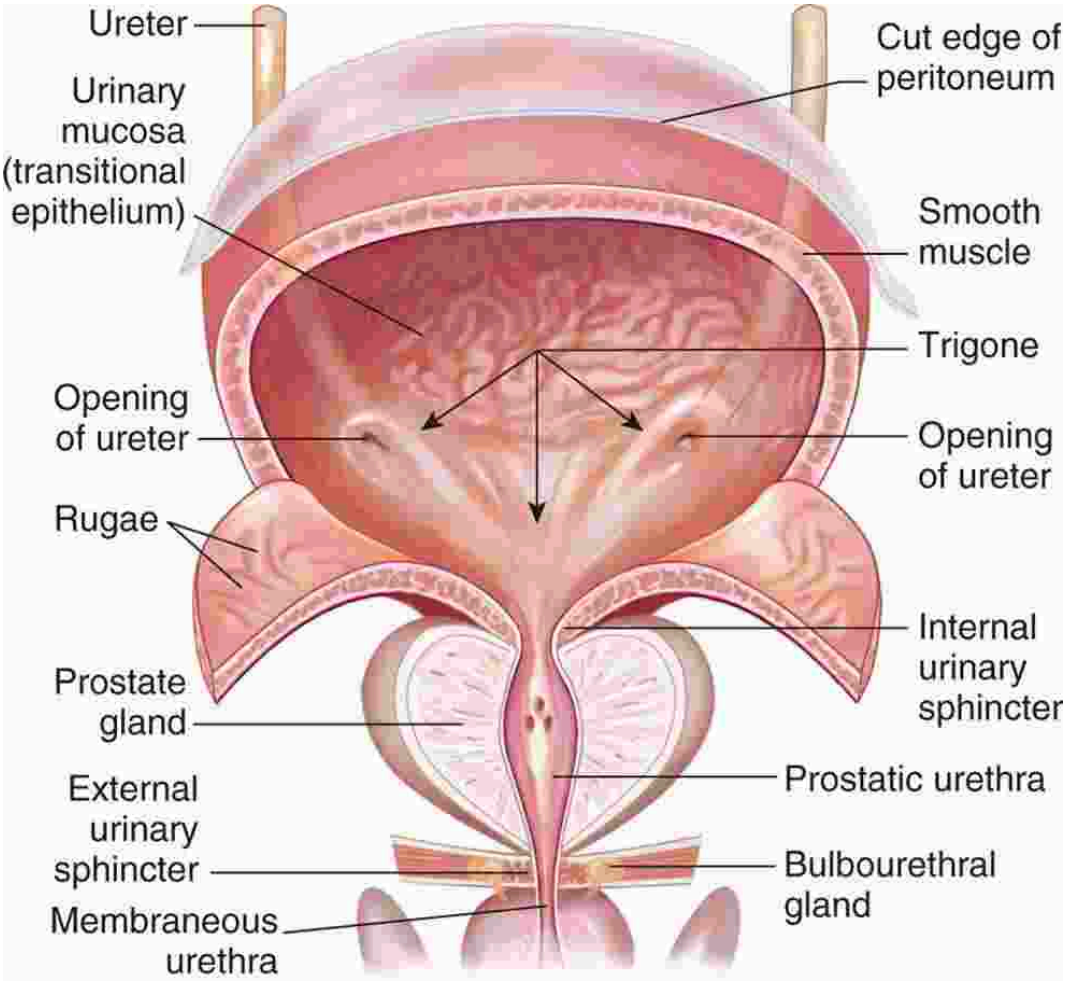

FIG. 37.7 Structure of the Urinary Bladder.
Frontal view of a dissected urinary bladder (male) in a fully distended position. No prostate is present in females. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby, 2018.)

An illustration showing the cross-sectional view of the urinary bladder labels the following structures: clockwise from the right: cut edge of peritoneum, smooth muscle, trigone, opening of ureter, internal urinary sphincter, prostatic urethra, bulbourethral gland, membranous urethra, external urinary sphincter, prostate gland, rugae,

opening of ureter, urinary mucosa (transitional epithelium), and ureter.

Sensory innervation for the upper part of the ureter arises from sympathetic inputs from the tenth thoracic nerve. The innervation of lower segments arises from parasympathetic sacral nerves. Ureteral pain (e.g., pain from a kidney stone in the ureter) can be referred pain to the flank, umbilicus, vulva, or penis. The ureters have a rich blood supply. The upper part of the ureter is supplied by the renal arteries; the middle part is supplied by the common iliac arteries and branches from the abdominal aorta and gonadal arteries; and the lower part of the ureter is supplied mainly by branches from the internal iliac and vesical arteries.

Bladder and Urethra

The **bladder** is a bag made of smooth muscle fibers that forms the **detrusor muscle** with its smooth lining of uroepithelium. As the bladder fills with urine, it distends and the layers of uroepithelium within the lining slide past each other and become thinner as bladder volume increases. The **uroepithelium** (transitional epithelium) forms the interface between the urinary space and the underlying vasculature and connective, nervous, and muscle tissue. Uroepithelium also lines the urinary tract from the renal pelvis to the urethra. The uroepithelium maintains an important barrier function to prevent movement of water and solutes between the urine and the blood. It communicates information about urine pressure and composition to surrounding nerve and muscle cells. The **trigone** is a triangular area of smooth muscle between the openings of the two ureters and the urethra (see Fig. 37.7). The position of the bladder varies with sex and age. In infants and young children, the bladder rises above the symphysis pubis, providing easy access for percutaneous aspiration. In adult females, the bladder is anterior to the vagina and inferior to the uterus. In adult males, the bladder lies between the pubic symphysis and rectum. The bladder has a profuse blood supply, accounting for the bleeding that readily occurs with trauma, surgery, or inflammation.

The **urethra** extends from the inferior side of the bladder to the outside of the body. A ring of smooth muscle forms the **internal urethral sphincter** at the junction of the urethra and bladder and is under involuntary muscle control. The **external urethral sphincter** is composed of striated skeletal muscle and is under voluntary motor control. The entire urethra is lined

with mucus-secreting glands. The female urethra is short (3 to 4 cm). The male urethra is long (18 to 20 cm) and has three main segments: prostatic, membranous, and penile. The prostatic urethra is closest to the bladder. It passes through the prostate gland and contains the openings of the ejaculatory ducts. Prostatic enlargement can obstruct the flow of urine in this segment. The membranous urethra passes through the floor of the pelvis. The penile segment forms the remainder of the tube. It is surrounded by the corpus spongiosum erectile tissue and contains the openings of the bulbourethral glands (see Figs. 24.11 and 24.15).

The innervation of the bladder and internal urethral sphincter is supplied by parasympathetic fibers of the autonomic nervous system that arise from the sacral levels of the spinal cord (S2 to S4) and contribute to bladder contraction and urine emptying. Sympathetic fibers originate from T11-L2 and inhibit the bladder body and excite the lower bladder and proximal urethral sphincter to retain urine. Sensory fibers from the bladder and urethra may extend as high as the T6 portion of the spinal cord. Somatic motor neurons in the pudendal nerve innervate the striated external urethral sphincter. The detrusor muscle is innervated by sympathetic nervous system fibers from the lumbar spinal cord and parasympathetic fibers from the sacral spinal cord. The reflex arc required for micturition is stimulated by mechanoreceptors that respond to stretching of tissue, sensing bladder fullness, and sending impulses to the sacral level of the cord. When the bladder accumulates 250 to 300 mL of urine, the bladder contracts and the internal urethral sphincter relaxes through activation of the spinal reflex arc (known as the *micturition reflex*). At this time, a person feels the urge to void. The reflex can be inhibited or facilitated by impulses coming from the brain, resulting in voluntary control of micturition by the relaxation or contraction of the external sphincter.

Renal Blood Flow and Glomerular Filtration

The kidneys are highly vascular organs and usually receive 1000 to 1200 mL of blood per minute, or about 20% to 25% of the cardiac output. With a normal hematocrit of 45%, about 600 to 700 mL of blood flowing through the kidney per minute is plasma. Of the renal plasma flow (RPF), 20% (approximately 120 to 140 mL/min) is filtered at the glomerulus and passes into the Bowman capsule. (The remaining 80% of plasma flows through the efferent arterioles to the peritubular capillaries.) The filtration of the plasma per unit of time is known as the **glomerular filtration rate (GFR)** (e.g., 120 to 140 mL/min), which is directly related to the perfusion pressure of the

glomerular capillaries. The ratio of glomerular filtrate to RPF per minute (e.g., 120/600 = 0.20) is called the *filtration fraction*. Normally, all but 1 to 2 mL/min of the glomerular filtrate is reabsorbed from nephron tubules and returned to the circulation by the peritubular capillaries.

The GFR is directly related to the RBF, which is regulated by intrinsic autoregulatory mechanisms, by neural regulation, and by hormonal regulation. In general, blood flow to any organ is determined by the arteriovenous pressure differences across the vascular bed. If the mean arterial pressure decreases or the vascular resistance increases, the RBF declines and urinary output decreases. Normal urinary output is about 30 mL/h minimum in adults or 0.5 to 1.0 mL/kg/h.

Autoregulation of Intrarenal Blood Flow

In the kidney, the autoregulation of the glomerular blood flow helps keep the GFR fairly constant over a range of systemic arterial pressures between 80 and 180 mm Hg (Fig. 37.8). This is necessary to maintain the clearance of metabolic wastes and the reabsorption of filtered electrolytes and nutrients by the renal tubules with the normal variations in systemic blood pressure. For example, systemic blood pressure increases during exercise and decreases during rest, but nephron blood flow and GFR remain fairly constant. This mechanism is known as the **autoregulation of intrarenal blood flow**.[3] It is maintained by two mechanisms working together to control the tone of the glomerular afferent arteriole. One mechanism responds to changes in afferent arterial pressure and another responds to changes in the sodium chloride concentration of the distal tubular fluid.

1. When the systemic blood pressure (perfusion pressure) in the afferent arteriole of each nephron increases causing stretch of the vessel, an intrinsic autoregulatory **myogenic mechanism** of afferent arteriolar contraction increases resistance, thus maintaining constant flow and GFR and also protecting the glomerulus from high filtration pressure. The opposite occurs with a decrease in the systemic blood pressure.
2. The **tubuloglomerular feedback mechanism** (Fig. 37.9) involves the macula densa cells in the distal tubule, the renin secreting juxtaglomerular cells of the afferent arteriole and mesangial cells. The macula densa cells are adjacent to the extraglomerular mesangial cells, which fill the angle formed by the afferent and

efferent arterioles of the glomerulus. This anatomic arrangement of macula densa cells, extraglomerular mesangial cells, afferent arteriolar smooth muscle cells, and renin-secreting cells of the afferent arterioles is known as the *juxtaglomerular apparatus*. As the blood pressure increases or decreases, the macula densa epithelial cells sense the resulting increase or decrease in the filtered amounts of sodium in the distal tubule. When the GFR and sodium concentration increase, the macula densa cells "feedback to" or stimulate afferent arteriolar vasoconstriction and decrease glomerular pressure and GFR, returning it to a normal range and preventing sodium loss. The decreased sodium load then entering the tubule inhibits tubuloglomerular feedback, shutting down the feedback system. When the blood pressure decreases, the juxtaglomerular cells secrete renin, resulting in an increase in blood pressure and an increase in GFR (See Section on Hormones and Other Factors Regulating RBF). Mesangial cells are also thought to contribute to afferent arteriolar vasoconstriction by contracting and secreting renin.[4]

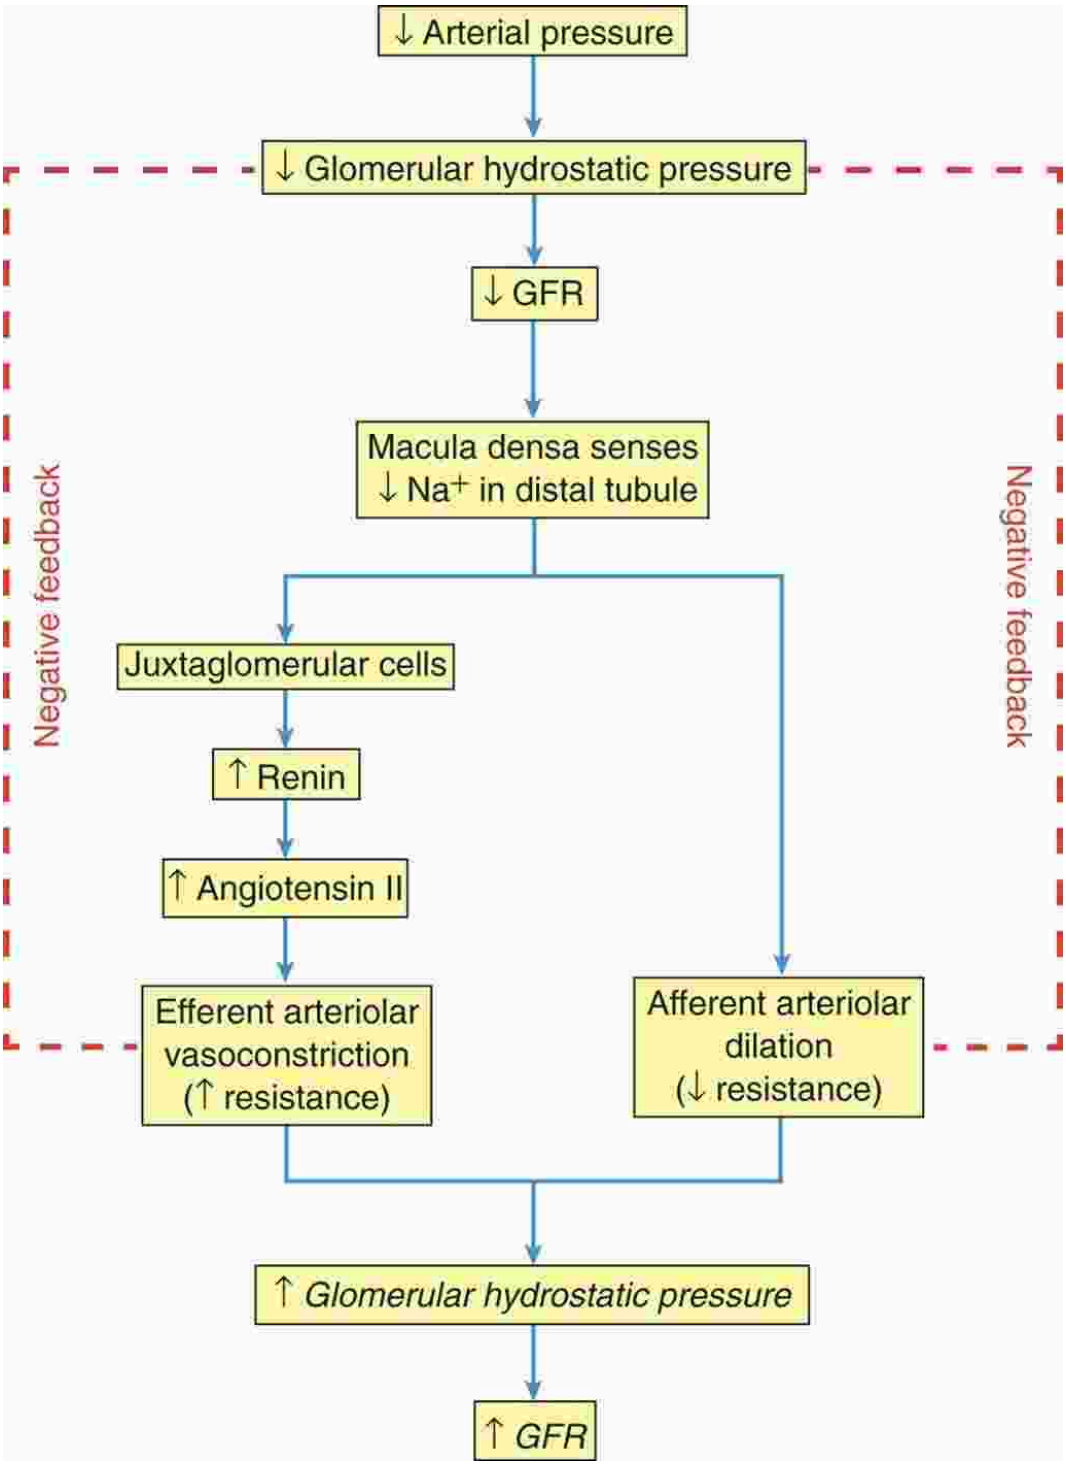

FIG. 37.9 Tubuloglomerular Feedback.
Negative feedback increases glomerular hydrostatic pressure and GFR. See text for details. *GFR*, Glomerular filtration rate.

A flowchart shows the tubuleglomerular feedback. 1. Decreased arterial pressure. Leads to 2. 2. Decreased glomerular hydrostatic pressure. Leads to 3. Negative feedback from 8 and 9. 3. Decreased G F R. Leads to 4. 4. Macula densa senses decreased sodium ions in distal tubule. Leads to 5 and 9. 5. Juxtaglomerular cells. Leads to 6. 6. Increased renin. Leads to 7. 7. Increased angiotensin 2. Leads to 8. 8. Efferent arteriolar vasoconstriction (increased resistance). Leads to 10. Negative feedback to 2. 9. Afferent arteriolar dilation (decreased resistance). Leads to 10. Negative feedback to 2. 10. Increased glomerular hydrostatic pressure. Leads to 11. 11. Increased G F R.

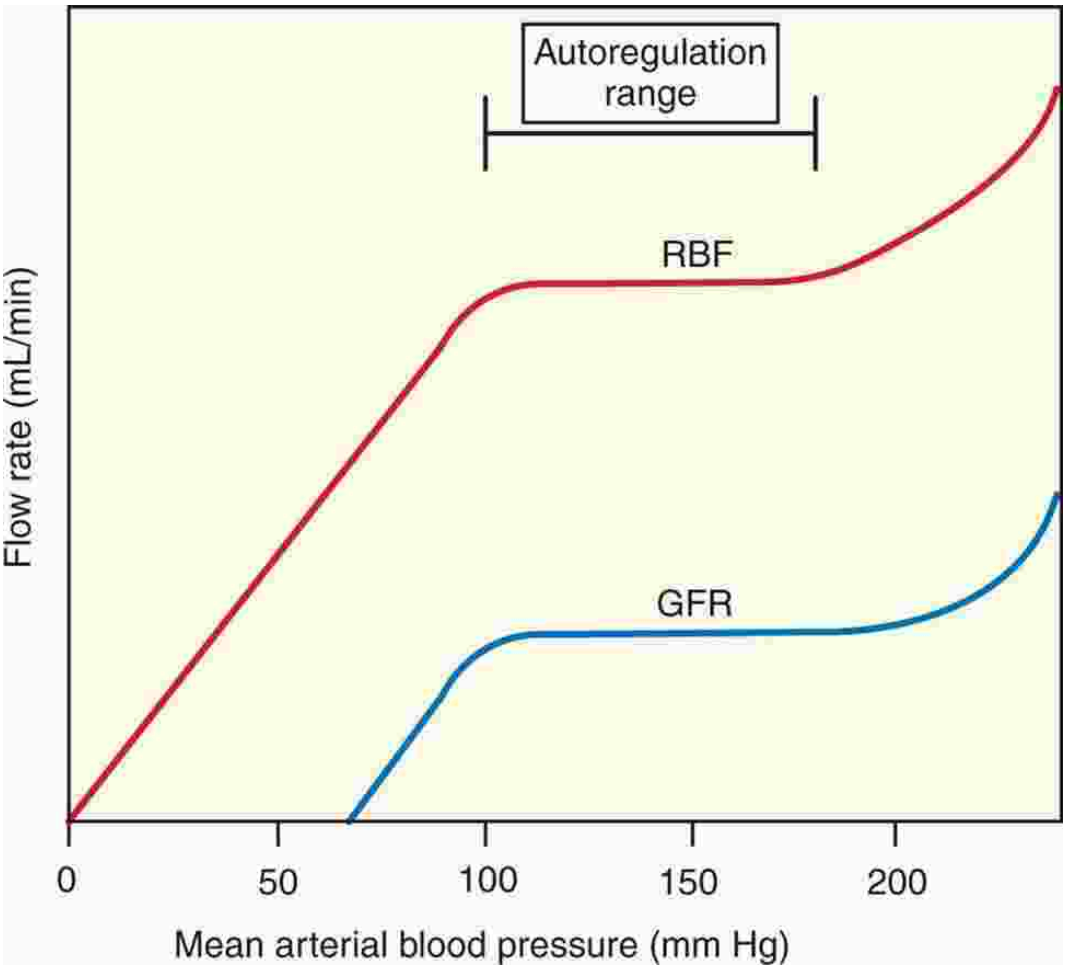

FIG. 37.8 Renal Autoregulation.
Renal blood flow *(RBF)* and glomerular filtration rate *(GFR)* are stabilized in the face of changes in perfusion pressure.

A graph plots flow rate in milliliters per minute over mean arterial blood pressure in millimeters of mercury. The autoregulation range is identified between 100 and 175 millimeters of mercury. Two curves are plotted on the graph. G F R rises linearly from 75 millimeters of mercury to about 100 millimeters of mercury. It stabilizes until 200 millimeters of mercury, after which it rises upward in a concave up manner. R B F rises linearly from 0 millimeters of mercury to about 100 millimeters of mercury. It

stabilizes until about 175 millimeters of mercury, after which it rises in a concave up manner. R B F is above G F R.

Neural Regulation of Renal Blood Flow

The blood vessels of the kidney are innervated by sympathetic nerve fibers located primarily on afferent arterioles. When the systemic arterial pressure decreases, increased renal sympathetic nerve activity is mediated reflexively through the carotid sinus and the baroreceptors of the aortic arch. The renal sympathetic nerves release catecholamines. This stimulates afferent renal arteriolar vasoconstriction and decreases the RBF and GFR, increases renal tubular sodium and water reabsorption, and increases the systemic blood pressure. Decreased afferent renal sympathetic nerve activity produces the opposite effects. The integrated response regulates water and sodium balance. **Renalase** is a hormone released by the kidney, heart, and other organs. It is a growth factor that maintains renal tubular function and, as a monoamine oxidase, promotes the metabolism of catecholamines and, in this way, participates in lowering the blood pressure and GFR. Renalase also has a protective role in cardiovascular and chronic kidney diseases. (See Emerging Science Box: Renalase). The sympathetic nervous system also participates in hormonal regulation of the RBF (i.e., stimulates the renin-angiotensin-aldosterone system [RAAS]). There is no significant parasympathetic innervation. The innervation of the kidney arises primarily from the celiac ganglion and greater splanchnic nerve.

Emerging Science BoxRenalase

Renalase is highly expressed in the proximal tubule, but also in the heart, skeletal muscle and small intestine. Elevated plasma catecholamines activate renalase enzymatic activity and lead to a threefold to fourfold stimulation of renalase secretion, causing a significant fall in blood pressure. Renalase single nucleotide polymorphisms (a variation at a single position in a DNA sequence) are found to be associated with essential hypertension, higher left ventricular mass index, lower left ventricular ejection fraction, lower exercise capacity and ischemic stroke. Increases in renalase signaling, independent of its enzymatic activity in breaking down catecholamines, are known to improve cardiac and renal

function by activating cytoprotective intracellular signals to lower blood pressure, protect ischemic tissue via anti-apoptotic and anti-inflammatory mechanisms, and promote atherosclerotic plaque stability in cardiovascular disease. Renal function also affects renalase levels, and serum renalase levels are higher in individuals with chronic kidney disease. Renalse may have a pathologic role in the survival and growth of cancer cells, particularly malignant melanoma. Anti-renalase therapy in mouse models decreased melanoma cell survival, and blocked tumor growth. Mechanisms of renalase regulation are not well understood, and elevations may be associated with increased production and secretion, limited filtration or increased reabsorption under conditions of increased demand in different disease states. Efforts are in progress to develop more standardized and validated methods to evaluate the activity and levels of renalase in tissue and body fluids, including blood and urine. These measures will help to distinguish the pathophysiological relevance and diagnostic/therapeutic utility of renalase as a biomarker of disease and guide the development of both replacement therapy and/or inhibition.

Hormones and Other Factors Regulating Renal Blood Flow

Hormones and other mediators can alter the resistance of the renal vasculature by stimulating vasodilation or vasoconstriction. A major hormonal regulator of RBF is the RAAS, which can increase systemic

arterial pressure, reabsorption of sodium and water, and RBF. Renin is an enzyme formed and stored in the granular cells of the afferent arterioles of the JGA. Renin release is triggered by a decreased blood pressure in the afferent arterioles, a decreased sodium chloride concentration in the distal convoluted tubule, sympathetic nerve stimulation of β-adrenergic receptors on the juxtaglomerular cells, and the release of prostaglandins.

When renin is released, it cleaves an α-globulin (angiotensinogen produced by liver hepatocytes) in the plasma to form angiotensin I, which is physiologically inactive. In the presence of angiotensin-converting enzyme (ACE) produced from the pulmonary and renal endothelium, angiotensin I is converted to angiotensin II. **Angiotensin II** stimulates secretion of aldosterone by the adrenal cortex, is a potent vasoconstrictor, and stimulates antidiuretic hormone (ADH) secretion and thirst.

Numerous physiologic effects of the RAAS stabilize the systemic blood pressure and preserve the extracellular fluid volume during hypotension or hypovolemia. Actions include sodium reabsorption, systemic vasoconstriction, sympathetic nerve stimulation, and thirst stimulation, with an increased fluid intake. The effects of aldosterone combine with those of ADH in regulating blood volume (Fig. 37.10).

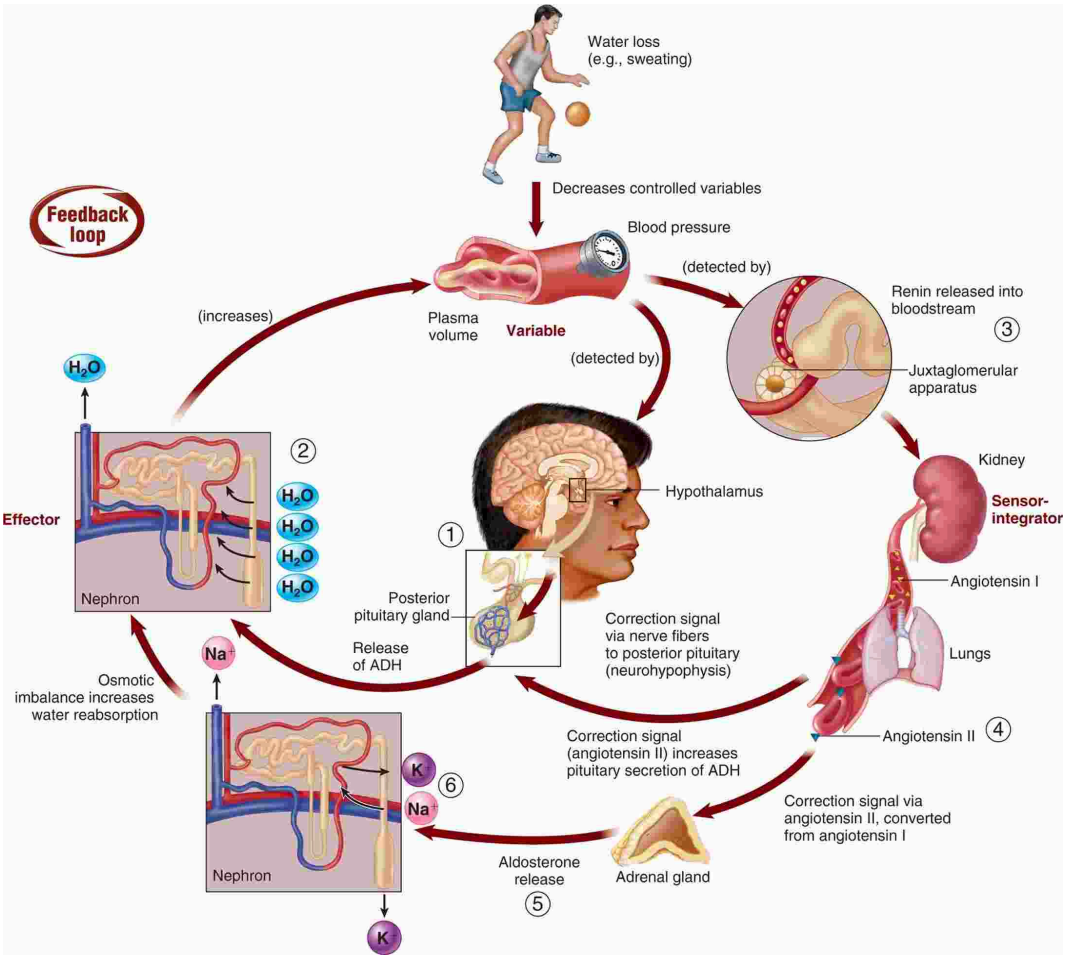

FIG. 37.10 Cooperative Roles of Antidiuretic Hormone (ADH) and Aldosterone in Regulating Urine and Plasma Volume.

The drop in blood pressure that accompanies loss of fluid from the internal environment triggers the hypothalamus to rapidly release ADH from the posterior pituitary gland **(1)**. ADH increases water reabsorption by the kidney by increasing water permeability of the distal tubules and collecting ducts **(2)**. The drop in blood pressure also is detected by each nephron's juxtaglomerular apparatus, which responds by secreting renin **(3)**. Renin triggers the formation of angiotensin II **(4)**, which stimulates release of aldosterone from the adrenal cortex **(5)**. Aldosterone then slowly boosts water reabsorption by the kidneys by increasing reabsorption of Na^+**(6)**. Because angiotensin II also stimulates secretion of ADH, it serves as an additional link between

the ADH and aldosterone mechanisms. (From Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Mosby; 2019)

An illustrated flowchart shows the cooperative roles of antidiuretic hormone and aldosterone in regulating urine and plasma volume. 1. An illustration shows the right lateral view of a person's head with the brain highlighted. The hypothalamus is highlighted. An accompanying illustration shows a magnified view of the posterior pituitary gland. The gland releases A D H. 2. The A D H triggers the nephron, which absorbs and releases water through the effector, increasing plasma volume. Complemented by water loss (example, sweating), the blood pressure decreases. 3. The drop in pressure is detected by the brain and the juxtaglomerular apparatus. Renin is released into bloodstream, triggering the kidney (sensor-integrator). 4. Angiotensin 1 passes through the lungs, sending correction signal via nerve fibers to posterior pituitary (neurohypophysis) and via angiotensin 2, converted from angiotensin 1, to the adrenal gland. Correction signal (angiotensin 2) increases pituitary secretion of A D H. 5. The adrenal gland releases aldosterone. 6. The nephron releases potassium ions and absorbs sodium ions. Sodium ions from the nephron generates an osmotic imbalance, which increases water reabsorption.

Natriuretic peptides are synthesized and released from the heart and are natural antagonists to the RAAS (see Fig. 3.5). Natriuretic peptides cause vasodilation, increase sodium and water excretion, and decrease the blood pressure. Thus, they assist in protecting the heart from volume overload. **Urodilatin** is a renal natriuretic peptide produced by cells in the distal

tubule and collecting duct. It increases RBF, causing diuresis. Other hormones and mediators that influence RBF are summarized in Table 37.1.

Table 37.1

Hormones, Mediators, and Renal Blood Flow

Hormone or Mediator	Effect on Renal Blood Flow
Adenosine	Produced within kidney; causes vasoconstriction of afferent arteriole; decreases RBF and GFR
Angiotensin II	Produced systemically and within kidneys; constricts afferent and efferent arterioles; decreases RBF and GFR
Atrial and brain natriuretic peptides	Produced by atria and ventricles of the heart with hypertension and increased blood volume; cause vasodilation of afferent arteriole and vasoconstriction of efferent arteriole; modest increase in GFR with little change in RBF
Bradykinin	Produced in kidney from kininogen and causes vasodilation by release of nitric oxide and prostaglandins; increases RBF and GFR
Dopamine	Produced by the proximal tubule; increases RBF; inhibits renin secretion
Endothelin	Produced by renal vessel endothelial cells, mesangial cells, and distal tubule cells in response to bradykinin, angiotensin II, epinephrine, and stretch; most active with renal disease; profound vasoconstriction of afferent and efferent arterioles; decreases RBF and GFR
Histamine	Produced locally within the kidney; modulates RBF in basal state and during inflammation; increases RBF by decreasing afferent and efferent arteriolar resistance and does not decrease GFR
Nitric oxide	Produced by renal vessel endothelial cells with increased stretch and by stimulation of acetylcholine, histamine, bradykinin, ATP;

Hormone or Mediator	Effect on Renal Blood Flow
	increases vasodilation of afferent and efferent arterioles
Prostaglandins, PGI_2, PGE_2	Produced locally within kidney with decreased RBF; dampen vasoconstriction caused by sympathetic nerves and angiotensin II; prevent harmful vasoconstriction and renal ischemia
Urodilatin (a natriuretic peptide)	Produced by distal tubule and collecting duct when there is increased circulating volume and increased blood pressure; inhibits sodium and water reabsorption from medullary part of collecting duct, thereby producing diuresis

ATP, Adenosine triphosphate; *GFR*, glomerular filtration rate; *PGE2*, prostaglandin E2; *PGI2*, prostaglandin I2; *RBF*, renal blood flow.

Kidney Function

Nephron Function

The major function of the nephron is urine formation, which it does by performing many functions simultaneously (Fig. 37.11):

1. Filtering plasma at the glomerulus
2. Reabsorbing and secreting different substances along the tubular structures
3. Forming a filtrate of protein-free fluid (ultrafiltration)
4. Regulating the filtrate to maintain the body fluid volume, electrolyte composition, and pH within narrow limits

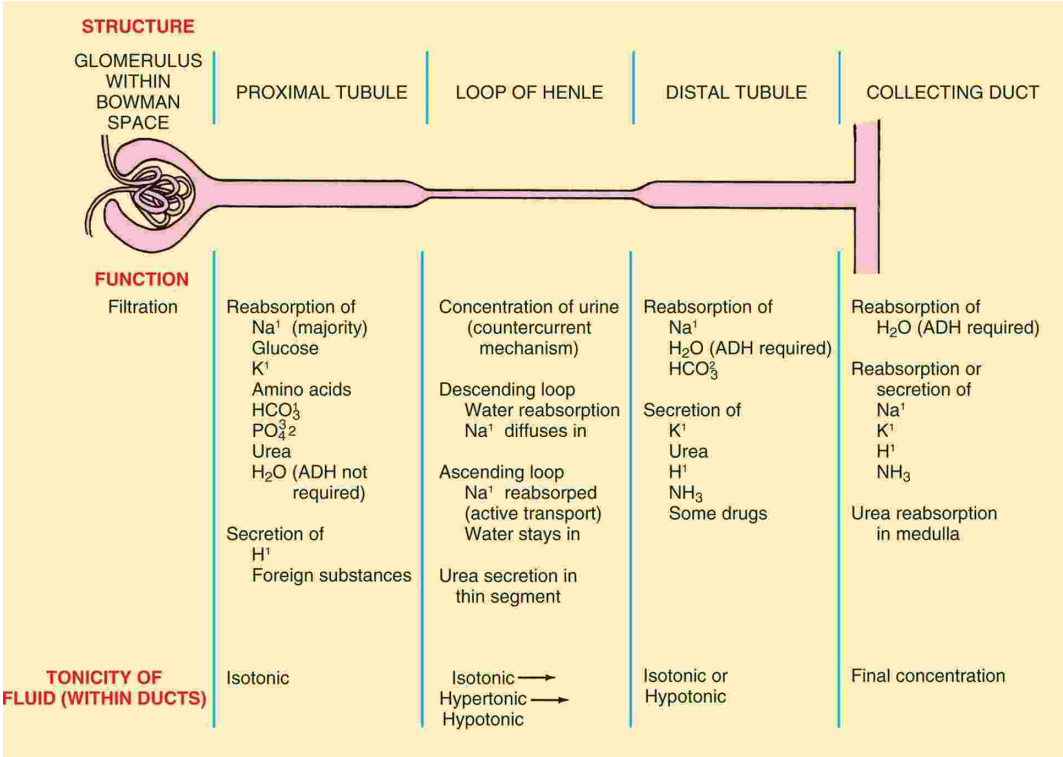

FIG. 37.11 Major Functions of Nephron Segments. *ADH*, Antidiuretic hormone. (Modified from Hockenberry MJ et al. *Wong's nursing care of infants and children*, 8th edition. St. Louis: Mosby; 2007.)

An illustration shows the structure, function, and tonicity of fluid (within ducts) of nephron segments. • The glomerulus within Bowman space performs the function of filtration. • The proximal tubule is responsible for the following functions: reabsorption of sodium (majority), glucose, potassium, amino acids, bicarbonate, phosphate, urea, and water (A D H not required); and secretion of hydrogen and foreign substances. The fluid within the ducts is isotonic. • The loop of Henle is responsible for the following functions: concentration of urine (countercurrent mechanism); descending loop including water reabsorption and sodium diffuses in; ascending loop

including sodium reabsorbed (active transport) and water stays in; and urea secretion in thin segment. The fluid within the ducts changes from isotonic to hypertonic to hypotonic. • The distal tubule is responsible for the following functions: reabsorption of sodium, water (A D H required), and bicarbonate; and secretion of potassium, urea, hydrogen, ammonia, and some drugs. The fluid within the ducts is isotonic or hypotonic. • The collecting duct is responsible for the following functions: reabsorption of water (A D H required); reabsorption or secretion of sodium, potassium, hydrogen, and ammonia; and urea reabsorption in medulla. The fluid within the ducts is in final concentration.

Glomerular filtration is the movement of fluid and solutes across the glomerular capillary membrane into the Bowman space. **Tubular reabsorption** is the movement of fluids and solutes from the tubular lumen into the peritubular capillary plasma. **Tubular secretion** is the transfer of substances from the plasma of the peritubular capillary to the tubular lumen (Fig. 37.12). The transport mechanisms are both active and passive (processes defined in Chapter 1). **Excretion** is the elimination of a substance in the final urine.

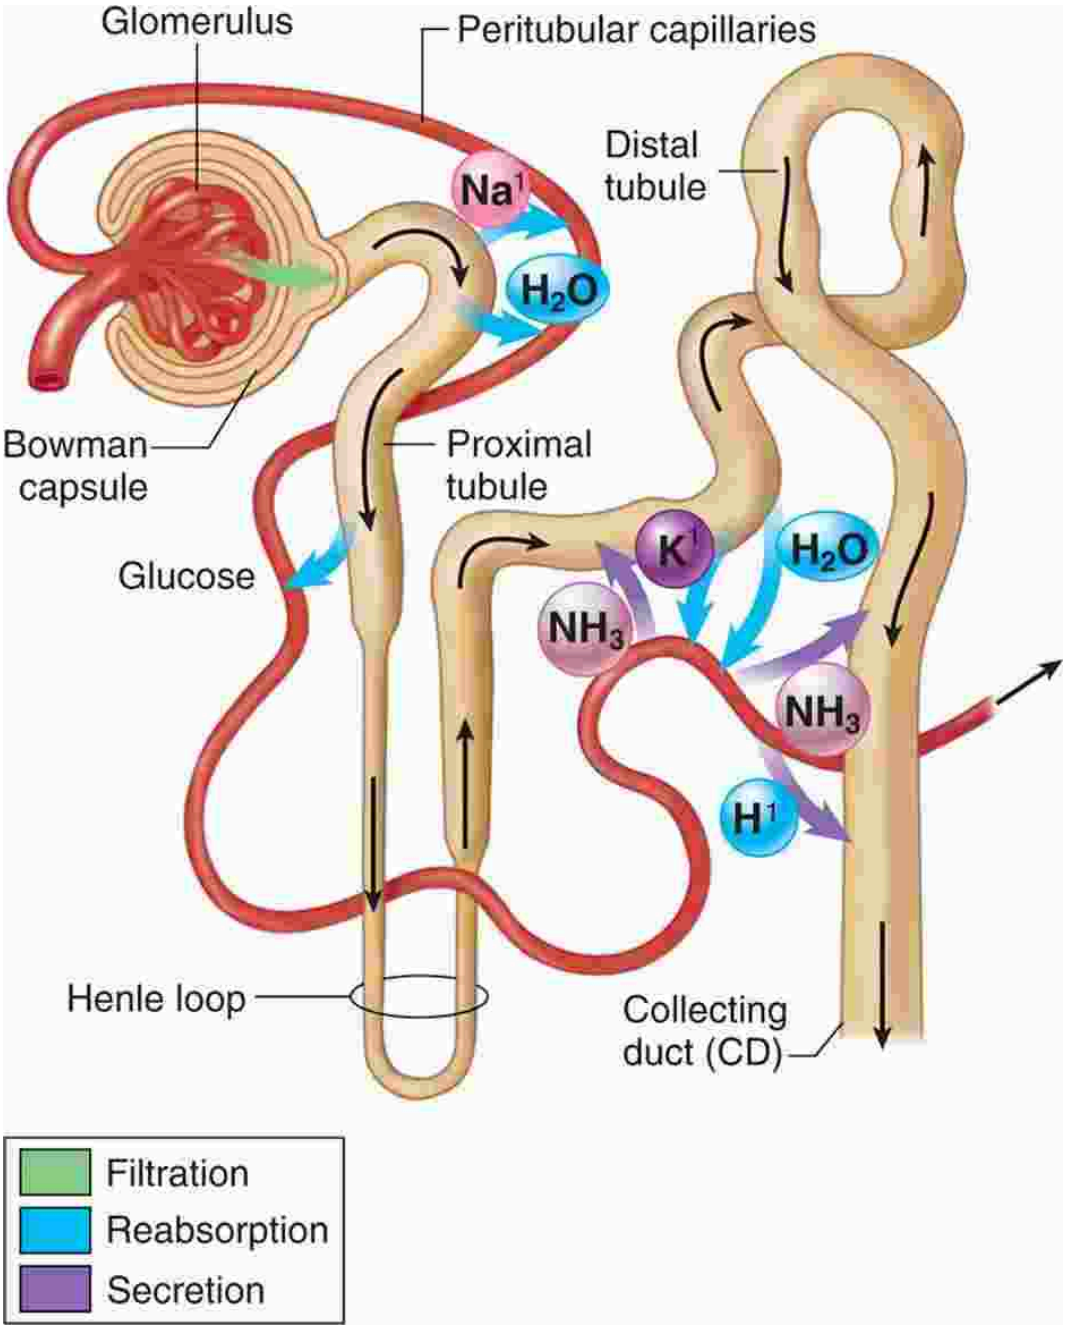

FIG. 37.12 Urine Formation: Glomerular Filtration, Tubular Reabsorption, and Tubular Secretion.
These are the three processes by which the kidneys excrete urine. Water, electrolytes, glucose, and organic molecules are filtered at the glomerulus. Sodium and glucose are reabsorbed into peritubular capillaries by active transport from the proximal convoluted tubules, and water reabsorption follows by osmosis. Sodium is

reabsorbed by active transport from distal convoluted tubules; more sodium is conserved when aldosterone is secreted. Osmotic reabsorption of water from the distal tubules occurs when antidiuretic hormone is present. Secretion of ammonia (NH_3), hydrogen, and potassium occurs from peritubular capillaries into distal tubules by active transport. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

An illustration shows the formation of urine. The following structures are labeled: glomerulus, Bowman capsule, peritubular capillaries, Henle loop, proximal tubule, distal tubule, and collecting duct (C D). The glomerulus filters the liquid, releasing sodium and water, which are reabsorbed by the peritubular capillaries. Ammonia and hydrogen are secreted into the proximal tube, which are transported to the collecting duct.

Glomerular Filtration

The fluid filtered across the glomerular capillary filtration membrane and released into the proximal convoluted tubule is protein free but contains electrolytes (e.g., sodium, chloride, and potassium) and organic molecules (e.g., creatinine, urea, and glucose) in the same concentrations as those found in plasma. As are other capillary membranes, the glomerulus is freely permeable to water and relatively impermeable to large colloids, such as plasma proteins. The molecule's size and the small size of the filtration slits in the glomerular epithelium affect the permeability of substances crossing the glomerulus and entering the PT. The negative charge along the filtration membrane further impedes the passage of negatively charged macromolecules, particularly proteins (because like forces repel each other). Positively charged macromolecules therefore permeate the membrane more readily than neutrally charged particles.

In addition to permeability, capillary pressures also affect glomerular filtration. The hydrostatic pressure within the capillary is the major force for pushing water and solutes across the filtration membrane and into the

Bowman capsule. This pressure is determined by the systemic arterial pressure and the resistances to blood flow in the afferent and efferent arterioles. Two forces oppose the filtration effects of the glomerular capillary hydrostatic pressure: (1) the hydrostatic pressure in the Bowman space, and (2) the effective oncotic pressure of the glomerular capillary blood. Remember, hydrostatic pressure is a pushing pressure, and oncotic pressure is a pulling pressure in relation to water. Because the fluid in the Bowman space normally contains only very small amounts of protein, it does not usually have an oncotic influence on the plasma of the glomerular capillary (Fig. 37.13).

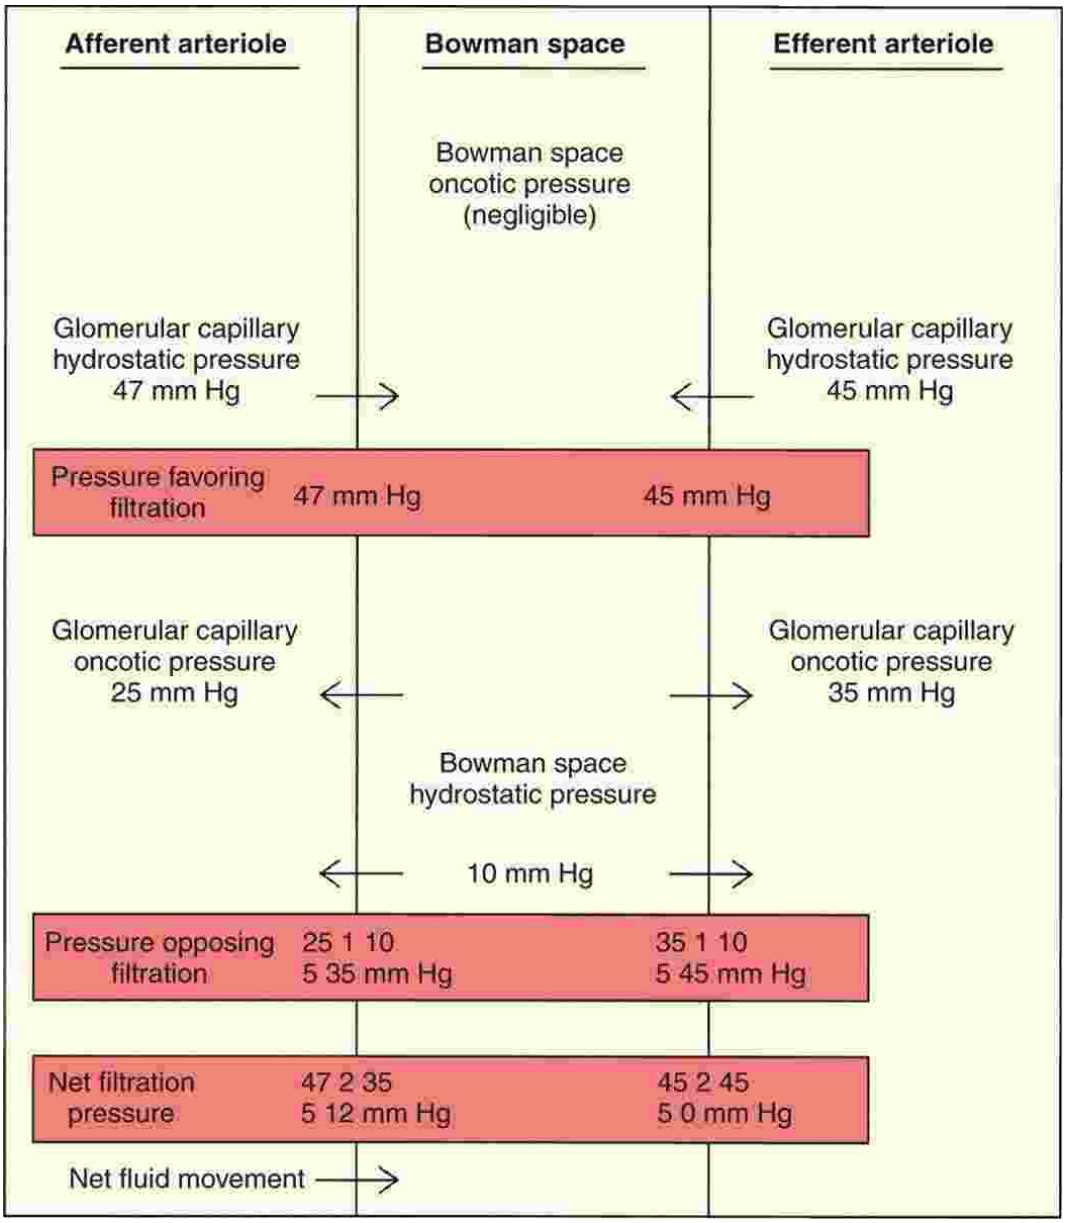

FIG. 37.13 Glomerular Filtration Pressures.

A tabular illustration shows the glomerular filtration pressures. The table shows three columns: afferent arteriole, Bowman space, and efferent arteriole. The pressures are as follows. • Pressure favoring filtration: glomerular capillary hydrostatic pressure of 47 millimeters of mercury, from the left; Bowman space oncotic pressure (negligible); and glomerular capillary hydrostatic pressure

of 45 millimeters of mercury, from the right. • Pressure opposing filtration: glomerular capillary oncotic pressure of 25 millimeters of mercury (25 1 10, 5 25 millimeters of mercury), to the left; Bowman space hydrostatic pressure; and glomerular capillary oncotic pressure of 35 millimeters of mercury (35 1 10, 5 45 millimeters of mercury), to the right. • Net filtration pressure: 47 2 35, 5 12 millimeters of mercury, to the left; 35 2 45, 5 0 millimeters of mercury, to the right. • Net fluid movement: from afferent arteriole to Bowman space to efferent arteriole, from the left.

The combined effect of forces favoring and forces opposing filtration determines the filtration pressure. The **net filtration pressure (NFP)** is the sum of forces favoring and opposing filtration. The estimated values contributing to the forces of net filtration are presented in Fig. 37.13.

The plasma oncotic pressure increases and the hydrostatic pressure decreases in the glomerular capillary, as the protein-free fluid is filtered into the Bowman capsule. The increase in the glomerular capillary oncotic pressure is great enough to reduce the NFP to zero at the efferent end of the capillary and to stop the filtration process effectively. The low hydrostatic pressure and the increased oncotic pressure in the efferent arteriole then are transferred to the peritubular capillaries. This facilitates the reabsorption of fluid from the PTs back into the circulating blood.

Filtration rate

The total volume of fluid filtered by the glomeruli averages 180 L/day, or approximately 120 mL/min, a phenomenal amount considering the size of the kidneys. Because only 1 to 2 L of urine is excreted per day, 99% of the filtrate is reabsorbed into the peritubular capillaries and returned to the blood. The factors determining the GFR are directly related to the pressures that favor or oppose filtration (see Fig. 37.13). Obstruction of the outflow of urine (e.g., caused by strictures, stones, or tumors along the urinary tract) can cause a retrograde increase in hydrostatic pressure at the Bowman space and a decrease in the GFR. Low levels of plasma protein in the blood

from severe malnutrition or liver disease can also result in a decrease in the glomerular capillary oncotic pressure, which increases the GFR. Excessive loss of protein-free fluid as a result of vomiting, diarrhea, use of diuretics, or excessive sweating can increase the glomerular capillary oncotic pressure and decrease the GFR. Renal disease also can cause changes in pressure relationships by altering capillary permeability and the surface area available for filtration (see Chapter 38).

Proximal tubule

By the end of the PT, approximately 60% to 70% of filtered sodium and water and about 50% of urea have been actively reabsorbed, along with 90% or more of potassium, glucose, bicarbonate, calcium, phosphate, amino acids, and uric acid. Chloride, water, and urea are reabsorbed passively but linked to the active transport of sodium (a cotransport mechanism). For some molecules, active transport in the renal tubules is limited as the carrier molecules become saturated, a phenomenon known as **transport maximum (T_m)**. For example, when the carrier molecules for glucose reabsorption in the PT become saturated (i.e., with the development of hyperglycemia), the excess will be excreted in the urine, causing glucosuria.

Active reabsorption of sodium is the primary function of the convoluted segment of the PT. Water, most other electrolytes, and organic substances are cotransported with sodium. The osmotic force generated by active sodium transport promotes the passive diffusion of water out of the tubular lumen and into the peritubular capillaries. Passive transport of water is further enhanced by the elevated oncotic pressure of the blood in the peritubular capillaries, which is created by the previous filtration of water at the glomerulus. The reabsorption of water leaves an increased concentration of urea within the tubular lumen, creating a gradient for its passive diffusion to the peritubular plasma. As the positively charged sodium ions leave the tubular lumen, negatively charged chloride ions passively follow to maintain electroneutrality. Because the inner membrane of the proximal tubular cell has a limited permeability to chloride, chloride reabsorption lags behind that of sodium.

Bicarbonate is completely filtered at the glomerulus, and approximately 90% is reabsorbed in the PT. In the tubular lumen, hydrogen ions are actively exchanged for sodium. The hydrogen ions combine with bicarbonate ions and form carbonic acid (H_2CO_3), which rapidly breaks down, or dissociates, to carbon dioxide (CO_2) and water (H_2O). The CO_2 and H_2O then diffuse into the tubular cell, where the enzyme carbonic

anhydrase again catalyzes the CO_2 and H_2O to form HCO_3^- and H^+. The H^+ is secreted into the tubular lumen again, and HCO_3^- combines with sodium and is transported to the peritubular capillary blood as $NaHCO_3$ (a sodium bicarbonate buffer). Bicarbonate is thus conserved. The hydrogen combines with hydroxide ion (OH^-) and is reabsorbed as water. Therefore, in the PT, these ions normally do not contribute to the urinary excretion of acid or the addition of acid to the blood.

In the PT, secretory transport mechanisms exist for creatinine, other organic bases, and endogenous and exogenous organic acids, including para-aminohippurate (PAH) and penicillin (Box 37.2). These secretory mechanisms eliminate drugs and other exogenous chemical products from the body, often after first conjugating (combining) them with sulfate and glucuronic acid in the liver. Many drugs and their metabolites are eliminated from the body in this way. When the renal tubules are damaged, metabolic by-products and drugs may accumulate, causing toxic levels in the body.

Box 37.2

Substances Transported by Renal Tubules

Reabsorption	Secretion
Albumin	Choline
Ascorbate	Creatinine
Fructose	Histamine
Galactose	Methylguanidine
Glutamae	*para*-Aminohippurate
Glucose	Penicillin and many other drugs
Phosphate	Steroid glucuronides
Sulfate	Thiamine
Xylose	

Normally, 99% of the glomerular filtrate is reabsorbed. When the GFR spontaneously decreases or increases, the renal tubules, primarily the PTs, automatically adjust their rate of reabsorption of sodium and water to balance the change in the GFR. Thus, a constant fraction of filtered sodium and water is reabsorbed from the PT. This prevents wide fluctuations in the excretion of sodium and water into the urine and is known as **glomerulotubular balance (GTB)**. GTB and tubuloglomerular feedback together regulate sodium and water balance.

Loop of Henle and distal tubule

Urine can be hypotonic, isotonic, or hypertonic, depending on the concentration or dilution of the urine. **Urine concentration** or **dilution** occurs principally in the loop of Henle, distal tubules, and collecting ducts. The structural features of the medullary hairpin loops allow the kidney to concentrate urine and conserve water for the body. The transition of the filtrate into the final urine reflects the concentrating ability of the loops. Final adjustments in urine composition are made by the distal tubule and collecting duct according to the body's needs.

Production of concentrated urine involves a **countercurrent exchange system**, in which fluid flows in opposite directions through the parallel tubes of the loop of Henle. A concentration gradient in the medulla causes fluid to be exchanged across the parallel pathways. The longer the loop the greater the concentration gradient. The concentration gradient increases from the cortex to the tip of the medulla. The *loops of Henle multiply the concentration gradient*, and the vasa recta blood vessels (located parallel to the loops of Henle) act as a *countercurrent exchanger* for maintaining the gradient. The process is initiated in the thick ascending limb of the loop of Henle with the active transport of chloride and sodium out of the tubular lumen and into the medullary interstitium (Fig. 37.14). Because the lumen of the ascending limb is impermeable to water, water cannot follow the sodium-chloride transport. This causes the ascending tubular fluid to become hypoosmotic and the medullary interstitium to become hyperosmotic.

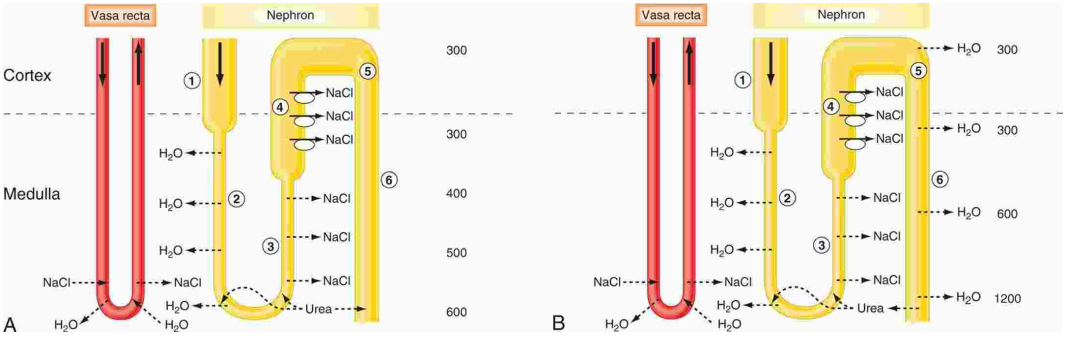

FIG. 37.14 Countercurrent Mechanism for Concentrating and Diluting Urine.
(A) Urine dilution; **(B)** urine concentration. *1*, Filtrate isotonic to plasma. *2*, Descending thin limb permeable to water. *3*, Ascending thin limb impermeable to water; permeable to ions. *4*, Ascending thick limb actively transports NaCl; impermeable to water and urea. *5*, Distal tubule actively resorbs NaCl; resorbs water in presence of antidiuretic hormone. *6*, Medullary collecting duct actively resorbs NaCl, and slightly permeable to water and urea. (NOTE: Numbers on illustration represent milliosmoles [mOsm]). *H_2O*, water; *NaCl*, sodium chloride. See text for details. (From Koeppen BM, Stanton BA. *Berne and Levy physiology [updated]*, 6th edition. St. Louis: Mosby; 2010.)

Two illustrations, A and B, show the countercurrent mechanism for concentrating and diluting urine. Both illustration show the vasa recta (with cortex at the top and medulla at the bottom) and a nephron.

The descending limb of the loop, which receives fluid from the PT, is highly permeable to water, but it is the only place in the nephron that does not actively transport either sodium or chloride. Sodium and chloride may, however, diffuse into the descending tubule from the interstitium. The hyperosmotic medullary interstitium causes water to move out of the descending limb, and the remaining fluid in the descending tubule becomes increasingly concentrated as it flows toward the tip of the medulla. When the tubular fluid rounds the loop and enters the ascending limb, sodium

and chloride are removed, and water is retained as described previously. The fluid then becomes more and more dilute as it encounters the distal tubule.

The slow rate of blood flow and the hairpin structure of the vasa recta blood vessels allow blood to flow slowly through the medullary tissue without disturbing the osmotic gradient. When blood flows into the descending limb of the vasa recta, it encounters the increasing osmotic concentration gradient of the medullary interstitium. Water moves out, and sodium and chloride diffuse into the descending vasa recta. The plasma becomes increasingly concentrated as it flows toward the tip of the medulla.

As blood flows away from the tip of the medulla and toward the cortex, the surrounding interstitial fluid becomes comparatively more dilute. Water then moves back into the vasa recta, and sodium and chloride diffuse out and the plasma again becomes more dilute. The net result is a preservation of the medullary osmotic gradient. If blood were to flow rapidly through the vasa recta, as occurs in some renal diseases, the medullary concentration gradient would be washed away and the ability to concentrate urine and conserve water would be lost. The efficiency of water conservation is related to the length of the loops of Henle: the longer the loops, the greater the ability to concentrate the urine, and the slower the flow of blood through the vasa recta.

Urea is the major constituent of urine, along with water. The glomerulus freely filters urea, and tubular reabsorption depends on the urine flow rate, with less reabsorption at higher flow rates. Approximately 50% of urea is excreted in the urine, and 50% is recycled within the kidney. This recycling contributes to the osmotic gradient within the medulla and is necessary for the concentration and dilution of urine (see Fig. 37.14). Because urea is an end product of protein metabolism, individuals with protein deprivation cannot maximally concentrate their urine.

Another function of the ascending loop of Henle is the production of **uromodulin** (also known as **Tamm-Horsfall protein [THP]**), the most abundant protein in human urine. This protein prevents the attachment of *Escherichia coli* to uroepithelial cell receptors by binding to the type 1 fimbria adhesin (FimH) and removing other uropathogens. It also modulates renal ion channel activity, salt/water balance, renal and systemic inflammatory responses, intertubular communication, mineral crystallization, and bacterial adhesion. Consequently, uromodulin participates in the countercurrent gradient formation for urine concentration, protects the uroepithelium from injury and kidney stone formation, regulates blood

pressure, and functions as an immune regulatory molecule against infections in the urinary system.[5] Uromodulin is also a biomarker for the progression of kidney disease and genetic mutations that are associated with congenital urolithiasis, hereditary hyperuricemia/gout, and medullary cystic kidney diseases.[6]

The convoluted portion of the distal tubule is poorly permeable to water but readily reabsorbs ions and contributes to the dilution of the tubular fluid. The later, straight segment of the distal tubule and the collecting duct are permeable to water as controlled by ADH released from the posterior pituitary gland. Sodium is readily reabsorbed by the later segment of the distal tubule and collecting duct under the regulation of the hormone aldosterone (see Chapter 21). Potassium is actively secreted by principal cells and is reabsorbed in lesser amounts by intercalated cells in these segments. Potassium secretion is controlled by aldosterone and other factors related to the concentration of potassium in body fluids.

Hydrogen is secreted by the distal tubule and combines with nonbicarbonate buffers (i.e., ammonium and phosphate) for the elimination of acids in the urine. The distal tubule thus contributes to the regulation of acid-base balance by excreting hydrogen ions into the urine and by adding new bicarbonate to the plasma (see Fig. 3.13). The mechanism is similar to the conservation of bicarbonate by the PT, except that the hydrogen ion is excreted in the urine and influences the acid-base balance. The specific mechanisms of acid-base balance and acid excretion are described in Chapter 3.

Urine Composition

Urine is normally clear yellow or amber in color. Cloudiness may indicate the presence of bacteria, cells, or a high solute concentration. The pH ranges from 4.6 to 8.0, but it is normally acidic, providing protection against bacteria. The specific gravity ranges from 1.001 to 1.035. Normal urine does not contain glucose or blood cells and only occasionally contains traces of protein, usually in association with rigorous exercise.

Hormones and Nephron Function

Antidiuretic Hormone

The distal tubule in the cortex receives the hypoosmotic urine from the ascending limb of the loop of Henle. The **specific gravity**, or concentration, of the final urine is controlled by **antidiuretic hormone (ADH)**, which is

secreted from the posterior pituitary or neurohypophysis. ADH increases water permeability and reabsorption in the last segment of the distal tubule and along the entire length of the collecting ducts, which pass through the inner and outer zones of the medulla. The water diffuses into the ascending limb of the vasa recta and returns to the systemic circulation to maintain fluid balance. The excreted urine can have a high osmotic concentration, up to 1400 mOsm. The volume is normally reduced to about 1% of the amount filtered at the glomerulus.

Excess ADH secretion is therefore one cause of **oliguria**, or diminished excretion of urine, clinically defined as less than 400 mL/day or 30 mL/h. The syndrome of inappropriate secretion of ADH occurs when the posterior pituitary hypersecretes ADH, resulting in excess water reabsorption and water excess in the plasma (see Chapters 3 and 22). Inadequate secretion of ADH results in diabetes insipidus and causes the distal tubules and collecting ducts to become impermeable to water. Water remains in the tubular lumen and is excreted as a dilute and large volume of urine. (The mechanism for the regulation of ADH and plasma osmolality is described in Chapters 3 and 21.)

Aldosterone

Aldosterone is synthesized and secreted by the adrenal cortex under the regulation of the RAAS (see Chapter 21 and the previous discussion of the RAAS in this chapter). Aldosterone stimulates the epithelial cells of the distal tubule and collecting duct to reabsorb sodium (promoting water reabsorption) and increases the excretion of potassium and hydrogen ion.

Natriuretic Peptides

Natriuretic peptides are a group of vasoactive hormones that promote sodium and water excretion, including **atrial natriuretic peptide (ANP or A-type natriuretic peptide**), secreted from myocardial cells in the atria, **brain natriuretic peptide (BNP or B-type natriuretic peptide)**, secreted from myocardial cells in the cardiac ventricles, and several other variants.[7] When the heart dilates during volume expansion or heart failure, ANP and BNP inhibit sodium and water absorption by the kidney tubules, inhibit secretion of renin and aldosterone, vasodilate the afferent arterioles, and constrict the efferent arterioles. The result is increased urine formation (diuresis), leading to a decrease in blood volume and blood pressure. *C-type natriuretic peptide* is secreted from the vascular endothelium; it causes vasodilation in the nephron and complements the action of ANP and BNP.

Urodilatin, an extended form of ANP, is secreted by the distal convoluted tubules and collecting ducts that causes vasodilation and natriuretic and diuretic effects.

Diuretics as a Factor in Urine Flow

A **diuretic** is any agent enhancing the flow of urine. Clinically, diuretics interfere with renal sodium reabsorption and reduce the extracellular fluid volume. Diuretics are commonly used to treat hypertension and edema caused by heart failure, cirrhosis, and nephrotic syndrome. However, side effects may include dehydration, hypokalemia, systemic acidosis, metabolic alkalosis, nausea, and headache.

Diuretics are divided into five general categories: (1) osmotic diuretics, (2) carbonic anhydrase inhibitors (inhibitors of urinary acidification), (3) inhibitors of loop sodium or chloride transport, (4) potassium sparing (i.e., aldosterone receptor antagonists), and (5) aquaretics. (The physiologic mechanism related to each category is summarized in Table 37.2.)

Table 37.2

Action of Diuretics

Diuretic	Site of Action	Action	Side Effects
Osmotic Diuretic			
Mannitol Glycerol Urea	Proximal tubule	Freely filtered but not reabsorbed; osmotically attracts water and diminishes sodium reabsorption	Hypokalemia, dehydration
Carbonic Anhydrase Inhibitors			
Acetazolamide	Proximal tubule	Inhibits carbonic anhydrase; blocks hydrogen ion secretion and reabsorption of sodium and bicarbonate	Hypokalemia, systemic acidosis, alkaline urine
Inhibitors of Sodium/Chloride Reabsorption (Loop Diuretics)			
Thiazides	Between end of ascending loop and beginning of distal tubule	Blocks sodium and chloride reabsorption; mildly suppresses carbonic anhydrase	Hypokalemia, metabolic alkalosis

Diuretic	Site of Action	Action	Side Effects
Furosemide Ethacrynic acid Torsemide	Thick ascending limb of Henle loop	Blocks active transport of chloride, sodium, and potassium	Hypokalemia, uric acid retention
Bumetanide	Cortical vasodilation	Increased rate of urine formation	Hypokalemia, uric acid retention
Potassium Sparing			
Spironolactone Eplerenone	Distal tubule	Inhibits aldosterone, blocks sodium reabsorption, and results in potassium retention	Hyperkalemia, nausea, confusion, gynecomastia
Triamterene Amiloride	Distal tubule	Blocks sodium reabsorption and inhibits potassium excretion	Nausea, vomiting, headache, and amiloride granulocytopenia, skin rash
Aquaretics			
Vasopressin (V2 receptor) blockers (e.g., conivaptan)	Distal tubule and collecting ducts	Blocks action of antidiuretic hormone	Dehydration

Renal Hormones

Certain hormones are either activated or synthesized by the kidney. These hormones have significant systemic effects and include urodilatin (see earlier text), the active form of vitamin D, Epo, renin-angiotensin-aldosterone, and natriuretic hormones.

Vitamin D

Vitamin D is a hormone that is necessary for the absorption of calcium and phosphate by the small intestine. The normal serum concentration is 50 nmol/L (i.e., 20 ng/mL). It can be obtained in the diet or synthesized by the action of ultraviolet radiation (sun exposure) on cholesterol in the skin. These forms of vitamin D_3 (cholecalciferol) are inactive and require two hydroxylations (which adds an OH^- group to a compound) to establish a metabolically active form. The first hydroxylation occurs in the liver and the second in the kidneys. The renal hydroxylation step is stimulated by parathyroid hormone (see Chapter 21). The end product is 1,25-dihydroxy-vitamin D_3 (1,25-OH_2D_3), or **calcitriol**, the active form of vitamin D. Calcitriol is necessary for the absorption of calcium and phosphate by the small intestine. A decreased plasma calcium level (less than 10 mg/dL) stimulates the secretion of parathyroid hormone. Parathyroid hormone then stimulates a sequence of events to help return the plasma calcium concentration toward normal levels (9 to 10.5 mg/dL):

1. Calcium mobilization from bone
2. Synthesis of 1,25-dihydroxy-vitamin D_3
3. Absorption of calcium from the intestine
4. Increased renal calcium reabsorption
5. Decreased renal phosphate reabsorption

Fluctuations in the serum phosphate concentration also influence the renal hydroxylation of vitamin D. Decreased levels stimulate active 1,25-dihydroxy-vitamin D_3 formation, and increased levels inhibit formation. This results in compensatory changes in phosphate absorption from the bones and intestine. Individuals with renal disease have a deficiency of 1,25-OH_2D_3 and manifest symptoms of disturbed calcium and phosphate balance (see Chapters 3, 21, and 38).

Erythropoietin

Erythropoietin (Epo) is produced by the fetal liver and the adult kidney and is essential for normal erythropoiesis. Epo stimulates the bone marrow to produce red blood cells in response to tissue hypoxia and may have tissue protective effects. Erythrocyte production is discussed in Chapter 28. The stimulus for Epo release is decreased oxygen delivery in the kidneys. Oxygen-sensing Epo-producing cells are peritubular fibroblast-like cells located in the juxtamedullary cortex. The anemia of chronic renal failure, in which kidney cells have become nonfunctional, can be related to the lack of this hormone (see Chapter 38.)

Tests of Renal Function

Renal Clearance

A number of specific renal functions can be measured by renal clearance. Renal clearance techniques or formulas determine how much of a substance can be cleared from the blood by the kidneys per given unit of time. The application of this principle permits an indirect measure of the GFR, tubular secretion, tubular reabsorption, and the RBF.

Clearance and Glomerular Filtration Rate

The GFR provides the best estimate of functioning renal tissue and is important for assessing or monitoring kidney damage and drug dosing. Damage to the glomerular membrane or loss of nephrons leads to a corresponding decrease in the GFR. Measurement of the GFR requires the use of a substance that does not influence GFR; has a stable plasma concentration; is not protein bound; is freely filtered at the glomerulus; is not secreted, reabsorbed, or metabolized by the tubules; is constantly infused to maintain a stable plasma level; and is easy to measure. Inulin (a fructose polysaccharide) is one substance that meets the criteria for measurement of GFR. The kidney "clears" inulin from the plasma by filtering it at the glomerulus, reabsorbing nearly all of the fluid, and excreting the inulin left behind in the urine. However, the accurate determination of clearance requires constant infusion to maintain a stable plasma level. This is time consuming, inconvenient, and prone to error.

Therefore, the clearance of **creatinine**, a natural substance produced by muscle and released into the blood at a relatively constant rate, is commonly used as an estimate clinically. It is freely filtered at the glomerulus and is not reabsorbed by the renal tubules, but a small amount is secreted by the renal tubules, meaning creatinine clearance overestimates

the GFR, but within tolerable limits. **Creatinine clearance** provides a good clinical measure of the GFR, because only one blood sample is required in addition to an accurately collected 24-hour volume of urine. The GFR estimated by creatinine clearance is calculated by multiplying the creatinine concentration of urine (U_{CR}) by the volume of urine per unit of time V (usually 24 hours) divided by the plasma creatinine (P_{CR}) concentration, as follows:

$$\text{GFR}(\text{mL/min}) = \frac{U_{CR} \times V}{P_{CR}}$$

Cystatin C is a stable protein in serum filtered at the glomerulus and metabolized in the tubules. Serum levels of cystatin C also are a marker for estimating the GFR, particularly for mild to moderate impaired renal function. Formulas are used to estimate the GFR. Calculators for estimates of the GFR use a variety of formulas and are readily available on the internet (see an example at http://touchcalc.com/ip_epi_gfr/ip_ckd_epi). Normal GFR values are 90 to 120 mL/min.

Plasma Creatinine Concentration

A chronic decline in the GFR over weeks or months is reflected in the **plasma creatinine (P_{CR}) concentration** (normal value = 0.7 to 1.2 mg/dL). The P_{CR} concentration has a stable value when the GFR is stable because creatinine has a constant rate of production as a product of muscle metabolism. The amount filtered is approximately equal to the amount excreted. When the GFR declines, the P_{CR} increases proportionately. Thus, the GFR and P_{CR} are inversely related. If the GFR were to decrease by 50%, the filtration and excretion of creatinine would be reduced by 50% and creatinine would accumulate in the plasma to twice the normal value. Therefore, elevated P_{CR} values represent a decreasing GFR. In the new steady state, however, the total amount of creatinine excreted in the urine would remain the same because of the proportionate decrease in the GFR and increase in the P_{CR}.

The application of this principle is simple and useful for monitoring progressive changes in renal function. The test is most valuable for monitoring the progress of chronic rather than acute renal disease because it takes 7 to 10 days for the P_{CR} level to stabilize when the GFR declines. Serial

measures can be obtained over a long time and plotted as a curve of glomerular function. Normal P_{CR} value decreases with advanced age, since older adults experience a decrease in lean muscle mass. The P_{CR} also becomes elevated during trauma or the breakdown of muscle tissue. In such instances, the value is then not useful for estimating the GFR.

Blood Urea Nitrogen

The concentration of urea nitrogen in the blood reflects glomerular filtration and urine-concentrating capacity. Because urea is filtered at the glomerulus, **blood urea nitrogen (BUN)** levels increase as glomerular filtration drops. Urea is reabsorbed by the blood through the permeable tubules, so the BUN value rises in states of dehydration and with acute and chronic renal failure when the passage of fluid through the tubules slows. BUN values also change as a result of altered protein intake and protein catabolism making it a poor measure of GFR. The normal range for the BUN level in adults is 10 to 20 mg/dL of blood.

Clearance and Renal Blood Flow

A clearance formula also can be devised to estimate the RPF and RBF using the PAH molecule. When PAH is administered intravenously, some of it is filtered at the glomerulus, and most of the remainder is secreted into the tubules in one circulation through the kidney. A blood sample and urine sample are obtained simultaneously to measure the amount of PAH in each sample. If all the PAH is removed from the plasma during a single pass through the kidney, the total RPF can be determined. Because the supporting and non-secreting structures of the kidney receive 10% to 15% of the **effective renal blood flow (ERBF)**, the clearance of PAH measures only what is known as the **effective renal plasma flow (ERPF)**, which is 85% to 90% of the true RPF

$$\text{ERBF} = \frac{\text{ERPF}}{1 - \text{Hematocrit}}$$
$$(1.0 - 0.45)$$

Evaluation of the biochemical components of the blood and urine provides valuable information regarding renal function.

Urinalysis

Urinalysis is a noninvasive and relatively inexpensive diagnostic procedure. The best results are obtained from a fresh, cleanly voided specimen, because decay permits changes in the composition of the urine. Urinalysis includes evaluation of the color, turbidity, protein, pH, specific gravity, sediment, and supernatant. Urine tests are listed in Table 37.3.

Table 37.3

Renal Function Test Results

Test	Normal Value	Interpretation of Abnormal Result
Urine		
Color	Amber-yellow	Drugs and foods may change color
Turbidity	Clear	Purulent matter causes cloudiness
pH	4.6–8	Bacteria create an alkaline urine
Specific gravity	*Adults:* 1.010–1.025 *Infants:* 1.010–1.018	Represents concentrating ability or density of urine in relation to density of water (1.000) (i.e., higher when contains glucose or protein; lower with dilute urine)
Blood	Negative	Bleeding along urinary tract
Microscopic Urine		
Bacteria	None	Infection
Red blood cells	Negative	Bleeding along urinary tract
White blood cells	Negative	Urinary tract infection
Crystals	Negative	May have potential for stones
Fat	Negative	Can be associated with nephrosis
Casts	Occasional	A few are normal; may represent renal disease
Urinary Chemistry		
Bilirubin	Negative	Increases may cause dark orange color

Test	Normal Value	Interpretation of Abnormal Result
Urobilinogen	Less than 4 mg/24 h	Increases may indicate red blood cell hemolysis
Ketones	Negative	Indicate an increase in fat metabolism
Glucose	Negative	Usually signifies hyperglycemia
Sodium	100–260 mEq/24 h	Can increase or decrease with renal disease
Potassium	25–100 mEq/24 h	Can increase or decrease with renal disease, potassium intake, aldosteronism, or diuretic use
Protein	Negative-trace	Dysfunction of glomerulus
Normal Serum Values		
Blood urea nitrogen (BUN)	7–18 mg/dL	Elevated with diseased kidneys
Creatinine	*Male:* 0.6–1.5 mg/dL *Female:* 0.6–1.1 mg/dL	Elevated with decreased glomerular filtration rate (GFR)
Cystatin C	0.8–2.1 mg/L	Early detection of decreased GFR
Potassium		Elevated in renal failure

Urine color is normally a clear, light yellow because of urochrome and other pigments. When formed substances (crystals, blood cells, or casts) are in the urine, it appears turbid. Protein in the urine creates marked foaming when shaken, and the foam is yellow or orange when the urine contains bile pigments. Urine does not normally contain protein or bile.

Urine pH normally ranges between 5 and 6.5, but it may vary from 4.5 to 8. Urine is more alkaline after eating and then becomes less alkaline before the next meal. Because sleep is accompanied by intermittent

hypoventilation, urine is more acidic on awakening. Dipstick evaluations may be falsely high when urine pH is less than 6 and falsely low when the pH is more than 7.

Specific gravity is an estimated measure of the solute concentration of the urine. The specific gravity of any solution is measured by comparing the weight of the solution with an equal volume of distilled water. Hence, specific gravity is not a true measure of the number or concentration of particles, but it correlates well with osmolality and is a useful clinical tool. Specific gravity usually is measured with a hydrometer in a cylinder of urine; the normal value is 1.010 to 1.025.

The final urine osmolality is primarily a function of ADH, which controls water reabsorption in the collecting ducts. If the kidney is unable to concentrate or dilute urine, given a stimulus, the cause is usually a malfunction of the renal tubules or inappropriate ADH secretion by the posterior pituitary gland. The state of hydration also affects the urine specific gravity, so hydration status should be evaluated before making a diagnosis. This determination is helpful for differentiating oliguria caused by intrinsic renal disease from hypovolemia as a result of dehydration.

Urine Sediment

The urine sediment is examined microscopically and may contain cells, casts, crystals, and bacteria. Epithelial cells may be seen in the microscopic field because they are shed naturally throughout the urinary tract.

Normal urine contains few or no red blood cells. If a large number of red cells are present, this is known as **hematuria**, and the sediment may be red or brown. An alkaline or hypotonic urine causes lysis of red cells, however, so that the cells will not be seen. Urine then will be positive for hemoglobin, and the specific gravity will be elevated. Hematuria can occur with the administration of anticoagulants and with several renal diseases.

Casts (accumulations of cellular precipitates) originate in the renal tubules, from which they take their shape. They are cylindrical with distinct borders. Casts arise primarily from the ascending limb of the distal tubule. Red cell casts indicate bleeding into the tubules or escape of red blood cells through the glomerulus; white cell casts are associated with an inflammatory process. Epithelial cell casts indicate degeneration of the tubular lumen or necrosis of the renal tubules. The type of cast identified suggests the disease process occurring in the kidney.

Numerous kinds of crystals can be observed in the urine. They may be composed of cystine, uric acid, calcium oxalate, or phosphate. They may not

be initially observable, but as the urine cools, crystals will form. Crystals tend to form in a concentrated acidic or alkaline urine. Crystal formation is diagnostically significant, usually indicating inflammation, infection, or a metabolic disorder.

White blood cells (WBCs) in the urine (a condition termed **pyuria**) are indicative of urinary tract infection, particularly when bacteria are present. Glomerulonephritis and nephrotic syndrome also may demonstrate pyuria but usually in combination with proteinuria, red cells, and casts. The finding of WBC casts reflects a kidney infection because these casts are not formed in the bladder or prostate. If WBCs are present in the urine, a culture should be done for specific identification of bacteria and sensitivity of bacteria to antibiotics.

Other Measures

Dipsticks and reagent strips are available for detecting other substances in the urine, including glucose, bilirubin, urobilinogen, leukocyte esterase and nitrates, ketones, proteins, hemoglobin, and myoglobin.

Pediatric Considerations

Nephrogenesis continues until 34–36 weeks of gestation and all the nephrons are present at birth. Their numbers do not increase as the kidney grows and matures. The glomerular filtration rate (GFR) in infants does not reach adult levels until 1–2 years of age, and newborns have a decreased ability to efficiently remove excess water and solutes.[8] Their shorter loops of Henle also decrease concentrating ability and produce a more dilute urine than that produced by adults. Risks for metabolic acidosis are increased during the first few months of life, while the mechanisms for excreting acid and retaining bicarbonate are maturing. These normal developmental processes result in a narrow safety margin for fluid and electrolyte balance when there is any disturbance, such as diarrhea, infection, fever, fasting for diagnostic tests, improper feeding, fluid replacement, or drug administration.[9] Newborns diurese 2–3 days after birth, which is reflected by a decrease in total body water and body weight. An increased risk of toxicity accompanies drug administration. Low birth weight infants have a delay in achieving full renal function and may not have a full GFR until 8 years of age. They also are at greater risk for low nephron numbers and chronic kidney disease as adults.[10] Tubular secretion is immature at birth and approaches adult values by 7–12 months. Maturation of tubular

reabsorption continues into adolescence, with the greatest increase occurring between 1 and 3 years of age.[11]

Geriatric Considerations

Aging and Renal Function

Throughout life the kidney responds to an increased workload by compensatory hypertrophy. This hypertrophy is marked in individuals who have donated a kidney for transplant or have lost functioning nephrons from trauma or disease. The glomeruli increase in diameter, and the tubules enlarge effectively to maintain the regulatory functions of the kidney. Hypertrophy occurs more rapidly and with a larger size increase in younger individuals and in those with high protein intake.

Changes in the kidneys occur throughout life, resulting in a reduction in size and a linear decrease in RBF and GFR; however, it is less pronounced in healthy individuals. Reference values for estimated GFR are available by age group.[12] The number and size of nephrons decrease with aging, possibly related to oxidative stress, inflammation, mitochondrial dysfunction, and associated clinical conditions (e.g., hypertension and diabetes mellitus). The primary mechanism appears to be a change in the renal vasculature and perfusion patterns related to atherosclerosis that leads to a reduction in numbers of nephrons and nephrosclerosis. Tubular atrophy also occurs. The rate of nephron loss accelerates after 50 years of age. By about 75 years of age, the nephron population is reduced by 30% to 50% with loss of renal mass occurring primarily in the cortex.[13] Degenerative changes within nephrons also occur with aging. The glomerular capillaries become sclerotic, and remaining glomeruli become hypertrophic. The arcuate and interlobular arteries become tortuous, contributing to ischemia. The loss of the glomerular tuft may cause a shunt between the afferent and efferent arterioles. Although loss of juxtaglomerular nephrons still allows the vasa recta to be perfused, the combination of events contributes to a reduction in the autoregulation of blood flow and ability to excrete a concentrated urine.[14] Thus, the specific gravity of the urine in older individuals tends to be on the low side of normal.

Tubular transport changes with aging, although under normal conditions the tubules function adequately. Adaptation to stressful conditions is more difficult. Glucose, bicarbonate, and sodium are not as efficiently reabsorbed,

and hyperkalemia is more common because of decreased secretion. Response to acid or base loads is delayed and prolonged. Sudden or large changes in pH or fluid load may lead to serious imbalances with increased risk of hypervolemia or hypovolemia. Acute losses or chronic fluid deficits can lead to renal insufficiency in the older adult. Administration of drugs eliminated by renal processes may require dose modifications and more astute observations for toxic side effects. Contrast agents and nonsteroidal anti-inflammatory drugs should be used with caution.[15]

The T_m for glucose reabsorption decreases with age, contributing to a greater amount of glucose in the urine. This is an important consideration when glycosuria is used for screening or monitoring the process of diabetes mellitus in older adults. These changes occur independently of disease, however, indicating a normal process of aging and relating to a decline in sodium-glucose cotransporter 2 function.[16] An age-related decline in renal activation of vitamin D decreases intestinal absorption of calcium, and older adults need more vitamin D to overcome diminishing renal function, lack of exposure to sunlight, and lower concentrations of provitamin D3 in the skin.[17]

Previous or concurrent renal disease or urinary tract obstruction may amplify age-related changes in bladder function. Bladder symptoms are common among older adults and include frequency, urgency, and nocturia. Ischemic-induced neurogenic and myogenic changes in bladder structure and function may contribute to some symptoms, as well as influences outside the urinary tract (i.e., cardiovascular disease, prostatic disease, uterine prolapse, stool impaction and hormonal changes). Changes in neurotransmission, blood flow, and uroepithelium influence the micturition reflex and bladder capacity and may lead to an overactive or underactive bladder and incomplete bladder emptying.[18,19]

Summary Review

Structures of the Renal System

1. The kidneys are paired structures lying bilaterally between the twelfth thoracic and third lumbar vertebrae and behind the peritoneum of the abdominal cavity.
2. The kidney is surrounded by the renal capsule and is composed of an outer cortex and an inner medulla. The cortex contains the

glomerulus, proximal tubule, and parts of the distal tubule. The medulla contains the loops of Henle and collecting ducts.

3. The calyces are chambers that receive urine from the distal tubules and join to form the renal pelvis, which is continuous with the upper end of the ureter.
4. The nephron is the urine-forming unit of the kidney and is composed of the renal corpuscle (glomerulus, Bowman capsule, mesangial cells), proximal tubule, loops of Henle, distal tubule, and collecting duct.
5. The glomerulus contains loops of capillaries (afferent and efferent arterioles) supported by mesangial cells. The capillary walls serve as a filtration membrane for the formation of the primary urine.
6. The juxtaglomerular apparatus is located in the glomerulus and is composed of renin-secreting juxtaglomerular cells (around the afferent arteriole) and sodium-sensing macula densa cells (distal tubule) and mesangial cells (between the glomerular capillaries).
7. The proximal tubule is lined with microvilli to increase the surface area and enhance reabsorption of water, solutes, and electrolytes.
8. The loops of Henle transport solutes and water, contributing to the hypertonic state of the medulla, and are important for the concentration and dilution of urine.
9. The distal tubule adjusts acid-base balance by excreting acid into the urine and forming new bicarbonate ions.
10. The ureters extend from the renal pelvis to the posterior wall of the bladder. Urine flows through the ureters and into the bladder by means of peristaltic contraction of the ureteral muscles.
11. The bladder is a bag composed of the detrusor and trigone muscles and innervated by the autonomic nervous system. When the accumulation of urine reaches 250 to 300 mL, mechanoreceptors, which respond to stretching of tissue, stimulate the micturition reflex and elimination of urine through the urethra.

Renal Blood Flow and Glomerular Filtration

1. Renal blood flows at about 1000 to 1200 mL/min, or 20% to 25% of the cardiac output.
2. The GFR is the filtration of plasma per unit of time and is directly related to the perfusion pressure of RBF.

3. Blood flow through the glomerular capillaries is maintained at a constant rate in spite of a wide range of arterial pressures by autoregulation of the glomerular capillaries.
4. Renin is an enzyme secreted from the juxtaglomerular apparatus in response to decreased blood pressure and causes the generation of angiotensin II, a potent vasoconstrictor. The RAAS is thus a regulator of renal blood flow.

Kidney Function

1. The major function of the nephron is urine formation, which involves the processes of glomerular filtration, tubular reabsorption, and tubular secretion and excretion.
2. Glomerular filtration is favored by capillary hydrostatic pressure and opposed by oncotic pressure in the capillary and hydrostatic pressure in the Bowman capsule. The NFP is the balance of favoring and opposing filtration forces.
3. The GFR is approximately 120 mL/min to 140 mL/min, and 99% of the filtrate is reabsorbed.
4. The proximal tubule reabsorbs about 60% to 70% of the filtered sodium and water and 90% of other electrolytes.
5. Because most molecules are reabsorbed by active transport, the carrier mechanism can become saturated at a point known as the transport maximum. Molecules not reabsorbed are excreted with the urine.
6. The concentration or specific gravity of the final urine is a function of the level of ADH. This hormone stimulates the distal tubules and collecting ducts to reabsorb water. The countercurrent exchange system of the long loops of Henle and their accompanying capillaries establishes a concentration gradient within the renal medulla to facilitate the reabsorption of water from the collecting duct.
7. The kidney secretes or activates a number of hormones having systemic effects, including vitamin D, erythropoietin, and the natriuretic hormone urodilatin.

Tests of Renal Function

1. Creatinine, a substance produced by muscle, is measured in both plasma and urine to calculate a commonly used clinical measurement of the GFR.
2. The plasma creatinine concentration, cystatin C level, and BUN level are estimates of glomerular function. The BUN value also is an indicator of hydration status.
3. Urinalysis involves evaluation of the color, turbidity, protein, pH, specific gravity, sediment, and supernatant. The presence of bacteria, red blood cells, white blood cells, casts, or crystals in the urine sediment may indicate a renal or bladder disorder.

Pediatrics and Renal Function

1. Glomerular filtration rate reaches adult levels by 2 to 3 months of age.
2. Compared with adults, infants and children have a more dilute urine because of higher blood flow and shorter loops of Henle. Tubular maturation is complete by adolescence.
3. Children are more affected than adults by fluid imbalances resulting from diarrhea, infection, or improper feeding because of their limited ability to quickly regulate changes in pH or osmotic pressure.

Aging and Renal Function

1. As a person ages, a decrease occurs in the number and size of nephrons. Renal blood flow and glomerular filtration rate decline.
2. Tubular transport and reabsorption decrease with age. Response to acid-base changes and reabsorption of glucose are delayed. Drugs eliminated by the kidney can accumulate in the plasma, causing toxic reactions.
3. Neurogenic, myogenic, and blood flow changes in the bladder may lead to symptoms of urgency and frequency or urine retention.

The renal system plays a major role in homeostasis by filtering nearly 200 L of blood every 24 hours. Approximately 1 L of filtered fluid is converted into urine and excreted through micturition per day. Because the kidneys filter the blood, the renal system is directly linked to every other organ system. A variety of disorders affects renal function by inhibiting the kidney's ability to regulate plasma volume and osmolality. Disease may be limited to only the kidney and urinary tract or may include systemic diseases that cause acute kidney injury (AKI), chronic kidney disease (CKD), or difficulty eliminating urine (e.g., infection, neurologic injury, or diabetes mellitus). Infection of the kidney or urinary tract is the most common disorder affecting renal function. Stones, tumors, inflammation, or consequences of medical procedures can obstruct and/or cause injury to the upper or lower urinary tract (LUT). Renal injury, whether acute or chronic, can affect other organs and become life-threatening.

Urinary Tract Obstruction

Urinary tract obstruction is an anatomic (structural) or functional abnormality that causes interference with the flow of urine at any site along the urinary tract (Fig. 38.1). An obstruction impedes urine flow, increases hydrostatic pressure, dilates structures proximal to the blockage, which increases risk of

infection, and compromises renal function. Anatomic changes in the urinary system caused by obstruction are referred to as an **obstructive uropathy**, which may be acute or chronic, partial, or complete, and unilateral or bilateral. The severity of an obstructive uropathy is determined by the:

1. location of the obstructive lesion,
2. involvement of ureters and kidneys,
3. severity (completeness) of the blockage,
4. duration of the blockage, and
5. nature of the obstructive lesion.

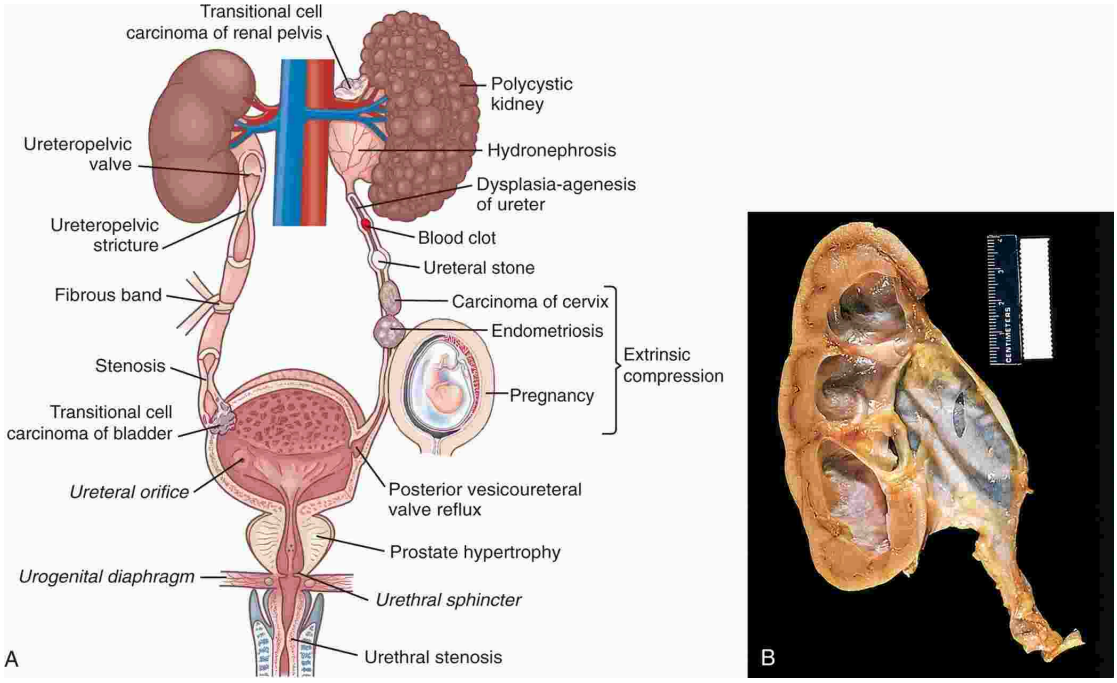

FIG. 38.1 Urinary Tract Obstruction and Hydronephrosis.
(A) Major sites of urinary tract obstruction. **(B)** Hydronephrosis of the kidney. There is marked dilation of the renal pelvis and calyces with thinning of the overlying cortex and medulla due to compression atrophy. (B, From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.)

Left panel, A. The illustration shows the urinary system. The followings structures are labeled, clockwise from the top: transitional cell carcinoma of renal pelvis, polycystic kidney, hydronephrosis, dysplasia-agenesis of ureter, blood clot, ureteral stone, extrinsic compression (carcinoma of cervix, endometriosis, and pregnancy), posterior vesicoureteral valve reflux, prostate hypertrophy, urethral sphincter, urethral stenosis, urogenital diaphragm, ureteral orifice, transitional cell carcinoma of bladder, stenosis, fibrous band, ureteropelvic stricture, and ureteropelvic valve.

Obstructions may be relieved, or partially alleviated, by correction of the obstruction, although permanent impairments such as hydronephrosis occur if a complete or partial obstruction persists over a period of weeks to months or longer.

Upper Urinary Tract Obstruction

A stricture or compression of the calyx, ureteropelvic, or ureterovesical (ureter-bladder) junction is a common cause of upper urinary tract obstructions and is commonly caused by kidney stones (calculi). Ureteral compressions or blockages can be caused from an aberrant vessel, tumor, stone, or abdominal inflammation and scarring (retroperitoneal fibrosis).[1] The most common cause in children is a congenital anomaly (see Chapter 39); in young adults, the common cause is renal calculi; and in older adults, renal calculi, ureteral strictures, and tumors are more common.

Obstruction of the upper urinary tract causes a "backing up" of urine and dilation of the ureter, renal pelvis, calyces, and renal parenchyma proximal to the site of urinary blockage. Dilation of the ureter is referred to as **hydroureter** (accumulation of urine in the ureter). Dilation of the renal pelvis and calyces proximal to a blockage is referred to as **hydronephrosis** or **ureterohydronephrosis** (dilation of both the ureter and the pelvicaliceal system) (see Fig. 38.1B). The backup of urine into the Bowman space from an obstruction opposes the hydrostatic pressure of glomerular filtration and decreases the glomerular filtration rate (GFR).[1] Unless the obstruction is relieved, the dilation leads to tubulointerstitial fibrosis, which damages renal nephrons and can lead to CKD.

Tubulointerstitial fibrosis is the deposition of excessive amounts of extracellular matrix (collagen and other proteins) by activated inflammatory cells including macrophages and myofibroblasts with associated areas of tubular atrophy.[2] Tubulointerstitial fibrosis occurs with kidney injury including obstructive uropathies. Although deposition of extracellular matrix is a normal process of kidney repair and maintenance, activation of inflammatory cells and production of growth factors, such as transforming growth factor-beta-1 (TGF-β1), promotes the process of tubulointerstitial fibrosis and irreversible kidney damage.[3]

Apoptosis is a normal process that the body uses to replace damaged or senescent cells with new ones (see Chapter 1). An imbalance in growth factors provoked by obstruction contributes to excess cellular destruction with a transition from apoptosis to necrosis and inflammation, ultimately resulting in the loss of functioning nephrons.[4]

The magnitude of this damage, and the kidney's ability to recover normal homeostatic function, is affected by the severity and duration of the obstruction. With complete obstruction, damage to the renal tubules and compression of the renal vasculature occur in a matter of hours, and irreversible damage occurs within 3 to 4 weeks. Nevertheless, even in the face of a complete obstruction, the human kidney may recover at least partial homeostatic function provided the blockage is removed. Recovery can take up to 3 months.[5]

When there is unilateral obstruction, the body is able to partially counteract the negative consequences by a process called **compensatory hypertrophy** and **hyperfunction**. The compensatory response is guided by growth factors that cause the unobstructed kidney to increase the size and function of individual glomeruli and tubules, but not the total number of functioning nephrons. Consequently, the obstructed kidney can remain silent for a long time. Partial obstruction that is not relieved, in the absence of renal infection, leads to more subtle, but ultimately permanent impairments including loss of the kidney's ability to concentrate urine, reabsorb bicarbonate, excrete ammonia, and regulate metabolic acid-base and fluid and electrolyte balance. The process is reversible when relief of obstruction results in recovery of function by the obstructed kidney. The ability of the body to engage in compensatory hypertrophy and hyperfunction diminishes with age. Complete bilateral obstruction causes anuria because the retrograde increase in tubular hydrostatic pressure completely opposes glomerular filtration.

Relief of upper urinary tract obstruction is usually followed by a brief period of diuresis, commonly called **postobstructive diuresis**. Postobstructive diuresis is a physiologic response and is typically mild, representing a restoration of fluid and electrolyte imbalance caused by retention of fluid related to the obstructive uropathy. Occasionally, relief of obstruction will cause rapid excretion of large volumes of water, sodium, or other electrolytes, resulting in a urine output of 200 mL/h for two consecutive hours or more than 3 L in 24 hours. Minimal normal daily urine output is approximately 720 mL/day.[6] Rapid postobstructive diuresis causes dehydration and fluid and electrolyte imbalances that must be promptly corrected. Risk factors for severe postobstructive diuresis include chronic, bilateral obstruction;

impairment of one or both kidneys' ability to concentrate urine or reabsorb sodium (nephrogenic diabetes insipidus); hypertension; edema and weight gain; congestive heart failure; and uremic encephalopathy.

Nephrolithiasis

Nephrolithiasis, also commonly known as **kidney stones or renal calculi**, are masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults. Stones can be located anywhere along the urinary tract including in the kidneys, ureters, and urinary bladder. However, the favored sites of stone formation are in the renal calyces, renal pelvis, and bladder. Stones are unilateral in about 80% of individuals. The prevalence of kidney stones in the United States is approximately 11% in males and 7% in females with an incidence of about 1% per year.[7] The cumulative risk of recurrence at 5 years is approximately 53% overall, with a lower rate of 26% for those with a single stone episode.[8] The risk of stone formation is influenced by a number of factors, including age, sex, race, geographic location, seasonal factors, fluid intake, diet, occupation, and genetic predisposition.[9] Diseases that predispose individuals for stone formation are urinary tract infection (UTI), hypertension, atherosclerosis, metabolic syndrome, obesity, and type 2 diabetes.[10] While stones are more prevalent in males before the age of 50 years, there is increasing incidence seen in females. Geographic location influences the risk of stone formation because of indirect factors. Warmer climates with high humidity and rainfall influence a person's fluid intake and dietary patterns. Persons who regularly consume an adequate volume of water are at reduced risk when compared with persons who consume lower volumes of water.[9]

Stones are classified according to the primary minerals (salts) that make up the stones. The most common stone types include calcium oxalate or calcium phosphate (70% to 80%), struvite (magnesium–ammonium–phosphate) (5% to 10%), and uric acid (5% to 10%) (Table 38.1).[11] Cystine stones are rare (≤2%), and so are stones that are formed from the metabolic effects of some medications (e.g., atazanavir, ceftriaxone, and N-acetyl-sulfadiazine) in individuals treated for a lengthy period of time for chronic diseases.[12,13]

Table 38.1

Renal Calculi Prevalence and Type

Prevalence	Stone Type

Pictures in right column from Daudon M, Dessombz A, Frochot V, et al. Comprehensive morpho-constitutional analysis of urinary stones improves etiological diagnosis and therapeutic strategy of nephrolithiasis. *Comptes Rendus Chimie*, 2016;19(11–12):1470–1491. https://doi.org/10.1016/j.crci.2016.05.008.

Stones are also classified according to location and size. *Staghorn calculi* are large and fill the minor and major calyces. *Nonstaghorn calculi* are of variable size but tend to be smaller and are located in the renal calyces, renal pelvis, or at various sites along the ureter.

Pathophysiology

Stone formation is complex and related to:

1. supersaturation of one or more salts in the urine,
2. precipitation of the salts from a liquid to a solid state (crystals),
3. growth through crystallization or agglomeration (sometimes called *aggregation*), and
4. the presence or absence of stone inhibitors (e.g., uromodulin [Tamm-Horsfall protein]).

Supersaturation is the presence of a higher concentration of a solute (salt) within a solvent (in this case, the urine) than can be dissolved. Human urine contains many ions capable of *precipitating* from solution and forming a variety of salts. The salts form crystals that are retained and grow into stones. *Crystallization* is the process by which crystals grow from a small nucleus, or nidus, to larger stones in the presence of supersaturated urine. Although supersaturation is essential for free stone formation, the urine need not remain continuously supersaturated for a stone to grow once its nucleus has precipitated from solution. Intermittent periods of supersaturation after the ingestion of a meal or during times of dehydration from limited oral intake or secondary to continued use of diuretics are sufficient for stone growth in many individuals. In addition, the renal tubules and papillae have many surfaces that may attract a crystalline nidus (known as a Randall plaque) and add biologic material (matrix), forming a stone. *Matrix* is an organic material (i.e., mucoprotein) in which the components of a kidney stone are embedded. Randall plaques start in the suburothelial layer and gradually grow until they break through into the renal pelvis. Once in continuous contact with urine, layers of calcium oxalate typically start to form on the calcium phosphate nidus (see Table 38.1).[14] The pH of the urine influences the risk of precipitation and calculus formation. An alkaline urinary pH (pH > 7.0) significantly increases the risk of calcium phosphate stone and struvite stone formation, whereas acidic urine (pH < 5.0) increases the risk of uric acid stone formation. Cystine and xanthine also precipitate more readily in acidic urine.

Substances capable of inhibiting *stone* or *crystal growth include* potassium citrate, Tamm-Horsfall protein, pyrophosphate, and magnesium.[15] These substances normally reduce the risk of calcium phosphate or calcium oxalate precipitation in the urine and prevent subsequent stone formation.

Retention of *crystal particles* occurs primarily at the papillary collecting ducts. Most crystals are flushed from the tract through the normal flow of urine. Urinary stasis (e.g., from benign prostatic hyperplasia, neurogenic bladder), anatomic abnormalities (strictures), or inflamed epithelium within the urinary tract may prevent prompt flushing of crystals from the system, thus increasing the risk of stone formation.

The size of a stone determines the likelihood that it will pass through the urinary tract and be excreted through micturition. Stones smaller than 5 mm have about a 50% chance of spontaneous (painful) passage, whereas stones that are larger than 1 cm have almost no chance of spontaneous passage.[16]

Both genetic and environmental factors may increase the susceptibility of **calcium stones**. Most affected individuals have *idiopathic calcium oxalate urolithiasis (ICOU)*, a condition the exact etiology of which has not yet been determined. Stones can form freely in supersaturated urine or detach from interstitial sites of formation (e.g., from Randall plaque). Hypercalciuria, hyperoxaluria, hyperuricosuria, hypocitraturia, mild renal tubular acidosis, crystal growth inhibitor deficiencies, and

alkaline urine are associated with calcium stone formation. Hypercalciuria and hyperoxaluria are usually attributable to intestinal hyperabsorption and less commonly to a defect in renal calcium reabsorption. Hyperparathyroidism and bone demineralization associated with prolonged immobilization are also known to cause hypercalciuria.[17]

Struvite stones primarily contain magnesium, ammonium, and phosphate as well as varying levels of a matrix. Matrix forms in an alkaline urine and during infection with a urease-producing bacterial pathogen, such as a *Proteus, Klebsiella*, or *Pseudomonas*.[18] Struvite calculi may grow quite large and branch into a staghorn configuration (**staghorn calculus**) that approximates the pelvicaliceal collecting system. Women are at greater risk for struvite stones because they have an increased incidence of UTI.

Uric acid stones occur in persons who excrete excessive uric acid in the urine, such as those with gouty arthritis. Uric acid is primarily a product of biosynthesis of endogenous purines and is secondarily affected by consumption of purines (e.g., meat and beer) in the diet. A consistently acidic urine greatly increases this risk, including defective excretion. *Cystinuria* and *xanthinuria* are genetic disorders of amino acid metabolism, and their excess in urine can cause **cystine** or **xanthine stone** formation in the presence of acidic urine.[19]

Clinical Manifestations

Renal colic is pain related to dilation and spasms of smooth muscle related to ureteral obstruction. Moderate to severe pain often originates in the flank and radiates to the groin, and usually indicates obstruction of the renal pelvis or proximal ureter. Colic that radiates to the lateral flank or lower abdomen typically indicates obstruction in the midureter. Bothersome LUT symptoms (urinary urgency, frequency, incontinence) indicate obstruction of the lower ureter or ureterovesical junction. The pain can be incapacitating and may be accompanied by nausea and vomiting. Gross or microscopic hematuria may be present.

Evaluation and Treatment

The evaluation and diagnosis of nephrolithiasis is based on presenting symptoms and history combined with a focused physical assessment. Imaging studies determine the location of the stone, severity of obstruction, and associated obstructive uropathy. Imaging of kidney stones can include plain abdominal radiography, ultrasound, intravenous pyelography, computed tomography (CT), and magnetic resonance imaging (MRI). The history queries dietary habits, age of the first stone episode, stone analysis, and presence of complicating factors, including hyperparathyroidism or recent gastrointestinal or genitourinary surgery. Urinalysis (including pH) is obtained, and a 24-hour urine is completed to identify calcium oxalate, calcium citrate, and other significant constituents. In addition, every effort is made to retrieve and analyze stones that are passed spontaneously or retrieved through aggressive intervention. To diagnose and manage underlying metabolic disorders, additional tests are completed for those with suspected hyperparathyroidism (elevated serum calcium levels), cystine calculi, or uric acid (high purine diet) stones.

The goals of treatment are to manage acute pain, promote stone passage, reduce the size of stones already formed, and prevent new stone formation.[20] The components of treatment include:

1. managing pain (can require narcotic medication),
2. reducing the concentration of stone-forming substances by increasing urine flow rate with high fluid intake,
3. adjusting the pH of the urine (e.g., make it more alkaline with potassium citrate administration or more acid with potassium acid phosphate),
4. decreasing the amount of stone-forming substances in the urine by decreasing dietary intake or endogenous production or by altering urine pH, and
5. removing stones using percutaneous nephrolithotomy, ureteroscopy, or ultrasonic or laser lithotripsy to fragment stones for excretion in the urine.[21]

Obstructing kidney stones with a suspected proximal UTI are urologic emergencies requiring emergent decompression, stone removal, and antibiotics.[22] Prevention of recurrent stones includes increasing fluid intake to generate 2.5 L of urine per day, avoiding intake of colas and other soft drinks acidified with phosphoric acid, avoiding dietary oxalate (e.g., chocolate, beets, nuts, rhubarb, spinach, strawberries, tea, wheat bran), eating less animal protein, and limiting sodium intake. Maintaining a dietary calcium intake of 1000 to 1200 mg/day is helpful for calcium stone prevention. Potassium citrate may be used to prevent calcium stone aggregation and to raise urinary pH.[23]

Lower Urinary Tract Obstruction

Obstructions of the LUT are inherently caused by a structural or anatomic disorder or an alteration in neurologic function (neurogenic bladder). These disorders are related to alterations of urine storage in the bladder or emptying of urine through the bladder outlet. Incontinence is a common symptom associated with LUT obstructions. The types of incontinence are summarized in Table 38.2.

Table 38.2

Types of Urinary Incontinence

Type	Description
Urge incontinence (most common in older adults)	Involuntary loss of urine associated with an abrupt and strong desire to void (urgency). Often associated with involuntary contractions of the detrusor (detrusor overactivity). When associated with a neurologic disorder, this is called *detrusor hyperreflexia*. When no neurologic disorder exists, this is called *detrusor instability*. May be associated with decreased bladder wall compliance.
Stress incontinence (most common in women younger than 60 years and men who have had prostate surgery)	Involuntary loss of urine during coughing, sneezing, laughing, or other physical activity associated with increased abdominal pressure.
Mixed incontinence (most common in older women)	A combination of stress and urge incontinence.
Overflow incontinence	Involuntary loss of urine with overdistention of the bladder. Associated with neurologic lesions below S1, polyneuropathies, and urethral obstruction (i.e., an enlarged prostate) or detrusor underactivity.
Functional incontinence	Involuntary loss of urine caused by dementia or immobility.
Continuous incontinence	Continuous loss of urine related to vesicovaginal or vesico-uterine fistulas. Extreme intrinsic sphincter deficiency.
Insensible incontinence	Not clearly accompanied by either urgency or stress incontinence (i.e. increase in intra-abdominal pressure). Intrinsic sphincter deficiency. Detrusor overactivity with impaired bladder sensation.

Type	Description
Urge incontinence (most common in older adults)	Involuntary loss of urine associated with an abrupt and strong desire to void (urgency). Often associated with involuntary contractions of the detrusor (detrusor overactivity). When associated with a neurologic disorder, this is called *detrusor hyperreflexia*. When no neurologic disorder exists, this is called *detrusor instability*. May be associated with decreased bladder wall compliance.
Stress incontinence (most common in women younger than 60 years and men who have had prostate surgery)	Involuntary loss of urine during coughing, sneezing, laughing, or other physical activity associated with increased abdominal pressure.
Mixed incontinence (most common in older women)	A combination of stress and urge incontinence.
Overflow incontinence	Involuntary loss of urine with overdistention of the bladder. Associated with neurologic lesions below S1, polyneuropathies, and urethral obstruction (i.e., an enlarged prostate) or detrusor underactivity.
Functional incontinence	Involuntary loss of urine caused by dementia or immobility.
Continuous incontinence	Continuous loss of urine related to vesicovaginal or vesico-uterine fistulas. Extreme intrinsic sphincter deficiency.
Insensible incontinence	Not clearly accompanied by either urgency or stress incontinence (i.e. increase in intra-abdominal pressure). Intrinsic sphincter deficiency. Detrusor overactivity with impaired bladder sensation.

Anatomic Obstructions to Urine Flow

Anatomic causes of resistance to urine flow include urethral stricture, prostatic enlargement in men, pelvic prolapse (bladder and uterus) in women, and tumor compression. A **urethral stricture** is a narrowing of its lumen and occurs when infection, injury, or surgical manipulation produces a scar that reduces the caliber of the urethra. The severity of obstruction is influenced by its location within the urethra, its length, and the severity of the stricture. Strictures that are longer than 1 centimeter and in the proximal urethra cause more severe obstruction. They are more common in men because of a longer urethra (see Chapter 26).[24] Urethral stricture is treated with urethral dilation accomplished by using a steel instrument shaped like a catheter (urethral sound) or a series of incrementally increasing catheter-like tubes (filiforms and followers). Long, dense strictures typically require surgical repair (urethroplasty) to prevent recurrence. **Prostate enlargement** is caused by acute inflammation, benign prostatic hyperplasia, or prostate cancer (see Chapter 26). Severe **pelvic organ prolapse** (see Chapter 25) in a woman causes bladder outlet obstruction when a cystocele (the downward protrusion/herniation of the bladder into the vagina) or the uterus descends into the vagina below the level of the urethral outlet. In men, the bladder may rarely herniate into the scrotum, causing a similar type of obstruction. Each of these disorders can cause compression of the urethra with obstruction to urine flow.

Partial obstruction of the bladder outlet or urethra initially causes an increase in the force of detrusor contraction. If the obstruction persists, afferent nerves within the bladder wall are adversely affected, leading to urinary urgency and, in some cases, overactive detrusor contractions (a myogenic cause of overactive bladder). When obstruction persists, there is an increased deposition of collagen within the smooth muscle bundles of the detrusor muscle *(trabeculation)*. Ultimately, the bladder wall loses its ability to stretch and accommodate urine, a condition called **low bladder wall compliance** (loss of elasticity), and the detrusor loses its ability to contract efficiently, resulting in urine retention. This underactive bladder (UAB) syndrome can also occur as a consequence of bladder radiation treatment. Low bladder wall compliance chronically elevates intravesicular pressure, increasing the likelihood of hydroureter, hydronephrosis, impaired renal function, incontinence, and UTI.

Symptoms of obstruction include:

1. frequent daytime voiding (micturition more than every 2 hours while awake);
2. nocturia (awakening more than once each night to urinate for adults younger than 65 years of age or more than twice for older adults);
3. poor force of stream;
4. intermittency of urinary stream;
5. bothersome urinary urgency, often combined with hesitancy; and
6. feelings of incomplete bladder emptying despite micturition.

Overactive and Underactive Bladder Syndrome

Overactive bladder syndrome (OAB) is a dysfunction of urine storage with nonspecific symptoms characterized by urinary urgency, frequency, and nocturia with or without incontinence in the absence of UTI or other known pathology (e.g., neurologic disorders). OAB affects a significant number of adults (approximately 16%).[25] The specific cause is not clearly known and several mechanisms could be involved including myogenic or neurogenic alterations in sensory and motor function.[26] The symptoms are usually associated with involuntary contractions of the detrusor muscle during the bladder-filling phase, often resulting in urge incontinence and nocturia. Risk factors in women include vaginal birth with episiotomy or use of forceps, surgery for pelvic organ prolapse, and decreased estrogen associated with menopause or hysterectomy. Loss of estrogen results in thinning and loss of urethral muscle strength. Risk factors in men include enlarged prostate with urinary obstruction and surgical treatment for prostate cancer. Risk factors include the use of diuretics, antidepressants, alpha-agonists, beta-antagonists, sedatives, anticholinergics, and analgesics.

Both behavioral and pharmacologic therapy are first- and second-line treatments for OAB. Behavioral therapy includes pelvic floor (Kegel) exercises (detrusor contraction can be inhibited by pelvic floor muscle contraction providing time to get to the toilet), bladder training with timed voiding, management of fluid intake and use of caffeine and alcohol, managing constipation, and biofeedback techniques. Drug therapy to manage incontinence includes topical vaginal estrogen in women and drugs that increase urethral sphincter contraction or relax the bladder wall.

Because the parasympathetic nervous system controls detrusor muscle contraction with cholinergic (muscarinic) signals and the bladder neck consists of circular smooth muscle with α-adrenergic innervation, OAB may be managed by anticholinergic therapy (antimuscarinic) and adrenergic medications. Anticholinergics increase urethral pressure, and β_3-adrenergic agonists relax the bladder wall, increasing bladder capacity. These medications must be monitored closely for adverse side effects. When these therapies are not successful, neuromodulation therapy is considered, including intradetrusor injection of onabotulinumtoxinA (Botox) (inhibits release of acetylcholine), peripheral tibial nerve stimulation, and sacral neuromodulation. Low bladder wall compliance (loss of elasticity) may be managed by antimuscarinic drugs, intradetrusor onabotulinumtoxin A injections, and intermittent catheterization.[27] OAB syndrome should be discussed during health assessments; however, many individuals are reluctant to discuss OAB syndrome with their health care provider. Untreated OAB is an economic burden, impairs health and quality of life, and causes symptoms such as skin breakdown because of leakage, sleep disturbance, fall-related injuries, depression, prolonged hospital stays, and admission to long-term care facilities.

UAB syndrome is a voiding dysfunction characterized by the International Continence Society Working Group as bladder contraction of reduced strength and/or duration, resulting in prolonged bladder emptying or a failure to achieve complete bladder emptying, or both, within a normal time span. Symptoms include a slow urinary stream, hesitancy, and straining to void, with or without a feeling of incomplete bladder emptying and dribbling.[28] Disruption of bladder innervation can occur with spinal cord injury, stroke, multiple sclerosis, Parkinson disease, and diabetic neuropathy. Aging can be a contributing factor. The symptoms may be indistinguishable from symptoms of LUT obstruction, including weak stream, intermittency, hesitancy, and straining to void. In some cases, UAB and OAB may occur together with detrusor overactivity during storage but poor detrusor contraction in the voiding phase. Urodynamic studies are required for evaluation. Treatment depends on the cause of the disorder and may include sacral neuromodulation, drugs that increase bladder contractility, and/or drugs that induce urethral relaxation.[29]

Evaluation and Treatment

Diagnosis of LUT obstructions requires a detailed history; physical examination, including neurologic and pelvic examinations; urinalysis; and determining if pathologic causes of urgency and frequency, such as prostatic enlargement, pelvic organ prolapse, urethral strictures, and neurologic disorders or systemic disease, are present. Diaries and questionnaires are helpful to determine the pattern and severity of incontinence. However, no symptom or cluster of symptoms has been identified that accurately differentiates the various causes of these disorders. For example, symptoms such as urgency, urge incontinence, frequent urination, and nocturia may develop because of overactive bladder or either increased or decreased bladder outlet resistance. Reduced resistance is associated with the symptom of stress incontinence (incontinence with coughing or sneezing), and symptoms of increased resistance are similar to bladder outlet obstruction, including poor force of urinary stream, hesitancy, and feelings of incomplete bladder emptying. Various urodynamic tests (Box 38.1) assist with the evaluation of how efficient the bladder, sphincters, and urethra are in storing and releasing urine. An evaluation of renal function, including functional imaging studies and measurement of serum creatinine (SCr) level, is completed particularly when the obstruction is severe and associated with elevated residual urine or UTI.

Box 38.1

Urodynamic Tests

1. *Postvoid residual urine* measures the amount of urine remaining in the bladder after urination.
2. *Uroflowmetry* provides a graphic representation of urine flow rate and voiding time (the force of the urinary stream expressed as milliliters voided per second) and evaluates the presence of obstruction.
3. *Cystometric test* uses a catheter and manometer to evaluate bladder urine volume and pressure in relation to the occurrence of involuntary bladder contraction (the leak point pressure) and the urge to void.
4. Electromyography uses sensors to measure detrusor and sphincter muscle contraction strength during urination.
5. *Multichannel urodynamic testing* measures pressure in both the bladder and rectum during urination.
6. *Video-urodynamic recording* takes pictures and videos of the bladder using ultrasound or x-rays during bladder filling and emptying and can demonstrate overactive bladder and detrusor sphincter dyssynergia (lack of coordination between the bladder and sphincter).

Neurogenic Bladder

Neurogenic bladder is a general term for bladder dysfunction caused by neurologic disorders (Table 38.3).[30] The types of dysfunctions are related to the sites in the nervous system that control sensory and motor bladder function (Fig. 38.2). Lesions in the upper motor neurons of the brain and spinal cord result in detrusor hyperreflexia (overactive bladder) and bladder **dyssynergia** (loss of coordinated neuromuscular contraction). Lesions in the sacral area of the spinal cord or peripheral nerves result in underactive, hypotonic, or atonic (flaccid) bladder function, often with loss of bladder sensation. (See Chapter 15 for upper and lower motor neuron function.)

Table 38.3

Neurogenic Bladder

Cause (Symptoms)	Site of Lesion	Diseases
Detrusor hyperreflexia (urgency and urine leakage)	Lesions above C2 involve pontine micturition center (UMN disorder)	Stroke, traumatic brain injury, multiple sclerosis (MS), hydrocephalus, cerebral palsy, Alzheimer disease, brain tumors
Detrusor hyperreflexia with vesicosphincter dyssynergia (functional bladder outlet obstruction)	Lesions between C2 and S1 (UMN disorder)	Spinal cord injury C2–T12, MS, transverse myelitis, Guillain-Barré syndrome, disk problems
Acontractile detrusor, with or without urethral sphincter incompetence (stress urinary incontinence)	Lesions below S1 (cauda equina syndrome) (LMN disorder)	Myelodysplasia, peripheral polyneuropathies, MS, tabes dorsalis, spinal injury T12–S1, cauda equina syndrome, herpes simplex/zoster

LMN, Lower motor neuron; *UMN*, upper motor neuron.

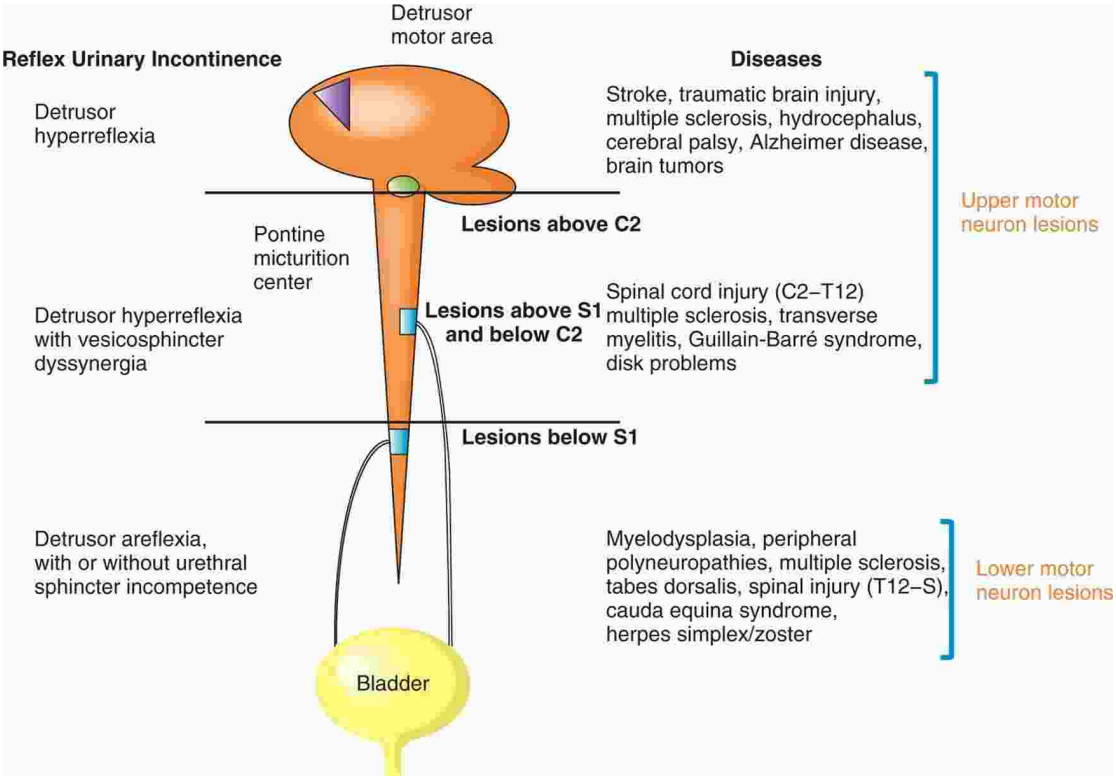

FIG. 38.2 Sites of Neurologic Injury Associated With Neurogenic Bladder. (Adapted from Doughty DB, ed. *Urinary and fecal incontinence management* concepts, 3rd edition. Philadelphia: Mosby: 2006.)

An illustration shows the sites of neurologic injury associated with neurogenic bladder. The illustration shows and labels the following structures, from the top to the bottom: the detrusor motor area, lesions above C 2, the pontine micturition center, lesions above S 1 and below C 2, lesions below S 1, and bladder. Reflex urinary incontinence in the detrusor motor area is detrusor hyperreflexia. The diseases (upper motor neuron lesion) include stroke, traumatic brain injury, multiple sclerosis, hydrocephalus, cerebral palsy, Alzheimer disease, and brain tumors. Reflex urinary incontinence in the pontine micturition center is detrusor hyperreflexia with vesicosphincter dyssynergia. The diseases (upper motor neuron lesions) include spinal cord injury (C 2 to T 12), multiple sclerosis, transverse myelitis, Guillain-Barre syndrome, and disk problems. Reflex urinary incontinence in the bladder is detrusor areflexia, with or without urethral sphincter incompetence. The diseases (lower motor neuron lesions) include myelodysplasia, peripheral polyneuropathies, multiple sclerosis, tabes dorsalis, spinal injury (T 12 to S), cauda equina syndrome, and herpes simplex or zoster.

Neurologic disorders that develop above the pontine micturition center (located near the posterior pons) result in **detrusor (bladder muscle) hyperreflexia (overactivity)**, also known as an uninhibited or reflex bladder or neurogenic overactive bladder. This is an upper motor neuron disorder in which the

bladder empties automatically (without voluntary control) when it becomes full and the urethral sphincter functions normally. Because the pontine micturition center remains intact, there is coordination between detrusor muscle contraction and relaxation of the urethral sphincter. Stroke, traumatic brain injury, dementia, and brain tumors are examples of disorders that result in detrusor hyperreflexia. Symptoms include urine leakage and incontinence.

Neurologic lesions that occur below the pontine micturition center but above the sacral micturition center (between C2 and S1) are also upper motor neuron lesions and result in **detrusor sphincter dyssynergia** (**detrusor hyperreflexia with vesicosphincter dyssynergia)** (loss of coordinated function between the bladder and sphincter). There is loss of pontine coordination of detrusor muscle contraction and external sphincter relaxation, so both the bladder and the sphincter are contracting at the same time (dyssynergia), causing a functional obstruction of the bladder outlet. Spinal cord injury, multiple sclerosis, Guillain-Barré syndrome, and vertebral disk problems are causes of this disorder. There is diminished bladder relaxation during storage with small urine volumes and high intravesicular (inside the bladder) pressures. The result is an OAB with symptoms of frequency, urgency, urge incontinence, and increased risk for UTI. Diagnosis includes a medical history, physical examination, urinalysis, and urodynamic testing. Detrusor sphincter dyssynergia may be managed by intermittent catheterization in combination with higher dose antimuscarinic drugs to prevent overactive detrusor contractions and associated dyssynergia, while ensuring regular, complete bladder evacuation by catheterization. Transurethral botulinum toxin A injection has shown temporary efficacy in reducing bladder outlet obstruction. Transurethral sphincterotomy can be beneficial.[31]

Neurologic lesions involving the sacral micturition center (below S1, also termed *cauda equina syndrome*) or peripheral nerve lesions result in **detrusor areflexia** (acontractile detrusor, atonic bladder, or UAB), a lower motor neuron disorder. The atonic bladder causes retention of urine and distention with stress and overflow incontinence. There is prolonged urination time with or without a sensation of incomplete bladder emptying, usually with hesitancy, reduced sensation on filling, and a slow stream. If the *sensory innervation* of the bladder is intact, the full bladder will be sensed but the detrusor may not contract. Myelodysplasia, multiple sclerosis, tabes dorsalis (deterioration of the posterior columns of the spinal cord associated with untreated syphilis), spinal cord injury, and peripheral polyneuropathies (i.e., diabetic neuropathy) are associated with this disorder.

Diagnosis includes disease history, clinical examination, urinalysis, and urodynamic studies (see Box 38.1). Bethanechol chloride (Urecholine) is a cholinergic agent (muscarinic agonist) that stimulates the bladder to empty and can be helpful in some cases. Intermittent catheterization or indwelling catheters are commonly required.

Tumors

Kidney (Renal) Tumors

Kidney (Renal) tumors were estimated at 76,080 (4%) of new cancer cases and 13,780 deaths for 2021.[32] Renal **cell carcinoma (RCC)** (also known as **renal cell adenocarcinoma**) usually occurs in men (about three times more often than in women) between 50 and 60 years of age. Risk factors include cigarette smoking, obesity, and uncontrolled hypertension. With surgical resection, 5-year survival is about 93% for stage I (encapsulated) cancer.

Pathophysiology

There are several different types of RCCs. They are classified according to subtypes and extent of metastasis. *Clear cell RCC* is the most common renal neoplasm (80% of all renal neoplasms) and represents about 2% of cancer deaths.[32,33] It occurs primarily in the proximal tubule of the renal cortex. Other types include papillary (small fingerlike growths) and chromophobe RCC (larger cells), and both occur in the distal tubules of the kidneys.[34] Confinement within the renal capsule, together with treatment, is associated with a better survival rate. The tumors usually occur unilaterally (Fig. 38.3). **Renal transitional cell carcinoma (RTCC)** is rare and primarily arises in the renal parenchyma and renal pelvis near the ureteral orifice. **Renal adenomas** (benign tumors) are uncommon but are increasing in number. The tumors are encapsulated and are usually located near the cortex of the

kidney. Some tumors are unclassified because they have multiple cell types. Because the tumors can become malignant, they are usually surgically removed.

FIG. 38.3 Renal Cell Carcinoma.
Renal cell carcinomas usually are spheroidal masses composed of yellow tissue mottled with hemorrhage, necrosis, and fibrosis. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis, MA: Mosby; 1996.)

Clinical Manifestations

The classic clinical manifestations of renal tumors are hematuria, dull and aching flank pain, palpable flank mass, and weight loss, but all these symptoms occur in fewer than 10% of cases. Further, they represent an advanced stage of disease, whereas earlier stages are often silent (painless hematuria). About 25% to 30% of individuals with RCC present with metastasis.[35] The most common sites of distant metastasis are the lung, lymph nodes, liver, bone, thyroid gland, and central nervous system.

Evaluation and Treatment

Diagnosis is based on the clinical symptoms and imaging procedures. The tumor, node, metastasis (TNM) classification is used to stage RCC. Treatment for localized disease is surgical removal of the affected kidney (radical nephrectomy) or partial nephrectomy for smaller tumors, with combined use of chemotherapeutic agents. Radiofrequency ablation also may be used for early-stage tumors when

surgery is not an option. Metastatic disease is treated with immunotherapy and targeted molecular therapies.[36] Survival is related to tumor grade, tumor cell type, and extent of metastasis.

Bladder Tumors

Bladder tumors represent about 4.5% of all malignant tumors with 64,280 new cases each year and 12,260 deaths.[32] The development of bladder cancer is most common in men older than 60 years. Risk factors include smoking, exposure to occupational chemicals, heavy consumption of phenacetin, uroepithelial schistosomiasis infection, or a genetic predisposition. *Transitional cell (urothelial) carcinoma* is the most common bladder malignancy, and tumors are usually superficial. More advanced tumors are muscle invasive. Less common forms are squamous cell and adenocarcinoma (cells that produce mucus).

Pathophysiology

Tumors present as flat or papillary and progress from in situ to invasive into the muscle and bladder wall (Fig. 38.4). Metastasis is usually to lymph nodes, liver, bones, or lungs. The TNM classification is used for staging bladder carcinoma. Secondary bladder cancer develops by invasion of cancer from bordering organs, such as cervical carcinoma in women or prostatic carcinoma in men.

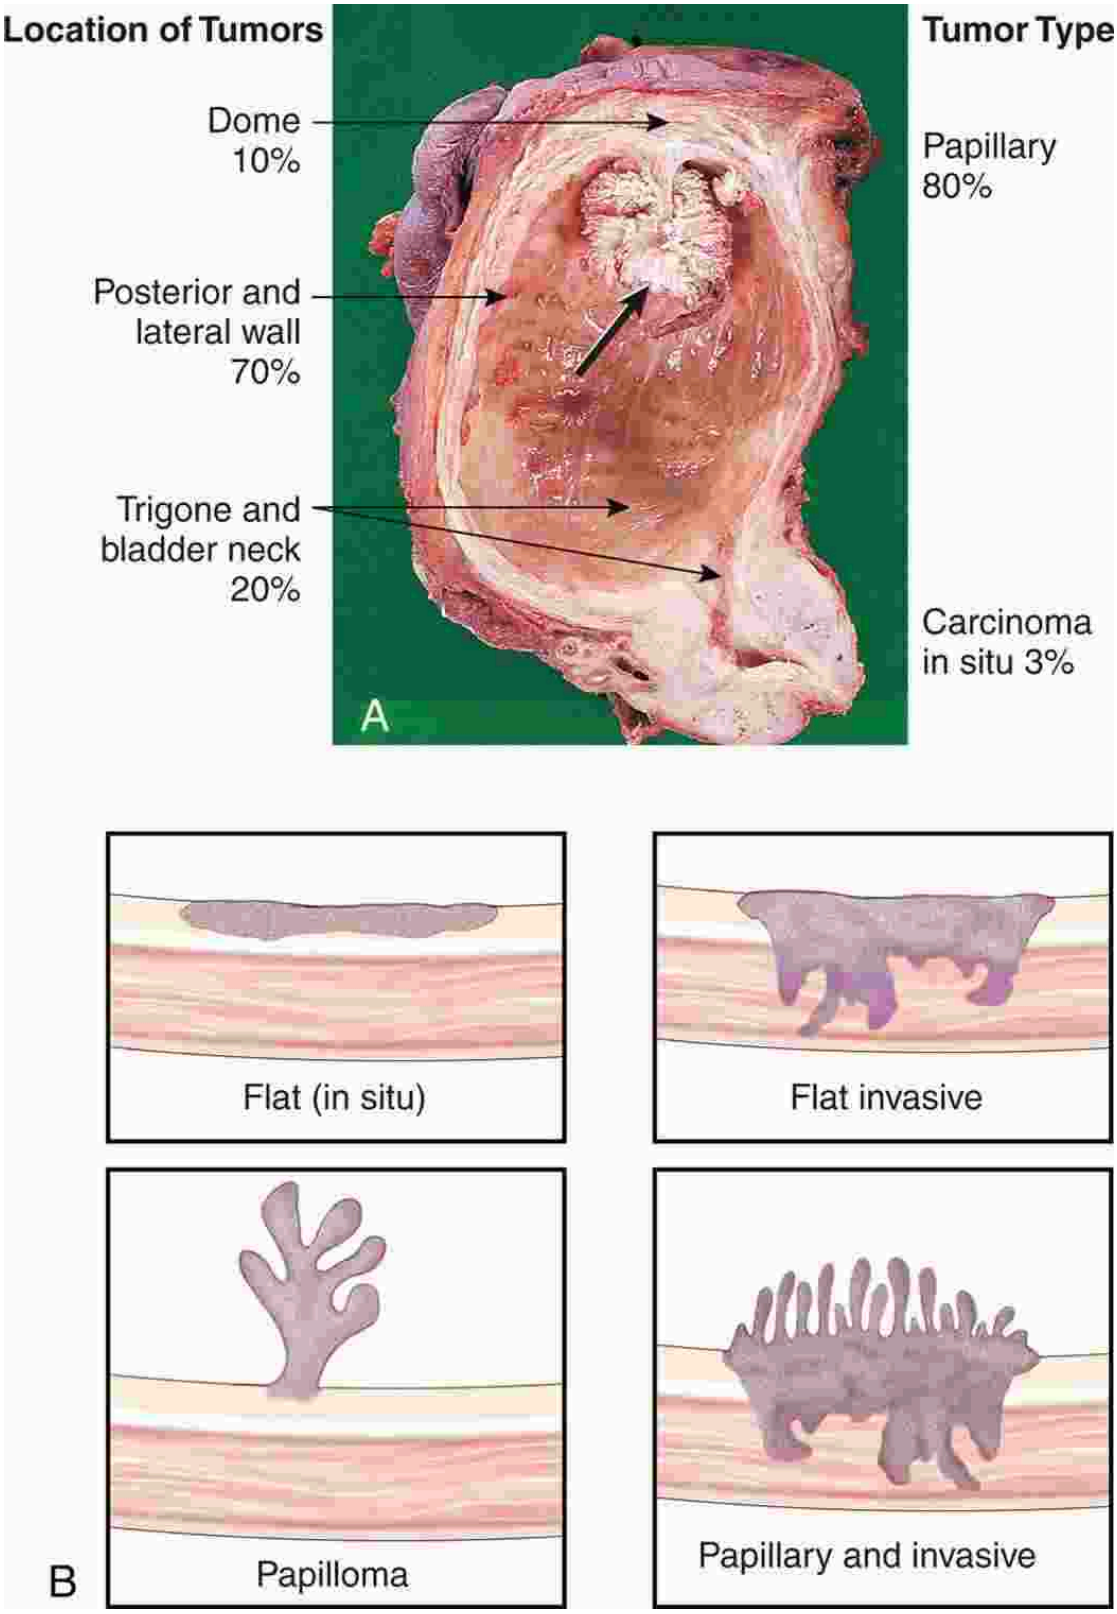

FIG. 38.4 Carcinoma of the Bladder.
(A) Papillary transitional cell carcinoma arising in the dome of the bladder as a cauliflower-like lesion *(black arrow);* location and frequency of bladder tumor types

noted. **(B)** Bladder cancer with morphologic patterns of most common tumors. (A, From Stevens A, Lowe J, Scott I, eds. *Core pathology*, 3rd edition. London: Mosby; 2009; 2009. B, Adapted from Kissane JM, ed. *Anderson's pathology*, 9th edition. St. Louis: Mosby; 1990.)

Top panel, A. A closeup of a cross-section of the dome of the bladder. The locations of tumors are as follow: 10 percent in the dome; 70 percent in the posterior and lateral wall; and 20 percent in trigone and bladder neck. Tumor types are 80 percent papillary and 3 percent carcinoma in situ. Bottom panel, B. The illustration on the top-left shows a flat tumor on the surface. The illustration on the top-right shows a flat invasive tumor, penetrating the layers. The illustration on the bottom-left shows a papilloma on the surface. The illustration on the bottom-right shows a papillary and invasive tumor, penetrating the layers.

Clinical Manifestations

Gross painless hematuria is the archetypal clinical manifestation of bladder cancer. Episodes of hematuria tend to recur, and they are often accompanied by bothersome LUT symptoms including daytime voiding frequency, nocturia, urgency, and urge urinary incontinence, particularly for carcinoma in situ. Flank pain may occur if tumor growth obstructs one or both ureterovesical junctions.

Evaluation and Treatment

Urine cytologic study (pathologic analysis of sloughed cells within the urine) is used for screening. Cystoscopy with tissue resection and biopsy is the first stage of treatment and confirms the diagnosis of bladder cancer. Use of biologic markers for bladder cancer diagnosis and treatment prognosis are available.[37] Transurethral resection or laser ablation, combined with intravesical chemotherapy or immunotherapy, is effective for superficial tumors. Radical cystectomy (removal of the prostate and seminal vesicles in men and removal of the uterus, ovaries, and part of the vagina in women) with urinary diversion and adjuvant chemotherapy is required for locally invasive tumors.[38]

Urinary Tract Infection

Causes of Urinary Tract Infection

A **UTI** is an inflammation of the urinary epithelium (mucosa) usually caused by bacteria from gut flora. UTI can occur anywhere along the urinary tract, including the urethra, prostate, bladder, ureter, or kidney. At risk are premature newborns; prepubertal children; sexually active and pregnant women; women treated with antibiotics that disrupt vaginal flora; spermicide users; estrogen-deficient postmenopausal women; individuals with indwelling catheters; and individuals with diabetes mellitus, neurogenic bladder, or urinary tract obstruction. Cystitis is more common in women because of the shorter urethra and the closeness of the urethra to the anus (increasing the possibility of bacterial contamination). Adult women have a 50% to 60% lifetime incidence of UTI.[39]

Several factors normally combine to protect against UTIs. Most bacteria are washed out of the urethra during micturition. The low pH and high osmolality of urea, the presence of Tamm-Horsfall protein or uromodulin (secreted by renal tubular cells in the distal loop of Henle), and secretions from the uroepithelium provide a bactericidal effect. The ureterovesical junction closes during bladder contraction, preventing reflux of urine to the ureters and kidneys. Both the longer urethra and the presence of prostatic secretions decrease the risk of infection in men. UTI occurs when a pathogen circumvents or overwhelms the body's natural defense mechanisms and rapidly reproduces. *Uncomplicated UTIs* are mild with a self-limiting course and occur in individuals without any functional or anatomical anomalies in the urinary tract. A *complicated UTI* develops when there is an abnormality in

the urinary system or a secondary disease, syndrome, or illness that compromises an individual's defenses, such as diabetes mellitus, neurogenic bladder, urinary tract obstruction, renal transplant, or spinal cord injury.[40] UTI may occur alone or in association with pyelonephritis, prostatitis, or nephrolithiasis. Up to 30% of cases of septic shock are caused by urosepsis (a systemic response to an infection in the urogenital tract that can include symptoms of shock).[41] The mechanisms associated with UTI including bacterial and human factors are summarized in Fig. 38.5. *Recurrent UTI* is commonly defined as three or more UTIs within 12 months or two or more occurrences within 6 months. Recurrence is more common in women as compared to men. UTI may occur as a *relapse* when there is a second infection within the urinary tract caused by the same pathogen within 2 weeks of the original treatment or a *reinfection* that occurs more than 2 weeks after completion of treatment for the same or different pathogen.[40] Guidelines are available for clinical management.[42]

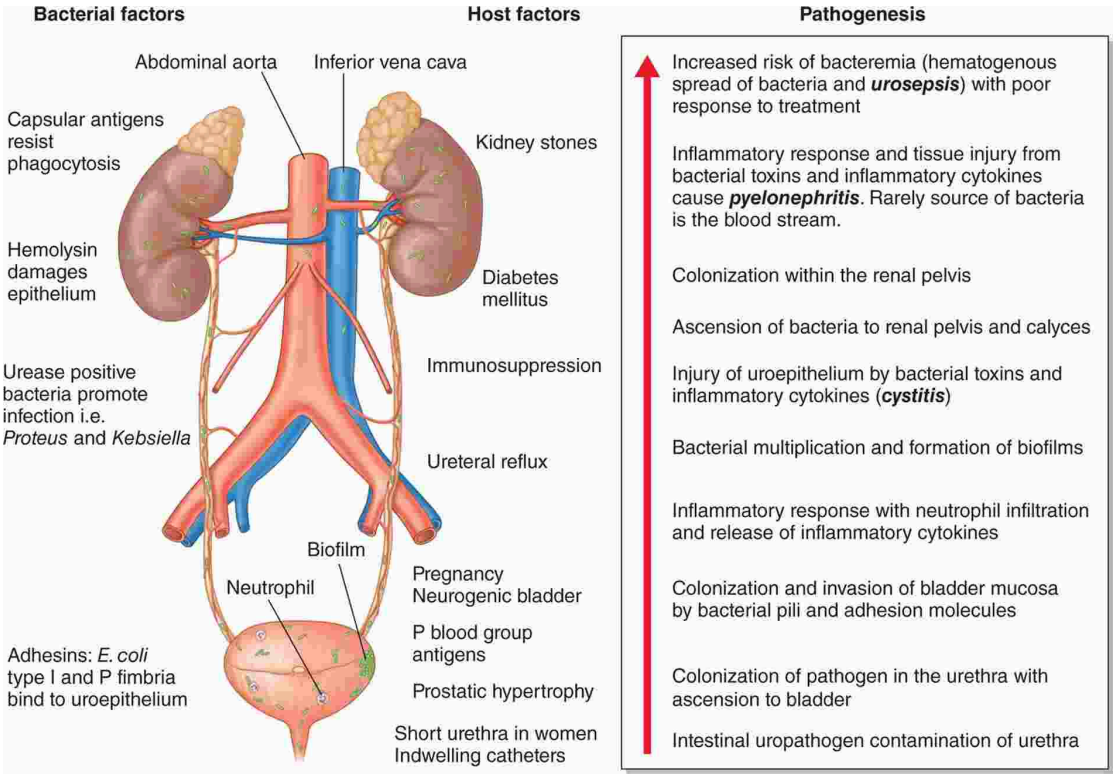

FIG. 38.5 Mechanisms of Urinary Tract Infection.

An illustration shows the mechanisms of urinary tract infection. The illustration shows and labels the following structures on the urinary system: abdominal aorta, inferior vena cava, biofilm, and neutrophil. The bacterial factors include capsular antigens resist phagocytosis; hemolysin damages epithelium; urease positive bacteria promote infection, that is proteus and kebsiella; and adhesins: E coli type 1 and P fimbria bind to uroepithelium. The host factors include kidney stones; diabetes mellitus; immunosuppression; ureteral reflux; pregnancy neurogenic bladder; P blood group antigens; prostatic hypertrophy; and short urethra in women indwelling catheters. The pathogenesis, from the bottom to the top, is as follows. • Intestinal uropathogen contamination of urethra. • Colonization of urethra with ascension to bladder. • Colonization and invasion of bladder mucosa by bacterial pili and adhesion molecules. • Inflammatory response with neutrophil infiltration and release of inflammatory cytokines. • Bacterial multiplication and formation of biofilms. • Injury of uroepithelium by bacterial toxins and inflammatory cytokines (cystitis). • Ascension of bacteria to renal pelvis and calyces. • Colonization of renal pelvis. • Inflammatory response and tissue injury from bacterial toxins and inflammatory cytokines cause pyelonephritis. Rarely source of bacteria is the blood stream. • Increased risk of bacteremia (hematogenous spread of bacteria and urosepsis) with poor response to treatment.

Types of Urinary Tract Infection

Cystitis

Cystitis is an inflammation of the bladder, which is the most common site of UTI. The appearance of the bladder through a cystoscope describes the different types of cystitis:

1. *Mild cystitis* shows a hyperemic (red) mucosa.
2. *Hemorrhagic cystitis* shows diffuse mucosal hemorrhages and occurs with more advanced inflammation.
3. *Suppurative cystitis* shows mucosal pus formation or suppurative exudates.
4. *Ulcerative cystitis* results from prolonged infection with ulcers that may lead to sloughing of the mucosa.
5. *Gangrenous cystitis* is necrosis of the bladder wall and occurs with the most severe infections.

Pathophysiology

Two factors account for the development of UTI: the virulence of the pathogen and the efficiency of host defense mechanisms. The most common infecting microorganisms are uropathic strains of *Escherichia coli*, and the second most common is *Staphylococcus saprophyticus*. Less common microorganisms include *Klebsiella, Proteus, Pseudomonas*, fungi, viruses, parasites, or tubercular bacilli. Schistosomiasis is the most common parasitic invasion of the urinary tract on a global basis, particularly Africa and areas of the Middle East, and has a strong association with bladder cancer.[43] Bacterial contamination of the normally sterile urine usually occurs by retrograde (backward) movement of gastrointestinal gram-negative bacilli into the urethra and bladder from the opening of the urethra. The microorganisms overcome normal defense mechanisms and can then move into the ureter and kidney. Uropathic strains of *E. coli* have *type-1 fimbriae* (also termed pili or fingerlike projections) that bind to receptors on the uroepithelium. Consequently, they resist flushing during normal micturition. They also can bind to latex catheters used for urinary drainage. Some women may be genetically susceptible to certain strains of *E. coli* attachment. In these cases, women have P blood group antigen (a glycolipid) that binds to *P. fimbriae* (pyelonephritis-associated fimbriae) of *E. coli* on the uroepithelium, allowing the pathogen to ascend the urinary tract. Infection initiates an inflammatory response and the symptoms of cystitis. The inflammatory edema in the bladder wall stimulates activation of stretch receptors. The activated stretch receptors initiate symptoms of bladder fullness with small volumes of urine, producing the urgency and frequency of urination associated with cystitis.

Clinical Manifestations

Clinical manifestations of cystitis are related to the inflammatory response and usually include polyuria, urinary frequency, urgency, dysuria (painful urination), and suprapubic and low back pain. Hematuria, cloudy or malodorous urine, flank pain, and mental status changes are more serious symptoms. Many individuals with bacteriuria are asymptomatic. Individuals with a complicated UTI may present with systemic symptoms such as fever, chills, mental status changes, tachycardia, hypotension, nausea, vomiting, pain, and incontinence. The elderly have the highest risk and may present with only confusion or vague abdominal discomfort.

Evaluation and Treatment

Cystitis in symptomatic individuals is diagnosed by urine culture of specific microorganisms with counts of 100,000/mL or more from freshly voided urine.[44] The standard diagnostic test for UTI is urinalysis, which is both cost-effective and noninvasive. The most accurate way to obtain a urine specimen is a midstream clean catch. Positive nitrates and leukocyte esterase on the dipstick analysis are accurate indicators of UTI. Urinalysis screening of asymptomatic bacteriuria is only recommended in women during pregnancy and for individuals prior to undergoing invasive urologic procedures.[45] Women reporting typical symptoms of uncomplicated lower UTI do not require any laboratory or diagnostic testing.[46] Risk factors, such as urinary tract obstruction, should be identified and treated.

Evidence of bacteria from urine culture and antibiotic sensitivity warrants treatment with a microorganism-specific antibiotic. Optimal therapy depends on the severity and local bacterial resistance patterns. Acute uncomplicated cystitis in nonpregnant women can be diagnosed without an office visit or urine culture. If urine culture and sensitivity are ordered, the urine specimen must be obtained before the initiation of any antibiotic therapy; 3 to 7 days of treatment is most common.[42]

Complicated UTI requires 7 to 14 days of treatment. Relapsing infection within 7 to 10 days requires prolonged antibiotic treatment. Clinical symptoms are frequently relieved, but bacteriuria may still be present. Repeat cultures are not necessary as a test for cure post-treatment. For chronic infection with a continuation of symptoms, cultures should be obtained every 3 to 4 months until 1 year after treatment for evaluation and treatment of recurrent infection. Guidelines are available for the treatment of community-acquired UTIs, uncomplicated cystitis and pyelonephritis in women, complicated cystitis, and for the prevention of catheter-associated cystitis.[47]

Painful Bladder Syndrome/Interstitial Cystitis

Interstitial cystitis/bladder pain syndrome (IC/BPS) is defined as an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder associated with LUT symptoms of more than 6 weeks' duration in the absence of infection or other identifiable causes. It is most commonly diagnosed in women and in the fourth decade of life or after.

Pathophysiology. The cause of IC/BPS is unknown. IC/BPS can be conceptualized as a bladder pain disorder that is often associated with voiding and other systemic chronic disorders such as fibromyalgia, irritable bowel disease, chronic fatigue syndrome, Sjogren's syndrome, chronic headaches, and vulvodynia.[48] An autoimmune reaction may be responsible for the inflammatory response, which includes mast cell activation, altered uroepithelial permeability, and increased sensory nerve sensitivity. The inflammation is associated with a derangement of the glycosaminoglycan layer of the bladder mucosa that makes it more susceptible to penetration by bacteria and noxious urinary solutes.Clinical Manifestations. Inflammation and fibrosis of the bladder wall (uroepithelium) are accompanied by pain. Bladder volume may decrease as a result of fibrosis. IC/BPS is also categorized by the presence or absence of hemorrhagic ulcers (Hunner ulcers or lesions). Absence of Hunner ulcers is a non-inflammatory phenotype with little evidence of bladder etiology and presents with somatic and/or psychological symptoms that commonly result in central nervous sensitization.[49]

Evaluation and Treatment. Diagnosis of IC/PBS requires a thorough history, physical examination and urinalysis, analysis of cystoscopy findings, the presence or absence of Hunner ulcers, and the exclusion of other diagnoses. The hallmark symptom of IC/PBS is pain, including sensations of pressure and discomfort located in the suprapubic area, urethra, vulva, vagina, rectum, lower abdomen, or back lasting longer than 6 weeks. Other characteristic symptoms of IC/PBS include bladder fullness, urinary urgency, frequency (including nocturia) with small urine volume, and chronic pelvic pain. No single treatment is effective. Treatment should focus on improving quality of life through self-care practices and behavioral modifications. Oral and intravesical therapies, sacral nerve stimulation, and intradetrusor botulinum toxin A are used for symptom relief. Fulguration with laser or electrocautery and/or injection with triamcinolone should be performed if Hunner ulcers are present. Surgery is used in refractory cases.[50] Guidelines are available for the treatment of IC/BPS.[51]

Acute Pyelonephritis

Pyelonephritis is an infection of one or both upper urinary tracts (ureter, renal pelvis, and kidney interstitium). Common causes are summarized in Table 38.4. Urinary obstruction and reflux of urine from the bladder (vesicoureteral reflux) are the most common underlying risk factors, with most cases occurring in women. One or both kidneys may be involved.

Table 38.4

Common Causes of Pyelonephritis

Predisposing Factors	Pathologic Mechanisms
Nephrolithiasis	Obstruction and stasis of urine contributing to bacteriuria and hydronephrosis; irritation of epithelial lining with entrapment of bacteria
Vesicoureteral reflux	Chronic reflux of urine up the ureter and into kidney during micturition, contributing to bacterial infection
Pregnancy	Dilation and relaxation of ureter with hydroureter and hydronephrosis; partly caused by obstruction from enlarged uterus and partly from ureteral relaxation caused by higher progesterone levels
Neurogenic bladder	Neurologic impairment interfering with normal bladder and urethral sphincter contraction with residual urine and ascending infection
Instrumentation	Introduction of organisms into urethra and bladder by catheters and endoscopes introduced into the urinary tract for diagnostic purposes
Female sexual trauma	Movement of organisms from the urethra into the bladder with infection and retrograde spread to kidney

Pathophysiology

Microorganisms usually associated with acute pyelonephritis include *E. coli* (most common), *Proteus*, or *Pseudomonas*. The latter two microorganisms are more commonly associated with infections after urethral instrumentation or urinary tract surgery. These microorganisms also split urea into ammonia, making an alkaline urine that increases the risk of stone formation. The infection is likely spread by ascending uropathic microorganisms along the ureters. Dissemination also may occur by way of the bloodstream. The inflammatory process primarily affects the pelvis, calyces, and medulla of the kidney. The infection causes infiltration of leukocytes with renal inflammation, renal edema, and purulent urine. In severe infections, localized abscesses may form in the medulla and extend to the cortex. The tubules are primarily affected, while the glomeruli are usually spared. Necrosis of renal papillae can develop. After the acute phase, healing occurs with fibrosis and atrophy of affected tubules. The number of bacteria decreases until the urine again becomes sterile. Acute pyelonephritis rarely causes renal failure.

Clinical Manifestations

The onset of symptoms is usually acute, with fever, chills, tachycardia, nausea, vomiting, and flank or groin pain. Symptoms characteristic of UTI, including frequency, dysuria, incontinence, and costovertebral tenderness, may precede systemic signs and symptoms.[46] Older adults may have early nonspecific symptoms, such as low-grade fever, confusion, and malaise.

Evaluation and Treatment

Differentiating symptoms of cystitis from those of pyelonephritis by clinical assessment alone is difficult. The specific diagnosis is established by urine culture, urinalysis, and clinical manifestations. White blood cell casts formed in the renal tubules and flushed into the urine indicate pyelonephritis. However casts are not always present in the urine. A urine culture assay establishes a definitive diagnosis through identification of the uropathogen. A positive culture is characterized by bacteriuria of at least 10^5 CFU/mL.[44] Individuals with complicated pyelonephritis may require blood cultures and diagnostic imaging if there is no response to antibiotic treatment or if there is a suspected obstruction. Optimal therapy for acute uncomplicated pyelonephritis depends on severity and local resistance patterns.[52] Current guidelines recommend empiric therapy with a broad-spectrum antibiotic (e.g.,

fluoroquinolone) for patients with pyelonephritis, not requiring hospitalization. A urine specimen for culture and sensitivity must be collected prior to initiation of antibiotics.[46] A post-treatment test of cure urinalysis or urine culture in asymptomatic individuals is not performed.[42] However, follow-up urine cultures are obtained at 1 and 4 weeks after treatment if symptoms recur. Antibiotic-resistant microorganisms or reinfection may occur in cases of urinary tract obstruction or reflux. Intravenous pyelography and voiding cystourethrography are used to identify surgically correctable lesions.

Chronic Pyelonephritis

Chronic pyelonephritis is a persistent or recurrent infection of one or both of the kidneys leading to scarring. The specific cause of chronic pyelonephritis may be unknown (idiopathic) or associated with chronic UTIs, vesicoureteral reflux, or kidney stone obstructive uropathy. Other causes include drug toxicity from analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs), ischemia, irradiation, and immune-complex diseases.

Pathophysiology

Chronic urinary tract obstruction prevents elimination of bacteria and starts a process of progressive inflammation. Alterations occur within the renal pelvis and calyces from the obstruction and inflammation (Fig. 38.6). There is destruction of the tubules and diffuse scarring, which impairs urine-concentrating ability. The lesions of chronic pyelonephritis are sometimes termed chronic interstitial nephritis because the inflammation and fibrosis are located in the interstitial spaces between the tubules.

FIG. 38.6 Pyelonephritis.
(Right) Small, shrunken, irregularly scarred kidney of an individual with chronic pyelonephritis. *(Left)* Kidney is of normal size but also shows scarring on the upper pole. From Damjanov I. *Pathology for the health professions*, 4th edition. Philadelphia: Saunders; 2012.

Clinical Manifestations

The early symptoms of chronic pyelonephritis are often minimal and may include urinary frequency, dysuria, flank pain, and hypertension. Progression can lead to kidney failure, particularly in the

presence of other risk factors (e.g., obstructive uropathy or diabetes mellitus). There is an inability to conserve sodium with loss of tubular function and development of hyperkalemia and metabolic acidosis. Risk for dehydration must be considered if there is loss of the ability to concentrate the urine.

Evaluation and Treatment

Urinalysis, intravenous pyelography, and ultrasound are used as diagnostic tests to evaluate chronic pyelonephritis. Treatment is related to the underlying cause. Obstruction must be relieved. Antibiotics may be given, with prolonged antibiotic therapy for recurrent infection.

Glomerular Disorders

Glomerulonephritis

Acute glomerulonephritis is an inflammation isolated to the kidney glomerulus caused by *primary glomerular injury*, including infection, immunologic responses, ischemia, free radicals, drugs, toxins, and vascular disorders. *Secondary glomerular injury* is a glomerular injury that occurs as a consequence of systemic diseases, including diabetes mellitus, hypertension, bacterial toxins, systemic lupus erythematosus, congestive heart failure, and HIV-related kidney disease.

Pathophysiology

Immune mechanisms are a major component of both primary and secondary glomerular injury. (Fig. 38.7). The injury damages the glomerular capillary filtration membrane. The most common type of immune injury is related to the presence of antigen-antibody complexes within the glomerulus (Table 38.5). Nonimmune glomerular injury is related to injury or ischemia from metabolic disorders, toxin exposure, drugs, vascular disorders, and infection. Different causes of injury may result in more than one type of glomerular lesion; thus, lesions are not necessarily disease specific (Table 38.6).

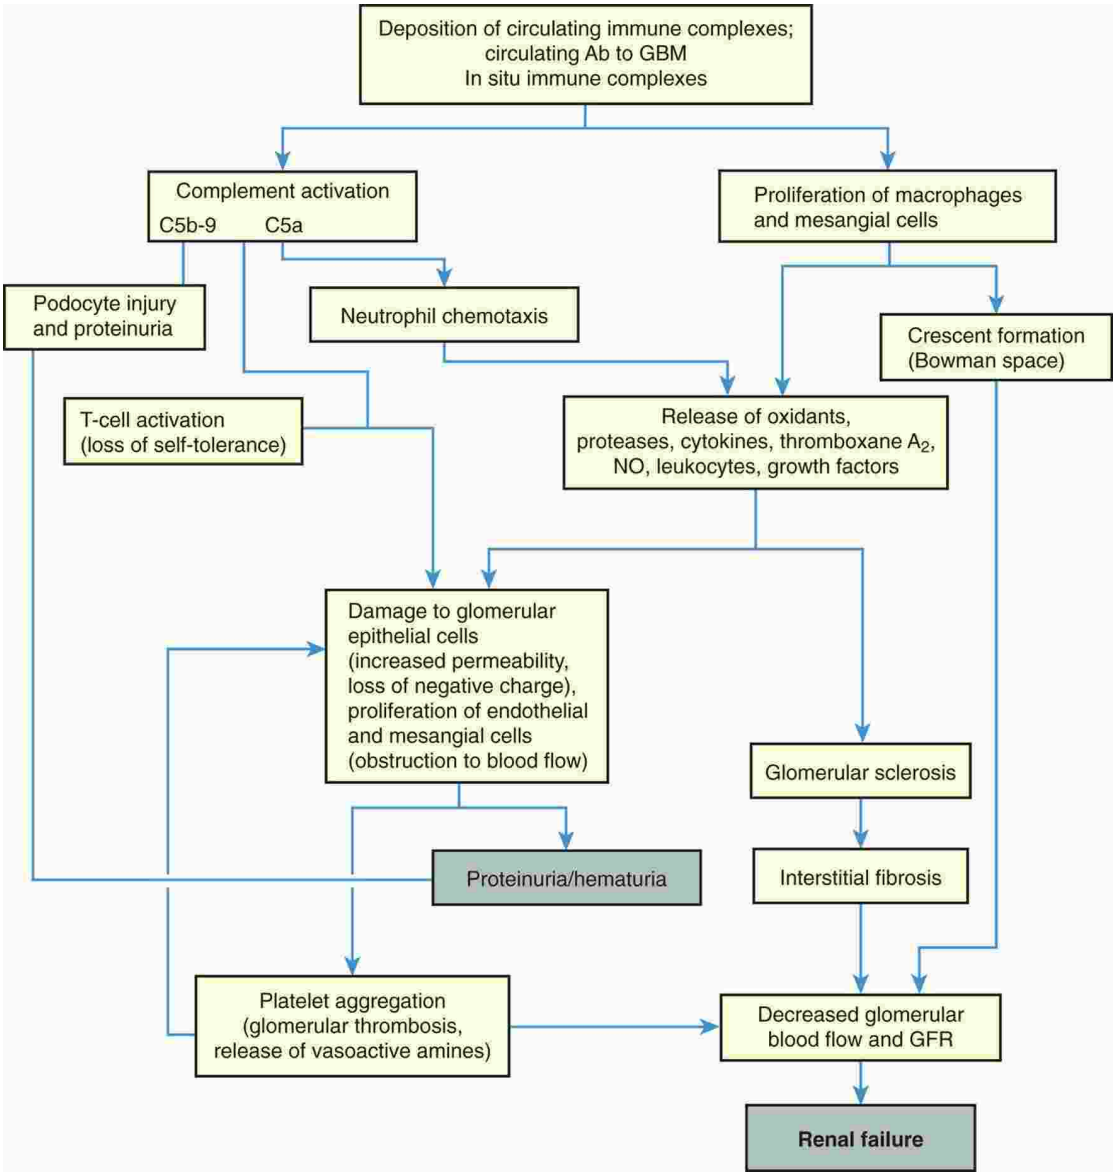

FIG. 38.7 Mechanisms of Glomerular Injury.
Ab, Antibody; *GBM*, glomerular basement membrane; *GFR*, glomerular filtration rate; *NO*, nitric oxide.

A flowchart shows the mechanisms of glomerular injury. 1. Deposition of circulating immune complexes; circulating Ab to G B M; and In situ immune complexes. Leads to 2 and 3. 2. Complement activation (C 5 b-9 and C 5 a). Leads to 4, 5, 7, and 9. 3. Proliferation of macrophages and mesangial cells. Leads to 6 and 8. 4. Podocyte injury and proteinuria. Leads to 11. 5. Neutrophil chemotaxis. Leads to 8. 6. Crescent formation (Bowman space). Leads to 14. 7. T-cell activation (loss of self-tolerance). Leads to 9. 8. Release of oxidants, proteases, cytokines, thromboxane A sub 2, N O, leukocytes, growth factors. Leads to 9 and 10. 9. Damage to glomerular epithelial cells (increased permeability, loss of negative charge), proliferation of endothelial and mesangial

cells (obstruction to blood flow). Leads to 11 and 13. 10. Glomerular sclerosis. Leads to 12. 11. Proteinuria/hematuria. 12. Interstitial fibrosis. Leads to 14. 13. Platelet aggregation (glomerular thrombosis, release of vasoactive amines). Leads to 9 and 14. 14. Decreased glomerular blood flow and G F R. Leads to 15. 15. Renal failure.

Table 38.5

Immunologic Pathogenesis of Glomerulonephritis

Glomerular Injury	Mechanism
Soluble immune-complex glomerulonephritis (90%)	Formation of antibodies stimulated by the presence of endogenous or exogenous antigens results in circulating soluble antigen-antibody complexes, which are deposited in glomerular capillaries, or the in situ formation of immune complexes to planted antigens or to structural components within the glomerulus; glomerular injury occurring with complement deposition and activation and release of immunologic substances that lyse cells and increase membrane permeability; immune deposits with a microscopic appearance that fluoresce in a *granular pattern* when stained with fluorescein and viewed under ultraviolet light; severity of glomerular injury related to the number of complexes formed; a type III hypersensitivity reaction; immunoglobulin A (IgA) nephropathy and poststreptococcal glomerulonephritis are examples
Antiglomerular basement membrane glomerulonephritis (5%)	Antibodies are formed and act directly against the glomerular basement membrane (type IV collagen); immune response that causes crescent formation and a *linear pattern* of immunofluorescence; generally associated with rapidly progressive renal failure such as Goodpasture syndrome (type II hypersensitivity reaction)
Alternative complement pathway	An immune mechanism associated with circulating autoantibodies and C3 complement and membranoproliferative glomerulonephritis
Cell-mediated immunity	A delayed hypersensitivity response that damages glomerulus; actual cellular mechanism not clearly understood but may involve cytokine secretion, activation of effector cells such as macrophages or by inducing autoantibodies or immune complexes; cytotoxic CD8+ T-cell responses and failure of regulatory T cells may represent two additional types of antirenal hypersensitivity (type IV hypersensitivity); often seen in rapidly progressive glomerulonephritis

Table 38.6

Classification of Glomerular Lesions

Lesion	Distribution When Many Glomeruli Considered
Diffuse	Relatively uniform involvement of most (>50%) or all glomeruli; most common form of glomerulonephritis
Focal	Changes in only some glomeruli (>50%), whereas others are normal

Lesion	Distribution When Single Glomeruli Considered
Global	A lesion involving the entire glomerulus
Segmental-local	Changes in one part of the glomerulus with other parts unaffected

Immune injury is caused by activation of the inflammatory response (i.e., complement activation, leukocyte recruitment, and release of cytokines from leukocytes). Injury begins after the antigen-antibody complexes have deposited or formed in the glomerular capillary wall or mesangium. Complement is deposited with the antibodies and complement activation can cause cell injury or serve as a chemotactic stimulus for attraction of leukocytes (neutrophils, monocytes, and T lymphocytes). These phagocytes, along with activated platelets, further the inflammatory reaction by releasing mediators that injure the glomerular filtration membrane including epithelial cells, glomerular basement membrane, and endothelial cells (podocytes and filtration slits).[53] The injury increases glomerular filtration membrane permeability and reduces glomerular membrane surface area.

There may be hypertrophy and proliferation of mesangial cells and expansion of the extracellular matrix in the Bowman space. The deposition of these substances and cell proliferation forms a crescent shape within the Bowman space that can be seen under a microscope and can assist with diagnosis if a biopsy is performed. The result of these processes is compression of glomerular capillaries, decreased glomerular blood flow, hypoxic injury, decreased driving glomerular hydrostatic pressure, alteration in the filtration membrane, and decreased GFR. Crescent formation is associated with rapidly progressive glomerulonephritis.[54]

Loss of the normal negative electrical charge across the glomerular filtration membrane and increase in filtration pore size enhance movement of proteins into the urine. Proteins are normally repelled because they also have a negative charge and thus are not filtered into the urine. Red blood cells also escape if pore size is large enough. Consequently, proteinuria and/or hematuria develop. The severity of glomerular damage and decline in glomerular function is related to the size, number, and location (i.e., focal [affecting some glomeruli] or diffuse [affecting glomeruli throughout the kidney]) of cells injured; duration of exposure; and type of antigen-antibody complexes formed.

Clinical Manifestations

The onset of glomerulonephritis may be sudden or insidious. A significant loss of nephron function can occur before symptoms develop. Acute glomerulonephritis may be silent, mild, moderate, or severe in symptom presentation. Severe or progressive glomerular disease causes oliguria (urine output of 30 mL/h or less), hypertension, and renal failure. Focal lesions tend to produce less severe clinical symptoms. Salt and water are reabsorbed, contributing to fluid volume expansion, edema, and hypertension.

Two distinct symptoms of more severe or rapidly progressive glomerulonephritis are (1) hematuria with red blood cell casts (the red blood cells accumulate in the kidney tubules and are washed into the urine in the form of a cast of the tubule) and (2) proteinuria exceeding 3 to 5 g/day with albumin (macroalbuminuria). Glomerular bleeding provides prolonged contact with the acidic urine and transforms hemoglobin to methemoglobin, which has a brownish color and no blood clots.

Evaluation and Treatment

The diagnosis of glomerular disease is confirmed by the progressive development of clinical manifestations and abnormal laboratory findings. Common urinalysis findings associated with glomerular disease include proteinuria, red blood cells, white blood cells, and casts. Reduced GFR during glomerulonephritis is evidenced by elevated plasma urea, cystatin C, and creatinine concentrations, or by reduced renal creatinine clearance (see Chapter 37). Microscopic evaluation from renal biopsy can provide a specific determination of renal injury and the type of pathologic lesion (i.e., the formation of glomerular crescents as previously described and location and character of glomerular lesions). Patterns of antigen-antibody complex deposition within the glomerular capillary filtration membrane have been established using light, electron, and immunofluorescent microscopy. Electron microscopy differentiates morphologic changes within the glomerular capillary wall (e.g., subendothelial and mesangial electron-dense deposits, increased mesangial matrix, mesangialization of capillary loops, and foot process fusion). Staining with fluorescein identifies complement and different antibodies (i.e., immunoglobulin G [IgG] or immunoglobulin A [IgA]) and associated configurations when viewed under ultraviolet light with light microscopy. Findings with microscopy provide information about the distribution and lesions of immune response injury and guide therapy.[55]

Reduced GFR during glomerulonephritis is evidenced by elevated plasma urea, cystatin C, and creatinine concentrations, or by reduced creatinine clearance (see Tests of Renal Function in Chapter 37). Edema, caused by excessive sodium and water retention and or loss of plasma proteins (see Chapter 3 for the pathophysiology of edema), may require the use of diuretics or dialysis.

Management principles for treating glomerulonephritis are related to treating the primary cause, preventing or minimizing immune responses, and correcting accompanying problems. Accompanying problems include edema, hypertension, hypoalbuminemia, and hyperlipidemia. Specific treatment regimens are necessary for particular types of glomerulonephritis. Antibiotic therapy is essential for the management of underlying infections that may be contributing to ongoing antigen-antibody responses. Corticosteroids decrease antibody synthesis and suppress inflammatory responses. Cytotoxic agents (e.g., cyclophosphamide) may be used to suppress the immune response in corticosteroid-resistant cases. Anticoagulants may be useful for controlling fibrin crescent formation in rapidly progressive glomerulonephritis.

Types of Glomerulonephritis

The types of glomerulonephritis can be described according to cause, pathologic lesions determined by biopsy (Table 38.7), disease progression (acute, rapidly progressive, chronic), or clinical presentation (nephrotic syndrome, nephritic syndrome, acute or chronic renal failure). In nearly all types of glomerulonephritis, the epithelial or podocyte layer of the glomerular capillary membrane is disturbed with loss of negative charges and changes in membrane permeability. Plasma proteins (albumin) and red blood cells can escape into the urine and can cause proteinuria and/or hematuria. The mesangial matrix may be expanded, or the basement membrane thickened decreasing blood flow through the glomerular capillaries and decreasing GFR. Many types of glomerular injury occur most often in children or young adults, including acute postinfectious glomerulonephritis and minimal change nephropathy (lipoid nephrosis). Details of these diseases are presented in Chapter 39.

Table 38.7

Characteristic Patterns of Glomerular Lesion

Lesion	Lesion Characteristics
Mesangial	Deposits of immunoglobulins in the mesangial matrix; mesangial cell proliferation
Membranous	Thickening of the glomerular capillary wall with immune deposits (i.e., immunoglobulin G [IgG] and complement 3 [C3])
Proliferative	Increase in the number of glomerular cells: endothelial, epithelial, mesangial
Sclerotic	Glomerular scarring from previous glomerular injury
Crescentic	Accumulation of proliferating cells within Bowman space, making the appearance of a crescent
Interstitial fibrosis	Scarring between the glomerulus and the tubules

Complications of systemic diseases, such as diabetic nephropathy and systemic lupus erythematosus, can affect the entire nephron with significant glomerular injury. Different patterns of injury develop over the course of these diseases, and there is usually chronic progression. They are described in the next section.

Chronic Glomerulonephritis

Chronic glomerulonephritis encompasses several glomerular diseases with a progressive course leading to chronic kidney failure. There may be no history of kidney disease before the diagnosis. Hypercholesterolemia and proteinuria have been associated with progressive glomerular and tubular injury (Fig. 38.8). The proposed mechanism is related to those observed in glomerulosclerosis and interstitial injury, such as inflammatory processes and glomerular hyperfiltration. The primary cause may be difficult to establish because advanced pathologic changes may obscure specific disease characteristics. Diabetes nephropathy and lupus nephritis are examples of secondary causes of chronic glomerular injury. Renal insufficiency usually begins to develop after 10 to 20 years of disease, followed by nephrotic syndrome (see next section) and an accelerated progression to end-stage renal failure (ESRF). Symptom patterns vary depending on the underlying cause and the areas of the kidney that are damaged. The specific pathologic changes are identified by renal biopsy, which is best performed in the early stages of CKD to identify specific treatment options. Management of the underlying disease and use of steroids, immunosuppressive agents, dipeptidyl peptidase-4 (DPP-4) inhibitors, glucagon-like peptide-1 (GLP-1) receptor agonists, sodium-glucose co-transporter-2 (SGLT2) inhibitors, renin-angiotensin-aldosterone (RAAS) inhibitors, and angiotensin-receptor blockers (ARBs) can prolong remissions and preserve renal function (see Emerging Science Box: Renin–Angiotensin–Aldosterone System Inhibitors in Patients With COVID-19). Dialysis or kidney transplantation ultimately may be needed.

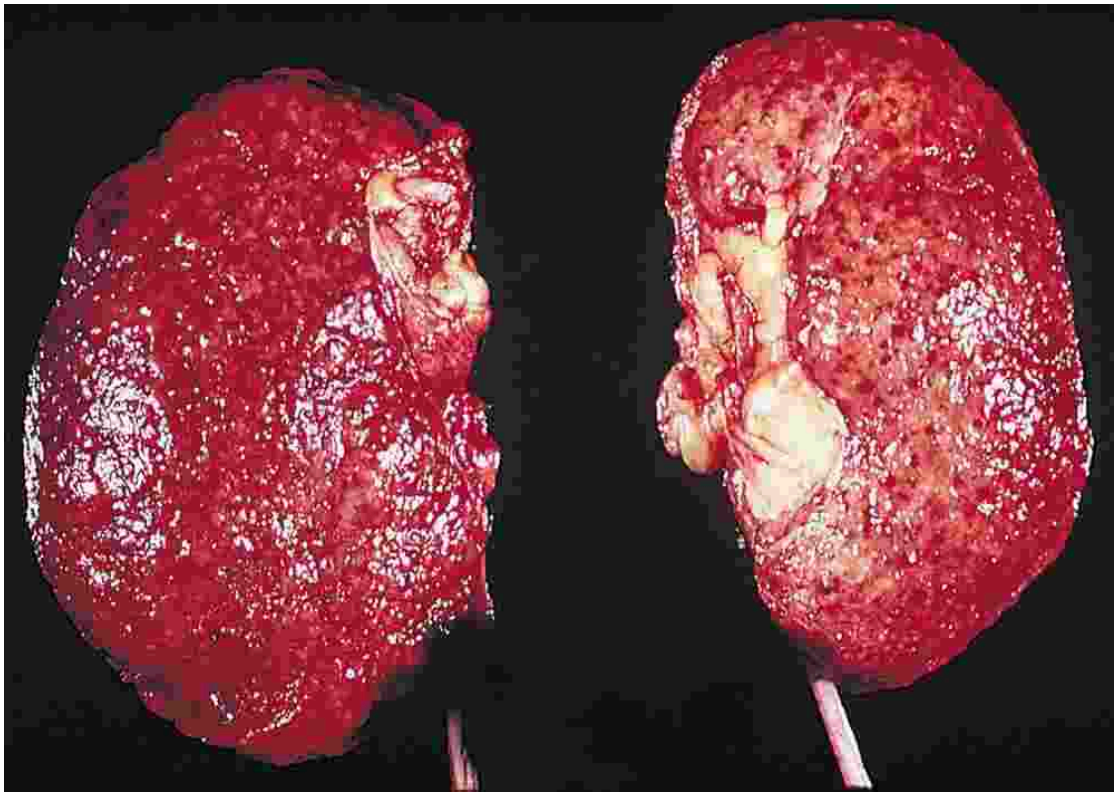

FIG. 38.8 Chronic Glomerulonephritis.
The kidneys appear small, are uniformly shrunken, and have a finely granular external surface. (From Damjanov I. *Pathology for the health professions*, 4th edition. Philadelphia: Saunders, 2012.)

Diabetic nephropathy develops from metabolic (accumulation of advanced glycosylated end products), inflammatory (transforming growth factor-beta and protein kinase C), and macrovascular and microvascular complications related to chronic hyperglycemia (see Chapter 22). Changes in the glomerulus are characterized by podocyte injury, progressive thickening and fibrosis of the glomerular basement membrane, expansion of the mesangial matrix (diffuse diabetic glomerulosclerosis), and nodular glomerulosclerosis (Kimmelstiel-Wilson nodules; see Fig. 38.9) with albuminuria, loss of tubular cells, and progression to chronic kidney disease. Although albuminuria is the classic phenotype of progressive diabetic renal disease, two new phenotypes have emerged (i.e., "nonalbuminuric renal impairment" and "progressive renal decline"), suggesting there can be progressive failure of renal function (i.e., declining GFR) without albuminuria. These "new" phenotypes may be the consequence of improved treatment. Work is in progress to determine if diagnostic and treatment guidelines should be modified for the management of these different phenotypes.[56] Diabetic nephropathy is the most common cause of CKD and end-stage renal disease (ESRD) for both type 1 and type 2 diabetes.[57] ESRD requires treatment with dialysis or renal transplantation.[58]

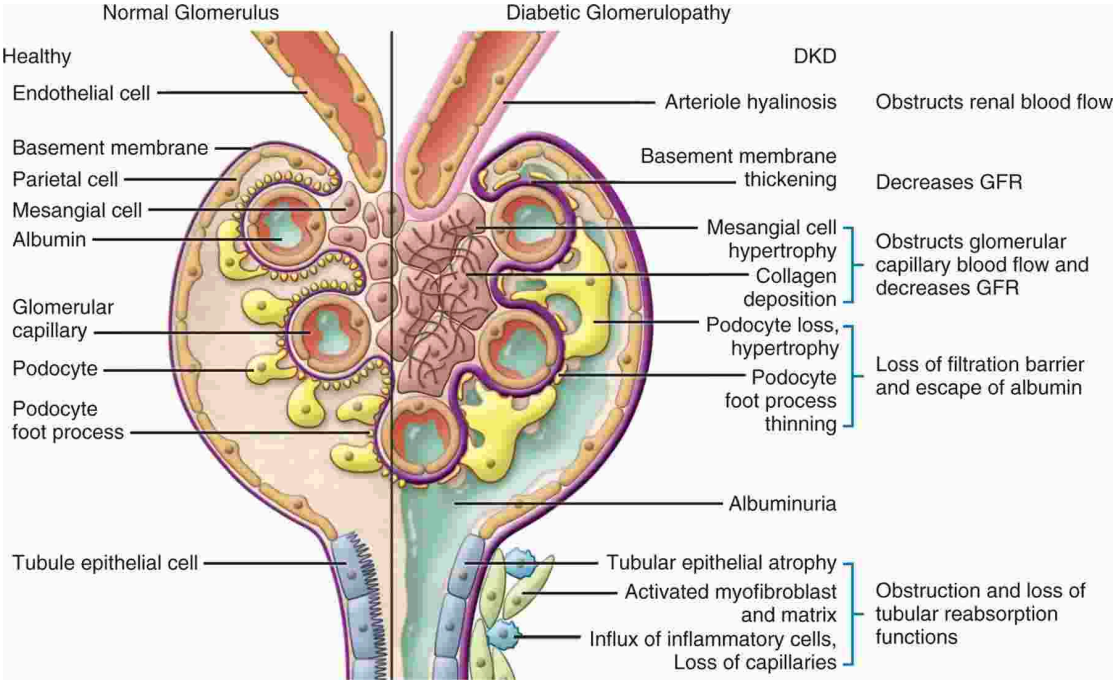

FIG. 38.9 Diabetic Glomerulopathy. (Used with permission from RReidy K, Kang HM, Hostetter T, et al. Molecular mechanisms of diabetic kidney disease. *Journal of Clinical Investigation*, 2014;124(6):2333–2340.)

An illustration of the cross-section of the glomerulus compares the structures of normal glomerulus and diabetic glomerulopathy. Normal glomerulus: healthy endothelial cell, basement membrane, parietal cell, mesangial cell, albumin, glomerular capillary, podocyte foot process, and tubule epithelial cell. Diabetic glomerulopathy: D K D, obstructs renal blood flow (arteriole hyalinosis), decreases G F R (basement membrane thickening), obstructs glomerular capillary blood flow and decreases G F R (mesangial cell hypertrophy, collagen deposition), loss of filtration barrier and escape of albumin (podocyte loss, hypertrophy, podocyte foot process thinning), albuminuria, and obstruction and loss of tubular reabsorption functions (tubular epithelial atrophy, activated myofibroblast and matrix, and influx of inflammatory cells, loss of capillaries).

Lupus nephritis is an inflammatory complication of the chronic autoimmune syndrome systemic lupus erythematosus (see Chapter 9). The renal component of the disease may be caused by the formation of autoantibodies against double-stranded DNA and nucleosomes with glomerular deposition of the immune complexes. Immune complexes also may be formed in situ by binding to planted antigens of circulating autoantibodies. There is complement activation and a cascade of inflammatory events resulting in damage to the glomerular membrane with mesangial expansion (see Chapter 8).[59] Various glomerular lesion patterns are identifiable on biopsy, including membranous, mesangial, membranoproliferative, and diffuse proliferative glomerulonephritis; tubular fibrosis can also be present (Table 38.8). Symptom presentation is variable depending on lesion involvement and can include proteinuria, microscopic hematuria, edema, and other signs of nephrotic syndrome. Disease progression may be silent or may progress to ESRD over a period of years. Treatment includes the use

of immunosuppressive agents and efforts to protect the kidney from secondary nonimmune consequences of acute injury.[60]

Table 38.8

Features of the Common Types of Glomerulonephritis

Type and Cause	Histopathophysiology
Associated with Nephritic Syndrome	
Acute postinfectious glomerulonephritis (PIGN) (e.g., group A beta-hemolytic streptococci [more common in children]; staphylococcus [more common in older adults])	Subepithelial deposits of IgG and complement complexes; infiltration of neutrophils and monocytes; proliferation of mesangial and epithelial cells with occlusion of glomerular capillary blood flow and decreased glomerular filtration; usually diffuse lesions
Rapidly progressive or crescentic glomerulonephritis (a clinical syndrome): *Type I:* Formation of IgG antibodies against pulmonary capillary and glomerular basement membrane (Goodpasture syndrome); activation of complement and neutrophils; more common in young men; causes pulmonary hemorrhage and renal failure *Type II:* Mesangial immune-complex deposition (PIGN, SLE, IgA nephropathy) *Type III:* Pauci-immune, lack of antiglomerular basement membrane antibodies antibodies or immune complexes; presence of serum antineutrophil cytoplasmic (ANC) antibodies associated with systemic vasculitides (usually idiopathic); nonspecific response to glomerular injury; can occur in any severe glomerular disease	Accumulation of fibrin, macrophages, and epithelial cell proliferation into the Bowman space forms crescents and occludes glomerular capillary blood flow, decreasing glomerular filtration; antiglomerular basement membrane antibodies lead to necrotizing, proliferative glomerulonephritis, and renal failure; diffuse lesions
Mesangial proliferative glomerulonephritis Can be associated with IgA nephropathy or lupus nephritis	Deposits of immune complexes in the mesangium with mesangial cell proliferation; results in decreased glomerular blood flow and glomerular filtration; leads to hematuria/proteinuria and nephrotic syndrome
Associated with Nephrotic Syndrome	
Minimal change nephropathy (lipoid nephrosis) Glomerular basement membrane appears normal Most common cause of nephrotic syndrome in children (see Chapter 39)	Glomeruli look normal under light microscopy; electron microscopy reveals uniform diffuse effacement of epithelial (podocyte) foot processes; loss of negative charge in basement membrane and increased permeability lead to severe proteinuria and nephrotic syndrome

Type and Cause	Histopathophysiology
Usually idiopathic	
Focal segmental glomerulosclerosis Usually idiopathic Can be associated with HIV infection, IgA nephropathy	Focal proliferation of endothelial and mesangial cells and glomerulosclerosis from hyaline deposits in segmental parts of the glomerular membrane; there is effacement (thinning or deletion) of epithelial podocytes, with a significant increase in pore size resulting in proteinuria and nephrotic syndrome; can progress to involve entire glomerulus and development of tubulointerstitial fibrosis
Membranous nephropathy (autoimmune response to unknown renal antigen) Usually idiopathic; can be associated with systemic diseases (i.e., hepatitis B virus, hepatitis C virus, systemic lupus erythematosus, solid malignant tumors)	Diffuse thickening of glomerular basement membrane and capillary wall from deposits of antibody, complement, and release of inflammatory cytokines; increased permeability with proteinuria and leading cause of nephrotic syndrome in white adults
Membranoproliferative glomerulonephritis (MPGN)	Mesangial cell proliferation; thickening of basement membrane; subendothelial deposits of immune-complex occlude glomerular capillary blood flow and decrease glomerular filtration; diffuse lesions
Usually idiopathic; associated with hypocomplementemia *Type I:* Activation of classical complement pathway with nephrotic syndrome (hepatitides B and C, SLE) *Type II:* Activation of alternate complement pathway with hematuria (idiopathic); no circulating immune complexes *Type III:* Activation of alternative complement pathway with nephrotic syndrome; can be familial	
IgA Nephropathy (Berger Disease) Usually idiopathic (can be associated with cirrhosis and minimal change disease); elevated IgA plasma levels (also see Henoch-Schönlein purpura nephritis in Chapter 39)	Mesangial proliferation with deposition of IgA; release of inflammatory mediators with cellular proliferation; crescent formation, glomerulosclerosis, interstitial fibrosis, decreased GFR and hematuria; usually focal, some diffuse lesions

Type and Cause	Histopathophysiology
Associated with Nephritic Syndrome	
Acute postinfectious glomerulonephritis (PIGN) (e.g., group A beta-hemolytic streptococci [more common in children]; staphylococcus [more common in older adults])	Subepithelial deposits of IgG and complement complexes; infiltration of neutrophils and monocytes; proliferation of mesangial and epithelial cells with occlusion of glomerular capillary blood flow and decreased glomerular filtration; usually diffuse lesions
Rapidly progressive or crescentic glomerulonephritis (a clinical syndrome): *Type I:* Formation of IgG antibodies against pulmonary capillary and glomerular basement membrane (Goodpasture syndrome); activation of complement and neutrophils; more common in young men; causes pulmonary hemorrhage and renal failure *Type II:* Mesangial immune-complex deposition (PIGN, SLE, IgA nephropathy) *Type III:* Pauci-immune, lack of antiglomerular basement membrane antibodies antibodies or immune complexes; presence of serum antineutrophil cytoplasmic (ANC) antibodies associated with systemic vasculitides (usually idiopathic); nonspecific response to glomerular injury; can occur in any severe glomerular disease	Accumulation of fibrin, macrophages, and epithelial cell proliferation into the Bowman space forms crescents and occludes glomerular capillary blood flow, decreasing glomerular filtration; antiglomerular basement membrane antibodies lead to necrotizing, proliferative glomerulonephritis, and renal failure; diffuse lesions
Mesangial proliferative glomerulonephritis Can be associated with IgA nephropathy or lupus nephritis	Deposits of immune complexes in the mesangium with mesangial cell proliferation; results in decreased glomerular blood flow and glomerular filtration; leads to hematuria/proteinuria and nephrotic syndrome
Associated with Nephrotic Syndrome	
Minimal change nephropathy (lipoid nephrosis) Glomerular basement membrane appears normal Most common cause of nephrotic syndrome in children (see Chapter 39) Usually idiopathic	Glomeruli look normal under light microscopy; electron microscopy reveals uniform diffuse effacement of epithelial (podocyte) foot processes; loss of negative charge in basement membrane and increased permeability lead to severe proteinuria and nephrotic syndrome
Focal segmental glomerulosclerosis Usually idiopathic Can be associated with HIV infection, IgA nephropathy	Focal proliferation of endothelial and mesangial cells and glomerulosclerosis from hyaline deposits in segmental parts of the glomerular membrane; there is effacement (thinning or deletion) of epithelial podocytes, with a significant increase in pore size resulting in proteinuria and nephrotic syndrome; can progress to involve entire glomerulus and development of tubulointerstitial fibrosis
Membranous nephropathy (autoimmune response to unknown renal antigen) Usually idiopathic; can be associated with systemic diseases (i.e., hepatitis B virus, hepatitis C virus, systemic lupus erythematosus, solid malignant tumors)	Diffuse thickening of glomerular basement membrane and capillary wall from deposits of antibody, complement, and release of inflammatory cytokines; increased permeability with proteinuria and leading cause of nephrotic syndrome in white adults
Membranoproliferative glomerulonephritis (MPGN) Usually idiopathic; associated with hypocomplementemia *Type I:* Activation of classical complement pathway with nephrotic syndrome (hepatitides B and C, SLE) *Type II:* Activation of alternate complement pathway with hematuria (idiopathic); no circulating immune complexes *Type III:* Activation of alternative complement pathway with nephrotic syndrome; can be familial	Mesangial cell proliferation; thickening of basement membrane; subendothelial deposits of immune-complex occlude glomerular capillary blood flow and decrease glomerular filtration; diffuse lesions
IgA Nephropathy (Berger Disease) Usually idiopathic (can be associated with cirrhosis and minimal change disease); elevated IgA plasma levels (also see Henoch-Schönlein purpura nephritis in Chapter 39)	Mesangial proliferation with deposition of IgA; release of inflammatory mediators with cellular proliferation; crescent formation, glomerulosclerosis, interstitial fibrosis, decreased GFR and hematuria; usually focal, some diffuse lesions

GBM, Glomerular basement membrane; *GFR*, glomerular filtration rate; *HIV*, human immunodeficiency virus; *IgA*, immunoglobulin A; *IgG*, immunoglobulin G; *SLE*, systemic lupus erythematosus.

Nephrotic and Nephritic Syndromes

Nephrotic and nephritic syndromes are consequences of glomerular injury and present with a pattern of clinical manifestations. **Nephrotic syndrome** is the excretion of 3.5 g or more of protein in the urine per day. It occurs when glomerular filtration of plasma proteins, particularly albumin, exceeds tubular reabsorption. *Primary causes of nephrotic syndrome* include particular types of glomerular injury including minimal change nephropathy (lipoid nephrosis) (see Chapter 39), membranous glomerulonephritis, and focal segmental glomerulosclerosis (see Table 38.8. *Secondary forms of nephrotic syndrome* occur in systemic diseases, including diabetes mellitus (see Chapter 22), amyloidosis, systemic lupus erythematosus (see Chapter 9), and IgA vasculitis (Henoch–Schönlein purpura) (see Chapter 39). Nephrotic syndrome is also associated with certain medications (e.g., NSAIDs), infections, malignancies, and vascular disorders. Familial or inherited forms of nephrotic syndrome result from genetic defects that affect the function and composition of the glomerular capillary wall (i.e., alterations in basement membrane type IV collagen [Alport syndrome] and podocyte dysfunction resulting in steroid resistance).[61] It often signifies a more serious prognosis when present as a secondary complication. Nephrotic syndrome is more common in children (see Chapter 39) than in adults and is more commonly idiopathic in adults.

Nephritic syndrome is characterized by hematuria and red blood cell casts in the urine. Hypertension, edema, and oliguria also are components of the syndrome. Proteinuria is present but is usually less severe than in nephrotic syndrome. It occurs primarily with infection-related glomerulonephritis (e.g., hepatitis B and C and acute poststreptococcal glomerulonephritis), rapidly progressive crescentic glomerulonephritis, antiphospholipid syndrome (production of antiphospholipid antibodies that cause thrombotic microangiopathy), and lupus nephritis.[59]

Pathophysiology

In nephrotic syndrome, injury to the glomerular filtration membrane leads to increased permeability and loss of an electrical negative charge. Normally, plasma proteins, which carry a negative charge, are repelled by the negative charge at the glomerular filtration membrane and thus remain in the plasma. Movement of plasma proteins, particularly albumin and some immunoglobulins, occurs across the injured membrane. The plasma proteins are then lost into the urine, resulting in decreased plasma oncotic pressure and edema (Fig. 38.10). Hypoalbuminemia results from urinary loss of albumin combined with a diminished synthesis of replacement albumin by the liver. Albumin is lost in the greatest quantity because of its high plasma concentration and low molecular weight. Decreased dietary intake of protein from anorexia, malnutrition, or accompanying liver disease may also contribute to lower levels of plasma albumin. Loss of albumin stimulates lipoprotein synthesis by the liver, causing hyperlipidemia, which can promote the progression of glomerular disease. Loss of immunoglobulins may increase susceptibility to infections. Sodium retention is common, further contributing to edema and hypertension.

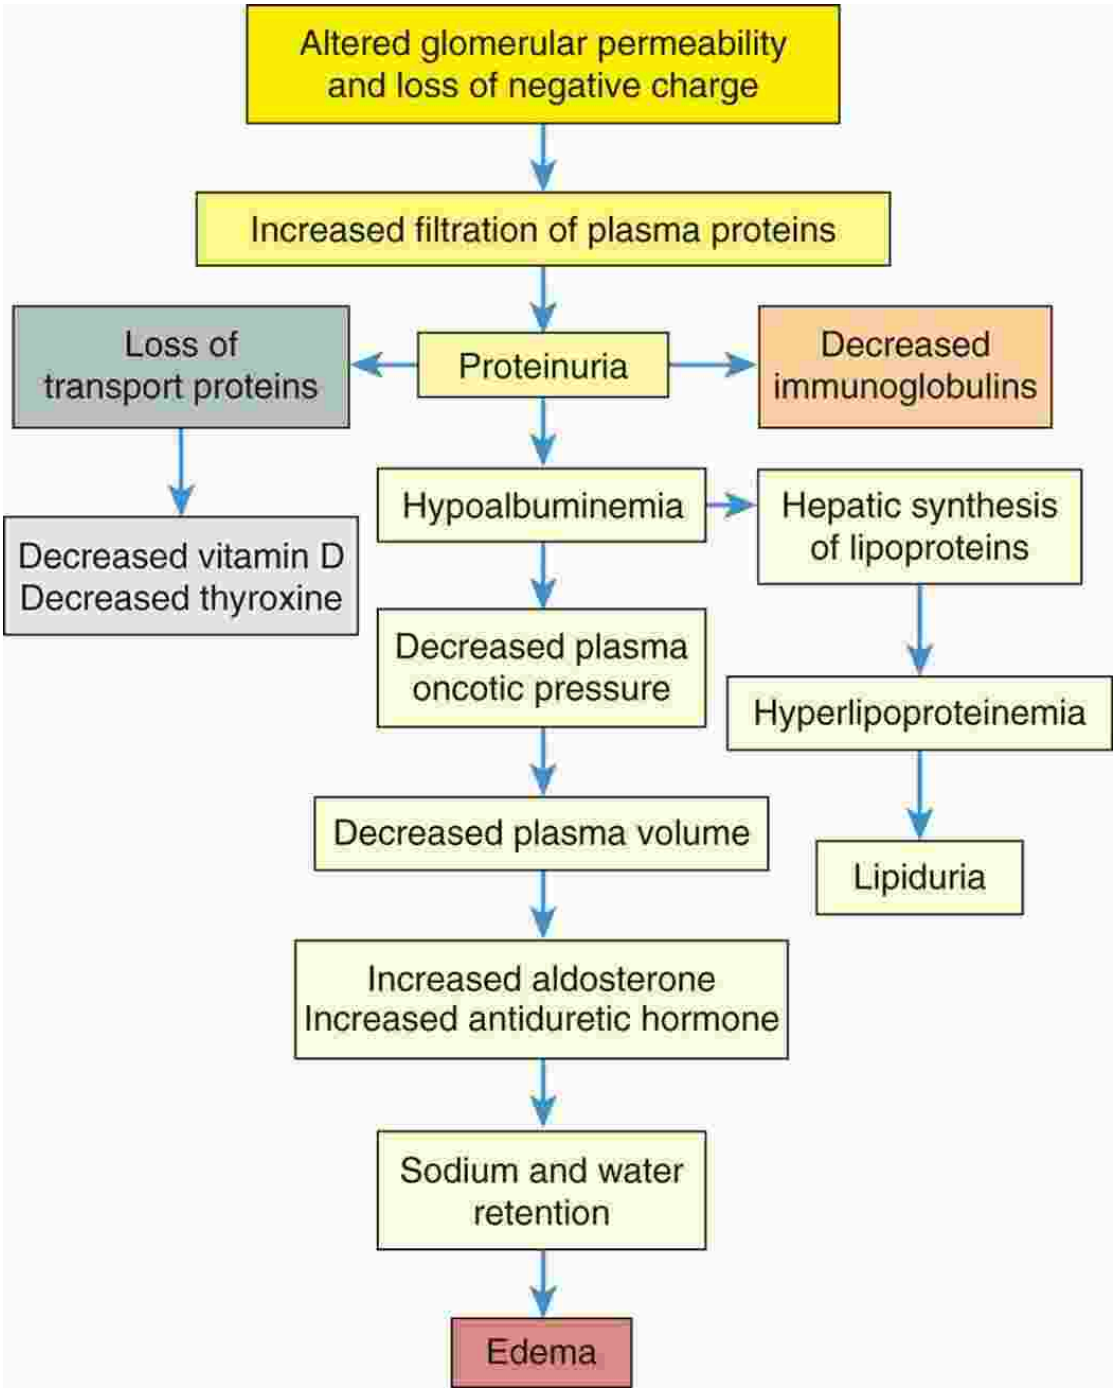

FIG. 38.10 Pathophysiology of Nephrotic Syndrome.

A flowchart shows the pathophysiology of nephrotic syndrome. 1. Altered glomerular permeability and loss of negative charge. Leads to 2. 2. Increased filtration of plasma proteins. Leads to 3. 3. Proteinuria. Leads to 4, 10, and 12. 4. Hypoalbuminemia. Leads to 5 and 13. 5. Decreased plasma oncotic pressure. Leads to 6. 6. Decreased plasma volume. Leads to 7. 7. Increased aldosterone Increased antidiuretic hormone. Leads to 8. 8. Sodium and water retention.

Leads to 9. 9. Edema. 10. Loss of transport proteins. Leads to 11. 11. Decreased vitamin D; decreased thyroxine. 12. Decreased immunoglobulins. 13. Hepatic synthesis of lipoproteins. Leads to 14. 14. Hyperlipoproteinemia. Leads to 15. 15. Lipiduria.

Nephritic syndrome is caused by increased permeability of the glomerular filtration membrane with pore sizes large enough to allow the passage of red blood cells and protein. The pathophysiology is related to immune injury of the glomerulus, as previously described. Hypertension and uremia (accumulation of urea and other nitrogen-based metabolic products) occur in advanced stages of disease.

Clinical Manifestations

Many clinical manifestations of nephrotic and nephritic syndrome are related to loss of serum proteins and associated sodium retention (Table 38.9). The manifestations of both nephrotic and nephritic syndrome include edema (periorbital and pedal), hypoproteinemia, proteinuria, hyperlipidemia, lipiduria, vitamin D deficiency, and hypothyroidism. In addition, voided urine that appears foamy from protein loss is associated with nephrotic syndrome, and hematuria, hypertension, and oliguria are associated with nephritic syndrome. Vitamin D deficiency is related to loss of serum transport proteins and decreased vitamin D activation by the kidney. Hypothyroidism can result from urinary loss of thyroid-binding protein and thyroxine. Renal loss of anti-clotting factors and increased liver synthesis of clotting factors can cause hypercoagulability and may lead to thromboembolic events.[62]

Table 38.9

Clinical Manifestations of Nephrotic Syndrome

Manifestations	Contributing Factors	Result
Proteinuria	Increased glomerular permeability, decreased proximal tubule reabsorption	Edema, increased susceptibility to infection from loss of immunoglobulins
Hypoalbuminemia	Increased urinary losses of protein	Edema
Edema	Hypoalbuminemia (decreased oncotic pressure, sodium and water retention, increased aldosterone and antidiuretic hormone [ADH] secretion), unresponsiveness to atrial natriuretic peptides	Soft, pitting, generalized edema
Hyperlipidemia	Decreased serum albumin; increased hepatic synthesis of very-low-density lipoproteins; increased cholesterol, phospholipids, triglycerides	Increased atherogenesis
Lipiduria	Sloughing of tubular cells containing fat (oval fat bodies); free fat from hyperlipidemia	Fat droplets that may float in urine
Decreased vitamin D	The globulin to which 1,25-dihydroxy-vitamin D_3 is attached for transport passes through the glomerulus and is lost in the urine	Decreased absorption of calcium from gut Risk for osteodystrophies
Hypothyroidism	Loss of thyroid-binding globulin and other thyroid hormone transport proteins in the urine	May be asymptomatic; may have elevated thyroid-stimulating hormone

Manifestations	Contributing Factors	Result
Proteinuria	Increased glomerular permeability, decreased proximal tubule reabsorption	Edema, increased susceptibility to infection from loss of immunoglobulins
Hypoalbuminemia	Increased urinary losses of protein	Edema
Edema	Hypoalbuminemia (decreased oncotic pressure, sodium and water retention, increased aldosterone and antidiuretic hormone [ADH] secretion), unresponsiveness to atrial natriuretic peptides	Soft, pitting, generalized edema
Hyperlipidemia	Decreased serum albumin; increased hepatic synthesis of very-low-density lipoproteins; increased cholesterol, phospholipids, triglycerides	Increased atherogenesis
Lipiduria	Sloughing of tubular cells containing fat (oval fat bodies); free fat from hyperlipidemia	Fat droplets that may float in urine
Decreased vitamin D	The globulin to which 1,25-dihydroxy-vitamin D_3 is attached for transport passes through the glomerulus and is lost in the urine	Decreased absorption of calcium from gut Risk for osteodystrophies
Hypothyroidism	Loss of thyroid-binding globulin and other thyroid hormone transport proteins in the urine	May be asymptomatic; may have elevated thyroid-stimulating hormone

Evaluation and Treatment

Nephrotic syndrome is diagnosed when the protein level in a 24-hour urine collection is greater than 3.5 g. Serum albumin level decreases (to <3 g/dL), and concentrations of serum cholesterol, phospholipids, and triglycerides increase. Fat bodies may be present and float in the urine. The presence of lipiduria (lipids within tubular cells or casts, or as free glubules) suggests a glomerular disorder.

Nephrotic syndrome is commonly treated by consuming a moderate protein restriction (i.e., 0.8 g/kg body weight/day), low-fat, salt-restricted diet, and by prescribing corticosteroids and diuretics. Glucocorticoids are used to control immune-mediated disease and may be combined with immunosuppressive drugs (e.g., rituximab). Targeted immune therapy is considered for steroid-resistant nephrotic syndrome.[63] Diuretics are used to control hypertension and eliminate fluid. Care must be taken to observe for hypovolemia and hypokalemia or potassium toxicity in the presence of renal insufficiency. Spironolactone may be combined with loop diuretics to suppress aldosterone activity to conserve potassium. Anticoagulants are used for prophylactic anticoagulation. Angiotensin-converting enzyme (ACE) inhibitors or ARBs lower urine protein excretion and control blood pressure.[63]

The evaluation and treatment of nephritic syndrome are similar to those described for nephrotic syndrome. Red blood cells and red blood cell casts will be found in the urine. The course of glomerulonephritis is usually more severe with nephritic syndrome. High-dose corticosteroids and cyclophosphamide represent the standard therapy for rapidly progressive crescentic glomerulonephritis. Treatment also may include supportive care with antihypertensives, diuretics, and antibiotics. The addition of plasma exchange (plasmapheresis) and dialysis may be required.

Acute Kidney Injury

Classification of Kidney Dysfunction

Kidney injury may be acute and rapidly progressive (within hours) or may become chronic, progressing to ESRD over several months or years. The terms *renal insufficiency*, *renal failure*, *uremia*, and *azotemia* are associated with decreasing kidney function but are not specific in relation to the cause of kidney disease. Generally, **renal insufficiency** refers to a decline in renal function to about 25% of normal or a GFR of 25 to 30 mL/min. Levels of SCr and urea are mildly elevated. AKI captures the diverse nature of this syndrome, ranging from minimal or subtle changes in kidney function to complete kidney failure requiring renal replacement therapy. **Renal failure** refers to a significant loss of function. When less than 10% of kidney function remains, this is termed **ESRD**. Specific criteria for AKI are discussed in the next section. **Uremia (uremic syndrome)** is a syndrome of renal failure and includes elevated blood urea nitrogen (BUN) and creatinine levels accompanied by fatigue, anorexia, nausea, vomiting, pruritus, and neurologic changes. Uremia represents numerous consequences related to kidney failure, including retention of toxic wastes, deficiency states, electrolyte disorders, and immune activation promoting a proinflammatory state. **Azotemia** is characterized by increased BUN levels (normal is 8 to 20 mg/dL) and frequently increased SCr levels (normal is 0.7 to 1.4 mg/dL). Renal insufficiency or kidney failure causes azotemia. Both azotemia and uremia indicate an accumulation of nitrogenous waste products in the blood, a common characteristic that explains the overlap in definitions of terms.

Acute Kidney Injury

AKI is a sudden decline in kidney function with a decrease in glomerular filtration caused by a defect in the excretion of water, salts, and nitrogenous waste products, which accumulate in the blood as demonstrated by an elevation in SCr level and decrease in urine volume.[64] Classification criteria have been developed to guide the diagnosis of AKI (Table 38.10). The Kidney Disease: Improving Global Outcomes (KDIGO) developed clinical practice guidelines for AKI and is based on the Risk, Injury, Failure, Loss, End-Stage Renal Disease (RIFLE) and AKI Network (AKIN) criteria.[65] The KDIGO guideline is the commonly accepted definition and classification system for AKI clinical trials and clinical practice.[64] AKI is a complex syndrome that is classified according semi-anatomical categories (i.e., pre-renal, intrinsic, and post-renal). However, in recent years, AKI has been further differentiated

into specific syndromes (i.e., hepatorenal, cardiorenal, nephrotoxic, and sepsis-associated), each having a unique pathophysiologic process and treatment course.[64]

Table 38.10

Criteria for Acute Kidney Injury

Category Staging		Kidney Disease: Improving Global Outcomes (KDIGO)	Risk, Injury, Failure, Loss, End-Stage Renal Disease (RIFLE)	Acute Kidney Injury Network (AKIN)
Criteria to make diagnosis of AKI		Increased SCr by 50% in 7 daysOR≥0.3 mg/dL in 48 h	Increased SCr of >50% in <7 days	Increased SCr of 50% or more in <48 h OR≥ 0.3 mg/dL in 48 h
Risk	Stage 1	Increased SCr of 1.5–1.9 × baseline OR ≧0.3 mg/dL within 48 h	Increased SCr of 1.5 × baseline OR GFR decrease >25% UO <0.5 mL/kg/h × 6 h	Increased SCr of 1.5–2.0 × baseline OR ≥0.3 mg/dL UO <0.5 mL/kg/h × 6 h
Injury	Stage 2	Increased SCr of 2.0–2.9 × baseline within 48 h	Increased SCr of 2 × baseline OR GFR decrease >50% UO <0.5 mL/kg/h × 12 h	Increased SCr of 2.0–3.0 × baseline UO <0.5 mL/kg/h × 12 h
Failure	Stage 3	Increased SCr of ≥3.0 × baseline within 48 h OR Increased SCr to ≥4.0 mg/dL OR Initiation of renal replacement therapy OR in individuals <18 years, with decrease in e GFR to <35 mL/min/1.73 m^2	Increased SCr of 3 × baseline OR GFR decrease >75% UO <0.3 mL/kg/h × >24 h or anuria × 12 h	Increased SCr of >3.0 × baseline OR If SCr baseline is ≧4.0 mg/dL, an increased SCr >0.5 mg/dL UO <0.3 mL/kg/h × 24 h or anuria × 12 h
Loss			Persistent AKI (complete loss of kidney function) >4 weeks requiring

Pathophysiology

AKI results from ischemic injury related to extracellular volume depletion, renal hypoperfusion, exposure from chemicals, drugs, or endogenous toxins, sepsis, intra-abdominal hypertension, progressive glomerulonephritis, acute interstitial nephritis, infection, or an obstructive process. Injured, hypoxic, and ischemic tissues initiate a complex inflammatory immunopathophysiological response that results in microcirculatory and macrocirculatory disturbances in the kidney, functional impairment, and ultimately cell death.[66] The simultaneous activation of components of innate immunity, including leukocytes, coagulation factors, and complement proteins, drives kidney inflammation, glomerular and tubular damage, and breakdown of the blood-urine barrier.[66] This profound immune response is an integral part of multi-organ dysfunction associated with AKI. Alterations in kidney function may be minimal or severe.[67] AKI is an evolving clinical syndrome with multiple, often simultaneous, and overlapping causes. AKI is currently broadly classified according to the underlying pathophysiologic process as prerenal (renal hypoperfusion), intrarenal (intrinsic disorders involving renal parenchymal or interstitial tissue), or postrenal (urinary tract obstructive disorders) (Table 38.11).[68]

Table 38.11

Causes of Acute Kidney Injury

Area of Dysfunction	Possible Causes
Prerenal	**Hypovolemia** Hemorrhagic blood loss (trauma, gastrointestinal bleeding, complications of childbirth) Loss of plasma volume (burns, peritonitis) Water and electrolyte losses (severe vomiting or diarrhea, diuretics, uncontrolled diabetes mellitus) Poor oral intake
	Reduced Cardiac Output Systemic hypotension or hypoperfusion Acute myocardial infarction Heart failure Cardiac tamponade Massive pulmonary embolism
	Renal Vasomodulation/Shunting (increased vascular resistance) Iodinated contrast Medications (ACEi, aminoglycosides, ARBs, cyclosporines, NSAIDs) Hypercalcemia Increased intra-abdominal pressure (abdominal compartment syndrome) Anesthesia/Surgery
	Systemic Vasodilation Sepsis (gram negative bacteremia) Shock Systemic inflammation Cirrhosis

Area of Dysfunction	Possible Causes
	Analphylaxis Hepatorenal syndrome
Intrarenal (Intrinsic)	**Vascular** Renal artery stenosis Renal vein thrombosis Arterial/venous cross-clamping (postischemic or nephrotoxic)
	Microvascular Vascular damage (malignant hypertension, vasculitis, atheroembolic disease) Thrombotic microangiopathies (Coagulation defects (TTP, HUS, DIC, APS), scleroderma renal crisis, preeclampsia/HELLP syndrome, drug-induced)
	Glomerular Immune-complex diseases (postinfectious glomerulonephritis, endocarditis, lupus nephritis, immunoglobulin A glomerulonephritis, Goodpasture syndrome, Wegener disease) Nephrotic-range proteinuria with associated AKI (HIV-associated nephropathy - secondary FSGS), minimal change disease with ATN/AIN)
	Tubulointerstitium ATN (surgery, ischemia (shock, surgery, hemorrhage), inflammatory (sepsis, burns), nephrotoxicity (contrast media or medications [aminoglycosides, NSAIDs, ACEi, ARBs, and antibiotics]) AIN (tumors, toxins, medications, infection, rhabdomyolysis, massive hemolysis, medications (acyclovir, sulfonamides, protease inhibitors (indinavir, azatanavir), methotrexate, ethylene glycol), myeloma-associated AKI (cast nephropathy) Bilateral acute pyelonephritis
Postrenal	**Bladder Outlet** Benign prostatic hypertrophy Bladder neck obstruction (tumor, stricture, emboli) Neurogenic bladder

Area of Dysfunction	Possible Causes
	Ureteral (bilateral obstruction) Obstructive uropathy (retroperitoneal fibrosis, malignancy, nephrolithiasis) Ureteral destruction (edema, tumors, nephrolithiasis, emboli, improperly placed catheter)
	Renal Pelvis Papillary necrosis (NSAIDs) nephrolithiasis

Area of Dysfunction	Possible Causes
Prerenal	**Hypovolemia**
	Hemorrhagic blood loss (trauma, gastrointestinal bleeding, complications of childbirth)
	Loss of plasma volume (burns, peritonitis)
	Water and electrolyte losses (severe vomiting or diarrhea, diuretics, uncontrolled diabetes mellitus)
	Poor oral intake
	Reduced Cardiac Output
	Systemic hypotension or hypoperfusion
	Acute myocardial infarction
	Heart failure
	Cardiac tamponade
	Massive pulmonary embolism
	Renal Vasomodulation/Shunting (increased vascular resistance)
	Iodinated contrast
	Medications (ACEi, aminoglycosides, ARBs, cyclosporines, NSAIDs)
	Hypercalcemia

Acute kidney injury: From diagnosis to prevention and treatment strategies. *Journal of Clinical Medicine*, 2020;9(6):1704. doi:10.3390/jcm9061704.

Prerenal AKI or inadequate kidney perfusion is the most common reason for AKI. Poor perfusion can result from hypovolemia, reduced cardiac output, renal vasomodulation/shunting, and systemic vasodilation (see Table 38.11).[69] During the early phases of hypoperfusion, protective autoregulatory mechanisms maintain GFR at a relatively constant level through afferent arteriolar dilation and efferent arteriolar vasoconstriction (mediated by angiotensin II). Tubuloglomerular feedback mechanisms also maintain GFR and distal tubular nephron flow (see Chapter 37). The GFR declines because of the decrease in glomerular filtration pressure. Failure to restore blood volume or blood pressure and oxygen delivery can cause ischemic cell injury and **acute tubular necrosis (ATN)** or acute interstitial necrosis, a more severe form of AKI. Reperfusion (reoxygen) injury with cell death also can occur (see Fig. 2.10 also see Chapters 32 and 48). AKI can occur with CKD if a sudden stress is imposed on already poorly functioning kidneys, hastening the progression to ESRD.

Intrarenal (intrinsic) AKI can result from vascular, microvascular, glomerular, and tubulointerstitium causes (see Table 38.11). The most commonly seen cause of intrarenal AKI is ATN. Ischemic ATN most often occurs after surgery but also is associated with prerenal causes such as sepsis, obstetric complications, and severe hemorrhagic trauma or severe burns. Whereas *nephrotoxic ATN* is usually caused by exposure to radiocontrast media or nephrotoxic medications (e.g., aminoglycosides, NSAIDs, ACEi, ARBs, and antibiotics).

Hypotension associated with hypovolemia produces ischemia and the inflammatory response, generating toxic oxygen free radicals that cause cellular swelling, injury, and necrosis. Intrarenal microcirculatory vasoconstriction occurs in response to injury and inflammation and decreases blood flow. Ischemic necrosis results and tends to be patchy and may be distributed along any part of the nephron. Nephrotoxic ATN is associated with radiocontrast media and numerous antibiotics, particularly the aminoglycosides (neomycin, gentamicin, tobramycin) because these drugs accumulate in the renal cortex.[69] Other substances, such as excessive myoglobin (oxygen-transporting substance from muscles; released with crush injuries), carbon tetrachloride, heavy metals (mercury, arsenic), or methoxyflurane anesthetic, and bacterial toxins may promote kidney injury. Dehydration, advanced age, concurrent renal insufficiency, and diabetes mellitus tend to enhance nephrotoxicity. Necrosis caused by nephrotoxins is usually uniform and limited to the proximal tubules. This is due to the high surface area of the brush border (microvilli) of the proximal tubular cells and the reabsorption properties of epithelial cells, which make the proximal tubules more vulnerable to toxic injury.

Postrenal AKI is caused by an obstruction within the urinary tract that affects the kidneys bilaterally (e.g., bladder outlet obstruction, ureteral obstruction, or renal pelvis obstruction) (see Table 38.11). A

pattern of several hours of anuria with flank pain followed by polyuria is a characteristic finding. The obstruction causes an increase in intraluminal hydrostatic pressure upstream from the site of obstruction with a gradual decrease in GFR.

Oliguria, or a urine output of <400 mL/24 h, occurs in AKI and can be differentiated from prerenal, intrarenal, and ATN (Table 38.12). Three mechanisms have been proposed to account for the decrease in urine volume in AKI. All three mechanisms contribute to oliguria in varying combinations and degrees throughout the course of the disease (Fig. 38.11). These mechanisms are as follows[70]:

1. *Alterations in renal blood flow*. Efferent arteriolar vasoconstriction may be produced by intrarenal release of angiotensin II or there may be a redistribution of blood flow from the cortex to the medulla. Autoregulation of blood flow may be impaired, resulting in decreased GFR. Microthrombi may obstruct blood flow. Changes in glomerular permeability and decreased GFR also may result from ischemia.
2. *Tubular obstruction*. Necrosis of the tubules causes sloughing of cells, cast formation, and obstruction to urine flow. There can be ischemic edema that results in tubular obstruction, which causes a retrograde increase in hydrostatic pressure, and opposes the hydrostatic pressure of glomerular filtration, thus reducing the GFR. Kidney failure can occur within 24 hours.
3. *Tubular backleak*. Tubular reabsorption of filtrate is accelerated as a result of increased permeability caused by ischemia and increased tubular pressure from obstruction. The increased reabsorption of filtrate contributes to oliguria.

Table 38.12

Differentiation of Acute Oliguric Kidney Failure

	Urine Volume	Urine Specific Gravity	Urine Osmolality	Urine Sodium Concentration	Blood Urea Nitrogen (BUN)/Plasma Creatinine Ratio	FE_{Na}[a]
Normal values	800–2000 mL	1.010–1.030	500–800 mOsm	20 mEq/L	10:1–20:1	1%
Prerenal failure	<400 mL	1.016–1.020	>500 mOsm	<10 mEq/L	>20:1 BUN is elevated relative to plasma creatinine Dehydration or hypoperfusion is suspected	<1% (also seen glomerulo Sodium is rea to increase volume
Intrarenal failure (i.e., acute tubular necrosis)	<400 mL	1.010–1.012	<400 mOsm	>30 mEq/L	<10:1 Intrarenal damage causes reduced reabsorption of BUN	>1% (also seen urinary tra obstructio renal pare disease) Sodium is los tubular da

	Urine Volume	Urine Specific Gravity	Urine Osmolality	Urine Sodium Concentration	Blood Urea Nitrogen (BUN)/Plasma Creatinine Ratio	FE_{Na}[a]
Normal values	800–2000 mL	1.010–1.030	500–800 mOsm	20 mEq/L	10:1–20:1	1%
Prerenal failure	<400 mL	1.016–1.020	>500 mOsm	<10 mEq/L	>20:1 BUN is elevated relative to plasma creatinine Dehydration or hypoperfusion is suspected	<1% (also seen in acute glomerulonephritis) Sodium is reabsorbed to increase plasma volume
Intrarenal failure (i.e., acute tubular necrosis)	<400 mL	1.010–1.012	<400 mOsm	>30 mEq/L	<10:1 Intrarenal damage causes reduced reabsorption of BUN	>1% (also seen in acute urinary tract obstruction and renal parenchymal disease) Sodium is lost due to tubular damage

[a].

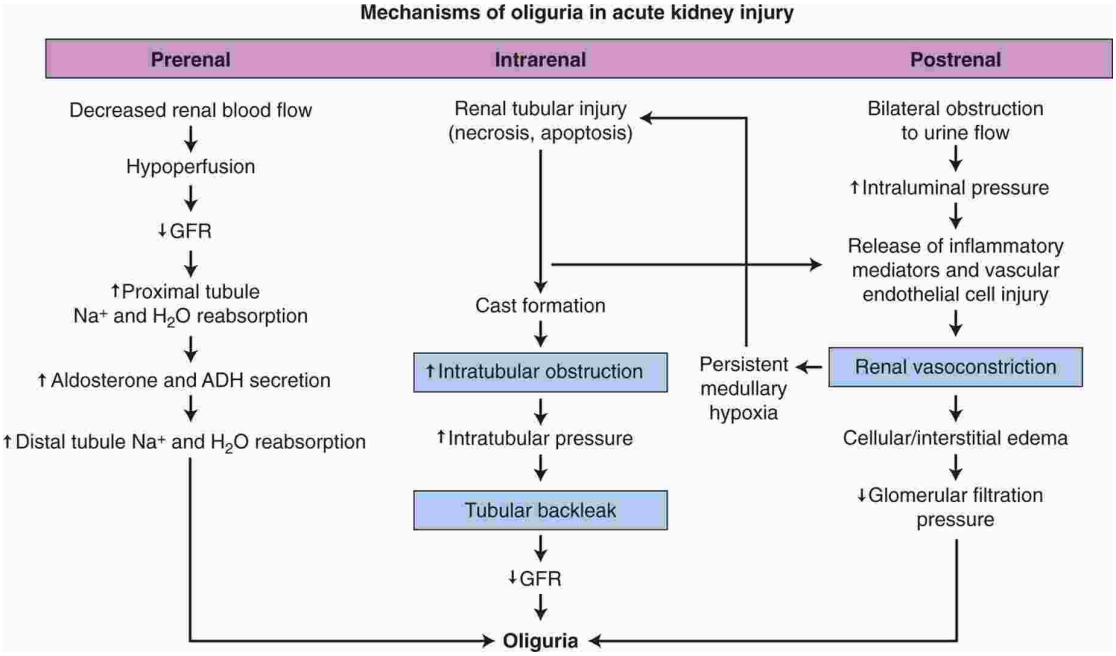

FIG. 38.11 Acute Kidney Injury and Mechanisms of Oliguria.
ADH, Antidiuretic hormone; *GFR*, glomerular filtration rate.

A flowchart shows prerenal, intrarenal, and postrenal mechanisms of oliguria in acute kidney injury. The mechanism for prerenal oliguria is as follows. 1. Decreased renal blood flow. Leads to 2. 2. Hypoperfusion. Leads to 3. 3. Decreased G F R. Leads to 4. 4. Increased proximal tubule; sodium ion and water reabsorption. Leads to 5. 5. Increased aldosterone and A D H secretion. Leads to 6. 6. Increased distal tubule sodium ions and water reabsorption. The mechanism for intrarenal oliguria is as follows. 1. Renal tubular injury (necrosis, apoptosis). Leads to 2 or 3 of postrenal oliguria. 2. Cast formation. Leads to 3. 3. Increased intratubular obstruction. Leads to 4. 4. Increased intratubular pressure. Leads to 5. 5. Tubular back leak. Leads to 6. 6. Increased G F R. The mechanism for postrenal oliguria is as follows. 1. Bilateral obstruction to urine flow. Leads to 2. 2. Increased intraluminal pressure. Leads to 3. 3. Release of inflammatory mediators and vascular endothelial cell injury. Leads to 4. 4. Cellular or interstitial edema. Leads to 5 or persistent medullary hypoxia leading to 1 of intrarenal oliguria. 5. Decreased glomerular filtration pressure.

Oliguria begins within 1 day after a hypotensive event and lasts 1 to 3 weeks, but may regress in several hours or extend for several weeks depending on the duration of ischemia or the severity of injury or obstruction.

AKI also can present with **nonoliguric kidney failure (high output kidney failure)** and represents less severe injury, particularly with intrinsic kidney injury associated with nephrotoxins. The renal tubules have impaired reabsorption and concentration and dilution function. The urine output may be normal or high in volume, but the BUN and plasma creatinine concentrations increase. **Anuria** (urine output <50 mL/day) can occur in AKI but is uncommon in ATN. It involves both kidneys and suggests bilateral renal artery occlusion, obstructive uropathy, or acute cortical necrosis.

Clinical Manifestations

The clinical progression of AKI due to ATN, the most common cause of AKI, occurs in four overlapping phases: initiation, extension, maintenance, and recovery.[71] Each phase is described as follows:

1. The *initiation phase* occurs with the onset of renal hypoperfusion or toxicity resulting in severe cellular ATP depletion leading to acute cell injury and dysfunction (renal tubular epithelial cell injury is a key feature). Prevention of injury is possible during this phase and the next phase with therapeutic interventions, but there is a short window of opportunity.
2. The *extension phase* is initiated by continued hypoxia following the initial ischemic event and an inflammatory response. Cells continue to undergo injury and death with necrosis and apoptosis present in the outer medulla. However, in the outer cortex, where blood flow has returned to near normal levels, the proximal tubule cells undergo cellular repair during this phase.
3. The *maintenance* or *oliguric phase* is the period of established kidney injury and dysfunction after the initiating event has been resolved. Cells undergo repair, migration, apoptosis, and proliferation, which may last from weeks to months with urine output lowest during this phase. During this phase, SCr, BUN, and serum potassium levels increase; metabolic acidosis develops; there is salt and water overload; and urine output is decreased with oliguria.
4. The *recovery* or *polyuria phase* is the interval when glomerular function returns but the regenerating tubules cannot yet concentrate the filtrate. Diuresis is common during this phase, with a decline in SCr and urea concentrations and an increase in creatinine clearance. Cellular differentiation continues, epithelial polarity is reestablished, and homeostasis is established. As renal function improves, the increase in urine volume (diuresis) is progressive. The tubules are still damaged early in the recovery phase and have not recovered secretion and reabsorption functions. Polyuria can result in excessive loss of sodium, potassium, and water. Fluid and electrolyte balance must be carefully monitored, and excessive losses replaced. Serial measurements of SCr concentration provide an index of renal function during the *recovery phase*. Return to normal status may take 3 to 12 months; some individuals do not gain full recovery of a normal GFR or tubular function, and plasma creatinine concentration will remain higher than normal.

The hallmark features of AKI are increased SCr, reduced GFR, and decreased urine output. In the presence of fever, rash, joint pains, pulmonary infiltrates, abnormal urine analysis, thrombocytopenia, and hemolytic anemia, less common causes (e.g., glomerulopathy, vasculitis, and hemolytic uremic syndrome) of AKI should be considered.[67] Other manifestations of altered urine excretion include hyperkalemia, hyperphosphatemia, and metabolic acidosis. Edema and congestive heart failure can be associated with fluid retention.

A diagnostic challenge is to differentiate prerenal AKI from ATN. Urine composition may provide helpful diagnostic clues to changes in tubular function (Table 38.13). The ratios of BUN to plasma creatinine concentration and fractional excretion of sodium (the ratio of filtered sodium to excreted sodium) are helpful diagnostic indicators because the tests reflect renal tubular reabsorption ability. In prerenal AKI, tubular function is maintained, and salt, water, and urea are reabsorbed. With ATN, reabsorption and urinary concentration abilities are compromised. Other causes of renal failure also may exhibit similar clinical findings. Cystatin C, a serum protein constantly produced by nucleated cells, is freely filtered by the glomerulus, and its concentration can serve as a measure of GFR and may be useful for detecting early changes in GFR. Serial measurements of plasma creatinine concentration provide an index of renal function during the recovery phase. However, changes in SCr level occur only if more than 50% of glomerular filtration is lost. The SCr level may not reflect this decrease in glomerular filtration for 24 hours or more. Such diagnostic delays make the implementation of early therapy very difficult, contributing to disease progression and mortality.

Table 38.13

Differentiating Prerenal Acute Kidney Injury from Acute Tubular Necrosis

Prerenal	Acute Tubular Necrosis
Causes	
Hypovolemia	IV radiocontrast
Hypotension	Nephrotoxic medications
Hypoperfusion	Trauma
Clinical Manifestations	
Oliguria	Nonoliguria
Urine fractional excretion of sodium <1%	Urine fractional excretion of sodium >2%
Urine sodium concentration <20 mEq/L	Urine sodium concentration >40 mEq/L
Normal urine sediment	Urine sediment muddy-brown with granular casts, epithelial cell casts, free renal tubular epithelial cells
Response to Effective Fluid Resuscitation	
Timing of serum creatinine response to effective intravenous fluid resuscitation differentiates prerenal acute kidney injury from acute tubular necrosis.	
Responds within 48 h	Response takes at least 72 h

Prerenal	Acute Tubular Necrosis
Causes	
Hypovolemia	IV radiocontrast
Hypotension	Nephrotoxic medications
Hypoperfusion	Trauma
Clinical Manifestations	
Oliguria	Nonoliguria
Urine fractional excretion of sodium <1%	Urine fractional excretion of sodium >2%
Urine sodium concentration <20 mEq/L	Urine sodium concentration >40 mEq/L
Normal urine sediment	Urine sediment muddy-brown with granular casts, epithelial cell casts, free renal tubular epithelial cells
Response to Effective Fluid Resuscitation	
Timing of serum creatinine response to effective intravenous fluid resuscitation differentiates prerenal acute kidney injury from acute tubular necrosis.	
Responds within 48 h	Response takes at least 72 h

Evaluation and Treatment

Prevention of AKI is the most important therapeutic approach and involves avoidance of hypotension, hypovolemia, and nephrotoxicity. However, once AKI has occurred, determination of the etiology of AKI is essential for appropriate management. There are recent developments in ways to assess, monitor, and evaluate AKI progression before the SCr increases. One advancement is the emergence of biomarker testing to aid in the risk assessment for moderate or severe AKI (see Emerging Science Box: Biomarkers

for AKI Risk Stratification).[72] Other newer developments related to monitoring and evaluating risk progression include e-alert systems, machine-learning algorithms and artificial intelligence for AKI recognition and monitoring, as well as models based upon the renal angina index, and furosemide stress test (FST).[73]

The diagnosis of AKI is related to the cause of the disease. Therefore, a complete history must be obtained and include medications (prescribed and over the counter); recent exposure to nephrotoxic agents; recent surgery, trauma, or infection; and past medical history of cardiovascular disorders, obstructive uropathies (e.g., an enlarged prostate or kidney stones), or AKI (see Table 38.13).

Laboratory evaluation should include SCr, serum urea, electrolytes, complete blood count, liver function tests, glucose level, bone profile, urine analysis, and urine microscopic examination.[67] Other laboratory testing can provide information related to the cause such as an assessment of antineutrophil cytoplasmic antibodies (ANCA), antiglomerular basement membrane antibodies (anti-GBM), antinuclear antibodies (ANA), anti-double-stranded DNA (anti-dsDNA) antibodies, complement factors, rheumatoid factor, antistreptolysin O titer (ASOT), cryoglobulins, serum electrophoresis, immunoglobulins, serum free light chains, hepatitis, and HIV serology.[67] Diagnostic imaging should include a renal ultrasound, to exclude obstruction, and chest x-ray to determine a potential cause, such as pneumonia or vasculitis, and to evaluate volume status.[67]

Management principles directly related to physiologic alterations generally include the following[69,73]:

1. ensuring adequate hydration and volume status;
2. correcting electrolyte disturbances, particularly hyperkalemia;
3. managing hemodynamics, including blood pressure;
4. preventing and treating infections;
5. avoiding nephrotoxic agents and drugs;
6. maintaining adequate nutrition; and
7. glucose control.

Fluid and electrolyte replacement must be carefully calculated with consideration of urine losses, insensible losses (up to 1000 mL/day), and production of endogenous water by oxidation (450 mL/day). Overhydration of individuals dilutes plasma sodium concentration and can precipitate pulmonary, cerebral, myocardial, and liver edema. A positive fluid balance is independently associated with increased mortality in individuals with AKI and contributes to worse outcomes in critically ill persons.[67] Metabolic acidosis is treated when serum bicarbonate concentration is less than 22 mEq/L.

Hyperkalemia can be managed by restricting dietary sources of potassium, using loop diuretics, and using cation exchange resins, which may be administered orally or rectally. These resins exchange potassium for another cation, such as sodium in the bowel, and the potassium is then excreted attached to the resin.[69] With severe hyperkalemia (more than 6.5 mEq/L), dialysis may be required, or potassium can be temporarily driven back into the cells by administering insulin (followed by glucose to prevent hypoglycemia), or by infusing sodium bicarbonate or administering albuterol. Insulin administered with glucose facilitates the uptake of glucose into the cell, which results in potassium shifting from the extracellular environment to the intracellular fluid. (Glucose metabolism is discussed in (see Chapters 1 and 22). Using sodium bicarbonate to cause alkalemia also shifts potassium into cells in exchange for hydrogen ions but requires consideration of hypervolemia. Careful monitoring of the electrocardiogram for peaking T waves is essential for individuals with hyperkalemia. Intravenous infusion of calcium is the most rapid method of treating cardiac effects of hyperkalemia. Calcium decreases the threshold potential and reduces the membrane excitability caused by hyperkalemia (see Chapter 3). Calcium should be used only in emergencies, however, because hypercalcemia also may cause cardiac arrest.

Azotemia is generally controlled and nutrition maintained with a low-protein, high-carbohydrate diet. Essential amino acid replacement can be given orally or parenterally. Adequate carbohydrate intake slows protein catabolism and helps prevent release of potassium from cellular breakdown. Because sepsis is a common serious and potentially fatal complication of renal failure, observation for

signs of infection and early treatment with antibiotics are necessary. Drug dosage levels may require adjustment if they are metabolized or excreted by the kidneys. Recovery may take up to 1 year.

Continuous renal replacement therapy (CRRT) (mechanical removal of water, electrolytes, and toxins from the blood) is indicated for uncontrollable hyperkalemia, acidosis, or severe fluid overload. CRRT is particularly promising in critically ill individuals with multiple organ dysfunction or sepsis. According to the KDIGO guideline, CRRT is a complementary therapy in the treatment of AKI.[69] The timing and optimal dose-response relationships for CRRT are individually determined with consideration to hemodynamic status, degree of volume overload, bleeding risk, and the treating facility's availability/experience.[74]

Chronic Kidney Disease

CKD is the progressive and irreversible loss of renal function indicated by a decline in GFR to below 60 mL/min/1.73 m^2 for 3 months or more with implications for health. CKD is associated with systemic diseases, such as diabetes mellitus (most significant risk factor), hypertension, and systemic lupus erythematosus. CKD also is associated with intrinsic kidney diseases, such as AKI, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders (Table 38.14).

Table 38.14

Stages of Chronic Kidney Disease

Stage	Description	Signs/Symptoms
I	Normal kidney function Normal or high GFR (>90 mL/min)	Usually none Hypertension common
II	Mild kidney damage, mild reduction in GFR (60–89 mL/min)	Subtle Hypertension Increasing creatinine and urea levels
III	Moderate kidney damage GFR 30–59 mL/min	Mild As above
IV	Severe kidney damage GFR 15–29 mL/min	Moderate As above Erythropoietin deficiency anemia Hyperphosphatemia Increased triglycerides Metabolic acidosis Hyperkalemia Salt/water retention
V	End-stage kidney disease Established kidney failure GFR <15 mL/min	Severe As above

Stage	Description	Signs/Symptoms
I	Normal kidney function Normal or high GFR (>90 mL/min)	Usually none Hypertension common
II	Mild kidney damage, mild reduction in GFR (60–89 mL/min)	Subtle Hypertension Increasing creatinine and urea levels
III	Moderate kidney damage GFR 30–59 mL/min	Mild As above
IV	Severe kidney damage GFR 15–29 mL/min	Moderate As above Erythropoietin deficiency anemia Hyperphosphatemia Increased triglycerides Metabolic acidosis Hyperkalemia Salt/water retention
V	End-stage kidney disease Established kidney failure GFR <15 mL/min	Severe As above

GFR, Glomerular filtration rate.

Pathophysiology

The progression phase of the disease is characterized by a persistent state of inflammation and hypoxia and oxidative stress that contribute to the development of renal fibrosis.[75] The kidneys have a remarkable ability to adapt to the loss of nephron mass. Symptomatic changes result from increased plasma levels of creatinine, urea, and potassium. Alterations in salt and water balance usually do not become apparent until renal function declines to less than 25% of normal when adaptive renal reserves have been exhausted.[76]

Different theories have been proposed to account for the adaptation to the loss of renal function. The *intact nephron hypothesis* proposes that loss of nephron mass with progressive kidney damage causes the surviving nephrons to increase their capacity to maintain solute and water regulation. These nephrons are capable of a compensatory hypertrophy and expansion or hyperfunction in their rates of filtration, reabsorption, and secretion. Although the urine of an individual with CKD may contain abnormal amounts of protein and red and white blood cells or casts, the major end products of excretion are similar to those of normally functioning kidneys until the advanced stages of renal failure when there is a significant reduction of functioning nephrons.

The *particular location of kidney damage* influences loss of kidney function. For example, tubular interstitial diseases damage primarily the tubular or medullary parts of the nephron, producing problems such as renal tubular acidosis, salt wasting, and difficulty diluting or concentrating the urine. Proteinuria, hematuria, and nephrotic syndrome are more prominent when the damage is primarily vascular or glomerular. With severe or repeated injury, interstitial capillary loss, and fibroblast proliferation result in progressive glomerulosclerosis and tubulointerstitial fibrosis. These conditions contribute to CKD and ESRD. A summary of factors involved in the progression of CKD is outlined in Table 38.15 and Fig. 38.12.

Table 38.15

Factors Representing Progression of Chronic Kidney Failure

Factor	Characteristics
Proteinuria	Glomerular hyperfiltration of protein contributes to tubular interstitial injury by accumulating in interstitial space and promoting inflammation and progressive fibrosis.
Creatinine and urea clearance	In chronic renal failure, the GFR falls and the plasma creatinine concentration increases by a reciprocal amount; because there is no regulatory adjustment for creatinine, plasma levels continue to rise and serve as an index of changing glomerular function.
	As GFR declines, urea clearance increases. (Note: Urea is both filtered and reabsorbed and varies with state of hydration.)
Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate, calcium and magnesium balance	Changes in acid-base balance affect phosphate and calcium balance. Major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-dihydroxy-vitamin D_3, and hypocalcemia.
	Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.
	Hypermagnesemia tends to develop with impaired fractional excretion of magnesium in relation to declining GFR. Hypomagnesemia may develop associated with decreased intestinal absorption, alterations in parathyroid hormone and effects of medication.
Hematocrit	Because of anemia that accompanies chronic renal failure, lethargy, dizziness, and low hematocrit are common.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops.
	Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels.
	As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH. Metabolic acidosis begins when GFR reaches 30%–40%.
	Metabolic acidosis and hyperkalemia may be severe enough to require dialysis when end-stage renal failure develops.
Dyslipidemia	Chronic hyperlipidemia may induce glomerular and tubulointerstitial injury, contributing to progression of chronic renal disease.

Factor	Characteristics
Proteinuria	Glomerular hyperfiltration of protein contributes to tubular interstitial injury by accumulating in interstitial space and promoting inflammation and progressive fibrosis.
Creatinine and urea clearance	In chronic renal failure, the GFR falls and the plasma creatinine concentration increases by a reciprocal amount; because there is no regulatory adjustment for creatinine, plasma levels continue to rise and serve as an index of changing glomerular function.
	As GFR declines, urea clearance increases. (Note: Urea is both filtered and reabsorbed and varies with state of hydration.)
Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate, calcium and magnesium balance	Changes in acid-base balance affect phosphate and calcium balance. Major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-dihydroxy-vitamin D_3, and hypocalcemia.
	Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.
	Hypermagnesemia tends to develop with impaired fractional excretion of magnesium in relation to declining GFR. Hypomagnesemia may develop associated with decreased intestinal absorption, alterations in parathyroid hormone and effects of medication.
Hematocrit	Because of anemia that accompanies chronic renal failure, lethargy, dizziness, and low hematocrit are common.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops.
	Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels.
	As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH. Metabolic acidosis begins when GFR reaches 30%–40%.
	Metabolic acidosis and hyperkalemia may be severe enough to require dialysis when end-stage renal failure develops.
Dyslipidemia	Chronic hyperlipidemia may induce glomerular and tubulointerstitial injury, contributing to progression of chronic renal disease.

GFR, glomerular filtration rate.

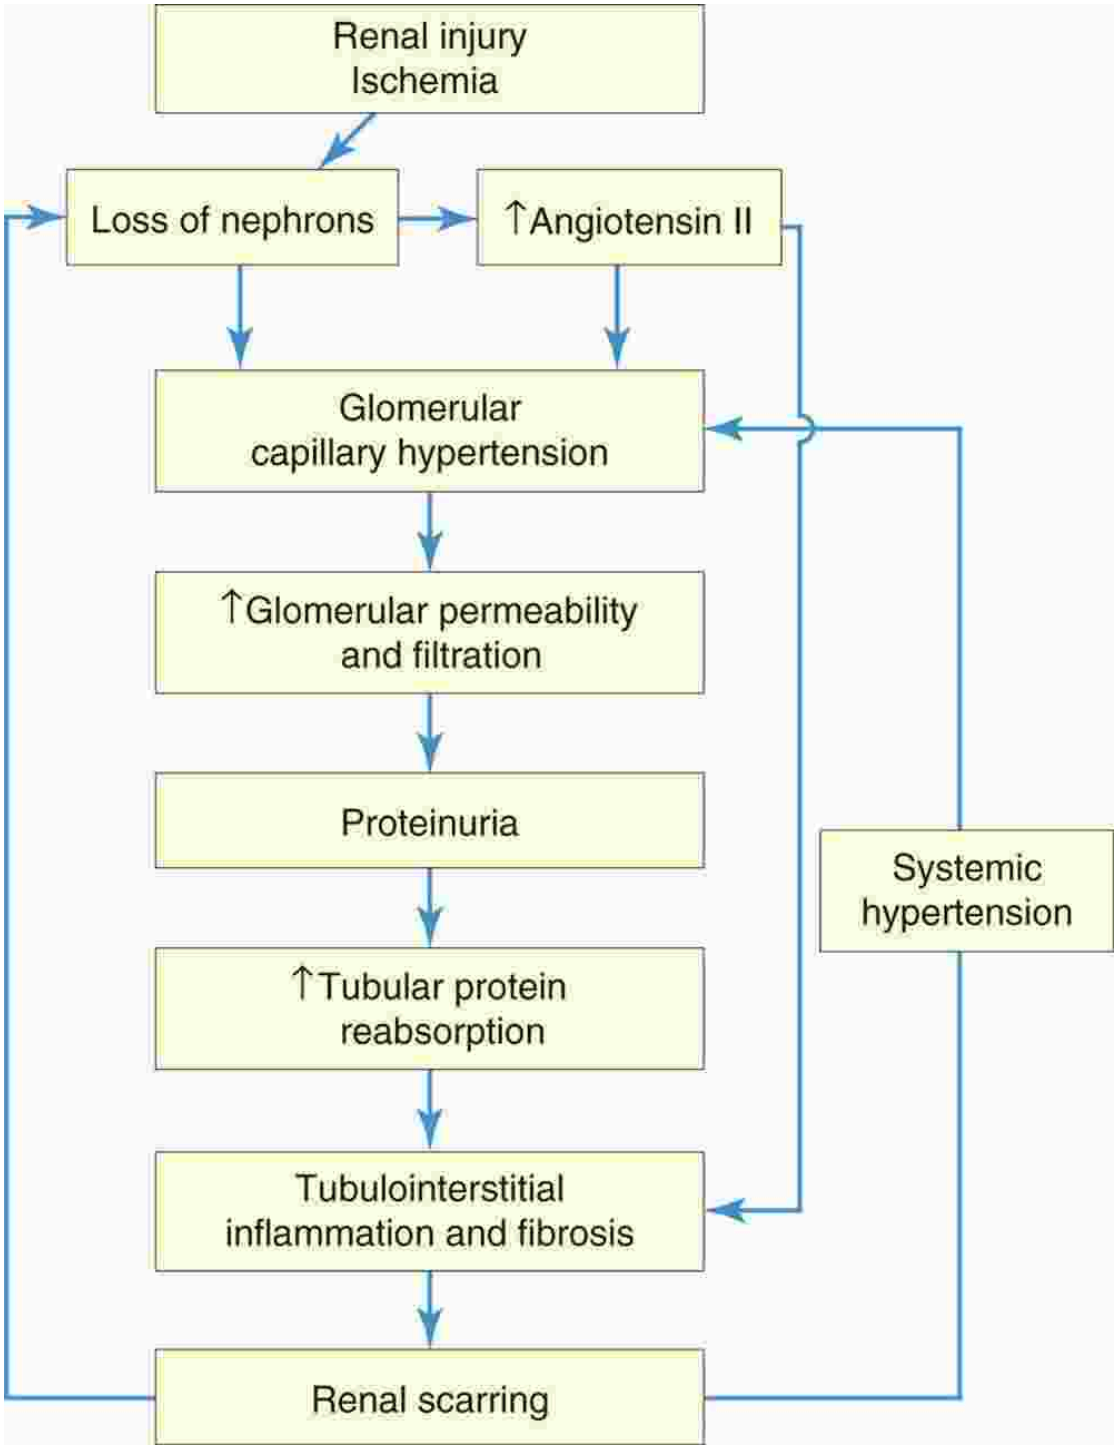

FIG. 38.12 Mechanisms Related to the Progression of Chronic Kidney Disease.

A flowchart shows the mechanisms related to the progression of chronic kidney disease. 1. Renal injury; ischemia. Leads to 2. 2. Loss of nephrons. Leads to 3 and 4. 3. Increased angiotensin 2. Leads to 3 and 8. 4. Glomerular capillary hypertension. Leads to 5. 5. Increased glomerular permeability and filtration. Leads to 6. 6. Proteinuria. Leads to 7. 7. Increased tubular protein reabsorption.

Leads to 8. 8. Tubulointerstitial inflammation and fibrosis. Leads to 9. 9. Renal scarring. Leads to 2 and 10. 10. Systemic hypertension.

The factors that contribute to the pathogenesis of CKD are complex and involve the interaction of many cells, cytokines, and structural alterations. Two factors that have consistently been recognized to advance renal disease are proteinuria and angiotensin II activity. Glomerular hyperfiltration, increased glomerular capillary permeability, and loss of negative charge may lead to proteinuria. *Proteinuria* contributes to tubulointerstitial injury by accumulating in the interstitial space of the nephron tubules. There is activation of complement proteins and other mediators and cells, such as macrophages, that promote inflammation and progressive fibrosis. *Angiotensin II* (from activation of the renin-angiotensin-aldosterone system [RAAS]) causes efferent arteriolar vasoconstriction that promotes glomerular hypertension, systemic hypertension, and hyperfiltration. Hyperfiltration is also associated with hyperglycemia and diabetic nephropathy. The chronically high intraglomerular pressure increases glomerular capillary permeability, contributing to proteinuria. Angiotensin II promotes the activity of inflammatory cells and growth factors that participate in tubulointerstitial fibrosis and scarring.[3]

The progression of AKI to CKD is related to incomplete or maladaptive tissue repair, setting in motion processes promoting the development of interstitial fibrosis.[77] CKD and progressive renal dysfunction are also characterized by an amplification of oxidative stress.[78] Oxidative stress accompanied by inflammation (in which the cells of the innate immune response system are mainly involved) has a significant role in the pathogenesis of CKD.[78] The effect of reactive oxidative stress (ROS) disrupts the excretory function of each section of the nephron, preventing the maintenance of intra-systemic homeostasis and leading to the accumulation of metabolic products.[78] Renal regulatory mechanisms, such as tubular glomerular feedback and the RAAS, are also affected, making it impossible for the kidney to compensate for water–electrolyte and acid-base disturbances. Without appropriate compensatory mechanisms, there is further intensification of oxidative stress resulting in the progression of CKD and a spectrum of complications such as malnutrition, calcium phosphate abnormalities, atherosclerosis, and anemia.[78] Hypertension can be used as an example. Oxidative stress in the kidney and vascular tissue causes hypertension, and hypertension promotes oxidative stress. Now add in the inflammation component. Chronic inflammation is a significant contributor to the promotion of oxidative stress.[78] Therefore, oxidative stress, along with inflammation, is a critical component of CKD-related pathologies that can adversely affect the human body (e.g., diabetes mellitus, hypertension).[78]

Clinical Manifestations

The clinical manifestations of CKD are often described using the terms *azotemia* and *uremia*. **Azotemia** is manifested by increased levels of serum urea, SCr, and other nitrogenous compounds related to decreasing kidney function. **Uremia** is the accumulation of urea and other nitrogenous compounds and toxins. Sources of toxins include the accumulation of end products of protein metabolism, alterations in fluid and electrolytes, metabolic acidosis, intestinal absorption of toxins produced by gut bacteria, and results of altered renal hormone synthesis (e.g., anemia, hyperphosphatemia, and hypocalcemia). The accumulation of toxins has systemic effects known as **uremic syndrome**.[79] The manifestations involve almost every organ system and include hypertension; anorexia; nausea; vomiting; diarrhea or constipation; malnutrition and weight loss; pruritus; edema; anemia; clotting disorders; neurologic, cardiovascular, and endocrine disease; and skin and skeletal changes. The manifestations are summarized in Table 38.16 and Fig. 38.13. Details of the systemic manifestations associated with CKD are discussed in the following sections.

Table 38.16

Systemic Effects of Chronic Kidney Disease and Uremia

System	Manifestations	Mechanisms	Treatment
Skeletal	Spontaneous fractures and bone pain Deformities of long bones	Chronic kidney disease—mineral bone disorder: bone inflammation with fibrous degeneration related to hyperparathyroidism; bone resorption associated with vitamin D and calcium deficiency	Control of hyperphosphatemia to reduce hyperparathyroidism; administration of calcium and aluminum hydroxide antacids, which bind phosphate in the gut, together with a phosphate-restricted diet; vitamin D replacement; avoidance of magnesium antacids because of impaired magnesium excretion
Cardiopulmonary	Pulmonary edema, Kussmaul respirations	Fluid overload associated with pulmonary edema and metabolic acidosis leading to Kussmaul respirations	Angiotensin-converting enzyme (ACE) inhibitors; combination of propranolol, hydralazine, and minoxidil for those with high levels of renin; bilateral nephrectomy with dialysis or transplantation
Cardiovascular	Left ventricular hypertrophy, cardiomyopathy, and ischemic heart disease; hypertension, dysrhythmias, accelerated atherosclerosis; pericarditis with fever, chest pain, and pericardial friction rub	Extracellular volume expansion and hypersecretion of renin associated with hypertension; anemia increases cardiac workload; hyperlipidemia promotes atherosclerosis; toxins precipitate into pericardium	Volume reduction with diuretics that are not potassium sparing (to avoid hyperkalemia); lipid-lowering drugs; blood pressure–lowering strategies; dialysis

System	Manifestations	Mechanisms	Treatment
Neurologic	Encephalopathy (fatigue, loss of attention, difficulty with problem solving); peripheral neuropathy (pain and burning in the legs and feet, loss of vibration sense and deep tendon reflexes); loss of motor coordination, twitching, fasciculations, stupor, and coma with advanced uremia	Progressive accumulation of uremic toxins associated with end-stage renal disease Stroke or intracerebral hemorrhage associated with chronic dialysis	Dialysis or successful kidney transplantation
Endocrine	Restricted growth in children Higher incidence of goiter Osteomalacia	Elevated parathyroid hormone levels Decreased thyroid hormone	Endogenous recombinant human growth hormone; thyroid hormone replacement Same as skeletal above
Hematologic	Anemia, usually normochromic normocytic; platelet disorders with prolonged bleeding times	Reduced erythropoietin secretion and reduced red cell production; uremic toxins shorten red blood cell survival and alter platelet function	Dialysis; recombinant human erythropoietin (controversial) and iron supplementation; conjugated estrogens; DDAVP (1-deamino-[8-C-arginine] vasopressin); transfusion
Gastrointestinal	Anorexia, nausea, vomiting; mouth ulcers, stomatitis, urinous breath (uremic factor), hiccups, peptic ulcers, gastrointestinal bleeding, and pancreatitis associated with end-stage renal failure	Retention of metabolic acids and other metabolic waste products	Protein-restricted diet for relief of nausea and vomiting; Na^+-based alkali or alkali-inducing food

System	Manifestations	Mechanisms	Treatment
Integumentary	Abnormal pigmentation and pruritus	Retention of urochromes, contributing to sallow, yellow color; high plasma calcium levels and neuropathy associated with pruritus	Dialysis with control of serum calcium and phosphate levels
Immunologic	Increased risk of infection that can cause death; increased risk of carcinoma	Suppression of cell-mediated immunity; reduction in number and function of lymphocytes, diminished phagocytosis	Routine dialysis
Reproductive	Sexual dysfunction: menorrhagia, amenorrhea, infertility, and decreased libido in women; decreased testosterone levels, infertility, and decreased libido in men	Dysfunction of ovaries and testes; presence of neuropathies	No specific treatment

System	Manifestations	Mechanisms	Treatment
Skeletal	Spontaneous fractures and bone pain Deformities of long bones	Chronic kidney disease—mineral bone disorder: bone inflammation with fibrous degeneration related to hyperparathyroidism; bone resorption associated with vitamin D and calcium deficiency	Control of hyperphosphatemia to reduce hyperparathyroidism; administration of calcium and aluminum hydroxide antacids, which bind phosphate in the gut, together with a phosphate-restricted diet; vitamin D replacement; avoidance of magnesium antacids because of impaired magnesium excretion
Cardiopulmonary	Pulmonary edema, Kussmaul respirations	Fluid overload associated with pulmonary edema and metabolic acidosis leading to Kussmaul respirations	Angiotensin-converting enzyme (ACE) inhibitors; combination of propranolol, hydralazine, and minoxidil for those with high levels of renin; bilateral nephrectomy with dialysis or transplantation
Cardiovascular	Left ventricular hypertrophy, cardiomyopathy, and ischemic heart disease; hypertension, dysrhythmias, accelerated atherosclerosis; pericarditis with fever, chest pain, and pericardial friction rub	Extracellular volume expansion and hypersecretion of renin associated with hypertension; anemia increases cardiac workload; hyperlipidemia promotes atherosclerosis; toxins precipitate into pericardium	Volume reduction with diuretics that are not potassium sparing (to avoid hyperkalemia); lipid-lowering drugs; blood pressure–lowering strategies; dialysis
Neurologic	Encephalopathy (fatigue, loss of attention, difficulty with problem solving); peripheral neuropathy (pain and burning in the legs and feet, loss of vibration sense and deep tendon reflexes); loss of motor coordination, twitching, fasciculations, stupor, and coma with advanced uremia	Progressive accumulation of uremic toxins associated with end-stage renal disease Stroke or intracerebral hemorrhage associated with chronic dialysis	Dialysis or successful kidney transplantation
Endocrine	Restricted growth in children Higher incidence of goiter Osteomalacia	Elevated parathyroid hormone levels Decreased thyroid hormone	Endogenous recombinant human growth hormone; thyroid hormone replacement Same as skeletal above
Hematologic	Anemia, usually normochromic normocytic; platelet disorders with prolonged bleeding times	Reduced erythropoietin secretion and reduced red cell production; uremic toxins shorten red blood cell survival and alter platelet function	Dialysis; recombinant human erythropoietin (controversial) and iron supplementation; conjugated estrogens; DDAVP (1-deamino-[8-C-arginine] vasopressin); transfusion
Gastrointestinal	Anorexia, nausea, vomiting; mouth ulcers, stomatitis, urinous breath (uremic factor), hiccups, peptic ulcers, gastrointestinal bleeding, and pancreatitis associated with end-stage renal failure	Retention of metabolic acids and other metabolic waste products	Protein-restricted diet for relief of nausea and vomiting; Na^+-based alkali or alkali-inducing food
Integumentary	Abnormal pigmentation and pruritus	Retention of urochromes, contributing to sallow, yellow color; high plasma calcium levels and neuropathy associated with pruritus	Dialysis with control of serum calcium and phosphate levels
Immunologic	Increased risk of infection that can cause death; increased risk of carcinoma	Suppression of cell-mediated immunity; reduction in number and function of lymphocytes, diminished phagocytosis	Routine dialysis
Reproductive	Sexual dysfunction: menorrhagia, amenorrhea, infertility, and decreased libido in women; decreased testosterone levels, infertility, and decreased libido in men	Dysfunction of ovaries and testes; presence of neuropathies	No specific treatment

Data from Almeras C, Argilés A. The general picture of uremia. *Seminars in Dialysis*, 2009;22(4):329–333; Keane WF. The role of lipids in renal disease: Future challenges. *Kidney International Supplement*, 75:S27–S31, 2000; Thomas R, Kanso A, Sedor JR. Chronic kidney disease and its complications. *Primary Care*, 2008;35(2):329–344.

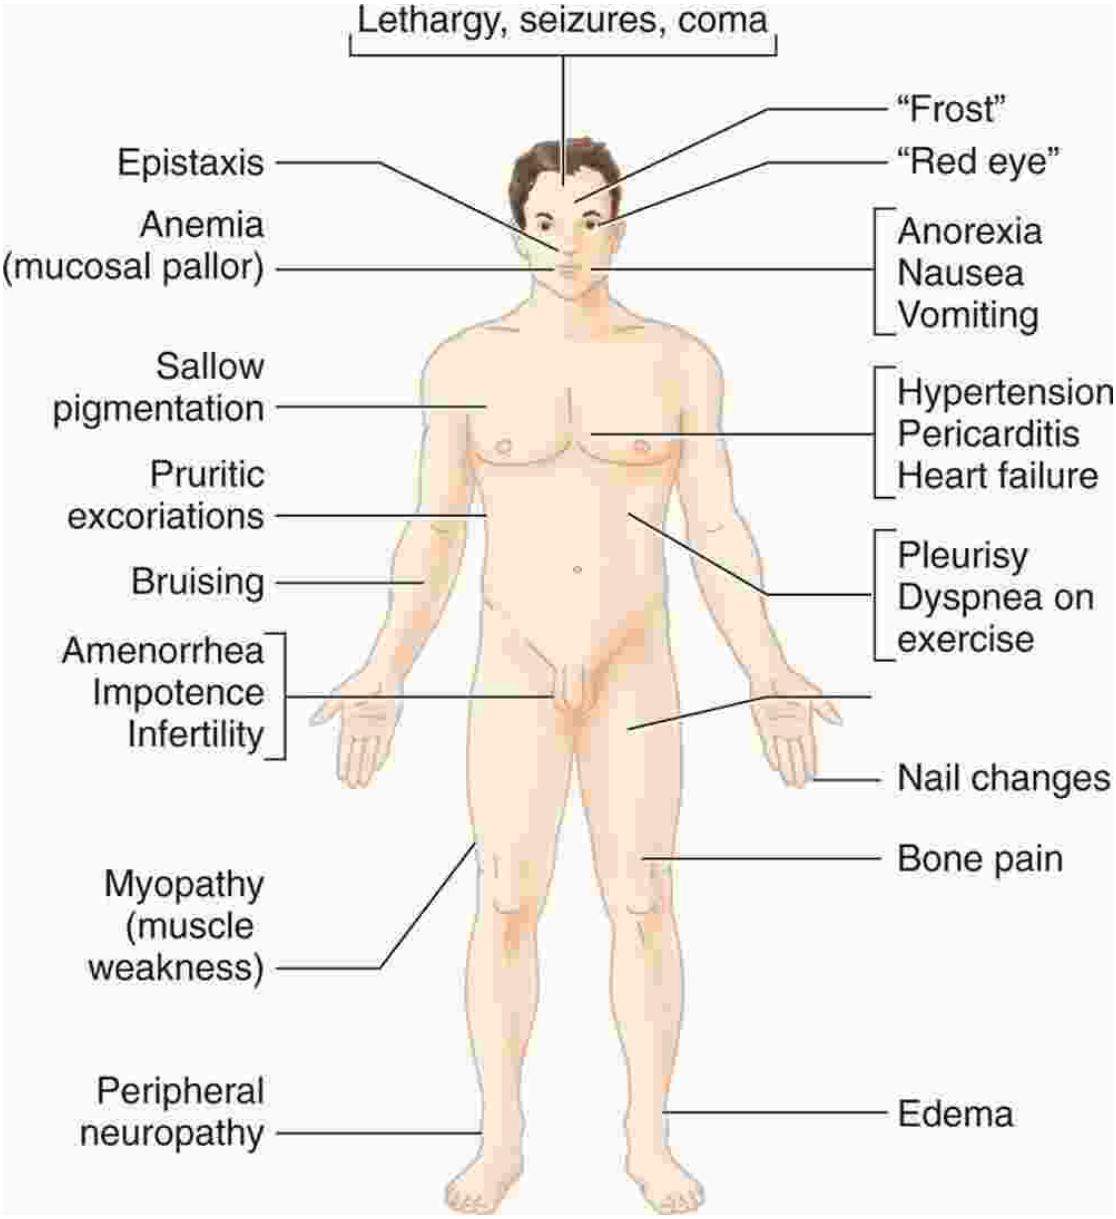

FIG. 38.13 Common Signs and Symptoms of Kidney Dysfunction. (From Goldman L, Schafer AI. *Goldman-Cecil medicine*, 25th edition. Philadelphia: Saunders; 2016; redrawn from Forbes CD, Jackson WF. *Color atlas and text of clinical medicine*, 3rd edition. London: Mosby; 2003.)

An illustration of the anterior view of the human body identifies the common signs and symptoms of kidney dysfunction, clockwise from the top: lethargy, seizures, coma; frost; red eye; anorexia, nausea, vomiting; hypertension, pericarditis, heart failure; pleurisy, dyspnea on exercise; nail changes; bone pain; edema; peripheral neuropathy; myopathy (muscle weakness); amenorrhea, impotence, infertility; bruising; pruritic excoriations; sallow pigmentation; anemia (mucosal pallor); and epistaxis.

Creatinine, Cystatin C, and Urea Clearance

Creatinine is constantly released from muscle and excreted primarily by glomerular filtration. In CKD, as GFR declines, the SCr level increases by a reciprocal amount to maintain a constant rate of excretion (Fig. 38.14). With continuing decline in GFR, the plasma creatinine concentration increases. Measures of SCr can serve as an index of changing glomerular function. However, SCr as an estimate of GFR is limited when there is reduced muscle mass or fluid overload. Equations including cystatin C or combined with SCr provide a better index. The clearance of *urea* follows a similar pattern, but urea is both filtered and reabsorbed. The measured urea level varies with the state of hydration; therefore, urea concentration is not a good index of GFR. However, as the GFR decreases, plasma urea concentration increase.

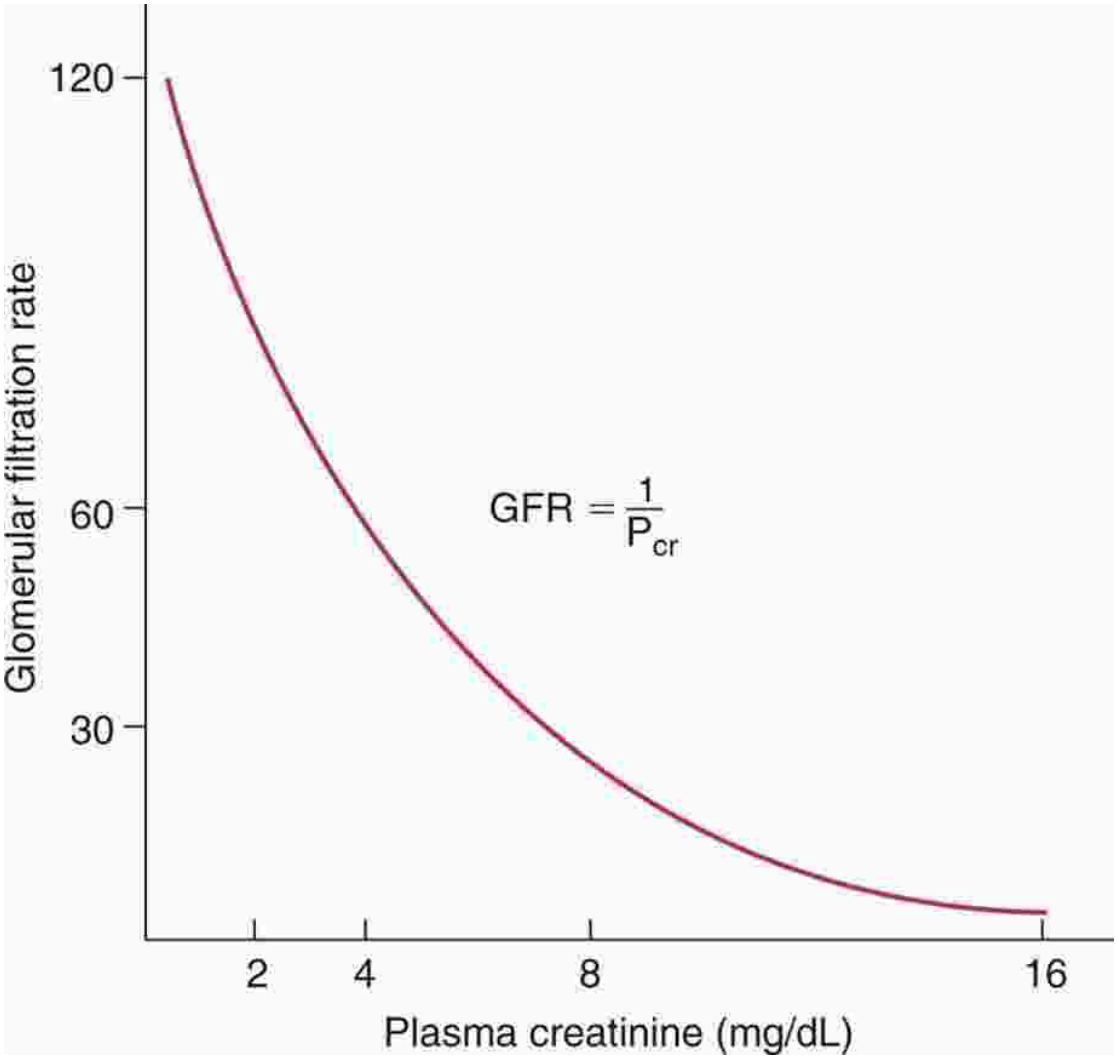

FIG. 38.14 Plasma Creatinine (P_{cr}) and Glomerular Filtration Rate (GFR).

A graph plots glomerular filtration rate against plasma creatinine (in milligrams per deciliter). The horizontal axis ranges from 0 to 16, and the vertical axis ranges from 0 to 120. A concave-up downward sloping curve represents the equation G F R equals 1 over P sub c r.

Fluid and Electrolyte Balance

Fluid and electrolyte and acid-base balances are significantly disturbed with CKD.[80] A summary of electrolyte and acid-base balance alterations is presented in Table 38.17.

Table 38.17

Electrolyte and Acid-Base Alterations of Chronic Kidney Disease

Factor	Characteristics
Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate, calcium and magnesium balance	Changes in acid-base balance affect phosphate and calcium balance. The major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-$(OH)_2$-vitamin D_3 (calcitriol), and hypocalcemia. Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result. Serum magnesium levels are elevated in late stages of renal failure related to loss of renal excretion.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops. Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels. As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH.
	Metabolic acidosis begins to develop when GFR decreases to 30%–40% of normal. When end-stage renal failure develops, the metabolic acidosis may be severe enough to require dialysis.

GFR, Glomerular filtration rate.

Levels of *sodium* must be regulated within narrow limits because sodium is the major extracellular solute. In CKD, sodium and water balance is maintained very close to normal until the development of stage V ESRD (see Table 38.14). This occurs because of the increased fractional excretion of sodium, particularly in the distal nephron, in relation to decreasing GFR. Hormones including aldosterone, prostaglandins, and natriuretic peptides also modulate sodium excretion, and their levels are elevated with progressive kidney disease. Individual variation in the underlying pathology of CKD must be considered in the management of sodium intake or restriction. Sodium wasting may be present with tubulointerstitial causes of CKD, and there may also be extra renal losses of sodium from vomiting, diarrhea, or fever. Sodium retention is more likely in ESRD particularly in the presence of nephrotic syndrome or heart failure. Sodium retention contributes to hypertension, edema, heart failure, and mortality. Interdialytic water intake can cause volume overload and dilutional hyponatremia prior to dialysis. Management of salt and water balance requires individual assessment, and both hyponatremia and hypernatremia require management.[81,82]

The regulation of *water balance* and osmolality is normally achieved by urinary concentration mediated by antidiuretic hormone (ADH). As GFR is reduced, the ability to concentrate and dilute the urine diminishes. In earlier stages of renal disease, this may be caused by osmotic diuresis produced by increased fractional excretion of solutes by the remaining functioning nephrons or by a decreased tubular response to ADH. Individual nephrons can maintain water balance until severe renal failure occurs and GFR declines to 15% to 20% of normal with extensive loss of nephron and tubular function. At this stage, the urinary concentration becomes fixed and approaches that of the plasma at 285 mOsm/L with a specific gravity of about 1.010.

Urinary excretion of *potassium* is related primarily to distal tubular secretion mediated by aldosterone and sodium-potassium adenosine triphosphatase (see Chapter 3). In renal failure, there is increased tubular secretion that provides effective regulation until the onset of oliguria. With hyperkalemia, larger

amounts of potassium can be eliminated through the bowel.[83] Although nonoliguric patients can maintain potassium excretion with normal dietary intake, they are more prone to develop hyperkalemia with increased loading (i.e., use of salt substitutes). Use of potassium-sparing diuretics, such as spironolactone (aldactone), volume depletion, acute infection, severe acidosis, or marked hyperglycemia also may precipitate elevated levels of serum potassium. With progression of disease to ESRD, total body potassium can increase to life-threatening levels and must be controlled by dietary restriction, loop diuretics, cation exchange resins, and dialysis. Sodium polystyrene sulfonate (a nonspecific sodium-cation exchange resin in the colon), patiromer sorbitex calcium (exchanges calcium for potassium in the colon), and sodium zirconium cyclosilicate (traps potassium in the colon) are effective in managing hyperkalemia.[84] Hyperkalemia also can be a side effect of ACE inhibitors or angiotensin receptor blockers (ARB) often used to prevent diabetic nephropathy. Severe acute hyperkalemia is treated with intravenous 10% calcium gluconate or 10% calcium chloride, intravenous dextrose, and insulin, and nebulized or intravenous salbutamol (sympathetic beta$_2$ agonist, promotes Na^+-K^+-ATPase pump and intracellular movement of potassium). Renal replacement therapy may be required to manage hyperkalemia (support of renal function using hemodialysis or peritoneal dialysis).

The intake of a normal diet produces 50 to 100 mEq of hydrogen per day. These ions are secreted from the renal tubules and excreted in the urine combined with phosphate and ammonia buffers (buffering is described in Chapter 3). *Metabolic acidosis* (Chapter 3) develops when the GFR decreases to less than 20% to 25% of normal. The causes of acidosis are primarily related to decreased hydrogen ion elimination and decreased bicarbonate reabsorption. With ESRD, metabolic acidosis may be severe enough to require alkali therapy and dialysis.[85]

Calcium, Phosphate, Magnesium, and Bone

Bone and skeletal changes develop with alterations in calcium, phosphate, magnesium, and vitamin D metabolism (Table 38.18).[86] These changes begin when the GFR decreases to 25% or less. *Hypocalcemia* is accelerated by impaired renal synthesis of 1,25-dihydroxy-vitamin D_3 (calcitriol) with decreased intestinal absorption of calcium. Renal phosphate excretion also decreases, and the increased serum phosphate binds calcium, further contributing to hypocalcemia. Acidosis also contributes to a negative calcium balance. Decreased serum calcium level stimulates parathyroid hormone secretion with mobilization of calcium from bone. The combined effect of *secondary hyperparathyroidism* and *vitamin D deficiency* can result in renal osteodystrophies (i.e., *osteomalacia* and *osteitis fibrosa* with increased risk for fractures) (see Chapter 44) and vascular calcification, including coronary artery calcification. Fractional excretion of magnesium increases as compensation for the decline in GFR with the progression of CKD. With ESRD, fractional excretion of magnesium is inadequate and serum magnesium levels must be monitored considering dietary intake, intestinal absorption, alterations in parathyroid hormone, and effects of different medications. Generally, there is a tendency to develop hypermagnesemia. However, hypomagnesemia can develop in some cases and requires modification of the dialysate magnesium concentration.[87] Hypomagnesemia has been associated with osteoporosis in postmenopausal women,[88] but the effects on bone in ESRD are not clearly known.

Table 38.18

Calcium, Phosphate, and Magnesium Metabolism in Chronic Kidney Disease

Kidney	Plasma	Bone
Decreased renal production of vitamin D_3	Decreased calcium absorption from gut	Decreased calcium deposition
	Decreased ionized calcium	
	Increased PTH secretion (secondary hyperparathyroidism)	
Decreased phosphate excretion	Elevated phosphate	Release of calcium and phosphate
	Formation of $CaHPO_4$	Osteitis fibrosa, osteomalacia, calcium deposits in soft tissue and vascular calcification (occurs when kidney fails to respond to PTH secretion because of loss of renal mass and calcium and phosphate continues to be absorbed from bone)
Decreased magnesium excretion	Elevated magnesium in late-stage disease	Effect on bone not clearly known

$CaHPO_4$, Calcium hydrogen phosphate; *PTH*, parathyroid hormone.

Protein, Carbohydrate, and Fat Metabolism

Protein, carbohydrate, and fat metabolism are altered in CKD. *Proteinuria*, metabolic acidosis, inflammation, and a catabolic state contribute to a negative nitrogen balance. Levels of serum proteins diminish, including albumin, complement, and transferrin, and there is loss of muscle mass. The amount of proteinuria is also related to the extent of renal injury and predicts disease progression. Proteinuria may independently cause renal damage by promoting tubular inflammation and fibrosis from particular protein-bound fatty acids.[89] Monitoring of proteinuria using the urine albumin-to-creatinine ratio can assist in staging CKD.[90]

Insulin resistance and glucose intolerance are common and may be related to proinflammatory cytokines and alterations in adipokines (high leptin and low adiponectin levels) that interfere with insulin action. In both nondiabetic and diabetic persons with CKD, oxidative stress can contribute to renal tubular and vascular injury as antioxidant systems become inadequate.[91]

Dyslipidemia is common among individuals with CKD. There is a high ratio of low-density lipoprotein (LDL) to high-density lipoprotein (HDL), a high level of triglycerides, and an accumulation of LDL particles with accelerated atherosclerosis and vascular calcification. Uremia causes a deficiency in lipoprotein lipase and a decreased level of hepatic triglyceride lipase. Decreased lipolytic activity results in a reduction and protection effects of the HDL level. Apolipoprotein concentration also is elevated, thereby accelerating atherogenesis.[92]

Hematologic System

Hematologic alterations include *normochromic-normocytic anemia, impaired platelet function*, and *hypercoagulability*. Inadequate production of erythropoietin decreases red blood cell production and causes anemia. Chronic inflammation, iron deficiency, and decreased half-life of erythrocytes are also contributing factors. Anemia contributes to decreased tissue oxygenation and to progression of kidney disease. Low serum levels of hemoglobin and symptoms of anemia, such as lethargy, weakness, and dizziness, are common findings. Treatment of anemia includes infusion of erythropoiesis stimulating agents (ESAs) (i.e., recombinant human erythropoietin), and intravenous iron. Hypoxia-inducible factor-prolyl hydroxylase inhibitors, oral agents that stimulate endogenous erythropoietin production and enhance iron availability, are in clinical trials and may replace ESAs.[93]

Disorders of hemostasis in CKD are primarily related to defective platelet aggregation, impaired adhesion of platelets to the vascular endothelium, and alterations in coagulation factors and in the fibrinolytic pathway. The consequence is either (1) an increased bleeding tendency (more common with later stages of CKD) manifested by bruising, epistaxis and other mucosal bleeding, gastrointestinal bleeding, and cerebrovascular hemorrhage or (2) excessive formation of thrombi (e.g., deep vein thrombosis, pulmonary embolism, and cardiovascular events), which is more common in earlier stages of CKD.[94]

Cardiovascular System

Cardiovascular disease is a major cause of morbidity and mortality in CKD. Proinflammatory cytokines, oxidative stress, metabolic derangements, dyslipidemia, uremic toxins, and anemia are significant contributors.

Hypertension is the result of excess sodium and fluid volume and arteriosclerosis. Endothelial cell dysfunction and calcium deposits lead to a loss of vessel elasticity and vascular calcification. Elevated renin concentration also stimulates the secretion of aldosterone, increasing sodium and water reabsorption.

Dyslipidemia promotes atheromatous plaque formation (see section on Protein, Carbohydrate and Fat Metabolism). The resulting vascular disease increases the risk for *ischemic heart disease, left ventricular hypertrophy, congestive heart failure, stroke*, and *peripheral vascular disease* in individuals with uremia.[95]

Pericarditis can develop from pericardial inflammation caused by the presence of uremic toxins. Accumulation of fluid in the pericardial space can compromise ventricular filling and cardiac output.[96]

Congestive heart failure can develop from fluid overload, hypertension, cardiac remodeling with hypertrophy and fibrosis (cardiorenal syndrome).[97]

Anemia increases demands for cardiac output and adds to the cardiac workload.

Pulmonary System

Pulmonary complications are associated with fluid overload causing pulmonary edema, congestive heart failure, and dyspnea. Pulmonary edema leads to respiratory acidosis causing Kussmaul respirations. Pulmonary hypertension is associated with left ventricular dysfunction or uremic-related pulmonary vascular changes.[98]

Immune System

Immune system dysregulation develops with the uremia of CKD.Chemotaxis, phagocytosis, antibody production, and cell-mediated immune responses are suppressed. Malnutrition, metabolic acidosis, and hyperglycemia may amplify immunosuppression. Release of inflammatory cytokines results in systemic inflammation. Failure of antioxidant systems also promotes inflammation. There are deficient responses to vaccination, increased risk for infection, and virus-associated cancers (e.g., human papillomavirus, hepatitis B and C viruses, Epstein–Barr virus).[99]

Neurologic System

Neurologic symptoms are common and progressive with CKD. Symptoms are related to dysfunction of lower motor and sensory neurons associated with uremic toxicity, chronic hyperkalemic depolarization, and anemia. The symptoms may include headache, pain, drowsiness, sleep disorders, impaired concentration, memory loss, and impaired judgment (known as uremic encephalopathy). In advanced stages of kidney failure, symptoms may progress to seizures and coma. Neuromuscular irritation can cause hiccups, muscle cramps, and muscle twitching. Peripheral neuropathies associated with uremic toxins also can develop with impaired sensations, particularly in the lower limbs causing decreased tendon reflexes, muscle weakness, and muscle atrophy. Symptoms improve with renal replacement therapy (i.e., hemodialysis or peritoneal dialysis) or kidney transplant.

Gastrointestinal System

Gastrointestinal complications are common in individuals with CKD. Uremic gastroenteritis can cause bleeding ulcer and significant blood loss. Nonspecific symptoms include anorexia, nausea, vomiting, constipation, or diarrhea. Uremic fetor is a form of bad breath caused by the breakdown of urea by salivary enzymes. Malnutrition is common.

Endocrine and Reproductive Systems

Endocrine and reproductive alterations develop with progression of CKD. Both males and females have a decrease in levels of circulating sex steroids. Males often experience a reduction in testosterone levels and may be impotent. Oligospermia and germinal cell dysplasia can result in infertility. Females have reduced estrogen levels, amenorrhea, anovulation, difficulty maintaining a pregnancy to term, and early menopause.[100–102]

Insulin resistance is common in uremia, and as CKD progresses, the ability of the kidney to degrade insulin is reduced and the half-life of insulin is prolonged. Individuals with diabetes mellitus and CKD need to carefully manage their insulin dosages.

CKD also causes alterations in thyroid hormone metabolism, particularly hypothyroidism, known as *nonthyroidal illness syndrome*. Uremia delays the response of thyroid-stimulating hormone receptors, and triiodothyronine (T_3) levels are often low.

Integumentary System

Skin changes are associated with other complications that develop with CKD. Anemia can cause pallor and bleeding into the skin and results in hematomas and ecchymosis. Retained urochromes manifest as a sallow skin color. Hyperparathyroidism and uremic skin residues (known as uremic frost) are associated with inflammation, irritation, and pruritus with scratching, excoriation, and increased risk for infection. Half-and-half nails (half white and half red or brown) are common.

Evaluation and Treatment

Early screening and evaluation of CKD is based on risk factors, health history, presenting signs and symptoms, and diagnostic testing. Decreased GFR (< 80) with elevated SCr and BUN concentrations are consistent with CKD. Markers of kidney damage include measurement of urine protein level, particularly albumin, and examination of urine sediment. Imaging will show small kidney size, and renal biopsy confirms the diagnosis.

Management involves promotion of adequate caloric intake with dietary restriction of protein, sodium, potassium, and phosphate. Supplementation with vitamin D or vitamin D receptor activators aids in the management of hyperphosphatemia. Maintenance of sodium and fluid balance may require fluid restriction. Management of dyslipidemias includes both pharmacological (statins and fibrates) and nonpharmacological measures (lifestyle and behavioral modifications). Erythropoietin can be used as needed to increase red blood cells. ACE inhibitors or ARBs are often used to control systemic hypertension, reduce proteinuria, provide renoprotection, and prevent progressive renal damage. CKD related to diabetic nephropathy can be significantly reduced with glycemic control. SGLT2 inhibitors are nephroprotective and provide blood pressure and hemodynamic regulation, protection from

lipotoxicity, uric acid control, anti-inflammatory actions, and renal gluconeogenesis inhibition.[103] ESRD is treated with conservative care, CRRT, supportive therapy, and renal transplantation.

Summary Review

Urinary Tract Obstruction

1. Obstruction can occur anywhere in the urinary tract. It may be anatomic (structural) or functional. Obstruction impedes flow and dilates structures proximal to the blockage, increases risk for infection, and compromises renal function.
2. Upper urinary tract obstructions are caused by kidney stones or tumors within the kidney; or compression from a tumor, stone, or fibrosis along the ureter or at the ureter-bladder junction,
3. Complications of upper urinary tract obstruction include hydronephrosis, hydroureter, ureterohydronephrosis, and tubulointerstitial fibrosis.
4. Hypertrophy and hyperfunction of the unobstructed kidney compensate for loss of function of the kidney with obstructive disease.
5. Relief of obstruction is usually followed by postobstructive diuresis and may cause fluid and electrolyte imbalance.
6. Kidney stones are caused by supersaturation of the urine with precipitation of stone-forming substances and changes in urine pH.
7. Stones can be located in the kidneys, ureters, and urinary bladder. The most common kidney stone is formed from calcium oxalate.
8. LUT obstructions include both structural or anatomic disorders and alterations in neurologic function (neurogenic bladder), or both. They are related to urine storage and emptying.
9. Anatomic causes of resistance to urine flow include urethral stricture, prostatic enlargement in men, pelvic prolapse in women, and tumor compression.
10. Partial obstruction of the bladder can result in an increase in the force of detrusor contraction. If obstruction persists, there is deposition of collagen in the bladder wall over time, resulting in decreased bladder wall compliance and ineffective detrusor muscle contraction.
11. OAB is a dysfunction of urine storage with uncontrollable or premature contraction of the bladder that results in urgency with or without incontinence, frequency, and nocturia.
12. UAB syndrome is a voiding dysfunction resulting in prolonged bladder emptying or a failure to achieve complete bladder emptying, or both, within a normal time span.
13. A neurogenic bladder is caused by a neural lesion that interrupts innervation of the bladder.
14. Upper motor neuron lesions above the pontine micturition center result in overactive (hyperreflexive) bladder function and bladder dyssynergia (loss of coordinated neuromuscular contraction).
15. Lesions in the sacral area of the spinal cord or peripheral nerves result in underactive, hypotonic, or atonic bladder function.
16. Detrusor sphincter dyssynergia is failure of the urethrovesical junction smooth muscle to release urine during bladder contraction and causes a functional obstruction.
17. Kidney (renal) tumors include RCC (the most common), RTCC s and renal adenomas. RCC can metastasize to the lung, lymph nodes, liver, bone, thyroid gland, and central nervous system.
18. Bladder tumors are commonly composed of transitional cells with a papillary appearance and a high rate of recurrence

Urinary Tract Infection

1. UTIs are commonly caused by the retrograde movement of bacteria into the urethra and bladder and can ascend to the kidney. UTIs are uncomplicated when the urinary system is normal or complicated when there is an abnormality. Types of UTI include cystitis, interstitial cystitis, and acute or chronic pyelonephritis.

2. Host defenses that protect against UTI include high osmolality and acidic pH of urine, mucus, uromodulin, and other antimicrobial proteins that activate the immune response, sphincters that prevent reflux, and urine flow that washes out bacteria.
3. Virulent uropathogens have pili or fimbriae, or both, that promote binding to the uroepithelium and retrograde movement in the urinary tract. Formation of biofilms enhances colonization and resists host defenses and antimicrobial therapy.
4. Cystitis is an inflammation of the bladder commonly caused by bacteria and may be mild, hemorrhagic, suppurative, ulcerative, or gangrenous.
5. Interstitial cystitis/painful bladder syndrome is a bladder pain disorder associated with LUT symptoms of more than 6 weeks' duration in the absence of infection or other identifiable causes. It is likely related to an inflammatory autoimmune reaction with a derangement of the glycosaminoglycan layer of the bladder mucosa that makes it more susceptible to penetration by bacteria and noxious urinary solutes.
6. Acute pyelonephritis is an inflammation of the upper urinary tracts (ureter, renal pelvis, and kidney interstitium). Infection due to urinary obstruction and reflux of urine from the bladder are the most common underlying risk factors. Severe infections may cause localized abscess formation.
7. Chronic pyelonephritis is an acute or chronic inflammation of the renal pelvis often related to ascending infection and obstructive uropathies leading to scarring of one or both kidneys and alteration in renal function. Untreated, chronic pyelonephritis can lead to kidney failure.

Glomerular Disorders

1. Glomerular disorders are a group of related diseases of the glomerulus that can be primary and caused by immune injury, infection, ischemia, toxins or drugs, or vascular disorders or, secondarily, caused by systemic diseases.
2. Acute glomerulonephritis commonly results from inflammatory damage to the glomerulus as a consequence of immune reactions including deposition of circulating immune complexes, antibodies reacting in situ to planted antigens, antibodies directed against the glomerular basement membrane, and complement activation.
3. Chronic glomerulonephritis is related to a variety of diseases that cause deterioration of the glomerulus and a progressive course leading to chronic kidney failure.
4. Diabetic nephropathy is the most common cause of glomerular injury progressing to CKD and is related to chronic hyperglycemia, inflammatory mediators, and microvascular and macrovascular complications.
5. Lupus nephritis is caused by the formation of autoantibodies against double-stranded DNA and nucleosomes with glomerular deposition of the immune complexes or formation of immune complexes against planted antigens in the glomerulus.
6. Nephrotic syndrome is the excretion of at least 3.5 g of protein (primarily albumin) in the urine per day primarily because of glomerular injury with increased capillary permeability and loss of membrane negative charge.
7. Nephritic syndrome is characterized by hematuria and red blood cell casts with less severe proteinuria.
8. The manifestations of both nephrotic and nephritic syndrome include edema, hypoproteinemia, proteinuria, hyperlipidemia, lipiduria, vitamin D deficiency, and hypothyroidism.

Acute Kidney Injury

1. AKI is a sudden decline in kidney function with a decrease in GFR and urine output and with an elevation in plasma creatinine and BUN levels.
2. Prerenal AKI is caused by decreased renal perfusion with ischemia, decreased GFR, and tubular necrosis.

3. Intrarenal AKI is associated with several systemic diseases but is commonly related to acute tubular necrosis.
4. Postrenal kidney injury is associated with diseases that obstruct the flow of urine from the kidneys.
5. Oliguria is urine output that is less than 400 mL/24 h and can be caused by alterations in renal blood flow, tubular obstruction, or tubular fluid backleak, or by a combination of these events.

Chronic Kidney Disease

1. CKD is the progressive loss of renal function for 3 months or more, with implications for health. Plasma creatinine levels gradually become elevated as GFR declines; sodium is lost in the urine; potassium is retained; acidosis develops; calcium, phosphate, magnesium, and vitamin D metabolism are altered; and erythropoietin production is diminished. All organ systems are affected by CKD.
2. Symptomatic changes usually do not become evident until renal function declines to less than 25%.
3. Glomerular hypertension, hyperfiltration, and chronic inflammation, oxidative stress, and fibrosis contribute to the progression of CKD. Proteinuria and angiotensin II promote the pathologic changes of chronic renal injury.
4. Uremic syndrome is a proinflammatory state with the accumulation of urea and other nitrogenous compounds as well as toxins and alterations in fluid, electrolyte, and acid-base balance that result from chronic kidney failure.
5. All organ systems are affected and contribute to disease symptoms.

Emerging Science BoxRenin–Angiotensin–Aldosterone System Inhibitors in Patients With COVID-19

COVID-19, similar to other severe acute respiratory syndromes (SARS-CoV-1), is thought to interact with the RAAS through the angiotensin-converting enzyme 2 (ACE2). The RAAS coordinates key processes in human physiology to regulate blood pressure. The ACE2 functions as a receptor for SARS viruses and physiologically counters RAAS activation. To gain entry into the host cells, the viral surface spike (S) protein of SARS-CoV-2, the virus that causes COVID-19, binds to the ACE2 through the spike protein activation by transmembrane protease serine 2. This interaction is suggested as a potential associative factor of infectivity. However, there is currently conflicting evidence as to whether or not the use of angiotensin-receptor blockers (ARBs) and angiotensin-converting-enzyme (ACE) inhibitors may alter ACE2, which could drive disease virulence in the ongoing COVID-19 pandemic.

Emerging Science BoxBiomarkers for Acute Kidney Injury Risk Stratification

A novel approach to detecting acute kidney injury (AKI) early is using biomarkers. Most biomarkers are expressed prior to the rise in serum creatinine and are more sensitive and specific than urine output. Currently, biomarkers being investigated are cystatin C, chitinase-3-like protein-1 (UCHI3L1), neutrophil gelatinase-associated lipocalin (NGAL), interleukin-18 (IL-18), kidney injury molecule-1 (KIM-1), and interferon-gamma-inducible protein 10 (IP-10/CXCL-10). The biomarker with the highest sensitivity (92%) and specificity (100%) was IL-18. Second generation AKI biomarkers have obtained regulatory approval and are currently being studied in clinical trials. These markers include

tissue inhibitor of metalloproteinases-2 (TIMP-2) and insulin-like growth factor-binding protein 7 (IGFBP7). Higher levels of these markers are associated with adverse outcomes.

Urinary Incontinence 1281

Renal and urinary disorders occur in children as well as adults. The incidence and type of renal and urinary tract disorders experienced by children vary with age and maturation. Newborn disorders may involve congenital malformations. During childhood, the kidney and genitourinary structures are continuing to develop, so renal dysfunction may be associated with mechanisms and manifestations that are different from those in adults. In addition, some renal and urinary disorders are congenital and involve structural anomalies of the kidney and urinary drainage system.

Structure and Function of the Urinary System in Children

Development of the Urinary System

The embryonic urinary system develops as three sets of sequentially replaced organs: the pronephros, mesonephros, and metanephros. The **pronephros** is a nonfunctional structure that arises at the level of the cervical and upper thoracic regions during the third fetal week and connects the primitive mesonephritic duct (wolffian duct) to the cloaca. As the kidney develops, the cloaca degenerates by apoptosis and becomes part of the foundation for male sexual development. While the kidneys mature, the cloaca divides into two parts; one part becomes the rectum and the other part becomes the urogenital sinus. The urogenital sinus differentiates into the vesicourethral canal, which forms the bladder and the urethra. The development of the **mesonephros** and **metanephros** is described in Fig. 39.1. The Wilms tumor 1 *(WT1)* gene plays an important role at all stages of kidney development and maintenance of kidney function.

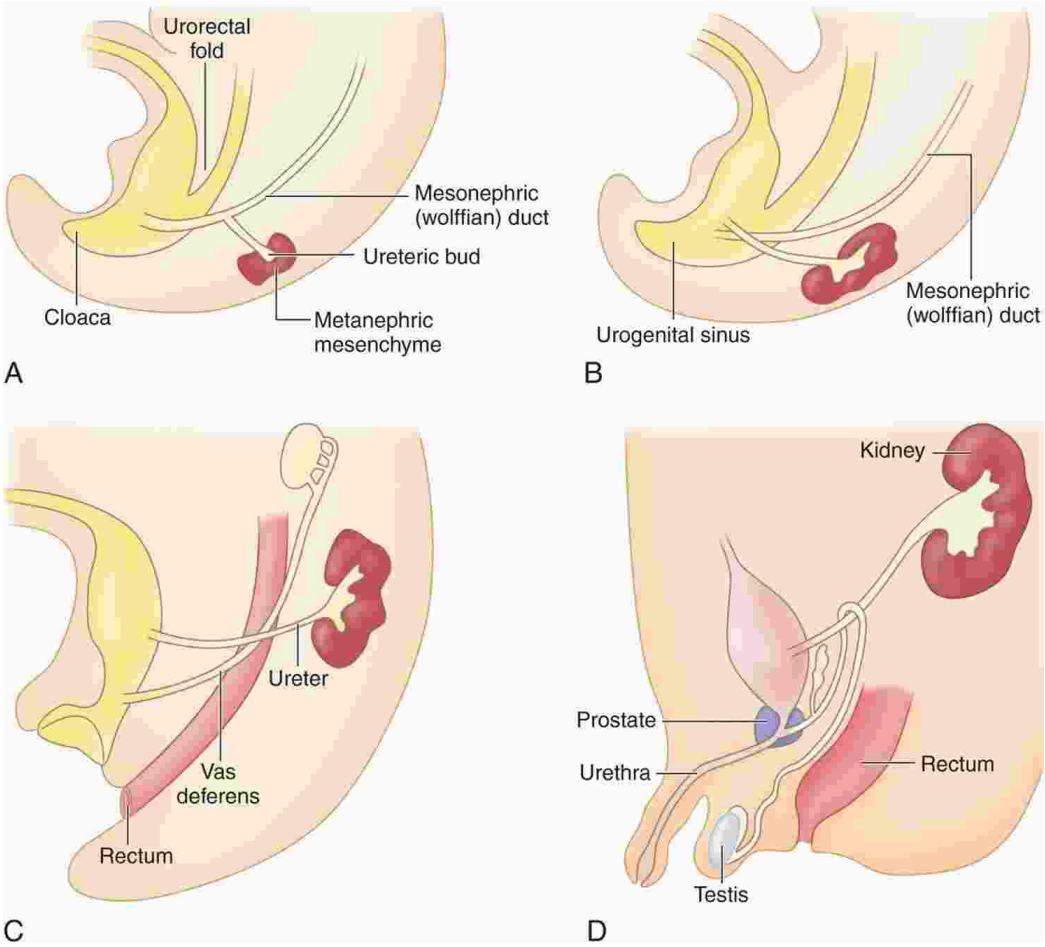

FIG. 39.1 Embryonic Development of the Kidneys.
(A) Pronephros, **(B)** mesonephros, **(C)** metanephros, and **(D)** fully developed embryonic kidney (From Goldman L, Schafer AI. *Goldman's Cecil medicine*, 24th edition. Philadelphia: Saunders; 2012.)

Four illustrations of lateral views of a developing embryo show the development of the kidneys. Top-left panel, A. The following structures are labeled on the illustration: urorectal fold, mesonephric (wolffian) duct, ureteric bud, metanephric mesenchyme, and cloaca. Top-right panel, B. The following structures are labeled on the illustration:

mesonephric (wolffian) duct. Bottom-left panel, C. The following structures are labeled on the illustration: ureter, vas deferens, and rectum. Bottom-right panel, D: The following structures are labeled on the illustration: kidney, prostate, urethra, rectum, and testis.

After glomeruli and tubules form, the tissues organize and progressively differentiate over approximately 30 days. Initial glomerular development is staggered, so there are glomeruli in various stages. A few of the first glomeruli that are formed degenerate and disappear during the later stages of fetal development. Progressive development continues into the ninth fetal month, when all metanephrogenic tissue disappears.

As the embryo develops and the vertebral column straightens, the kidneys appear to ascend to the sacral area at about 6 weeks, to the third lumbar area by the third month, and to the first lumbar area at term. The kidneys rotate 90 degrees as they ascend so that renal tissue is lateral and the collecting system is medial.

At birth, the kidneys occupy a large portion of the posterior abdominal wall, and the ureters are proportionately shorter than those of an adult. All the nephrons are present at birth, and their number does not increase as the kidney grows and matures. The kidney reaches adult size by adolescence and, because of maturation of the tubular system, increases in weight fivefold from the time of birth.

Urine formation and excretion begin by the third month of gestation, contributing to the amniotic fluid. In infancy the bladder lies close to the abdominal wall, making urinary bladder aspiration for diagnostic purposes a relatively simple procedure. The bladder descends into the pelvis with growth, changing from a cylindrical organ to the adult pyramidal shape. Although small amounts of

urine are found in the bladder at birth, the newborn may not void for 12 to 24 hours.

Immediately at birth the renal blood flow and glomerular filtration rate (GFR) increase because of a decrease in vascular resistance and the need to perform excretory functions no longer performed by the placenta. Renal vascular resistance remains higher in newborns and infants, which may be attributed to increased levels of circulating renin. The resistance progressively declines during the first year of development, with an increasing fraction of the cardiac output going to the kidney. The GFR continues to increase, achieving adult levels by 2 years of age.

Alterations in Renal and Bladder Function in Children

Congenital Abnormalities

Congenital abnormalities of the kidney and urinary tract (CAKUT) range from minor or easily correctable anomalies to those that are incompatible with life (Fig. 39.2). For example, the kidneys may fail to ascend from the pelvis to the abdomen, causing ectopic kidneys (abnormal location), which usually function normally. The lower poles of the kidneys may fuse as they ascend during fetal development, causing a single, U-shaped **horseshoe kidney**. Approximately one-third of individuals with horseshoe kidneys are asymptomatic, with the most common problems being infection, stone formation, hydronephrosis (from obstruction of urine flow), and rarely, renal malignancies.[1] Collectively, structural anomalies of the renal system account for approximately 40% to 50% of cases of renal failure in children in developed countries.[2] Many are linked to gene defects and may be associated with other structural malformations. (See Emerging Science Box: Promising Biomarkers to Predict Chronic Kidney Disease in Children With CAKUT.)

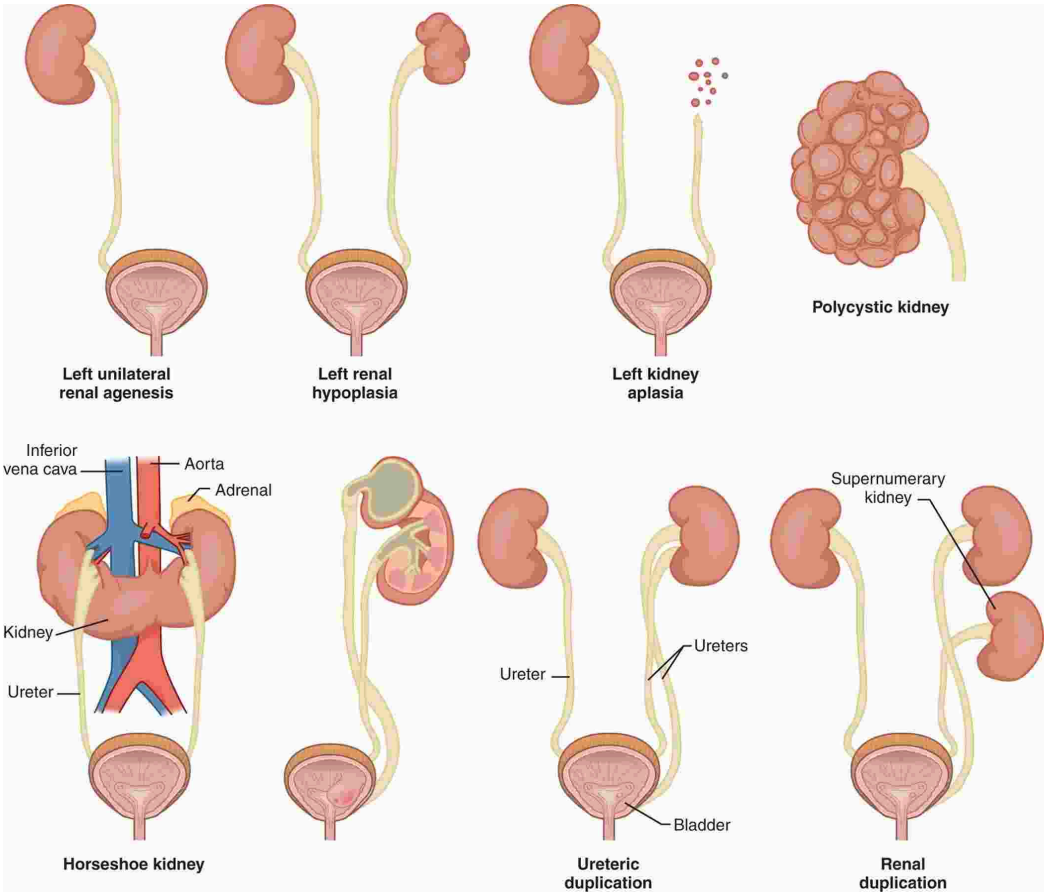

FIG. 39.2 Congenital Anomalies of the Kidney and Urinary Tract.

A series of the illustrations shows congenital anomalies of the kidney and urinary tract. • Left unilateral renal agenesis. The illustration shows a normal right kidney, the right ureter, and the bladder. • Left renal hypoplasia. The illustration shows a normal right kidney, the right ureter, the left ureter, and an atrophied right kidney. • Left kidney aplasia. The illustration shows a normal right kidney, the right ureter, an atrophied left ureter, and a disintegrated left kidney. • Polycystic kidney. The

illustration shows the right kidney covered in multiple tiny cysts. • Horseshoe kidney. The illustration shows a fused kidney, the inferior vena cava, aorta, adrenal, ureter, and bladder. • An illustration shows two left ureters, two atrophied kidneys, and the bladder. • Uretic duplication. The illustration shows a normal right kidney, the right ureter, the bladder, a normal left kidney, and two left ureters. • Renal duplication. The illustration shows a normal right kidney, the right ureter, the bladder, two left ureters, and two left kidneys, where the lower kidney is identified as the supernumerary kidney.

Some anomalies are obvious at birth, whereas others remain silent or become apparent in childhood. The following structural anomalies can be associated with urinary tract malformations:

- Low-set, malformed ears, sensorineural deafness
- Chromosomal disorders, especially trisomy 13 (Patau syndrome) and trisomy 18
- Absent abdominal muscles (prune-belly syndrome)
- Vertebral and extremity anomalies
- Imperforate anus
- Renal (nephroblastoma) and extrarenal tumors
- Ocular abnormalities (coloboma of the iris, congenital cataracts)
- Hepatic cysts or cirrhosis

Hypoplastic/Dysplastic Kidneys

During embryologic development, the ureteric duct grows into the metanephric tissue (see Fig. 39.1), triggering the formation

Emerging Science Box

Promising Biomarkers to Predict Chronic Kidney Disease in Children With Congenital Anomalies of Kidney and Urinary Tract

Children with congenital anomalies of kidney and urinary tract (CAKUT) have an increased risk of progressive kidney disease and developing chronic kidney disease (CKD) stage 5. There are emerging scientific studies on a promising, new peptide biomarker to predict functional deterioration on the kidneys.

Recent research studies revealed urinary trefoil family factors (TFFs) have a significant correlation with renal dysfunction in the pediatric population with CAKUT. TFF are a group of peptides, which include TFF_1, TFF_2, and TFF_3. These small peptides are mainly secreted in the mucous epithelia of the gastrointestinal system, respiratory system, urogenital system, and conjunctiva. TFFs are expressed in the entire urinary tract, with TTF_1 expression limited to the collecting ducts of medulla, and urothelium of the pelvis; TTF_2 expression within the bladder; and TTF3 has a pronounced expression in the cortex and medulla of the kidneys. Previous research has indicated that TTF_3 aids in mucosal protection, wound healing, cell proliferation, and cell migration in vivo and in vitro. TTF_3 is released when there is damage or inflammation to the kidneys, and therefore, an increase of TTF_3 levels in the urine is considered to be part of the compensatory and regenerative capacity of the kidney.

Because of the emerging research, TTFs are proving to be an instrumental peptide in determining functional deterioration on the kidneys in children with CAKUT. TTF_3 has been validated as a

biomarker in a few studies with more to come. With the emergence of evidence, a urine TTF_3 should be included in the biomarker panel when assessing children with CAKUT for CKD.

Data from Anand S, et al. Urinary biomarkers as point-of-care tests for predicting progressive deterioration of kidney function in congenital anomalies of kidney and urinary tract: Trefoil family factors (TFFs) as the emerging biomarkers. *Pediatric Nephrology*, 2021;36:1465–1472. https://doi.org/10.1007/s00467-020-04841-8;

Stankovic A. Promising biomarkers in pediatric chronic kidney disease through the kaleidoscope of CAKUT background complexity. *Pediatric Nephrology*, 2021;36:1321–1325. https://doi.org/10.1007/s00467-020-04877-w.

of the kidneys.[3] If this growth does not occur, the kidney is absent—a condition called **renal aplasia**. A **hypoplastic kidney** is small with fewer nephrons. These conditions may be unilateral or bilateral. The occurrence may be incidental or familial. Bilateral hypoplastic kidneys are a common cause of chronic kidney disease (CKD) in children. Renal segmental hypoplasia (failure of parts of the renal cortex to develop)—the **Ask-Upmark kidney**—is a rare disorder and may be congenital or secondary to vesicoureteral reflux (VUR). Systemic hypertension is a common presentation.[4]

Renal dysplasia (abnormal development of renal tissue) usually results from abnormal differentiation of the renal tissues. For example, primitive glomeruli and tubules, cysts, and nonrenal tissue (such as cartilage) are found in the dysplastic kidney. Dysplasia may be secondary to antenatal obstruction of the urinary tract from ureteroceles (an outpouching of the ureter where it enters the bladder), posterior urethral valves (an obstructing membrane in the male urethra), or prune-belly syndrome (congenital absence of abdominal muscles).

Polycystic Kidney Disease

Polycystic kidney disease (PKD) is an inherited condition occurring in about 1 of 1000 live births in the United States.[5] PKD is associated with mutation of two genes: *PDK1* (autosomal dominant, chromosome 16) or *PDK2* (autosomal recessive, chromosome 4, more rare). Affected kidneys have multiple cysts that interfere with renal function. Autosomal dominant PKD (ADPKD) usually presents in late childhood or adulthood with the development of cysts. Defects in the formation of epithelial cells and their cilia result in cyst formation in all parts of the nephron. Cysts in other organs, including the liver, pancreas, and ovaries, may occur. Hypertension, aortic and intracranial aneurysms, and heart valve defects may develop. Autosomal recessive PKD (ARPKD) is often first suspected on a prenatal ultrasound. Epithelial hyperplasia and fluid secretion result in collecting duct cysts. Hepatic disease and hypertension typically accompany PKD. Renal dialysis is usually required during childhood or adolescence.

Renal Agenesis

Renal agenesis (the absence of one or both kidneys) may be unilateral or bilateral and may occur randomly or be hereditary. It may be an isolated entity or associated with anomalies in other organs.

Unilateral renal agenesis (congenital solitary functioning kidney) occurs in about 1 in 1000 live births in the United States. Males are more often affected, and it is usually the left kidney that is absent. The single remaining kidney is often completely normal so that the child can expect a normal healthy life. By the time the child is several years old, the volume of this kidney may approach twice the normal size to compensate for the absence of a second kidney. In some instances, the single kidney is abnormally formed and associated with abnormalities of its collecting system. Because the child has fewer nephrons, there is a risk of glomerular hyperfiltration injury, increasing the chance of developing proteinuria, hypertension, and CKD.[6] Extrarenal congenital abnormalities of the urogenital, skeletal, cardiac, and other systems may coexist.

Bilateral renal agenesis (also called **Potter syndrome**) is a rare disorder incompatible with extrauterine life. Approximately 75% of affected newborns are males. The term **Potter syndrome** refers to the association of a specific group of facial anomalies (wide-set eyes, parrot-beak nose, low-set ears, and receding chin). Bilateral renal agenesis results from either an abnormal development of the normal progression from pronephros to mesonephros to metanephros or an isolated bilateral failure of development of the ureteral buds from lack of growth factors. **Oligohydramnios** (low amount of amniotic fluid) resulting from inadequate fetal urine production leads to underdeveloped lungs. Infants with this condition rarely live more than 24 hours because of pulmonary insufficiency. Approximately 40% of affected infants are stillborn. Renal agenesis can be detected prenatally by ultrasound.

Ureteropelvic Junction Obstruction

Ureteropelvic junction (UPJ) obstruction is a partial or total blockage of the section where the renal pelvis transitions into the ureter. UPJ obstruction is the most common cause of hydronephrosis (distention of the renal pelvis and calyces with urine) in neonates. An intrinsic malformation of smooth muscle or urothelial development produces an obstruction in most cases. Extrinsic compression abnormalities are less common. **Secondary ureteropelvic junction (UPJ) obstruction** may be caused by kinking or secondary scarring as a complication of surgical repair. Children with UPJ obstruction have an increased risk of VUR. Diagnosis of a UPJ obstruction can be made by ultrasound. Obstruction of the distal ureter **(ureterovesical junction obstruction)** causes dilation of the entire ureter, renal pelvis, and calyceal system (megaureter). **Megaureter** can occur when a short acontractile segment of the ureter develops just above the ureterovesical junction or from ureteral reflux.[7] A **ureterocele** is a ballooning dilation of the ureter where it enters the bladder and impedes urine drainage. It often occurs when two ureters drain from one kidney instead of one ureter. The most commonly associated problems are hydronephrosis

and infection. Open or endoscopic surgery to relieve an obstruction is performed if there is decline of renal drainage or function.[8] There is controversy about the preoperative use of continuous antibiotic prophylaxis, as in many cases, it does not prevent infection. An individualized approach is taken until the obstruction is surgically corrected.[9]

Hypospadias

Hypospadias is a congenital condition in which the cardinal feature is an ectopic urethral opening anywhere on the glans, penile shaft, base of the penis, penoscrotal junction, or in the perineum. Commonly, the urethral meatus is on the ventral side or undersurface of the penis (Fig. 39.3).[10] This is the most common anomaly of the penis, with an estimated prevalence of 64.7 cases per 10,000 male live births in the United States.[11] Partial absence of the foreskin, inguinal hernia, and cryptorchidism (undescended testes; see Chapter 26) are associated with the anomaly. The cause of this condition is multifactorial and includes genetic, endocrine, and environmental factors; advanced maternal age; low birth weight; and prematurity.[12]**Chordee**, or **penile torsion**, may accompany cases of hypospadias. In chordee, a shortage of skin on the ventral surface causes the penis to bend or "bow ventrally" (Fig. 39.4). Penile torsion is rotation, usually in a counterclockwise direction, of the penile shaft.

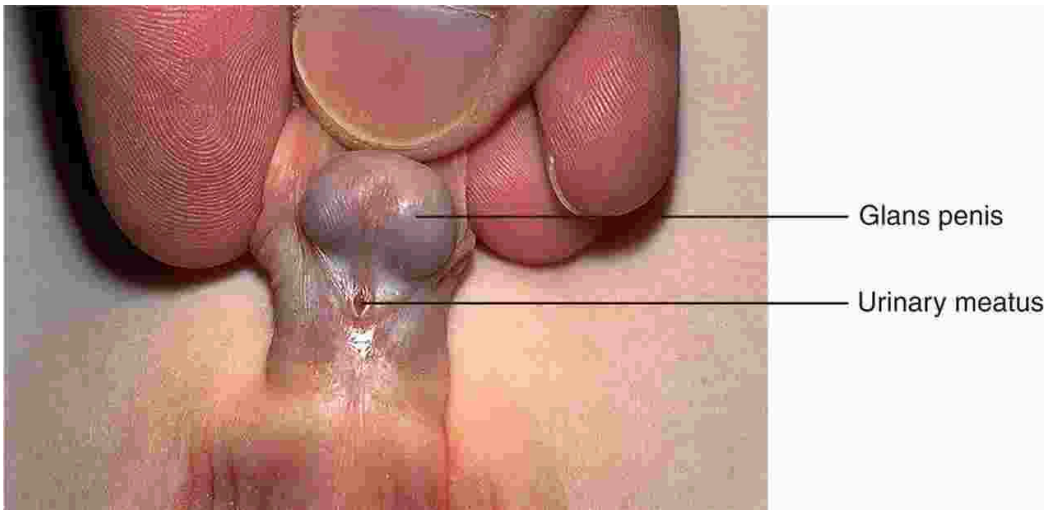

FIG. 39.3 Hypospadias. (Courtesy H. Gil Rushton MD, Children's National Medical Center, Washington, DC. From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

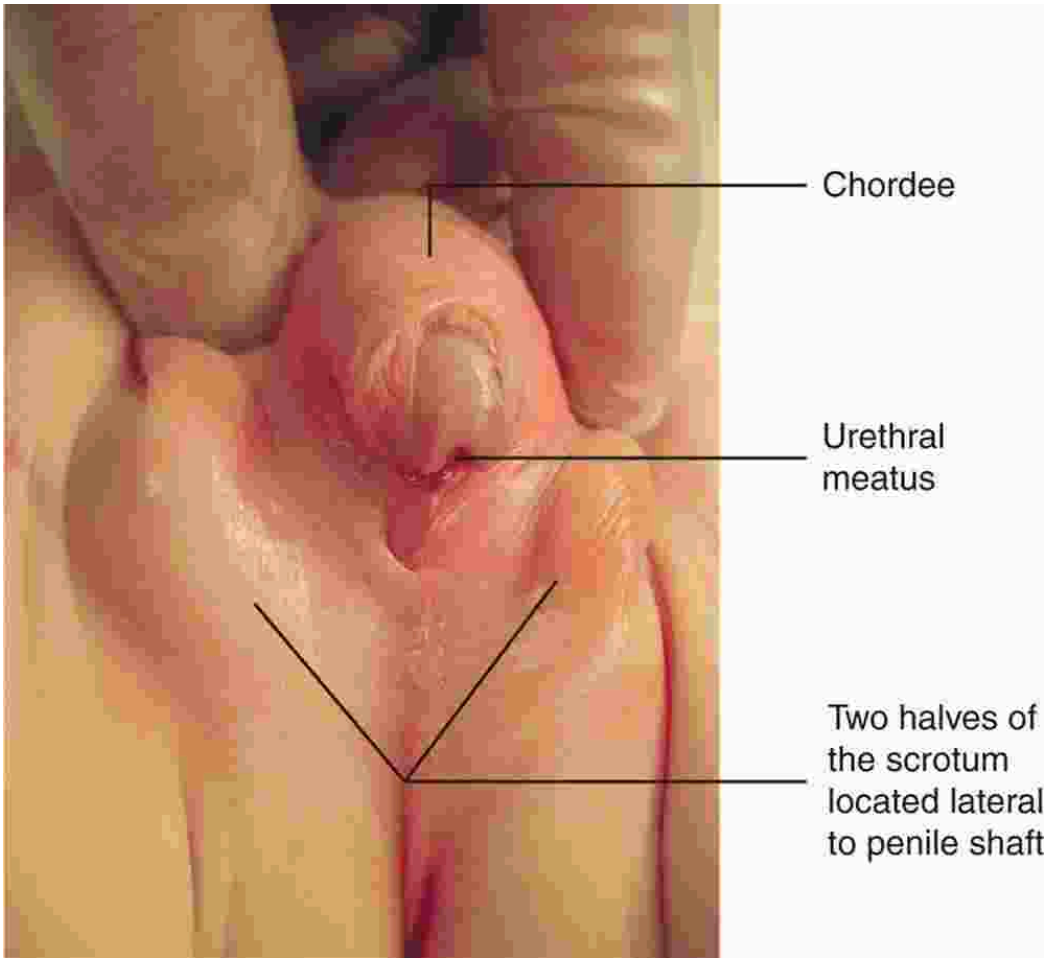

FIG. 39.4 Hypospadias With Significant Chordee.
(From Kliegman RM et al., eds. *Nelson textbook of pediatrics*, 19th edition. Philadelphia: Saunders; 2011.)

The goals for corrective surgery on a child with hypospadias are (1) a straight penis when erect to facilitate intercourse as an adult, (2) a uniform urethra of adequate caliber to prevent spraying during urination, (3) a cosmetic appearance satisfactory to the individual, and (4) repair completed in as few procedures as possible. Surgery is usually performed between 6 and 12 months of age.

Epispadias and Exstrophy of the Bladder

Epispadias and exstrophy of the bladder are the same congenital defect but expressed to a different degree. The dorsal urethra is not fused in epispadias and has failed to form a tube. In males, the

meatus may be small and situated behind the glans (glanular epispadias), a fissure may extend the entire length of the penis and into the bladder neck (penile epispadias), or the meatus is found near the pubic bone (penopubic epispadias). In females, a cleft along the ventral urethra usually extends to the bladder neck. The incidence of epispadias is about 1 per 117,000 births.[13] Continence is determined, in part, by the location of the defect. In children with distal epispadias, urinary incontinence rates can be up to 75%.[14] Treatment is surgical reconstruction.

Exstrophy of the bladder is a rare, extensive congenital anomaly of herniation of the bladder through the abdominal wall. The bony part of the pelvis remains open (Fig. 39.5). The posterior portion of the bladder mucosa is exposed through the abdominal opening and appears bright red. The incidence of bladder exstrophy in the United States is about 1.7 per 100,000 live births.[15]

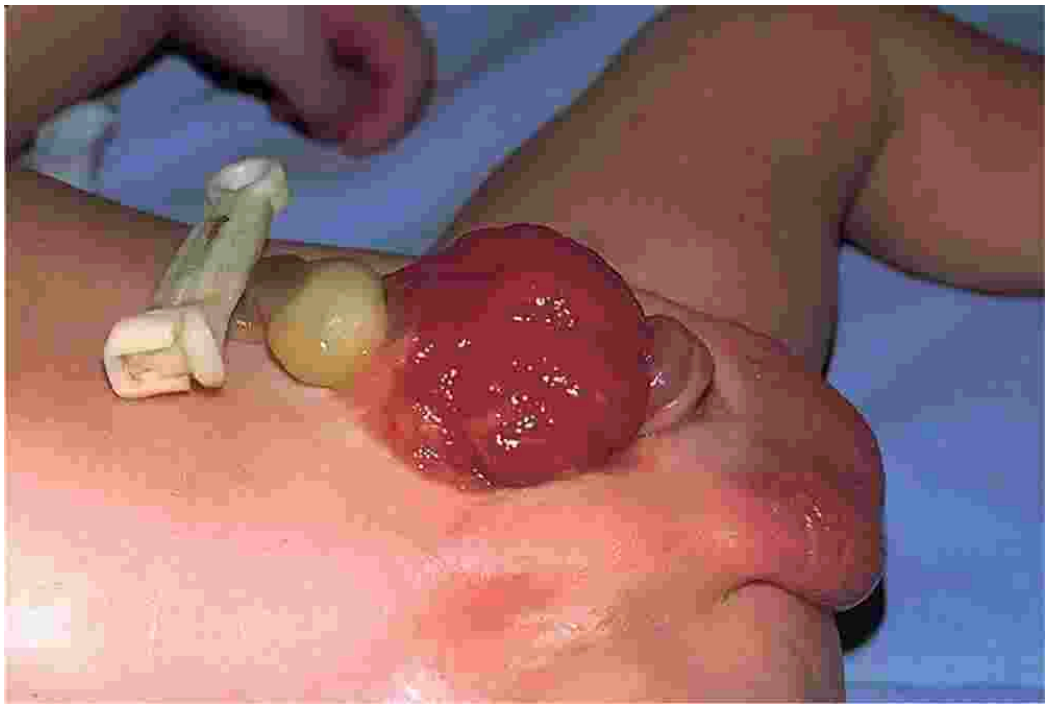

FIG. 39.5 Exstrophy of Bladder. (Courtesy H. Gil Rushton MD, Children's National Medical Center, Washington, DC. From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

Exstrophy of the bladder is caused by intrauterine failure of the abdominal muscles and the anterior bladder to fuse during embryonic development. The pubic rami (bony projections of the pubic bone) are not joined. This causes a waddling gait when the child first learns to walk, but most children quickly learn to compensate. The clitoris in girls is divided into two parts with the urethra between each half. The penis in boys is epispadias. Urine seeps onto the abdominal wall from the ureters, causing a constant odor of urine and excoriation of the surrounding skin. Because the exposed bladder mucosa becomes hyperemic and edematous, it bleeds easily and is painful.

The unrepaired exstrophic bladder is prone to cancerous changes as soon as 1 year after birth. Ideally, the bladder and pubic defect should be closed before the infant is 72 hours old. Surgical reconstruction is usually performed within the first year, either as a

complete primary repair or as staged procedures. Staged procedures may include bladder augmentation, bladder neck reconstruction, and epispadias repair.[16] Objectives of management include preservation of renal function, attainment of urinary control, prevention of infection, and improvement of sexual function. Diagnosis is often made by prenatal ultrasound.

Bladder Outlet Obstruction

Congenital causes of bladder outlet obstruction are rare and include urethral valves and polyps. A **urethral valve** is a thin membrane of tissue that occludes the urethral lumen and obstructs urinary outflow, usually in the posterior urethra in males. **Urethral polyps** are a benign fibroepithelial growth and are very rare in children. The timing and presentation of these conditions depend on the degree of obstruction they cause. Severe obstruction may impair renal embryogenesis and lead to renal failure. Congenital urethral valves or polyps can be diagnosed with prenatal ultrasound and treated with prenatal bladder shunting or with resection during the first days of life.

Glomerular Disorders

Glomerular disease or injury can result from genetic, immunologic, perfusion, or coagulation disorders. The most common glomerular disorders in children are glomerulonephritis, nephrotic syndrome, and hemolytic uremic syndrome (HUS). Most glomerular diseases are acquired and immunologically mediated. The disease can be acute or chronic. The likelihood of developing renal failure depends on the specific condition.

Glomerulonephritis

Acute glomerulonephritis includes several renal disorders in which inflammation of the glomeruli are secondary to an immune mechanism (Table 39.1) (other types of glomerulonephritis are

described in Chapter 38 and Table 38.5). Chronic glomerulonephritis accounts for about 8% of the cases of CKD in children in the United States and is the causative factor for 15% to 29% of end-stage renal disease (ESRD) in children worldwide.[17,18]

Table 39.1

Primary Glomerulonephritis in Children

Classification	Findings
Cause	Poststreptococcal infection Related to other bacterial or viral infection Unknown
Immunologic mechanism	Antigen-antibody complex deposition Planted antigens with immune complex formed in situ Formation of antiglomerular basement membrane antibodies (rare) No immunologic cause established
Histopathology	No lesion Diffuse, focal, or segmented Membranous, proliferative, or combination of types Lobular, exudative, necrotizing, and other types

Classification	Findings
	Chronic with glomerular proliferation
Clinical manifestations of disease	Acute glomerulonephritis Persistent (chronic) glomerulonephritis Idiopathic nephrotic syndrome

Classification	Findings
Cause	Poststreptococcal infection Related to other bacterial or viral infection Unknown
Immunologic mechanism	Antigen-antibody complex deposition Planted antigens with immune complex formed in situ Formation of antiglomerular basement membrane antibodies (rare) No immunologic cause established
Histopathology	No lesion Diffuse, focal, or segmented Membranous, proliferative, or combination of types Lobular, exudative, necrotizing, and other types Chronic with glomerular proliferation
Clinical manifestations of disease	Acute glomerulonephritis Persistent (chronic) glomerulonephritis Idiopathic nephrotic syndrome

Acute Poststreptococcal Glomerulonephritis

Acute poststreptococcal glomerulonephritis (PSGN) is caused by nephritogenic strains of *Streptococcus pyrogenes*, also called group A β-hemolytic Streptococcus (cause hemolysis on blood agar plates). PSGN is one of the most common immune complex–mediated renal diseases in children and a major cause of morbidity in group A β-hemolytic Streptococcal infections.[19] Glomerulonephritis develops with the deposition of antigen-antibody complexes or the formation of complexes in the glomerulus. The antigen-antibody complex activates complement and the release of inflammatory mediators

that recruit neutrophils and macrophages and damages endothelial and epithelial cells lying on the glomerular basement membrane. Damage to the glomerular basement membrane alters membrane permeability and leads to hematuria and proteinuria.

PSGN is most common in children ages 5 to 12 years and uncommon in children before the age of 3 years.[20] Symptoms usually begin 1 to 2 weeks after an infection, such as an upper respiratory tract infection (pharyngitis, more common during cold weather), and up to 6 weeks after a skin infection (impetigo, more common during warm weather). Differential diagnosis includes systemic lupus erythematosus, endocarditis, membranoproliferative glomerulonephritis, an acute exacerbation of chronic glomerulonephritis, and other causes associated with streptococcal or staphylococcal microorganisms, or after viral diseases, such as varicella-zoster and hepatitis B and C. Confirmation of PSGN from a positive throat culture or rising antibody titer to streptococcal antigen can provide evidence of prior streptococcal infection.[20]

The onset of symptoms is abrupt, varying with disease severity. The child typically has gross or microscopic hematuria, proteinuria, edema, and renal insufficiency. Oliguria may be present. Hypertension occurs because of increased vascular volume. Acute hypertension may cause headache, vomiting, somnolence, and other central nervous system (CNS) manifestations. Cardiovascular symptoms, such as dyspnea, tachypnea, and an enlarged tender liver are related to circulatory overload and are compounded by hypertension. The most severely affected children develop acute kidney injury with oliguria. As many as half of affected children are asymptomatic.

The disease usually runs its course in 1 month, but urine abnormalities may be found for up to 1 year or longer after the onset. Most children recover completely. Treatment is supportive and symptom-specific for the acute effects of renal dysfunction and hypertension. A 10-day course of systemic antibiotic therapy with penicillin is recommended to limit the spread of the nephritogenic

organisms; however, antibiotic therapy does not affect the natural history of PSGN.[20,21]

Immunoglobulin A Nephropathy

Immunoglobulin A (IgA) nephropathy is the most common form of glomerulonephritis in children worldwide and occurs more often in males. It is an autoimmune disease characterized by deposition primarily of secretory or mucosal IgA immune complexes with activation of complement proteins initiating an inflammatory response in the mesangium of the glomerulus.[22] Children with the disease have recurrent microscopic or gross hematuria concurrent with a respiratory tract infection (e.g., tonsillitis) or gastroenteritis. Most continue to have microscopic hematuria between the attacks of gross hematuria and have a mild proteinuria as well. Treatment is supportive. Some children recover completely, whereas 20% or more will eventually require dialysis and transplantation. IgA nephropathy may recur after transplantation.

Immunoglobulin A vasculitis (Henoch-Schönlein purpura nephritis) is a rare form of IgA nephropathy. It is the most common form of systemic vasculitis in children. Symptoms include palpable purpura (usually on the legs), arthralgia, abdominal pain, hematuria, and/or proteinuria. Complete recovery usually occurs, but some children progress to ESRD.[23]

Nephrotic Syndrome

Nephrotic syndrome is a group of symptoms characterized by severe proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The syndrome is more common in children than in adults. When no identifiable cause is found, the condition is called **primary (idiopathic) nephrotic syndrome** (Fig. 39.6). If it results from a systemic disease or other causes (e.g., systemic lupus erythematosus, IgA vasculitis, malignancy [lymphoma and leukemia], and infections [hepatitis, HIV, and malaria]), it is called secondary nephrotic syndrome. Primary nephrotic syndrome is found predominantly in

the preschool-age child, with a peak incidence of onset between ages 2 and 3 years. It is rare after age 6 years. Males are affected more often than females. No prevalent racial or geographic distributions are evident. The incidence is approximately 1 to 3 per 100,000 children younger than 16 years of age per year.[20]

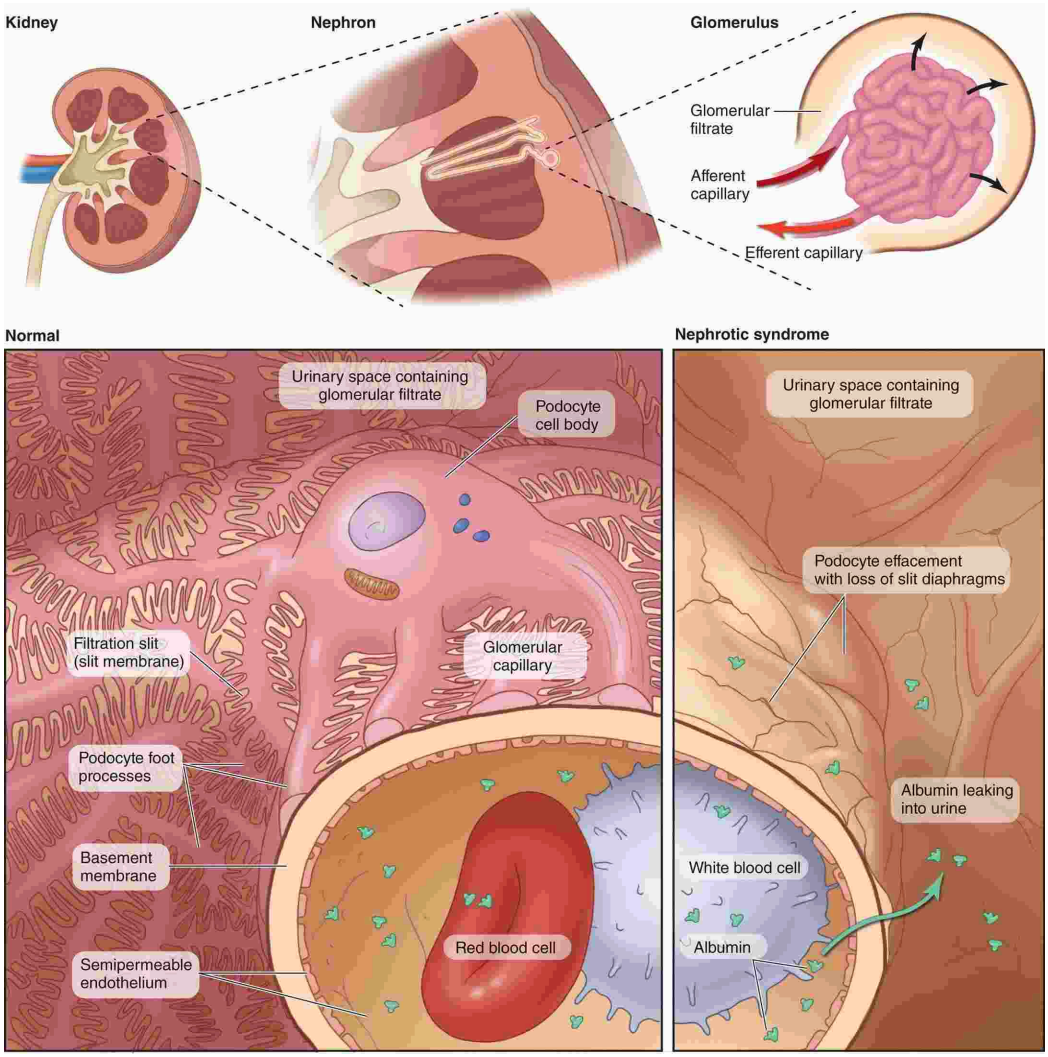

FIG. 39.6 Primary Nephrotic Syndrome.
The Glomerulus and Pathogenesis of Idiopathic Nephrotic Syndrome. Within the kidney the glomerular capillary filters blood from the systemic circulation. The podocyte, glomerular basement membrane and semipermeable glomerular endothelium comprise the glomerular filtration barrier allowing the ultrafiltrate to enter the urinary space. The podocyte has extensive cellular extensions (foot processes) that interdigitate and are connected by slit membranes. In nephrotic syndrome, there is extensive effacement (thinning and shortening) of

the podocytes with loss of their negative charge and loss of slit diaphragms (cell junctions between podocytes), allowing excessive serum albumin to leak into the urine causing proteinuria. The pathogenesis of idiopathic nephrotic syndrome is hypothesized to be either immune-mediated or a genetic variation in glomerular capillary structure. Numerous mutations are associated with steroid-resistant form of nephrotic syndrome that affect various parts of the podocyte itself, or other constituent proteins of the glomerular basement membrane. (Reprinted with permission from Elsevier (From Noone DG, Iijima K, Parekh R. Idiopathic nephrotic syndrome in children. *The Lancet* 2018;392(10141):61–74. https://doi.org/10.1016/s0140-6736(18)30536-1)

Top panel. An illustration shows kidney, nephron, and glomerulus. The following structures of the glomerulus are labeled: glomerular filtrate, afferent capillary, and efferent capillary. Bottom-left panel. An illustration shows urinary space containing glomerular filtrate. The following structures are labeled: red blood cell, podocyte cell body, urinary space containing glomerular filtrate, filtration slit (slit membrane), podocyte foot processes, basement membrane, and semipermeable endothelium. Bottom-left panel. An illustration shows urinary space containing glomerular filtrate. The following structures are labeled: urinary space containing glomerular filtrate, podocyte effacement with loss of

slit diaphragms, albumin leaking into urine, white blood cell, and albumin.

Pathophysiology

Nephrotic syndrome is caused by increased permeability of the glomerular capillary wall, which leads to massive proteinuria and hypoalbuminemia. The most common causes of primary nephrotic syndrome in children are minimal change nephropathy (MCN) and focal segmental glomerulosclerosis (FSGS).[24]**Minimal change nephropathy (MCN, lipoid nephrosis)** is associated with an alteration in immune function and is characterized by fusion of the glomerular podocyte foot processes, which are seen by electron microscopy. The glomeruli appear normal by light microscopy. This leads to a decrease in number of functional podocytes and altered glomerular membrane integrity. The result is increased protein leakiness across the glomerular capillary wall into the urinary space. Loss of the electrical negative charge and increased permeability within the glomerular capillary wall lead to albuminuria. Hypoalbuminemia (causing decreased plasma oncotic pressure) and sodium retention contribute to edema. Hyperlipidemia leads to lipiduria (lipoprotein fat bodies in the urine) and primarily results from increased hepatic lipid synthesis and decreased plasma lipid catabolism in response to a decrease in plasma oncotic pressure.[25]

In idiopathic **focal segmental glomerulosclerosis (FSGS)**, there is both focal (some glomeruli) and segmental (parts of glomeruli) scarring. Electron microscopy reveals segmental scarring of the glomerular tuft with loss of glomerular capillaries along with podocyte injury.[26]

Clinical Manifestations

Onset of nephrotic syndrome is often insidious, with periorbital edema as the first sign. The edema is most noticeable in the morning and subsides during the day as fluid shifts to the abdomen, genitalia,

and lower extremities. Parents may notice diminished, frothy, or foamy urine output or, when edema becomes pronounced with ascites, respiratory difficulty from pleural effusion or labial or scrotal swelling (Fig. 39.7). Edema of the intestinal mucosa may cause diarrhea, anorexia, and poor absorption. Edema often masks the malnutrition caused by malabsorption and protein loss. Pallor, with shiny skin and prominent veins, also is common. Blood pressure is usually normal. Children with nephrotic syndrome are more susceptible to infections such as cellulitis, spontaneous bacterial peritonitis, and bacteremia. This occurs partially as a result of the urinary losses of immunoglobulin G causing hypoglobulinemia.[20] Irritability, fatigue, and lethargy are common. **Congenital nephrotic syndrome (Finnish type)** is caused by an autosomal recessive mutation of the *NPHS1* gene. *NPHS1* normally encodes an immunoglobulin-like protein, nephrin, at the podocyte filtration membrane. Lack of nephrin alters membrane permeability and causes heavy proteinuria, hypoproteinemia, and edema in the first 3 months of life. These babies do not respond to steroid treatment (termed steroid resistance) and require albumin infusion and diuretics to manage their fluid balance.

Evaluation and Treatment

The diagnosis of nephrotic syndrome is evident from urinalysis findings of proteinuria, hematuria, and lipiduria; hematologic evidence of hyperlipidemia and hypoalbuminemia; and assessment of edema. Diagnostic testing, including kidney biopsy, may be required to determine whether the cause is an intrinsic renal disease or a consequence of systemic disease. Basic management of nephrotic syndrome includes administering corticosteroids (prednisone) (Table 39.2); adhering to a low sodium (<1500 mg/day), well-balanced diet; performing good skin care; and, if edema becomes problematic, prescribing diuretics (furosemide, metolazone).[27] Immunosuppressive agents (i.e., cyclophosphamide) may be used with children who have frequent relapses or who develop steroid toxicity or are resistant to steroid therapy (steroid-resistant nephrotic syndrome) which is more common with FSGS.[28]

Long-term outcomes depend on the underlying cause of the nephrotic syndrome. Children with minimal change disease tend to do very well, whereas those with FSGS may develop ESRD.

Table 39.2

Corticosteroid Response in Children With Nephrotic Syndrome

Response to Corticosteroid	Outcomes
Steroid sensitive	May have just one or recurrent episodes.
Steroid dependent or frequently relapsing	May require low-dose prednisone or treatment with other immunosuppressive agents to prevent recurrence
Steroid resistant	Treatment with immunosuppressive and nonimmunosuppressive medications; risk for development of end-stage kidney disease

Interventions for idiopathic steroid-resistant nephrotic syndrome in children. *Cochrane Database Systems Review*, 2016;10:CD003594; Larkins N, Kim S, Craig J, et al. Steroid-sensitive nephrotic syndrome: An evidence-based update of immunosuppressive treatment in children. *Archives of Disease in Childhood*, 2016;101(4):404–408.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is an acute disorder characterized by hemolytic anemia, thrombocytopenia (a decrease in blood platelets), and acute renal failure. HUS is a thrombotic microangiopathy and the most common cause of community acquired acute kidney injury in children. The disease occurs most

often in infants and children younger than 4 years of age but has been known to occur in adolescents and adults.

Pathophysiology

HUS has been associated with bacterial and viral agents, as well as endotoxins, such as Shiga toxin-producing *Escherichia coli* (known as D^+,STEC-HUS, or diarrhea associated HUS). Potential sources of exposure include animals, unpasteurized beverages, undercooked meat, and vegetables. Genetic forms of HUS (nondiarrhea, or atypical) are rare and known as D^- disease. It is caused by other microorganisms or by an inherited abnormality in complement alternate pathway regulation (e.g., von Willebrand factor–cleaving protease).[29] A major characteristic of genetic or alternative forms of HUS is the absence of prodromal diarrhea, thus the designation D^-.

In HUS D^+ (with diarrhea), toxins are absorbed from the intestine into the blood and bind to white blood cells, which are transported to the kidney. In the kidney, white blood cells cause damage to the glomerular endothelium with activation of the coagulation cascade and aggregation of platelets. The glomerular arterioles become swollen and occluded with platelets and fibrin clots. There is decreased glomerular filtration, and the damaged glomerular membrane results in hematuria and proteinuria. Narrowed glomerular vessels damage passing erythrocytes and platelets. These damaged red blood cells and platelets are removed by the spleen, causing acute hemolytic anemia and thrombocytopenia. Fibrinolysis, the process of dissolution of a clot, acts on precipitated fibrin, causing the fibrin split products to appear in serum and urine. Varying degrees of renal vascular occlusion cause altered renal perfusion and renal insufficiency or failure.[30]

Clinical Manifestations

HUS is characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency. A prodromal gastrointestinal illness (diarrhea with or without vomiting) or, less frequently, an upper respiratory tract infection often precedes the

onset by 1 to 2 weeks. After a symptom-free 1- to 5-day period, there is sudden onset of pallor, bruising or purpura, irritability, weakness, and oliguria. Slight fever, anorexia, vomiting, diarrhea (with the stool characteristically watery and blood stained), abdominal pain, mild jaundice, and circulatory overload are accompanying symptoms. Seizures and lethargy indicate CNS involvement. In severe cases, renal failure is apparent within the first days of onset. The renal failure causes metabolic acidosis, azotemia (accumulated nitrogenous wastes in the blood), hyperkalemia, and often hypertension.

Evaluation and Treatment

Clinical evaluation includes history of preexisting illness, presenting symptoms, and urine and blood analysis. Management is supportive with fluid and electrolyte management. Blood transfusions with packed red cells may be needed to maintain reasonable hemoglobin levels. Eculizumab, a complement inhibitor, has provided effective treatment for atypical or D^- HUS.[30] Most children recover completely. Potential long-term sequelae include renal (hypertension, proteinuria, CKD, and ESRD) and nonrenal abnormalities (diabetes mellitus, neurologic manifestations). Up to half of patients may require dialysis support during the acute phase of the disease.[20] The major causes of morbidity and mortality are due to extrarenal complications such as CNS involvement, infection, or myocardial causes.[31]

Nephroblastoma

Nephroblastoma (Wilms tumor) is a rare embryonal tumor of the kidney arising from undifferentiated mesoderm. Approximately 650 children are diagnosed each year in the United States, and most are younger than 5 years of age. The peak incidence occurs between 2 and 3 years of age and is more common in girls than boys. Nephroblastoma is less common in Asian-American children.[32]

Pathophysiology

Nephroblastoma has both sporadic and inherited origins. The sporadic form occurs in children with no known genetic predisposition. Inherited cases, which are relatively rare, are transmitted in an autosomal dominant fashion. Syndromic and nonsyndromic causes of nephroblastoma have been linked to mutation of several tumor-suppressor genes (i.e., *WT1* and *WT2* mutations; these genes are important for development of the kidney).[33]

Some children who have nephroblastoma also have other congenital anomalies. The anomalies include aniridia (lack of an iris in the eye), hemihyperplasia (an asymmetry of the body), and genitourinary malformations (i.e., horseshoe kidneys, hypospadias, ureteral duplication, polycystic kidneys).

Clinical Manifestations

Most children with nephroblastoma present with an enlarging asymptomatic abdominal mass before the age of 5 years.[34] Many tumors are discovered by the child's parent, who feels or notices abdominal swelling, usually while dressing or bathing the child. The child appears healthy and thriving. Other presenting complaints include vague abdominal pain, hematuria, anemia, and fever. Hypertension may be present, often as a result of excessive renin secretion by the tumor.[35]

Nephroblastoma may occur in any part of the kidney and varies greatly in size at the time of diagnosis. Bilateral tumors are very rare. The tumor generally appears as a solitary mass surrounded by a smooth, fibrous external capsule and may contain cystic or hemorrhagic areas. A pseudocapsule generally separates the tumor from the renal parenchyma.

Evaluation and Treatment

On physical examination, the tumor feels firm, nontender, smooth, and is confined to one side of the abdomen. If the tumor is palpable

past the midline of the abdomen, it may be large or may be arising from a horseshoe or ectopic kidney.

Diagnosis is based on selected laboratory tests and surgical biopsy. Laboratory tests assist with differentiation of a nephroblastoma from a neuroblastoma (a mimicker of nephroblastoma).

Diagnostic imaging demonstrates a solid intrarenal mass and can identify the presence or absence of metastasis. The most common sites of metastasis are regional lymph nodes and the lungs, and less commonly the liver, brain, and bone. Several staging systems for nephroblastoma have been developed and serve as guides to treatment. The most widely accepted system has been developed by the Children's Oncology Group (Table 39.3). Primary treatment is usually surgical exploration and resection, including nephron sparing surgery or chemotherapy, and then surgical resection depending on stage of disease and treatment guidelines.[36] Because of the long-term side effects of radiation therapy, it is primarily used for children with higher stages of disease, recurrent disease, and metastases. In these cases, radiation therapy may be combined with chemotherapy therapy and hematopoietic stem cell transplantation. Survival is greater than 90% for localized disease and more than 70% for higher stages. Heart failure, renal failure, (see Table 39.3) and hypertension occur more frequently in long-term survivors than in the general population.[37]

Table 39.3

Staging and Survival Rates for Nephroblastoma (Wilms Tumor)

Stage	Tumor Characteristics	4 Year Survival Rates for Favorable Histology Focal Anaplastic Diffuse Anaplastic
I	Tumor limited to one kidney; renal capsule intact; cancer not spread into blood vessels or other kidney; completely resected with no biopsy	95%–100% 85%–90% 75%–80%
II	Tumor involves perirenal fat, lymphatic vessels outside kidney, or infiltrates adjacent organs; completely resected with no biopsy	95%–100% 80%–85% 80%–85%
III	Residual nonhematogenous tumor confined to abdomen and involved regional lymph nodes; biopsy before removal of kidney.	95%–100% 75%–90% 50%–70%

IV	Hematogenous metastases to organs such as lungs, liver, bone, brain, or lymph nodes away from the kidneys	85%–90% 70%–75% 30%–45%
V	Bilateral kidney tumors disease either at diagnosis or later, then staged for each kidney	95%–100% 95%–100% 65%–70%

Stage	Tumor Characteristics	4 Year Survival Rates for Favorable Histology Focal Anaplastic Diffuse Anaplastic
I	Tumor limited to one kidney; renal capsule intact; cancer not spread into blood vessels or other kidney; completely resected with no biopsy	95%–100% 85%–90% 75%–80%
II	Tumor involves perirenal fat, lymphatic vessels outside kidney, or infiltrates adjacent organs; completely resected with no biopsy	95%–100% 80%–85% 80%–85%
III	Residual nonhematogenous tumor confined to abdomen and involved regional lymph nodes; biopsy before removal of kidney.	95%–100% 75%–90% 50%–70%
IV	Hematogenous metastases to organs such as lungs, liver, bone, brain, or lymph nodes away from the kidneys	85%–90% 70%–75% 30%–45%
V	Bilateral kidney tumors disease either at diagnosis or later, then staged for each kidney	95%–100% 95%–100% 65%–70%

Bladder Disorders

Urinary Tract Infections

Urinary tract infections (UTIs) are one of the most common bacterial infections in childhood. UTIs are caused by colonization of a pathogen anywhere along the urinary tract (urethra, bladder, ureter, kidney) and occurs equally in males and females during the first year of life, with incidence in females increasing after age 1 year. During the neonatal period, children with congenital renal abnormalities and noncircumcised males are at increased risk; whereas in adolescence, sexually active females are at increased risk as a result of perineal bacteria, especially *E. coli*, ascending the urethra. An abnormal urinary tract (presence of reflux, obstruction, stasis, or stones) is a risk factor for infection.

Cystitis, or infection of the bladder, results in mucosal inflammation and congestion. This causes detrusor muscle hyperactivity resulting in dysuria, urinary urgency, frequency, and a decrease in bladder capacity.[38] It may also cause distortion of the ureterovesical junction (UVJ), leading to transient reflux of infected urine up the ureters, causing acute or chronic pyelonephritis.

Symptoms in children are nonspecific, and differentiating whether an infection is in the bladder or in the kidneys (pyelonephritis) is difficult based on symptoms alone. Infants may be asymptomatic or develop fever, lethargy, abdominal pain, vomiting, diarrhea, or asymptomatic jaundice. Children may present with fever of undetermined origin, frequency, urgency, dysuria, enuresis or incontinence in a previously dry child, flank or back pain, and sometimes hematuria. **Acute pyelonephritis**, an infection in the kidney, usually causes chills, high fever, and flank or abdominal pain, along with enlarged kidney(s) caused by inflammatory edema.[38]**Chronic pyelonephritis** may be asymptomatic.

Diagnosis of UTI is by urine culture which should be obtained prior to the initiation of antibiotic therapy. Dipstick urinalysis may be used as a screening tool and may reveal nitrites, leukocyte esterase, and blood which are used to support the diagnosis. Leukocyturia, regarded by the American Association of Pediatrics as a prerequisite to making the diagnosis, is found in most children with a UTI, but not found in all, hence the reasoning for obtaining a urine culture.[38,39] Diagnostic imaging (e.g., ultrasound, computed tomography [CT], and cystogram) and laboratory tests, in particular inflammatory markers (C-reactive protein and procalcitonin), may be necessary to rule out obstructions, infectious processes, renal scarring, or functional abnormalities.[38]

Treatment of UTI is based on presenting symptoms, the child's previous medical history, and local resistance patterns of uropathogens.[38] Children with acute cystitis are treated with a less broad-spectrum antibiotic (i.e., nitrofurantoin or trimethoprim) for a short duration (1 to 3 days).[38] Previously healthy children, with a high suspicion of acute pyelonephritis without microbe identification, are prescribed treatment with broad-spectrum antibiotics. However, once the pathogen is identified, then the antimicrobial must be tailored to cover the offending organism. With treatment, symptoms are usually relieved in 1 to 2 days, and the urine becomes sterile. A 3-to-5-day course of oral antibiotics is effective for uncomplicated UTI and 7 to 14 days for complicated UTI.[40] Longer treatment may be required if the child has a history of recurrent UTIs, congenital abnormalities of the urinary tract, or upper UTI. If there is no improvement in 2 days, the child should be reevaluated.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder into the kidney or ureters, or both. Reflux allows infected urine from the bladder to reach the kidneys. VUR is usually present in children with CAKUT, specifically congenital renal dysplasia.[38]

VUR occurs more often in females and is uncommon in Black Americans. The actual incidence is unknown because VUR is often undiagnosed. An estimated 30% to 40% of children younger than 5 years who develop a UTI have VUR. Siblings of those affected have about a 27% to 51% chance of having reflux, and children with parents who had childhood reflux have almost a 70% chance of reflux.[41] Although reflux is considered abnormal at any age, the shortness of the submucosal tunnel of the ureter during infancy and childhood renders the antireflux mechanism relatively inefficient and delicate. Thus, reflux is seen commonly in association with infections during early childhood but rarely in older children and adults.

Pathophysiology

The normal distal ureter enters the bladder through the detrusor muscle and passes through a submucosal tunnel before opening into the bladder lumen via the ureteral orifice. As the bladder fills with urine, the ureter is compressed within the bladder wall, preventing reflux. *Primary reflux* results from a congenital, abnormally short submucosal tunnel and ureter that permits reflux by the rising pressure of the filling bladder (Fig. 39.8). Urine sweeps up into the ureter and then flows back into the empty bladder. The reflux perpetuates infection by preventing complete emptying of the bladder and providing a reservoir for infection. With bladder filling, the intravesical pressure can be transmitted up the ureter to the renal pelvis and calyces. The combination of reflux lower UTI is an important cause of pyelonephritis. Renal parenchymal injury, scarring, hypertension, and CKD can occur many years later, making early diagnosis and treatment important. *Secondary reflux* develops in association with acquired conditions (e.g., neurogenic bladder dysfunction, ureteral obstruction, voiding disorders, or surgery on the UVJ). Reflux may be unilateral or bilateral and is graded on a scale of I (mild) to V (severe) using the International Reflux Grading System with 95% of VUR in children ranging from grades I to III (Fig. 39.9).[38] The grades are as follows:

Grade I: reflux into a nondilated distal ureter
Grade II: reflux into the upper collecting system without dilation
Grade III: reflux into a dilated ureter or blunting of calyceal fornices
Grade IV: reflux into a grossly dilated ureter and calyces
Grade V: massive reflux with urethral dilation and tortuosity and effacement of the calyceal details

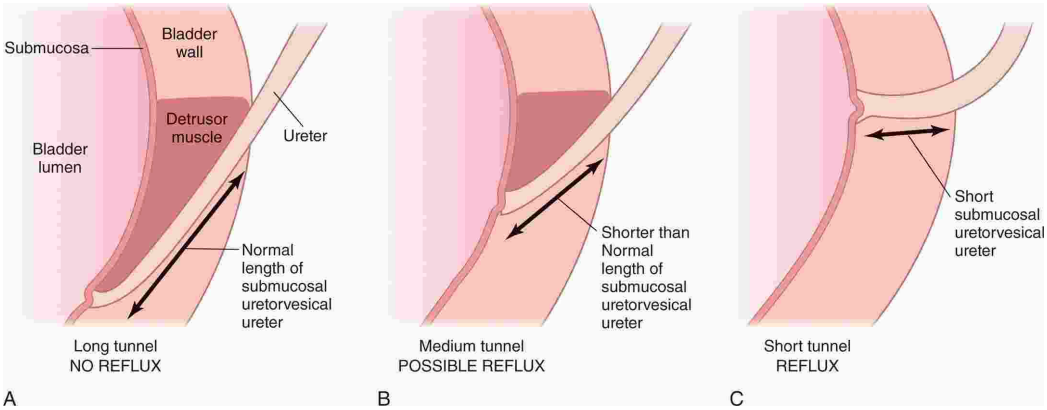

FIG. 39.8 Normal and Abnormal Configurations of the Ureterovesical Ureter. A refluxing ureterovesical ureter **(B)** and **(C)** has the same anatomic features as a nonrefluxing ureter **(A)**, except for the shorter length of the intravesical ureter, which allows reflux of urine during filling of the bladder. (Adapted from Liaw A, Cunha GR, Shen J, et al. Development of the human bladder and ureterovesical junction. *Differentiation*, 2018;103;66–73. https://doi.org/10.1016/j.diff.2018.08.004.)

Three illustrations show configurations of the ureterovesical ureter. The illustrations show a lateral view of the bladder wall, detrusor muscle, and ureter. The submucosa and bladder lumen are labeled. Left panel, A, long tunnel (no reflux). Normal length of submucosal uretorvesical ureter. Middle panel, B, medium tunnel (possible reflux). Shorter than normal length of submucosal uretorvesical ureter. Right panel, C, short tunnel (reflux). Short submucosal uretorvesical ureter.

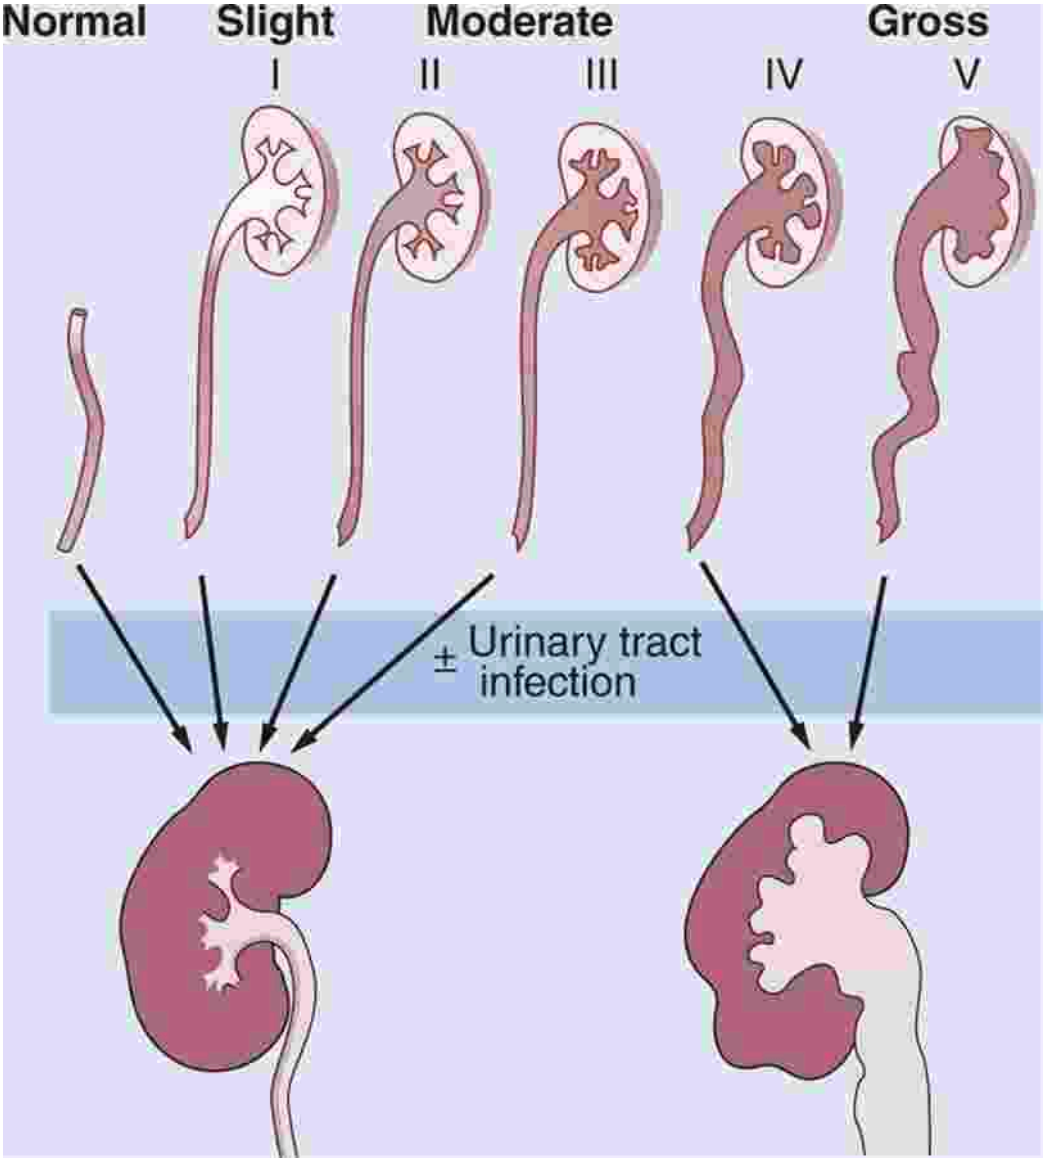

FIG. 39.9 Grades of Vesicoureteral Reflux.
(Adapted from Johnson JR, Feehally J, Floege J. *Comprehensive clinical nephrology*, 5th edition. Philadelphia: Saunders; 2015.)

An illustration shows grades of vesicoureteral reflex. Normal. The flow is highlighted halfway through the ureter. Slight 1. The flow is highlighted until the upper part of the ureter. Moderate 2. The flow is

highlighted up and into the kidney. Moderate 3. The flow is highlighted until the kidney with slight swelling. Normal, slight 1, moderate 2 and moderate 3 result in increase or decrease in urinary tract infection. Gross 4. The flow is highlighted up and into the kidney, with the ureter swollen. Gross 5. The flow is highlighted up and into the kidney, with the ureter swollen and the kidney full. Gross 4 and gross 5 result in increase or decrease in urinary tract infection.

Clinical Manifestations

Children with reflux may be asymptomatic or have recurrent UTIs, unexplained fevers, poor growth and development, irritability, and feeding problems. The family history may reveal VUR or UTIs.

Evaluation and Treatment

In addition to the history of recurrent UTI and other symptoms, a voiding cystourethrogram is the primary diagnostic procedure. While VUR spontaneously resolves in most children several years after detection, prompt treatment of UTIs in children with reflux is important to minimize the risk of pyelonephritis and renal scarring. Spontaneous remission of grades I, II, and III reflux may occur in 50% to 80% of children younger than 5 years of age. Approximately 20% of grades IV and V will resolve. Because of the spontaneous remission, treatment of children with VUR is controversial. There are three options are available: correcting the VUR with surgery, using long-term antimicrobial prophylaxis, or careful monitoring of the child. The goal is to prevent kidney infection and reduce scarring.[38,42]

Urinary Incontinence

Urinary incontinence refers to the involuntary passage of urine by a child, without underlying anatomical neurological abnormalities, who is beyond the age when voluntary bladder control should have been acquired. Bladder control is accomplished by most children before the age of 5 years, although this is largely influenced by cultural beliefs and parental toilet training practices. Wetness that occurs during the day is called **daytime incontinence**. Nighttime wetting is called **nocturnal enuresis**. **Functional incontinence** is urinary incontinence in which no structural or neurologic abnormality can be identified.

The incidence of incontinence is difficult to determine because it is not a problem parents often discuss. The incidence of enuresis in children older than 5 years ranges from 15% to 20%. Boys are more enuretic than girls by a ratio of 2:1. Enuresis resolves at a rate of 15% per year. Daytime incontinence occurs in approximately 9% of early school-age children.[43]

Pathophysiology

A combination of factors is likely to be responsible for incontinence. A reasonable approach is to eliminate organic or physiologic causes before exploring psychological ones. Organic causes account for a minority of cases and include UTIs; neurologic disturbances; congenital defects of the meatus, urethra, or bladder neck; and allergies. Disorders that increase the normal output of urine, such as diabetes mellitus and diabetes insipidus, or disorders that impair the concentrating ability of the kidney, such as CKD or sickle cell disease, must be considered during evaluation. Other conditions that may be associated with incontinence include perinatal anoxia, CNS trauma, seizures, attention-deficit/hyperactivity disorder, developmental delay, imperforate anus, bladder trauma or surgery, obesity, and occult spinal dysraphism. Altered sleep arousal or obstructive sleep apnea may be associated with enuresis. Stressful psychologic situations, such as a new sibling, may cause

incontinence or enuresis to develop. Constipation is frequently present in children with urinary incontinence.

Genetic factors contribute to some types of incontinence. At least four gene loci associated with enuresis have been identified. Urinary incontinence occurs with high frequency among parents, siblings, and other near relatives of symptomatic children. There is a high concordance rate in monozygotic twins with enuresis.[44]

Clinical Manifestations

Primary incontinence (enuresis) means the child has never been continent. **Secondary incontinence** (enuresis) means the child has been continent for at least 6 months before wetting recurs. A child may have daytime incontinence, enuresis, or a combination of both. Types of incontinence and clinical manifestations are defined in Table 39.4.

Table 39.4

Types of Incontinence

Type	Definition
Diurnal enuresis	Decreased: 3 or fewer voids per day
Daytime voiding frequency	Increased: 8 or more voids per day
Dysfunctional voiding	Habitual contraction of urethral sphincter during voiding; observed by uroflow measurements; normal micturition frequency, incontinence, urinary tract infections, enuresis
Nocturnal Enuresis	Incontinence of urine while sleeping
Incontinence, continuous	Continuous leakage, not in discrete portions
Incontinence, stress	Leakage with raised intra-abdominal pressure
Urgency	Sudden, unexpected, immediate need to void
Overactive bladder	Increased detrusor contractions; urinary urgency; increased micturition frequency; and/or incontinence may or may not be present
Underactive bladder	Decreased detrusor contractions; low micturition frequency; decreased micturition frequency with use of raised intra-abdominal pressure to void

Type	Definition
Urge incontinence	Incontinence in children with urgency

Type	Definition
Diurnal enuresis	Decreased: 3 or fewer voids per day

Daytime urinary incontinence in children and adolescents. *Lancet Child Adolescent Health*, 2019;3(7):492–501; Nevéus T, von Gontard A, Hoebeke P, et al. The standardization of terminology of lower urinary tract function in children and adolescents: Report from the Standardisation Committee of the International Children's Continence Society. *Journal of Urology*, 2006;176(1):314–324.

Evaluation and Treatment

Evaluation of incontinence includes assessment of associated conditions summarized above, use of questionnaires, drinking and voiding charts, physical examination, and urinalysis. Underlying pathology, including kidney disease, VUR, UTI, or neurogenic bladder, needs to be excluded. Radiologic and urodynamic evaluation may be required to identify anatomical abnormalities of the genitourinary tract.[38] While bladder dysfunction tends to spontaneously resolve over time, therapeutic management of

incontinence begins with education. If the child and family understand the probable etiology of the child's condition, they are better able to choose and participate in therapies that are most likely to succeed. Treatment of daytime incontinence includes behavioral therapy, including timed voiding; fluid management; treatment of constipation, UTI, and other coexisting conditions if present; and medication (e.g., desmopressin). Enuresis treatment also may include enuresis alarms.[45]

Summary Review

Structural Abnormalities

1. Congenital abnormalities of the kidney and urinary tract are related to gene alterations in about 50% of cases, range in severity from minor conditions that need no treatment to those incompatible with life, and often occur with other structural malformations.
2. A hypoplastic kidney is small, with a decreased number of nephrons. A dysplastic kidney is the result of abnormal differentiation of renal tissues.
3. Polycystic kidney disease is a cystic genetic disorder that can be autosomal dominant or autosomal recessive and results in multiple kidney cysts that interfere with renal function and cause hypertension.
4. Renal agenesis is the absence of one or both kidneys and may occur as an isolated entity or in association with other disorders.
5. Ureteropelvic junction obstruction is blockage where the renal pelvis joins the ureter or at the bladder neck or posterior urethra and is often caused by smooth muscle or urothelial malformation or by secondary scarring as a complication of corrective surgery. Complications include hydronephrosis and infection.

6. Hypospadias is a congenital anomaly in which the urethral meatus can be located anywhere on the ventral surface of the glans, the penile shaft, the midline of the scrotum, or the perineum.
7. Epispadias and exstrophy of the bladder are congenital malformations expressed to a different degree. Epispadias involves the dorsal urethra failing to form a tube. In exstrophy, the pubic bones are separated, and the posterior wall of the bladder is everted through the opening.
8. Urethral valves and polyps are congenital formations of tissue that block the urethra.

Glomerular Disorders

1. Glomerulonephritis is an inflammation of the glomeruli. The cause is unknown but is often immune mediated.
2. Acute poststreptococcal glomerulonephritis usually follows infection by nephritic strains of group A β-hemolytic streptococcus. Immune deposits or formation promote injury and increase glomerular capillary permeability leading to hematuria, proteinuria, edema, hypertension, and renal insufficiency.
3. Immunoglobulin A (IgA) nephropathy occurs with autoimmune deposition of IgA in the glomerulus, causing glomerular injury with gross hematuria. IgA vasculitis (Henoch-Schönlein purpura nephritis) is a particular form of IgA nephropathy that involves a systemic vasculitis.
4. Nephrotic syndrome is a group of symptoms characterized by severe proteinuria, hypoalbuminemia, hyperlipidemia, and edema. Metabolic, biochemical, or physiochemical disturbances in the glomerular basement membrane may lead to increased permeability to protein. Minimal change nephropathy and focal segmental glomerulosclerosis are the most common causes of nephrotic syndrome in children.

5. Hemolytic uremic syndrome is an acute thrombotic microangiopathy characterized by hemolytic anemia, thrombocytopenia, and may cause acute renal failure. Typical HUS is associated with bacterial and viral toxins, particularly Shiga toxin of *Escherichia coli* infection and diarrhea.

Nephroblastoma

1. Nephroblastoma (Wilms tumor) is an embryonal tumor of the kidney that usually presents as a solid, smooth abdominal mass between birth and 5 years of age. Survival is high after treatment by surgery, a combination of drugs, and, for advanced disease, combination chemotherapy, radiation therapy, and stem cell therapy.

Bladder Disorders

1. Urinary tract infections (UTIs) result from bacteria ascending the urethra and occur anywhere along the urinary tract. The bladder alone is infected in cystitis. The infection ascends to one or both kidneys in pyelonephritis.
2. Vesicoureteral reflux is the retrograde flow of bladder urine into the kidney or ureter, or both, increasing the risk for pyelonephritis. It can be unilateral or bilateral; primary or secondary.

Urinary Incontinence

1. Urinary incontinence is the involuntary passage of urine by a child beyond the age of 5 years when bladder control should have been acquired. It may occur during the day (daytime incontinence) or at night (nocturnal enuresis), or both.

Maturational delay, UTIs, constipation, and many other physiologic and emotional factors may contribute.

- Exocrine Pancreas 1313

The digestive system includes the gastrointestinal (GI) tract and accessory organs of digestion: the liver, gallbladder, and exocrine pancreas (Fig. 40.1). The GI system carries out at least four major functions: digestion of food, absorption of nutrients, secretion of hormones, and defense against pathogens. The digestive system breaks down ingested food, prepares it for uptake by the body's cells, absorbs fluid, and eliminates wastes. The GI tract and gut microbiome provide important immune and protective functions. Except for chewing, swallowing, and defecation of solid wastes, the movements of the digestive system (peristalsis) are all controlled by hormones and the autonomic nervous system (ANS).

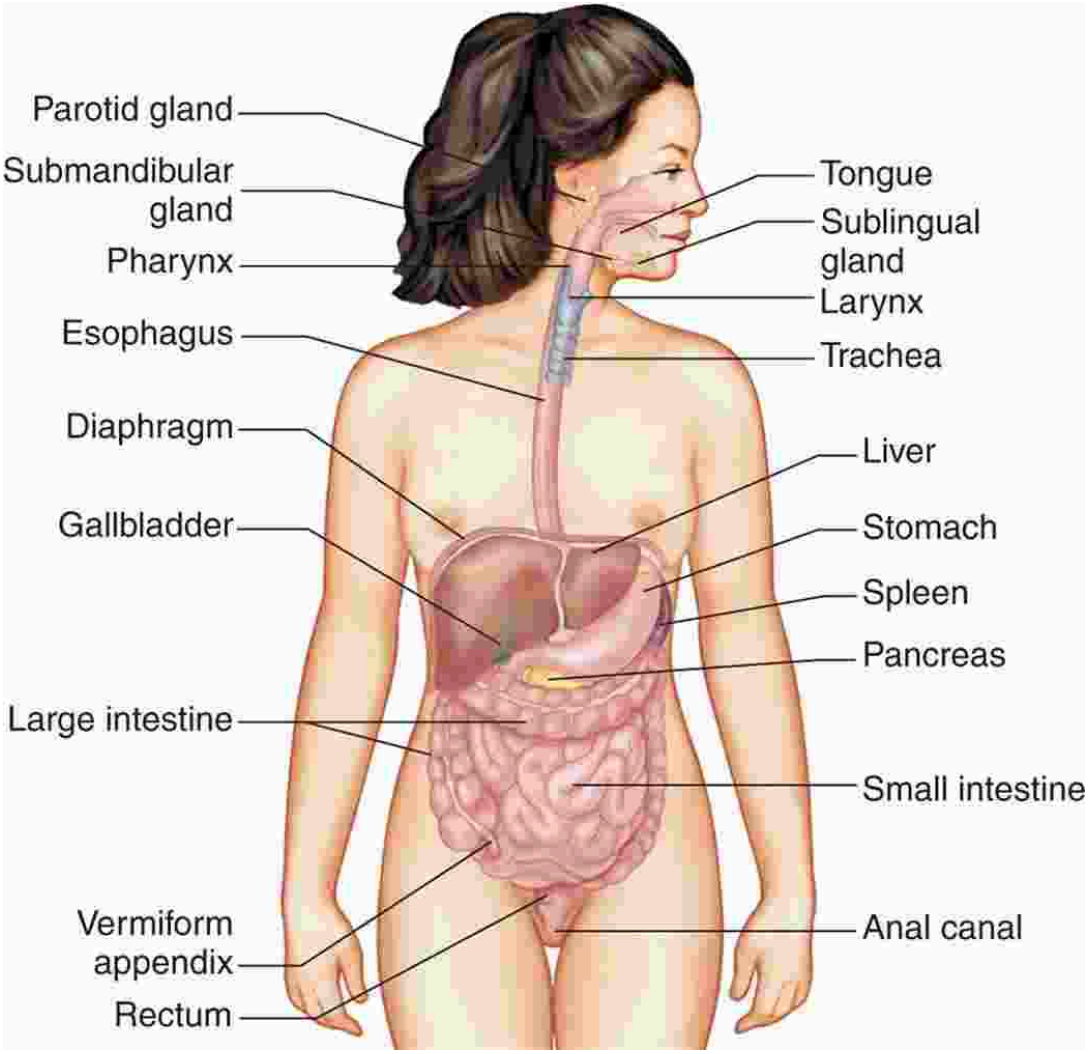

FIG. 40.1 Structures of the Digestive System. (From Patton KT, Thibodeau GA. *The Human Body in Health & Disease*. 7th ed. St Louis: Elsevier; 2018.)

An illustration depicts the organs of the human digestive system. The organs are labeled from top to bottom as follows: Parotid gland, tongue, sublingual gland, submandibular gland, pharynx, larynx, trachea, esophagus, diaphragm, liver, stomach, spleen, gallbladder, pancreas, large intestine, small intestine, vermiform appendix, rectum, and anal canal.

Food breakdown begins in the mouth with chewing and continues in the stomach, where food is mixed with acid, mucus, and enzymes. From the stomach, the fluid and partially digested food pass into the small intestine, where bile and enzymes secreted

by the intestinal cells, liver, gallbladder, and exocrine pancreas break it down into absorbable components of proteins, carbohydrates, and fats. These nutrients pass through the walls of the small intestine into underlying blood and lymphatic vessels, which carry them to the liver for storage or further processing. Ingested substances and secretions not absorbed in the small intestine pass into the large intestine, where fluid continues to be absorbed. Fluid wastes travel to the kidneys and are eliminated in the urine. Solid wastes pass into the rectum and are eliminated from the body through the anus.

The Gastrointestinal Tract

The **gastrointestinal tract (alimentary canal)** is a single, hollow tube that consists of the mouth, esophagus, stomach, small intestine, large intestine, rectum, and anus (see Fig. 40.1). It carries out these digestive processes:

1. Ingestion of food
2. Propulsion of food and wastes from the mouth to the anus
3. Secretion of mucus, water, and enzymes (Box 40.1)
4. Mechanical digestion of food particles
5. Chemical digestion of food particles
6. Absorption of digested food
7. Elimination of waste products by defecation
8. Immune and microbial protection against infection

- Dipeptidase

From Johnson LR. *Gastrointestinal Physiology*. 9th ed. St Louis: Mosby; 2019.

Histologically, the GI tract consists of four layers. From the inside out they are the mucosa, submucosa, muscularis, and serosa or adventitia (Fig. 40.2). These concentric layers vary in thickness, and each layer has sublayers. Neurons forming the **enteric nervous system** are located solely within the GI tract and are controlled by local and ANS stimuli. The enteric nervous system comprises three nerve plexuses located in different layers of the GI walls (see Fig. 40.2). The **submucosal (Meissner) plexus** is located in the muscularis mucosae, the **myenteric (Auerbach) plexus** is between the inner circular and outer longitudinal muscle layers in the muscularis, and the **subserosal plexus** is just beneath the serosa. The neurons from the entire **enteric (intramural) plexus** regulate motility reflexes, blood flow, absorption, secretions, and immune response.

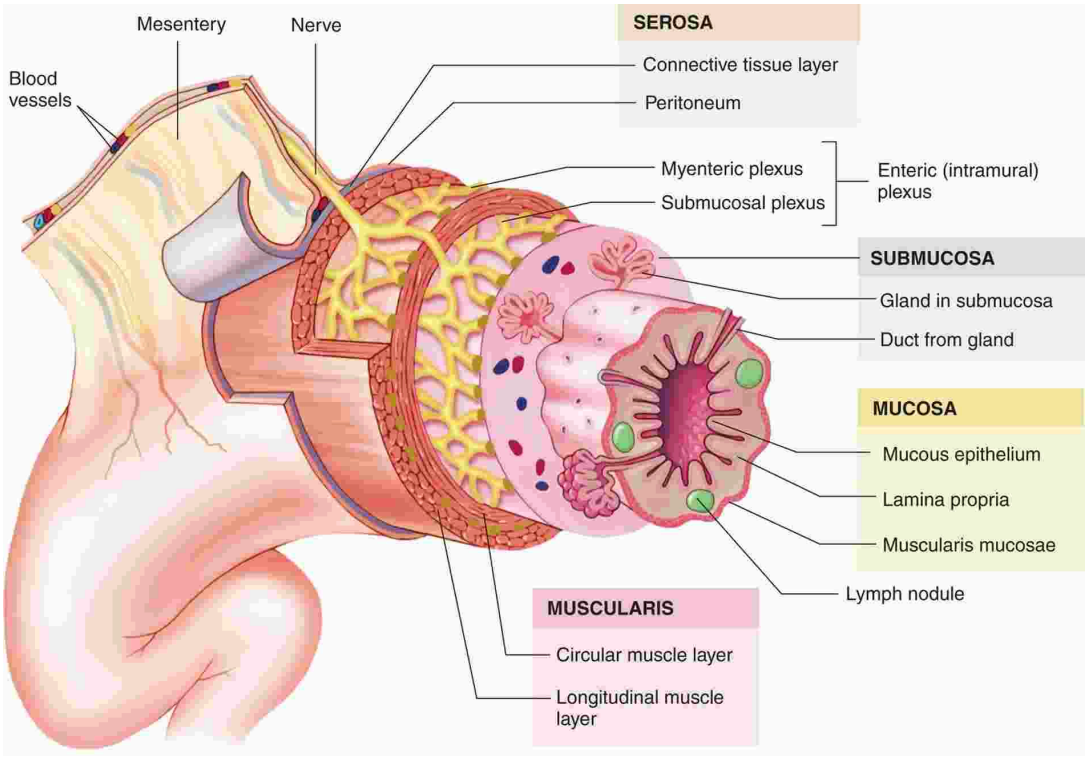

FIG. 40.2 Wall of the Gastrointestinal Tract.
The wall of the gastrointestinal tract is made up of four layers with a network of nerves between the layers. This generalized diagram shows a segment of the gastrointestinal tract. Note that the serosa is continuous with a fold of serous membrane called the *mesentery*. Note also that digestive glands may empty their products into the lumen of the gastrointestinal tract by way of ducts. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th ed. St Louis: Mosby, 2018.)

An illustration depicts a segment of the gastrointestinal tract, divided into four concentric layers. The layers from inside to outside are mucosa, submucosa, muscularis, and serosa. Mucosa is made up of mucous epithelium, lamina propria, and muscularis mucosae. Submucosa consists of glands and ducts from glands. Muscularis comprises circular muscle layer and longitudinal muscle layer. Serosa comprises connective tissue layer and peritoneum, and a membrane, labeled mesentery. A main nerve is branched out and the nerve cell bodies of the enteric or intramural

plexus are located as myenteric plexus in the muscularis and as submucosal ganglia between submucosa and muscularis.

Mouth and Esophagus

The **mouth** is the site for **mastication (chewing)** and mixing of food with saliva. There are 32 permanent teeth in the adult mouth, and they are important for speech and mastication. As food particles become smaller and move around in the mouth, taste buds are continuously stimulated, adding to the satisfaction of eating. The tongue's surface and soft palate have thousands of taste buds that contain taste receptors. These can distinguish salty, sour, bitter, sweet, and savory (umami) tastes. Tastes and food odors, which stimulate the olfactory nerve (cranial nerve [CN] I), help to initiate salivation and the secretion of gastric juice in the stomach.

Salivation

The four pairs of **salivary glands**—the submandibular, sublingual, parotid, and tubarial glands (Fig. 40.3) secrete about 1 to 1.5 L of saliva per day.[1] **Saliva** consists mostly of water with varying amounts of mucus, sodium, bicarbonate, chloride, potassium, and **salivary α-amylase (ptyalin)**, an enzyme that initiates carbohydrate digestion in the mouth and stomach.

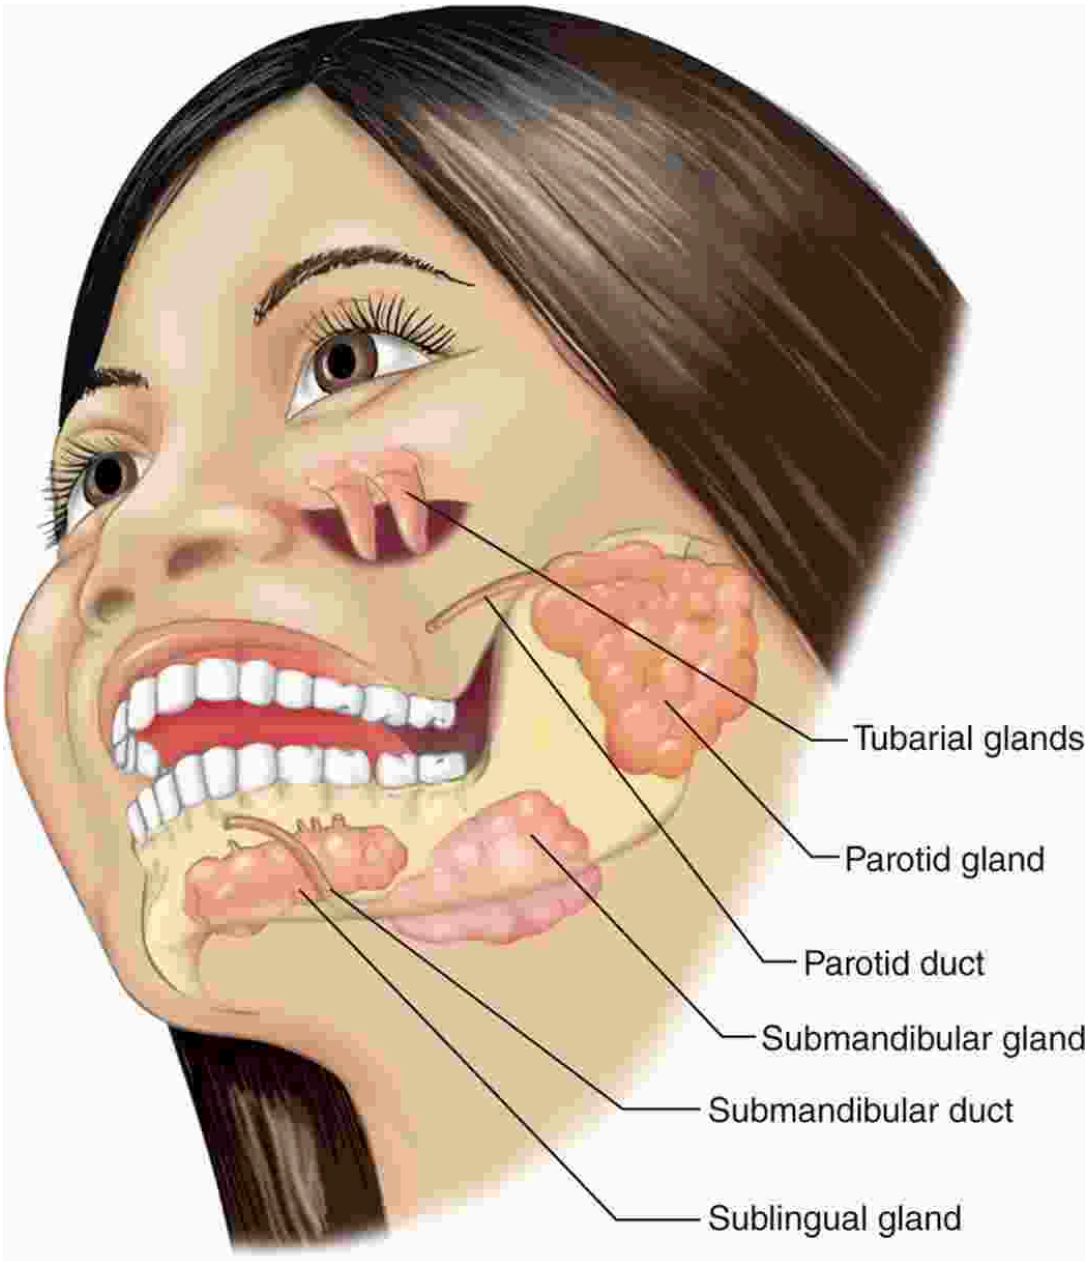

FIG. 40.3 Salivary Glands. (Adapted from Patton KT, Thibodeau GA. *The Human Body in Health & Disease*. 7th ed. St Louis: Elsevier; 2018.)

An illustration depicts the salivary glands that make saliva and ducts that secrete saliva into the mouth. The glands and ducts are labeled from top to bottom as follows: Tubarial glands, parotid glands, parotid duct, submandibular gland, submandibular duct, and sublingual gland.

The composition of saliva and other gastric juices depends on the rate of secretion (Fig. 40.4A). Aldosterone can increase the epithelial exchange of sodium for potassium, increasing sodium conservation and potassium excretion. The bicarbonate concentration of saliva sustains a pH of about 7.4, which neutralizes bacterial acids and prevents tooth decay. Saliva also contains mucin, immunoglobulin A (IgA), and other antimicrobial substances, which help prevent infection. Mucin provides lubrication. Exogenous fluoride (e.g., fluoride in drinking water) is also secreted in the saliva, providing additional protection against tooth decay.

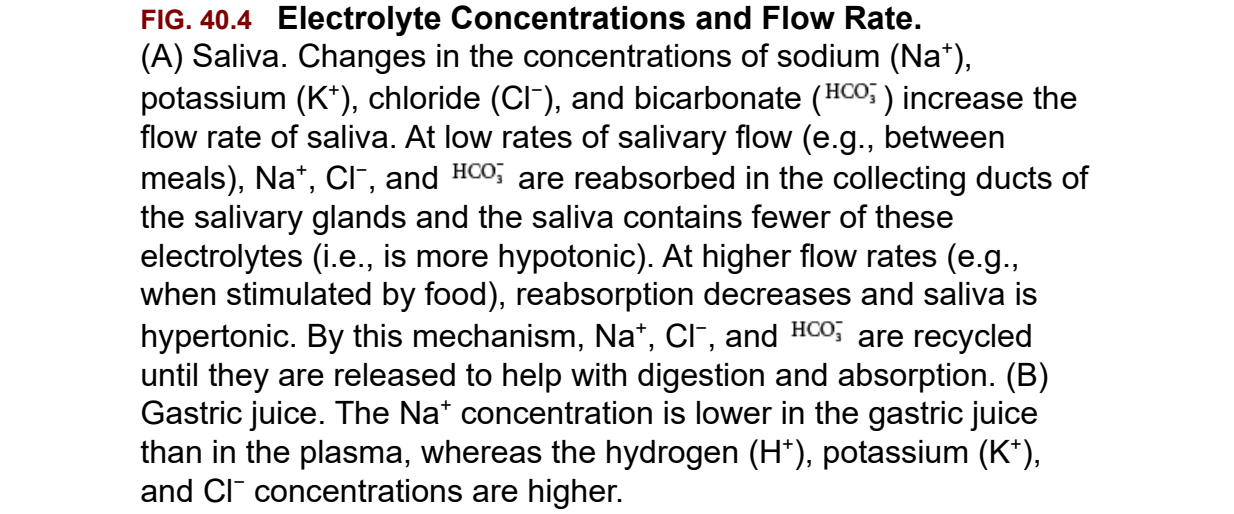

FIG. 40.4 Electrolyte Concentrations and Flow Rate.
(A) Saliva. Changes in the concentrations of sodium (Na^+), potassium (K^+), chloride (Cl^-), and bicarbonate (HCO_3^-) increase the flow rate of saliva. At low rates of salivary flow (e.g., between meals), Na^+, Cl^-, and HCO_3^- are reabsorbed in the collecting ducts of the salivary glands and the saliva contains fewer of these electrolytes (i.e., is more hypotonic). At higher flow rates (e.g., when stimulated by food), reabsorption decreases and saliva is hypertonic. By this mechanism, Na^+, Cl^-, and HCO_3^- are recycled until they are released to help with digestion and absorption. (B) Gastric juice. The Na^+ concentration is lower in the gastric juice than in the plasma, whereas the hydrogen (H^+), potassium (K^+), and Cl^- concentrations are higher.

Two graphs depict the dependence of concentration of saliva and gastric juice on secretory rate. Part A: Horizontal axis is labeled secretory rate and lists low, medium, and high. Vertical axis is labeled salivary concentration in milliequivalents per liter and lists 0, 50, and 100. Curve for chloride ion, is along (low, 0), (medium, 18), and (high, 50). Curve for potassium ion, K positive, is along (low, 40), (medium, 20), and (high, 30). Curve for bicarbonate ion, H C O 3 negative, is along (low, 10), (medium, 60), and (high, 55). Curve for sodium ion is along (low, 10), (medium, 70), and (high, 90). Part b: Horizontal axis is labeled secretory rate and lists low, medium, and high. Vertical axis is labeled gastric juice concentration in milliequivalents per liter and lists 0, 50, and 100. Curve for chlorine is along (low, 120), (medium, 160), and (high, 150). Curve for potassium is along (low, 20), (medium, 18), and (high, 15). Curve for hydrogen is along (low, 20), (medium, 125), and (high, 130). Curve for sodium is along (low, 100), (medium, 20), and (high, 5).

Both the sympathetic and parasympathetic divisions of the ANS control salivation. Cholinergic parasympathetic fibers stimulate the salivary glands, and atropine (an anticholinergic agent) inhibits salivation and makes the mouth dry. β-Adrenergic stimulation from sympathetic fibers also increases salivary secretion. Hormones do not regulate salivary gland secretion, although hormones are found in saliva (e.g., cortisol, testosterone, and estradiol) and aldosterone regulates salivary sodium

secretion. Changes in salivary hormones can be tested in a variety of conditions, including monitoring of fetal development during pregnancy.[2]

Swallowing

Swallowing is a complex event by which a food bolus travels from the oropharynx through the esophagus and into the stomach. Swallowing is mediated by the trigeminal nucleus, nucleus tractus solitarius, and reticular formation of the brainstem, as well as other brain regions, including the insula/claustrum and cerebellum. In addition to ensuring the sequential movement of food from the oropharynx into the esophagus, these neural pathways modulate the swallowing process to accommodate changing size and viscosity of a food bolus.[3]

Swallowing occurs in two phases: the oropharyngeal phase and the esophageal phase. During the **oropharyngeal (voluntary) phase**, which takes 1 or 2 seconds, the movements of the tongue and pharyngeal constrictors propel the food into the esophagus in a series of coordinated events. The following steps occur:

1. Food is segmented into a bolus by the tongue and forced posteriorly toward the pharynx as the tongue pushes upward against the hard palate.
2. The superior constrictor muscle of the pharynx contracts so the food cannot move into the nasopharynx.
3. Respiration is inhibited, and the epiglottis slides down to prevent the food from entering the larynx and trachea.
4. The **upper esophageal sphincter (cricopharyngeal muscle)** opens to allow the food bolus to pass into the esophagus, then closes again to prevent air from entering the esophagus during respiration.[4]

During the **esophageal (involuntary) phase**, which takes 8 to 10 seconds, the bolus is transported to the stomach by the coordinated sequential contraction and relaxation of outer longitudinal and inner circular layers of smooth muscle around the esophageal lumen. This phase proceeds as follows:

1. The bolus of food enters the esophagus.
2. Waves of muscular relaxation move along the esophagus, preparing for the movement of the bolus.
3. Peristalsis, the sequential waves of muscular contractions that travel down the esophagus, transports the food to the lower esophageal sphincter.
4. The lower esophageal sphincter relaxes, and the bolus enters the stomach, after which the sphincter muscles return to their resting tone.

The **esophagus** is a hollow, muscular tube approximately 25 cm long that conducts substances from the oropharynx to the stomach (see Fig. 40.1). The esophageal mucosa consists of squamous epithelium that transitions to columnar epithelium at the gastroesophageal junction. The pharynx and upper third of the esophagus contain

striated muscle (voluntary) that is directly innervated by skeletal motor neurons that control swallowing. The middle third contains a mix of striated and smooth muscle, and the lower third contains smooth muscle (involuntary) that is innervated by preganglionic cholinergic fibers from the vagus nerve (CN X).

Peristalsis that immediately follows the oropharyngeal phase of swallowing is called **primary peristalsis**. Primary peristalsis results from the contraction of striated muscle in the upper esophagus. Increased tension in the esophageal wall stimulates stretch receptors to activate vagal afferent nerves that then elicit impulses from the swallowing center of the brain.[5] These impulses cause sequential contraction and relaxation of the smooth muscle in the mid and lower esophagus called **secondary peristalsis**, which propels the food bolus toward the gastroesophageal junction.

The **lower esophageal sphincter (cardiac sphincter)** is located near the gastroesophageal junction—the opening in the diaphragm just below where the esophagus ends at the stomach. At rest, the tonic contraction of circular muscle fibers called clasp fibers in the lower esophageal sphincter prevents gastroesophageal reflex.[6] The muscle tone of the lower esophageal sphincter changes with neural and hormonal stimulation and relaxes with swallowing. Cholinergic vagal input and the digestive hormone gastrin increase sphincter tone. Nitric oxide is the main neurotransmitter involved in relaxation of the sphincter muscles.[5] Noradrenergic, noncholinergic vagal impulses relax the lower esophageal sphincter, as do the hormones progesterone, secretin, and glucagon.

The Abdominal Cavity

The abdominal cavity contains all the organs of digestion including the lower part of the esophagus, stomach, intestines, liver, gallbladder, pancreas, spleen, kidneys, adrenal glands and their blood, lymphatic supply, and innervation. The supporting structures of the abdominal cavity are the mesentery, peritoneum, and omentum. The boundaries of the abdominal cavity are the diaphragm (superior), the inferior muscular layer of the true pelvic cavity (inferior), the vertebral column (posterior), and the abdominal muscles (anterior).

The **mesentery** is a double fold of peritoneum composed of several contiguous segments. Classically, the segments were thought to be discontinuous and only provide structural support. Recent evidence from embryology, tissue analysis, and imaging have redefined the mesentery as an internal organ in which all abdominal digestive organs develop and maintains these organs in systemic continuity in adulthood. Organs not of "mesenteric" embryonic origin and anatomical position are described as "non-mesenteric" and includes the kidneys and adrenal glands.[7] The mesentery provides a conduit for lymphatics, blood vessels, and nerves and is continuous from the esophago-gastric to anorectal junction. It has different segments or regions generally named for the parts of the intestine to which it attaches (Fig. 40.5A and B). It is these segments that were classically thought not to be components of a single organ. The small intestinal mesentery segment is fan shaped and arises from the *mesenteric root*. The root is about 15 cm long and 20 cm wide and extends

from the duodenojejunal flexure (near the left part of the second lumbar vertebrae) to the ileocolic junction (at the right sacroiliac joint). Toldt fascia provides the points of anchorage between the mesentery and the abdominal wall with additional support from the peritoneum and omentum. The mesenteric segments have both structural and physiologic functions (Box 40.2).[8]

(A) Location of the continuous mesentery: **1**. Small-intestinal mesentery—connects the loops of jejunum and ileum to the posterior abdominal wall and is a mobile structure; **2**. Right mesocolon runs flat against the right posterior abdominal wall; **3**.Transverse mesocolon—a mobile area of mesentery that lies between the colic flexures; **4**. Left mesocolon: runs flat against the left posterior abdominal wall; **5**. Mesosigmoid—has a medial portion which is flattened against the posterior abdominal wall, whereas the region of mesentery associated with the sigmoid colon itself is mobile; **6**. Mesorectum—assists in anchoring the rectum through the pelvis. **(B)** Digital representation of the intestinal mesentery. (Data from A, Cresci GAM, Izzo K. Gut microbiome. In *Adult Short Bowel Syndrome*. 2019;45–54. https://doi.org/10.1016/b978-0-12-814330-8.00004-4. B, From Coffey JC, O'Leary DP. The mesentery: structure, function, and role in disease. *Lancet Gastroenterol Hepatol*. 2016;1[3];238–247. https://doi.org/10.1016/s2468-1253(16)30026-7.)

An illustration and a digital representation depict the different segments of the mesentery. Part A: The small intestine and large intestine are labeled. The segments are numbered 1 through 6. Part B: The different segments are labeled and a thread is drawn along the segments, in order, as follows: small intestinal mesentery, right mesocolon, transverse mesocolon, mesosigmoid, and mesorectum.

Box 40.2

Functions of the Mesentery

Functions of the Mesentery

Supports embryonic development of abdominal organs of digestion by providing molecular and cellular signals (mesenteric organogenesis).
Maintains abdominal digestive organs in position and in continuity with all other body systems.
Reduces friction and supports free movement, prevents twisting, and dislocation into the pelvic area.
Stores fat, regulates glycemic and lipid metabolism, and provides organs with rapid access to metabolic substrates.

Is a major source of systemic C-reactive protein when there is intestinal inflammation.

The superior and inferior mesenteric arteries and veins provide the circulation to the mesentery. Innervation is provided by the superior mesenteric plexus which divides into many secondary plexuses and contains parasympathetic and sympathetic innervation to the organs associated with the mesentery. Both lymph nodes and lymph vessel are contained within the mesentery.

Considering the mesentery as an organ, with both structural and functional significance, expands clinical implications of the mesentery as an organ of disease or contributing to the cause of systemic diseases. The mesentery can become a significant source of fat deposition. Excess fat is associated with metabolic syndrome and inflammation. In diseases such as Crohn disease (an autoimmune inflammatory bowel disease–see Chapter 41), the mesentery may be a source of inflammation, contributing to increased permeability and bacterial invasion making the mesentery a target for pharmacologic interventions.[9] The conceptualization is also important in selecting and interpreting different radiologic techniques and findings as well as surgical decisions about whether to remove mesenteric tissue for cancer treatment or inflammatory diseases of the intestine and other digestive organs.[8] The mesentery as an organ has been implicated in the development of systemic inflammation. Mechanisms by which the mesentery contributes to systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome are under investigation.

The **peritoneum** is a serous membrane surrounding the organs of the abdomen and pelvic cavity. It is analogous to the pericardium around the heart and the pleura around the lungs. The *visceral peritoneum* lies on the surface of the organs, and the *parietal peritoneum* lines the wall of the body cavity. The space between these two layers is called the **peritoneal cavity (peritoneal space)** and normally contains a thin layer of fluid to lubricate the two layers and prevent friction during organ movement.

The **omentum** is an intraabdominal organ composed of a large flat layer of adipose tissue with two parts. The *greater omentum* arises from the greater curvature of the stomach and spleen, drapes over the transverse colon, and separates the abdomen into greater and lesser sacs. It has a double fold that connects the stomach to the posterior abdominal wall. The *lesser omentum* arises from the lesser curvature of the stomach and contains the only opening between the greater and lesser sacs (epiploic foramen or foramen of Winslow) providing communication between them. As an organ, the omentum has multiple functions including fat storage; protection of underlying structures; immune regulation (contains immune cells known as "milky spots"); participation in infection control; and wound healing and tissue regeneration, including activation of stem cells and neovascularization.[10]

Stomach

The **stomach** is a hollow, muscular organ just below the diaphragm (Fig. 40.6) that stores food during eating, secretes digestive juices, mixes food with these juices, and

propels partially digested food, called **chyme**, into the duodenum of the small intestine. Functional areas are the **fundus** (upper portion), **body** (middle portion), and **antrum** (lower portion). Its major anatomic boundaries are:

- The lower esophageal sphincter, where food passes through the **cardiac orifice** at the gastroesophageal junction into the stomach.
- The **pyloric sphincter**, which relaxes as food is propelled through the **pylorus (gastroduodenal junction)** into the duodenum.

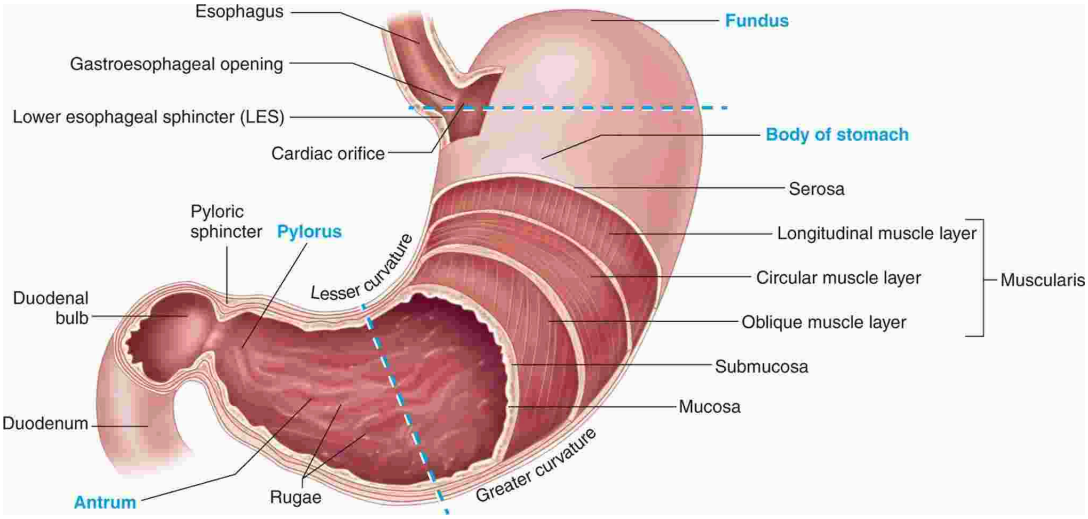

FIG. 40.6 The Stomach.
A portion of the anterior wall has been excised to reveal the muscle layers of the stomach wall. Note that the mucosa lining the stomach forms folds called *rugae*. The dashed lines distinguish the fundus, body, and antrum of the stomach. (Modified from Patton KT, Thibodeau GA. *The Human Body in Health & Disease*. 7th ed. St Louis: Elsevier; 2018.)

An illustration depicts the sections of the stomach and the layers of the wall of the digestive tract. The parts are labeled from esophagus through duodenum as follows: esophagus; gastroesophageal opening; lower esophageal sphincter; cardiac orifice; fundus; body of stomach; serosa; muscularis comprising three muscle layers: longitudinal, circular, and oblique; submucosa; mucosa; rugae; antrum; pylorus; pyloric sphincter; duodenal bulb; and duodenum. The lesser and greater curvatures of the stomach are labeled. Dashed lines are drawn between the sections of the stomach, namely, fundus, body, and antrum.

The stomach has three layers of smooth muscle: an outer, longitudinal layer; a middle, circular layer; and an inner, oblique layer (see Fig. 40.6).[6] These layers become progressively thicker in the body and antrum where food is mixed, churned, and pushed into the duodenum. The circular layer is most prominent, the oblique layer is the least complete, and the longitudinal layer is absent on the anterior and posterior surfaces. The interior of the stomach is lined with mucosa. When the stomach is empty, this mucosal layer sits in folds called **rugae**. Few substances are absorbed in

the stomach. The stomach mucosa is impermeable to water but can absorb alcohol and aspirin because they are lipid soluble.

The stomach's blood supply comes from a branch of the celiac artery (Fig. 40.7) and is so abundant that nearly all arterial vessels would need to be blocked before ischemic changes occur in the stomach wall. A series of small veins (short gastric, left and right gastric, and left and right gastro-omental) drain blood from the stomach toward the hepatic portal vein. Hepatic disorders that increase pressure in the portal vein can cause these gastric veins to dilate (varices) and bleed (see Chapter 41).

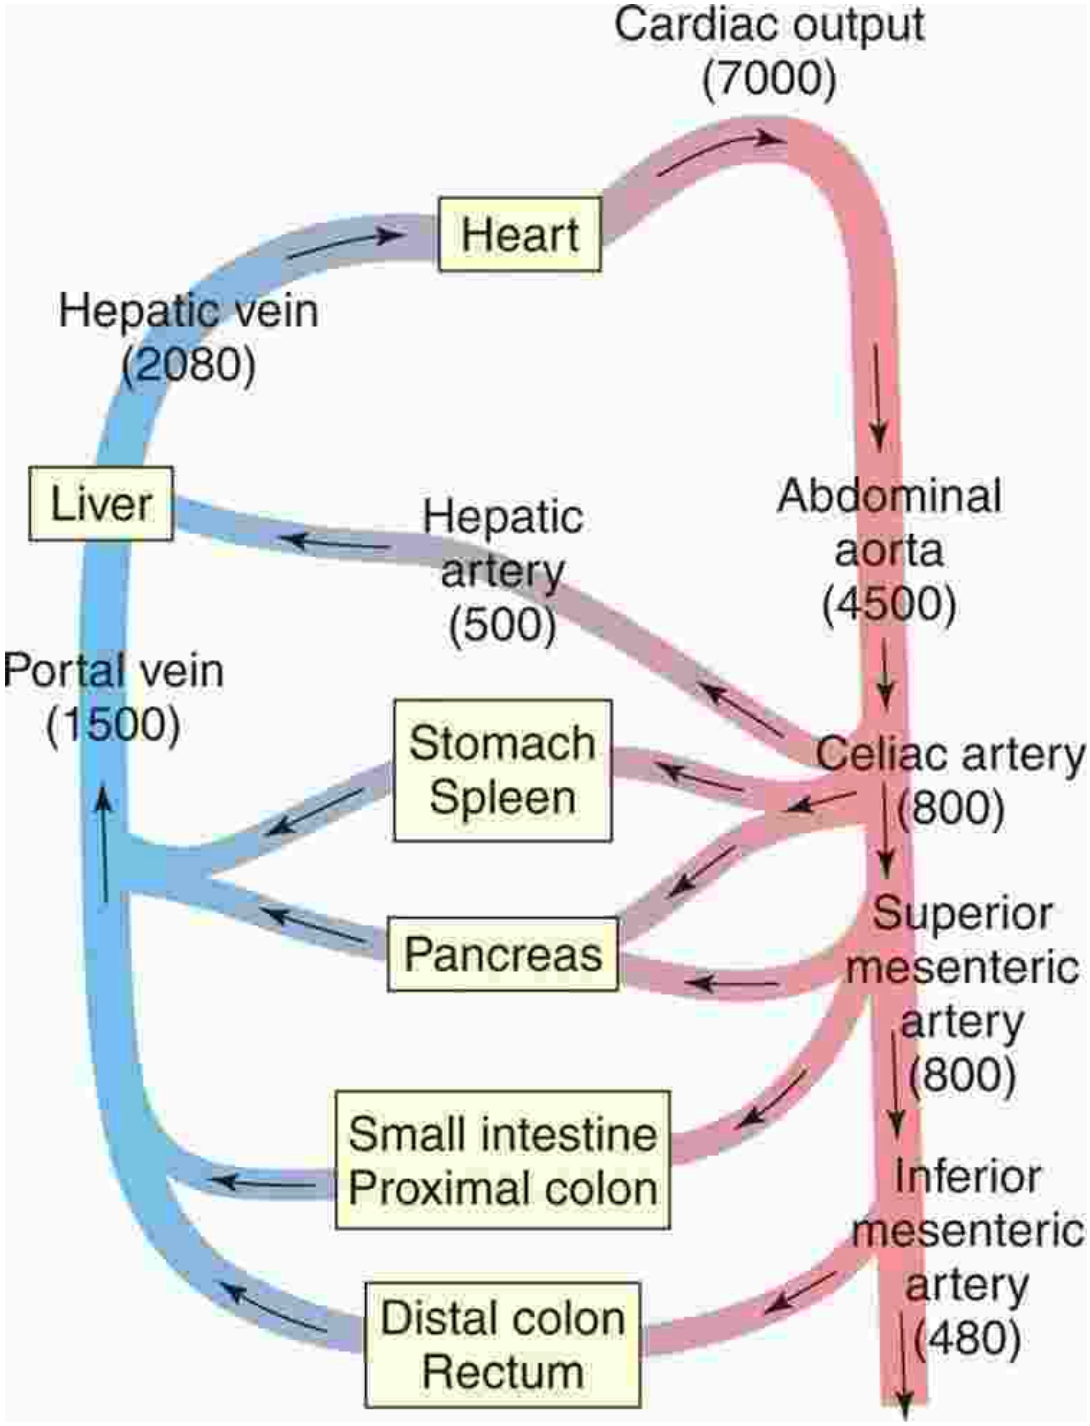

FIG. 40.7 Major Blood Vessels and Organs Supplied With Blood in the Splanchnic Circulation.
Numbers in parentheses reflect approximate blood flow values (mL/min) for each major vessel in an 80-kg (176 lb) normal, resting, adult human. Arrows indicate the direction of blood flow.
(Modified from Johnson LR. *Gastrointestinal Pathophysiology*. St Louis: Mosby; 2001.)

An illustration depicts the blood flow in value of milliliters per minute to splanchnic organs through the major arteries of abdominal aorta. Cardiac output of 7000 is indicated from heart to abdominal aorta. Blood flow of 4500 for abdominal aorta is routed to splanchnic organs through: celiac artery of 800 to hepatic artery of 500, stomach, spleen, and pancreas; superior mesenteric of 800 to pancreas, small intestine, and distal colon; inferior mesenteric of 480 to colon. Flow from hepatic artery to liver; from the organs through portal vein of 1500 to liver; and from hepatic vein of 2080 to heart are indicated.

The sympathetic and parasympathetic divisions of the ANS innervate the stomach. Some of the autonomic fibers are extrinsic—that is, they originate outside the stomach. Impulses through these external autonomic fibers are controlled by nerve centers in the brain. The vagus nerve provides parasympathetic innervation and branches of the celiac plexus innervate the stomach sympathetically. The myenteric (Auerbach) plexus and submucosal (Meissner) plexus are intrinsic and part of the enteric (intramural) nervous system. They originate within the stomach and respond to local stimuli.

Gastric Motility

In its resting state, the stomach is small and contains about 50 mL of fluid. There is minimal wall tension, and the muscle layers in the fundus contract very little. Swallowing causes the fundus to relax (receptive relaxation) to receive a bolus of food from the esophagus. Relaxation is coordinated by efferent, noradrenergic, noncholinergic vagal fibers and is facilitated by two polypeptide hormones secreted by the GI mucosa—**gastrin** and **cholecystokinin**. (The actions of digestive hormones are summarized in Table 40.1.) These two hormones also play important roles in protecting the gastric mucosa during digestion and help to maintain the integrity of the islet cells in the pancreas.[11]Food is stored in vertical or oblique layers as it arrives in the fundus, whereas fluids flow relatively quickly down to the antrum.

Table 40.1

Selected Hormones[a] and Neurotransmitters of the Digestive System

Source	Hormone/Neurotransmitter	Stimulus for Secretion	Action
Mucosa of the stomach	Gastrin	Presence of partially digested proteins in the stomach	Stimulates gastric glands to secrete hydrochloric acid, pepsinogen, and histamine; growth of gastric mucosa
	Histamine	Gastrin	Stimulates acid secretion
	Somatostatin	Acid in stomach	Inhibits acid, pepsinogen, and histamine secretion and release of gastrin
	Acetylcholine	Vagus and local nerves in stomach	Stimulates release of pepsinogen and acid secretion
	Gastrin-releasing peptide (bombesin)	Vagus and local nerves in stomach	Stimulates gastrin and release of pepsinogen and acid secretion
	Ghrelin	High during fasting	Stimulates growth hormone secretion and hypothalamus to increase appetite

[a]The digestive hormones are not secreted into the gastrointestinal lumen, but rather into the bloodstream, where they travel to target tissues. Multiple peptide hormone genes and more than 100 hormonally active peptides are expressed in the gastrointestinal tract.

Modified from Johnson LR. *Gastrointestinal Physiology*.8th ed. St Louis: Mosby; 2014. Data from Feldman M, et al. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia, PA: Saunders; 2015.

Gastric (stomach) motility increases with the initiation of peristaltic waves, which sweep over the body of the stomach toward the antrum. The rate of peristaltic contractions is approximately three per minute and is influenced by neural and hormonal activity. Gastrin, **motilin** (an intestinal hormone), and the vagus nerve increase the rate of contraction by lowering the threshold potential of muscle fibers. (The neural and biochemical mechanisms of muscle contraction are described in Chapter 43.) Motilin also impacts the brain-pancreas axis and influences insulin secretion during meals.[12] Sympathetic activity and **secretin** (another intestinal

hormone) are inhibitory and raise the threshold potential as well as decrease gastric secretion (see Table 40.1). The rate of peristalsis is mediated by pacemaker cells that initiate a wave of depolarization (basic electrical rhythm), which moves from the upper part of the stomach to the pylorus.

Gastric mixing and subsequent emptying of gastric contents (chyme) from the stomach takes several hours. Mixing occurs as food is propelled toward the antrum. As food approaches the pylorus, the velocity of the peristaltic wave increases. This forces the contents back toward the body of the stomach. This **retropulsion** effectively mixes food with digestive juices, and the oscillating motion breaks down large food particles. With each peristaltic wave, a small portion of the chyme passes through the pylorus and into the duodenum. The pyloric sphincter is about 1.5 cm long and is always open about 2 mm. It opens wider during contraction of the antrum. Normally there is no regurgitation from the duodenum into the antrum.

The rate of **gastric emptying** (movement of chyme into the duodenum) depends on the volume, osmotic pressure, and chemical composition of the gastric contents. Larger volumes of food increase gastric pressure, peristalsis, and rate of emptying. Solids, fats, and nonisotonic solutions (i.e., hypertonic or hypotonic gastric tube feedings) delay gastric emptying. (Osmotic pressure and tonicity are described in Chapters 1 and 3.) Products of fat digestion, which are formed in the duodenum by the action of bile from the liver and enzymes from the pancreas, stimulate the secretion of cholecystokinin. This hormone inhibits food intake, reduces gastric motility, and decreases gastric emptying so that fats are not emptied into the duodenum at a rate that exceeds the rate of bile and enzyme secretion. Osmoreceptors in the wall of the duodenum are sensitive to the osmotic pressure of duodenal contents. The arrival of hypertonic or hypotonic gastric contents activates the osmoreceptors, which delays gastric emptying to facilitate formation of an isosmotic duodenal environment. The rate at which acid enters the duodenum also influences gastric emptying. Secretions from the pancreas, liver, and duodenal mucosa neutralize gastric hydrochloric acid in the duodenum. The rate of emptying is adjusted to the duodenum's ability to neutralize the incoming acidity. Peristaltic activity in the stomach is also affected by blood glucose levels. Low blood glucose levels stimulate the vagus nerve and gastric smooth muscles, increasing the rate of contraction and gastric emptying. Hyperglycemia delays gastric emptying.[13]

Gastric Secretion

Specialized cells located throughout the gastric mucosa secrete large volumes of gastric secretions, including acid, pepsinogen, mucus, enzymes, hormones, intrinsic factor, and gastroferrin. Acid converts inactive pepsinogen into the enzyme pepsin. Most of these secretions are released directly into the stomach lumen under neural and hormonal regulation. **Intrinsic factor** is necessary for the intestinal absorption of vitamin B_{12} (see Chapter 28), and **gastroferrin** facilitates the absorption of iron in the small intestine by preventing the formation of insoluble iron salts. Gastric hormones are secreted into the blood and travel to target tissues.

In the fundus and body of the stomach, the **gastric glands** of the mucosa are the primary secretory units (Fig. 40.8). Several of these glands empty into a common duct known as the **gastric pit**. The **parietal cells** within the glands secrete hydrochloric acid, intrinsic factor, and gastroferrin. The **chief cells** within the glands secrete pepsinogen, an enzyme precursor that is readily converted to pepsin in the gastric fluid, and acidic lipase. The pyloric gland mucosa, in the antrum, synthesizes and releases the hormone gastrin from **G cells**. **Enterochromaffin-like cells** secrete **histamine**, and **D cells** secrete **somatostatin**.

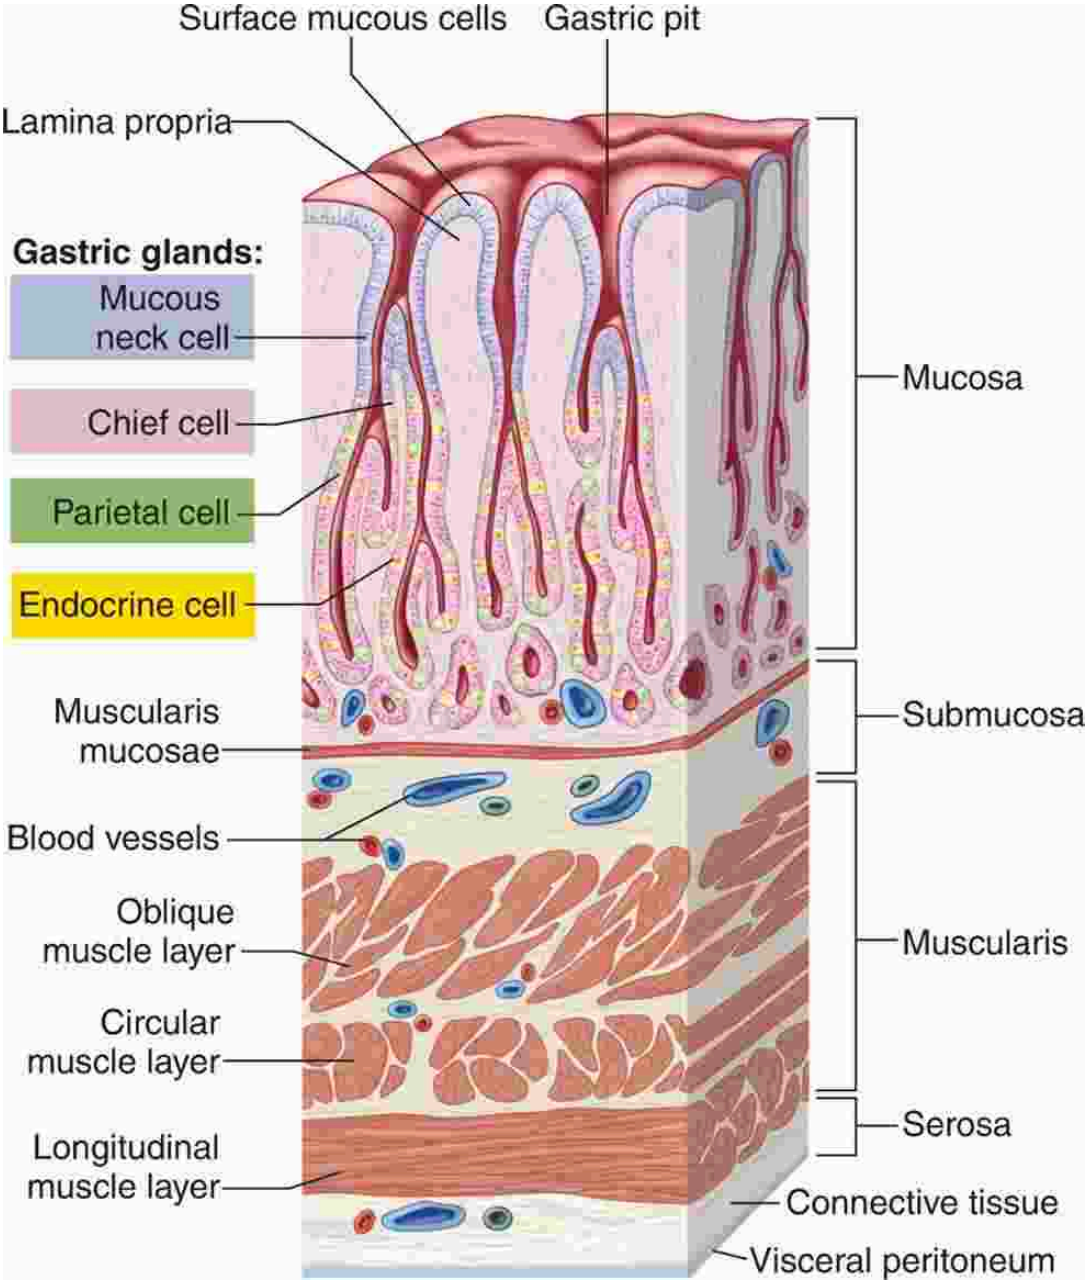

FIG. 40.8 Gastric Pits and Gastric Glands.
Gastric pits are depressions in the epithelial lining of the stomach. At the bottom of each pit are one or more tubular *gastric glands*. Chief cells produce pepsinogen, which is converted to pepsin (a proteolytic enzyme); parietal cells secrete hydrochloric acid and intrinsic factor; G cells produce gastrin; endocrine cells (enterochromaffin-like cells and D cells) secrete histamine and somatostatin. (From Patton KT, et al. *Essentials of Anatomy & Physiology*. St Louis: Mosby; 2012.)

A diagram of the stomach wall depicts the following: 1. Sections of the stomach: mucosa, submucosa, muscularis, and serosa. 2. The surface mucous cells, lamina propria, and gastric pit of mucosa. 3. The gastric glands located beneath the gastric pits within the gastric mucosa, and made up of mucous neck cell, chief cell, parietal cells, and endocrine cell. 4. The deepest layer of mucosa, muscularis mucosae, which lies next to the submucosa. 5. The blood vessels of submucosa. 6. The muscle layers of muscularis, namely, oblique, circular, and longitudinal. 7. Connective tissue and visceral peritoneum of serosa.

Gastric secretion is stimulated by anticipating, smelling, and tasting food which activates chemoreceptors and mechanoreceptors in the oral and nasal cavities. These receptors stimulate vagal fibers in the stomach.[4] It is also stimulated by gastric distention, by the actions of the hormone **gastrin** and paracrine pathways (e.g., histamine, ghrelin, somatostatin), and by the effects of the neurotransmitter acetylcholine (ACh) and other chemicals (e.g., ethanol, coffee, protein). Together these stimuli facilitate the process of digestion. Gastric secretion is inhibited by somatostatin, unpleasant odors and tastes, and rage, fear, or pain. Mucus covering the entire mucosa, intercellular tight junctions, bicarbonate secretion, and submucosal acid sensors form a protective barrier against acid and proteolytic enzymes, which otherwise would damage the gastric lining.

The composition of gastric juice depends on volume and flow rate (see Fig. 40.4B). The rate of secretion varies with the time of day. Generally, the rate and volume of secretion are lowest in the morning and highest in the afternoon and evening. At low secretion rates, the gastric juice contains primarily sodium chloride, with small amounts of hydrogen ion, potassium, and bicarbonate.[4] At peak rates, the gastric juice is primarily composed of hydrogen chloride. The potassium level remains relatively constant, but its concentration is greater in gastric juice than in plasma. Loss of gastric juices through vomiting, drainage, or suction may decrease body stores of sodium and potassium and result in fluid, electrolyte (e.g., hyponatremia, hypokalemia, dehydration), and acid-base imbalances (e.g., metabolic alkalosis) (see Chapter 3).

Phases of gastric secretion

There are three phases of gastric secretion: the cephalic phase, gastric phase, and intestinal phase (Fig. 40.9).

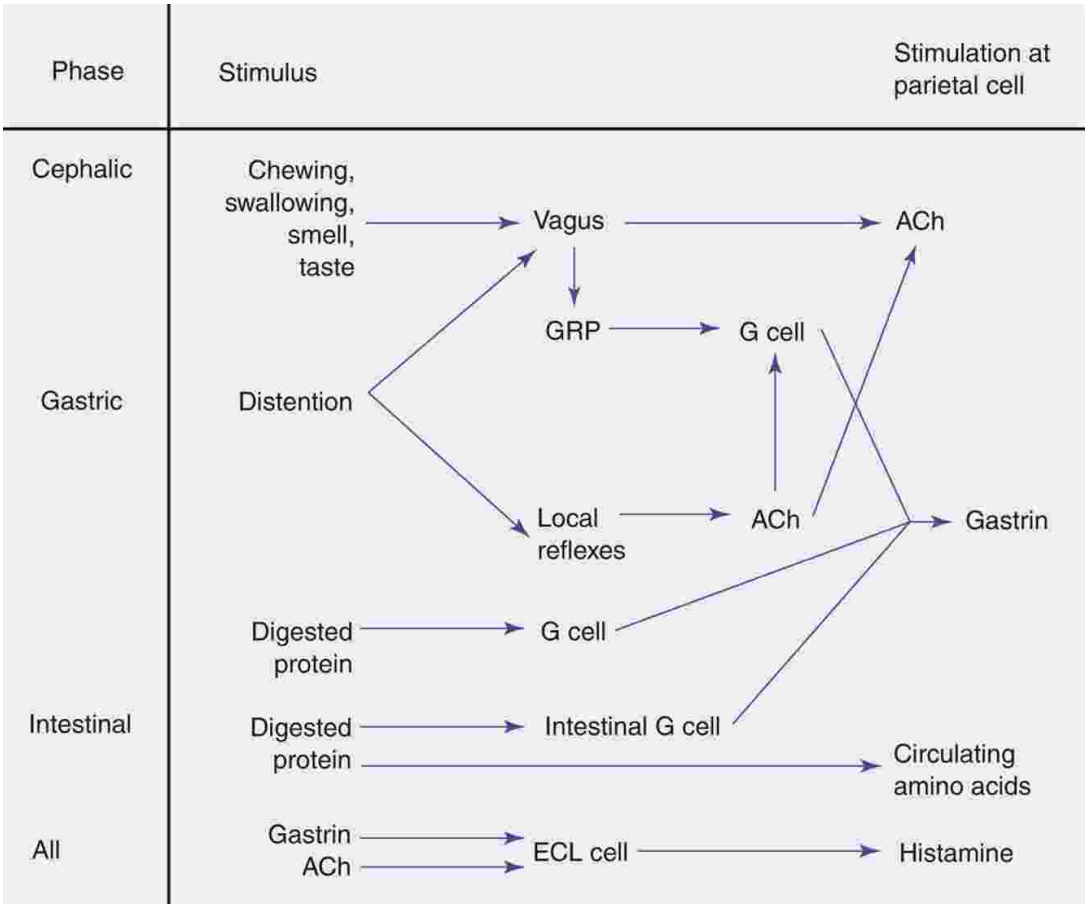

FIG. 40.9 Mechanisms for Stimulating Acid Secretion.
ACh, Acetylcholine; *ECL*, enterochromaffin-like cell; *GRP*, gastrin-releasing peptide. (From Johnson LR. *Gastrointestinal Physiology*. 9th ed. Philadelphia, PA: Mosby; 2019.)

A chart depicts the phases of gastric secretion. Cephalic phase: Stimulus is activated on chewing, swallowing, smell, and taste of food, and mediated through vagus nerve that releases gastrin-releasing peptide, G R P, onto G-cell. Acetylcholine, A C h, produced by vagus nerve exerts its effects on parietal cells. Gastric phase: Distention initiates vagus nerve and local reflexes; on mediation by A C h, G-cell releases gastrin. Intestinal phase: Digested protein is sensed by G cell that releases gastrin and Intestinal G cell that absorbs circulating amino acids. All: Gastrin and A C h trigger histamine secretion from enterochromaffin-like cell.

Cephalic phase

The anticipatory and sensory experiences of smelling, seeing, tasting, chewing, and swallowing food contribute to the **cephalic phase of secretion**. The cephalic phase is mediated by ACh produced by the vagus nerve which directly stimulates parietal cell secretion. Vagal stimulation also causes the release of gastrin-releasing peptide which stimulates G cells to produce gastrin. Hypoglycemia caused by insulin secretion by the endocrine pancreas also is a strong stimulus for gastric secretion and is mediated by the vagus nerve through sensors located in the hypothalamus.[4] Maintenance of steady serum glucose levels suppresses the gastric response to insulin.

Gastric phase

The **gastric phase of secretion** begins with the arrival of food in the stomach. Two major stimuli have a secretory effect: (1) distention of the stomach and (2) the presence of digested protein. The vagus and enteric nerve plexuses are stimulated by distention and contribute to gastric secretion through a local reflex. Both neural reflexes are mediated by ACh and can be blocked by atropine. As digestion proceeds, products of protein break down, stimulating the release of more gastrin from G cells.

Intestinal phase

The movement of chyme from the stomach into the duodenum initiates the **intestinal phase of secretion**. This phase represents a deceleration of the gastric secretory response; however, the presence of digested protein and amino acids in the duodenum continues to stimulate some gastric secretion.

Concurrently, in response to low duodenal pH and the presence of lipids, inhibitory vagal, and enteric reflexes decrease gastric motility when chyme enters the duodenum. The release of secretin and cholecystokinin stimulates pancreatic secretions and inhibits gastric secretions.

Acid

The major functions of gastric hydrochloric acid are to dissolve food fibers, act as a bactericide against swallowed microorganisms, and convert pepsinogen to pepsin. Gastric acid entering the duodenum facilitates the absorption of ferric iron. The production of acid by the parietal cells requires the transport of hydrogen and chloride from the parietal cells to the stomach lumen. Acid is formed in the parietal cells, primarily through the hydrolysis of water (Fig. 40.10). At a high rate of gastric secretion, bicarbonate moves into the plasma, producing an “alkaline tide” in the venous blood, which may result in a more alkaline urine.

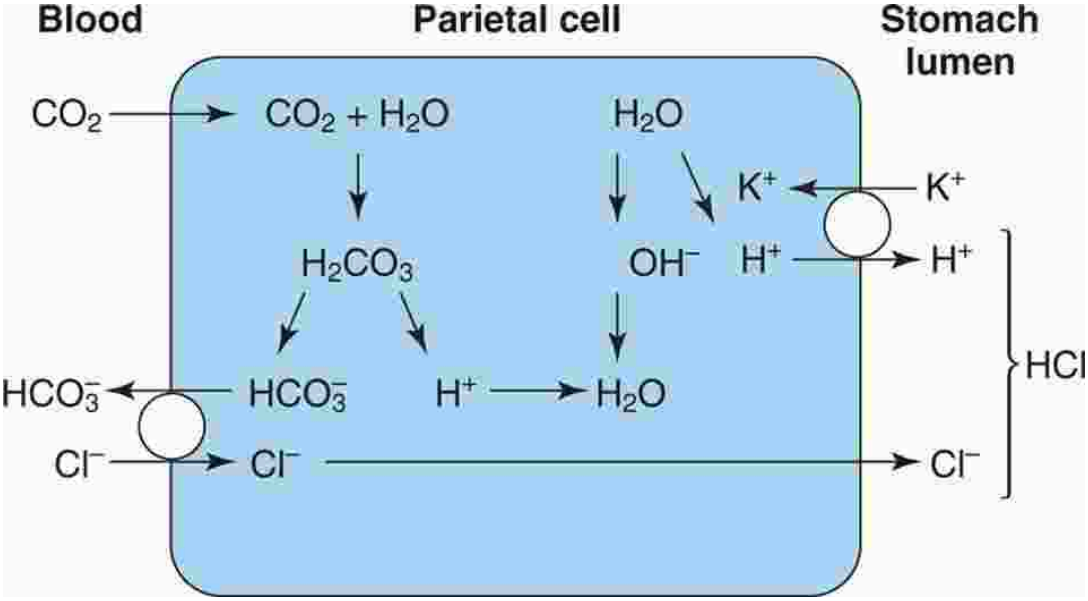

FIG. 40.10 Hydrochloric Acid Secretion by Parietal Cell.

Reactions depict the production of hydrochloric acid by parietal cells of the stomach. H 2 O combines with C O 2 from the blood to produce carbonic acid, H 2 C O 3. H 2 C O 3 dissociates into a hydrogen ion, H positive, and a bicarbonate ion, H C O 3 negative. The bicarbonate ion is transported out of the cell into the blood, in exchange for a chloride ion. The hydrogen and chloride ions are transported into the stomach lumen, forming hydrochloric acid. H positive is exchanged for K positive.

Acid secretion is stimulated by the vagus nerve, which releases ACh and stimulates the secretion of gastrin; gastrin then stimulates the release of histamine from enterochromaffin cells (mast cells; see Chapter 7) in the gastric mucosa. Histamine stimulates acid secretion by activating histamine receptors (H_2 receptors) on acid-secreting parietal cells. Caffeine, calcium, and ghrelin also stimulate acid secretion. Acid secretion is inhibited by somatostatin, secretin, cholecystokinin, glucagon-like peptide-1, atrial natriuretic peptide, and prostaglandins.[14]

Pepsin and gastric lipase

The ACh, gastrin, and secretin stimulate the chief cells to release **pepsinogen** during eating. Pepsinogen is quickly converted to **pepsin** in the acidic gastric environment (optimum pH for pepsin activation = 2). Acid also stimulates a local cholinergic reflex and stimulates chief cells to secrete pepsin. Pepsin is a proteolytic enzyme—that is, it breaks down protein and forms polypeptides in the stomach. Once chyme has entered

the duodenum, the alkaline environment of the duodenum inactivates pepsin. **Gastric lipase** is an acid lipase and does not require bile for activation like alkaline pancreatic and intestinal lipases and is active in an acid environment. It accounts for about 30% of fat digestion in adults and up to 50% of fat digestion in infants. It cleaves only one monoglyceride from triglyceride so is less efficient than alkaline lipase.

Mucus

The gastric mucosa is protected from the digestive actions of acid and pepsin by intercellular tight junctions, a coating of mucus called the **mucosal barrier**, and gastric mucosal blood flow. The quality and quantity of mucus and the tight junctions between epithelial cells make gastric mucosa relatively impermeable to acid. Prostaglandins and nitric oxide protect the mucosal barrier by stimulating the secretion of mucus and bicarbonate and by inhibiting the secretion of acid. A break in the protective barrier may occur from ischemia or by exposure to *Helicobacter pylori*, aspirin, nonsteroidal anti-inflammatory drugs (inhibit prostaglandin synthesis), ethanol, or regurgitated bile. Breaks cause inflammation and ulceration (see Chapter 41).

Small Intestine

The **small intestine** is coiled within the abdominal cavity and is about 5 to 6 m long. It is suspended in loose folds from the posterior abdominal wall by the mesentery. Functionally, it is divided into three segments: the **duodenum**, **jejunum**, and **ileum** (Fig. 40.11A). The duodenum begins at the pylorus and ends where it joins the jejunum at a suspensory ligament called the *Treitz ligament*. The end of the jejunum and the beginning of the ileum are not distinguished by an anatomic marker. These structures are not grossly different, but the jejunum has a slightly larger lumen than the ileum. The **ileocecal valve**, or sphincter, controls the flow of digested material from the ileum into the cecum of the large intestine and prevents reflux into the small intestine.

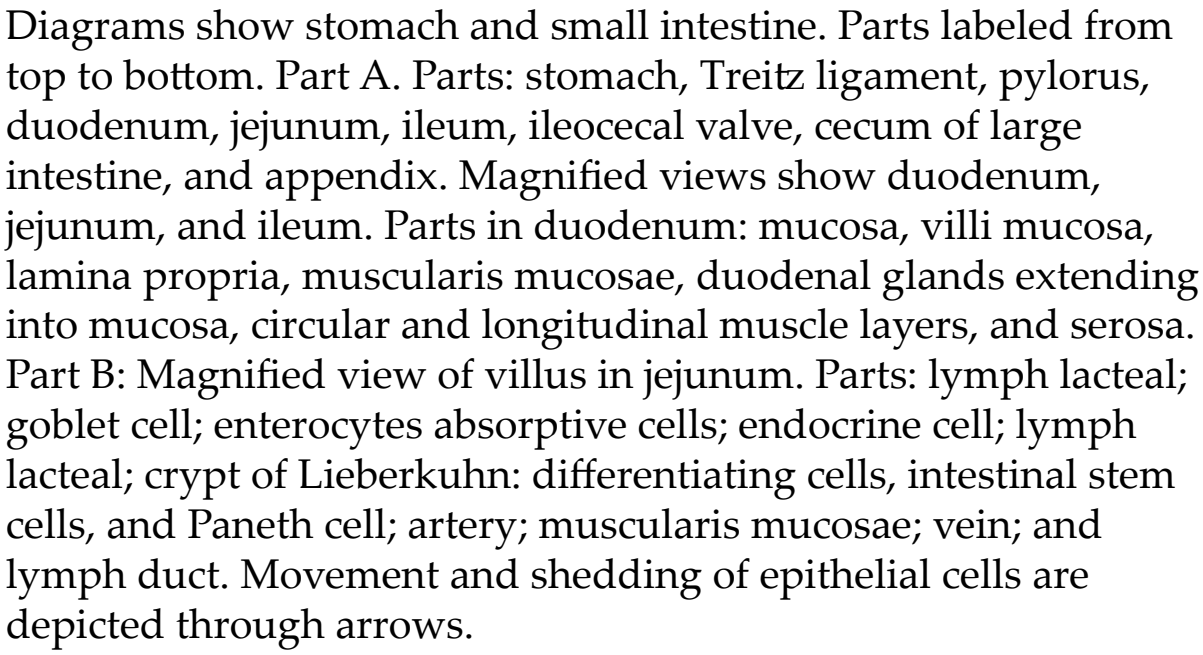
FIG. 40.11 The Small Intestine.
(A) Segments of the small intestine. Inserts show longitudinal sections of the duodenum, jejunum, and ileum. **(B)** Anatomy of a villus. Arrows show migration and then shedding of epithelial cells.



The arterial supply to the duodenum arises primarily from the gastroduodenal artery, a branch of the celiac artery. The jejunum and ileum are supplied by branches of the superior mesenteric artery (see Fig. 40.7). Blood flow increases significantly during digestion. The superior mesenteric vein drains blood from the entire small intestine and empties into the hepatic portal circulation. The regional lymph nodes and lymphatics drain into the thoracic duct, which empties into the subclavian vein.

Enteric nerves from both divisions of the ANS innervate the small intestine. Secretion, motility, pain sensation, and intestinal reflexes (e.g., relaxation of the lower esophageal sphincter) are mediated parasympathetically by the vagus nerve. Sympathetic activity inhibits motility and produces vasoconstriction. Intrinsic reflexive activity is mediated by the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus of the enteric nervous system.[4]

The smooth muscles of the small intestine are arranged in two layers: a longitudinal outer layer and a thicker inner circular layer (see Figs. 40.2 and 40.11A). Circular folds of the small intestine slow the passage of food, thereby providing more time for digestion and absorption. The folds are most numerous and prominent in the jejunum and proximal ileum.

Absorption occurs through **villi** (sing., **villus**), which cover the circular folds and are the functional units of the intestine. A villus is composed of absorptive columnar cells **(enterocytes)** and mucus-secreting goblet cells of the mucosal epithelium (see Fig. 40.11B). Each villus secretes some of the enzymes necessary for digestion and

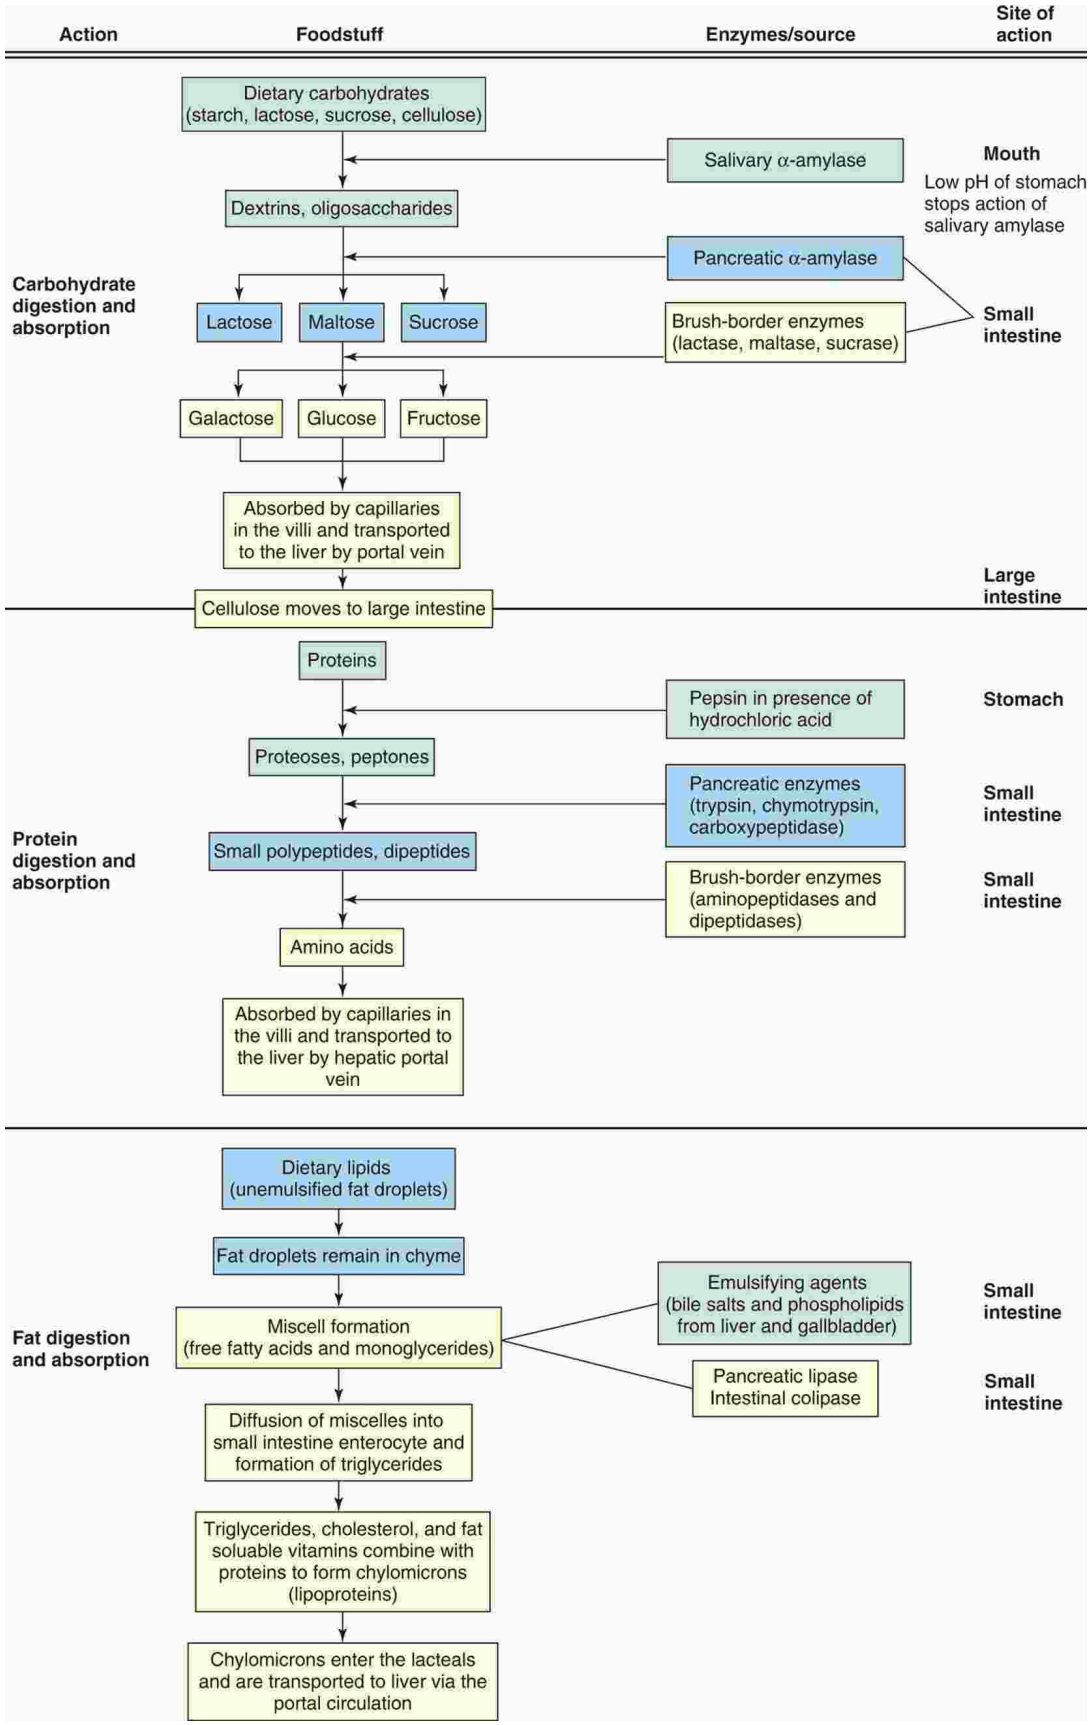
absorbs nutrients. Near the surface, columnar cells closely adhere to each other at sites called *tight junctions*. Water and electrolytes are absorbed through these intercellular spaces. The surface of each columnar epithelial cell on the villus contains tiny projections called **microvilli** (sing., **microvillus**). Together the microvilli create a mucosal surface known as the **brush border**. The villi and microvilli greatly increase the surface area available for absorption. Coating the brush border is an "unstirred" layer of water that is important for the absorption of water-soluble substances including emulsified micelles of fat. The **lamina propria** (a connective tissue layer of the mucous membrane) lies beneath the epithelial cells of the villi and contains lymphocytes and plasma cells, which produce immunoglobulins (see The Gastrointestinal Tract and Immunity section).

Central arterioles ascend within each villus and branch into a capillary array that extends around the base of the columnar cells and cascades down to the venules that lead to the hepatic portal circulation. The opposing ascending and descending blood flow provide a countercurrent exchange system for absorbed substances and blood gases. A central **lacteal**, or lymphatic capillary, also is contained within each villus and is important for the absorption and transport of fat molecules (see Fig. 40.11B). The contents of the lacteals flow to regional nodes and channels that eventually drain into the thoracic duct.

Between the bases of the villi are the **crypts of Lieberkühn**, which extend to the submucosal layer. Undifferentiated cells arise from stem cells at the base of the crypt, and move toward the tip of the villus, maturing to become columnar epithelial secretory cells (water, electrolytes, and enzymes) and goblet cells (mucus).[15] After completing their migration to the tip of the villus, they function for a few days and then are shed into the intestinal lumen and digested. Discarded epithelial cells are an important source of endogenous protein. The entire epithelial population is replaced about every 4 to 7 days. Many factors can influence this process of cellular proliferation. Starvation, vitamin B_{12} deficiency, and cytotoxic drugs or irradiation suppress cell division and shorten the villi. Decreased absorption across the epithelial membrane can cause diarrhea and malnutrition. Nutrient intake and intestinal resection stimulate cell production.

Intestinal Digestion and Absorption

The process of intestinal digestion is initiated in the stomach by the actions of gastric hydrochloric acid and pepsin, which break down food fibers and proteins. The chyme that passes into the duodenum is a liquid with small particles of undigested food. Digestion of food components continues in the proximal portion of the small intestine by the action of pancreatic enzymes, intestinal brush-border enzymes, and bile salts. As seen in Fig. 40.12, in the proximal small intestine, carbohydrates are broken down to monosaccharides and disaccharides, proteins are degraded further to amino acids and peptides, and fats are emulsified and reduced to fatty acids and monoglycerides.



Action

Sucrose
Brush-border enzymes (lactase, maltase, sucrase)
Small intestine
Galactose
Glucose
Fructose
Absorbed by capillaries in the villi and transported to the liver by portal vein
Large intestine
Cellulose moves to large intestine
Protein digestion and absorption
Proteins
Pepsin in presence of hydrochloric acid
Stomach
Proteoses, peptones
Pancreatic enzymes (trypsin, chymotrypsin, carboxypeptidase)
Small intestine
Small polypeptides, dipeptides
Brush-border enzymes (aminopeptidases and dipeptidases)
Small intestine
Amino acids
Absorbed by capillaries in the villi and transported to the liver by hepatic portal vein
Fat digestion and absorption
Dietary lipids (unemulsified fat droplets)
Fat droplets remain in chyme
Emulsifying agents (bile salts and phospholipids from liver and gallbladder)
Small intestine
Miscell formation (free fatty acids and monoglycerides)
Pancreatic lipase Intestinal colipase
Small intestine
Diffusion of miscelles into small intestine enterocyte and formation of triglycerides
Triglycerides, cholesterol, and fat soluable vitamins combine with proteins to form chylomicrons (lipoproteins)
Chylomicrons enter the lacteals and are transported to liver via the portal circulation

FIG. 40.12 Digestion and Absorption of Food.

A flow diagram depicts digestion and absorption of various foods. Carbohydrate digestion and absorption: Salivary alpha- amylase, the primary enzyme in mouth, breaks down dietary carbohydrates, namely, starch, lactose, sucrose, and cellulose, into dextrins and oligosaccharides, which are hydrolyzed into lactose, maltose, and sucrose by pancreatic alpha-amylase secreted into the small intestine. Maltose is broken down into galactose, glucose, and fructose by brush-border enzymes, namely, lactase, maltase, and sucrose, in the small intestine. These molecules are absorbed by capillaries in the villi and transported to the liver by portal vein. Cellulose moves to large intestine. Protein digestion and absorption: Once proteins reach the stomach, pepsin, in presence of hydrochloric acid, breaks them down into proteoses and peptones, which are broken down into small polypeptides and dipeptides by pancreatic enzymes in small intestine, namely, trypsin, chymotrypsin, and carboxypeptidase. The peptides are broken down into amino acids by brush-border enzymes, namely, aminopeptidases and dipeptidases, in the small intestine. The amino acids are absorbed by capillaries in the villi and transported to the liver by hepatic portal vein. Fat digestion and absorption: Dietary lipids, unemulsified fat droplets, aggregate into fat droplets that remain in chime, leading to micelle formation, free fatty acids and monoglycerides, by emulsifying agents, bile salts and phospholipids from liver and gallbladder, and by pancreatic lipase, activated by intestinal colipase, in the small intestine. This leads to diffusion of micelles into small intestine enterocyte and formation of triglycerides, further leading to combination of triglycerides, cholesterol, and fat soluble vitamins with proteins to form chylomicrons or lipoproteins. Chylomicrons enter the lacteals and are transported to liver via the portal circulation.

These nutrients, along with water, vitamins, and electrolytes, are absorbed across the intestinal mucosa and into the blood by active transport, diffusion, or facilitated

diffusion. Products of carbohydrate and protein breakdown move into villus capillaries and then to the liver through the hepatic portal vein. Digested fats move into the lacteals and reach the liver through the portal and systemic circulation. These components are metabolized within the liver (see the Metabolism of Nutrients section). Intestinal motility exposes nutrients to a large mucosal surface area by mixing chyme and moving it through the lumen. Different segments of the GI tract absorb different nutrients. Digestion and absorption of all major nutrients and many drugs occur in the small intestine. Sites of absorption are shown in Fig. 40.13. Box 40.3 outlines the major nutrients involved in this process.

FIG. 40.13 Sites of Absorption of Major Nutrients. (Modified from Patton KT. *Anatomy & Physiology*. 10th ed. St Louis: Elsevier; 2019.)

Box 40.3

Major Nutrients Absorbed in the Small Intestine

Water and Electrolytes

- Approximately 85%–90% of the water that enters the GI tract is absorbed in the small intestine.
- Sodium passes through tight junctions and is actively transported across cell membranes; it is exchanged for bicarbonate to maintain electroneutrality in the ileum; sodium absorption is enhanced by cotransport with glucose.
- Potassium moves passively across tight junctions with changes in the electrochemical gradient.

Carbohydrates

- Only monosaccharides are absorbed by the intestinal mucosa; therefore complex carbohydrates must be hydrolyzed to the simplest form.
- Salivary and pancreatic amylases break down starches to oligosaccharides (lactose, maltose, sucrose) in the stomach and duodenum; brush-border enzymes hydrolyze them in the small intestine so they can pass through the unstirred water layer by diffusion.
- Fructose diffuses into the bloodstream; glucose and galactose diffuse or are actively transported.
- Cellulose remains undigested and stimulates large intestine motility.

Proteins

- From 90%–95% of protein is absorbed; major hydrolysis is accomplished in the small intestine by the pancreatic enzymes trypsin, chymotrypsin, and carboxypeptidase.
- Brush-border enzymes break down proteins into smaller peptides that can cross cell membranes. In the cytosol, they are metabolized into amino acids, specifically neutral amino acids, basic amino acids, and proline and hydroxyproline.

Fats

Digestion and absorption occur in four phases:

- Phase 1—Emulsification and lipolysis: Emulsifying agents (bile salts) cover small fat particles and prevent them from reforming into fat droplets; then lipolysis with pancreatic lipases divides them into monoglycerides and free fatty acids.
- Phase 2—Micelle formation: A spherical formation of lipid products that are water soluble.
- Phase 3—Fat absorption: Fat products move from micelles to the absorbing surface of the intestinal epithelium and enter enterocytes.
- Phase 4—Triglycerides are resynthesized and, along with cholesterol, fat-soluble vitamins, and phospholipids, combine with proteins to form chylomicrons (lipoproteins). Chylomicrons leave the enterocyte, enter the lymphatics, and travel to the portal circulation.

Minerals

- Calcium—absorbed by passive diffusion and transported actively across cell membranes bound to a carrier protein; absorption primarily in the ileum.
- Magnesium—50% absorbed by active transport or passive diffusion in the jejunum and ileum.
- Phosphate—absorbed by passive diffusion and active transport in the small intestine.
- Iron—absorbed by epithelial cells of the duodenum and jejunum; vitamin C facilitates.

Vitamins

- Absorbed mainly by sodium-dependent active transport, with vitamin B_{12} bound to intrinsic factor and absorbed in the terminal ileum.

Water and electrolyte transport by the small intestine

The epithelial cell membranes of the small intestine are formed of lipids and are hydrophobic or tend to repel water. Therefore, water and electrolytes are transported in both directions (toward the capillary blood or toward the intestinal lumen) through the tight junctions and intercellular spaces rather than across cell membranes. Water diffuses passively across hydrostatic pressure and osmotic gradients established by the active transport of sodium and other substances. Approximately 85% to 90% of the water that enters the GI tract each day is absorbed in the small intestine. The remaining water and electrolytes are absorbed at a constant rate in the large intestine. Sodium passes through the tight junctions and is actively transported across cell membranes. Sodium and glucose share a common active transport carrier (sodium-glucose ligand transporter1 [SGLT1]) so that sodium absorption is enhanced by glucose transport (Fig. 40.14).[16] Potassium moves passively across the tight junctions with changes in the electrochemical gradient. Chloride is actively secreted throughout the large and small intestines.

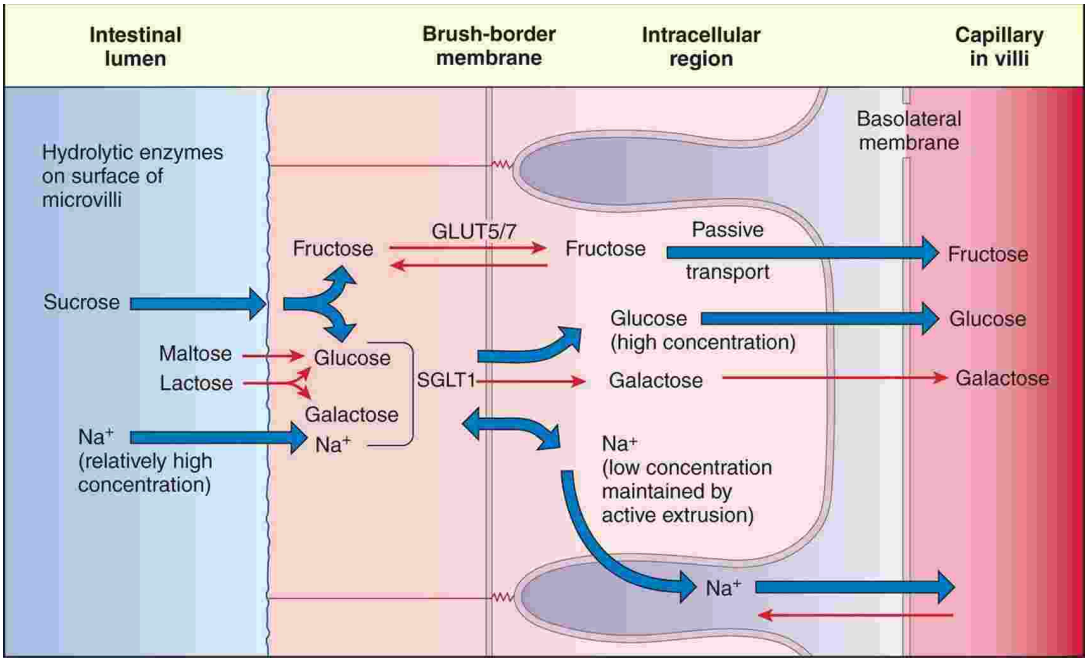

FIG. 40.14 Monosaccharides and Sodium Transport.
Schematic showing monosaccharides and sodium *(Na⁺)* transport through the small intestinal epithelium. Glucose, galactose, and sodium are transported into the epithelial cell by sodium-glucose ligand transporter 1 *(SGLT1)*. See text for details regarding other glucose transporters. *GLUT*, Glucose transporter.

A diagram depicts four regions in transport of monosaccharides and sodium. In intestinal lumen, hydrolytic enzymes on the surface of villi is indicated. Sucrose is broken down into fructose and glucose; maltose is converted into glucose; lactose is broken down into glucose and galactose. Glucose and galactose are taken into enterocyte by cotransport with sodium using transporter, S G L T 1. Fructose enters the cell from intestinal lumen through GLUT 5. Passive transport of fructose, high concentration of glucose, galactose, and low concentration of sodium maintained by active extrusion are transported from intracellular region into the capillaries in villi.

Carbohydrates

Only monosaccharides (ribose, galactose, glucose, fructose) are absorbed by the intestinal mucosa; the complex carbohydrates (polysaccharides and oligosaccharides)

must be hydrolyzed to their simplest form.[4] The major disaccharides are sucrose (glucose-fructose), maltose (glucose-glucose), and lactose (glucose-galactose) (see Fig. 40.14). Salivary and pancreatic amylases break down starches to oligosaccharides by splitting α-1,4-glucosidic linkages of long-chain molecules. Approximately half of starch hydrolysis occurs in the stomach and about half in the duodenum. In the small intestine, disaccharides are hydrolyzed by brush-border enzymes (sucrase, maltase, and lactase) to their respective monosaccharides.

The sugars are absorbed primarily in the duodenum and upper jejunum by facilitated diffusion mediated by glucose transporter proteins. The monosaccharides pass through the unstirred layer by diffusion. At the cell membrane, glucose and galactose are actively transported with a sodium carrier (SGLT1), and fructose absorption is facilitated by glucose transporter 5 (GLUT5) and GLUT7 (see Fig. 40.14).[17] Transport of all three monosaccharides from the cytosol to the bloodstream is facilitated by GLUT2. Insulin facilitates glucose transport into fat and muscle cells via glucose transporter 4 (GLUT4), but insulin is not required for the intestinal absorption of glucose.[18]

Proteins

Adults require 44 to 56 g of protein per day. Approximately 20 to 30 g of protein is derived endogenously from shed epithelial cells and small amounts of plasma proteins. Most ingested protein is absorbed; only 5% to 10% is eliminated in the stool.

The site of digestion of protein depends on the source of the protein. For example, casein from bovine milk precipitates in the stomach and is digested by gastric pepsin and acid, whereas the soluble proteins whey and soy pass rapidly through the stomach and are digested by pancreatic enzymes. Major protein hydrolysis is accomplished in the small intestine by the pancreatic enzymes trypsin, chymotrypsin, and carboxypeptidase (see Fig. 40.12).[4] **Trypsin** and **chymotrypsin** (endopeptidase) hydrolyze the interior bonds of the large molecules, and **carboxypeptidases** cleave the end amino acids (exopeptidase). Hydrolysis of proteins is also carried out by the brush-border enzymes and enzymes in the epithelial cytosol (intracellular fluid). The brush-border enzymes hydrolyze the large oligopeptides (proteins composed of three to six amino acids) into smaller peptides, which can cross cell membranes. Enzymes in the cytosol then break them down to amino acids. Amino acids are actively transported from the cytosol into the bloodstream by a sodium-dependent carrier in the basolateral membrane. There also are free amino acids that can be absorbed directly from the intestinal lumen using a membrane transport protein. Like the sugars, proteins are absorbed primarily in the proximal area of the small intestine.

Fats

Approximately 90 to 100 g of fat is consumed daily by the average American. **Fat** is an important source of calories and is a primary structural component of cell membranes and organelles. Sources of dietary fat are reviewed in Box 40.4. Although triglycerides are the major dietary lipids, cholesterol, phospholipids, and fat-soluble vitamins also have nutritional importance. The digestion and absorption of fat occur in four phases:

(1) emulsification and lipolysis, (2) micelle formation, (3) fat absorption, and (4) resynthesis of triglycerides and phospholipids.

Box 40.4

Dietary Fat

Saturated Fatty Acid (Palmitic Acid [$C_16H_{32}O_2$])

Solid at room temperature
Each carbon atom in the chain is linked by single bonds to adjacent carbon and hydrogen atoms
Found in animal fat and tropical oils (coconut and palm oils)
Increase the blood levels of low-density lipoprotein (LDL) cholesterol ("bad" cholesterol) and also the risk of coronary artery disease

Unsaturated Fatty Acid

Soft or liquid at room temperature

Monounsaturated Fatty Acids (e.g., oleic acid [$C_{18}H_{34}O_2$])

Contain one double bond in the carbon chain
Found in plants and animals
May be beneficial in reducing blood cholesterol, glucose levels, and systolic blood pressure; do not lower high-density lipoprotein (HDL) cholesterol ("good" cholesterol) level; low HDL levels have been associated with coronary heart disease.

Polyunsaturated Fatty Acids (e.g., linoleic acid [C18H32O2])

Contain two or more double bonds in the carbon chain
Found in plants and fish oils
Omega-6 fatty acids lower total and LDL cholesterol blood levels
Omega-3 fatty acids lower blood triglyceride levels; reduce platelet aggregation and blood-clotting tendencies; are necessary for growth and development; and may prevent coronary artery disease, hypertension, cancer, and inflammatory and immune disorders

The mechanical action of the stomach and small intestine disperses the triglyceride droplets into small particles. **Emulsification** is the process by which emulsifying agents (fatty acids, monoglycerides, lecithin, cholesterol, protein, bile salts) in the small intestinal lumen cover the small fat particles and prevent them from re-forming into fat droplets. Emulsified fat is then ready for **lipolysis** (lipid hydrolysis) by lingual

and gastric lipase (acid lipases), pancreatic lipase, phospholipase, and hydrolase (alkaline lipases).[4] **Lipase** breaks down triglycerides to diglycerides, monoglycerides, free fatty acids, and glycerol (see Fig. 40.12). The action of alkaline lipases requires the presence of **colipase**, a pancreatic coenzyme that allows lipase to penetrate the triglyceride molecule. **Phospholipase** cleaves fatty acids from phospholipids, and **cholesterol esterase** breaks cholesterol esters into fatty acids and glycerol.

The products of lipid hydrolysis must be made water soluble if they are to be absorbed efficiently from the intestinal lumen. This is accomplished by the formation of water-soluble molecules known as **micelles** (Fig. 40.15). Micelles are formed of bile salts, the products of fat hydrolysis, fat-soluble vitamins, and cholesterol. The fats form the core of the micelle, and the polar bile salts form an outer shell, with the hydrophobic ("water-repelling") side facing the interior and the hydrophilic ("water-loving") side facing the aqueous (water-like) content of the intestinal lumen. Because the unstirred layer of the brush border is aqueous, the micelles readily diffuse through it (Fig. 40.16). The micelles maintain the fat molecules in the dissolved or solubilized form, which allows them to move more rapidly from the micelle toward the absorbing surface of the intestinal epithelium. The fat products of the micelle then readily diffuse through the epithelial cell membrane, while the bile salts remain in the lumen and proceed to the ileum, where they are absorbed into the circulation and returned to the liver via the enterohepatic circulation (see Fig. 40.22). Almost all the bile salts are recycled in this way.

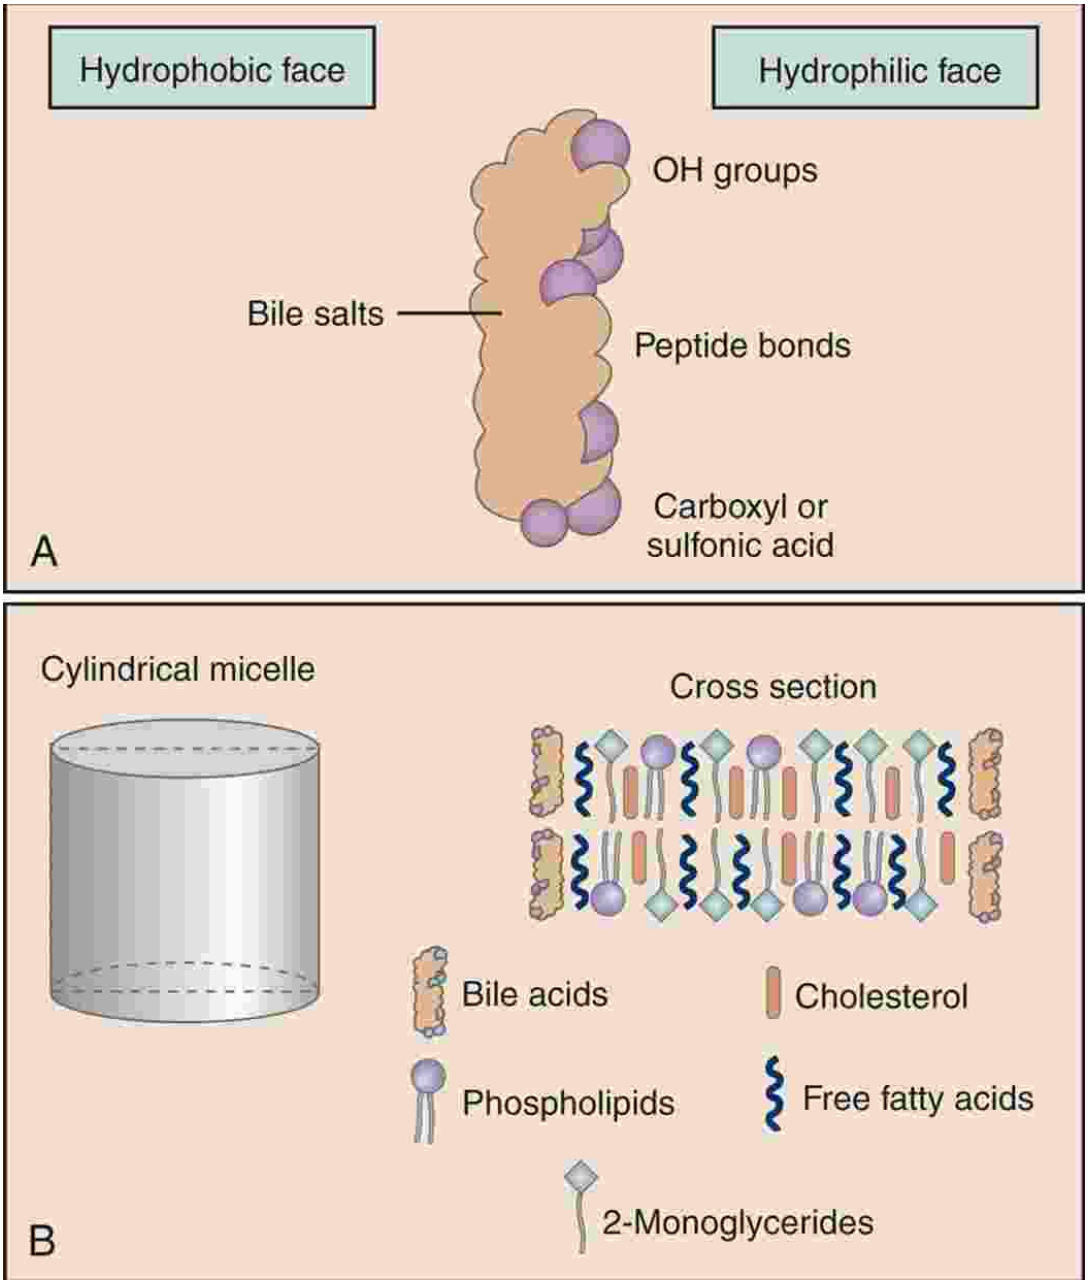

FIG. 40.15 Structure of Bile Acid and Micelle.
(A) A bile salt molecule in solution. The molecule is amphipathic in that it has a hydrophilic face and a hydrophobic face. The amphipathic structure is key in the ability of the bile salts to emulsify lipids and form micelles. **(B)** A model of the structure of a bile salt–lipid mixed micelle, an emulsified fat. (From Levy MN, Koeppen BM, Stanton BA. *Principles of Physiology*. 4th ed. St Louis: Mosby; 2006.)

Two illustrations depict the structure of bile acid and micelle. Part A shows a bile acid, with the hydrophobic and hydrophilic faces depicted and the parts labeled from top to bottom as follows: O H groups, peptide bonds, and carboxyl or sulfonic acid. Part B. Left: An illustration of a cylindrical structure, labeled micelle. Right: A cross section of a micelle shows the composition of free fatty acids, 2-monoglycerides, phospholipids, free cholesterol, and bile acids.

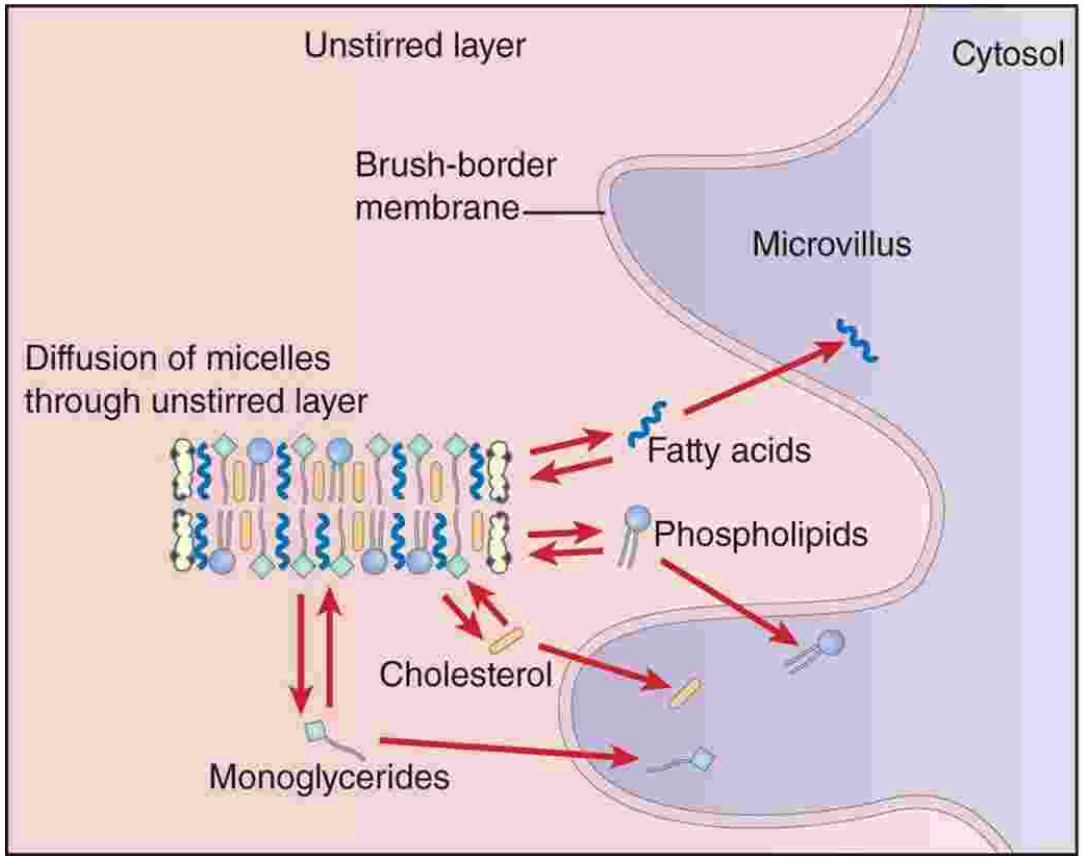

FIG. 40.16 Lipid Absorption in the Small Intestine.
Micelles of bile salts and products of lipid digestion diffuse through the unstirred layer and among the microvilli. As digestive products are absorbed from free solution by epithelial cells of the villi, more digestive products dissociate from the micelles. (From Levy MN, Koeppen BM, Stanton BA. *Principles of Physiology*. 4th ed. St Louis: Mosby; 2006.)

An illustration depicts lipid absorption in the small intestine, with the unstirred layer on one side and the cytosol on the other side with the brush-border membrane separating the layers. The presence of microvilli in the small intestine is depicted. Diffusion of micelles through unstirred layer is depicted. Mixed micelles comprise fatty acids, monoglycerides, phospholipids, free cholesterol, and bile salts. The concentration of these products is visible close to the brush-border membrane.

When the fat products reach the inside of the epithelial cell, they are resynthesized into triglycerides and phospholipids. The triglycerides are covered with

phospholipids, lipoproteins, and cholesterol to become particles called **chylomicrons**. The chylomicrons travel to the basolateral membrane of the columnar epithelial cells, where they are extruded into the intercellular spaces of the villus. From here they enter the lacteals and lymphatic channels and, eventually, the systemic circulation.

Minerals and vitamins

The recommended intake of **calcium** ranges from 1000 to 1500 mg/day. Between 500 and 600 mg is secreted or shed into the lumen with epithelial cell shedding. Not all this calcium is absorbed. Daily absorption of calcium is approximately 600 mg. This amount increases with increased intake.

Calcium homeostasis requires coordination between the intestine, kidney, bone, and parathyroid glands (see Chapter 21). Calcium is absorbed throughout the small intestine, primarily in the ileum. It is absorbed both between intestinal cells (paracellular) and through them (transcellular).[19] When its concentration in the lumen is greater than 5 mmol/L, calcium is absorbed by passive diffusion between cells through a paracellular mechanism. At concentrations less than 5 mmol/L, calcium enters intestinal epithelial cells through two calcium channels that respond to the presence of vitamin D_3. Once inside the cells, it is transported through the cytoplasm bound to carrier proteins called calbindins.[19] The calcium-protein complexes move through the basolateral membrane into the bloodstream by active transport using plasma membrane calcium-ATPase (PMCA) and the sodium/calcium exchanger (NCX1). Increased serum calcium concentration inhibits parathyroid hormone, which in turn decreases the formation of vitamin D_3 by the kidney, thus regulating calcium absorption.

Increased demand for calcium results in increased uptake, as evidenced by the fact that calcium is absorbed more rapidly in children and pregnant or lactating women.[19] Bile salts enhance calcium absorption indirectly by facilitating the absorption of vitamin D, which is fat soluble.

The recommended intake of **magnesium** for adults is 300 to 350 mg/day. Approximately 50% of it is absorbed by active transport or passive diffusion in the jejunum and ileum. **Phosphate** is also absorbed in the small intestine by passive diffusion and active transport.

The levels of **iron** in the body are regulated primarily by intestinal absorption and secretion. The average intake ranges from 15 to 30 mg/day. Of this amount, menstruating women absorb 1 to 1.5 mg and men absorb 0.15 to 1 mg. Generally, the amount of iron absorbed is equal to the amount required. Iron is absorbed more rapidly if a deficiency exists. A primary source of iron is heme from animal protein with a smaller amount of heme from recycling of old red blood cells. This iron is rapidly absorbed by the epithelial cells primarily in the proximal duodenum. Inorganic iron (e.g., iron in fruits, cereals, eggs, vegetables) is also readily absorbed. The presence of gastric acid and vitamin C in the duodenum reduces ferric iron to ferrous iron, which is the form more easily absorbed. Calcium phosphate and phosphoproteins (milk and antacids) in the intestinal lumen bind iron and reduce

absorption. Tea also binds iron and inhibits absorption by forming iron tannate complexes.

Iron is bound to *intestinal transferrin* in the lumen and is absorbed and bound to the protein *ferritin* and to amino acid chelates in the cytosol of the enterocytes. Transport of iron across the basolateral membrane is determined by the amount of iron in the circulation. It is transported in the blood by *plasma transferrin*, a glycoprotein, and is carried to body tissues. When there is less need for iron, it remains in the enterocyte as ferritin and is carried into the lumen when the cell is sloughed from the end of the villus. Following hemorrhage, the intestinal cells require 3 days to increase their rate of iron absorption. This is because the need for iron is perceived by the precursor stem cells in the crypts of Lieberkühn, and they take 3 days to mature and migrate to the tips of the villi, where they absorb more iron. **Hepcidin** is a protein synthesized by the liver that inhibits apical uptake of iron by enterocytes and modulates iron trafficking (see Chapter 28).[20]

The absorption of **vitamins** is summarized in Table 40.2. Most of the water-soluble vitamins are absorbed passively or by sodium-dependent active transport.[4] Most vitamin B_{12} (cobalamin) is bound to intrinsic factor (making it resistant to digestion) and absorbed in the terminal ileum, although a small amount of the vitamin is absorbed in its free (unbound) form.

Table 40.2

Intestinal Absorption of Vitamins

Vitamin	Mechanisms of Absorption	Site of Absorption
Fat-Soluble Vitamins		
A (retinal)	Micelle formation with bile salts; lipid diffusion	Ileum
D_3 (1,25-dihydroxy-vitamin D)		
E (α-tocopherol)		
K		
Water-Soluble Vitamins		
B_1 (thiamine)	Active transport (sodium dependent)	Duodenum and jejunum
B_2 (riboflavin)	Unknown	Duodenum and jejunum
Niacin (nicotinic acid)	Passive diffusion	Jejunum
C (ascorbic acid)	Passive diffusion; active transport (sodium dependent)	Ileum
Folic acid	Active transport (sodium dependent)	Jejunum
B_{12} (cobalamin)	Active transport (intrinsic factor dependent)	Terminal ileum
B_6 (pyridoxine, pyridoxamine, pyridoxal phosphate)	Passive diffusion	Jejunum
Pantothenic acid	Passive diffusion	Duodenum and jejunum
Biotin	Unknown	Unknown

Vitamin	Mechanisms of Absorption	Site of Absorption
Fat-Soluble Vitamins

Niacin (nicotinic acid)	Passive diffusion	Jejunum
C (ascorbic acid)	Passive diffusion; active transport (sodium dependent)	Ileum
Folic acid	Active transport (sodium dependent)	Jejunum
B_{12} (cobalamin)	Active transport (intrinsic factor dependent)	Terminal ileum
B_6 (pyridoxine, pyridoxamine, pyridoxal phosphate)	Passive diffusion	Jejunum
Pantothenic acid	Passive diffusion	Duodenum and jejunum
Biotin	Unknown	Unknown

Intestinal Motility

The movements of the small intestine facilitate digestion and absorption. Chyme leaving the stomach and entering the duodenum stimulates intestinal movements that help blend secretions from the liver, gallbladder, pancreas, and intestinal glands. A churning motion brings the luminal contents into contact with the absorbing cells of the villi. Propulsive movements then advance the chyme toward the large intestine. The two movements that promote motility are segmentation and peristalsis.

Segmentation consists of localized rhythmic contractions of the circular smooth muscles and occurs more frequently than peristalsis. The contraction waves occur at different rates in different parts of the small intestine in segments of 1 to 4 cm. Frequency is greatest (12/min) in the upper small intestine and least (8/min) in the distal part of the ileum. Segmentation divides and mixes the chyme, bringing it into contact with the absorbent mucosal surface. It also helps to propel the chyme toward the large intestine. The frequency of the segmentation is regulated intrinsically by the frequency of the basic electrical rhythm, which arises in the myenteric plexus of longitudinal smooth muscle and is controlled by the pacemaker cells of the GI tract.[4] Although the basic rate of contraction is controlled intrinsically, the force of contraction can be enhanced extrinsically by vagal stimulation.

Intestinal **peristalsis** is waves of contraction along short segments (about 10 cm) of longitudinal smooth muscle and propels chyme through the intestine. The intestinal villi move with contractions of the muscularis mucosae, a thin layer of muscle separating the mucosa and submucosa, with absorption promoted by the swaying of the villi in the luminal contents. The wave of contraction moves slowly (1 to 2 cm/s) to allow time for digestion and absorption.

Neural reflexes along the length of the small intestine facilitate motility, digestion, and absorption. Through reflex action, receptors in one part of the intestine transmit signals that influence the function of another part. The **ileogastric reflex** inhibits

gastric motility when the ileum becomes distended. This prevents the continued movement of chyme into an already distended intestine. The **intestinointestinal reflex** inhibits intestinal motility when one part of the intestine is overdistended or its mucosa is irritated. Both of these reflexes require extrinsic innervation. The **gastroileal reflex**, which is activated by an increase in gastric motility and secretion, stimulates an increase in ileal motility and relaxation of the ileocecal valve. This empties the ileum and prepares it to receive more chyme. The gastroileal reflex is regulated by the hormones gastrin and cholecystokinin or through the autonomic nerves.

During prolonged fasting or between meals, particularly overnight, slow waves sweep along the entire length of the intestinal tract from the stomach to the terminal ileum. This interdigestive myoelectric complex appears to propel residual gastric and intestinal contents into the colon.

The ileocecal valve (sphincter) marks the junction between the terminal ileum and the large intestine. This valve is intrinsically regulated and is normally closed. The arrival of peristaltic waves from the last few centimeters of the ileum causes the ileocecal valve to open, allowing a small amount of chyme to pass. Distention of the upper large intestine causes the sphincter to constrict, preventing further distention or retrograde flow of intestinal contents.

Large Intestine

The **large intestine** is approximately 1.5 m long and consists of the cecum, appendix, colon, rectum, and anal canal (Fig. 40.17A). The **cecum** is a pouch that receives chyme from

Emerging Science Box

The Appendix in Health and Disease

The appendix has long been considered an evolutionary redundancy. However, emerging evidence suggests that it has two key functions: (1) it contains large amounts of lymphoid tissue and is important in immune function, and (2) it hosts a microbiome that continuously sheds into the intestinal lumen thus preventing intestinal dysbiosis. The appendiceal mucosa contains numerous macrophages, T, and B lymphocytes, large amounts of immunoglobulin A and immunoglobulin G generating plasma cells and is located near numerous lymphoid follicles. It plays a key role in both immune activation and tolerance. There is increasing evidence that the appendix helps to maintain tolerance to food-borne microorganisms by shifting intestinal immune cells from proinflammatory to anti-inflammatory responses. It is postulated that appendicitis occurs when proinflammatory processes (e.g., production of high levels of interferon-γ) overcome its anti-inflammatory mechanisms. With regard to its role in maintaining the intestinal microbiome, biofilms of healthy microbiota in the appendix constantly inoculate the distal ileum and proximal colon. Variations in the intestinal microbiome that result from diet, illness, and medications result in increased shedding of microorganisms from the

appendix into the intestinal lumen, helping to maintain microbiome homeostasis. Recent studies suggest that individuals who have undergone appendectomy may be at some increased risk for inflammatory bowel disease and more severe complications from *Clostridium difficile* infection. In contrast, there is an emerging link between appendectomy and a decreased risk for the development of Parkinson disease. The appendix is highly innervated by the autonomic nervous system and contains a concentration of an intraneural protein called α-synuclein (α-syn). It is postulated that the complex interaction among the appendiceal microbiome, enteric nervous system, and immune system results in an autoimmune response to α-syn that spreads to the brain via the vagus nerve. Aggregates of this compound accumulate in Lewy Bodies, a hallmark of Parkinson disease.

The vermiform appendix: an immunological organ sustaining a microbiome inoculum. *Clin Sci*. 2019;133(1):1–8.

the ileum. Attached to it is the **vermiform appendix**, an appendage having limited physiologic function. However, recent studies suggest it may have an important protective role in gut immunity (Emerging Science Box: The Appendix in Health and Disease). From the cecum, chyme enters the **colon**, which loops upward, traverses the abdominal cavity, and descends to the anal canal. The four parts of the colon are the **ascending colon**, **transverse colon**, **descending colon**, and **sigmoid colon**. Two sphincters control the flow of intestinal contents through the cecum and colon: the ileocecal valve, which admits chyme from the ileum to the cecum; and the **rectosigmoid canal**, which controls the movement of wastes from the sigmoid colon into the rectum. A thick (2.5 to 3 cm) portion of smooth muscle surrounds the anal canal, forming the **internal anal sphincter**. Overlapping it distally is the striated skeletal muscle of the **external anal sphincter (anus)**.

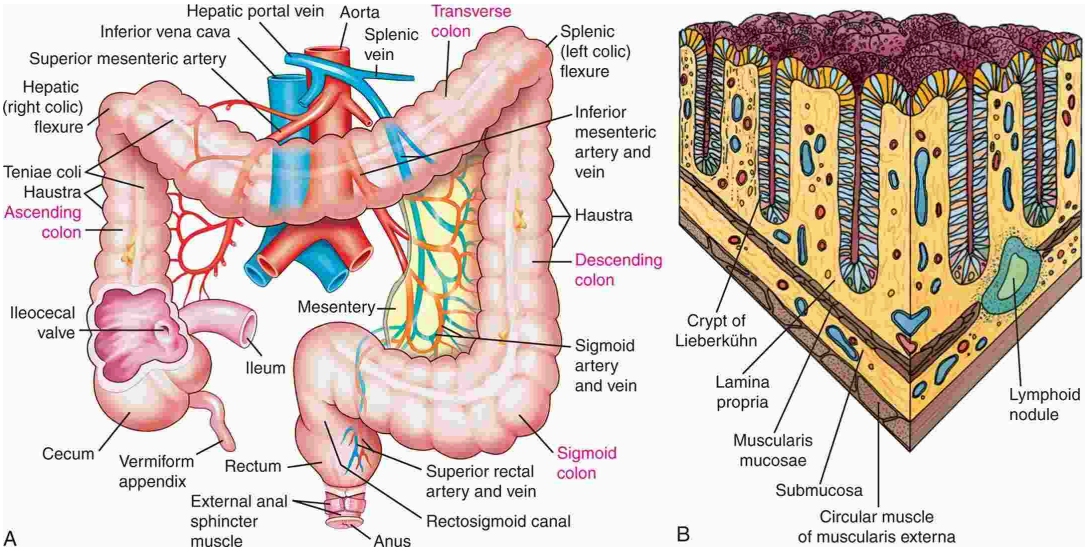

FIG. 40.17 The Large Intestine. **(A)** Structure of the large intestine. **(B)** Microscopic cross section illustrating cellular structures of the large intestine. The wall of the large intestine is lined with columnar epithelium, in contrast to the villi characteristics of the small intestine. The longitudinal layer of muscularis is reduced to become the teniae coli. (A, Modified from Patton KT, Thibodeau GA. *The Human Body in Health & Disease*. 7th ed. St Louis: Mosby; 2018; B, From Gartner LP, Hiatt JL. *Color Textbook of Histology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

Two illustrations depict different views of the large intestine. Part A: The parts of the large intestine are labeled from top to bottom as follows. aorta, hepatic portal vein, inferior vena cava, splenic vein, superior mesenteric artery, transverse colon, splenic or left colic flexure, hepatic or right colic flexure, inferior mesenteric artery and vein, teniae coli, haustra, ascending colon, mesentery, descending colon, ileocecal valve, ileum, cecum, vermiform appendix, sigmoid artery and vein, sigmoid colon, superior rectal artery and vein, rectum, external anal sphincter muscle, and anus. Part B depicts the cross section of large intestine with the parts labeled as follows: crypt of Lieberkuhn, submucosa, lamina propria, circular muscle of muscularis externa, muscularis mucosae, and lymphoid nodule.

In the cecum and colon, the longitudinal muscle layer consists of three longitudinal bands called **teniae coli** (see Fig. 40.17B). They are shorter than the colon and give it a gathered appearance. The circular muscles of the colon separate the gathered areas into outpouchings called **haustra** (sing., **haustrum**). The haustra become more or less prominent with the contractions and relaxations of the circular muscles. The mucosal surface of the colon has rugae (folds), particularly between the haustra, and crypts of Lieberkühn but no villi. Columnar epithelial cells and mucus-secreting goblet cells form the mucosa throughout the large intestine. The columnar epithelium absorbs fluid and electrolytes, and the mucus-secreting cells lubricate the mucosa.

In the large intestine, extrinsic parasympathetic innervation occurs through the vagus nerve. Vagal stimulation increases rhythmic contraction of the proximal colon from the cecum to the first part of the transverse colon. Vagal fibers reach the distal colon through the sacral parasympathetic splanchnic nerves. The internal anal sphincter is usually contracted, and its reflex response is to relax when the rectum is distended. The intrinsic myenteric plexus provides the major innervation of the internal anal sphincter but responds to sympathetic stimulation to maintain contraction and parasympathetic stimulation that facilitates relaxation when the rectum is full. Sympathetic innervation of this sphincter arises from the celiac and superior mesenteric ganglia and the sphincter nerve. The external anal sphincter is innervated by the pudendal nerve arising from sacral levels of the spinal cord. Sympathetic activity in the entire large intestine modulates intestinal reflexes, conveys somatic sensations of fullness and pain, participates in the defecation reflex, and constricts blood vessels. The blood supply of the large intestine and rectum is derived primarily from branches of the superior and inferior mesenteric arteries[21] (see Figs. 40.7 and 40.17A) and venous blood drains through the inferior mesenteric vein.

The primary type of colonic movement is segmental. The circular muscles contract and relax at different sites, shuttling the intestinal contents back and forth between the haustra, most commonly during fasting. The movements massage the intestinal contents, called the **fecal mass** at that point, and facilitate the absorption of water. Propulsive movement occurs with the proximal-to-distal contraction of several haustral units. Peristaltic movements also occur and promote the emptying of the colon. The **gastrocolic reflex** initiates propulsion in the entire colon, usually during or immediately after eating, when chyme enters from the ileum. The gastrocolic reflex causes the fecal mass to pass rapidly into the sigmoid colon and rectum, stimulating defecation. It is mediated by vagal stimulation along with gastrin and cholecystokinin.[4] Epinephrine inhibits contractile activity, as do exogenous opioids.

Approximately 500 to 700 mL of chyme flows from the ileum to the cecum per day. Most of the water is absorbed in the colon by diffusion and active transport. Aldosterone increases colon membrane permeability to sodium, thereby increasing both the diffusion of sodium into the cell and the active transport of sodium across the basolateral membrane to the interstitial fluid. (See Chapters 3 and 21 for a discussion of aldosterone secretion.) This increases the cell-to-lumen diffusion gradient for potassium. Potassium moves outward, and chloride is absorbed with sodium as the complementary anion. Chloride also enters the cell in exchange for bicarbonate. The

colon does not absorb monosaccharides and amino acids, but some short-chain free fatty acids, which are produced by bacterial fermentation, are absorbed.

Absorption and epithelial transport occur in the cecum, ascending colon, transverse colon, and descending colon. By the time the fecal mass enters the sigmoid colon, the mass consists entirely of wastes, called the **feces**, and is composed of food residue, unabsorbed GI secretions, shed epithelial cells, and bacteria.

The movement of feces into the sigmoid colon and **rectum** stimulates the **defecation reflex (rectosphincteric reflex)**. The rectal wall stretches, and the tonically constricted internal anal sphincter (smooth muscle with ANS control) relaxes, creating the urge to defecate. The defecation reflex can be overridden voluntarily by contraction of the external anal sphincter and muscles of the pelvic floor. The rectal wall gradually relaxes, reducing tension, and the urge to defecate passes. Retrograde contraction of the rectum may displace the feces out of the rectal vault until a more convenient time for evacuation. Pain or fear of pain associated with defecation (e.g., rectal fissures or hemorrhoids) can inhibit the defecation reflex. The defecation reflex is regulated by parasympathetic cholinergic fibers. Voluntary inhibition or facilitation of defecation is mediated from cortical projections onto the medulla and down to sacral segments of the cord.

Squatting and sitting facilitate defecation because these positions straighten the angle between the rectum and anal canal and increase the efficiency of straining (increasing intra-abdominal pressure). Intra-abdominal pressure is increased by initiating the **Valsalva maneuver**—that is, inhaling and forcing the diaphragm and chest muscles against the closed glottis to increase both intrathoracic and intra-abdominal pressure, which is transmitted to the rectum.

The Gastrointestinal Tract and Immunity

The GI tract's **gut-associated lymphoid tissue (GALT)** plays a major role in immune defenses by killing many pathogenetic microorganisms and preventing reaction to foreign proteins (dietary antigens) ingested in the diet. It also plays a fundamental role in modulating the systemic adaptive immune system through its interaction with resident microorganisms (microbiome) (see Chapter 8).[22] The mucosa of the intestine covers a large surface area, and mucosal secretions produce antibodies, particularly IgA, and enzymes that provide defenses against pathogenic microorganisms. Small intestinal **Paneth cells**, located near the base of the crypts of Lieberkühn (see Fig. 40.11B), produce defensins and other antimicrobial peptides and lysozymes important to mucosal immunity. Small intestinal **Peyer patches** (lymph nodules containing collections of lymphocytes, plasma cells, and macrophages) are most numerous in the ileum and produce antimicrobial peptides and IgA as a component of GALT in the small intestine (see Figs. 40.2 and 8.3). Peyer patches are important for antigen processing and immune defense (see Chapter 8).

Intestinal Microbiome

The type and number of bacterial flora vary greatly through-out the normal GI tract and among individuals. The normal flora of the GI tract are called the **intestinal microbiome**. There are an increasing number of bacteria from the proximal to the distal GI tract, with the highest number in the colon. Bacteria in the stomach are relatively sparse because of the secretion of hydrochloric acid that kills ingested pathogens or inhibits bacterial growth (with the exception of *H. pylori*). Bile acid secretion, intestinal motility, and antibody production suppress bacterial growth in the duodenum. In the duodenum and jejunum, there is a low concentration of aerobes, primarily streptococci, lactobacilli, staphylococci, enterobacteria, and *Bacteroides*. Anaerobes are found distal to the ileocecal valve but not proximal to the ileum. They constitute about 95% of the fecal flora in the colon and contribute one-third of the solid bulk of feces. *Bacteroides* (gram negative) and *Firmicutes* (gram positive) are the most common colon bacteria.

The microorganisms that inhabit the healthy GI tract (normal flora) generally do not have the virulence factors associated with pathogenic microorganisms. Intestinal bacteria play a role in the metabolism of bile salts, estrogens, androgens, lipids, carbohydrates, various nitrogenous substances, and drugs. They produce antimicrobial peptides, hormones, neurotransmitters, anti-inflammatory metabolites, vitamin K_2, and B vitamins; destroy toxins; prevent pathogen colonization; and alert the immune system to protect against infection. The GI microbiome also has regulatory influences on systemic innate and adaptive immune responses and inflammation, including expansion and activity of T-cell populations and systemic anti-inflammatory signaling (see Chapters 7 and 8).

Genetics, diet, environmental pollution, personal hygiene, vaccination, infection, antibiotics and other drugs, and radiation affect the normal composition of bacterial flora.[22] The intestinal tract is sterile at birth but becomes colonized within a few hours. Within 3 to 4 weeks after birth, the normal flora are established. The health of the gut microbiome in early life is a predictor of diseases such as allergy and autoimmune conditions in later life.[23] The number and diversity of bacteria decrease with aging, increasing the risk for infection and disease. Deleterious changes in the gut microbiome (dysbiosis) are associated with a large range of disorders including cardiac, pulmonary, endocrine, GI, and neurological diseases; obesity; cancer; viral and bacterial infections; sepsis; cognitive impairment; and mental health conditions. Dietary and lifestyle changes can improve the health of the intestinal microbiome. Fecal microbiota transplantation is being used to reverse GI dysbiosis for the treatment of many disorders including diabetes, cancer, and Parkinson disease.[24] With regard to GI diseases, fecal transplant has been used with considerable success for Clostridium difficile infection, as well as inflammatory bowel disease, irritable bowel disease, and liver disease.

Splanchnic Blood Flow

The **splanchnic (visceral) blood flow** provides blood to the esophagus, stomach, small and large intestines, liver, gallbladder, pancreas, and spleen (see Fig. 40.7).

Blood flow is regulated by cardiac output and blood volume, the ANS, hormones, and local autoregulatory blood flow mechanisms. The GI circulation serves as an important reservoir of blood volume to maintain circulation to the heart and lungs when needed.

Accessory Organs of Digestion

The liver, gallbladder, and exocrine pancreas all secrete substances necessary for the digestion of chyme. These secretions are delivered to the duodenum through the sphincter of Oddi at the major duodenal papilla (of Vater) (Fig. 40.18). The liver produces bile, which contains salts necessary for fat digestion and absorption. Between meals, bile is stored in the gallbladder. The exocrine pancreas produces (1) enzymes needed for the complete digestion of carbohydrates, proteins, and fats; and (2) an alkaline fluid that neutralizes chyme, creating a duodenal pH that supports enzymatic action.

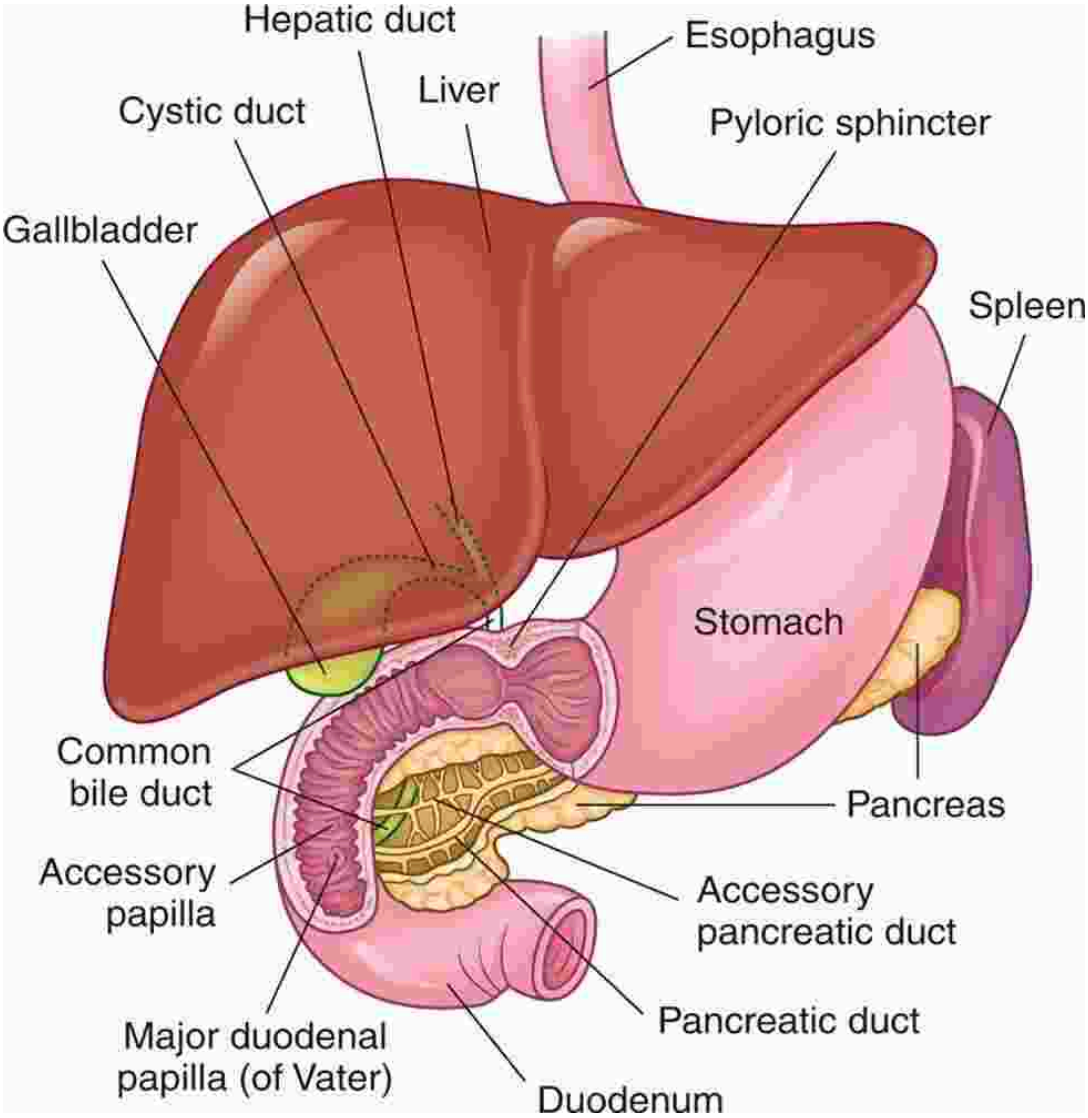

FIG. 40.18 Accessory Organs of Digestion.
Location of the liver, gallbladder, and exocrine pancreas.

An illustration depicts the major accessory organs of digestion. The organs are labeled from top to bottom as follows: esophagus, liver, spleen, stomach, hepatic duct, cystic duct, gallbladder, common bile duct, pancreas, accessory papilla, accessory pancreatic duct, pancreatic duct, major duodenal papilla of Vater, and duodenum.

The liver also receives nutrients absorbed by the small intestine and metabolizes or synthesizes them into forms that can be absorbed by the body's cells. It then releases the nutrients into the bloodstream or stores them for later use.

Liver

The **liver** weighs 1200 to 1600 g and is the largest solid organ in the body. It is located under the right diaphragm and is divided into right and left lobes (Fig. 40.19). The larger, right lobe is divided further into the caudate and quadrate lobes. The *falciform ligament* separates the right and left lobes and attaches the liver to the anterior abdominal wall. A fibrous cord that is a remnant of the umbilical vein, called the *round ligament (ligamentum teres)*, extends along the free edge of the falciform ligament, extending from the umbilicus to the inferior surface of the liver.[6] The *coronary ligament* branches from the falciform ligament and extends over the superior surface of the right and left lobes, binding the liver to the inferior surface of the diaphragm. The liver is covered by a fibroelastic capsule called the **Glisson capsule**, which contains blood vessels, lymphatics, and nerves. When the liver is diseased or swollen, distention of the capsule causes pain because it is innervated by sensory neurons of the lower intercostal nerves.

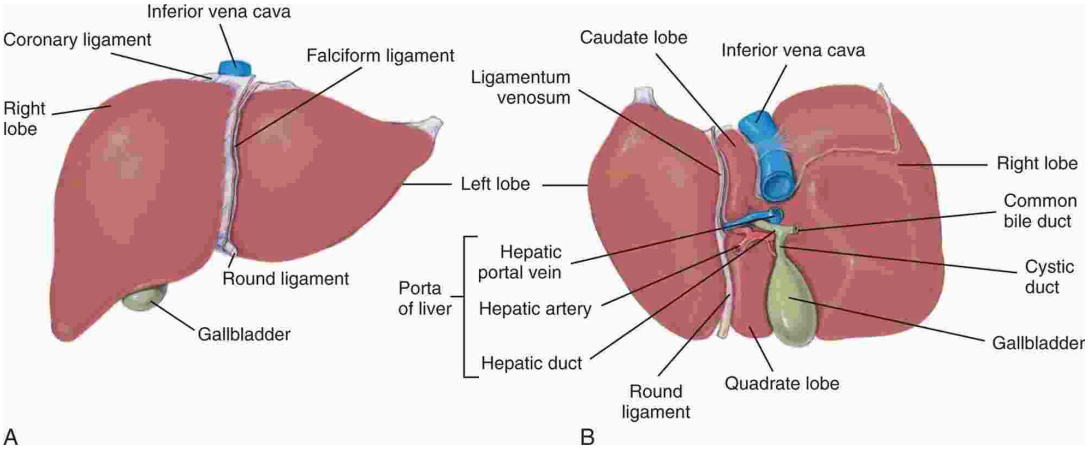

FIG. 40.19 Gross Structure of the Liver.
(A) Anterior surface. **(B)** Visceral surface. (From Applegate E. *The Anatomy and Physiology Learning System*. 4th ed. St Louis: Saunders; 2011.)

An illustration of two different surfaces of the liver labeled. Part A: The parts in the anterior surface are labeled from top to bottom as follows: inferior vena cava, coronary ligament, right lobe, left lobe, falciform ligament, round ligament, and gallbladder. Part b: The parts in the visceral surface are labeled from top to bottom as follows: inferior vena cava; caudal lobe; right lobe; left lobe; ligamentum venosum; porta of liver comprising hepatic portal vein, hepatic artery, and hepatic duct; common bile duct; cystic bile duct; quadrate lobe; and gallbladder.

The metabolic functions of the liver require a large amount of blood. The liver receives blood from both arterial and venous sources. The **hepatic artery** is formed by the merging of superior mesenteric and splenic veins and receives blood from the inferior mesenteric, gastric, and cystic veins. The hepatic artery supplies one-third of the blood supply, while the hepatic portal vein supplies two-thirds.[6] The liver receives approximately 25% of the overall cardiac output even though it only accounts for less than 3% of the total body weight. The hepatic artery provides arterial oxygenated blood to the liver, whereas the **hepatic portal vein** delivers deoxygenated blood which it receives from the inferior and superior mesenteric veins, the splenic vein, and the gastric and esophageal veins (see Fig. 40.7). The blood supplied by the hepatic portal vein is rich in nutrients that have been absorbed from the intestinal tract (Fig. 40.20).

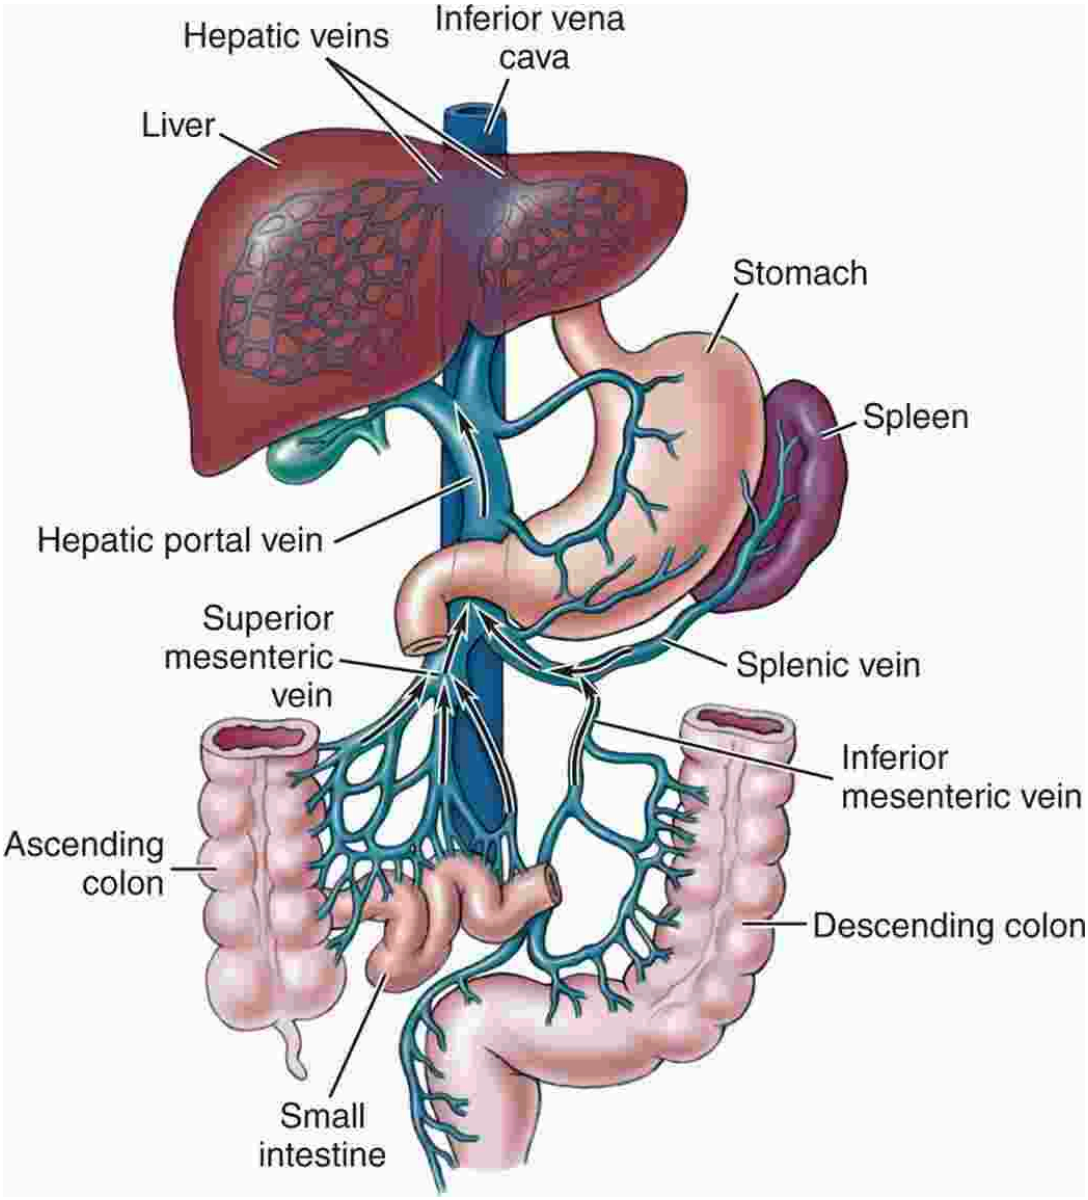

FIG. 40.20 Hepatic Portal Circulation.
In this unusual circulatory route, a vein is located between two capillary beds. The hepatic portal vein collects blood from capillaries in visceral structures located in the abdomen and empties into the liver. Hepatic veins return blood to the inferior vena cava. (From Herlihy B. *The Human Body in Health and Illness*. 5th ed. St Louis: Saunders; 2015.)

An illustration shows the hepatic portal system. The veins that are part of the system are: hepatic portal vein; splenic vein that carries blood from the spleen; superior mesenteric vein that carries blood from the small intestine and ascending colon; and inferior

mesenteric vein that carries blood from the descending colon. The inferior mesenteric vein connects on the splenic vein. The superior mesenteric vein and splenic vein come together to form the hepatic portal vein that passes the collected blood to the liver. The hepatic veins drain into the inferior vena cava.

Within the liver lobes are approximately 100,000 tiny anatomic units called **liver lobules** which are spatially zonated between the portal and central veins (Fig. 40.21). They are formed of cords or plates of **hepatocytes**, which are the functional cells of the liver. These cells line up along the porto-central blood flow, so that they can metabolize nutrients, as well as produce and recycle proteins.[25] They can regenerate; therefore, damaged or resected liver tissue can regrow. Hepatocytes secrete electrolytes, lipids, lecithin, bile acids, and cholesterol into the canaliculi. Plasma proteins are also synthesized and released into the bloodstream. Hepatocyte function is adjusted temporally to meet the changing metabolic demands of daily feeding cycles.[25]**Lipocytes** are star-shaped cells that store lipids, including vitamin A. Small capillaries, or **sinusoids**, are located between the plates of hepatocytes. They receive a mixture of venous and arterial blood from branches of the hepatic artery and portal vein. Blood from the sinusoids drains to a central vein in the middle of each liver lobule. Venous blood from all the lobules then flows into the **hepatic vein**, which empties into the inferior vena cava. The sinusoids of the liver lobules are lined with highly permeable endothelium. This permeability enhances the transport of nutrients from the sinusoids into the hepatocytes, where they are metabolized.

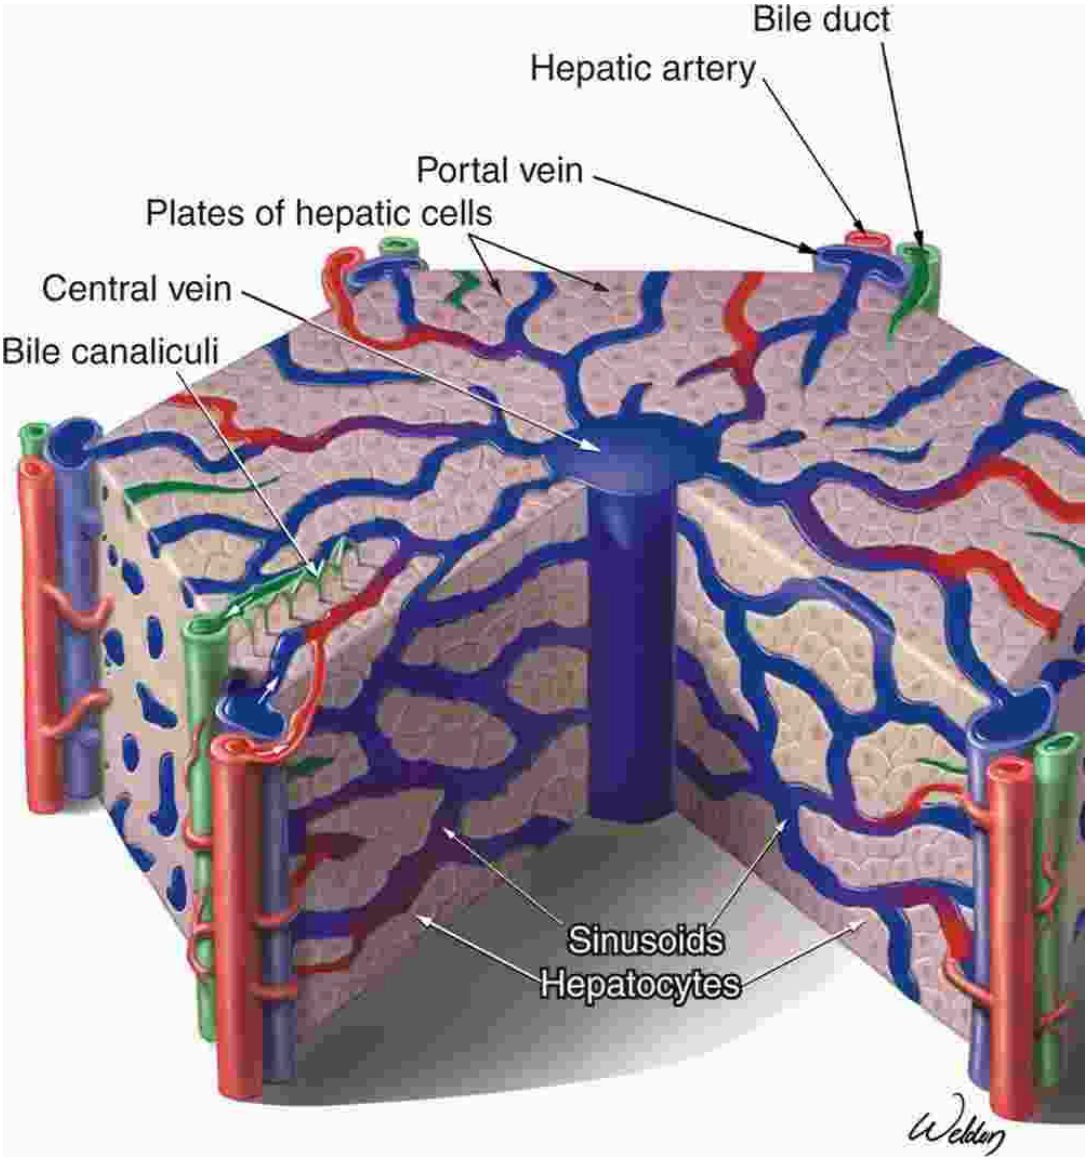

FIG. 40.21 Schematic of the Liver Lobule.
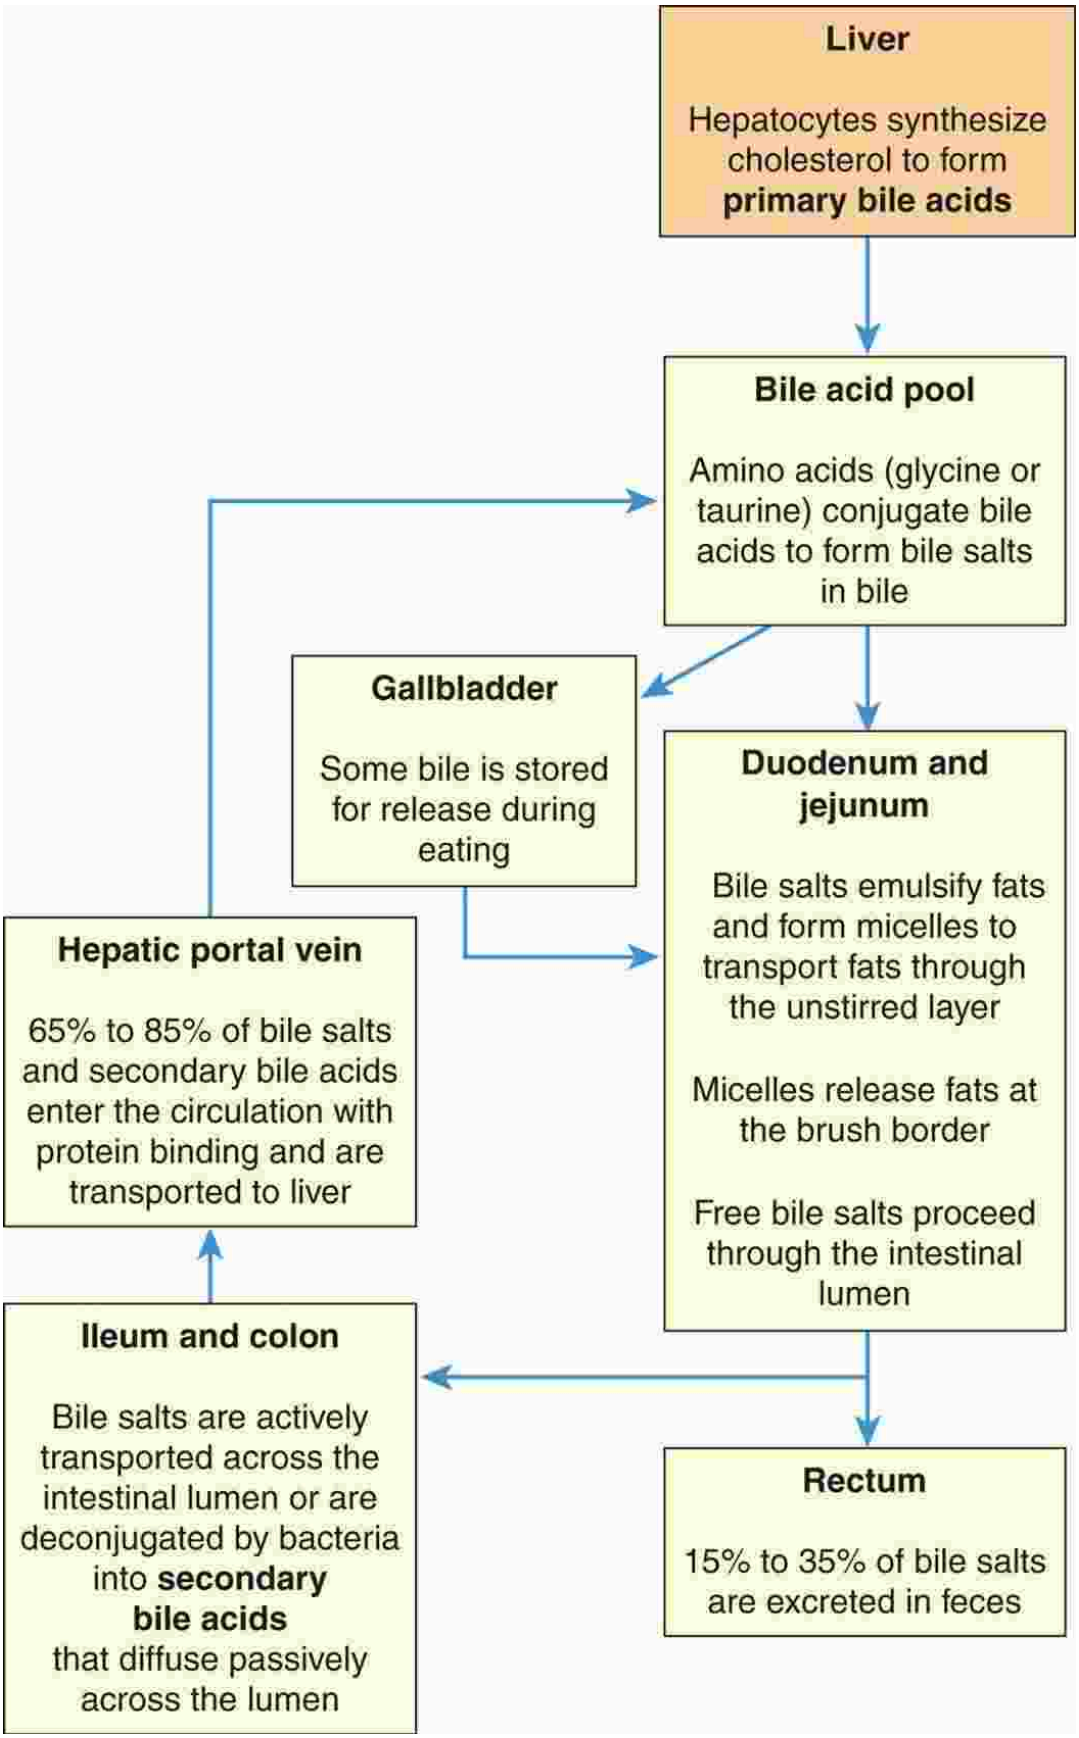
A cross section of a single liver lobule shows that, in whole, it is shaped like a hexagonal cylinder. The cut away area shows the central vein in the center of the lobule, separated by cords of hepatocytes forming sinusoids from six portal areas at the periphery. The portal areas contain a portal vein, hepatic artery, and bile duct. Blood flows toward the center of the lobule, whereas bile flows toward the portal triads at the margins. Note the hepatic artery providing oxygenated blood to the hepatic sinusoids. (From Polin RA, et al. *Fetal and Neonatal Physiology*. 4th ed. St Louis: Saunders; 2011.)

A diagram and a cut away portion show the parts of a liver lobule. The parts are labeled from outside to inside as follows: bile duct, hepatic artery branch, portal vein branch, plates of hepatic cells, and bile canaliculi. The cutaway portion has the following parts labeled: central vein, sinusoids, and hepatocytes.

The immune functions of the liver are carried out by various cells, including sinusoidal endothelial cells, Kupffer, stellate, and natural killer cells. Sinusoidal cells line the sinusoidal capillaries and, in addition to their barrier function, have immune functions including endocytosis, antigen presentation, and leukocyte recruitment. The sinusoids also are lined with phagocytic and bactericidal **Kupffer cells (tissue macrophages)**, which are part of the mononuclear phagocyte system. Kupffer cells are the largest population of tissue macrophages in the body and are central to innate and adaptive immunity. They play a key role in the identification and presentation of foreign antigens to the immune system, as well as phagocytose opsonized particles and iron molecules from the blood.[26] Kupffer cells are important for healing injury to the liver and are important for bilirubin production and lipid metabolism. **Stellate cells** contain retinoids (vitamin A), are contractile in liver injury, regulate sinusoidal blood flow, may proliferate into myofibroblasts, participate in liver fibrosis, produce erythropoietin, can act as antigen-presenting cells, remove foreign substances from the blood, and trap bacteria. They also contribute to the mature differentiation of Kupffer cells.[27]**Natural killer cells (pit cells)** also are found in the sinusoidal lumen; they produce interferon-γ and are important in tumor defense (see Chapter 7). Between the endothelial lining of the sinusoid and the hepatocyte is the **Disse space**, which drains interstitial fluid into the hepatic lymph system.

Secretion of Bile

The liver assists intestinal digestion by secreting 700 to 1200 mL of bile per day. **Bile** is an alkaline, bitter-tasting, yellowish green fluid that contains bile salts (conjugated bile acids), cholesterol, bilirubin (a pigment), electrolytes, and water. It is formed by hepatocytes and secreted into the bile canaliculi. **Bile canaliculi** are small channels that conduct bile outward to bile ducts and eventually drain into the **common bile duct** (see Figs. 40.18 and 40.21). This duct empties bile into the ampulla of Vater, and then into the duodenum through an opening called the **major duodenal papilla (sphincter of Oddi)**. **Bile salts** are required for the intestinal emulsification and absorption of lipids and fat-soluble vitamins, and the elimination of cholesterol. Having facilitated fat emulsification and absorption in the small intestine, most bile salts are actively absorbed in the terminal ileum and returned to the liver through the portal circulation for resecretion. The pathway for recycling of bile salts is termed the **enterohepatic circulation** (Fig. 40.22).



Liver
Hepatocytes synthesize cholesterol to form primary bile acids
Bile acid pool
Amino acids (glycine or taurine) conjugate bile acids to form bile salts in bile
Gallbladder
Some bile is stored for release during eating
Duodenum and jejunum
Bile salts emulsify fats and form micelles to transport fats through the unstirred layer
Micelles release fats at the brush border
Free bile salts proceed through the intestinal lumen
Hepatic portal vein
65% to 85% of bile salts and secondary bile acids enter the circulation with protein binding and are transported to liver
Ileum and colon
Bile salts are actively transported across the intestinal lumen or are deconjugated by bacteria into secondary bile acids that diffuse passively across the lumen
Rectum
15% to 35% of bile salts are excreted in feces

FIG. 40.22 Enterohepatic Circulation of Bile Salts.

A flow diagram depicts pathway for recycling of bile salts: • Liver: Hepatocytes synthesize cholesterol to form primary bile acids. • Bile acid pool: Amino acids, glycine or taurine, conjugate bile acids to form bile salts in bile. • Duodenum and jejunum: Bile salts emulsify fats and form micelles to transport fats through unstirred layer; Micelles release fats at brush border; Free bile salts proceed through intestinal lumen. • Gallbladder: Some bile is stored for release during eating. • Rectum: 15 to 35 percent of bile salts are excreted in feces. • Ileum and colon: Bile salts are actively transported across the intestinal lumen or deconjugated by bacteria into secondary bile acids diffusing passively across lumen. • Hepatic portal vein: 65 to 85 percent of bile salts and secondary bile acids enter circulation with protein binding and transported to liver.

Bile has two fractional components: the acid-dependent fraction and the acid-independent fraction. Hepatocytes secrete the **bile acid–dependent fraction**, which consists of bile acids, cholesterol, lecithin (a phospholipid), and bilirubin (a bile pigment).[4] The **bile acid–independent fraction**, which is secreted by the hepatocytes and epithelial cells of the bile canaliculi, is a bicarbonate-rich aqueous fluid that gives bile its alkaline pH and facilitates buffering of chyme entering the duodenum from the stomach.

Bile salts are conjugated in the liver from primary and secondary bile acids. In addition to their role in emulsifying lipids, bile acids serve as metabolites that regulate metabolic, immune, and inflammatory pathways.[28] The **primary bile acids** are cholic acid and chenodeoxycholic (chenic) acid. These acids are synthesized from cholesterol by the hepatocytes. The **secondary bile acids** are deoxycholic and lithocholic acid.[4] These acids are formed in the small intestine by intestinal bacteria, after which they are absorbed and flow to the liver (see Fig. 40.22). The content of bile can be influenced by the intestinal microbiome such that dysbiosis can lead to formation of gallstones.[29] Both forms of bile acids are conjugated with amino acids (glycine or taurine) in the liver to form bile salts. Conjugation makes the bile acids more water soluble, thus restricting their diffusion from the duodenum and ileum. The primary and secondary bile acids together form the **bile acid pool**.

Some bile salts are deconjugated by intestinal bacteria to secondary bile acids. These acids diffuse passively into the portal blood from both small and large intestines. An increase in the plasma concentration of bile acids accelerates the uptake

and resecretion of bile acids and salts by the hepatocytes. In pregnancy, deconjugation of bile acids by intestinal bacteria is enhanced and ileal uptake of bile acids is impaired which may lead to hypercholesterolemia.[30] The cycle of hepatic secretion, intestinal absorption, and hepatic resecretion of bile acids completes the enterohepatic circulation. Disruption of the enterohepatic circulation has been linked to the development of cholestatic liver disease, inflammatory bowel disease, metabolic syndrome, and colon cancer.[28]

Most bile secretion occurs during the digestion of meals. Bile secretion is called **choleresis**. A **choleretic agent** is a substance that stimulates the liver to secrete bile. One strong stimulus is a high concentration of bile salts. Other choleretics include cholecystokinin, vagal stimulation, and secretin, which increase the rate of bile flow by promoting contraction of the gallbladder and the secretion of bicarbonate from canaliculi and other intrahepatic bile ducts.[4]

Metabolism of Bilirubin

Bilirubin is a byproduct of the destruction of aged red blood cells. It gives bile a greenish black color and produces the yellow tinge of jaundice. Aged red blood cells are absorbed and destroyed by macrophages (Kupffer cells) of the mononuclear phagocyte system, primarily in the spleen and liver. Within these cells, hemoglobin is separated into its component parts: heme and globin (Fig. 40.23). The globin component is further degraded into its constituent amino acids, which go into the amino acid pool to form new protein. The heme component is converted to biliverdin by the enzymatic cleavage of iron. The iron attaches to transferrin in the plasma and can be stored in the liver or used by the bone marrow to make new red blood cells. The biliverdin is enzymatically converted to bilirubin in the Kupffer cell and then is released into the plasma where it binds to albumin and is known as **unconjugated bilirubin**, or free bilirubin, which is lipid soluble. Bilirubin also has a role as an antioxidant and provides cytoprotection.

Urine

FIG. 40.23 Bilirubin Metabolism.
See text for further explanation.

In the liver, unconjugated bilirubin moves from plasma in the sinusoids into the hepatocyte. Within hepatocytes, unconjugated bilirubin joins with glucuronic acid to form **conjugated bilirubin**. Conjugation transforms bilirubin from a lipid-soluble substance that can cross biologic membranes to a water-soluble substance that can be excreted. When conjugated bilirubin reaches the distal ileum and colon, it is deconjugated by bacteria and converted to **urobilinogen**. Urobilinogen is then reabsorbed in the intestines and transported to the kidney where it is excreted in the urine as urobilin, giving urine its yellow color. A small amount of urobilin is recirculated back into the liver and eliminated in feces as stercobilin (an end-product of heme metabolism), which contributes to the stool's brown pigmentation. The elimination of bilirubin is an important route for the elimination of cholesterol. Serum bilirubin levels are measured in the evaluation of numerous disorders including hepatobiliary disease, cardiovascular disease, prematurity, and cancer.

Vascular and Hematologic Functions

Because of its extensive vascular network, the liver can store a large volume of blood. The liver can release blood to maintain systemic circulatory volume in the event of hemorrhage. The liver also has hemostatic functions; it synthesizes most clotting factors (see Chapter 28). Vitamins K_1 and K_2, fat-soluble vitamins, are essential for the synthesis of the clotting factors. Because bile salts are needed for reabsorption of fats, vitamin K absorption depends on adequate bile production in the liver. Impairment of vitamin K absorption diminishes production of clotting factors and increases risk of bleeding.

Metabolism of Nutrients

Carbohydrates

The liver contributes to the stability of serum blood glucose levels by releasing glucose during hypoglycemia (low blood glucose level), absorbing glucose during hyperglycemia (high blood glucose level), and storing it as glycogen (glycogenesis) or converting it to fat. Hepatic glycogenesis is stimulated by insulin via the action of the enzyme glucokinase.[31] When all glycogen stores have been used, the liver can convert amino acids and glycerol to glucose (gluconeogenesis). Gluconeogenesis increases in diabetes and contributes to hyperglycemia. Dietary changes and hypoglycemic agents such as metformin suppress hepatic gluconeogenesis.[32]

Proteins

Protein synthesis requires the presence of all the essential amino acids (obtained only from food), as well as nonessential amino acids. Proteins perform many important functions in the body; these are summarized in Table 40.3.

Table 40.3

Importance of Proteins in the Body

Function	Example
Contraction	Actin and myosin enable muscle contraction.
Energy	Proteins can be metabolized for energy.
Fluid balance	Albumin is a major source of plasma oncotic pressure.
Protection	Antibodies, complement, and C-reactive protein protect against infection and foreign substances.
Regulation	Enzymes control chemical reactions; hormones regulate many physiologic processes.
Structure	Collagen fibers provide structural support to many parts of the body; keratin strengthens skin, hair, and nails.
Transport	Hemoglobin transports oxygen and carbon dioxide in the blood; plasma proteins serve as transport molecules; proteins in cell membranes control movement of materials into and out of cells.
Coagulation	Hemostasis is regulated by clotting factors and proteins that balance coagulation and anticoagulation.

Within hepatocytes, amino acids are converted to carbohydrates (keto acids) by the removal of ammonia (NH_3), a process known as **deamination**. The ammonia is converted to urea by the liver and passes into the blood to be excreted by the kidneys. Depending on the nutritional status of the body, the keto acids either are converted to

fatty acids for fat synthesis and storage or are oxidized by the Krebs tricarboxylic acid cycle (see Chapter 1) to provide energy for the liver cells.

The plasma proteins, including albumins and α- and β- globulins, are synthesized by the liver (gamma globulin are formed in lymph nodes and lymphoid tissue). They play an important role in preserving blood volume and pressure by maintaining plasma oncotic pressure. The liver also synthesizes several nonessential amino acids and serum enzymes that become elevated with liver injury (and other diseases):

- Aspartate aminotransferase (AST): also present in red blood cells and skeletal muscle; AST transfers an α-amino group between aspartate and glutamate.
- Alanine aminotransferase (ALT): also present in small amounts in the kidneys, heart, skeletal muscle, and pancreas; ALT transfers an amino group from alanine to α-ketoglutarate to form pyruvate and glutamate.
- Lactate dehydrogenase (LDH): catalyzes the conversion of lactate to pyruvate; LDH is widely distributed throughout the body and different isoenzymes are found in different tissues.
- Alkaline phosphatase: removes phosphate groups, particularly in an alkaline environment.
- Gamma-glutamyltransferase: transfers the gamma-glutamyl moiety of glutathione to an acceptor to form glutamate (neurotransmitter) and is a pro-oxidant.

Fats

Ingested fat absorbed by lacteals in the intestinal villi enters the liver circulation through the lymphatics, primarily as triglycerides. In the liver, the triglycerides can be hydrolyzed to glycerol and free fatty acids and used to produce metabolic energy called adenosine triphosphate (ATP), or they can be released into the bloodstream bound to proteins (lipoproteins). The lipoproteins are carried by the blood to adipose cells for storage. The liver also synthesizes phospholipids and cholesterol, which are needed for the hepatic production of bile salts, steroid hormones, components of plasma membranes, and other special molecules.

Metabolic Detoxification

The liver alters exogenous and endogenous chemicals (e.g., drugs), foreign molecules, and hormones to make them less toxic or less biologically active. This process, called **metabolic detoxification** or **biotransformation**, diminishes intestinal or renal tubular reabsorption of potentially toxic substances and facilitates their intestinal and renal excretion. In this way, alcohol, barbiturates, amphetamines, steroids, and hormones (including estrogens, aldosterone, antidiuretic hormone, and testosterone) are metabolized or detoxified, preventing excessive accumulation and adverse effects. Although metabolic detoxification is usually protective, the end products of metabolic detoxification sometimes become reactive metabolites (see Chapter 2). Reactive metabolites of alcohol metabolism, for example, are acetaldehyde and hydrogen. Acetaminophen toxicity occurs when its metabolite N-acetyl-p-benzoquinone imine

(NAPQI) overwhelms the glutathione pathway. Reactive metabolites can induce oxidative stress, bind to proteins, disrupt mitochondria, interfere with bile transport, or induce autoimmune responses.[33]

Storage of Minerals and Vitamins

The liver stores certain vitamins and minerals, including iron and copper, in times of excessive intake and releases them in times of need. Iron is stored in the liver as ferritin, an iron-protein complex, and is released as needed for red blood cell production (see Chapter 28). The liver can store vitamins B_{12} and D for several months and vitamin A for several years. The liver also stores vitamins E and K.

Gallbladder

The **gallbladder** is a sac-like organ on the inferior surface of the liver (see Fig. 40.23). Its primary function is to store and concentrate bile between meals. The wall of the gallbladder is composed of the mucous membrane, muscularis, and serosa. During the interdigestive period, bile flows from the liver through the right or left hepatic duct into the common hepatic duct and meets resistance at the closed sphincter of Oddi (duodenal papilla), which controls flow into the duodenum and prevents backflow of duodenal contents into the pancreatobiliary system. Bile then flows through the **cystic duct** into the gallbladder, where it is concentrated and stored. The mucosa of the gallbladder wall readily absorbs water and electrolytes, leaving a high concentration of bile salts, bile pigments, and cholesterol. The gallbladder holds about 90 mL of bile.

Within 30 minutes after eating, the gallbladder begins to contract, forcing stored bile through the cystic duct and into the common bile duct.[4] The sphincter of Oddi relaxes, and bile flows into the duodenum through the major duodenal papilla. During the cephalic and gastric phases of digestion, gallbladder contraction is mediated by cholinergic branches of the vagus nerve. Hormonal regulation of gallbladder contraction is derived primarily from the release of cholecystokinin secreted by the duodenal and jejunal mucosa in the presence of fat. Vasoactive intestinal peptide, pancreatic polypeptide, and sympathetic nerve stimulation relax the gallbladder.

Exocrine Pancreas

The **pancreas** is approximately 20 cm long. Its head is tucked into the curve of the duodenum, and its tail touches the spleen. The body of the pancreas lies deep in the abdomen, behind the stomach (see Figs. 40.1 and 40.24). The pancreas is unique in that it has both endocrine and exocrine functions. The endocrine pancreas secretes hormones—insulin, glucagon, somatostatin, and pancreatic polypeptide—from cells in the pancreatic islets (see Chapter 22).

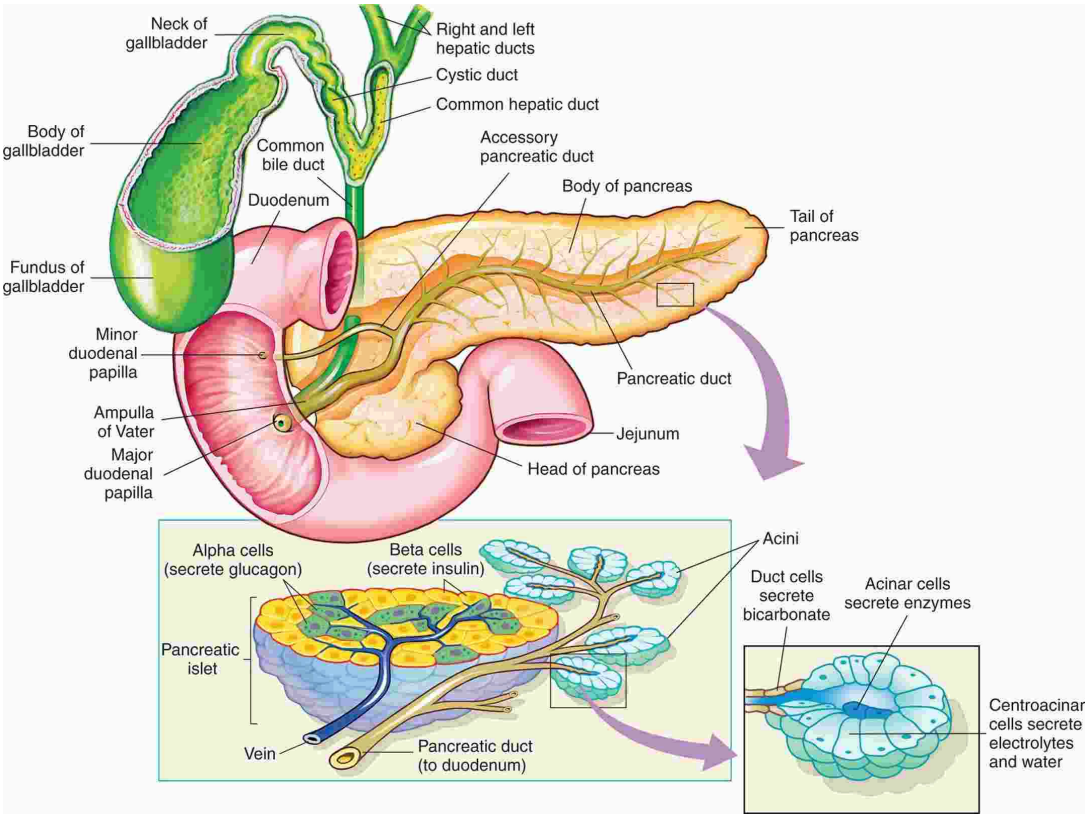

FIG. 40.24 Associated Structures of the Gallbladder, Pancreas, and Pancreatic Acinar Cells and Duct. (Modified from Thibodeau GA, Patton KT. *Anatomy & Physiology*. 6th ed. St Louis: Mosby; 2007.)

An illustration shows gallbladder, pancreas, and small intestine. Parts are labeled from top to bottom. Gallbladder: neck of gallbladder, right and left hepatic ducts, cystic duct, common hepatic duct, body of gallbladder, and common bile duct. Small intestine: duodenum, minor and major duodenal papilla, ampulla of Vater, and jejunum. Pancreas: body, pancreatic duct, accessory pancreatic duct, and tail. Magnified view of body of pancreas: pancreatic islet: vein, alpha cells secreting glucagon, and beta cells secreting insulin; pancreatic duct to duodenum; and acini. Magnified view of acini: duct cells secreting bicarbonate, acinar cells secreting enzymes, and centroacinar cells secreting electrolytes and water.

The **exocrine pancreas** is composed of acinar cells that secrete enzymes and networks of ducts that secrete alkaline fluids. Both have important digestive

functions. The acinar cells are organized into spherical lobules, called **acini**, around small secretory ducts (see Fig. 40.24). Secretions drain into a system of ducts that leads to the **pancreatic duct (Wirsung duct)**, which empties into the common bile duct at the **ampulla of Vater** and then through the duodenal papilla into the duodenum. In some individuals, an accessory duct (the duct of Santorini) branches off the pancreatic duct and drains directly into the duodenum at an opening called the minor duodenal papilla.

Arterial blood is supplied to the pancreas by branches of the celiac and superior mesenteric arteries (see Fig. 40.7). Venous blood leaves the head of the pancreas through tributaries to the portal vein, and the body and tail are drained through the splenic vein. All hormonal pancreatic secretions also pass through the hepatic portal vein into the liver.

Pancreatic innervation arises from parasympathetic neurons of the vagus nerve. These fibers activate postganglionic fibers, which stimulate enzymatic and hormonal secretion. Sympathetic postganglionic fibers from the celiac and superior mesenteric plexuses innervate the blood vessels, cause vasoconstriction, and inhibit pancreatic secretion.

The aqueous secretions of the exocrine pancreas are isotonic and contain potassium, sodium, bicarbonate, magnesium, calcium, and chloride. Sodium and potassium concentrations are about equal to those in the plasma. Pancreatic ductal cells secrete bicarbonate and the concentration in pancreatic juice varies directly with the secretory flow rate. As bicarbonate secretion increases, chloride secretion decreases to maintain a constant anionic concentration. The highly alkaline pancreatic juice neutralizes the acidic chyme that enters the duodenum from the stomach and provides the alkaline medium needed for the actions of digestive enzymes and intestinal absorption of fat.

In the pancreas, transport of water and electrolytes through the ductal epithelium involves both active and passive mechanisms. The ductal cells actively transport hydrogen into the blood and bicarbonate into the duct lumen. Potassium and chloride are secreted by diffusion according to changes in electrochemical potential gradients. As the secretion flows down the duct, water is osmotically transported into the pancreatic juice until it becomes isosmotic. At low flow rates bicarbonate is exchanged passively for chloride, but at higher flow rates there is less time for this exchange and bicarbonate concentration increases. Because eating stimulates the flow of pancreatic juice, the juice is most alkaline when it needs to be: during digestion.

The pancreatic enzymes can hydrolyze proteins (proteases), carbohydrates (amylases), and fats (lipases) (see Fig. 40.12). The proteolytic (protein-digesting) enzymes include trypsin, chymotrypsin, carboxypeptidase, and elastase. These enzymes are secreted in their inactive forms—that is, as trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase, respectively—to protect the pancreas from the digestive effects of its own enzymes. For further protection, the pancreas produces **trypsin inhibitor**, which prevents the activation of proteolytic enzymes while they are in the pancreas. Once in the duodenum, the inactive forms (proenzymes) are activated by **enterokinase**, an enzyme secreted by the duodenal mucosa. Trypsinogen is the first proenzyme to be activated. Its conversion to trypsin

stimulates the conversion of chymotrypsinogen to chymotrypsin and procarboxypeptidase to carboxypeptidase. Each of these enzymes cleaves specific peptide bonds to reduce polypeptides to smaller peptides.

Pancreatic α-amylase is secreted in active form and digests intestinal carbohydrate by cleaving interior α-1,4-glucosidic bonds to yield glucose and maltose at an optimum pH of approximately 6.9. **Pancreatic lipases** hydrolyze triglycerides, cholesterol, and phospholipids to free fatty acids in the intestine.

Secretion of the aqueous and enzymatic components of pancreatic juice is controlled by hormonal and autonomic stimuli. Both parasympathetic and sympathetic innervation affect exocrine pancreatic secretion. Secretion can be stimulated by meal anticipation and ingestion, ACh, insulin, amylin, glucagon, and pancreatic polypeptide.[34] The hormone secretin stimulates the acinar and duct cells to secrete the bicarbonate-rich fluid that neutralizes chyme and prepares it for enzymatic digestion. As chyme enters the duodenum, its acidity (pH of 4.5 or less) stimulates the **S cells** (secretin-producing cells) of the duodenum to release secretin, which is absorbed by the intestine and delivered to the pancreas in the bloodstream. In the pancreas, secretin causes ductal and acinar cells to release alkaline fluid. Secretin also inhibits the actions of gastrin, thereby decreasing gastric hydrochloric acid secretion and motility. The overall effect is to neutralize the contents of the duodenum.

Enzymatic secretion follows, stimulated by cholecystokinin, which activates ACh from the vagus nerve and release of ACh from pancreatic stellate cells. Cholecystokinin is released in the duodenum in response to the essential amino acids and fatty acids already present in chyme. Once in the small intestine, activated pancreatic enzymes inhibit the release of more cholecystokinin and ACh. This feedback mechanism inhibits the secretion of more pancreatic enzymes. Pancreatic polypeptide is released after eating and inhibits postprandial pancreatic exocrine secretion. (See Table 40.1 for a summary of hormonal stimulation of pancreatic secretions.) Selected tests of pancreatic function are listed in Table 40.4.

Table 40.4

Selected Tests of Gastrointestinal Function

Test	Normal Findings	Clinical Significance of Abnormal Findings
Stool studies	Resident microorganisms: clostridia, enterococci, *Pseudomonas*, a few yeasts	Detection of *Salmonella typhi* (typhoid fever), *Shigella* (dysentery), *Vibrio cholerae* (cholera), *Yersinia* (enterocolitis), *Escherichia coli* (gastroenteritis), *Staphylococcus aureus* (food poisoning), *Clostridium botulinum* (food poisoning), *Clostridium perfringens* (food poisoning), *Aeromonas* (gastroenteritis)
	Fat: 2–6 g/24 h	Steatorrhea (increased values) can result from intestinal malabsorption or pancreatic insufficiency
	Pus: none	Large amounts of pus are associated with chronic ulcerative colitis, abscesses, and anorectal fistula
	Occult blood: none (orthotolidine or guaiac test)	Positive tests associated with bleeding
	Ova and parasites: none	Detection of *Entamoeba histolytica* (amebiasis), *Giardia lamblia* (giardiasis), and worms
D-Xylose absorption	5-h urinary excretion: 4.5 g/L Peak blood level: >30 mg/dL	Differentiation of pancreatic steatorrhea (normal D-xylose absorption) from intestinal steatorrhea (impaired D-xylose absorption)
Gastric acid stimulation	11–20 mEq/h after stimulation	Detection of duodenal ulcers, Zollinger-Ellison syndrome

Test	Normal Findings	Clinical Significance of Abnormal Findings
		(increased values), gastric atrophy, gastric carcinoma (decreased values)
Manometry (use of water-filled catheters connected to pressure transducers passed into the esophagus, stomach, colon, or rectum to evaluate contractility)	Values vary at different levels of the intestine	Inadequate swallowing, motility, sphincter function
Culture and sensitivity of duodenal contents	No pathogens	Detection of *Salmonella typhi* (typhoid fever)
Breath tests		
Glucose or D-xylose breath test	Negative for hydrogen or CO_2	May indicate intestinal bacterial overgrowth
Urea breath test	Negative for isotopically labeled CO_2	Presence of *Helicobacter pylori* infection
Lactose breath test	Negative for exhaled hydrogen	Lactose intolerance

Test	Normal Findings	Clinical Significance of Abnormal Findings
Stool studies	Resident microorganisms: clostridia, enterococci, *Pseudomonas*, a few yeasts	Detection of *Salmonella typhi* (typhoid fever), *Shigella* (dysentery), *Vibrio cholerae* (cholera), *Yersinia* (enterocolitis), *Escherichia coli* (gastroenteritis), *Staphylococcus aureus* (food poisoning), *Clostridium botulinum* (food poisoning), *Clostridium perfringens* (food poisoning), *Aeromonas* (gastroenteritis)
	Fat: 2–6 g/24 h	Steatorrhea (increased values) can result from intestinal malabsorption or pancreatic insufficiency
	Pus: none	Large amounts of pus are associated with chronic ulcerative colitis, abscesses, and anorectal fistula
	Occult blood: none (orthotolidine or guaiac test)	Positive tests associated with bleeding
	Ova and parasites: none	Detection of *Entamoeba histolytica* (amebiasis), *Giardia lamblia* (giardiasis), and worms
D-Xylose absorption	5-h urinary excretion: 4.5 g/L Peak blood level: >30 mg/dL	Differentiation of pancreatic steatorrhea (normal D-xylose absorption) from intestinal steatorrhea (impaired D-xylose absorption)
Gastric acid stimulation	11–20 mEq/h after stimulation	Detection of duodenal ulcers, Zollinger-Ellison syndrome (increased values), gastric atrophy, gastric carcinoma (decreased values)
Manometry (use of water-filled catheters connected to pressure transducers passed into the esophagus, stomach, colon, or rectum to evaluate contractility)	Values vary at different levels of the intestine	Inadequate swallowing, motility, sphincter function
Culture and sensitivity of duodenal contents	No pathogens	Detection of *Salmonella typhi* (typhoid fever)
Breath tests		
Glucose or D-xylose breath test	Negative for hydrogen or CO_2	May indicate intestinal bacterial overgrowth
Urea breath test	Negative for isotopically labeled CO_2	Presence of *Helicobacter pylori* infection
Lactose breath test	Negative for exhaled hydrogen	Lactose intolerance

Tests of Digestive Function

Gastrointestinal Tract

Although important diagnostic information can be obtained from an individual's medical history and presenting symptoms, numerous disease-specific tests must be performed to evaluate the structure and function of the GI tract. A description of selected studies is presented in Tables 40.4 and 40.5. Of interest in relation to infection with coronavirus 2 (SARS-nCoV-2) is the evaluation of liver function related to disease severity and fecal testing for presence of the virus (Emerging Science Box: Digestive Manifestations Related to Covid 19). Radiography and imaging techniques —including radionuclide, positron emission tomography (PET), magnetic resonance imaging (MRI), computed tomography (CT) scanning, and ultrasound—are procedures for evaluating structure and function. Plain radiographs using contrast

media such as barium- or iodine-containing compounds can be used to outline the GI lumen, biliary tree and pancreatic ducts, fistulae, and arteriovenous systems. CT scanning is particularly useful for diagnosis of intestinal lesions and pancreatic or hepatic tumors or cysts. Ultrasonic scanning is a safe, simple, and relatively inexpensive technique used to detect gallstones and intraabdominal masses, particularly abscesses.

Table 40.5

Selected Studies of Gastrointestinal Structure

Test	Description	Application
Plain roentgenograms	Use of high-energy electromagnetic radiation to evaluate tissue structure by radiopacity or radiolucency	Visualization of the position, size, and structure of abdominal contents
Air or barium contrast roentgenograms	Introduction of radiopaque substances into the upper or lower gastrointestinal tract	Enhanced visualization of the contours, position, and size of the gastrointestinal tract to detect umbilical hernia, ulcers, diverticula, congenital anomalies, polyps, tumors, strictures, obstructions
Endoscopy Esophagoscopy (esophagus) Gastroscopy (stomach) Duodenoscopy (duodenum) Colonoscopy (large intestine) Sigmoidoscopy (sigmoid colon)	Passage of rigid or flexible (fiberoptic) endoscope into the gastrointestinal tract for visualization or biopsy	Visualization or biopsy of inflamed hernias, polyps, ulcers, strictures, varices, tumors, sites of bleeding, mucosal or neoplastic lesions and for culture of *Helicobacter pylori* from stomach
Ultrasound	Use of piezoelectric crystal to generate sound waves that are reflected from tissue interfaces to provide an image	Imaging of abdominal organs (gallbladder, liver, pancreas, spleen), masses, stones, abscesses, structural abnormalities
Computed tomography (CT)	Use of a computer to integrate differences in absorption of a large	Imaging of gallbladder, liver, pancreas, spleen, cysts, hematomas, abscesses,

Test	Description	Application
	number of x-rays to produce a cross-sectional image; may be done with contrast agents	stones, extrahepatic bile ducts, and portal vein
Magnetic resonance imaging	Projection of differences in magnetic properties of molecules within different cells and tissues, using the field of a large magnet	Same applications as CT scan; also can detect blood flow and vessel patency

Test	Description	Application
Plain roentgenograms	Use of high-energy electromagnetic radiation to evaluate tissue structure by radiopacity or radiolucency	Visualization of the position, size, and structure of abdominal contents
Air or barium contrast roentgenograms	Introduction of radiopaque substances into the upper or lower gastrointestinal tract	Enhanced visualization of the contours, position, and size of the gastrointestinal tract to detect umbilical hernia, ulcers, diverticula, congenital anomalies, polyps, tumors, strictures, obstructions
Endoscopy Esophagoscopy (esophagus) Gastroscopy (stomach) Duodenoscopy (duodenum) Colonoscopy (large intestine) Sigmoidoscopy (sigmoid colon)	Passage of rigid or flexible (fiberoptic) endoscope into the gastrointestinal tract for visualization or biopsy	Visualization or biopsy of inflamed hernias, polyps, ulcers, strictures, varices, tumors, sites of bleeding, mucosal or neoplastic lesions and for culture of *Helicobacter pylori* from stomach
Ultrasound	Use of piezoelectric crystal to generate sound waves that are reflected from tissue interfaces to provide an image	Imaging of abdominal organs (gallbladder, liver, pancreas, spleen), masses, stones, abscesses, structural abnormalities
Computed tomography (CT)	Use of a computer to integrate differences in absorption of a large number of x-rays to produce a cross-sectional image; may be done with contrast agents	Imaging of gallbladder, liver, pancreas, spleen, cysts, hematomas, abscesses, stones, extrahepatic bile ducts, and portal vein
Magnetic resonance imaging	Projection of differences in magnetic properties of molecules within different cells and tissues, using the field of a large magnet	Same applications as CT scan; also can detect blood flow and vessel patency

Fiberoptic endoscopy, using flexible endoscopes, allows direct visualization of the GI tract. A biopsy channel allows tissue sampling, and suction can be applied to remove GI secretions or blood. Analysis of stool, gastric secretions, tissue, and plasma provides important clues to infection, malabsorption syndromes, ulcerative lesions, and tumor growth.

Liver

A variety of diagnostic tests can be performed to evaluate liver function (Table 40.6). Imaging techniques similar to those described for the GI tract also are useful for evaluating liver structure and function. Elevated plasma levels of liver enzymes are associated with many liver diseases because of the release of cytoplasmic enzymes into the circulation when there is damage to the hepatocyte. Of particular importance are elevations of aminotransferases and LDH.

Table 40.6

Common Tests of Liver Function

Test	Normal Value	Interpretation
Serum Enzymes		
Alkaline phosphatase	35–150 units/L	Increases with biliary obstruction and cholestatic hepatitis
Gamma-glutamyl transpeptidase	Male: 12–38 units/L Female: 9–31 units/L	Increases with biliary obstruction and cholestatic hepatitis
Aspartate aminotransferase (previously serum glutamate-oxaloacetate transaminase)	Male: 8–40 units/L Female: 6–34 units/L	Increases with hepatocellular injury and injury in other tissues (e.g., skeletal and cardiac muscle)
Alanine aminotransferase (previously serum glutamate-pyruvate transaminase)	Male: 10–40 units/L Female: 9–32 units/L	Increases with hepatocellular injury and necrosis
Lactate dehydrogenase	110–220 units/L	Isoenzyme LD5 is elevated with hypoxic and primary liver injury
5′-Nucleotidase	2–11 units/L	Increases with increase in alkaline phosphatase and cholestatic disorders
Bilirubin Metabolism		
Serum bilirubin		
Unconjugated (indirect)	0.1–1 mg/dL	Increases with hemolysis (lysis of red blood cells)

Test	Normal Value	Interpretation
Conjugated (direct)	0.1–0.4 mg/dL	Increases with hepatocellular injury or obstruction
TOTAL	<1 mg/dL	Increases with biliary obstruction
Urine bilirubin	0	Increases with biliary obstruction
Urine urobilinogen	0–4 mg/24 h	Increases with hemolysis or shunting of portal blood flow
Serum Proteins		
Albumin	3.5–5.5 g/dL	Reduced with hepatocellular injury
Globulin	2–4 g/dL	Increases with hepatitis
TOTAL	6–7 g/dL	
Albumin/globulin ratio	1.5 :1 to 2.5 :1	Ratio reverses with chronic hepatitis or other chronic liver disease
Transferrin	250–300 mcg/dL	Liver damage with decreased values, iron deficiency with increased values
Alpha fetoprotein	6–20 ng/mL	Elevated values in primary hepatocellular carcinoma
Blood-Clotting Functions		
Prothrombin time	10–13 s or 90%–100% of control	Increases with chronic liver disease (cirrhosis) or vitamin K deficiency
Partial thromboplastin time	22–37 s	Increases with severe liver disease or heparin therapy
Bromsulphthalein excretion	<6% retention in 45 min	Increased retention with hepatocellular injury

Test	Normal Value	Interpretation
Serum Enzymes		
Alkaline phosphatase	35–150 units/L	Increases with biliary obstruction and cholestatic hepatitis
Gamma-glutamyl transpeptidase	Male: 12–38 units/L Female: 9–31 units/L	Increases with biliary obstruction and cholestatic hepatitis
Aspartate aminotransferase (previously serum glutamate-oxaloacetate transaminase)	Male: 8–40 units/L Female: 6–34 units/L	Increases with hepatocellular injury and injury in other tissues (e.g., skeletal and cardiac muscle)
Alanine aminotransferase (previously serum glutamate-pyruvate transaminase)	Male: 10–40 units/L Female: 9–32 units/L	Increases with hepatocellular injury and necrosis
Lactate dehydrogenase	110–220 units/L	Isoenzyme LD5 is elevated with hypoxic and primary liver injury
5′-Nucleotidase	2–11 units/L	Increases with increase in alkaline phosphatase and cholestatic disorders
Bilirubin Metabolism		
Serum bilirubin		
Unconjugated (indirect)	0.1–1 mg/dL	Increases with hemolysis (lysis of red blood cells)
Conjugated (direct)	0.1–0.4 mg/dL	Increases with hepatocellular injury or obstruction
TOTAL	<1 mg/dL	Increases with biliary obstruction
Urine bilirubin	0	Increases with biliary obstruction
Urine urobilinogen	0–4 mg/24 h	Increases with hemolysis or shunting of portal blood flow
Serum Proteins		
Albumin	3.5–5.5 g/dL	Reduced with hepatocellular injury
Globulin	2–4 g/dL	Increases with hepatitis
TOTAL	6–7 g/dL	
Albumin/globulin ratio	1.5 :1 to 2.5 :1	Ratio reverses with chronic hepatitis or other chronic liver disease
Transferrin	250–300 mcg/dL	Liver damage with decreased values, iron deficiency with increased values
Alpha fetoprotein	6–20 ng/mL	Elevated values in primary hepatocellular carcinoma
Blood-Clotting Functions		
Prothrombin time	10–13 s or 90%–100% of control	Increases with chronic liver disease (cirrhosis) or vitamin K deficiency
Partial thromboplastin time	22–37 s	Increases with severe liver disease or heparin therapy
Bromsulphthalein excretion	<6% retention in 45 min	Increased retention with hepatocellular injury

Obstruction of bile canaliculi or ducts results in regurgitation of bile back into the hepatic sinusoids and into the circulation, manifesting with elevation of conjugated bilirubin levels. Prothrombin times (a measure of clotting tendency) are

Emerging Science Box

Digestive Manifestations Related to COVID-19

The digestive system has emerged as a site of severe acute respiratory syndrome novel coronavirus 2 (SARS-nCoV-2) expression and may also be implicated in the

severity of disease and viral transmission. To date it has been determined that SARS-nCoV-2 infects the gastrointestinal (GI) tract of about 50% of infected persons based on the high incidence of digestive symptoms, expression of angiotensin-converting enzyme 2 receptors (viral target for cellular entry in digestive system), and presence of viral RNA in the feces. Persons infected with SARS-nCoV-2 have clinical manifestations related to the alimentary canal including sore throat, dysgeusia, diarrhea, abdominal pain, nausea, vomiting, and hematochezia. Furthermore, abnormal liver function is present in up to 50% of infected persons seen on liver function testing (LFTs). Additionally, viral RNA in stools is rarely tested, but is positive in 0%–48.1% of tests.

Data from Aroniadis OC, et al. Current knowledge and research priorities in the digestive manifestations of COVID-19. *Clin Gastroenterol Hepatol*. 2020;18(8):1682–1684. Xiao F, et al. Evidence for gastrointestinal infection of SARS-CoV-2. *Gastroenterology*. 2020;158:1831–1833; Prolonged presence of SARS-CoV-2 viral RNA in faecal samples. *Lancet Gastroenterol Hepatol*. 2020; 5:434–435; Zhang C, et al. Liver injury in COVID-19: management and challenges. *Lancet Gastroenterol Hepatol*. 2020;5:428–430. Xu Z, et al. Pathological findings of COVID-19 associated with acute respiratory distress syndrome. *Lancet Respir Med*. 2020;8:420–422. Almeida JFM, et al. COVID-19 and the gastrointestinal tract: what do we already know? *Einstein (Sao Paulo)*. 2020;18:eRW5909.

often prolonged with both hepatitis and chronic liver disease. In severe disease, other plasma proteins, such as albumin and globulins, may be diminished as a result of hepatocyte damage. Liver biopsies are often performed to evaluate the extent of liver involvement or degeneration with cirrhosis, hepatitis, or fatty liver disease.

Gallbladder

Evaluation of structural alterations in the gallbladder may be achieved by the use of various imaging techniques. Table 40.7 summarizes these techniques. Obstructive pathology of the bile ducts results in elevated values for both conjugated and total serum bilirubin, increased urine urobilinogen level, clay-colored stools, and development of jaundice. Fat absorption can be impaired and the prothrombin time prolonged if vitamin K is not absorbed. With inflammation of the gallbladder, the white cell count is elevated.

Table 40.7

Diagnostic Evaluation of the Gallbladder

Test	Application
Plain roentgenogram of the abdomen	Visualization of calcified gallstones
Oral cholecystogram (use of an oral contrast medium such as iopanoic acid, which is excreted with bile and concentrated in the gallbladder for visualization by radiography; may be administered as a double dose)	Visualization of gallstones; evaluation of filling and emptying of gallbladder
Intravenous cholangiography (use of intravenous contrast agents for visualization of gallbladder and bile ducts)	Diagnosis of acute gallbladder inflammation (cholecystitis) or disease of bile ducts
Cholecystography (ultrasound imaging of gallbladder and bile ducts including endoscopic ultrasound)	Preferred method for detecting gallstones; differentiation of hepatic disease from biliary obstruction; diagnosis of chronic cholecystitis
Cholescintigraphy (radioisotope imaging of gallbladder)	Diagnosis of cholecystitis in individuals allergic to iodine-containing contrast agents; diagnosis of cystic duct obstruction
Endoscopic retrograde cholangiography (instillation of contrast medium through cannulation of ampulla of Vater with a duodenoscope)	Differentiation of intrahepatic or extrahepatic obstructive jaundiceDiagnosis of gallstones
Computed tomography	Diagnosis of biliary obstruction or malignancy when ultrasound is not successful
Magnetic resonance cholangiography	Diagnosis of complicated cholelithiasis or choledocholithiasis

Exocrine Pancreas

Tests of pancreatic function are summarized in Table 40.8. Evaluation of serum lipase and urinary amylase provides particularly significant measures of pancreatic injury. Inflammation or obstruction of the pancreas results in an early increase in serum amylase levels. Serum lipase level remains elevated after serum amylase has returned to normal levels and provides greater sensitivity with delayed presentation of pancreatitis. Elevation of urine amylase level also occurs later (after 48 hours) when serum amylase may have returned to normal levels. Urinary trypsinogen 2 (available as dipstick) is used to diagnose acute pancreatitis and is comparable to serum amylase and lipase. Increased stool fat can reflect pancreatic insufficiency caused by decreased lipase secretion when biliary function is normal.

Table 40.8

Selected Tests of Pancreatic Function

Test	Normal Value	Clinical Significance
Serum amylase	25–125 units/mL	Elevated levels with pancreatic inflammation
Serum lipase	20–240 units/mL	Elevated levels with pancreatic inflammation (may be elevated with other conditions; differentiates with amylase isoenzyme study)
Urine amylase	35–260 Somogyi units/h	Elevated levels with pancreatic inflammation
Secretin test	Volume: 1.8 mL/kg/h Bicarbonate concentration: >80 mEq/L Bicarbonate output: >10 mEq/L/30 s	Decreased volume with pancreatic disease as secretin stimulates pancreatic secretion
Stool fat	2–5 g/24 h	Measures fatty acids; decreased pancreatic lipase increases stool fat (malabsorption)
Fecal elastase	>200 μg/g of stool	Decreased in pancreatic insufficiency

Test	Normal Value	Clinical Significance
Serum amylase	25–125 units/mL	Elevated levels with pancreatic inflammation
Serum lipase	20–240 units/mL	Elevated levels with pancreatic inflammation (may be elevated with other conditions; differentiates with amylase isoenzyme study)
Urine amylase	35–260 Somogyi units/h	Elevated levels with pancreatic inflammation
Secretin test	Volume: 1.8 mL/kg/h Bicarbonate concentration: >80 mEq/L Bicarbonate output: >10 mEq/L/30 s	Decreased volume with pancreatic disease as secretin stimulates pancreatic secretion
Stool fat	2–5 g/24 h	Measures fatty acids; decreased pancreatic lipase increases stool fat (malabsorption)
Fecal elastase	>200 μg/g of stool	Decreased in pancreatic insufficiency

GERIATRIC CONSIDERATIONS

Age-related change in GI function is variable among individuals and is related to health status and disease treatments, genetics, and environmental factors. Changes can begin to occur before 50 years of age. Tooth enamel and dentin wear down, making the teeth vulnerable to cavities. Teeth are lost, often as a result of periodontal (gum) disease, recession of the gums, osteoporotic bone changes, and more brittle roots that fracture easily.[35] Taste buds decline in number, and the sense of smell diminishes. Together these losses decrease the sense of taste. These oral and sensory changes make eating less pleasurable and reduce appetite in very old adults.[36] Salivation decreases, and food may not be chewed or lubricated sufficiently, making swallowing difficult. The esophagus develops decreased motility, and changes in the upper esophageal sphincter, history of stroke, and dementia may affect swallowing and contribute to gastroesophageal reflux.[35] Age diminishes gastric motility, secretion, and blood flow with increased risk for mucosal injury.[36] Acid content of gastric juice is related to gastric atrophy, which results in hypochlorhydria (insufficient hydrochloric acid), delayed gastric emptying, and compromise of the gastric mucosal barrier.[35] Decreased production of intrinsic factor leads to inadequate small intestinal absorption of vitamin B_{12} and pernicious anemia. Aging may be associated with a change in the composition of the intestinal microflora, loss of intestinal mucosal integrity, and a decline in pathogen-specific IgA with increased susceptibility to disease. GALT and overall immunity declines.[36] The ileal villi of the small intestine may become broader and shorter, perhaps because of a decrease in cell turnover. Degeneration and density of the enteric nervous system neurons can decrease intestinal absorption, motility, and blood flow, impairing nutrient absorption. Proteins, fats, minerals (including iron and calcium), and vitamins are absorbed more slowly and in lesser amounts, and absorption of carbohydrates is decreased. Intestinal transit time is delayed. Constipation is often described as a condition of old age, but it is probably caused by lifestyle factors (e.g., diet, immobility, lack of fluid intake) rather than physiologic decline, although studies demonstrate there can be alterations in both enteric and external intestinal innervation.[35]

The liver is remarkably resilient during the aging process, but abnormalities in various functions do occur. Liver aging results from alterations in the metabolic epigenome. Low-grade inflammation and cellular senescence contribute to hepatocyte, sinusoidal, stellate cell, and Kupffer cell dysfunction in the elderly.[37] The rate of liver regeneration decreases with advancing age, but the volume of the liver can be maintained. Liver blood flow and enzyme activity decrease with age and can influence the efficiency of drug and alcohol metabolism. However, liver function test results often remain within relatively normal ranges. Alterations in liver function in older individuals are usually a sign of a pathologic condition. The pancreas undergoes structural changes, such as fibrosis, fatty acid deposits, and atrophy, and there is a decline in β-cell function. Pancreatic secretion decreases, but there is usually

no observable dysfunction. Aging does not cause apparent changes in the structure and function of the gallbladder and bile ducts, but the incidence of gallstones increases.

Summary Review

The Gastrointestinal Tract

1. The major functions of the GI tract are the mechanical and chemical breakdown of food and the absorption of digested nutrients.
2. Except for swallowing and defecation, which are controlled voluntarily, the functions of the GI tract are controlled by extrinsic and intrinsic autonomic nerves and intestinal hormones.
3. The GI tract is a hollow tube that extends from the mouth to the anus.
4. The walls of the GI tract have four layers. From the inside out they are the mucosa, submucosa, muscularis, and serosa.
5. Digestion begins in the mouth, with chewing and salivation. The digestive component of saliva is α-amylase, which initiates carbohydrate digestion.
6. The esophagus is a muscular tube that transports food from the mouth to the stomach. The tunica muscularis in the upper part of the esophagus is striated muscle, and that in the lower part is smooth muscle.
7. Food is propelled through the esophagus by peristalsis (waves of sequential relaxations and contractions of the layers of muscles).
8. Swallowing is controlled by the swallowing center in the medulla of the brain. The two phases of swallowing are the oropharyngeal phase (voluntary swallowing) and the esophageal phase (involuntary swallowing).
9. The lower esophageal sphincter opens to admit swallowed food into the stomach and then closes to prevent regurgitation of food back into the esophagus.
10. The stomach is a bag-like structure that secretes digestive juices, mixes and stores food, and propels partially digested food (chyme) through the pylorus into the duodenum.
11. The vagus nerve stimulates gastric (stomach) secretion and motility.
12. The hormones gastrin and motilin stimulate gastric emptying; the hormones secretin and cholecystokinin delay gastric emptying.
13. The stomach secretes large volumes of gastric secretions, including acid, pepsinogen, mucus, enzymes, hormones, intrinsic factor (needed for vitamin B_{12} absorption), and gastroferrin (facilitates absorption of iron).
14. The three phases of gastric secretion by the stomach are the cephalic phase (anticipation and swallowing), the gastric phase (food in the stomach), and the intestinal phase (chyme in the intestine).
15. Parietal cells produce hydrochloric acid, which dissolves food fibers, kills microorganisms, and activates the enzyme pepsin. Acid secretion is

stimulated by the vagus nerve, gastrin, and histamine and is inhibited by sympathetic stimulation and intestinal hormones.

16. Chief cells in the stomach secrete pepsinogen, which is converted to pepsin in the acidic environment created by hydrochloric acid. Pepsin breaks down proteins and forms polypeptides.
17. Mucus is secreted throughout the stomach and protects the stomach wall from acid and digestive enzymes.
18. The abdominal cavity includes all the organs of digestion, and the mesentery, peritoneum and omentum.
19. The mesentery is an organ formed from a double fold of peritoneum and composed of several contiguous segments that have both structural and physiologic function.
20. The peritoneum is a double layer of membranous tissue. The visceral layer covers the abdominal organs, and the parietal layer extends along the abdominal wall. The peritoneal cavity is the space between the two layers
21. The omentum is composed of a large flat layer of adipose tissue with two parts, the greater and lesser omentum has fat storage, protective, immune, wound healing, and tissue regeneration functions
22. The small intestine is 5 m long and has three segments: the duodenum, jejunum, and ileum.
23. The duodenum lies behind the peritoneum (retroperitoneal).
24. The ileocecal valve connects the small and large intestines and prevents reflux into the small intestine.
25. Villi are small finger-like projections that extend from the small intestinal mucosa and increase its absorptive surface area.
26. Enzymes secreted by the small intestine (maltase, sucrase, lactase), pancreatic enzymes, and bile salts act in the small intestine to digest proteins, carbohydrates, and fats.
27. Digested substances are absorbed across the intestinal wall and then transported to the liver, where they are metabolized further. Carbohydrate and protein components move into villus capillaries and to the liver through the hepatic portal vein.
28. Bile salts emulsify and hydrolyze fats and incorporate them into water-soluble micelles. The fat content of the micelles diffuses through the epithelium into lacteals (lymphatic ducts) in the villi. From there, fats flow into lymphatics and into the systemic circulation, which delivers them to the liver.
29. Minerals and water-soluble vitamins are absorbed by both active and passive transport throughout the small intestine.
30. Contractions of the circular muscles (segmentation) mix the chyme, and peristaltic movements created by longitudinal muscles propel the chyme along the intestinal tract.
31. The ileogastric reflex inhibits gastric motility when the ileum is distended. The intestinointestinal reflex inhibits intestinal motility when one intestinal

segment is overdistended. The gastroileal reflex increases intestinal motility when gastric motility increases.

32. The large intestine consists of the cecum, appendix, colon (ascending, transverse, descending, and sigmoid), rectum, and anal canal.
33. The teniae coli are three bands of longitudinal muscle that extend the length of the colon and give it a gathered appearance. Haustra are pouches of colon formed with alternating contraction and relaxation of the circular muscles.
34. The mucosa of the large intestine contains mucus-secreting cells and mucosal folds, but no villi.
35. The large intestine massages the fecal mass and absorbs water and electrolytes.
36. Distention of the ileum with chyme causes the gastrocolic reflex, or the mass propulsion of feces to the rectum.
37. Defecation is stimulated when the rectum is distended with feces. The tonically contracted internal anal sphincter relaxes, and if the voluntarily regulated external sphincter relaxes, defecation occurs.
38. The immune system of the GI tract consists of Paneth cells, which produce defensins and other antimicrobial peptides and lysozymes; and the lymph nodes of Peyer patches, which contain lymphocytes, plasma cells, and macrophages.
39. The largest number of intestinal bacteria (intestinal microbiome) is in the colon. The most numerous anaerobes are *Bacteroides* and *Firmicutes*. Intestinal bacteria are important for metabolism of bile salts, metabolism of selected drugs and hormones, destruction of pathogens, and prevention of pathogen colonization.
40. The intestinal tract is sterile at birth and becomes totally colonized within 3 to 4 weeks.
41. The splanchnic blood flow provides blood to the esophagus, stomach, small and large intestines, gallbladder, pancreas, and spleen.

Accessory Organs of Digestion

1. The liver, gallbladder, and exocrine pancreas secrete substances necessary for digestion. These secretions flow through an opening guarded by the sphincter of Oddi.
2. The liver sits under the diaphragm. It has digestive, metabolic, hematologic, vascular, and immunologic functions.
3. The liver is divided into the right and left lobes and is supported by the falciform, round, and coronary ligaments.
4. Plates of hepatocytes, which are the functional cells of the liver, together form anatomic units called liver lobules.
5. Hepatocytes synthesize bile and secrete it into the bile canaliculi, which are small channels between the hepatocytes. The bile canaliculi drain bile into the

common bile duct and then into the duodenum through an opening called the major duodenal papilla (sphincter of Oddi).

6. Sinusoids are capillaries located between the plates of hepatocytes. Blood from the portal vein and hepatic artery flows through the sinusoids to a central vein in each lobule and then to the hepatic vein and inferior vena cava.
7. Kupffer cells, which are part of the mononuclear phagocyte system, line the sinusoids and destroy microorganisms in sinusoidal blood; they are important in bilirubin production and lipid metabolism.
8. The liver produces 700 to 1200 mL of bile per day. Bile is made up of bile salts, cholesterol, bilirubin, electrolytes, and water.
9. The primary bile acids are synthesized from cholesterol by the hepatocytes. The primary acids are then conjugated to form bile salts. The secondary bile acids are the product of bile salt deconjugation by bacteria in the intestinal lumen.
10. Most bile salts and acids are recycled. The absorption of bile salts and acids from the terminal ileum and their return to the liver are known as the enterohepatic circulation of bile.
11. Bilirubin is a pigment liberated by the lysis of aged red blood cells in the liver and spleen. Unconjugated bilirubin is fat soluble and can cross cell membranes. Unconjugated bilirubin is converted to water-soluble, conjugated bilirubin by hepatocytes and is secreted with bile.
12. The liver produces clotting factors and can store a large volume of blood.
13. The liver plays a major role in the metabolism of carbohydrates, proteins, and fats and stores minerals, vitamin B_{12}, and fat-soluble vitamins.
14. The liver metabolically transforms or detoxifies hormones, toxic substances, and drugs to less active substances. This process is known as metabolic detoxification.
15. The gallbladder is a sac-like organ located on the inferior surface of the liver. The gallbladder stores bile between meals and ejects it when chyme enters the duodenum.
16. Stimulated by cholecystokinin, the gallbladder contracts and forces bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes, enabling bile to flow through the major duodenal papilla into the duodenum.
17. The pancreas is a gland located behind the stomach. The endocrine pancreas produces hormones (glucagon, insulin) that facilitate the formation and cellular uptake of glucose. The exocrine pancreas secretes an alkaline solution and the enzymes (trypsin, chymotrypsin, carboxypeptidase, α-amylase, lipase) that digest proteins, carbohydrates, and fats.
18. Secretin stimulates pancreatic secretion of alkaline fluid, and cholecystokinin and ACh stimulate secretion of enzymes. Pancreatic secretions originate in acini and ducts of the pancreas and empty into the duodenum through the common bile duct or an accessory duct that opens directly into the duodenum.

Tests of Digestive Function

1. Numerous diagnostic tests can evaluate structure and function (digestion, secretion, absorption) of the GI tract. Radiographs and scans are most commonly used to evaluate structure, in addition to direct observation by endoscopy. Gastric and stool analysis and blood studies provide important information about digestion, absorption, and secretion.
2. Plasma chemistry levels and imaging procedures are commonly used to diagnose alterations in liver function. Of particular importance are the enzymes LDH, AST, and ALT. Plasma bilirubin levels reflect alterations in bilirubin and bile metabolism, and prothrombin times are prolonged in hepatitis and chronic liver disease.
3. Obstructive diseases of the gallbladder are evident by elevated serum bilirubin levels, elevated urine urobilinogen levels, and increased stool fat. The serum leukocyte levels become elevated with inflammation of the gallbladder.
4. The most significant indicators of pancreatic dysfunction are serum amylase and stool fat. Both values are increased with pathology of the pancreas.

Aging and the Gastrointestinal System

1. Advancing age is often associated with the loss or deterioration of teeth, diminished senses of taste and smell, and diminished salivary secretions, all of which may make eating difficult and reduce appetite.
2. Aging reduces gastric motility and secretions, particularly of hydrochloric acid. These changes slow gastric digestion and emptying.
3. Intestinal motility and absorption of carbohydrates, proteins, fats, and minerals decrease with age.
4. Efficiency of drug and alcohol metabolism decreases with age and can be related to decreased liver perfusion and decreased liver enzymes.

- Disorders of the Liver 1347
- Disorders of the Gallbladder 1353
- Disorders of the Pancreas 1355

Cancer of the Digestive System 1357
- Cancer of the Gastrointestinal Tract 1357
- Cancer of the Accessory Organs of Digestion 1363

Disorders of the gastrointestinal (GI) tract disrupt one or more of its structures and functions. The GI tract is a continuous, hollow organ that extends from the mouth to the anus. It includes the esophagus, stomach, small intestine, large intestine, and rectum. The accessory

organs of digestion include the salivary glands, liver, gallbladder, and pancreas. Structural and neural abnormalities can slow, obstruct, or accelerate the movement of intestinal contents at any level of the GI tract. Inflammatory and ulcerative conditions of the GI wall disrupt secretion, motility, and absorption. Inflammation or obstruction of the liver, pancreas, or gallbladder can alter metabolism and result in local and systemic symptoms. Many clinical manifestations of GI tract disorders are nonspecific and can be caused by a variety of impairments.

Disorders of the Gastrointestinal Tract

Clinical Manifestations of Gastrointestinal Dysfunction

Anorexia

Anorexia is the lack of desire to eat despite physiologic stimuli that would normally produce hunger (see Chapter 23). This nonspecific symptom is often associated with nausea, abdominal pain, diarrhea, psychological stress, and weight loss. Side effects of drugs and pathologic disease processes such as cancer, heart disease, renal disease, and liver disease are often accompanied by anorexia. Anorexia can lead to weight loss, protein energy malnutrition, sarcopenia, functional decline, and is often associated with cachexia.[1] The aging population exhibits a high prevalence of anorexia and is an independent predictor of morbidity and mortality in the community and in clinical care settings.[2,3]

Vomiting

Vomiting (emesis) is an involuntary, forceful emptying of stomach and intestinal contents (chyme) through the mouth. The vomiting center, called the *area postrema*, lies in the medulla oblongata. The vomiting center contains receptors that may be stimulated to cause vomiting. Stimulation of the vomiting center occurs by either irritants or indirect stimuli. Some causes of indirect stimulation

involve the cerebral cortex and thalamus (e.g., anxiety and pain); the vestibular system through the eighth cranial nerve (e.g., motion sickness); and several types of intestinal, vagal, as well as differing types of sympathetic input. Examples of vomiting caused by intestinal, vagal, or sympathetic input include presence of ipecac in the duodenum after ingestion; side effects of certain drugs; distention of the stomach or duodenum; and torsion or trauma affecting the ovaries, testes, uterus, bladder, or kidney. Serotonin (5-hydroxytryptamine [5-HT]) may also stimulate the vomiting center and appears to be released from enterochromaffin cells that lie in the intestinal wall. These cells activate vagal afferents leading to the chemoreceptor trigger zone (CTZ), which leads to vomiting by triggering receptors for dopamine (D_2), opioids, acetylcholine, substance P, serotonin (5-HT type 3), and neurokinin-1.

Nausea and retching (dry heaves) are distinct events that usually precede vomiting. **Nausea** is a subjective experience associated with various conditions, including abnormal pain, used of opioids, and labyrinthine stimulation (i.e., motion). Specific neural pathways that cause nausea have not been identified, but hypersalivation and tachycardia are common associated symptoms. **Retching** is the muscular event of vomiting without the expulsion of vomitus.

Vomiting begins with deep inspiration. The glottis closes, the intrathoracic pressure decreases, and the esophagus becomes distended. Simultaneously, the abdominal muscles contract, creating a pressure gradient from abdomen to thorax. The lower esophageal sphincter (LES) and body of the stomach relax, but the duodenum and antrum of the stomach spasm. The reverse peristalsis and pressure gradient force chyme from the stomach and duodenum up into the esophagus. Because the upper esophageal sphincter is closed, chyme does not enter the mouth. When the stomach is full of gastric contents, the diaphragm is forced high into the thoracic cavity by strong contractions of the abdominal muscles. The higher intrathoracic pressure forces the upper esophageal sphincter to open, and chyme is expelled from the mouth. Then the stomach relaxes and the upper part of the esophagus contracts, forcing the remaining

chyme back into the stomach. The LES then closes. The cycle is repeated if there is a volume of chyme remaining in the stomach. A diffuse sympathetic discharge causes the tachycardia, tachypnea, and diaphoresis that accompany retching and vomiting. The parasympathetic system mediates copious salivation, increased gastric motility, and relaxation of the upper and LESs.

Spontaneous vomiting not preceded by nausea or retching is called **projectile vomiting**. It is caused by direct stimulation of the vomiting center by neurologic lesions (e.g., increased intracranial pressure, tumors, or aneurysms) involving the brainstem (see Chapter 17), or it can be a symptom of GI obstruction (pyloric stenosis). The metabolic consequences of vomiting are fluid, electrolyte, and acid-base disturbances, including hyponatremia, hypokalemia, hypochloremia, and metabolic alkalosis (see Chapter 3). The management of nausea and vomiting includes fluid and electrolyte maintenance, use of medications, and complimentary nonpharmacologic therapies.[4]

Constipation

Constipation is difficult or infrequent defecation. It is a common problem, afflicting 24% of the United States population. Although it affects all age groups, prevalence increases with age.[5]

Constipation means a decrease in the number of bowel movements per week, hard stools, straining, abdominal pain, and difficult evacuation. The definition of constipation must be individually determined because normal bowel habits range from one to three evacuations per day to one per week.

Pathophysiology

Constipation can occur as a primary or secondary condition. Chronic idiopathic or primary constipation is generally classified into three categories: functional defecation disorder, slow transit constipation (STC), and constipation-predominant irritable bowel syndrome (IBS-C). Overlap may exist between these three classifications, and the classifications are not mutually exclusive.[6] *Functional constipation* is

similar between children and adults, but differences exist regarding the symptomology and pathophysiology of disease, as well as differences in required diagnostic work-up and treatment modalities.[7] Functional constipation involves a normal rate of stool passage but difficulty with stool evacuation. *STC* involves impaired colonic motor activity with symptoms of infrequent bowel movements, straining to defecate, mild abdominal distention, and palpable stool in the sigmoid colon. *IBS-C* is associated with chronic constipation and abdominal pain. The exact cause of IBS-C is poorly understood, but various factors that may contribute to the pathology of the disease include diet, genetics, colonic motility, absorption, socioeconomic status, daily behaviors, and medication use.[8] Lack of access to toilet facilities, consistent suppression of the urge to empty the bowel, pelvic floor dyssynergia, and dehydration may be other causes of primary constipation.

Secondary constipation can be caused by diet, medications, or neurogenic disorders (e.g., stroke, Parkinson disease, spinal cord lesions, multiple sclerosis, and Hirschsprung disease) in which neural pathways or neurotransmitters are diseased or degenerated, resulting in altered or delayed colon transit time. Rectal fissures, strictures, or hemorrhoids also may cause constipation. Antacids containing calcium carbonate or aluminum hydroxide, anticholinergics, iron, and bismuth tend to inhibit bowel motility causing constipation. *Opioid-induced constipation* is caused by drugs that activate μ-opioid receptors in the gut and slow transit time. Endocrine or metabolic disorders, which may also be associated with constipation, include hypothyroidism, diabetes mellitus, hypokalemia, and hypercalcemia. Pelvic hiatal hernia (herniation of the bowel through the floor of the pelvis), diverticula, irritable bowel syndrome (IBS) (constipation predominant), and pregnancy are associated with constipation. Aging may result in decreased mobility, changes in neuromuscular function, use of medications, and comorbid medical conditions causing constipation. Pain or weakness of the abdominal muscles may interfere with the generation of adequate intra-abdominal pressure needed to evacuate

stool from the rectum. Depression may also impair bowel evacuation due to a sedentary lifestyle and diet changes. It is important to remember that constipation or a notable change in bowel habits can be an indication of colorectal cancer (CRC).

Clinical Manifestations

Indicators of primary or functional constipation (not including IBS-C) are guided by the Rome IV criteria. The Rome IV criteria define chronic constipation as including at least two of the following symptoms: straining with defecation at least 25% of the time; lumpy or hard stools at least 25% of the time; sensation of incomplete emptying at least 25% of the time; feeling of anorectal obstruction/blockage at least 25% of the time; manual maneuvers to facilitate stool evacuation for at least 25% of defecations; and fewer than three bowel movements per week (see Table 41.1 for Rome IV criteria).[6,8] Changes in bowel evacuation patterns, such as less frequent defecation, smaller stool volume, hard stools, difficulty passing stools (e.g., straining), a feeling of bowel fullness and discomfort, or blood in the stools, require further assessment. Straining to evacuate stool may cause engorgement of the hemorrhoidal veins and hemorrhoidal disease or thrombosis with rectal pain, bleeding, and itching. Passage of hard stools can cause painful anal fissures. Fecal impaction (hard, dry stool retained in the rectum) is associated with rectal bleeding, abdominal or cramping type pain, nausea and vomiting, weight loss, and episodes of diarrhea. If left untreated, fecal impaction may cause increased pressure on the intralumen of the colon that may lead to ischemia with possible perforation of the colon and even death.[9]

Table 41.1

Definition of Chronic Constipation According to the Rome IV Criteria

nostic cri Diagnostic criteria Includes ≥2 of the following symptoms over the preceding three months:

- Straining during ≥25% of toilet visits
- Lumpy, hard feces on ≥25% of defecations
- Feeling of anorectal obstruction/blockage ≥25% of defecations
- Requirement of manual stimulation ≥25% of defecations
- Loose stools are rarely achievable without laxatives
- Symptoms do not fit the criteria for irritable bowel syndrome

nostic cri Diagnostic criteria Includes ≥2 of the following symptoms over the preceding three months:
• Straining during ≥25% of toilet visits
• Lumpy, hard feces on ≥25% of defecations
• Feeling of anorectal obstruction/blockage ≥25% of defecations
• Requirement of manual stimulation ≥25% of defecations
• Loose stools are rarely achievable without laxatives
• Symptoms do not fit the criteria for irritable bowel syndrome

Evaluation and Treatment

The history, current use of medications, physical examination, and stool diaries provide precise clues regarding the nature of constipation. The individual's description of the duration of symptoms, frequency of bowel movements, stool consistency, difficult rectal evacuation, sense of incomplete evacuation, presence

of blood with stools, and if evacuation was stimulated by enemas or laxatives is important. It is also important to note any abdominal pain or bloating and if any type of digital evacuation to remove stool has been performed. The clinician should also discuss comorbidities, previous GI disorders or surgeries, diet, fluid intake, and physical activity. As mentioned, sudden-onset constipation may signify a new or developing mass and requires careful evaluation for CRC. Abdominal palpation may disclose colonic distention, masses, and tenderness. Digital examination of the rectum and anorectal manometry are performed to assess sphincter tone and detect anal lesions. Colonic transit time and imaging techniques can assist in identifying the cause of constipation. Colonoscopy is used to visualize the bowel lumen directly and can help with identification of polyps, inflammatory bowel diseases (IBDs), or other suspicious lesions including tumors.

The treatment for constipation is to manage the underlying cause or disease. Lifestyle modifications can often help immensely. Management of constipation usually consists of bowel retraining, in which the individual establishes a satisfactory bowel evacuation routine without becoming preoccupied with bowel movements. The individual also may need to engage in moderate exercise and increase fluid and fiber intake. Fiber supplements and stool softeners are useful for some individuals. Many different types of laxatives are available; however, studies are lacking comparing the efficacy and safety of different categories of laxatives. Choice of laxative for an individual should be guided by a healthcare professional and should take into account individual preferences and cost.[5] Enemas can be used to establish a bowel routine, but they should not be used routinely. Biofeedback may be beneficial in some instances for forming new bowel evacuation habits. Colectomy with ileorectal anastomosis is rarely performed but may be done with individuals with severe symptoms that have not responded to other treatments.[5]

Diarrhea

Diarrhea is the presence of loose, watery stools and may be acute, persistent, or chronic. Diarrhea is defined as the passage of three or more loose or liquid stools per day, or more frequent passing of stools than what has routinely been "normal" for a specific individual.[10] Acute diarrhea is more than three loose stools developing within 24 hours and lasting less than 14 days. Persistent diarrhea is diarrhea in an individual that lasts longer than 14 to 30 days and chronic diarrhea is diarrhea that lasts longer than 4 weeks. Diarrhea can have high rates of morbidity and mortality in children younger than 5 years of age, particularly in developing countries (see Chapter 42), and in the elderly. Diarrheal disease is the second leading cause of death in children younger than age 5.[10]

Many factors determine stool volume, including water content of the colon, diet, presence of nonabsorbed food or material, and intestinal secretions. Stool volume in the normal adult averages less than 200 g/day. Stool volume in children depends on age and size. An infant may pass up to 100 g/day. The adult intestine processes approximately 9 L of luminal contents per day: 2 L are ingested, and the remaining 7 L consist of intestinal secretions. Of this volume, most of the fluid is absorbed: 90% (7 to 8 L) in the small intestine and a smaller amount 9% (1 to 2 L) in the colon. Normally, approximately 150 mL of water is excreted daily in the stool.

Pathophysiology

The intestinal mucosa is made up of a complex epithelium where absorption and secretion occur. The majority of water and electrolyte absorption occurs in the small intestine.[11] Diarrhea in which the volume of feces is increased is called *large-volume diarrhea*. It generally is caused by excessive amounts of water or secretions in the intestines. *Small-volume diarrhea*, in which the volume of feces is not increased, usually results from excessive intestinal motility and may be caused by an inflammatory disorder of the intestine, such as ulcerative colitis (UC), Crohn disease (CD), or microscopic colitis, but also can result from colon cancer or fecal impaction.

The three major mechanisms of diarrhea are osmotic, secretory, and motile.

1. **Osmotic diarrhea**. A nonabsorbable substance in the intestine draws excess water into the lumen of the intestine by osmosis and increases stool weight and volume, producing large-volume diarrhea. Large oral doses of poorly absorbed ions, such as magnesium, sulfate, and phosphate, can increase intraluminal osmotic pressure. Excessive ingestion of synthetic, nonabsorbable sugars (e.g., sorbitol); introduction of full-strength tube feeding formulas; and dumping syndrome associated with gastric resection draw water into the intestinal lumen. Once ingestion of the osmotic substance stops, the osmotic diarrhea will stop. Malabsorption related to lactase deficiency, pancreatic enzyme, or bile salt deficiency, small intestine bacterial overgrowth, or celiac disease also causes osmotic diarrhea.
2. **Secretory diarrhea**. A form of large-volume diarrhea caused by excessive mucosal secretions of chloride or bicarbonate-rich fluid or overall inhibition of net sodium absorption. Infectious causes include viruses (e.g., rotavirus), bacterial enterotoxins (e.g., *Escherichia coli*, *Vibrio cholera*, Shiga toxin), exotoxins (e.g., overgrowth of *Clostridioides difficile* following antibiotic therapy), or small bowel bacterial overgrowth. These infections cause secretion of transmitters from enteroendocrine cells (e.g., cells found in the wall of the bowel that have numerous processes in the body), activation of afferent neurons that stimulate submucosal secretomotor neurons, and altered sodium and chloride transport that results in decreased water absorption. Certain neoplasms (e.g., gastrinoma and thyroid carcinoma) also produce hormones that stimulate intestinal secretion, causing diarrhea.
   Small-volume diarrhea is usually caused by an inflammatory bowel disorder, such as UC or CD. Inflammation of the colon

causes smooth muscle contraction, cramping type pain, bowel urgency, and frequency. Small-volume diarrhea also can be caused by fecal impaction. The diarrhea caused from a fecal impaction consists of secretions of mucus of fluid produced by the colon to lubricate the impacted feces and move it toward the anal canal. These secretions flow around the impaction and cause low-volume, secretory diarrhea.

3. **Motility diarrhea**. Excessive motility decreases transit time and the opportunity for fluid absorption, resulting in diarrhea. This type of diarrhea is caused by resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, IBS–diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse.

Clinical Manifestations

Diarrhea can be acute or chronic, depending on the cause. Systemic effects of prolonged diarrhea are dehydration, electrolyte imbalance (hyponatremia, hypokalemia), metabolic acidosis, and weight loss. Manifestations of acute bacterial or viral infection include fever, with or without vomiting or cramping pain. Most diarrhea caused by infectious organisms lasts less than 2 weeks, although some causes of bacterial gastroenteritis may last longer, such as *C. difficile, Aeromonas*, or *Yersinia enterocolitica*. Fever, cramping pain, and bloody stools accompany chronic diarrhea caused by IBD or dysentery. **Steatorrhea** (fat in the stools), bloating, and diarrhea are common signs of malabsorption syndromes. Diarrhea may also cause anal and perineal skin irritation.

Evaluation and Treatment

A thorough history is taken to document the onset, frequency, volume of stools, duration of diarrhea, and presence of blood in the stools. Documentation of recent travel is important to obtain in the history. Iatrogenic diarrhea is suggested if the individual has undergone abdominal radiation therapy, intestinal resection, or

treatment with selected drugs (e.g., antibiotics, diuretics, antihypertensives, laxatives, anticoagulants, or chemotherapy). A thorough physical examination should be completed and can help identify underlying systemic disease. Stool studies, abdominal imaging, endoscopy, and intestinal biopsies provide more specific data, particularly for persistent diarrhea.

Treatment for diarrhea includes restoration of fluid and electrolyte balance, administration of antimotility (e.g., loperamide) and/or water-absorbent (e.g., attapulgite and polycarbophil) medications, and treatment of causal factors. Natural bran and commercial preparations of psyllium are inexpensive and effective treatments for mild diarrhea. Probiotics can be useful for preventing and treating *C. difficile*–associated diarrhea as an approach to restoring normal microflora in addition to antibiotic therapy. Fecal transplantation can be used for cases that are resistant to conventional therapies, particularly *C. difficile*–associated diarrhea. Nutritional deficiencies need to be corrected in cases of chronic diarrhea or malabsorption.[12]

Abdominal Pain

Abdominal pain is the presenting symptom of several GI diseases and can be acute or chronic. The causal mechanisms of abdominal pain are *mechanical, inflammatory*, or *ischemic*. Abdominal organs are sensitive to stretching and distention. This stretching activates nerve endings in both hollow and solid structures, causing pain. Pain accompanies rapid distention rather than gradual distention. Traction on the peritoneum caused by adhesions, distention of the common bile duct, or forceful peristalsis resulting from intestinal obstruction causes pain because of increased tension. Capsules that surround solid organs, such as the liver and gallbladder, contain pain fibers that are stimulated by stretching if these organs swell. Abdominal pain may be generalized to the abdomen or localized to a particular abdominal quadrant. The nature of the pain is often described as sharp, dull, or colicky.

Abdominal pain is usually associated with tissue injury and inflammation. Biochemical mediators of the inflammatory response,

such as histamine, bradykinin, and serotonin, stimulate organic nerve endings and produce abdominal pain. The edema and vascular congestion that accompany chemical, bacterial, or viral inflammation also cause painful stretching. Hindrance of blood flow from the distention of bowel obstruction or mesenteric vessel thrombosis produces the pain of ischemia and increased concentrations of tissue metabolites stimulate pain receptors.

Abdominal pain can be parietal (somatic), visceral, or referred. **Parietal pain**, originating from the parietal peritoneum, is more localized and intense than visceral pain, which arises from the organs themselves. Nerve fibers from the parietal peritoneum are predominantly A-delta fibers and travel with somatic peripheral nerves to the spinal cord. Parietal pain is caused by an irritation of fibers of the peritoneal peritoneum or lining. The sensation of pain is localized to the dermatome superficial to the area of painful stimuli. **Visceral pain** arises from a stimulus (distention, inflammation, ischemia) causing stretching, damage, or disruption of the organ or organ tissue involved and is transmitted via sympathetic fibers. Inflammatory mediators associated with chronic low-grade inflammation can cause pain hypersensitivity, and they include neurokinins, histamine, serotonin, and proteases.[13] These mediators can activate voltage-gated sodium ion channels.[14] Pain is usually near the midline in the epigastrium, midabdomen, or lower abdomen because sensory afferents enter the spinal cord bilaterally and lack specificity. The pain is usually poorly localized, diffuse, or vague with a radiating pattern because nerve endings in abdominal organs are sparse and multisegmented. Pain arising from the stomach, for example, is experienced as a sensation of fullness, cramping, or gnawing in the midepigastric area. **Referred pain** is visceral pain felt at some distance from a diseased or affected organ. It is usually well localized and is felt in the skin dermatomes or deeper tissues that share a central afferent pathway with the affected organ. For example, acute cholecystitis may have pain referred to the right shoulder or scapula.

Gastrointestinal Bleeding

Upper GI bleeding is bleeding in the esophagus, stomach, or duodenum and is characterized by frank, bright red bleeding or dark, grainy digested blood ("coffee grounds") in the stool (Table 41.2). Upper GI bleeding is commonly caused by bleeding esophageal or gastric varices, peptic ulcers, arteriovenous malformations, or a Mallory-Weiss tear at the esophageal-gastric junction caused by severe retching. Upper GI bleeding may also be associated with use of nonsteroidal antiinflammatory drugs (NSAIDs), selective serotonin reuptake inhibitors, and antiplatelet and anticoagulant drugs.[15,16]

Table 41.2

Presentations of Gastrointestinal Bleeding

Presentations	Definition
Acute Bleeding	
Hematemesis	Bloody vomitus; either fresh, bright red blood or dark grainy digested blood with "coffee grounds" appearance
Melena	Black, sticky, tarry, foul-smelling stools caused by digestion of blood in gastrointestinal tract; should be distinguished from black stools caused by dietary iron supplements, blackberries, or bismuth (e.g., Pepto-Bismol)
Hematochezia	Fresh, bright red blood passed from rectum
Occult Bleeding	Trace amounts of blood in normal-appearing stools or gastric secretions; detectable only with positive fecal occult blood test (guaiac test)

Presentations	Definition
Acute Bleeding	
Hematemesis	Bloody vomitus; either fresh, bright red blood or dark grainy digested blood with "coffee grounds" appearance
Melena	Black, sticky, tarry, foul-smelling stools caused by digestion of blood in gastrointestinal tract; should be distinguished from black stools caused by dietary iron supplements, blackberries, or bismuth (e.g., Pepto-Bismol)
Hematochezia	Fresh, bright red blood passed from rectum
Occult Bleeding	Trace amounts of blood in normal-appearing stools or gastric secretions; detectable only with positive fecal occult blood test (guaiac test)

Lower GI bleeding, or bleeding from the jejunum, ileum, colon, or rectum, can be caused by polyps, diverticulitis, inflammatory disease, cancer, or hemorrhoids. **Occult bleeding** is usually caused by slow, chronic blood loss that is not obvious and results in iron deficiency anemia as iron stores in the bone marrow are slowly depleted.

Physiologic response to GI bleeding depends on the amount and rate of the loss. Acute, severe GI bleeding can be life threatening, depending on the volume and rate of blood loss, associated diseases, the age of the individual, and the effectiveness of treatment. Changes in blood pressure and heart rate are the best indicators of massive blood loss in the GI tract. During the early stages of blood volume depletion, the peripheral arteries and arterioles constrict to shunt blood to vital organs, including the brain. Signs of large-volume blood loss are postural hypotension (a drop in blood pressure that occurs with a change from the recumbent position to a sitting or upright position), lightheadedness, and loss of vision. Tachycardia develops as a compensatory response to maintain cardiac output and tissue perfusion. If blood loss continues, hypovolemic shock develops (see Chapters 32 and 48). Diminished blood flow to the kidneys causes decreased urine output and may lead to oliguria (low urine output), tubular necrosis, and renal failure. Ultimately, insufficient cerebral and coronary blood flow causes irreversible anoxia and death (Fig. 41.1).

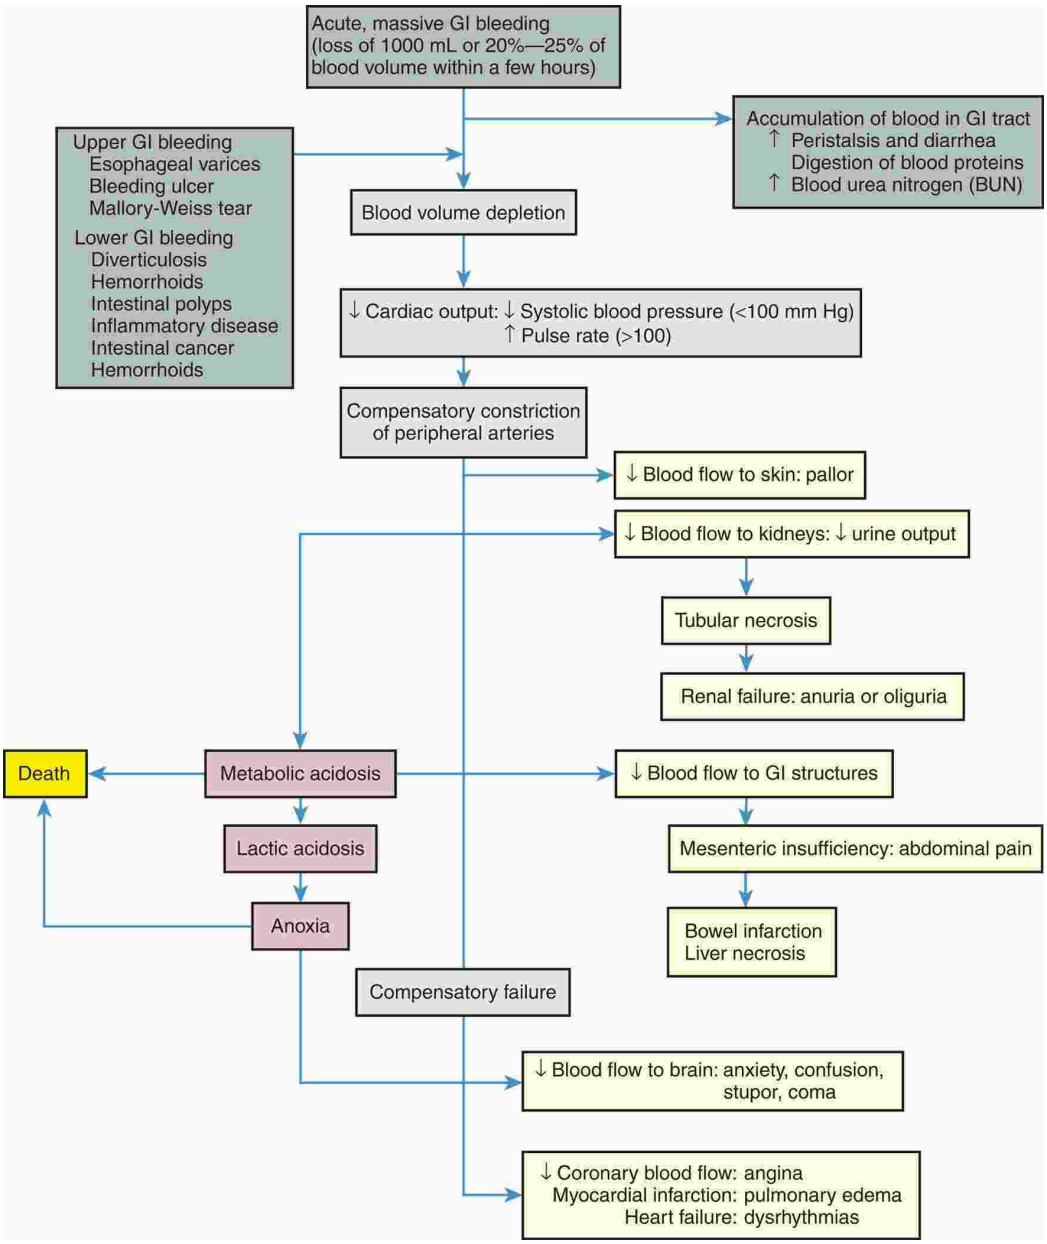

FIG. 41.1 Pathophysiology of Gastrointestinal Bleeding.

A flow diagram summarizes the pathophysiology of gastrointestinal bleeding, which beings as follows. • Upper G I bleeding consisting esophageal varices, bleeding ulcer, Mallory-Weiss tear; lower G I bleeding consisting of intestinal polyps,

inflammatory disease, intestinal cancer, hemorrhoids; acute or massive G I bleeding consisting of loss of 1000 milliliters or 20 percent to 25 percent of blood volume within a few hours leads to accumulation of blood in G I tract which increases peristalsis and diarrhea, digestion of blood proteins and blood urea nitrogen which further leads to blood volume depletion. • Blood volume depletion leads to a decrease in cardiac output, which consists of a decrease in systolic blood pressure of less than 100 millimeters of mercury and an increase in pulse rate of greater than 100. • Decrease cardiac output leads to compensatory constriction of peripheral arteries, which leads to compensatory failure due to decreased coronary blood flow: angina; myocardial infarction: pulmonary edema; heart failure: dysrhythmias. • Compensatory constriction of peripheral arteries includes a decrease in blood flow to skin: pallor; decreased blood flow to kidneys with decreased urine output leads to tubular necrosis and metabolic acidosis. • The tubular necrosis leads to renal failure: anuria or oliguria. • Metabolic acidosis leads to death due to a decrease in blood flow to G I structure, leads to mesenteric insufficiency or abdominal pain. • Mesenteric insufficiency or abdominal pain leads to bowel infarction or liver necrosis. • Metabolic acidosis leads to lactic acidosis.

- Lactic acidosis leads to anoxia due to a decrease in blood flow to the brain: anxiety, confusion, stupor, coma, and anoxia lead to death.

The presentations of GI bleeding are summarized in Table 41.2. The accumulation of blood in the GI tract is irritating and increases peristalsis, causing vomiting or diarrhea, or both. Hematemesis may be present. If bleeding is from the lower GI tract, **hematochezia** (bloody stools) may be present. Bleeding from the upper GI tract may also be rapid enough to produce hematochezia, but generally some digestion of the blood components will have occurred, producing **melena**. The digestion of blood proteins originating from massive upper GI bleeding is reflected by an increase in blood urea nitrogen (BUN) levels.

The hematocrit and hemoglobin values are not the best indicators of acute GI bleeding because plasma volume and red cell volume are lost proportionately. As the plasma volume is replaced, the hematocrit and hemoglobin values begin to reflect the extent of blood loss. The interpretation of these values is modified to account for exogenous replacement of fluids and the hydration status of the tissues. Anemia associated with chronic GI bleeding is caused by iron depletion. Evaluation and treatment involve identifying and treating the source of the bleeding and replacing iron losses. Administration of blood products may be used for massive hemorrhage. Guidelines are available for the diagnosis and management of GI bleeding that may include endoscopic management with upper GI bleeds.[16–18]

Disorders of Motility

Dysphagia

Pathophysiology

Dysphagia is difficulty swallowing or the perception of obstruction while swallowing. It can result from *mechanical obstruction* of the esophagus or from a functional disorder that impairs esophageal motility. Intrinsic obstructions originate in the wall of the esophageal lumen (e.g., esophageal dysphagia) and include tumors, strictures, and diverticular herniations (e.g., outpouchings). Extrinsic mechanical obstructions originate outside the esophageal lumen and narrow the esophagus by pressing inward on the esophageal wall. The most common cause of extrinsic mechanical obstruction is tumor.

Functional dysphagia is caused by neural or muscular disorders that interfere with voluntary swallowing or peristalsis. Disorders that affect the striated muscles of the hypopharyngeal area and upper esophagus interfere with the oropharyngeal (voluntary) phase of swallowing (oropharyngeal dysphagia). Typical causes are dermatomyositis (a muscle disease) and neurologic impairments caused by cerebrovascular accidents, Parkinson disease, multiple sclerosis, muscular dystrophy, or achalasia.

Achalasia is a rare form of dysphagia related to loss of inhibitory neurons in the myenteric plexus with smooth muscle atrophy in the middle and lower portions of the esophagus. A proposed mechanism is that myenteric neurons are attacked by a cell-mediated and antibody-mediated immune response against an unknown antigen (e.g., a virus). This leads to altered esophageal peristalsis and failure of the LES to relax, causing functional obstruction of the lower esophagus with varying severity. Food accumulates above the obstruction, distends the esophagus, and causes dysphagia. Cough and aspiration can occur. As hydrostatic pressure increases, food is slowly forced past the obstruction into the stomach. Chronic inflammation from esophageal food retention can increase risk for esophageal cancer.

Clinical Manifestations

Clinical manifestations of dysphagia vary according to the location of the obstruction. Distention and spasm of the esophageal muscles

during eating or drinking may cause a mild or severe stabbing pain at the level of obstruction. Discomfort occurring 2 to 4 seconds after swallowing is associated with upper esophageal obstruction. Discomfort occurring 10 to 15 seconds after swallowing is more common in obstructions of the lower esophagus. If obstruction results from a growing tumor, dysphagia begins with difficulty swallowing solids and advances to difficulty swallowing semisolids and liquids. If motor function is impaired, both solids and liquids are difficult to swallow. Regurgitation of undigested food, an unpleasant taste sensation, vomiting, aspiration, and weight loss are common manifestations of all types of dysphagia. Aspiration of esophageal contents can lead to cough and pneumonia.

Evaluation and Treatment

Knowledge of the individual's history and clinical manifestations contributes significantly to a diagnosis of dysphagia. Imaging is used to visualize the contours of the esophagus and identify potential structural defects. Esophageal motility testing documents abnormal pressure changes associated with obstruction or loss of neural regulation. Esophageal endoscopy is performed to examine the esophageal mucosa and obtain biopsy specimens.

The individual is taught to manage symptoms by eating small meals slowly, taking fluid with meals, and sleeping with the head elevated to prevent regurgitation and aspiration. Food and medications may need to be formulated with a thickening agent so they can be swallowed. Tube feedings may be required for some individuals, particularly following stroke. Mechanical dilation of the esophageal sphincter and surgical separation of the lower esophageal muscles with a longitudinal incision (myotomy) may be an effective treatment for achalasia.[19]

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the reflux of acid and pepsin or bile salts from the stomach into the esophagus, causing esophagitis. The prevalence of GERD is estimated at 18% to 27% in

North America.[20] Risk factors for GERD include increasing age, obesity, hiatal hernia, and drugs or chemicals that relax the LES (anticholinergics, nitrates, calcium channel blockers, nicotine). GERD may be a trigger for asthma or chronic cough. Gastroesophageal reflux that does not cause symptoms is known as *physiologic reflux*. In *nonerosive reflux disease (NERD)*, individuals have symptoms of reflux disease but no visible or minimal esophageal mucosal injury (functional heartburn).

Pathophysiology

Abnormalities in LES function, esophageal motility, and gastric motility or emptying can cause GERD. The resting tone of the LES has an average pressure of approximately 20 mm Hg that prevents gastric content from refluxing into the esophagus. Spontaneous relaxation of the LES may be triggered by gastric distention after meals and trigger acid reflux. Acid reflux may be triggered by diet and lifestyle factors such as food intake that causes delayed gastric emptying, acidic foods, and obesity. Sliding hiatal hernia facilitates reflux.[21] Vomiting, coughing, lifting, bending, and pregnancy also increase abdominal pressure, contributing to the development of reflux esophagitis.

The severity of the esophagitis depends on the composition of the gastric contents and the esophageal mucosa exposure time. If the gastric contents are highly acidic or contain bile salts and pancreatic or intestinal enzymes, reflux esophagitis can be severe. In individuals with weak esophageal peristalsis, refluxed chyme remains in the esophagus longer than usual. The refluxate causes mucosal injury and inflammation, with hyperemia, increased capillary permeability, edema, tissue fragility, and erosion (Fig. 41.2). Fibrosis and thickening may develop. Precancerous lesions (Barrett esophagus [BE]; see the Esophageal Cancer section) can be a long-term consequence. Precancerous lesions can progress to adenocarcinoma.

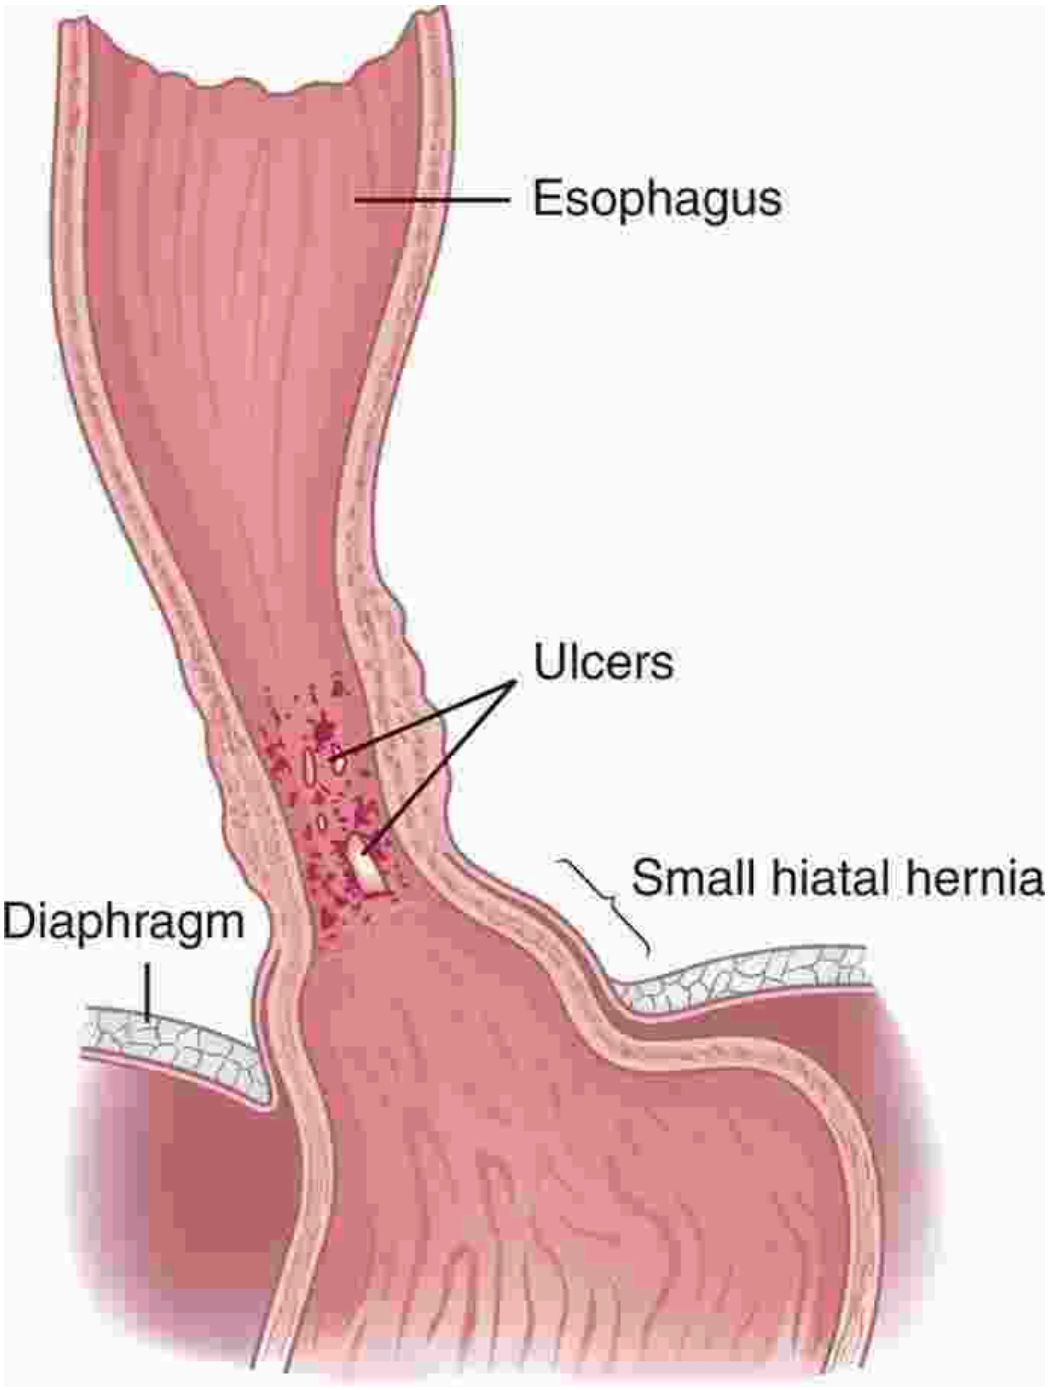

FIG. 41.2 Esophagitis With Esophageal Ulcerations.

Clinical Manifestations

The clinical manifestations of erosive reflux esophagitis are related to mucosal injury from acid regurgitation. Manifestations are heartburn (e.g., pyrosis) and acid regurgitation. Dysphagia, chest pain, chronic cough, asthma attacks (see Chapter 35), laryngitis, hoarseness, and upper abdominal pain that occurs within 1 hour of eating are less common. The symptoms worsen if the individual lies down or if intra-abdominal pressure increases (e.g., as a result of coughing, vomiting, or straining at stool). Edema, strictures, esophageal spasm, or decreased esophageal motility may result in dysphagia with weight loss. Alcohol or acid-containing foods, such as citrus fruits, can cause discomfort during swallowing.

Evaluation and Treatment

The diagnosis of GERD is based on the history and clinical manifestations. Esophageal endoscopy shows hyperemia, edema, erosion, and strictures. Dysplastic changes, such as occurs with BE (see section on esophageal carcinoma), can be identified by tissue biopsy. Impedance/pH monitoring measures the movement of stomach contents upward into the esophagus and the acidity of the refluxate. Heartburn may be experienced as chest pain, so cardiac ischemia must be ruled out.

Treatment includes once-daily proton pump inhibitors (PPIs) for 4 weeks, and continuing therapy if esophagitis or BE is present.[21] Weight reduction, smoking cessation, elevation of the head of the bed 6 inches, and avoiding tight clothing may also help to alleviate symptoms. The most common surgical treatment is laparoscopic fundoplication. Emerging surgical treatments include magnetic sphincter augmentation (a device placed around the distal esophagus and comprises titanium beads with magnets in the center that augment lower esophageal tone and thus prevent reflux), radiofrequency ablation, and transoral incisionless fundoplication.

Eosinophilic esophagitis (EoE) is an idiopathic chronic allergic/immune disease of the esophagus characterized by infiltration of eosinophils in the esophagus. EoE is most associated with atopic disease, including asthma, allergic rhinitis, eczema, and

food allergies that occur in both children and adults, but the symptoms may vary by age. EoE causes many white blood cells to be found in the inner lining of the esophagus. Typically, eosinophils are not found in the esophagus, although other conditions (e.g., acid reflux disease) may contribute to the presence of eosinophils in the esophagus. Manifestations of the disease are caused by esophageal inflammation (See Chapter 42).[22] Dysphagia, decreased appetite, recurring abdominal pain, vomiting, and weight loss are common symptoms. Diagnosis is made by endoscopy with biopsy that identifies the eosinophilic infiltration and differentiates this condition from GERD. Treatment is symptomatic and includes acid inhibitors, elimination diets, and corticosteroids.[22] Other conditions associated with EoE, such as food allergies, asthma, or eczema, must also be treated appropriately (see Chapter 42).

Hiatal Hernia

Pathophysiology

Hiatal hernia is a common disorder characterized by a protrusion or bulging of an abdominal structure into the thoracic cavity. Causation is from a weakening of the diaphragm muscle.[23] (Fig. 41.3) The most common type is a **sliding hiatal hernia (type 1)** (see Fig. 41.3 A). In this type of hernia, the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus. The esophageal hiatus is an opening in the diaphragm for the esophagus and vagus nerves. A congenitally short esophagus, fibrosis, excessive vagal nerve stimulation, or weakening of the diaphragmatic muscles at the gastroesophageal junction contributes to this type of hernia. Laying in the supine position causes the lower esophagus and stomach to be pulled into the thorax. As an individual stands, the organs slide back into the abdomen. Coughing, bending, tight clothing, ascites, obesity, and pregnancy accentuate the hernia in association with the resting pressure of the LES.

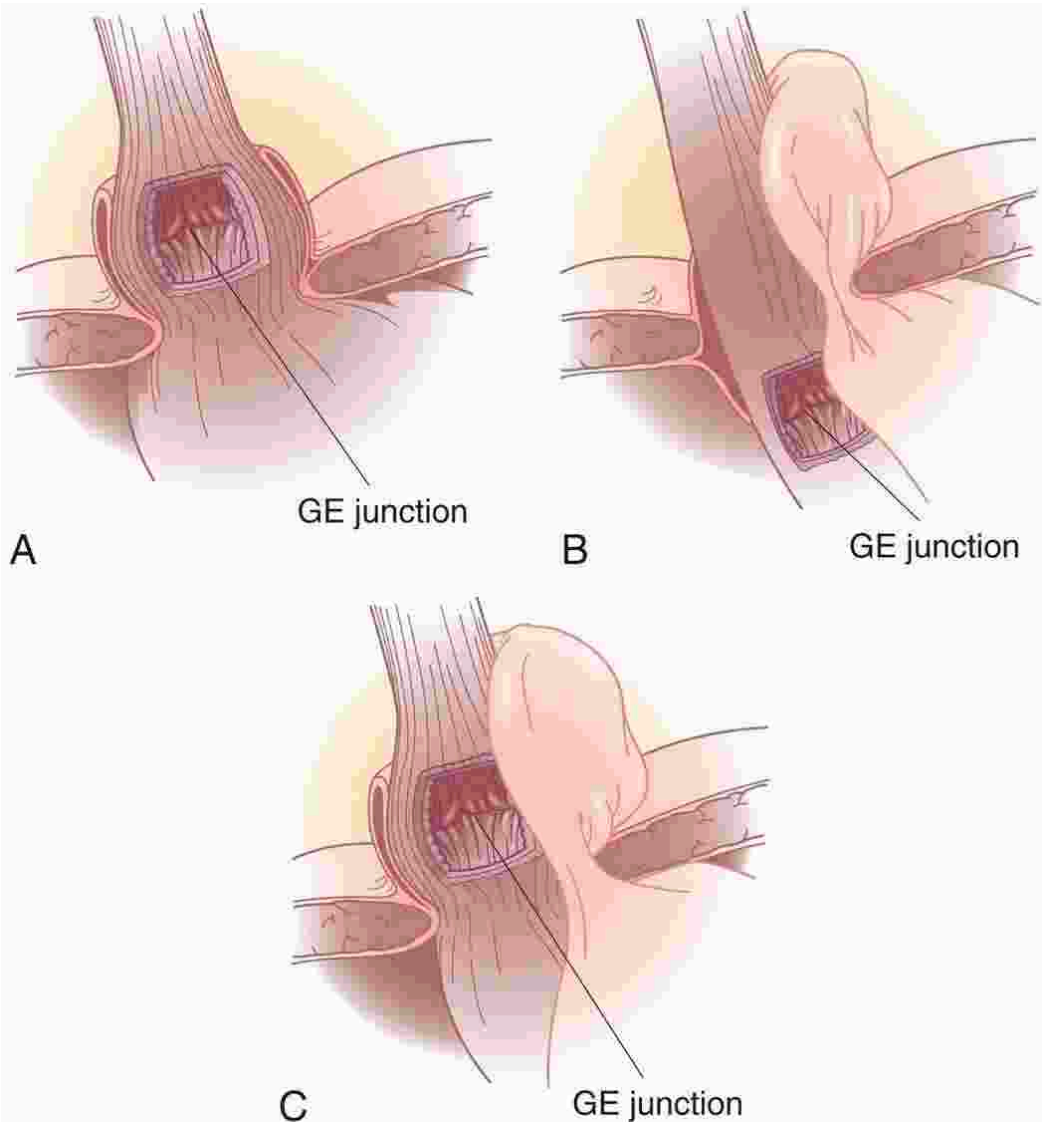

FIG. 41.3 Three Types of Hiatal Hernia.
(A) Type I—*sliding hernia*. The visceral peritoneum remains intact and restrains the size of the hernia in sliding hiatal hernia. **(B)** Type II—*paraesophageal* or *rolling hernia*. The membrane becomes thinner or defective in a paraesophageal hernia, allowing a true peritoneal sac to protrude into the posterior mediastinum, where negative intrathoracic pressure causes it to enlarge. **(C)** Type III—*mixed hernia*. *GE*, Gastroesophageal. Note: Type IV—complex paraesophageal hernia is not shown. (From

Townsend CM, et al. *Sabiston textbook of surgery: The biologic basis surgical practice*, 21st edition. St. Louis: Elsevier; 2022)

Three illustrations depict the three types of hiatal hernia. Illustration A depicts the sliding hernia, which shows the G E junction above the level of diaphragmatic hiatus. Illustration B depicts the rolling hernias, which shows a normal position to the G E junction, but a portion of the fundus above the hiatus. Illustration C depicts the mixed hernia, which shows displacement of both the G E junction and fundus above the hiatus.

Paraoesophageal hiatal hernia (type 2) is a herniation of the greater curvature of the stomach through a secondary opening in the diaphragm alongside the esophagus that moves into the thorax above the diaphragm (see Fig. 41.3 B). This abnormal positioning of a portion of the stomach causes congestion of mucosal blood flow, leading to gastritis and ulcer formation. Reflux is uncommon with this type of hernia. Strangulation of the hernia is a major complication that results with occlusion of blood vessels and causes vascular engorgement with resulting edema, ischemia, and hemorrhage. Manifestations or symptoms of this type of hernia include vomiting and epigastric/retrosternal epigastric pain and is a surgical emergency.

Mixed hiatal hernia (type 3), less common, is a combination of sliding and paraoesophageal hiatal hernias (see Fig. 41.3 C). It tends to occur in conjunction with several other diseases, including reflux esophagitis, peptic ulcer, cholecystitis, cholelithiasis, chronic pancreatitis, and diverticulosis. A mixed hiatal hernia may progress to a type 4 hernia. This type of hernia involves the presence of a

structure other than the stomach (e.g., omentum, colon, or small bowel) within the hernia sac.[23]

Clinical Manifestations

Hiatal hernias are often asymptomatic. In general, a wide variety of symptoms develop later in life; symptoms are associated with other GI disorders, including GERD, and include heartburn, regurgitation, dysphagia, and epigastric pain. Ischemia from hernia strangulation causes acute pain that may include severe chest or epigastric pain and other associated symptoms of nausea, vomiting, and GI bleeding.

Evaluation and Treatment

Many diagnostic procedures may be indicated in diagnosing a hiatal hernia. The mainstays of evaluation are upper endoscopy and barium swallows.[23] Plain chest radiographs, contrast studies, esophagogastroduodenoscopy (EGD), manometry, pH testing, and nuclear medicine studies may also be ordered. Computed tomography (CT) scan may be indicated in an urgent situation for an individual with suspected complications.[23]

Treatment for a sliding hiatal hernia is usually conservative. The individual can diminish reflux by eating small, frequent meals and avoiding the recumbent position after eating. Abdominal supports and tight clothing should be avoided, and weight control is recommended for obese individuals. Antacids may help to alleviate reflux esophagitis. Individuals who are uncomfortable at night may benefit from sleeping with the head of the bed elevated 6 inches. PPIs alleviate reflux esophagitis. Histamine 2 (H_2) receptor antagonists and antacids are typically less effective treatments. Drugs that relax the LES, such as anticholinergic type drugs, nitrates, and calcium channel blockers, are contraindicated due to delaying gastric emptying. If medical management fails to provide symptom control or a paraesophageal hiatal hernia is present, a laparoscopic fundoplication may be indicated, and permanent mesh maybe used to prevent recurrence.[24]

Gastroparesis is delayed gastric emptying in the absence of a mechanical gastric outlet obstruction. It is most associated with diabetes mellitus, surgical vagotomy, or fundoplication but may be idiopathic. The pathophysiology is not well understood but involves abnormalities of the autonomic nervous system, smooth muscle cells, enteric neurons, and GI hormones. Diabetic gastroparesis represents a form of neuropathy involving the vagus nerve. Symptoms include nausea, vomiting, abdominal pain, and postprandial fullness or bloating. Treatment options for gastroparesis are challenging due to the availability of therapies demonstrating poor evidence of efficacy or long-term safety concerns.[25] Current treatments include dietary management, prokinetic drugs, endoscopic techniques, and, in some cases, gastric electrical stimulation or surgical venting gastrostomy.[25–27]

Pyloric Obstruction

Pathophysiology

Pyloric obstruction (gastric outlet obstruction) is the consequence of diseases causing narrowing or blocking of the opening between the stomach and the duodenum. This condition can be congenital (e.g., infantile hypertrophic pyloric stenosis; see Chapter 42) or acquired. Acquired obstruction is caused by peptic ulcer disease or carcinoma near the pylorus. Duodenal ulcers are more likely than gastric ulcers to obstruct the pylorus. Ulceration causes obstruction resulting from inflammation, edema, spasm, fibrosis, or scarring. Tumors cause obstruction by growing into the pylorus.

Clinical Manifestations

Early in the course of pyloric obstruction, the individual experiences vague epigastric fullness, which becomes more distressing after eating and at the end of the day. Nausea and epigastric pain may occur as the muscles of the stomach contract in an attempt to force chyme (pulpy acidic gastric secretions) past the obstruction. These symptoms disappear when the chyme finally moves into the

duodenum. As the obstruction progresses, anorexia and accompanying weight loss may occur. Severe obstruction causes gastric distention and atony (lack of muscle tone and gastric motility). Gastric distention stimulates gastric secretion, which increases the feeling of fullness. Rolling or jarring of the abdomen produces a sloshing sound called the *succussion splash*. At this stage, vomiting is a cardinal sign of obstruction. It is usually copious and occurs several hours after eating. The vomitus contains undigested food but no bile. Prolonged vomiting leads to dehydration, which is accompanied by a hypokalemic and hypochloremic metabolic alkalosis caused by loss of gastric potassium and acid. Food is not able to enter the intestine, making stools infrequent and small. Prolonged pyloric obstruction causes severe malnutrition, dehydration, and extreme debilitation.

Evaluation and Treatment

Diagnosis is based on clinical manifestations, a history of ulcer disease, and examination of residual gastric contents. Endoscopy is performed if gastric carcinoma is the suggested cause of pyloric obstruction.

Obstructions resulting from ulceration often resolve with conservative management. A nasogastric tube is used to aspirate stomach contents and relieve distention. Nasogastric suction is typically placed to decompress the stomach and to help restore normal motility. Gastric secretions that contribute to inflammation and edema can be suppressed with PPIs or H_2-receptor antagonists. Fluids and electrolytes (saline and potassium) are given intravenously to promote rehydration and correct hypokalemia and alkalosis (see Chapter 3). Severely malnourished individuals may require parenteral hyperalimentation (artificial nutrients, usually intravenous nutrition). Surgery or the placement of pyloric stents may be required to treat gastric carcinoma or persistent obstruction caused by fibrosis and scarring.[28]

Intestinal Obstruction and Paralytic Ileus

Intestinal obstruction can be caused by any condition that prevents the normal flow of chyme through the intestinal lumen (Table 41.3). Obstructions can occur in either the small or the large intestine (Table 41.4). The small intestine is more commonly obstructed because of its narrower lumen. Classifications of intestinal obstruction are summarized in Table 41.5. Intestinal obstruction is classified by cause as simple or functional. *Simple obstruction* caused by fibrous adhesions of the small intestine is the most common type of intestinal obstruction. **Paralytic ileus**, or *functional or pseudo-obstruction*, is a failure of normal intestinal motility often occurring after intestinal or abdominal surgery, acute pancreatitis, intestinal infection, cardiac dysfunction, or hypokalemia. Acute obstructions usually have mechanical causes, such as adhesions or hernias (Fig. 41.4). In a strangulated obstruction, blood flow is compromised, leading to intestinal ischemia and possible necrosis and perforation if left untreated. Chronic pseudo-obstruction is often idiopathic and partial obstructions are often associated with tumors or inflammatory disorders, particularly of the large intestine.[29–31]

Table 41.3

Common Causes of Intestinal Obstruction

Cause	Pathophysiology
Hernia	Protrusion of intestine through weakness in abdominal muscles or through inguinal ring
Intussusception	Telescoping of one part of intestine into another; this usually causes strangulation of the blood supply; more common in infants 10–15 months of age than in adults (see Fig. 41.4D)
Torsion (volvulus)	Twisting of the intestine on its mesenteric pedicle, with occlusion of the blood supply; often associated with fibrous adhesions; occurs most often in middle-aged and elderly men
Diverticulosis	Inflamed saccular herniations (diverticula) of mucosa and submucosa through tunica muscularis of the colon; diverticula are interspersed between thick, circular, fibrous bands; most common in obese individuals older than 60 years (see Fig. 41.14)
Tumor	Tumor growth into intestinal lumen; adenocarcinoma of the colon and the rectum is the most common tumoral obstruction; most common in individuals older than 60 years
Paralytic (adynamic) ileus	Loss of peristaltic motor activity in intestine; associated with abdominal surgery, peritonitis, hypokalemia, ischemic bowel, spinal trauma, or pneumonia

Cause	Pathophysiology
Fibrous adhesions	Peritoneal irritation from surgery, trauma, or Crohn disease leads to the formation of fibrin and adhesions that attach to intestine, omentum, or peritoneum and can cause obstruction; most common in small intestine

Table 41.4

Large and Small Bowel Obstruction

Type of Obstruction	Cause
Small bowel obstruction	Adhesions: secondary to previous abdominal surgeries—75% Hernia: inguinal, ventral, or femoral—10% Tumors: may be associated with intussusception—10% Mesenteric ischemia—3–5% Crohn disease—<1%
Large bowel obstruction	Colon/rectal cancer—90% Volvulus—4–5% Diverticular disease—3–5% Other causes (inflammatory bowel disease, adhesions, hernia)

Type of Obstruction	Cause
Small bowel obstruction	Adhesions: secondary to previous abdominal surgeries—75% Hernia: inguinal, ventral, or femoral—10% Tumors: may be associated with intussusception—10% Mesenteric ischemia—3–5% Crohn disease—<1%
Large bowel obstruction	Colon/rectal cancer—90% Volvulus—4–5% Diverticular disease—3–5% Other causes (inflammatory bowel disease, adhesions, hernia)

Data from Mizell JS, Turnage RH. Intestinal obstruction. In: Feldman M, et al, eds. *Sleisenger & Fordtran's gastrointestinal and liver disease*, 10th edition. Philadelphia: Saunders; 2016: pp 2154–2170.

Table 41.5

Classifications of Intestinal Obstruction

Criteria for Classification	Definition
Onset	
Acute	Sudden onset; often caused by torsion, intussusception, or herniation
Chronic	Protracted onset; more commonly from tumor growth or progressive formation of strictures
Extent of Obstruction	
Partial	Incomplete obstruction of intestinal lumen
Complete	Complete obstruction of intestinal lumen
Location of Obstructing Lesion	
Intrinsic	Obstruction develops within intestinal lumen; examples: gut wall edema or hemorrhage, foreign bodies (gallstones), tumors, or gut wall fibrosis
Extrinsic	Obstruction originates outside intestine; examples: tumors, torsion, fibrosis, hernia, intussusception
Effects on Intestinal Wall	
Simple	Luminal obstruction without impairment of blood supply
Strangulated	Luminal obstruction with occlusion of blood supply
Closed loop	Obstruction at each end of a segment of intestine

Criteria for Classification	Definition
Casual Factors	
Mechanical	Blockage of intestinal lumen by intrinsic or extrinsic lesions; usually treated surgically
Functional (paralytic ileus)	Paralysis of intestinal musculature caused by trauma, peritonitis, electrolyte imbalances, or spasmolytic agents; usually treated by decompression with suction or surgery if death of tissue

Criteria for Classification	Definition
Onset	
Acute	Sudden onset; often caused by torsion, intussusception, or herniation
Chronic	Protracted onset; more commonly from tumor growth or progressive formation of strictures
Extent of Obstruction	
Partial	Incomplete obstruction of intestinal lumen
Complete	Complete obstruction of intestinal lumen
Location of Obstructing Lesion	
Intrinsic	Obstruction develops within intestinal lumen; examples: gut wall edema or hemorrhage, foreign bodies (gallstones), tumors, or gut wall fibrosis
Extrinsic	Obstruction originates outside intestine; examples: tumors, torsion, fibrosis, hernia, intussusception
Effects on Intestinal Wall	
Simple	Luminal obstruction without impairment of blood supply
Strangulated	Luminal obstruction with occlusion of blood supply
Closed loop	Obstruction at each end of a segment of intestine
Casual Factors	
Mechanical	Blockage of intestinal lumen by intrinsic or extrinsic lesions; usually treated surgically
Functional (paralytic ileus)	Paralysis of intestinal musculature caused by trauma, peritonitis, electrolyte imbalances, or spasmolytic agents; usually treated by decompression with suction or surgery if death of tissue

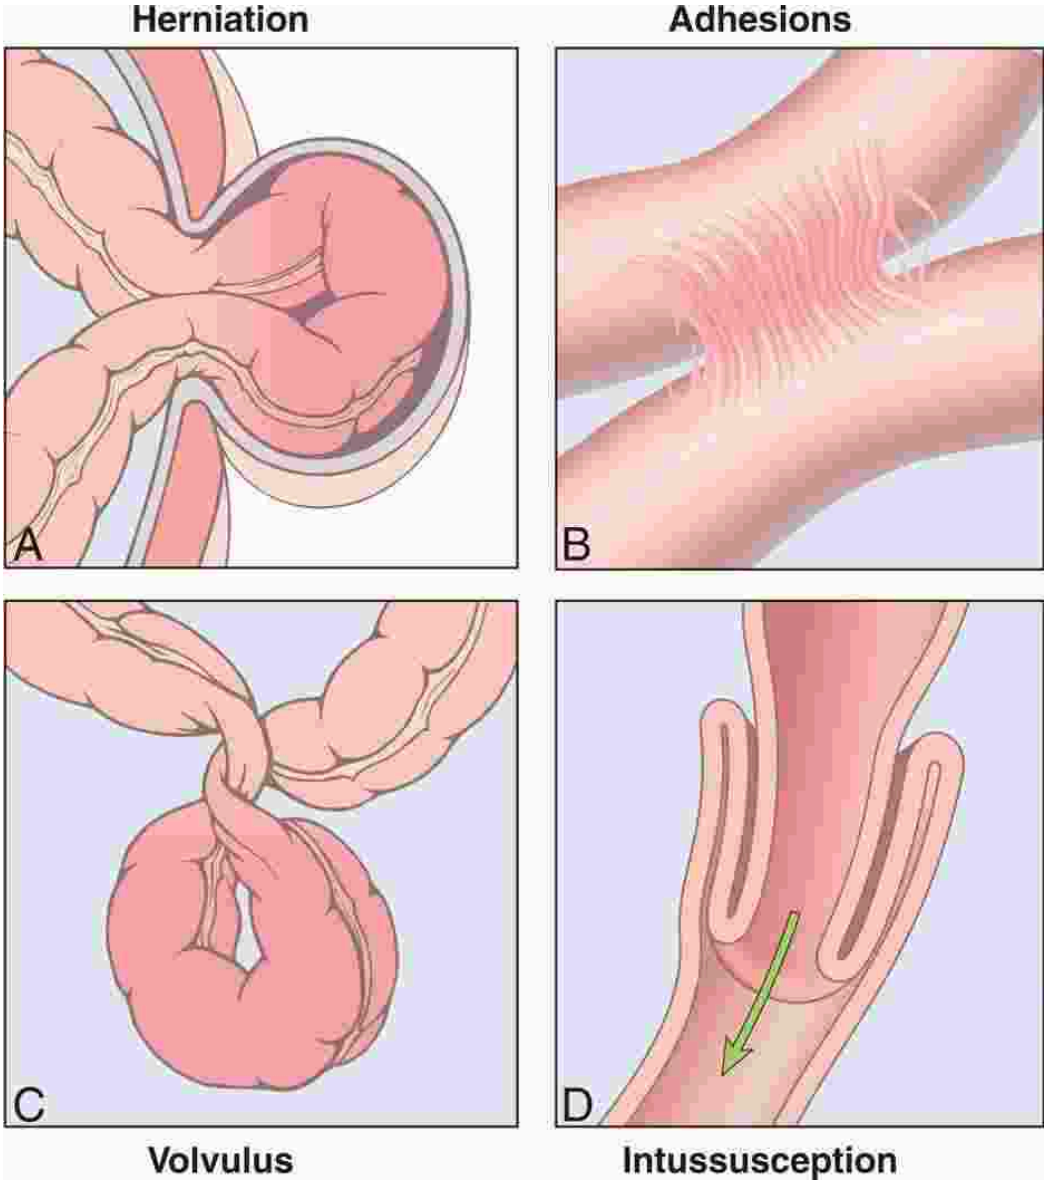

FIG. 41.4 Intestinal Obstructions.
(A) Hernia. **(B)** Constrictions from adhesions. **(C)** Volvulus. **(D)** Intussusception. (From Kumar V, et al. *Robbins basic pathology*, 10th edition. Philadelphia: Elsevier; 2018.)

Four illustrations, A through D, depicts the intestinal obstruction. Illustration A depicts the herniation, which shows the small intestine pushing through the

abdominal wall. Illustration B depicts the adhesion, which shows fibrous bands formed between the tissues and organs. Illustration C depicts the volvulus, which shows the twisting of the bowel upon itself. Illustration D depicts the intussusception, which shows the small intestine in the large intestine.

Pathophysiology

The consequences of intestinal obstruction are related to the onset and location of the obstruction, as well as the presence and severity of associated ischemia. The major pathophysiologic alterations are presented in Fig. 41.5. The exact cause of postoperative paralytic ileus remains unknown, but it is thought to be a multifactorial and complex interaction between the autonomic and central nervous system that alters the equilibrium of the intestine, resulting in disorganized electrical activity and paralysis.[32]

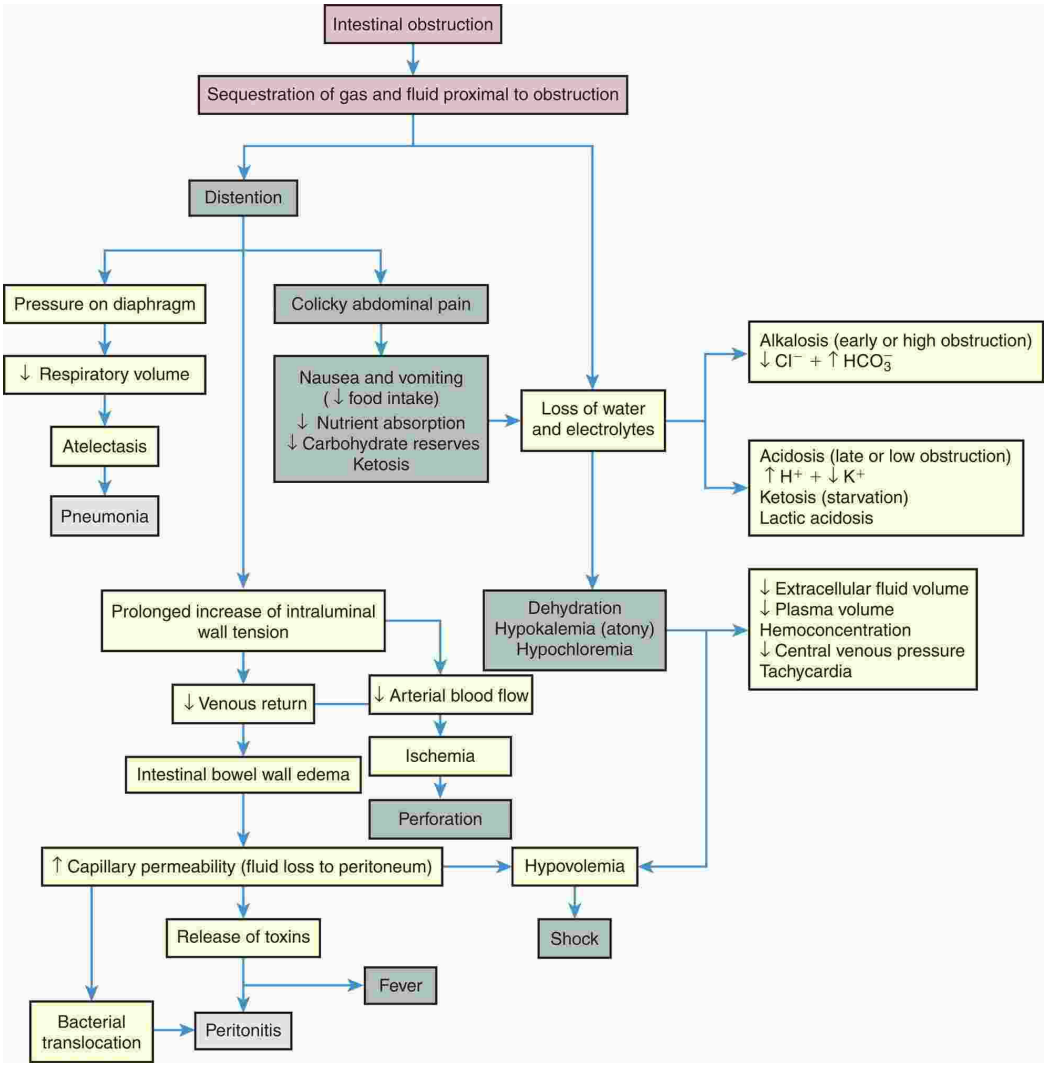

FIG. 41.5 Pathophysiology of Intestinal Obstruction.

A flow diagram illustrates the pathophysiology of intestinal obstruction. The diagram begins as follows. • Intestinal obstruction due to sequestration of gas and fluid proximal to obstruction leads to distention and loss of water and electrolytes. • Distention leads to a prolonged increase of intraluminal wall tension, pressure on the diaphragm, and colicky abdominal pain. •Pressure on the diaphragm leads to decreased

respiratory volume, leading to atelectasis and causing pneumonia. • Colicky abdominal pain leads to nausea and vomiting with decreased food intake, nutrient absorption, carbohydrates reserves ketosis leads to loss of water and electrolytes, causing dehydration, hypokalemia, and hypochloremia. • Prolonged increase of intraluminal wall tension leads to decrease venous return, arterial BF causing intestinal bowel wall edema and ischemia. • Ischemia leads to perforation. • Intestinal bowel wall edema leads to increase capillary permeability or fluid loss to the peritoneum, causing hypovolemia which leads to shock. • An increase in capillary permeability also leads to the release of toxins and bacterial translocation, causing peritonitis and fever. • The loss of water and electrolytes leads to alkalosis, acidosis, increased ketosis, and lactic acidosis. • Dehydration, hypokalemia, and hypochloremia lead to a decrease in extracellular fluid volume, plasma volume, hemoconcentration, central venous pressure tachycardia, causing hypovolemia which leads to shock.

Small bowel obstruction (SBO) is often caused by postoperative adhesions, tumors, CD, and hernias. SBO leads to distention caused by impaired absorption and increased secretion with the accumulation of fluid and gas inside the lumen proximal to the obstruction.[33] Distention decreases the intestine's ability to absorb

water and electrolytes and increases the net secretion of these substances into the lumen. Copious vomiting or sequestration of fluids in the intestinal lumen prevents their reabsorption and produces severe fluid and electrolyte disturbances. Extracellular fluid volume and plasma volume decrease, causing dehydration, increased hematocrit level, hypotension, and tachycardia. Severe dehydration leads to hypovolemic shock. Metabolic alkalosis initially develops because of excessive loss of hydrogen ions that would normally be reabsorbed from the gastric juice and vomiting. Prolonged obstruction or obstruction lower in the intestine may contribute to metabolic acidosis because bicarbonate from pancreatic secretions and bile cannot be reabsorbed. Hypokalemia from vomiting and decreased potassium absorption can be extreme, promoting acidosis and atony of the intestinal wall. Metabolic acidosis also may be accentuated by ketosis, which is the result of declining carbohydrate stores caused by starvation. In addition, lack of circulation permits the buildup of significant amounts of lactic acid, which worsens the metabolic acidosis. If pressure from the distention is severe enough, it occludes arterial circulation and causes ischemia, necrosis, perforation, and peritonitis. Fever and leukocytosis are often associated with overgrowth of bacteria, ischemia, and bowel necrosis. Bacterial proliferation and translocation across the mucosa to the systemic circulation cause peritonitis or sepsis. The release of inflammatory mediators into the circulation causes remote organ failure.

Large bowel obstruction is less common and often related to cancer. Diverticulitis, IBD, and other causes of obstruction are less common. **Acute colonic pseudo-obstruction (Ogilvie syndrome)** is a pathologic massive dilation of the colon without underlying mechanical obstruction or other identified organic causes. This occurs mostly in individuals with serious comorbidities. The pathologic basis remains unclear but may be caused from a functional disturbance in the enteric nervous system.[34]

Clinical Manifestations

Signs and symptoms of *small intestine obstruction* include distention and colicky type pain, followed by nausea and vomiting. Pain usually intensifies for seconds or minutes as a peristaltic wave of muscle contraction meets the obstruction. Pain may be continuous with severe distention and then diminish in intensity. If ischemia occurs, the pain loses its colicky character and becomes more constant and severe. Sweating and tachycardia occur as a sympathetic nervous system response to hypotension. Fever, severe leukocytosis, abdominal distention, and rebound tenderness develop as ischemia progresses to necrosis, perforation, and peritonitis.

Obstruction at the pylorus causes early, profuse vomiting. Obstruction in the proximal small intestine causes mild distention and vomiting of bile-stained fluid. Lower obstruction in the small intestine causes more pronounced distention because a greater length of intestine is proximal to the obstruction. In this case, vomiting may occur later and contain fecal material. Partial obstruction can cause diarrhea or constipation, whereas complete obstruction usually causes constipation only. Complete obstruction increases the number of bowel sounds, which may be accompanied by peristaltic rushes and crampy type abdominal pain. Signs of hypovolemia and metabolic acidosis may be observed as early as 24 hours after the occurrence of complete obstruction. Distention may be severe enough to push against the diaphragm and decrease lung volume. This can lead to atelectasis and pneumonia, particularly in debilitated individuals.

Large bowel obstruction usually presents with hypogastric type pain and abdominal distention. Pain can vary from vague to excruciating, depending on the degree of ischemia and the development of peritonitis. Vomiting occurs late in the obstructive process. Small and large intestinal perforation presents with the same acute, persistent type abdominal pain, nausea, vomiting, and fever. *Acute colonic pseudo-obstruction* has the absence of mechanical obstruction and is characterized by abdominal distention, abdominal pain, nausea, and vomiting. Bowel sounds are usually present.

Evaluation and Treatment

Evaluation is based on clinical manifestations and imaging studies. Successful management requires early identification of the location and type of obstruction. Replacement of fluid and electrolytes and decompression of the lumen with gastric or intestinal suction are essential forms of therapy. Laparoscopic procedures can release adhesions. Immediate surgical intervention is required for strangulation, complete obstruction, or perforation. Colonic stents may be placed for malignant obstruction. If conservative methods are not successful, neostigmine, a parasympathomimetic, may be used for colonic pseudo-obstruction. Neostigmine increases the activation of muscarinic receptors by inhibition of the breakdown of acetylcholine. This stimulates colonic motor activity and increases intestinal transit time. Pseudo-obstruction is often managed symptomatically.[31,35]

Gastritis

Gastritis is a nonspecific inflammatory disorder of the gastric mucosa. Gastritis can present as an acute manifestation or may be chronic and often will progress to chronic gastritis if not treated in the acute phase.[36] The most common causes of gastritis are use of NSAIDs, *Helicobacter pylori* infection, and physiologic stress–related mucosal changes. Alcohol, digitalis, and metabolic disorders, such as uremia, also are contributing factors.

Acute gastritis is caused by injury of the protective mucosal barrier. NSAIDs (e.g., ibuprofen, naproxen, indomethacin, and aspirin) cause gastritis by inhibition of prostaglandin synthesis, which normally stimulates the secretion of mucus. Alcohol, histamine, digitalis, and metabolic disorders, such as uremia, are contributing factors. *H. pylori*–associated acute gastritis causes inflammation, increased gastric secretion in antral gastritis, decreased gastric secretion in fundal gastritis, pain, nausea, and vomiting (Box 41.1 and Fig. 41.6). The clinical manifestations of acute gastritis can include vague abdominal discomfort, epigastric tenderness, and bleeding. Healing usually occurs spontaneously within a few days. Discontinuing injurious drugs, using antacids, or

decreasing acid secretion with H_2 receptor antagonist or PPIs facilitates healing.

BOX 41.1

Pathologic Characteristics of *Helicobacter pylori*

H. pylori is a gram-negative spiral bacterium with a flagellum and is a major cause of acute and chronic gastritis, peptic ulcer disease in the duodenum and stomach, gastric adenocarcinoma, and gastric mucosa-associated lymphoid tissue (MALT) lymphoma in approximately 20% of infected individuals. *H. pylori* is transmitted through the fecal-oral route and is usually acquired in childhood. Infection is asymptomatic in approximately 70% of cases. In other cases, inflammation and immune responses promote mucosal ulcerations or prevent healing of injured tissue. Gene-environment interaction and different pathogenic strains of *H. pylori* increase risk for disease. Patterns of gastritis and development of adenocarcinoma vary by site of infection and strain of *H. pylori*. Pathogenic and virulence factors include the following:

1. An ability to colonize and adhere to gastric epithelial cells
2. The possession of flagella, which allows movement through the luminal mucous layer to a site of higher pH
3. A lipopolysaccharide membrane component evades immune protection and promotes inflammation
4. Secretion of urease that produces ammonia and carbon dioxide, resulting in a more alkaline environment and neutralization of the protective properties of hydrochloric acid
5. Release of vacuolating cytotoxin *(VacA)* that promotes bacterial survival and causes epithelial injury
6. The presence of cytotoxin-associated gene *(CagA)* strains that can escape normal immune responses and cause

inflammation with release of inflammatory cytokines and reactive oxygen metabolites that damage mucosal epithelial cells and cause loss of the protective mucosal barrier; they also promote tumor development by degrading *tp53* tumor suppression

7. An ability of adherent strains to suppress acid secretion to improve their survival, particularly *CagA* and *VacA* strains
8. Recruitment and activation of neutrophils, macrophages, and mast cells with release of inflammatory cytokines (tumor necrosis factor [TNF]-α, interleukin [IL]-1, IL-6, IL-8, IL-17, histamine) that promote cellular injury
9. Downregulation of antral somatostatin leading to increased gastrin, increased acid, impaired mucosal bicarbonate production, and increased mucosal exposure to acid and pepsin
10. Activation or inhibition of T- and B-cell immune responses that may contribute to mucosal injury
11. Release of cytokines and chemokines that promote gastric epithelial cell death (apoptosis) that can result in atrophy, ulcers or cell proliferation, and dysplasia or malignant growth

FIG. 41.6 Acute Erosive Gastritis.
Acute erosive gastritis is shown in the opened stomach. The mucosa appears hyperemic, and the foci of superficial ulceration are manifested as scattered, small, red areas termed erosions. (From Kumar V, et al. *Pathologic basis of disease*, 7th edition. Philadelphia: Saunders; 2006.)

Chronic gastritis causes chronic inflammation of the gastric mucosa which progresses to atrophic gastritis, characterized by the loss of normal mucosal glands.[36] Chronic gastritis is classified as type A immune (fundal) or type B nonimmune (antral), depending on the pathogenesis and location of the lesions. When both types of chronic gastritis occur, it is known as type AB, or pangastritis, and the antrum is more severely involved. Type C gastritis is associated with reflux of bile and pancreatic secretions into the stomach, causing chemical injury.

Chronic immune (fundal) gastritis (autoimmune gastritis) is the rarest form of gastritis and is a recessive, multigenetic disease. It is associated with the loss of T-cell tolerance and the development of

autoantibodies to acid-secreting parietal cells. *H. pylori* infection may trigger the immune response through molecular mimicry (a mechanism of autoimmune disease with similarities between foreign and self-antigens sufficient to result in the cross-activation of autoreactive T or B cells).[37] The gastric mucosa degenerates extensively in the fundus (body) of the stomach, leading to gastric atrophy. Loss of parietal cells diminishes acid and intrinsic factor secretion. Pernicious anemia can develop from decreased vitamin B_{12} absorption (see Chapter 29). The feedback mechanism that normally inhibits gastrin secretion (i.e., loss of acid secretion) is also impaired, causing elevated plasma levels of gastrin, thus stimulating gastric secretion. Chronic fundal gastritis occurs in association with other autoimmune diseases (e.g., rheumatoid arthritis, autoimmune thyroid disease, or type 1 diabetes mellitus) and is a risk factor for gastric carcinoma, particularly in individuals who develop pernicious anemia.

Chronic nonimmune (antral) gastritis generally involves the antrum only and is more common than fundal gastritis.[38] Chronic use of alcohol, tobacco, and NSAIDs and *H. pylori* infection are contributing factors. There are high levels of hydrochloric acid secretion with an increased risk of duodenal ulcers. *H. pylori* infection also can progress to autoimmune atrophic gastritis and involve the fundus, thus becoming pangastritis.[39] There is greater risk for the development of gastric cancer in these cases.

Clinical Manifestations.Signs and symptoms of chronic gastritis often include vague symptoms, such as anorexia, fullness, nausea, vomiting, and epigastric pain. Gastric bleeding may be the only clinical manifestation of gastritis. Gastroscopic examination and biopsy may show a long-standing inflammatory process and gastric atrophy in an individual with no history of abdominal distress. Gastric secretion analysis confirms achlorhydria (the absence of hydrochloric acid) and loss of intrinsic factor. Pernicious anemia can develop because intrinsic factor is less available to facilitate vitamin B_{12} absorption. Iron deficiency may also be present. The presence of antiparietal cell antibody and elevated plasma ghrelin level are

specified for atrophic gastritis. *H. pylori* infection is evidence for *H. pylori* chronic gastritis with infiltration of neutrophils and lymphocytes. Eradication of *H. pylori* is recommended for the prevention of gastric carcinoma.[40–42]

Evaluation and Treatment.Symptoms can usually be managed by eating smaller meals in conjunction with a soft, bland diet and by avoiding alcohol and NSAIDs. *H. pylori* infection is treated with antibiotics, and vitamin B_{12} is administered to correct pernicious anemia.

Peptic Ulcer Disease

A **peptic ulcer** is a break or ulceration in the protective mucosal lining, usually located in the stomach or proximal duodenum; however, they can be found in the esophagus (see Figs. 41.7 and 41.8). Ulcers develop when mucosal protective factors are overcome by erosive factors such as gastric acid secretion or pepsin. This causes an imbalance between the gastric mucosal protective factors and the destructive factors. Peptic ulcer disease has various causes; however, most cases are caused by *H. pylori* and NSAIDs. Additional risk factors for peptic ulcer disease include the use of the following medications: corticosteroids, bisphosphonates, potassium chloride, and fluorouracil. Smoking, alcohol consumption, and certain disease processes that can make the gastric lining a hypersecretory environment, such as Zollinger-Ellison syndrome, systemic mastocytosis, cystic fibrosis, hyperparathyroidism, and antral G-cell hyperplasia, are also risk factors.[43]

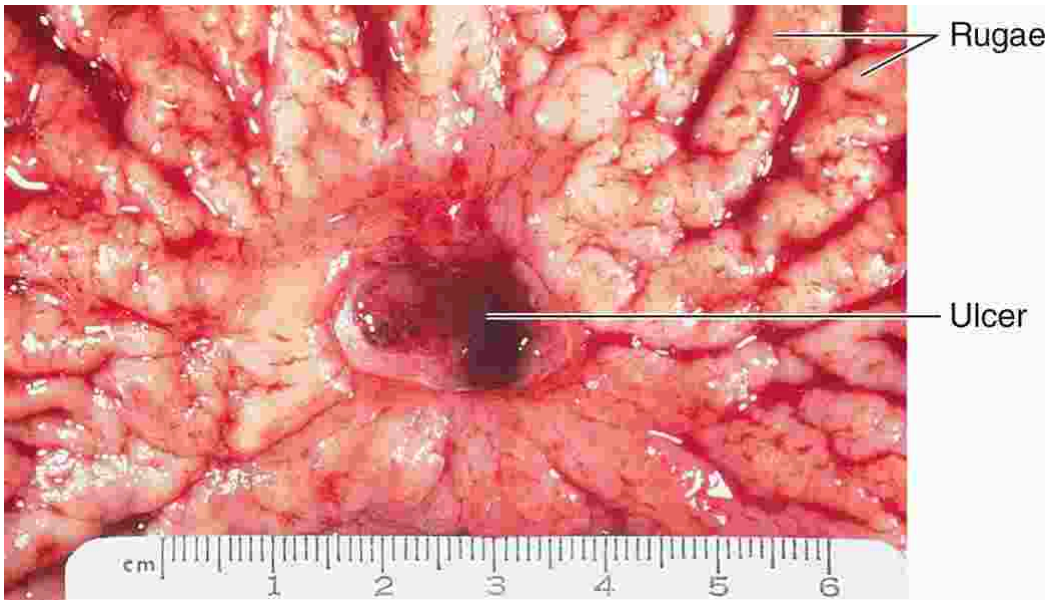

FIG. 41.7 Chronic Peptic Ulcer.
Gross photograph of a chronic peptic ulcer located in the lesser curvature, straddling the antrum and corpus of the stomach. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

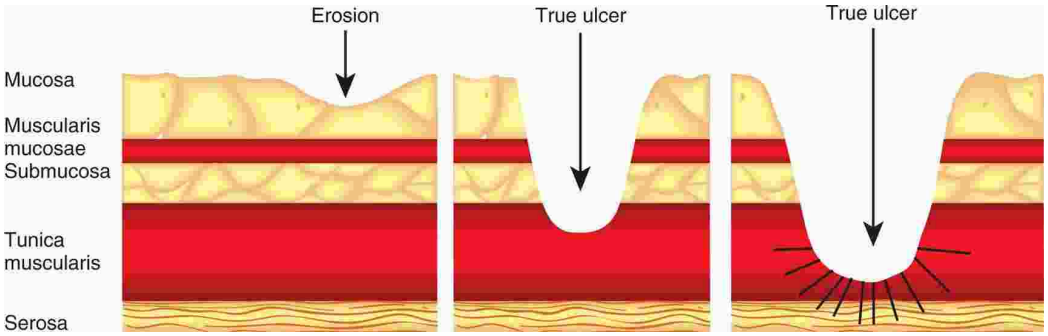

FIG. 41.8 Lesions Caused by Peptic Ulcer Disease.

Three illustrations depict lesions by peptic ulcer disease, which show the layers of the stomach labeled mucosa, muscularis mucosae, submucosa, tunica muscularis, and serosa. The first illustration depicts erosion where the lesion occurs in the mucosa. The second illustration depicts the true ulcer where the lesion extends to tunica muscularis. The third illustration depicts the true ulcer where the lesion extends to the serosa.

Peptic ulcers can be single or multiple, acute, or chronic, and superficial or deep. Superficial ulcerations are called *erosions* because they erode the mucosa but do not penetrate the muscularis mucosa. True ulcers extend through the muscularis mucosae and damage blood vessels, causing hemorrhage and possible perforation of the GI wall. Successful antibiotic treatment of *H. pylori* infection and the use of mucosal protecting agents during NSAID and *H. pylori* treatment have significantly reduced the incidence of peptic ulcer disease.

Zollinger-Ellison syndrome is a rare syndrome that also is associated with peptic ulcers caused by a gastrin-secreting neuroendocrine tumor or multiple tumors of the pancreas or

duodenum that release large amounts of acid. The body normally releases small amounts of gastrin after eating; gastrin then triggers the stomach to make gastric acid. Gastrin stimulates a proliferation of gastric parietal cells and chronic secretion of gastric acid. The resulting excess acid causes gastric and duodenal ulcers, gastroesophageal reflux with abdominal pain, diarrhea, bloating, burping, weight loss, and poor appetite. Diagnosis includes secretin or calcium- stimulated measures of gastrin levels, gastric pH levels less than 2, and symptomatic evidence of peptic ulcer disease. PPIs reduce gastric acid secretion, and surgical removal of tumors limits metastasis.[44]

Duodenal Ulcers

Duodenal ulcers occur with greater frequency than other types of peptic ulcers and are generally caused by *H. pylori* infection and NSAID use. Idiopathic duodenal ulcers are rare and can be associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.[45]

Pathophysiology

Causative factors, independently or in combination, cause acid and pepsin concentrations in the duodenum to increase and penetrate the mucosal barrier, causing ulceration (Fig. 41.9). The host response to chronic stomach antral *H. pylori* infection is increased levels of gastrin resulting in increased stomach acid secretion and an increased acid load in the duodenum. The increased duodenal acid promotes gastric metaplasia in the duodenum and favors *H. pylori* colonization. Both *H. pylori* and the increased acid result in decreased duodenal bicarbonate production. In addition, *H. pylori* infection activates immune cells (T and B lymphocytes with the infiltration of neutrophils) and the release of inflammatory cytokines which damage the mucosa. *H. pylori* also produces a toxin that causes loss of protective mucosal cells, resulting in ulceration. *H. pylori* mucosal infection can promote gastric cancer, but the

incidence is lower for duodenal ulcer than for gastric ulcer, and the mechanism is unknown.[46]

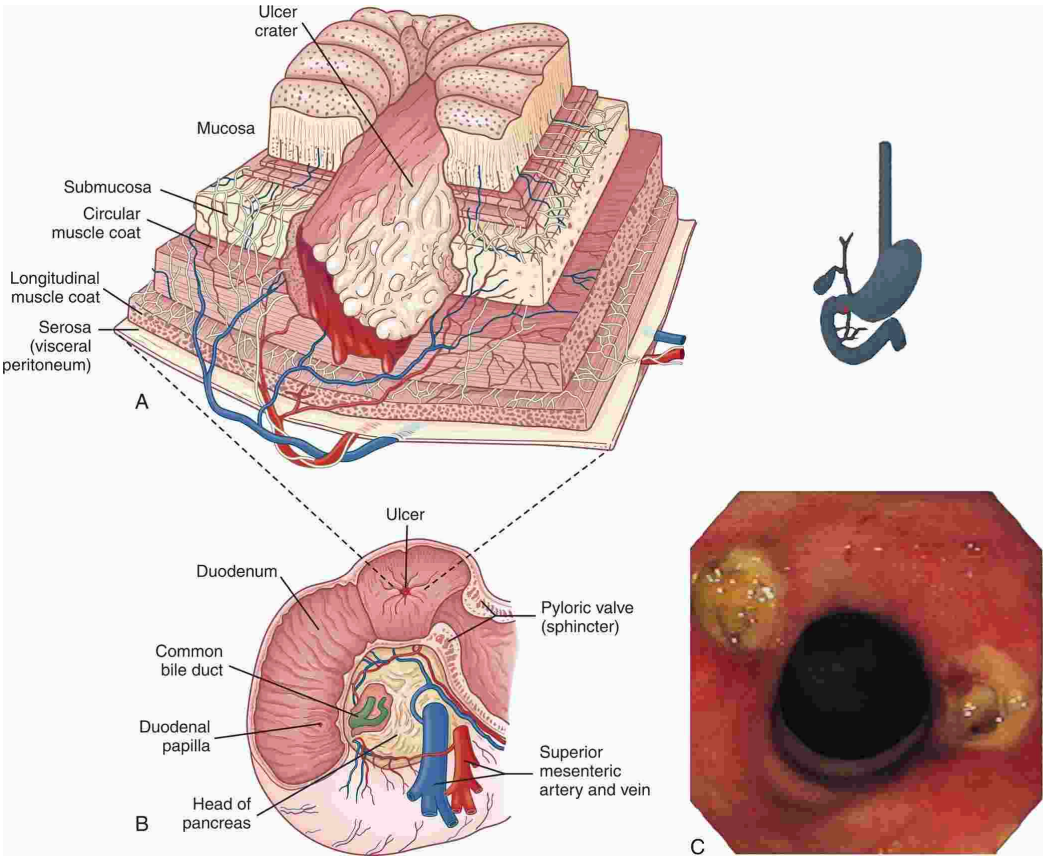

FIG. 41.9 Duodenal Ulcer.
(A) A deep ulceration in the duodenal wall extending as a crater through the entire mucosa and into the muscle layers. **(B)** Sequence of ulcerations from normal mucosa to duodenal ulcer. **(C)** Bilateral (kissing) duodenal ulcers in a person using nonsteroidal antiinflammatory drugs. (C, Courtesy David Bjorkman, MD, University of Utah School of Medicine, Department of Gastroenterology, Salt Lake City, UT.)

Illustration A depicts the cutaway section of the ulcerated duodenal wall with labels indicating ulcer crater, mucosa, submucosa, circular muscle coat, longitudinal muscle coat, and serosa or visceral peritoneum. Illustration B depicts the cross-section of

the stomach with labels indicating ulcer, duodenum, common bile duct, duodenal papilla, head of the pancreas, superior mesenteric artery and vein, and pyloric valve or sphincter. Image C represents the endoscopic view of bilateral duodenal ulcers.

Clinical Manifestations

The characteristic manifestation of a duodenal ulcer is chronic, intermittent pain in the epigastric area. The pain begins 2 or 3 hours after eating, when the stomach is empty. It is not unusual for pain to occur in the middle of the night and disappear by morning. Pain is relieved rapidly by ingestion of food or antacids, creating a typical pain-food-relief pattern. Some individuals with a duodenal ulcer may have no symptoms; the first manifestation may be hemorrhage or perforation, particularly with a history of NSAID or anticoagulant use. Complications of a duodenal ulcer include bleeding, perforation, and obstruction of the duodenum or outlet of the stomach. Bleeding is the most common cause of mortality, particularly among the elderly. Bleeding from duodenal ulcers causes hematemesis or melena. Perforation occurs with destruction of all layers of the duodenal wall and causes sudden, severe epigastric pain. Obstruction may be the result of edema from inflammation or scarring from chronic injury. Duodenal ulcers often heal spontaneously. However, repeat imaging is indicated if the ulcer was large, associated complications were present, or the individual has continued pain.[47]

Evaluation and Treatment

Several diagnostic approaches are used to differentiate duodenal ulcers from gastric ulcers or gastric carcinoma. Endoscopic evaluation allows visualization of lesions and biopsy. Radioimmune assays of gastrin levels are evaluated to identify ulcers associated

with gastric carcinomas. *H. pylori* is detected using the urea breath test, *H. pylori*–specific serum immunoglobulin G (IgG) and IgA antibodies, and the measurement of *H. pylori* stool antigen levels. Findings from the gastric biopsy detect *H. pylori* infection and can also confirm eradication after treatment. Polymerase chain reaction testing provides additional virulence and antibiotic sensitivity profiling.[48]

The management of duodenal ulcers is aimed at relieving the causes of the ulceration. The effects associated with the hyperacidity and pepsin present in the gut should be managed with diet and pharmacotherapy. Antacids neutralize gastric contents and relieve pain. Acid secretion can be suppressed with drugs that block H_2 receptors and inhibit the secretion of acid. PPIs inhibit acid production. *H. pylori* is treated with a combination of antibiotics and PPIs, but antibiotic resistance is an increasing problem.[49] Surgical resection may be required for bleeding or perforating ulcers, obstruction, or peritonitis.

Gastric Ulcers

Gastric ulcers are ulcers of the stomach. They occur about equally in males and females, usually between the ages of 55 and 65 years. They are less common than duodenal ulcers (Table 41.6).

Table 41.6

Characteristics of Gastric and Duodenal Ulcers

Characteristics	Gastric Ulcer	Duodenal Ulcer
Incidence		
Age at onset	50–70 years	20–50 years
Family history	Usually negative	Positive
Sex (prevalence)	Equal in women and men	Equal in men and women
Stress factors	Increased	Average
Ulcerogenic drugs	Normal use	Increased use
Cancer risk	Increased	Not increased
Pathophysiology		
Helicobacter pylori infection	Often present (60%–80%)	Often present (95%–100%)
Abnormal mucus	May be present	May be present
Parietal cell mass	Normal or decreased	Increased
Acid production	Normal or decreased	Increased
Serum gastrin	Increased	Normal
Serum pepsinogen	Normal	Increased
Associated gastritis	More common	Usually not present
Clinical Manifestations		

Characteristics	Gastric Ulcer	Duodenal Ulcer
Pain	Located in upper abdomen	Located in upper abdomen
	Intermittent	Intermittent
	Pain-antacid-relief pattern	Pain-antacid or food-relief pattern
	Food-pain pattern	Nocturnal pain common
Clinical course	Chronic ulcer without pattern of remission and exacerbation	Pattern of remissions and exacerbation for years

Characteristics	Gastric Ulcer	Duodenal Ulcer
Incidence		
Age at onset	50–70 years	20–50 years

Clinical course	Chronic ulcer without pattern of remission and exacerbation	Pattern of remissions and exacerbation for years

Pathophysiology

In general, gastric ulcers develop in the antral region, adjacent to the acid-secreting mucosa of the body. The primary defect is an

abnormality that increases the mucosal barrier's permeability to hydrogen ions. Gastric secretion may be normal or less than normal, and there may be a decreased mass of parietal cells. Chronic gastritis is often associated with the development of gastric ulcers and may precipitate ulcer formation by limiting the mucosa's ability to secrete a protective layer of mucus (Fig. 41.10). Other factors include:

- Decreased mucosal synthesis of prostaglandins
- Damage to the mucosal membrane from duodenal reflux of bile and pancreatic enzymes
- Use of NSAIDs (decreases prostaglandin synthesis)
- *H. pylori* infection

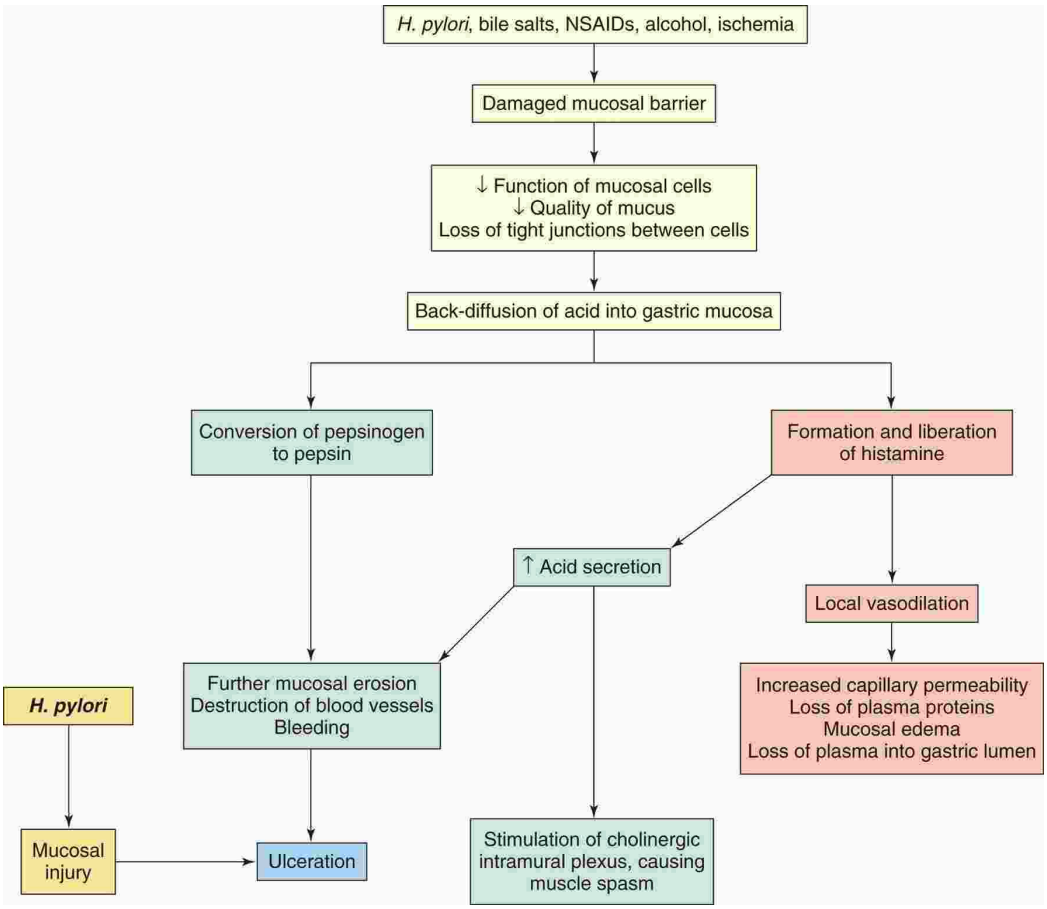

FIG. 41.10 Pathophysiology of Gastric Ulcer Formation.
NSAIDs, Nonsteroidal antiinflammatory drugs.

A flow diagram illustrates the pathophysiology of gastric ulcer formation. The diagram begins as follows. • H. pylori, bile salts, N S A I Ds, alcohol, ischemia leads to damaged mucosal barrier. • Damaged mucosal barrier leads to decrease function of mucosal cells, quality of mucus, loss of tight junctions between cells which further leads to back-diffusion of acid into gastric mucosa. • The diffusion of acid into gastric mucosa leads to the conversion of

pepsinogen to pepsin and the formation and liberation of histamine. •Conversion of pepsinogen leads to further mucosal erosion, destruction of blood vessels, and bleeding, causing ulceration. • H. pylori leads to mucosal injury and also causes ulceration. • Formation and liberation of histamine increase acid secretion, leads to stimulation of intramural cholinergic plexus causes muscle spasms and further mucosal erosion, destruction of blood vessels, and bleeding. • Formation and liberation of histamine lead to local vasodilation and causes increased capillary permeability, loss of plasma proteins, mucosal edema, and loss of plasma into the gastric lumen.

A break in the mucosal barrier permits hydrogen ions to diffuse into the mucosa, where they disrupt permeability and cellular structure. A vicious cycle can be established as the damaged mucosa liberates histamine, which stimulates the increase of acid and pepsinogen production, blood flow, and capillary permeability. The disrupted mucosa becomes edematous and loses plasma proteins. Destruction of small vessels causes bleeding.

Clinical Manifestations

The clinical manifestations of gastric ulcers are similar to those of duodenal ulcers (see Table 41.6). The pattern of pain is common, but the pain of gastric ulcers also occurs immediately after eating. Gastric ulcers also tend to be chronic rather than alternating between periods of remission and exacerbation, and they cause more anorexia and vomiting than duodenal ulcers. The pain associated with eating tends to suppress food intake, resulting in weight loss. The

evaluation and treatment of gastric ulcers are similar to those for duodenal ulcers. However, long-term use of PPIs is a reported risk factor for gastric cancer after *H. pylori* eradication and is related to hypergastrinemia and hyperplasia of enterochromaffin-like cells that promote the secretion of gastric acid.[50]

Stress-Related Mucosal Disease

A **stress-related mucosal disease (stress ulcer)** is an acute form of peptic ulcer that tends to accompany the physiologic stress of severe illness or major trauma. Usually, multiple sites of ulceration are distributed within the stomach or duodenum. Stress ulcers may be classified as ischemic ulcers or Cushing ulcers.

Ischemic ulcers develop within hours of an event such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis. Shock, anoxia, inflammation, and sympathetic responses cause ischemia of the stomach and duodenal mucosa, disrupting the mucosal barrier. Stress ulcers that develop as a result of burn injury are often called **Curling ulcers. Cushing ulcer** is a stress ulcer associated with severe brain trauma or brain surgery. Decreased mucosal blood flow and hypersecretion of acid caused by overstimulation of the vagal nuclei damage the mucosal barrier, causing erosions and ulceration.

The primary clinical manifestation of stress-related mucosal disease is bleeding, which is uncommon, but occurs more readily with the presence of coagulopathy and in the presence of more than 48 hours of mechanical ventilation. Prophylactic treatment regimens are used to prevent this disease. Stress ulcers seldom become chronic.[51]

Surgical Treatment of Ulcer

Advances in the medical treatment of peptic ulcer disease with acid suppression and eradication of *H. pylori* have reduced the number of cases requiring surgery. The most common indications for ulcer surgery are recurrent or uncontrolled bleeding and perforation of the stomach or duodenum. The primary objectives of surgical

treatment are to reduce stimuli for acid secretion, decrease the number of acid-secreting cells in the stomach, and correct complications of ulcer disease.

Acute complications of gastrectomy or anastomosis are relatively uncommon except in debilitated persons. However, chronic complications are likely to develop if a large portion of the stomach has been removed. These complications and their pathophysiologic mechanisms are described in the next section.

Postgastrectomy Syndromes

Postgastrectomy syndromes are a group of signs and symptoms that occur after gastric resection for the treatment of peptic ulcer, gastric carcinoma, or bariatric surgery for extreme obesity. They are caused by anatomic and functional changes in the stomach and upper small intestine[52] and include the following conditions.

Dumping syndrome is the rapid emptying of hypertonic chyme from the surgically created residual stomach (i.e., the smaller stomach component remaining after surgical resection following gastric or bariatric surgery) into the small intestine 10 to 20 minutes after eating. It occurs with varying severity and is promoted by loss of gastric capacity, loss of emptying control when pylorus is removed, and loss of feedback control by the duodenum once removed. Rapid gastric emptying and a creation of a nonphysiologic, high osmotic gradient within the small intestine cause a sudden shift of fluid from the vascular compartment to the intestinal lumen. Plasma volume decreases and rapid distention of the intestine occurs, producing symptoms such as cramping type pain, nausea, vomiting, osmotic diarrhea, hypotension, weakness, and pallor.

Late dumping syndrome occurs 1 to 3 hours after eating a high carbohydrate meal and is related to hyperinsulinemia with hypoglycemia. The symptoms of late dumping syndrome include weakness, diaphoresis, and confusion. Most cases of dumping syndrome respond to dietary management. Individuals should eat frequent small meals high in protein and low in carbohydrates.

Alkaline (bile) reflux gastritis occurs when there is a disruption of the mucosal barrier in the remnant stomach. Reflux of bile and alkaline pancreatic secretions containing proteolytic enzyme disrupts the mucosal barrier in the remnant stomach causing inflammation. Symptoms include nausea, bilious vomiting, and sustained epigastric pain that worsen after eating and is not relieved by antacids. It responds somewhat to avoidance of aspirin and alcohol, but surgical correction may be required.

Afferent loop obstruction is a rare complication of Billroth gastrojejunostomy. Symptoms include intermittent severe pain and epigastric fullness after eating because of volvulus, hernia, adhesion, or stenosis of the duodenal stump on the proximal side of the gastrojejunostomy. Vomiting typically relieves symptoms. Management includes low-fat diet, but decompression or surgery revision is required for complete obstruction.

Diarrhea is related to rapid gastric emptying and osmotic attraction of water into the gut, especially after a large intake of high-carbohydrate liquids. Small, dry meals and anticholinergic drugs are effective control measures.

Weight loss is commonly caused by inadequate caloric intake because the individual cannot tolerate carbohydrates or a normal-sized meal. The stomach also is less able to mix, churn, and break down food. In the case of bariatric surgery for extreme obesity, weight loss is the intended outcome, but nutrients, including vitamins and minerals, must be monitored and supplemented to prevent deficiencies.[53]

Anemia may occur if iron malabsorption results from decreased acid secretion or lack of duodenum after a Billroth II procedure (gastrojejunostomy). Deficiencies of iron, vitamin B_{12}, or folate also may result.

Bone and mineral disorders are related to altered calcium absorption and metabolism. This causes an increased risk of fractures and deformity, and malabsorption of vitamins and nutrients, such as vitamin D.

Malabsorption Syndromes

Malabsorption syndromes interfere with nutrient absorption in the small intestine. Historically they have been classified as maldigestion or malabsorption. **Maldigestion** is failure of the chemical processes of digestion that take place in the intestinal lumen or at the brush border of the intestinal mucosa. **Malabsorption** is failure of the intestinal mucosa to absorb the digested nutrients. Often these two syndromes are interrelated or occur together, making classification difficult. In general, maldigestion is caused by deficiencies of the enzymes needed for digestion or inadequate secretion of bile salts and inadequate reabsorption of bile in the ileum. Malabsorption is the result of mucosal disruption caused by gastric or intestinal resection, vascular disorders, or intestinal disease (also see Chapter 42).

Pancreatic Exocrine Insufficiency

The pancreatic enzymes (lipase, amylase, trypsin, chymotrypsin) are required for the digestion of proteins, carbohydrates, and fats. **Pancreatic insufficiency** is the deficient production of these enzymes, particularly lipase, by the pancreas. Causes include chronic pancreatitis, pancreatic carcinoma, pancreatic resection, and cystic fibrosis. Significant damage to or loss of pancreatic tissue must occur before enzyme levels decrease sufficiently to cause maldigestion. Although pancreatic insufficiency causes poor digestion of all nutrients, fat maldigestion is the chief problem. Absence of pancreatic bicarbonate in the duodenum and jejunum causes an acidic pH that worsens maldigestion by precipitating bile salts and preventing activation of the pancreatic enzymes that are present. A large amount of fat in the stool (steatorrhea) is the most common sign of pancreatic insufficiency. There is also a deficit of fat-soluble vitamins (A, D, E, and K) and weight loss. Several diagnostic tests are available to diagnose pancreatic exocrine insufficiency; however, there remains confusion regarding which testing procedure demonstrates the best approach. Treatment consists of

dietary management and lifestyle changes and pancreatic enzyme replacement therapy.[54]

Lactase Deficiency (Lactose Intolerance)

A deficiency of disaccharidase at the brush border of the small intestine is caused by a genetic defect in which a single enzyme, usually lactase, is lacking. **Lactase deficiency** inhibits the breakdown of lactose (milk sugar) into monosaccharides and therefore prevents lactose digestion and absorption across the intestinal wall. Lactase deficiency is most common in Blacks, Latinos, and Native Americans and usually does not develop until adulthood. Secondary (acquired) lactase deficiency can be caused by several diseases of the intestine, including gluten-sensitive enteropathy, enteritis, and bacterial overgrowth.

The undigested lactose remains in the intestine, where bacterial fermentation causes formation of gases. Undigested lactose also increases the osmotic gradient in the intestine, causing irritation and osmotic diarrhea. Clinical manifestations of lactose consumption with lactase deficiency are bloating, cramping type pain, diarrhea, and flatulence. The disorder is diagnosed by a lactose-tolerance test. Avoiding milk products and adhering to a lactose-free diet relieves symptoms.[55]

Bile Salt Deficiency and Malabsorption

Pathophysiology.Conjugated bile acids (BAs) (bile salts) are necessary for the digestion and absorption of fats. Bile salts are conjugated in the bile that is secreted from the liver. When bile enters the duodenum, the bile salts aggregate with fatty acids and monoglycerides to form micelles. Micelle formation makes fat molecules more soluble and allows them to pass through the unstirred layer at the brush border of the small intestinal villi (see Chapter 40). A minimum concentration of bile salts, termed the *critical micelle concentration*, is required to allow formation of micelles. Therefore conditions that decrease the production or secretion of bile result in bile salt deficiency and decreased micelle

formation and fat malabsorption. These conditions include advanced liver disease, which decreases the production of bile salts; obstruction of the common bile duct, which decreases flow of bile into the duodenum (cholestasis); intestinal stasis (lack of motility), which permits overgrowth of intestinal bacteria that deconjugate bile salts; and diseases of the ileum, which prevent the reabsorption and recycling of bile salts (enterohepatic circulation).[56]

Clinical Manifestations.Clinical manifestations of bile salt deficiency are related to poor intestinal absorption of fat and fat-soluble vitamins (A, D, E, and K). Increased fat in the stools (steatorrhea) leads to diarrhea and decreased levels of plasma proteins. The losses of fat-soluble vitamins and their effects include:

- Vitamin A deficiency results in night blindness.
- Vitamin D deficiency results in decreased calcium absorption with bone demineralization (osteoporosis), bone pain, and fractures.
- Vitamin K deficiency prolongs prothrombin time, leading to spontaneous development of purpura (bruising) and petechiae.
- Vitamin E deficiency has uncertain effects but may cause testicular atrophy and neurologic defects in children.

Evaluation and Treatment.The most effective treatment for fat-soluble vitamin deficiency is to increase consumption of medium-chain triglycerides in the diet, for example, by using coconut oil for cooking. Vitamins A, D, and K may be given parenterally. Oral bile salts are also an effective therapy.

Bile malabsorption is associated with a number is disorders, including ileal resection or inflammation, small intestinal bacterial overgrowth, and celiac disease. The accumulation of bile in the colon results in watery diarrhea known as BA diarrhea. Cholestyramine and colesevelam, which bind BA in the colon, are used for treatment. In the future, farsenoid X receptor agonists may also be effective because they regulate BA synthesis, conjugation, and transport.[57]

Inflammatory Bowel Disease

UC and CD are major types of chronic relapsing IBDs, and the cause is unknown. The prevalence of IBD is approximately 1.4 million people in the United States, with approximately 30,000 new cases annually.[58]

IBD causes an inflammation of the intestinal mucosa, which causes episodic abdominal pain, diarrhea, bloody stools, and weight loss. Inflammation and ulceration are caused by an influx of neutrophils and macrophages that produce proinflammatory cytokines, proteolytic enzymes, and free radicals (Table 41.7).[59]

Table 41.7

Features of Ulcerative Colitis and Crohn Disease

Feature	Ulcerative Colitis	Crohn Disease
Incidence		
Age at onset	Any age; 10–40 years most common	Any age; 10–30 years most common
Family history	Less common	More common
Sex	Prevalence equal in women and men	Prevalence about equal in women and men
Cancer risk	Increased	Increased
Nicotine use	Later and less severe disease; nicotine withdrawal may cause exacerbation	Increases disease risk and greater disease severity
Pathophysiology		
Location of lesions	Large intestine, continuous lesions Left side more common	Mouth to anus, "skip" lesions common Right side more common
Inflammation	Mucosal layer involved	Entire intestinal wall involved
Granulomata	Rare	Transmural granulomata common;

Feature	Ulcerative Colitis	Crohn Disease
		cobblestone appearance
Ulceration	Friable mucosa, superficial ulcers, crypt abscesses common	Deep fissuring ulcers and fistulae common
Anal and perianal fistulae	Rare	Common; abscesses
Narrowed lumen and possible obstruction	Rare	Common; obstruction
Clinical Manifestations		
Abdominal pain	Mild to severe	Moderate to severe
Diarrhea	Common; 4 times/day	May or may not be present
Bloody stools	Common	Less common
Weight loss	Less common	Common
Abdominal mass	Rare	Common
Small intestine malabsorption	None	Common
Clinical course	Remissions and exacerbations	Remissions and exacerbations
Comorbidities	Extraintestinal manifestations	Extraintestinal manifestations

Environmental factors or infections are thought to alter the barrier function of the mucosal epithelium, leading to loss of immune tolerance to normal intestinal antigens. Environmental triggers may include diet, psychological stress, viruses, and smoking.[58] There is possible loss of discrimination of potentially harmful pathogens from commensal microorganisms in the intestinal mucosa. The loss of tolerance activates immune cells. Production of proinflammatory mediators also damages the intestinal epithelium.

The risk of colon cancer has been significantly reduced with current approaches to treatment.[60] Future research is directed at an integration of these factors to refine our understanding of disease cause and trajectory, particularly interactions between genetics, the microflora, mucosa, and immune responses. The clinical manifestations of UC and CD are similar, but there are different pathologic features and extent of inflammatory involvement.

Ulcerative Colitis

Ulcerative colitis (UC) is a chronic inflammatory disease that causes ulceration of the colonic mucosa, most commonly in the rectum and sigmoid colon (Fig. 41.11). The lesions appear in susceptible individuals between 20 and 40 years of age. UC is less common in people who smoke or have had an appendectomy, and the mechanisms are not clearly known.[61]

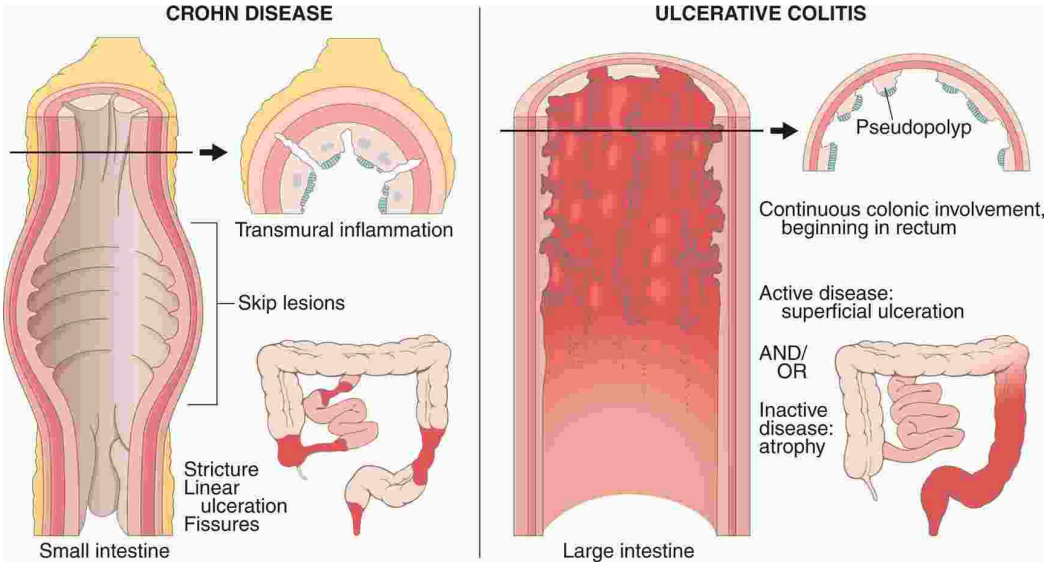

FIG. 41.11 Distribution Patterns of Crohn Disease and Ulcerative Colitis.
Comparison of distribution patterns of Crohn disease and ulcerative colitis as well as different conformations of ulcers and wall thickenings.
(From Kumar V, et al. *Robbins basic pathology*, 8th edition. St. Louis: Mosby; 2008.)

The illustration on the left depicts the distribution pattern of Crohn's disease, which shows the sectional view of the small intestine with labels indicating the skip lesion, stricture, linear ulceration, and fissures accompanied by the illustrations of a horizontal sectional view small intestine indicating the transmural inflammation. The illustration on the right depicts the distribution pattern of ulcerative colitis with labels indicating continuous colonic involvement, beginning in rectum; active disease: superficial ulceration; and or inactive disease:

atrophy accompanied by the horizontal section of the large intestine indicating the pseudopolyp.

Pathophysiology

The primary lesion of UC begins with inflammation at the base of the crypt of Lieberkühn in the large intestine. The disease begins in the rectum (proctitis) and may extend proximally to the entire colon (pancolitis). The lesions are limited to mucosal epithelium, are not transmural, and do not involve skip lesions. There is decreased secretion of mucin, which is antimicrobial and provides a protective layer against pathogens. Loss of this protection leads to increased permeability of the mucosa, increased passage of pathogens and other antigens, and stimulation of the gut immune system with an inflammatory response. There is activation of T cells and dendritic cells, triggering the production of proinflammatory cytokines and chemokines, including tumor necrosis factor (TNF)-α, interleukin (IL)-12 and IL-23, toxic oxygen free radicals, and interferon-gamma (IFN-γ), producing damage to the intestinal epithelium. In addition, there is activation of vascular adhesion molecules (integrins, e.g., mucosal addressin cellular adhesion molecule-1 [MadCAM-1]) which promote the trafficking of lymphocytes into the gut, furthering potentiation of the inflammatory response. Some of these molecules have become important targets for treatment.[62]

The mucosa is inflamed and is involved in a continuous fashion. With milder inflammation, the mucosa is hyperemic and edematous and may appear dark red. In more severe inflammation, the mucosa becomes hemorrhagic, and small erosions form and coalesce into ulcers. Abscess formation, necrosis, and ragged ulceration of the mucosa ensue. Edema and thickening of the muscularis mucosae may narrow the lumen of the involved colon. Mucosal destruction and inflammation cause bleeding, cramping pain, and an urge to defecate. Frequent diarrhea, with passage of small amounts of blood and purulent mucus, is common. Loss of the absorptive mucosal

surface and rapid colonic transit time cause large volumes of watery diarrhea.

Clinical Manifestations

The course of UC consists of intermittent periods of remission and exacerbation. Mild UC involves less mucosa, so the frequency of bowel movements, bleeding, and pain is minimal. Severe forms may involve the entire colon and are characterized by abdominal pain, fever, an elevated pulse rate, frequent diarrhea (10 to 20 stools/day), urgency, bloody stools, and continuous, crampy pain; dehydration, weight loss, anemia, and fever result from fluid loss, bleeding, and inflammation. Complications include anal fissures, hemorrhoids, and perirectal abscess. Severe hemorrhage is rare. Edema, strictures, or fibrosis can obstruct the colon. Perforation is an unusual but possible complication. Extraintestinal manifestations include cutaneous lesions (erythema nodosum), polyarthritis, episcleritis, uveitis, disorders of the liver, and alterations in coagulation.[63]

Evaluation and Treatment

The diagnosis of UC is based on the medical history, clinical manifestations, and laboratory, serologic, imaging, endoscopic, and histology findings. Infectious causes are ruled out by stool culture. Endoscopic evaluation shows an inflamed and hemorrhagic mucosa. Radiologic assessment may show ulceration and irregular mucosa. The laboratory data include low hemoglobin levels, hypoalbuminemia, and low serum potassium levels. The gold standard in making the diagnosis remains biopsy and histology.[63] The symptoms of UC are often similar to those of CD, making differential diagnosis challenging.

Treatment is individualized and depends on the severity of symptoms and the extent of mucosal involvement. A goal is to promote mucosal healing and avoid surgery. Mild to moderate disease is treated with 5-aminosalicylate therapy followed by steroids. Immunomodulatory agents are used for failure of first-line treatments or serious recurrent disease including TNF-α–blocking

agents (e.g., tacrolimus) or antiadhesion agents (i.e., vedolizumab). New small molecule drugs are being investigated.[64] New oral agents have recently been approved (see Emerging Science Box: Oral Treatments for Ulcerative Colitis). Severe, unremitting disease can require hospital admission for administration of intravenous fluids and steroids. Extreme malnutrition may require total parenteral nutrition (TPN). Surgical resection of the colon may be performed if other forms of therapy are unsuccessful or if there are acute serious complications (sepsis, hemorrhage, perforation, or obstruction). Surgical approaches for severe UC include total proctocolectomy with end ileostomy or ileorectal anastomosis, or ileal pouch–anal anastomosis (IPAA). *Pouchitis* is a common complication of restorative proctocolectomy with IPAA performed as surgical treatment for both UC and CD. There are more frequent bowel movements, urgency to defecate, blood in the stool, incontinence, and abdominal pain. Antibiotic treatment is usually successful, and chronic symptoms may be managed with steroids or immune modulators.[65]

Emerging Science Box

Oral Treatments for Ulcerative Colitis

Ulcerative colitis is a chronic inflammatory condition that often requires use of medications to maintain remission and stop flare up of the disease. Historically, this disease was treated with a bottom-up approach. Emerging science demonstrates that ulcerative colitis should be treated with a top-down strategy aiming to treat the underlying severity of disease with medications that are most appropriate for the level of disease severity. Two new oral drugs have been approved and are desirable due to their oral dosing. The drugs suppress lymphocyte trafficking and several inflammatory pathways, promote mucosal healing, and have a short half-life and good safety profile. Tofacitinib is a Janus kinase inhibitor and was approved for use in

the United States in 2018 for adults with moderate to severe ulcerative colitis who fail anti–tumor necrosis factor agents. Ozanimod (Zeposia) is a sphingosine 1-phosphate (S1P) receptor modulator approved in March 2020 for the treatment of moderate to severe ulcerative colitis and multiple sclerosis. These drugs still retain a side-effect profile, particularly infection, that can be significant and must be examined and prescribed by a treating provider after review of other medications and risk factors.

Data from Misselwitz B, et al. Swiss IBDnet, an official working group of the Swiss Society of Gastroenterology. Emerging treatment options in inflammatory Bowel disease: janus kinases, stem cells, and more. *Digestion*. 2020;101(suppl 1):69–82. Crohn Disease

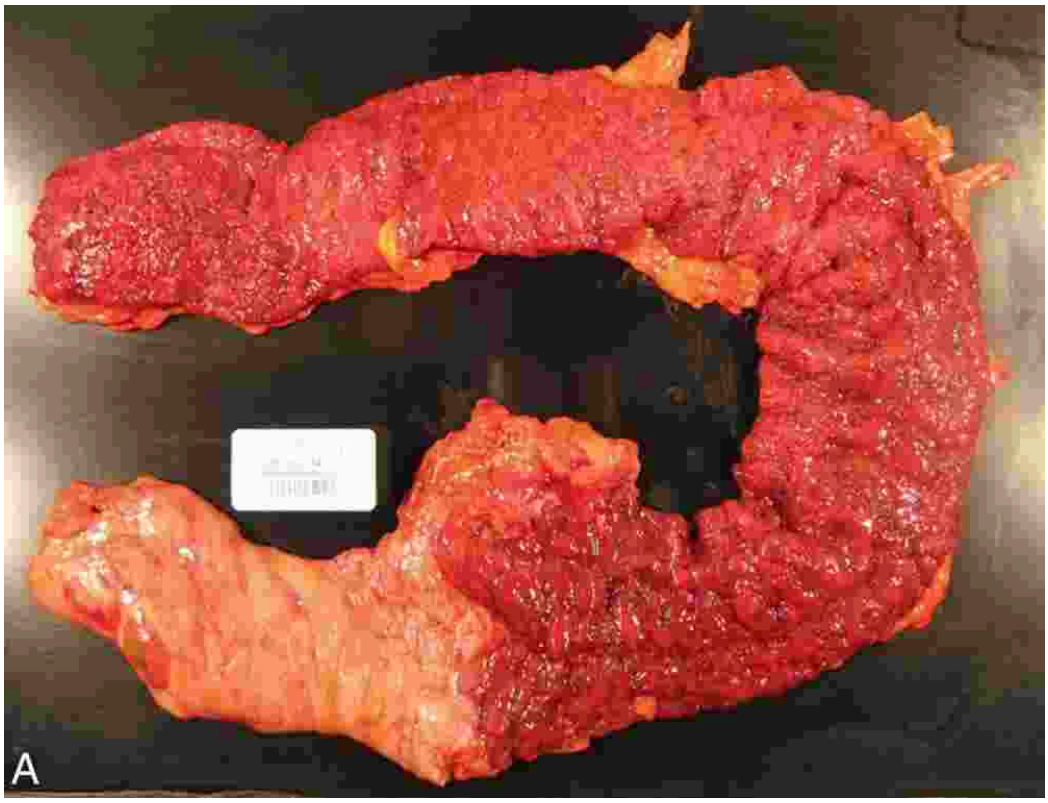
Crohn disease (CD) (granulomatous colitis, ileocolitis, or regional enteritis) is an inflammatory disorder that affects any part of the GI tract from the mouth to the anus. In a small percentage of cases, CD is difficult to differentiate from UC (see Table 41.7). Risk factors associated with CD include smoking, low fiber–high carbohydrate diet, medications such as NSAIDs, and an altered intestinal microbiome.[66] CD appears to have a multifactorial etiology in which both genetics and environmental factors manifest the disease. Smoking increases the risk of developing severe disease and may cause a poorer response to treatment. The inflammation is driven by a sustained immune response against luminal bacterial antigens with activation of leukocyte adhesion molecules (integrins), hyperactivity of T cells with excess production of inflammatory cytokines (e.g., IL-12, IL-23, and IL-34), and activation of cytotoxic enzymes resulting in tissue damage.[67]

Pathophysiology

Inflammation begins in the intestinal submucosa and spreads with discontinuous transmural involvement or "skip lesions" that can

involve any part of the GI tract from the mouth to the perianal area. Skip lesions are distinguished by inflamed areas mixed with uninflamed areas, noncaseating granulomas, fistulas, and deep penetrating ulcers. The distal small intestine and proximal large colon are most involved. The ulcerations of CD can produce fissures that extend inflammation into lymphoid tissue. The typical lesion associated with CD is a granuloma or a mass of inflammatory tissue with a cobblestone appearance of inflamed tissue (Fig. 41.12) surrounded by ulceration. Fistula may form in the perianal area between loops of intestine and may extend into the bladder, rectum, or vagina and form intra-abdominal abscesses. Strictures may develop, promoting obstruction.[67]



A

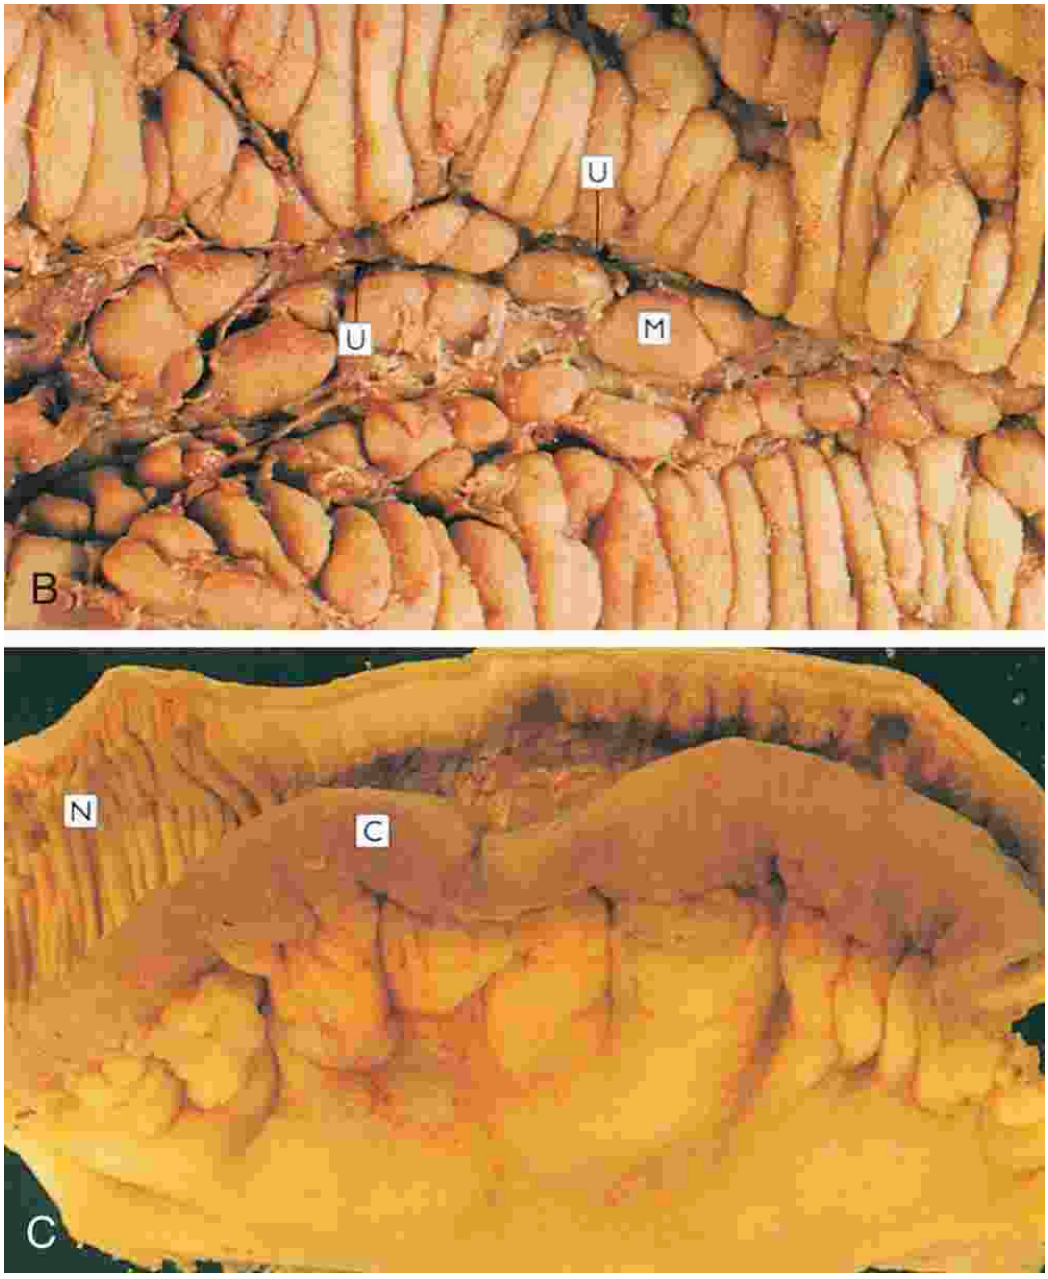


FIG. 41.12 **(A)** Acute ulcerative colitis. A gross specimen of subtotal ulcerative colitis showing diffuse continuous disease starting from the distal rectum and continuing up to the midportion of the ascending colon. *(B)* Crohn disease. The mucosa in Crohn disease demonstrates a cobblestone pattern as a result of fissured ulcers **(U)** with intervening areas of edematous mucosa *(M)*. **(C)** Compared with normal small bowel wall *(N)*, the

Crohn segment *(C)* shows wall thickening that has caused a stenosis. (A, From Odze RD, Goldblum JR, eds. *Surgical pathology of the GI tract, liver, biliary tract, and pancreas*, 2nd edition. Philadelphia: Saunders; 2009. B and C, From Kumar V, et al. *Pathologic basis of disease*, 7th edition. Philadelphia: Saunders; 2006.)

A. Close shot of gross specimen of the colon showing ulcerative colitis. B. Close shot of gross specimen representing longitudinal serpiginous ulcers separated by irregular islands of edematous mucosa. C. Close shot of gross specimen representing ileal segments, the mesenteric fat creeps from the mesentery to surround the bowel wall.

Clinical Manifestations

Individuals with CD may have no specific symptoms for several years. Symptoms vary according to the location of the disease but are similar to those for UC. Diarrhea is one of the most common symptoms, and occasionally rectal bleeding is noted if the colon is involved. Weight loss and abdominal pain accompany CD. Abdominal tenderness may also be noted over the lesions. If the ileum is involved, the individual may be anemic as a result of malabsorption of vitamin B_{12}. There also may be deficiencies in folic acid and vitamin D absorption. In addition, proteins may be lost, leading to hypoalbuminemia. Extraintestinal complications are similar to those occurring in UC. Additional complications include anal fissure, perianal abscess, and fistula. Individuals with CD of long duration also are at risk for intestinal adenocarcinoma. Extraintestinal manifestations include arthropathies, skin, oral, and ocular lesions.[68]

Evaluation and Treatment

The diagnosis and treatment of CD are similar to the diagnosis and treatment of UC. Imaging of the small intestine is used in the diagnosis of CD, including either a small bowel series or a capsule endoscopy (camera pill). There are no specific biomarkers or definitive treatments for the disease. Smoking cessation is a component of therapy. Steroids are used to induce remission, and immunosuppressants (e.g., thiopurines and methotrexate) are used to sustain remission. Anti–TNF-α, antiintegrins (target the adhesion molecular inhibiting leukocyte migration), and IL inhibitors (target IL-12 and IL-23) are used for the most severe forms of the disease. Surgery may be performed to manage complications, such as fistula, abscess, or obstruction. When treatment involves surgical resection of small intestinal segments, complications related to **short bowel syndrome** may occur. Complications of short bowel syndrome include malabsorption, diarrhea, and nutritional deficiencies. Since malnutrition affects a significant number of individuals with CD, diet management is a significant component of the care plan.[69] Routine colonoscopy for cancer screening should be performed for long-standing colonic disease.[66]

Microscopic Colitis

Microscopic colitis is a relatively common cause of nonbloody diarrhea. Although the mucosa appears normal, there are two histologic forms: lymphocytic and collagenous. Lymphocytic colitis shows an increase in the number of intraepithelial lymphocytes in the wall of the colon. Collagenous colitis is characterized by a thickened subepithelial collagen layer, with mucosal nodularity and an alteration of the vascular mucosal pattern. Risk factors include age 50 years or older, female sex, weight loss, smoking, use of PPIs, use of NSAIDs, and use of selective serotonin reuptake inhibitors. The cause of microscopic colitis is unknown, and proposed mechanisms include autoimmunity, genetic predisposition, an immune or inflammatory response to luminal antigens, certain medications, and abnormal collagen metabolism.[70]

The symptoms of frequent daily watery diarrhea are the same for both types and may be accompanied by abdominal pain and weight loss. Diagnosis is made from biopsy. Antidiarrheal agents and budesonide (an oral antiinflammatory steroid) are the best-documented treatments. The disease is negatively associated with CRC.

Irritable Bowel Syndrome

IBS currently is considered a disorder of brain-gut interaction (previously termed a functional GI disorder) characterized by recurrent abdominal pain with altered bowel habits.[71] It is estimated that in the United States 10% to 12% of adults suffer with IBS symptoms.[72] It is more common in women, with a higher prevalence during youth and middle age. Individuals with symptoms of IBS also are more likely to have anxiety, depression, and a reduced quality of life.[73]

Pathophysiology.The pathophysiology of IBS is unknown, and there are no specific biomarkers for the disease. There is increasing evidence to explain a multisystem interaction with variables, including infection, gut microbiota, immune activation, serotonin dysregulation, psychological stress, abnormal gut function and diet, as contributing factors to the varying symptom presentations. Mechanisms of pathophysiology are summarized as follows:

- *Visceral hypersensitivity or hyperalgesia* may originate in either the peripheral or the central nervous system. The mechanism may be related to a dysregulation of the bidirectional "brain-gut axis" (alterations in gut or central nervous system processing of gut-pain information). Factors include genetic-related changes in the function of serotonin-secreting cells of gut-brain pain modulation, alterations in gut microbiota metabolite production with activation of the gut immune system, increased visceral sensitivity and permeability, and altered motility and secretion.

- *Abnormal GI permeability, motility, secretion, and sensitivity* are associated with IBS. Individuals with diarrhea-type IBS have more rapid colonic transit times and increased intestinal permeability. Those with bloating and constipation have delayed transit times and decreased intestinal permeability. The mechanism may be related to dysregulation of the brain-gut axis, alterations in the function of gut neuroendocrine cells or dorsal root ganglion neurons, or changes in the activity of mast cells (produce histamine). Sex hormones may be a contributing factor.
- *Postinflammatory (infectious or noninfectious) IBS* is associated with intestinal infection (bacterial enteritis) and low-grade inflammation. Alterations in gut microbiota, immune activation in gut tissues, and changes in intestinal permeability have been proposed.
- *Alteration in gut microbiota (dysbiosis)* influences the sensory, motor, and immune systems of the gut and interacts with higher brain centers and may contribute to symptoms of IBS. Small intestine overgrowth of normal gut bacteria may be associated with IBS symptoms in some cases. Nonabsorbable antibiotics and prebiotics and probiotics may be helpful in some individuals.
- *Psychosocial factors (epigenetic factors)*—including early life trauma or abuse or emotional stress interacting with neuroendocrine, neuroimmune, autonomic nervous system, and pain modulatory responses—contribute to the symptoms of IBS.

Clinical Manifestations

IBS symptoms may be mild or debilitating. IBS is characterized by lower abdominal pain or discomfort and bloating. IBS can be grouped as diarrhea-predominant, constipation-predominant, or mixed diarrhea/constipation. Symptoms including gas, bloating, fecal urgency, incomplete evacuation, and nausea are usually relieved with defecation and do not interfere with sleep.

Evaluation and Treatment

The diagnosis of IBS is based on signs, symptoms, personal history, and includes the exclusion of structural or biochemical causes of disease such as IBD or intestinal infection. Diagnostic procedures to rule out other causes of symptoms may include endoscopic evaluations, CT scans, abdominal ultrasound, blood tests, and lactose intolerance test. Fecal calprotectin is evaluated in those with suspected IBS and diarrhea symptoms to rule out IBD.

The individual may be evaluated for food allergies, parasites, or bacterial growth. The Rome IV criteria for diagnosing IBS are presented in Box 41.2.

Box 41.2

Diagnostic Criteria[a] for Irritable Bowel Syndrome

Rome IV Criteria

Recurrent abdominal pain, on average, at least 1 day per week in the past 3 months associated with two or more of the following criteria:

- Related to defecation
- Associated with a change in frequency of stool
- Associated with a change in form (appearance) of stool

IBS subtypes include:

- IBS with predominant constipation (IBS-C)
- IBS with predominant diarrhea (IBS-D)
- IBS with mixed bowel habits (IBS-M)
- IBS unclassified (IBS-U)

IBS, Irritable bowel syndrome.

Adapted from Drossman DA. Functional gastrointestinal disorders: history, pathophysiology, clinical features and Rome IV. *Gastroenterology*, 2016;150(6):1262–1297; Lacey BE et al: *Gastroenterology*, 2016;150(6):1393–1407.

[a]Criteria met for the past 3 months with symptom onset at least 6 months before diagnosis.

There is no cure for IBS, and treatment is individualized.[74] Treatment of symptoms may include laxatives, fiber, antidiarrheals, antispasmodics, prosecretory drugs, low-dose antidepressants, visceral analgesics, and serotonin agonists or antagonists and supportive care is symptom related. Alternative therapies include prebiotics and probiotics to manipulate the microflora. Hypnosis, acupuncture, yoga, cognitive behavioral therapy, and dietary interventions have been used with varying results.[75] Research continues to advance the management and understanding of the pathophysiology of this complex syndrome.

Diverticular Disease of the Colon

Diverticula are herniations or sac-like outpouchings of the mucosa and submucosa through the muscle layers, usually located in the wall of the sigmoid colon and they are more common in older adults (Fig. 41.13). They rarely occur in the small intestine. **Diverticulosis** is asymptomatic diverticular disease. **Diverticulitis** represents inflammation of the diverticula and occurs in approximately 10% to 15% of cases of diverticular disease of the colon.[76] The cause of diverticular disease is unknown, but it is associated with increased intracolonic pressure, abnormal neuromuscular function, and alterations in intestinal motility. Predisposing factors include older age, genetic predisposition, obesity, smoking, diet, lack of physical activity, and medication use (e.g., aspirin and NSAIDs).[77] Lack of dietary fiber may or may not contribute to diverticular disease.

Altered intestinal microbiota, visceral hypersensitivity, and abnormal colonic motility also may be contributing factors.[78]

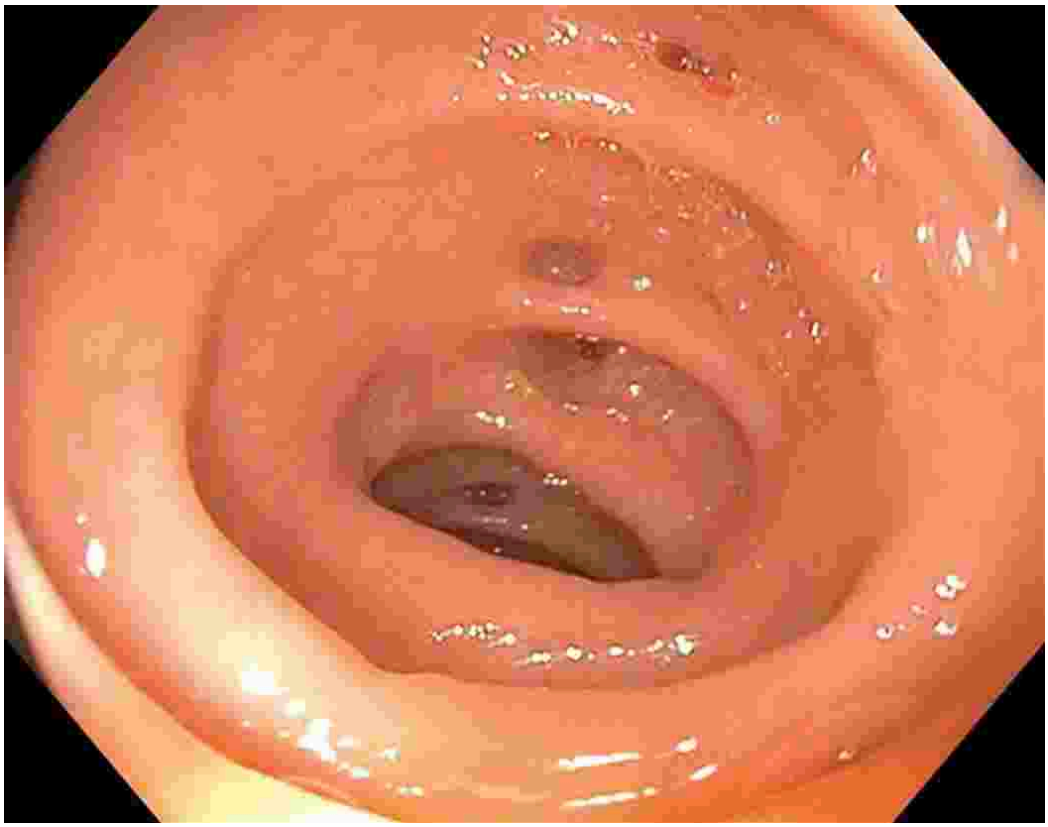

FIG. 41.13 Diverticular Disease.
In diverticular disease, the outpouches of mucosa seen in the sigmoid colon appear as slit-like openings from the mucosal surface of the opened bowel. (From Townsend CM, et al. *Sabiston textbook of surgery: The biologic basis of modern surgical practice*, 21st edition. St. Louis: Elsevier; 2022.)

Pathophysiology

Diverticula can occur anywhere in the GI tract, particularly at weak points in the colon wall, usually where arteries penetrate the tunica muscularis. The most common sites are the left sigmoid colon (more prevalent in Western countries) and the right colon (more prevalent

in Asian countries). A common associated finding of the disease is thickening of the circular muscles and shortening of the longitudinal (teniae coli) muscles surrounding the diverticula. Although not characterized as muscle hypertrophy, diverticular disease may cause increased collagen and elastin deposition and is associated with muscle thickening. This contributes to increased intraluminal pressure and herniation. According to the law of Laplace (see Chapter 34), wall pressure increases as the diameter of a cylindrical structure decreases. Therefore pressure within the narrow lumen can increase enough to rupture the diverticula, causing inflammation and diverticulitis. Bacteria and local ischemia also may be contributing factors. Complicated diverticulitis includes abscess, fistula, obstruction, bleeding, or perforation.

Clinical Manifestations

Symptoms of uncomplicated diverticular disease may be vague or absent. Cramping pain of the lower abdomen can accompany constriction of the thickened colonic muscles. Diarrhea, constipation, distention, or flatulence may occur. If the diverticula become inflamed or abscesses form, the individual develops fever, leukocytosis, and tenderness in the lower left quadrant.

Evaluation and Treatment

Diverticula are often discovered during diagnostic procedures performed for other problems. Ultrasound, sigmoidoscopy, or colonoscopy permits direct observation of the lesions. Abdominal CT is used for diagnosis of complicated cases.

An increase in dietary fiber intake often relieves symptoms by increasing bulk and lowering colonic pressure. Uncomplicated diverticulitis is usually treated with bowel rest and a clear, liquid diet, analgesia, and selective use of antibiotics. Complicated cases may require intravenous antibiotics and abscess drainage if needed. In severe cases, bowel resection surgery may be needed with or without a colostomy.[79]

Appendicitis

Appendicitis is an inflammation of the vermiform appendix, which is a projection from the apex of the cecum. Appendicitis is a medical emergency. It is the most common surgical emergency of the abdomen, usually occurring between 10 and 19 years of age (although it may develop at any age). The incidence in the United States is 10 cases per 10,000 persons.[80]

Pathophysiology

The exact mechanism of the cause of appendicitis is not well understood. Obstruction of the lumen with stool, tumors, or foreign bodies, with consequent bacterial infection, is the most common theory. The obstructed lumen does not allow drainage of the appendix, and as mucosal secretion continues, intraluminal pressure increases. The increased pressure decreases mucosal blood flow, and the appendix becomes hypoxic. The mucosa ulcerates, promoting bacterial or other microbial invasion, with further inflammation and edema. Inflammation may involve the distal or entire appendix. Gangrene develops from thrombosis of the luminal blood vessels, followed by a periappendicular abscess and perforation resulting in peritonitis in complex cases.[80,81]

Clinical Manifestations

Epigastric or periumbilical pain is the typical symptom of an inflamed appendix. The pain may be vague at first but will increase in intensity over 3 to 4 hours. It may subside and then migrate to the right lower quadrant, indicating extension of the inflammation to the surrounding tissues. Nausea, vomiting, and anorexia follow the onset of pain, and a low-grade fever is common. Diarrhea occurs in some individuals, particularly children; others have constipation. Perforation, peritonitis, and abscess formation are the most serious complications of appendicitis.

Evaluation and Treatment

In addition to clinical manifestations, there is pain with abdominal palpation and rebound tenderness, usually referred to the right lower quadrant. The white blood cell count is greater than 10,000 cells/mm^3, with increased neutrophils and C-reactive protein. Abdominal ultrasound, CT scans, and magnetic resonance imaging (MRI) (particularly for pregnant women and children) assist with diagnostic accuracy and help to rule out nonappendiceal disease. Antibiotics and appendectomy are the treatment for simple appendicitis.[82] Treatment for complicated appendicitis (perforation, abscess formation, peritonitis) also includes antibiotics and appendectomy; however, recovery may be more complicated.[80,83] There is an increased risk of colon cancer post appendectomy among individuals aged 50 to 54 years, and follow-up colonoscopy is recommended.[84]

Mesenteric Vascular Insufficiency

Mesenteric vascular insufficiency is rare, with an incidence of approximately 2 to 3 cases per 100,000 persons.[85] Three branches of the abdominal aorta supply the stomach and intestines: the celiac artery and the superior and inferior mesenteric arteries. The inferior mesenteric vein drains into the splenic vein, and the splenic vein and superior mesenteric vein join the portal vein. *Mesenteric venous thrombosis* is the least common of the causes of mesenteric vascular insufficiency. Malignancies, right-sided heart failure, and deep vein thrombosis are risk factors. Mesenteric venous thrombosis presents with abdominal pain and is treated with anticoagulants.

Acute mesenteric arterial insufficiency results in a significant reduction in mucosal blood flow to the large and small intestines.[86] Preexisting morbidities include dissecting aortic aneurysms, arterial thrombi, or emboli. Embolic obstruction is associated with atrial fibrillation, mitral valve disease, heart valve prostheses, and myocardial infarction. The superior mesenteric artery has a more direct line of flow from the aorta; therefore emboli enter it more readily than the inferior branch, causing ischemia and necrosis of the

small intestine. Ischemia, infarction, and necrosis all alter membrane permeability. Initially, there is increased motility, nausea and vomiting, urgent bowel evacuation, and severe abdominal pain. Ischemia leads to decreased motility and distention. The damaged intestinal mucosa cannot produce enough mucus to protect itself from digestive enzymes. Mucosal alteration causes fluid to move from the blood vessels into the bowel wall and peritoneum. Fluid loss causes hypovolemia and further decreases intestinal blood flow. As intestinal infarction progresses, shock, fever, bloody diarrhea, and leukocytosis develop. Bacteria invade the necrotic intestinal wall, causing gangrene and peritonitis.

Chronic mesenteric ischemia (CMI) is rare. The most common etiology is atherosclerotic stenosis or occlusion of the mesenteric arteries. CMI can be associated with congestive heart failure, acute myocardial infarction, hemorrhage, thrombus formation, or any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by the formation of collateral circulation. The collateral vessels may be able to nourish the resting intestine, but after eating, when the intestine requires more blood, the arterial supply may be insufficient. Ischemia develops, causing cramping abdominal pain or abdominal angina, which is a cardinal symptom reoccurring over a period of 3 months. Some individuals suffer significant weight loss because they stop eating to control the pain. Progressive vascular obstruction eventually causes continuous abdominal pain and necrosis of the intestinal tissue.

The diagnosis of acute and CMI is based on clinical manifestations, laboratory findings, and imaging studies. The diagnosis may be difficult because of the vagueness of symptoms. A bruit can often be heard over a partially occluded artery. Treatment includes aggressive rehydration and the use of antibiotics, anticoagulants, vasodilators, and inhibitors of reperfusion injury. Surgery, including percutaneous stenting or open techniques, is required to remove necrotic tissue, repair sclerosed vessels, and revascularize affected tissue. Acute occlusion is a surgical emergency, and the mortality rate is high (50% to 90%). Early

diagnosis and aggressive treatment result in the best survival rates.[87,88]

Disorders of the accessory Organs of Digestion

The accessory organs of digestion, including the liver, gallbladder, and pancreas, secrete substances necessary for digestion and in the case of the liver carry out metabolic functions needed to maintain life. Disorders of these organs include inflammatory disease, obstruction of ducts, and tumors. (Cancers of the digestive system are described at the end of this chapter.)

Common Complications of Liver Disorders

Of all the accessory organ disorders, acute or chronic liver disease leads to the most significant systemic, life-threatening complications. These complications are common to all liver disorders and include portal hypertension, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome (HRS).

Portal Hypertension

Portal hypertension is abnormally high blood pressure in the portal venous system caused by resistance to blood flow. Pressure in this system is normally 3 mm Hg; portal hypertension is an increase to at least 10 mm Hg.

Pathophysiology

Portal hypertension is caused by disorders that obstruct or impede blood flow through any component of the portal venous system or vena cava. *Intrahepatic causes* result from vascular remodeling with shunts, thrombosis, inflammation, or fibrosis of the sinusoids, as occurs in cirrhosis of the liver, biliary cirrhosis, viral hepatitis, or schistosomiasis (a parasitic infection). *Posthepatic causes* occur from hepatic vein thrombosis or cardiac disorders that impair the pumping ability of the right side of the heart. This causes blood to collect and increases pressure in the veins of the portal system. The

most common cause of portal hypertension is fibrosis and obstruction caused by cirrhosis of the liver. Long-term portal hypertension causes several pathophysiologic problems that are difficult to treat and can be fatal. These problems include varices, splenomegaly, ascites, hepatic encephalopathy, and hepatopulmonary syndrome (HPS) (see Emerging Science Box: Portal Hypertension).

Varices are distended, tortuous collateral veins. Prolonged elevation of pressure in the portal vein causes collateral veins to open between the portal vein and systemic veins. The prolonged pressure is distributed throughout the GI tract and results in transformation into varices, particularly in the lower esophagus and stomach, but also over the abdominal wall (known as the caput medusae [Medusa head]) and rectum (hemorrhoidal varices) (Fig. 41.14). The hyperdynamic circulation in the stomach and esophagus impairs mucosal defenses, promotes inflammation, and disrupts healing with increased risk of mucosal erosion, ulceration, and bleeding.[89] Rupture of varices can cause life-threatening hemorrhage.[90]

Emerging Science Box

Portal Hypertension

Portal hypertension is a severe complication in the progression of liver disease. Portal hypertension causes an increase in pressure gradients between the portal system and the hepatic veins and is the cause of most complications associated with liver disease. The past three decades have noted a great decline in mortality rates of individuals with portal hypertension as emerging science on the pathophysiology of this complication has helped decrease mortality. A pathogenesis-based approach to treatment has based the introduction of simvastatin for treatment to improve endothelial dysfunction and for use of its liver-protective effects. Pharmaceutical treatments also may involve use of carvedilol, a

nonselective ß-blocker, in place of historically used propranolol due to carvedilol having a vasodilatory effect, particularly for the prophylaxis of variceal bleeding. Emerging interventions include early transjugular intrahepatic portosystemic shunt (TIPS), esophageal stents, and balloon-occluded retrograde transvenous obliteration (BRTO).

Data from Bosch J. Portal hypertension and cirrhosis: From evolving concepts to better therapies. *Clinical Liver Disease*, 2020;15(suppl 1): S8-S12; Iwakiri Y, et al. Portal hypertension in cirrhosis: Pathophysiological mechanisms and therapy. JHEP Reports, 2021;3(4):100316.

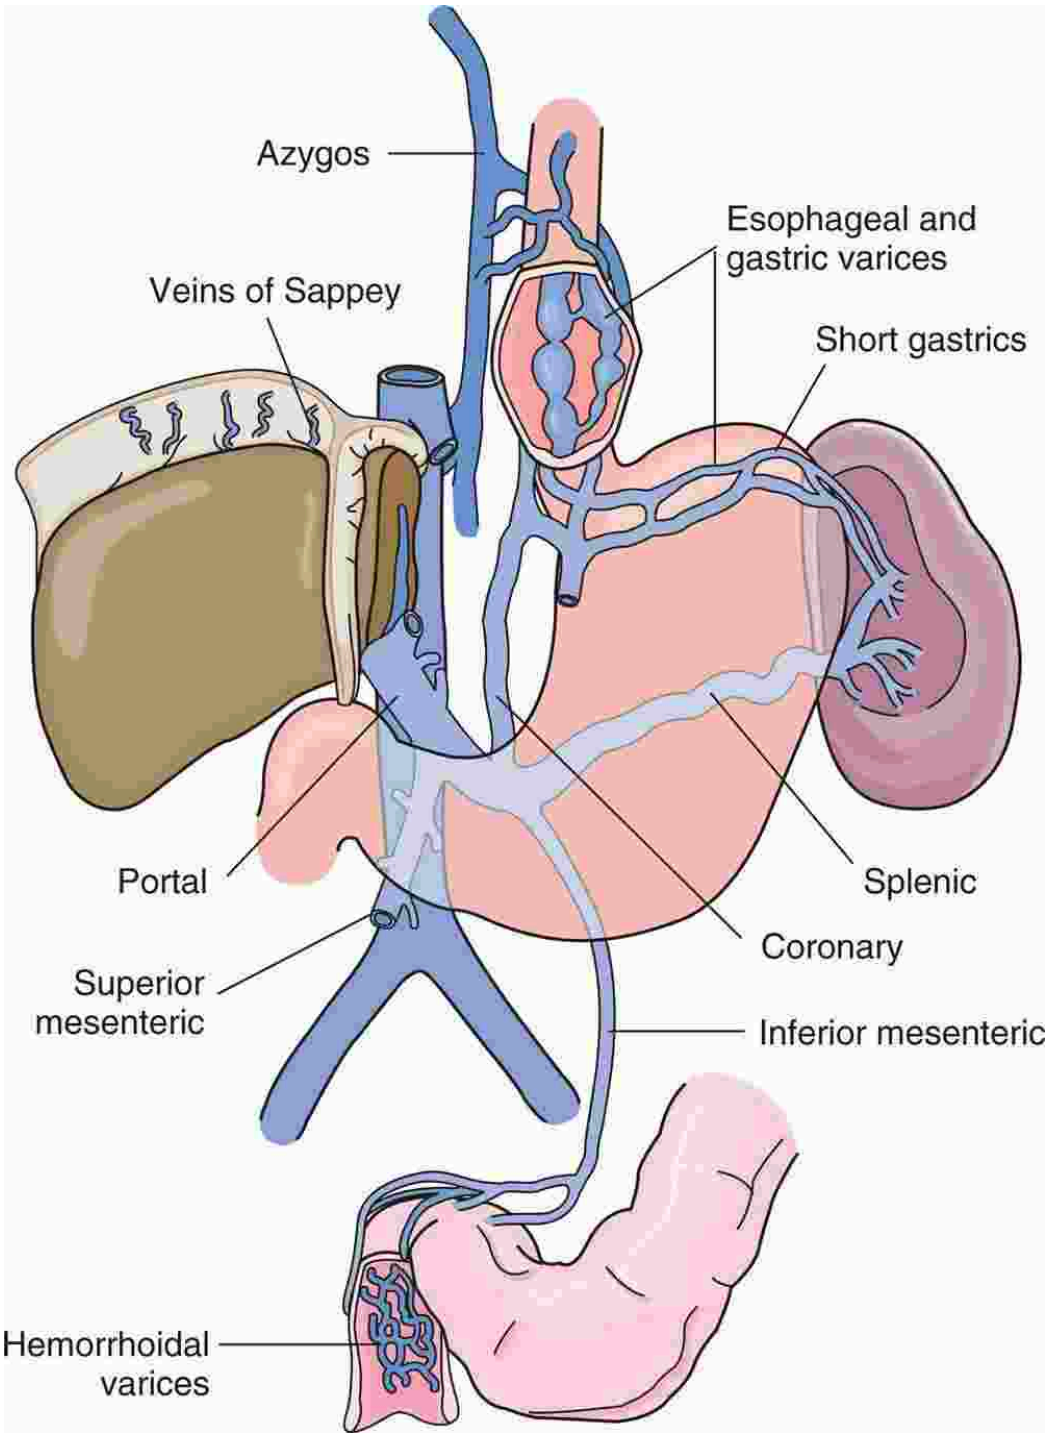

FIG. 41.14 Varices Related to Portal Hypertension.

The portal vein, its major tributaries, and the most important shunts (collateral veins) between the portal and caval systems. The shunted blood

returns to the systemic venous system, bypassing the liver. (From Monahan FD, et al. *Phipps' medical-surgical nursing: Concepts and clinical practice*, 8th edition. St. Louis: Mosby; 2007.)

An illustration depicts the varices encountered in portal hypertension showing the digestive system with labels indicating azygos, esophageal and gastric varices, short gastric, veins of Sappey, portal, superior mesenteric, hemorrhoidal varices, inferior mesenteric, coronary, splenic.

Splenomegaly is enlargement of the spleen caused by increased pressure in the splenic vein, which branches from the portal vein. Thrombocytopenia is the most common symptom of congestive splenomegaly. The enlarged spleen can often times be palpated. **HPS** and **portopulmonary hypertension (PPH)** are respiratory complications of liver disease and portal hypertension. The pathophysiology of both is complex and involves different effects of vasoactive substances. In HPS there is pulmonary vasodilation, probably because of the increased nitric oxide synthesis, increased pulmonary venous congestion, and right-to-left shunting that induces hypoxemias. PPH is associated with vasoconstriction and arterial vascular remodeling with thickening and fibrosis of the arterial wall that increases pulmonary artery resistance. Individuals may be asymptomatic, or fatigue, dyspnea, cyanosis, and clubbing may occur with or without signs of right heart failure (jugular venous distention, ascites, and peripheral edema).

Diagnosis includes pulmonary function tests, arterial blood gas analysis, contrast echocardiography, transthoracic echocardiography, and right heart catherization. In PPH, mean pulmonary artery pressure is greater than 25 mm Hg at rest. There is no specific treatment for HPS. Treatment of PPH includes targeting

the pulmonary arterial vasculature to reduce pulmonary hypertension with various medication options that include endothelin receptor antagonists, phosphodiesterase type 5 inhibitors, and prostanoids. Liver transplant may be indicated.[91]

Clinical Manifestations

Hematemesis from bleeding **esophageal varices** is the most common clinical manifestation of portal hypertension. Bleeding is usually from varices that have developed slowly over a period of years. Slow, chronic bleeding from varices causes anemia or melena. Acute rupture of esophageal varices causes hemorrhage and voluminous vomiting of dark-colored blood. The ruptured varices are usually painless. Rupture is caused by a combination of erosion by gastric acid and elevated venous pressure. Mortality from ruptured esophageal varices ranges from 30% to 60%. Recurrent bleeding of esophageal varices indicates a poor prognosis. Hemorrhoidal varices present as hematochezia with copious rectal bleeding.

Evaluation and Treatment

Portal hypertension is often diagnosed at the time of variceal bleeding and confirmed by upper GI endoscopy and evaluation of portal venous pressure. The individual usually has a history of jaundice, hepatitis, alcoholism, or cirrhosis. Liver elastography is an imaging test that provides a noninvasive measure of liver stiffness and can diagnose the extent of fibrosis.[92]

Emergency management of bleeding varices includes use of vasopressors and compression of the varices with an inflatable tube or balloon, sclerotherapy, variceal ligation, or portacaval shunt. Surgical construction of transjugular intrahepatic portosystemic shunts (TIPSs) and anastomosis of the portal vein to the inferior vena cava may decompress the varices. This treatment can precipitate encephalopathy. Emergency management will also include stabilization of the individual with fluid resuscitation, red blood cell replacement, and antibiotics. Liver transplantation is the most successful option for liver failure. Nonemergent or long-term

management may include nonselective β-blocking drugs to assist reducing the pressure in the portal venous system and to prevent variceal bleeding.[93]

Ascites

Ascites is the accumulation of fluid in the peritoneal cavity. Ascites traps body fluid in the peritoneal space, from which it cannot escape. Ascites reduces the amount of body fluid available for normal physiologic functions. Cirrhosis is the most common cause of ascites, but other causes include heart failure, constrictive pericarditis, abdominal malignancies, nephrotic syndrome, and malnutrition. Of individuals who develop ascites caused by cirrhosis, 25% die within 1 year. Continued heavy drinking of alcohol is associated with this mortality and is related to decompensated cirrhosis.

Pathophysiology

Several factors contribute to the development of ascites, including portal hypertension, splanchnic vasodilation, decreased synthesis of albumin by the liver, splanchnic arterial vasodilation, and renal sodium and water retention. Portal hypertension causes capillary hydrostatic pressure to exceed capillary osmotic pressure (see Chapter 3), pushing water into the peritoneal cavity. Portal hypertension also increases the production of hepatic lymph, which "weeps" into the peritoneal cavity. Reduced serum albumin levels reduce capillary oncotic pressure adding to the fluid shift. Splanchnic arterial vasodilation is associated with increased nitric oxide produced by the diseased liver and can decrease effective circulating blood volume, activating the renin-angiotensin-aldosterone system and antidiuretic hormone, which in turn promotes renal sodium and water retention. The sodium and water retention expands plasma volume, thereby accelerating portal hypertension and ascites formation. In addition, translocation of bacteria and release of endotoxin cause peritonitis with an inflammatory response that increases splanchnic vasodilation and mesenteric capillary permeability and fluid movement into the

peritoneal cavity, promoting ascites. Fig. 41.15 summarizes the mechanisms by which cirrhosis of the liver cause ascites.

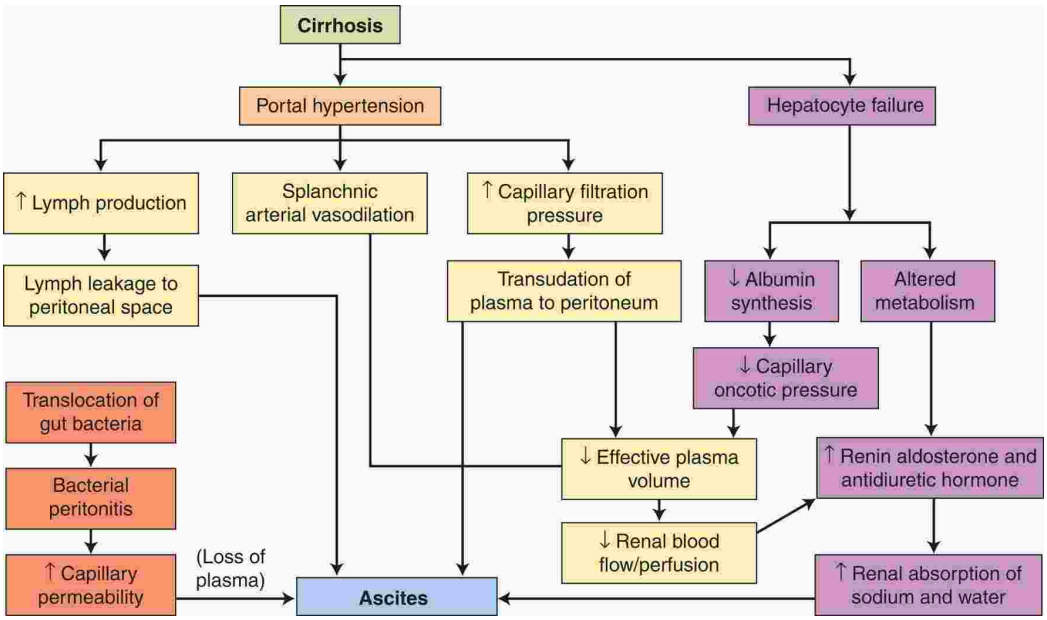

FIG. 41.15 Mechanisms of Ascites Caused by Cirrhosis.

A flow chart summarizes the mechanisms of ascites caused by cirrhosis. The diagram begins as follows. • Cirrhosis leads to portal hypertension and hepatocyte failure. • Portal hypertension leads to increased lymph production, splanchnic arterial vasodilation, and increased capillary filtration pressure. • Increased capillary filtration pressure leads to transudation of plasma to the peritoneum, decreasing effective plasm volume, and renal blood flow, or perfusion, causing ascites. • An increase in lymph production leads to lymph leakage to the peritoneal space causing ascites. • The translocation of gut bacteria leads to bacterial peritonitis, which increases capillary permeability, causing ascites. • Hepatocyte failure leads to a decrease in albumin

synthesis and altered metabolism. • Albumin synthesis leads to decreased oncotic capillary pressure causing decreased effective plasma volume and renal blood flow perfusion. •Altered metabolism leads to an increase in renin aldosterone and antidiuretic hormone and an increase in renal absorption of sodium and water, causing ascites.

Clinical Manifestations

The accumulation of ascitic fluid causes abdominal distention, increased abdominal girth, and weight gain (Fig. 41.16). Large volumes of fluid (10 to 20 L) displace the diaphragm and cause dyspnea by decreasing lung capacity. The respiratory rate increases, and the individual may need to assume a sitting position to relieve the dyspnea. Some peripheral edema is usually present. Dilutional hyponatremia may be noted because of excess fluid volume. Approximately 10% of individuals with ascites develop bacterial peritonitis, either spontaneously or because of paracentesis, which causes fever, chills, abdominal pain, decreased bowel sounds, and cloudy ascitic fluid.

FIG. 41.16 Massive Ascites in an Individual With Cirrhosis.
Distended abdomen, dilated upper abdominal veins, and inverted umbilicus are classic manifestations. (From Goldman L, Schafer AI. *Goldman's Cecil medicine*, 24th edition. Philadelphia: Saunders; 2012.)

Evaluation and Treatment

The diagnosis is usually based on clinical manifestations and identification of liver disease. Marked abdominal distention is associated with higher grades of ascites. The serum ascites albumin gradient (SAAG) from ascetic fluid analysis is the most specific diagnostic indicator for portal hypertension–related ascites. Ultrasonography, chest and abdominal x-rays, or CT scans are used to evaluate the cause and extent of the ascites and other complications of the disease. Serum electrolyte levels must be carefully monitored as the disease process puts an individual at risk

for hyponatremia and hypokalemia. Spontaneous bacterial peritonitis can occur with cirrhotic ascites, the neutrophil count will be elevated in ascetic fluid, and bacterial culture guides antibiotic therapy.

The goal of treatment is to relieve discomfort. If the restoration of liver function is possible (e.g., in ascites caused by viral hepatitis), the ascites diminishes spontaneously. Dietary salt restriction and potassium-sparing diuretics can reduce ascites. Vasopressin receptor-2 antagonists are effective for dilutional hyponatremia. Albumin may be given. Paracentesis is used to aspirate ascitic fluid for bacterial culture, biochemical analysis, and microscopic examination. Maintenance of caloric and protein intake is necessary to prevent malnutrition.

Palliative paracentesis in amounts of 1 or 2 L of ascitic fluid is completed to relieve respiratory distress. However, the removal of too much fluid too quickly relieves pressure on blood vessels and carries the risk of hypotension, shock, or death. Despite repeated paracentesis, ascitic fluid reaccumulates because of the persistent portal hypertension and reduced plasma albumin levels associated with irreversible disease. Peritonitis is treated with antibiotics. Other procedures include placement of a peritoneovenous shunt and TIPS. Individuals with ascites and portal hypertension have a poor prognosis, and liver transplantation is the best treatment option.[94]

Hepatic Encephalopathy

Hepatic encephalopathy (portal system encephalopathy) is a complex neurologic syndrome characterized by impaired behavioral, cognitive, and motor function. The syndrome may develop rapidly during acute fulminant hepatitis or slowly during the course of cirrhosis and the development of portal hypertension or after portosystemic bypass or shunting.

Pathophysiology

Hepatic encephalopathy results from a combination of biochemical alterations that affect neurotransmission and brain function. Liver

dysfunction and the development of collateral vessels that shunt blood around the liver to the systemic circulation permit toxins absorbed from the GI tract and normally removed by the liver, to accumulate and circulate freely to the brain. The accumulated toxins alter cerebral energy metabolism, interfere with neurotransmission, and cause edema. The most hazardous substances are end products of intestinal protein digestion, particularly ammonia, which cannot be converted to urea by the diseased liver. The digestion of blood from leaking or ruptured varices adds to the amount of ammonia present in systemic blood, as does the action of ammonia-forming bacteria in the colon. Ammonia that reaches the brain is metabolized to glutamine, with osmotic disturbances and alterations in cerebral blood flow that interfere with neurotransmitters and cause astrocyte edema or cytotoxic edema and oxidation. Disruption of the blood-brain barrier causes vasogenic edema and contributes to astrocytes swelling, brain edema, and intracranial hypertension. Excessive amounts of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter from intestinal flora, may contribute to reduced levels of consciousness. Infection, systemic inflammation, hemorrhage, and electrolyte imbalance (including zinc deficiency), constipation, and the use of sedatives and analgesics can precipitate hepatic encephalopathy in the presence of liver disease.[95]

Clinical Manifestations

Subtle changes in personality, memory loss, irritability, disinhibition, lethargy, and sleep disturbances are common initial manifestations of hepatic encephalopathy. Symptoms then can progress to confusion, disorientation to time and space, asterixis, slow speech, bradykinesia, stupor, convulsions, and coma, which are less frequent. Coma is usually a sign of liver failure and ultimately results in death. Variceal bleeding and ascites may develop concurrently. Symptoms may be episodic, recurrent, or persistent. Hepatic encephalopathy is often associated with bleeding varices and ascites.

Evaluation and Treatment

The diagnosis of hepatic encephalopathy is based on a history of liver disease, clinical manifestations, psychometric tests, and exclusion of other causes of brain dysfunction. Electroencephalography and blood chemistry tests provide supportive data. Tracking levels of serum ammonia can assist to assess treatment effectiveness and liver function, but the test is difficult to perform and may be influenced by hemolysis and severe jaundice.[96] Correction of fluid and electrolyte imbalances and withdrawal of depressant drugs metabolized by the liver are the first steps in the treatment of hepatic encephalopathy. Dietary protein is maintained to prevent malnutrition but at levels that reduce blood ammonia levels. Lactulose prevents ammonia absorption in the colon, and polyethylene glycol has also been used with success in reducing ammonia levels.[97] Neomycin eliminates ammonia-producing intestinal bacteria but can be nephrotoxic. Glutamase inhibitors reduce gut ammonia. Rifaximin (a nonabsorbable antibiotic) decreases intestinal production of ammonia and may be combined with lactulose or used alone for lactulose nonresponders. Extracorporeal liver support systems remove toxins from the blood and are an option for managing overt hepatic encephalopathy or as a bridge to liver transplantation.[96]

Jaundice

Jaundice, or **icterus**, is a yellow or greenish pigmentation of the skin caused by **hyperbilirubinemia** (plasma bilirubin concentrations greater than 2.5 to 3 mg/dL). Hyperbilirubinemia and jaundice can result from (1) extrahepatic (posthepatic) obstruction to bile flow, (2) intrahepatic obstruction, or (3) prehepatic excessive production of unconjugated bilirubin (i.e., excessive hemolysis of red blood cells) (Fig. 41.17). Jaundice in newborns is caused by impaired bilirubin uptake and conjugation (see Chapter 42).

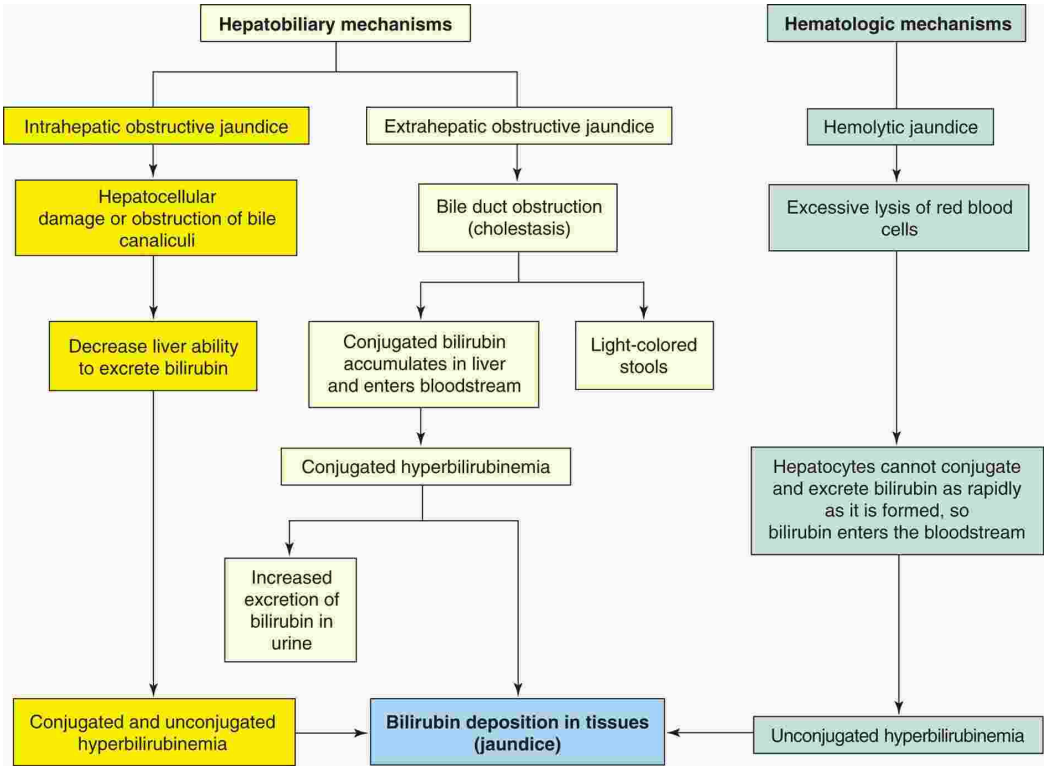

FIG. 41.17 Mechanisms of Jaundice.

A flow diagram summarizes the mechanism involved in the development of jaundice. The diagram begins as follows. • Hepatobiliary mechanisms involved intrahepatic obstructive jaundice and extrahepatic obstructive jaundice. • Intrahepatic obstructive jaundice leads to hepatocellular damage or obstruction of bile canaliculi. • Hepatocellular damage or obstruction of bile canaliculi leads to decrease in the liver's ability to excrete bilirubin. • Decrease liver ability leads to conjugated unconjugated hyperbilirubinemia causing bilirubin deposition in tissues or jaundice. • Extrahepatic obstructive jaundice leads to bile duct

obstruction causes conjugated bilirubin accumulation in the liver and enters the bloodstream and light-colored stools. • Conjugated bilirubin causes conjugated hyperbilirubinemia leading to an increase in excretion of bilirubin in urine. • Hematologic mechanisms cause hemolytic jaundice, leading to excessive lysis of red blood cells. • Excessive lysis of red blood cells leads to hepatocytes to not conjugate and excrete bilirubin as rapidly as it is formed, so bilirubin enters the bloodstream leading to unconjugated hyperbilirubinemia causing bilirubin deposition in tissues.

Pathophysiology

Obstructive jaundice can result from extrahepatic or intrahepatic obstruction.[98] *Extrahepatic obstructive jaundice* develops if the common bile duct is occluded. Occlusion may be from a gallstone, tumor, or inflammation. If occluded, bilirubin conjugated by the hepatocytes cannot flow through the obstructed common bile duct into the duodenum. Therefore bilirubin accumulates in the liver and enters the bloodstream, causing hyperbilirubinemia and jaundice. *Intrahepatic (hepatocellular) obstructive jaundice* involves disturbances in hepatocyte function and obstruction of bile canaliculi. The uptake, conjugation, or excretion of bilirubin can be affected with elevated levels of both conjugated and unconjugated bilirubin. Obstruction of bile canaliculi diminishes flow of conjugated bilirubin into the common bile duct. In mild cases, some of the bile canaliculi open. Consequently, the amount of bilirubin in the intestinal tract may be only slightly decreased.

Excessive hemolysis (destruction) of red blood cells can cause **hemolytic jaundice***(prehepatic* or *nonobstructive jaundice)*. Increased unconjugated bilirubin is formed through metabolism of the heme component of destroyed red blood cells and exceeds the conjugation ability of the liver, causing blood levels of unconjugated bilirubin to rise. Decreased bilirubin uptake or conjugation also causes unconjugated hyperbilirubinemia, as occurs with reaction to some drugs (e.g., rifampin), and in genetic disorders, such as Gilbert syndrome. Unconjugated bilirubin is not water soluble, so it will not be excreted in the urine. The causes of jaundice are summarized in Table 41.8.

Table 41.8

Three Common Types of Jaundice

Type	Mechanism	Causes
Hemolytic jaundice (predominantly unconjugated bilirubin)	Excessive destruction of erythrocytes	Membrane defect of erythrocytes Hemolytic anemias
		Immune reaction
		Severe infection
		Toxic substances in the circulation (e.g., snake venom)
		Transfusion of incompatible blood
Obstructive (cholestatic) jaundice (predominantly conjugated bilirubin)	Obstruction to passage of conjugated bilirubin from liver to intestine	Obstruction of bile duct by gallstones or tumor (extrahepatic obstructive jaundice)
		Obstruction of bile flow through the liver (intrahepatic

Type	Mechanism	Causes
		obstructive jaundice)
		Drugs
Hepatocellular jaundice (both conjugated and unconjugated bilirubin)	Failure of liver cells (hepatocytes) to conjugate bilirubin and of bilirubin to pass from liver to intestine	Genetic defect of hepatocyte (decreased enzymes), such as occurs in premature infants (see Chapter 42)
		Hepatitis or biliary cirrhosis

Type	Mechanism	Causes
Hemolytic jaundice (predominantly unconjugated bilirubin)	Excessive destruction of erythrocytes	Membrane defect of erythrocytes Hemolytic anemias
		Immune reaction
		Severe infection
		Toxic substances in the circulation (e.g., snake venom)
		Transfusion of incompatible blood
Obstructive (cholestatic) jaundice (predominantly conjugated bilirubin)	Obstruction to passage of conjugated bilirubin from liver to intestine	Obstruction of bile duct by gallstones or tumor (extrahepatic obstructive jaundice)
		Obstruction of bile flow through the liver (intrahepatic obstructive jaundice)
		Drugs
Hepatocellular jaundice (both conjugated and unconjugated bilirubin)	Failure of liver cells (hepatocytes) to conjugate bilirubin and of bilirubin to pass from liver to intestine	Genetic defect of hepatocyte (decreased enzymes), such as occurs in premature infants (see Chapter 42)
		Hepatitis or biliary cirrhosis

Clinical Manifestations

Conjugated bilirubin is water soluble and appears in the urine. The urine may darken several days before the onset of jaundice. The complete obstruction of bile flow from the liver to the duodenum

causes light-colored stools. With partial obstruction, the stools are normal in color and bilirubin is present in the urine.

Fever, chills, and pain often accompany jaundice resulting from viral or bacterial inflammation of the liver. Yellow discoloration may first occur in the sclera of the eye and then progress to the skin as bilirubin attaches to elastic fibers. Pruritus (itching) often accompanies jaundice because bilirubin accumulates in the skin, irritating itch receptors.

Evaluation and Treatment

Laboratory evaluation of serum establishes whether elevated plasma bilirubin is conjugated or unconjugated, or both. The history and physical examination identify underlying disorders, such as cirrhosis, exposure to hepatitis virus, gallbladder or pancreatic disease, or hematologic disorders. The treatment for jaundice consists of correcting the cause.

Hepatorenal Syndrome

HRS is functional renal failure that develops as a complication of advanced liver disease. The renal failure is not caused by primary renal disease or other extrinsic factors but rather by portal hypertension, cardiac impairment, and other circulatory alterations associated with advanced liver disease, such as cirrhosis or fulminant hepatitis with portal hypertension and decreased systemic vascular resistance. HRS is characterized by reduced renal blood flow and glomerular filtration rate.

Pathophysiology

Type 1 HRS–acute kidney injury occurs in less than 2 weeks and accompanies a sudden decrease in blood volume secondary to massive GI or variceal bleeding and hypotension caused by bleeding and peripheral vasodilation associated with failing liver function. Proinflammatory cytokines related to translocation of bacterial to ascetic fluid can promote systemic hypotension and reduced renal blood flow. Hypotension also can be caused by the excessive use of

diuretics to treat ascites or decreased cardiac output. The decrease in blood volume and hypotension result in decreased renal perfusion, decreased glomerular filtration, and oliguria (see Chapter 38). The serum creatinine increases to a concentration of greater than 0.3 mg/dL within 48 hours or a urine output less than 0.5 mL/kg body weight for greater than 6 hours.

Type 2 HRS–nonacute kidney injury (HRS-NAKI) develops slowly and is related to ascites resistant to diuretics. Ineffective circulating blood volume causes decreased glomerular filtration and oliguria. Intrarenal vasoconstriction may result from the selective effects of vasoactive substances that accumulate in the blood because of liver failure or as a compensatory response to portal hypertension and the pooling of blood in the splanchnic circulation. Vasoconstriction also may be a compensatory response to portal hypotension and vasodilation in the splanchnic circulation. There are two categories of NAKI. HRS–acute kidney disease (HRS-AKD) is diagnosed when the estimated glomerular filtration rate is less than 60 mL/min/1.73 m^2 for less than 3 months and the percent increase in serum creatinine is less than 50% compared with a baseline value obtained within the past 3 months. The kidney usually maintains a normal structure with this condition; HRS–chronic kidney disease (HRS-CKD) is diagnosed when the estimated glomerular filtration rate is less than 60 mL/min/1.73 m^2 for more than 3 months. The kidney usually maintains a normal structure, and there is absence of other structural causes of kidney disease.[99]

Clinical Manifestations

The onset of hepatorenal manifestations may be acute or gradual. Oliguria and complications of advanced liver disease, including jaundice, ascites, peripheral edema, hypotension, and GI bleeding, are usually present. Systolic blood pressure is usually less than 100 mm Hg. Nonspecific symptoms of HRS include anorexia, weakness, and fatigue.

Evaluation and Treatment

Diagnosis of HRS is made by excluding other causes of renal failure. Despite decreased glomerular filtration, serum potassium levels do not become dangerously elevated until the terminal stages of the HRS. Serial changes in serum creatinine provide an index for estimation of GFR, and values increase to 2.5 mg/dL or higher. Guidelines are available for determining AKI or CKD.[100] The BUN level increases, and metabolic acidosis develops. Urine osmolality increases, but urine sodium concentrations are less than normal. Urine specific gravity is greater than 1.015.

The prognosis is usually poor and is related to a failing liver, requiring liver transplantation. Secondary problems, including fluid and electrolyte disorders, bleeding, infections, and encephalopathy, are treated. Vasoconstrictors and albumin are often used as first line treatment of HRS. Liver transplant reverses HRS symptoms in most individuals and may be combined with kidney transplant.[101]

Disorders of the Liver

Acute Liver Failure

Acute liver failure is a rare clinical syndrome resulting in severe impairment or necrosis of liver cells without preexisting liver disease or cirrhosis. Acetaminophen overdose is a leading cause of acute liver failure in the United States.[102] N-acetyl cysteine is an available treatment for detoxification and should be given as soon as possible, preferably within 16 hours after the acetaminophen was taken. Acute liver failure also can occur with concurrent liver disease (acute on chronic liver failure), including complication of viral hepatitis, particularly hepatitis B virus (HBV) infection; compounded by infection with the delta virus; as well as metabolic liver disorders (Wilson disease and α_1-antitrypsin deficiency; see Chapter 42). Edematous hepatocytes and patchy areas of necrosis and inflammatory cell infiltrates disrupt liver tissue. The death of hepatocytes may also be caused by viral or toxic injury or immunologic and inflammatory damage.

Acute liver failure usually develops 6 to 8 weeks after the initial symptoms of viral hepatitis or a metabolic liver disorder, or within 5 days to 8 weeks of acetaminophen overdose. Anorexia, vomiting, abdominal pain, and progressive jaundice are initial signs, followed by ascites, GI bleeding and hepatic encephalopathy as described in previous sections. Liver function tests reflect liver injury and show elevations in the levels of both direct and indirect serum bilirubin, serum transaminases, and blood ammonia. The prothrombin time is prolonged. Renal failure and pulmonary dysfunction can occur. Treatment of acute liver failure requires rapid evaluation and critical care. The hepatic necrosis is irreversible, and there can be significant mortality. Liver transplantation may be lifesaving. Artificial liver support systems can provide a bridge to transplantation or to allow the liver to recover.[103]

Autoimmune Hepatitis

Autoimmune hepatitis is a rare chronic, progressive, autoimmune inflammatory liver disease that affects genetically susceptible individuals, usually female adults, and children. The cause is unknown, but certain infections and drugs are thought to trigger the autoimmune response. Autoreactive T cells trigger secretion of proinflammatory cytotoxic cytokines. Serologically, there are two types: type 1 with positivity for antinuclear and/or anti-smooth muscle antibody, and type 2 with anti-liver kidney microsomal type 1 antibody or anti-liver cytosol type 1 antibody. There is hypergammaglobulinemia and an elevation in aspartate and alanine aminotransferase. Biopsy confirms the diagnosis and shows lymphocytic infiltration with interface (parenchymal–connective tissue interface) hepatitis. The individual may be asymptomatic or present with jaundice, fatigue, loss of appetite, amenorrhea, or acute liver failure. Most individuals respond to immunosuppressive drug therapy (e.g., corticosteroids or in combination with azathioprine) with remission within 24 months. Relapses are common with treatment withdrawal. Approximately 10% of cases require liver transplant.[104]

Cirrhosis

Cirrhosis is an irreversible inflammatory, fibrotic liver disease. The prevalence of liver disease in the United States is approximately 4.5 million, with a mortality rate of 44,358 deaths yearly.[105] Hepatitis C, alcohol-related liver disease, nonalcoholic fatty liver disease (NAFLD), and hepatitis B are the most common causes of cirrhosis[106]; however, many disorders can cause cirrhosis (Box 41.3). Cirrhosis involves the replacement of normal healthy liver tissue with scar tissue.[106] The process of cellular injury depends on the cause of cirrhosis; however, not all pathologic mechanisms are clearly understood. Structural changes result from injury (e.g., viruses or toxicity from alcohol) and fibrosis, which is a consequence of infiltration of leukocytes, and release of inflammatory mediators with activation of stellate cells which transdifferentiate into fibrogenic myofibroblasts and promote fibrotic processes. Chaotic fibrosis alters or obstructs biliary channels and blood flow, producing jaundice and portal hypertension. New vascular channels form shunts, and blood from the portal vein bypasses the liver, contributing to portal hypertension, metabolic alterations, and toxin accumulation. The process of regeneration is disrupted by hypoxia, necrosis, atrophy, and, ultimately, liver failure. The formation of fibrous bands and regenerating nodules distorts the architecture of the liver parenchyma and gives the liver a cobbly appearance (Fig. 41.18). The liver may be larger or smaller than normal and is usually firm or hard when palpated.[107]

Box 41.3

Causes of Cirrhosis

Hepatitis viruses—B and C (common)
Excessive alcohol intake (common)
Idiopathic (common)
Nonalcoholic fatty liver disease (NAFLD), also known as *nonalcoholic steatohepatitis (NASH)*
Autoimmune disorders
    Autoimmune hepatitis
    Primary biliary cirrhosis
    Primary sclerosing cholangitis
Hereditary metabolic disorder
    α-Antitrypsin deficiency
    Hemochromatosis
    Wilson disease
    Glycogen or lipid storage diseases
Prolonged exposure to drugs or toxins (e.g., carbon tetrachloride, cleaning and industrial solvents, copper salts)
Hepatic venous outflow obstruction
    Budd-Chiari syndrome (blood clotting of the hepatic vein)
    Right-sided heart failure

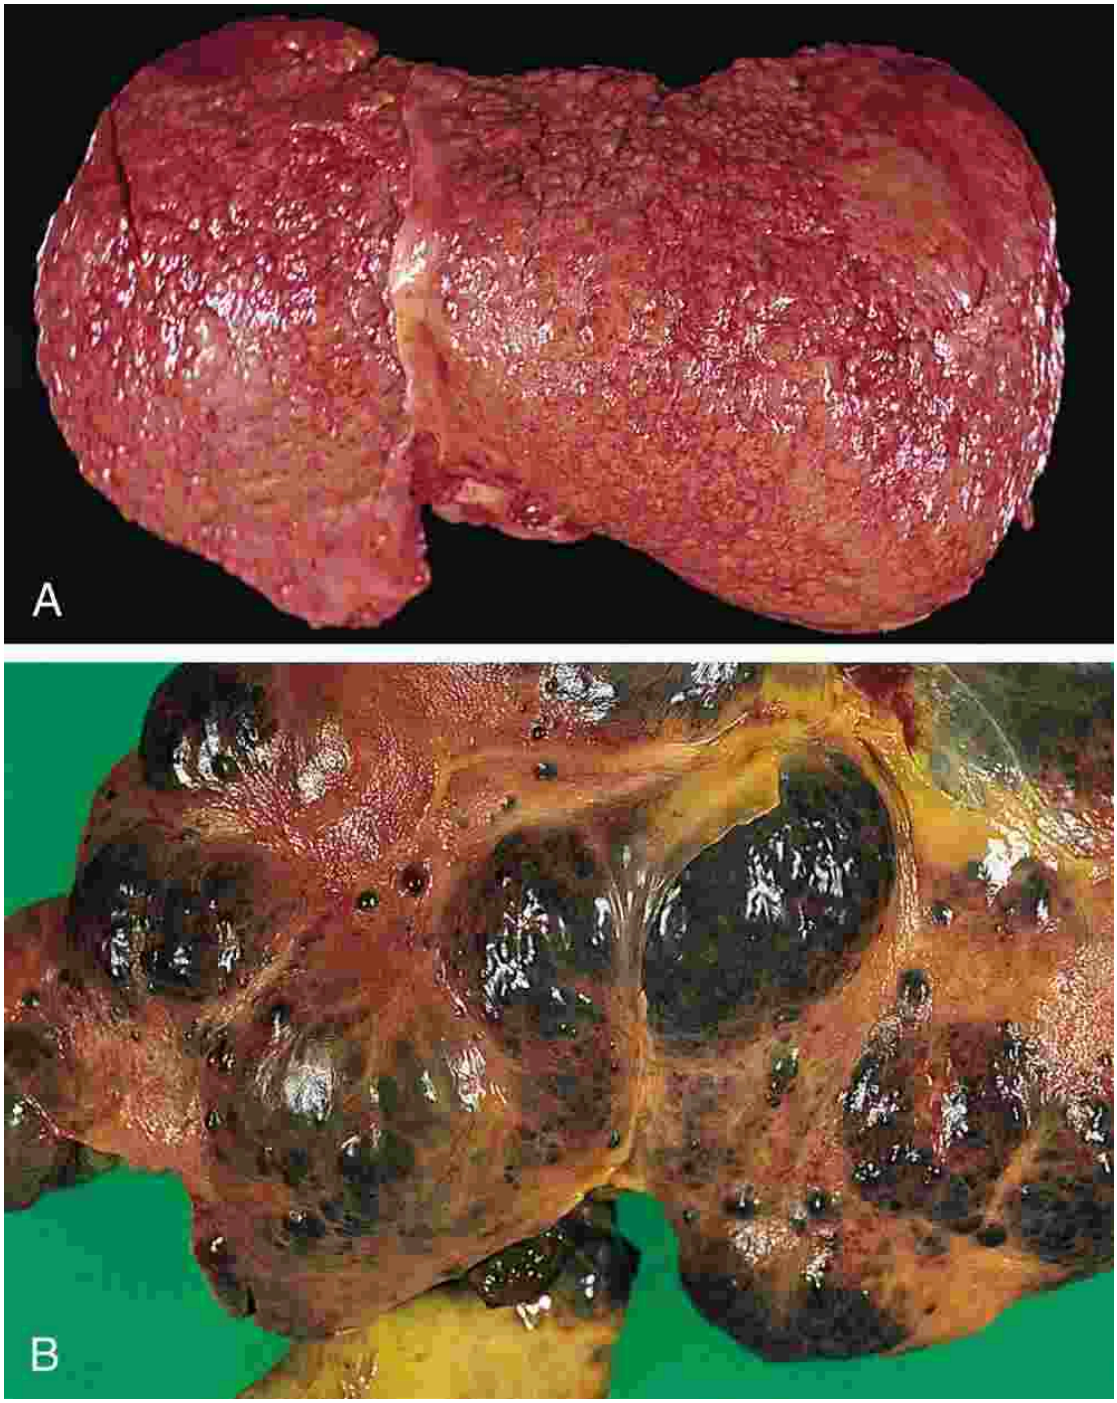

FIG. 41.18 Cirrhosis.
(A) Micronodular cirrhosis. The nodular appearance develops from regeneration of hepatocytes projecting through fibrous bands of tissue. **(B)** Macronodular cirrhosis.
(From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Cirrhosis develops slowly over a period of years. Its severity and rate of progression depend on the cause. If toxins, such as alcohol metabolites, are involved, the rate of cell death and the severity of inflammation depend on the amount of toxin present. Removal of the toxin slows the progression of liver damage and enhances the process of regeneration. Complications of cirrhosis include jaundice, portal hypertension, ascites, hepatic encephalopathy, varices with GI bleeding, HRS, HPS, and

portopulmonary syndrome, which have been previously described.[108] The pathophysiology of cirrhosis causes immune suppression and increases the risk for infection.[109]

Alcoholic Liver Disease

Alcoholic liver disease is related to the toxic effects of alcohol, the formation of acetaldehyde (see Chapter 2), and coexisting liver disease. In 2019, there were 24,110 deaths in the United States related to alcoholic liver disease.[110] The spectrum of alcoholic liver disease includes alcoholic fatty liver, alcoholic steatohepatitis, and alcoholic cirrhosis with progression to hepatocellular carcinoma (HCC) in some cases. The progression of liver injury is related to the amount and duration of alcohol use, and the influence of associated diseases (e.g., obesity, metabolic syndrome, and viral hepatitis). Although alcoholic cirrhosis is the most prevalent of the various types of cirrhosis, the occurrence of cirrhosis among persons with alcoholism is relatively low (approximately 25%).

Malnutrition contributes to the risk of complications and adverse outcomes associated with alcohol-related liver disease. Chronic alcohol abuse results in a catabolic state with upregulation of inflammatory mediators that suppress appetite and cause intestinal dysfunction with malabsorption of nutrients and pancreatic insufficiency. The chronic inflammatory state and altered metabolic pathways associated with alcoholic liver injury and anorexia lead to a hypermetabolic state, protein energy, caloric, and micronutrient malnutrition. The malnutrition and loss of muscle mass accelerate liver decompensation and disease progression.[111]

Pathophysiology

Alcoholic fatty liver disease (steatosis) is the mildest form of alcoholic liver disease, and there may be no symptoms. It can be caused by relatively small amounts of alcohol and is typically reversible with the cessation of drinking. The fat deposition (deposition of triglycerides) within the liver is caused primarily by increased lipogenesis, cholesterol synthesis, and decreased fatty acid oxidation by hepatocytes that occurs with increased alcohol metabolism.[112] Lipids mobilized from adipose tissue or dietary fat intake may contribute to fat accumulation.

Alcoholic steatohepatitis (alcoholic hepatitis) is a precursor of cirrhosis characterized by increased hepatic fat storage, inflammation, and degeneration and necrosis of hepatocytes with infiltration of neutrophils and lymphocytes. The inflammation and necrosis caused by alcoholic steatohepatitis stimulate the irreversible fibrosis characteristic of the cirrhotic stage of disease.

Alcoholic cirrhosis is caused by the toxic effects of alcohol metabolism in the liver, immunologic alterations, inflammatory cytokines, oxidative stress from lipid peroxidation, malnutrition, and an ongoing cycle of liver injury and regeneration. Alcohol is transformed to acetaldehyde; excessive amounts are toxic and significantly alter hepatocyte function and activate hepatic stellate cells, a primary cell involved in liver fibrosis. Enzyme and protein synthesis may be depressed or altered, and hormone and ammonia degradation is diminished. Acetaldehyde inhibits protein synthesis and export of proteins from the liver, alters metabolism of vitamins and minerals, and induces malnutrition. Kupffer cell (macrophage) activation attracts neutrophils promoting inflammation, endotoxins accumulate from translocation of gut bacteria, and cell-mediated immunity is suppressed. Cellular damage initiates an inflammatory response that, along with necrosis, results in activation of hepatic stellate cells and excessive collagen formation. Fibrosis and scarring interspersed with regenerating nodules alter the structure of the liver and obstruct biliary and vascular channels. Eventually hepatocytes lose their ability to regenerate with progression to liver failure.

Clinical Manifestations

Fatty infiltration causes no specific symptoms or abnormal liver function test results. The liver is usually enlarged and may be found during a routine examination. The individual has a history of continuous alcohol intake during the previous weeks or months.

The clinical manifestations of alcoholic steatohepatitis can be mild or severe. Nonspecific symptoms include fatigue, weight loss, and anorexia Manifestations of acute illness include nausea, anorexia, fever, abdominal pain, and jaundice. Cirrhosis is a multiple-system disease and causes hepatomegaly, splenomegaly, ascites, portal hypertension, GI hemorrhage, hepatic encephalopathy, and esophageal

varices. Anemia results from blood loss, malnutrition, and hypersplenism. Pulmonary syndrome and HRS are usually late complications (Fig. 41.19). Toxic effects of alcohol also can cause testicular atrophy, reduced libido, azoospermia, and decreased testosterone levels in men. Premenopausal women with cirrhosis experience anovulation or irregular ovulation related to alterations in hormone metabolism. The presence of numerous and severe manifestations increases the risk of death. Cirrhosis increases the risk of HCC because acetaldehyde has mutagenic effects on deoxyribonucleic acid (DNA).[113]

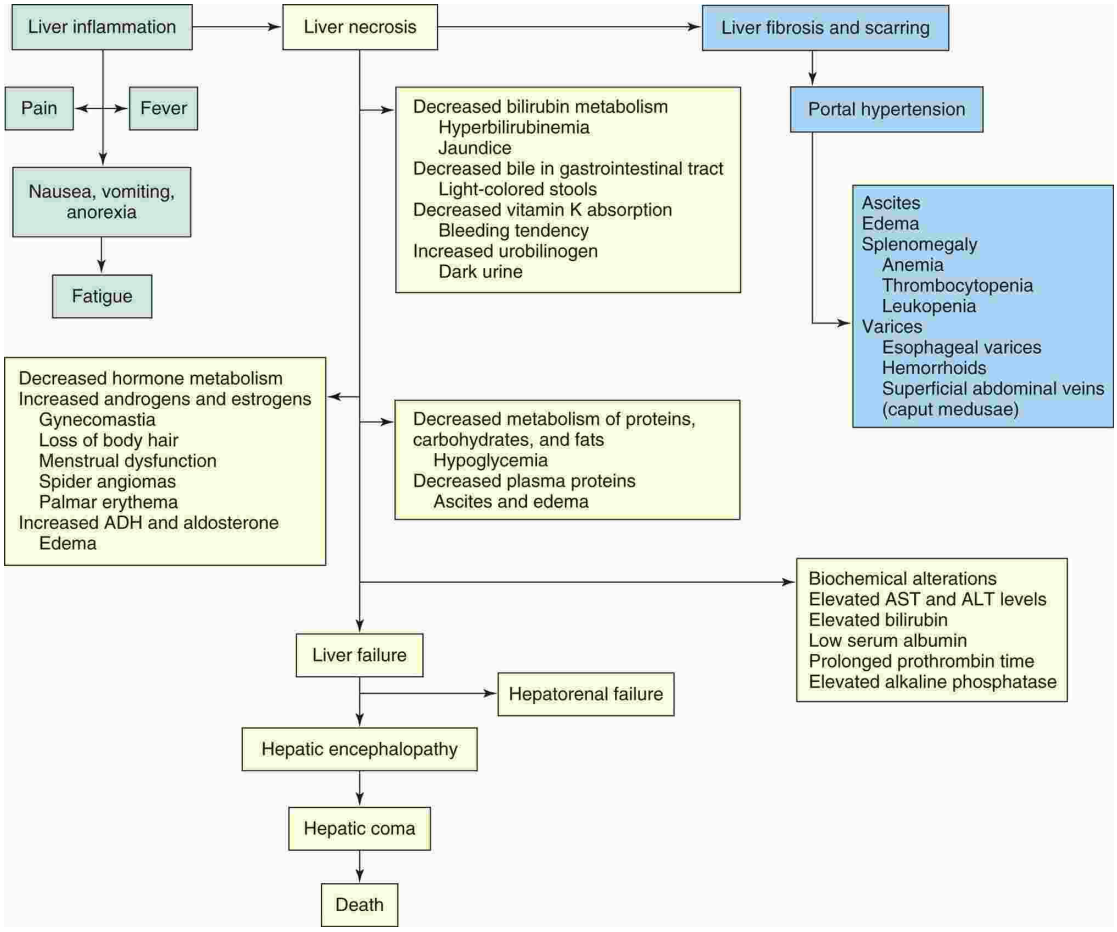

FIG. 41.19 Clinical Manifestations of Cirrhosis.
ADH, Antidiuretic hormone; *ALT*, alanine transaminase; *AST*, aspartate transaminase.

A flow chart summarizes the clinical manifestations of cirrhosis. The diagram begins as follows. • Liver inflammation causes pain, fever, nausea, vomiting, anorexia, and fatigue. • Liver inflammation leads to liver necrosis which causes liver fibrosis and scarring, leading to portal hypertension, which causes ascites, edema, splenomegaly, anemia, thrombocytopenia, leukopenia, varices, esophageal varices, hemorrhoids, superficial abdominal veins, caput-medusae. • Liver necrosis leads to decreased bilirubin metabolism, hyperbilirubinemia, jaundice, decreased bile in the gastrointestinal tract, light-colored stools, decreased vitamin K absorption, bleeding tendency, increased urobilinogen, dark urine, decreased metabolism of proteins, carbohydrates, fats, hypoglycemia, decreased plasma proteins, ascites, and edema, decreased hormone metabolism, increased androgens, and estrogens, gynecomastia, loss of body hair, menstrual dysfunction, spider angiomas, palmar erythema, increased

A D H and aldosterone, edema. • Liver necrosis leads to liver failure, hepatorenal failure, hepatic encephalopathy, and hepatic coma, causing death.

Evaluation and Treatment

The diagnosis of alcoholic steatohepatitis or cirrhosis is based on the individual's history of alcohol use and clinical manifestations.[114] The results of liver function tests are abnormal, and serologic studies show elevated levels of serum enzymes (i.e., alanine aminotransferase, aspartate aminotransferase, and γ-glutamyltransferase) and bilirubin, decreased levels of serum albumin, and a prolonged prothrombin time that is not easily corrected with vitamin K therapy. Liver biopsy can confirm the diagnosis of cirrhosis, but biopsy is not necessary if clinical manifestations of cirrhosis are evident.

There is no specific treatment for alcoholic steatohepatitis or cirrhosis. Rest, vitamin supplements, a nutritious diet, corticosteroids, antioxidants, drugs that slow fibrosis, and management of complications (e.g., ascites, GI bleeding, and encephalopathy) slow disease progression. Cessation of alcohol consumption slows the progression of liver damage, improves clinical symptoms, and prolongs life. Although the liver damage is irreversible, measures that halt the inflammation and destruction of liver cells prolong life, and many new drugs are being evaluated.[115] Liver transplantation is the treatment of end-stage liver disease.

Nonalcoholic Liver Disease and Nonalcoholic Steatohepatitis

Nonalcoholic fatty liver disease (NAFLD) is the infiltration of hepatocytes with fat, primarily in the form of triglycerides, that occurs in the absence of alcohol intake and inflammation. It is associated with obesity (including obese children), insulin resistance, high levels of cholesterol and triglycerides that exceed metabolic capacity, metabolic syndrome, and type 2 diabetes mellitus. NAFLD is the most common chronic liver disease in the United States. Some individuals with NAFLD will develop **nonalcoholic steatohepatitis (NASH)**, with hepatocellular injury, inflammation, and with or without fibrosis. NASH can be difficult to distinguish from alcohol-induced liver fibrosis. There are several noninvasive biomarkers to evaluate the progression of fibrosis in NASH.[116] In some cases biopsy may be required. Alcohol consumption may also promote disease progression in NAFLD.[117] Exercise and coffee consumption are thought to be protective environmental factors.

NAFLD is usually asymptomatic and may remain undetected for years. Individuals with type 2 diabetes mellitus are at high risk for NASH, and assessment for NAFLD should be part of their care with consideration of bariatric surgery.[118] The most severe forms of NASH progress to cirrhosis and end-stage liver disease. There can be progression to HCC. The most common cause of death among individuals with NAFLD is cardiovascular disease. Treatment is individualized and includes the use of behavioral modification, dietary counseling, and regular exercise. Pharmacotherapy with insulin sensitizers, vitamin E, and lipid-lowering drugs may be considered. Pioglitazone should be considered for those with NASH, especially if fibrosis is present. Liver transplant is the only option for liver failure.[119]

Primary Biliary Cholangitis

Primary biliary cholangitis (previously called primary biliary cirrhosis) is a rare, chronic, slowly progressive, autoimmune, cholestatic liver disease that slowly destroys the bile ducts in the liver. The disease begins in the bile canaliculi and bile ducts rather than in the hepatocytes as with other liver diseases. It is caused by autoimmune T lymphocyte and highly specific antimitochondrial antibody destruction of the small intrahepatic bile ducts and primarily affects middle-aged women. Primary biliary cholangitis often accompanies other autoimmune diseases. Pathogenesis includes inflammation, destruction, fibrosis, and obstruction of the intrahepatic bile ducts. Primary biliary cholangitis can be detected by biochemical evidence of cholestatic liver disease. Test findings include the presence of antinuclear antibodies, anticentromere antibodies, and the GP210 antinuclear antibody, as well as elevated alkaline phosphatase levels for at least 6 months. Ultrasound imaging of the liver or liver

biopsy assists with diagnosis. Manifestations progress insidiously from pruritus, hyperbilirubinemia, jaundice, and light or clay-colored stools to cirrhosis, portal hypertension, and encephalopathy. Life expectancy is 5 to 10 years after the onset of symptoms if the condition is not treated. Treatment with ursodeoxycholic acid (UDCA) has anticholestatic effects and slows disease progression. Obeticholic acid indirectly reduces BA synthesis and may be used in combination with or as second line therapy. It should be used with caution with severe liver disease. Other drugs used in combination with UDCA include bezafibrate (can also reduce pruritus) and budesonide.[120] Pruritus may be relieved by cholestyramine, which binds bile salts in the intestine. Liver transplantation is highly effective. Because of increased risk for cholangiocellular and gallbladder carcinoma, yearly screening is recommended.[121]

Secondary Biliary Cirrhosis

Secondary biliary cirrhosis develops when there is prolonged partial or complete obstruction of the common bile duct or its branches. The obstruction may be caused by gallstones, tumors, fibrotic strictures, or chronic pancreatitis. Biliary atresia and cystic fibrosis cause secondary biliary cirrhosis in children.

Chronic obstruction to extrahepatic bile flow increases pressure in the hepatic bile ducts and results in the accumulation of bile in the centrilobular spaces. Necrotic areas develop and are followed by proliferation and inflammation of the portal ducts that result in edema and fibrosis. Pools of bile form when the portal ducts rupture into surrounding necrotic areas. Injury is accompanied by regeneration of hepatic cells with the development of finely nodular cirrhosis.

Clinical manifestations are similar to those of primary biliary cholangitis, with jaundice and pruritus the most distressing symptoms. Right upper quadrant pain is common, and a low-grade fever may be present from bile duct inflammation (cholangitis).

Cholangiography provides the most definitive diagnosis. Laboratory tests usually show elevated conjugated bilirubin and alkaline phosphatase levels. Aminotransferase level increases if there is an accompanying cholangitis. Surgery or endoscopy relieves obstruction, prolongs survival, and diminishes or resolves symptoms. Continued obstruction leads to advanced cirrhosis and liver failure.

Viral Hepatitis

Viral hepatitis is a relatively common systemic disease that primarily affects the liver. Different strains of viruses cause different types of hepatitis. Since a widespread outbreak of hepatitis A virus (HAV) in the United States in 2016, 44,217 cases have been reported as of April 29, 2022.[122] In 2019, the estimated incidence in the United States was 3192 new cases of acute HBV and an estimated 20,700 cases after adjusting for under-ascertainment and under-reporting; 4136 new cases of hepatitis C virus (HCV) and an estimated 57,500 cases after adjusting for under-ascertainment and under-reporting.[123] Hepatitis A formerly was known as infectious hepatitis and hepatitis B as serum hepatitis. Characteristics of the different types of viruses that cause hepatitis are presented in Table 41.9. Viral hepatitis in children is presented in Chapter 42.

Table 41.9

Characteristics of Viral Hepatitis

Characteristic	Hepatitis A	Hepatitis B	Hepatitis D	Hepatitis C
Size of virus	27-nm RNA virus	47-nm DNA virus	36-nm RNA virus, defective virus with HBsAg coat	30- to 60-nm RNA virus
Incubation phase	30 days	60–180 days	30–180 days; dependent on HBV for multiplication	35–72 days
Route of transmission	Fecal-oral, parenteral, sexual	Parenteral, sexual	Parenteral, fecal-oral, sexual	Parenteral
Onset	Acute with fever	Insidious	Insidious	Insidious
Carrier state	Negative	Positive	Positive	Positive
Severity	Mild	Severe; may be prolonged or chronic	Severe	Mild to severe
Chronic hepatitis	No	Yes	Yes	Yes
Age-group affected	Children and young adults	Any	Any	Any
Prophylaxis	Hygiene, immune serum globulin, HAV vaccine	Hygiene, HBV vaccine	Hygiene, HBV vaccine	Hygiene, screening blood, interferor α or combined with ribavirin; treatment also related to HCV genotype ± cirrhosi
Treatment	None or symptomatic	Interferon-α and nucleoside/nucleotide analogues	Interferon-α and nucleoside/nucleotide analogues	Direct antiviral agents

Characteristic	Hepatitis A	Hepatitis B	Hepatitis D	Hepatitis C	Hepatitis E
Size of virus	27-nm RNA virus	47-nm DNA virus	36-nm RNA virus, defective virus with HBsAg coat	30- to 60-nm RNA virus	32-nm RNA virus
Incubation phase	30 days	60–180 days	30–180 days; dependent on HBV for multiplication	35–72 days	15–60 days
Route of transmission	Fecal-oral, parenteral, sexual	Parenteral, sexual	Parenteral, fecal-oral, sexual	Parenteral	Fecal-oral
Onset	Acute with fever	Insidious	Insidious	Insidious	Acute
Carrier state	Negative	Positive	Positive	Positive	Negative
Severity	Mild	Severe; may be prolonged or chronic	Severe	Mild to severe	Severe in pregnant women
Chronic hepatitis	No	Yes	Yes	Yes	No
Age-group affected	Children and young adults	Any	Any	Any	Children and young adults
Prophylaxis	Hygiene, immune serum globulin, HAV vaccine	Hygiene, HBV vaccine	Hygiene, HBV vaccine	Hygiene, screening blood, interferon-α or combined with ribavirin; treatment also related to HCV genotype ± cirrhosis	Hygiene, safe water and meat
Treatment	None or symptomatic	Interferon-α and nucleoside/nucleotide analogues	Interferon-α and nucleoside/nucleotide analogues	Direct antiviral agents	Ribavirin and interferon-α for severe infection

DNA, Deoxyribonucleic acid; *HAV*, hepatitis A virus; *HBsAg*, hepatitis B surface antigen; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *RNA*, ribonucleic acid.

Pathophysiology

Hepatitis means inflammation of the liver. The five main types of viral hepatitis (A, B, C, D, and E) can cause acute, icteric illness. HBV and HCV are the most common causes. HDV occurs as a coinfection with HBV and depends on the viral coat of HB surface antigen (HBsAg) molecules on HBV for its replication in pregnant women. HEV infection can be a serious disease. The pathologic lesions of hepatitis include hepatic cell necrosis, scarring (with chronic disease), and Kupffer cell hyperplasia. In addition, infiltration by mononuclear phagocytes occurs with varying severity. Cellular injury is promoted by cell-mediated immune mechanisms, release of inflammatory mediators, and persistent inflammation.[124,125] Regeneration of hepatic cells begins within 48 hours of injury. The inflammatory process can damage hepatocytes and obstruct bile canaliculi, leading to cholestasis and obstructive jaundice. In milder cases, the liver parenchyma is not damaged. Damage tends to be most severe in cases of HBV and HCV and can progress to chronic disease.

Acute fulminating hepatitis can cause acute liver failure and severe hepatic encephalopathy, which is manifested as confusion, stupor, coma, and coagulopathy. Coinfection with HBV, HCV, HDV, and the human immunodeficiency virus (HIV) is common because they share the same route of transmission. Progression of liver disease is more rapid in these cases.

Clinical Manifestations

The clinical manifestations of the various types of hepatitis are very similar, and onset of symptoms varies with the duration of the incubation phase. The spectrum of manifestations ranges from absence of symptoms to fulminating hepatitis, with rapid onset of liver failure and coma. Acute viral hepatitis causes abnormal liver function test results. The serum aminotransferase values, aspartate transaminase (AST) and alanine transaminase (ALT), are elevated but not consistent with the extent of cellular damage. The clinical course of hepatitis usually consists of three phases, preceded by an **incubation phase**. The incubation phase and manifestations vary depending on the virus (see Table 41.9). The other three phases are:

1. **Prodromal (preicteric) phase** begins approximately 2 weeks after exposure and ends with the appearance of jaundice; marked by fatigue, anorexia, malaise, nausea, vomiting, headache, hyperalgia, cough, and low-grade fever; the infection is highly transmissible during this phase.
2. **Icteric phase** begins 1 to 2 weeks after the prodromal phase and lasts 2 to 6 weeks; jaundice, dark urine, and clay-colored stools are common; the liver is enlarged, smooth, and tender, and percussion or palpation of the liver causes pain; GI and respiratory symptoms subside, but fatigue and abdominal pain may persist or become more severe. This is the actual phase of illness. Individuals who develop chronic HBV, HDV, or HCV infection do not become jaundiced and may not be diagnosed.
3. **Recovery phase** begins with resolution of jaundice, approximately 6 to 8 weeks after exposure; symptoms diminish, but the liver remains enlarged and tender; liver function returns to normal 2 to 12 weeks after the onset of jaundice.

Chronic active hepatitis is the persistence of clinical manifestations and liver inflammation after the acute stages of HBV, HBV/HDV coinfection, and HCV infection. Liver function tests remain abnormal for longer than 6 months, and the HBsAg persists. Chronic, active HBV or HCV infection is a predisposition to cirrhosis and primary HCC. Chronic active hepatitis constitutes a carrier state, and HBV and HCV can be transmitted from mothers to infants. Prolonged HCV infection promotes systemic inflammation and is a risk factor for insulin resistance, type 2 diabetes mellitus, and cardiovascular disease.[126]

Evaluation and Treatment

The diagnosis of HAV and HCV infections is based on the presence of anti-HAV and anti-HCV antibodies. The most specific diagnostic test for HBV is serologic analysis for specific hepatitis virus antigens (i.e., HB surface antigen [HBsAg], which is the marker for HBV). There are other markers for HBV, including hepatitis B surface antibody (anti-HBs), hepatitis B envelope antigen (HBeAg), hepatitis B envelope antibody (anti-HBe), hepatitis B core antibody (anti-HBc), IgM and IgG, and HBV DNA. The assay for HDV is the measurement of total antibody to hepatitis D antigen (anti-HDV) and serum HDV ribonucleic acid (RNA). HCV RNA quantification is important for assessment of the viral load, to evaluate antiviral therapy for chronic HCV infection. HEV infection is diagnosed from the presence of serum anti-HEV IgG and HEV RNA. HEV infection is usually a self-limiting disease, except in undeveloped countries, where it causes chronic hepatitis with an increased risk in pregnant women. Liver enzyme levels and function tests also can indicate other viral liver diseases, drug toxicity, or alcoholic hepatitis.[127]

Prophylaxis and treatments for different types of viral hepatitis are summarized in Table 41.9. Physical activity may be restricted, and a low-fat, high-carbohydrate diet is beneficial if bile flow is obstructed. For chronic hepatitis, treatment is directed at suppressing viral replication before irreversible liver cell damage or hepatic carcinoma occurs. Cyclic and combination therapy may prevent drug resistance, and treatment regimens may be genotype specific. Recent advances in the development of direct-acting antiviral agents (DAAs) have broadened first line treatment options for individuals with hepatitis C, and the World Health Organization has set 2030 as the target for eliminating hepatitis B and C.[128] Coinfection of HIV and HCV is common, and interruption of HIV antiretroviral therapy is not recommended prior to HCV DAA treatment.[129]

Outbreaks of HAV have been reported in the United States, and the prevalence is tracked by state health departments. Although HAV is transferred via the fecal-oral route through food and water contamination, it is more commonly spread from person to person in the United States, and outbreaks were identified in 2016.[130] After ingestion and GI uptake, HAV replicates in the liver and is secreted into the stool and blood. To prevent the transmission of HAV, proper hand hygiene and the use of gloves for disposing of bedpans and fecal matter are imperative. HAV may be shed in the stool for up to 3 months after the onset of symptoms. Molecular procedures are available for direct surveillance of HAV in food. Direct contact with blood or body fluids of individuals should be avoided. The administration of immune globulin before exposure or early in the incubation period can prevent HAV and HBV infection. A combined vaccine is available to protect against HAV and HBV infection. To prevent outbreaks of HAV, hepatitis A vaccine is recommended for adults at risk: people who use drugs (including drugs that are not injected), people experiencing homelessness, men who have sex with men, people with liver disease, and people who are or were recently in jail or prison. These recommendations are in addition to vaccine recommendations for children.[130] Preexposure vaccination is recommended for healthcare workers, liver transplant recipients, and others who are at risk for contact with infected body fluids, particularly children. There is no vaccine for HCV or HEV in the United States.

Disorders of the Gallbladder

Obstruction and inflammation are the most common disorders of the gallbladder. Obstruction is caused by **gallstones**, which are aggregates of substances in the bile. The gallstones may remain in the gallbladder or may be ejected, with bile, into the cystic duct. Gallstones that become lodged in the cystic duct obstruct the flow of bile into and out of the gallbladder and cause inflammation. Gallstone formation is termed **cholelithiasis**. Inflammation of the gallbladder or cystic duct is known as **cholecystitis**.

Cholelithiasis

Cholelithiasis (gallstones) is a prevalent disorder in developed countries, where the incidence is 10% to 20% of adults in the United States. Approximately 500,000 people will develop symptoms or complication of cholelithiasis annually.[131] Risk factors include obesity, female sex, pregnancy, use of oral contraceptives, gallbladder stasis, genetics, drugs, prolonged fasting with TPN, rapid weight loss, and certain medical conditions such as CD, cirrhosis, ileal resection, or other diseases of the ileum.[131,132]

Pathophysiology

Cholelithiasis is the presence of gallstones. Gallstones form in the biliary tract as a result of impaired metabolism of cholesterol, bilirubin, and BA and hypomotility of the gallbladder.[133] All gallstones contain a supersaturated amount of cholesterol, unconjugated bilirubin, bilirubin calcium salts, fatty acids, calcium carbonates and phosphates, and mucin glycoproteins. Stones form in three locations: the gallbladder or cystic duct (cholecystolithiasis), the extrahepatic bile duct (choledocholithiasis), and rarely in the intrahepatic bile duct (hepatolithiasis). There are three types of gallstones, determined by their chemical composition: cholesterol stones (70% cholesterol and the most common type [70% to 80% prevalence]), pigmented stones (black [hard] and brown [soft] with less than 30% cholesterol), and mixed stones. Cholesterol and black stones are more commonly formed within the gallbladder, and brown stones are formed in the bile ducts. *Cholesterol gallstones* form in bile that is supersaturated with cholesterol produced by the liver. Supersaturation sets the stage for cholesterol crystal formation (cholesterol nucleation), or the formation of "microstones." More crystals aggregate on the microstones, which grow to form "macrostones." This process more commonly occurs in the gallbladder. Prolonged exposure to supersaturated bile can decrease gallbladder motility, with incomplete postprandial emptying and biliary stasis also promoting gallbladder cholesterol stone formation. The stones may lie dormant or may become lodged in the cystic or common duct, causing obstruction, and pain when the gallbladder contracts. Bile stasis in the gallbladder can cause inflammation and cholecystitis. The stones can accumulate and fill the entire gallbladder (Fig. 41.20). *Black gallstones* are rare and are associated with chronic liver disease and hemolytic disease. They are composed of calcium bilirubinate with mucin

glycoproteins. *Pigmented brown gallstones* form from calcium bilirubinate and fatty acid soaps that bind with calcium They are associated with biliary stasis, bacterial infections (e.g., *E. coli*), and biliary parasites. Hepatocytes secrete bile that is supersaturated with cholesterol promoting stone formation. Several possible mechanisms are related to this process, and they are summarized in Box 41.4.

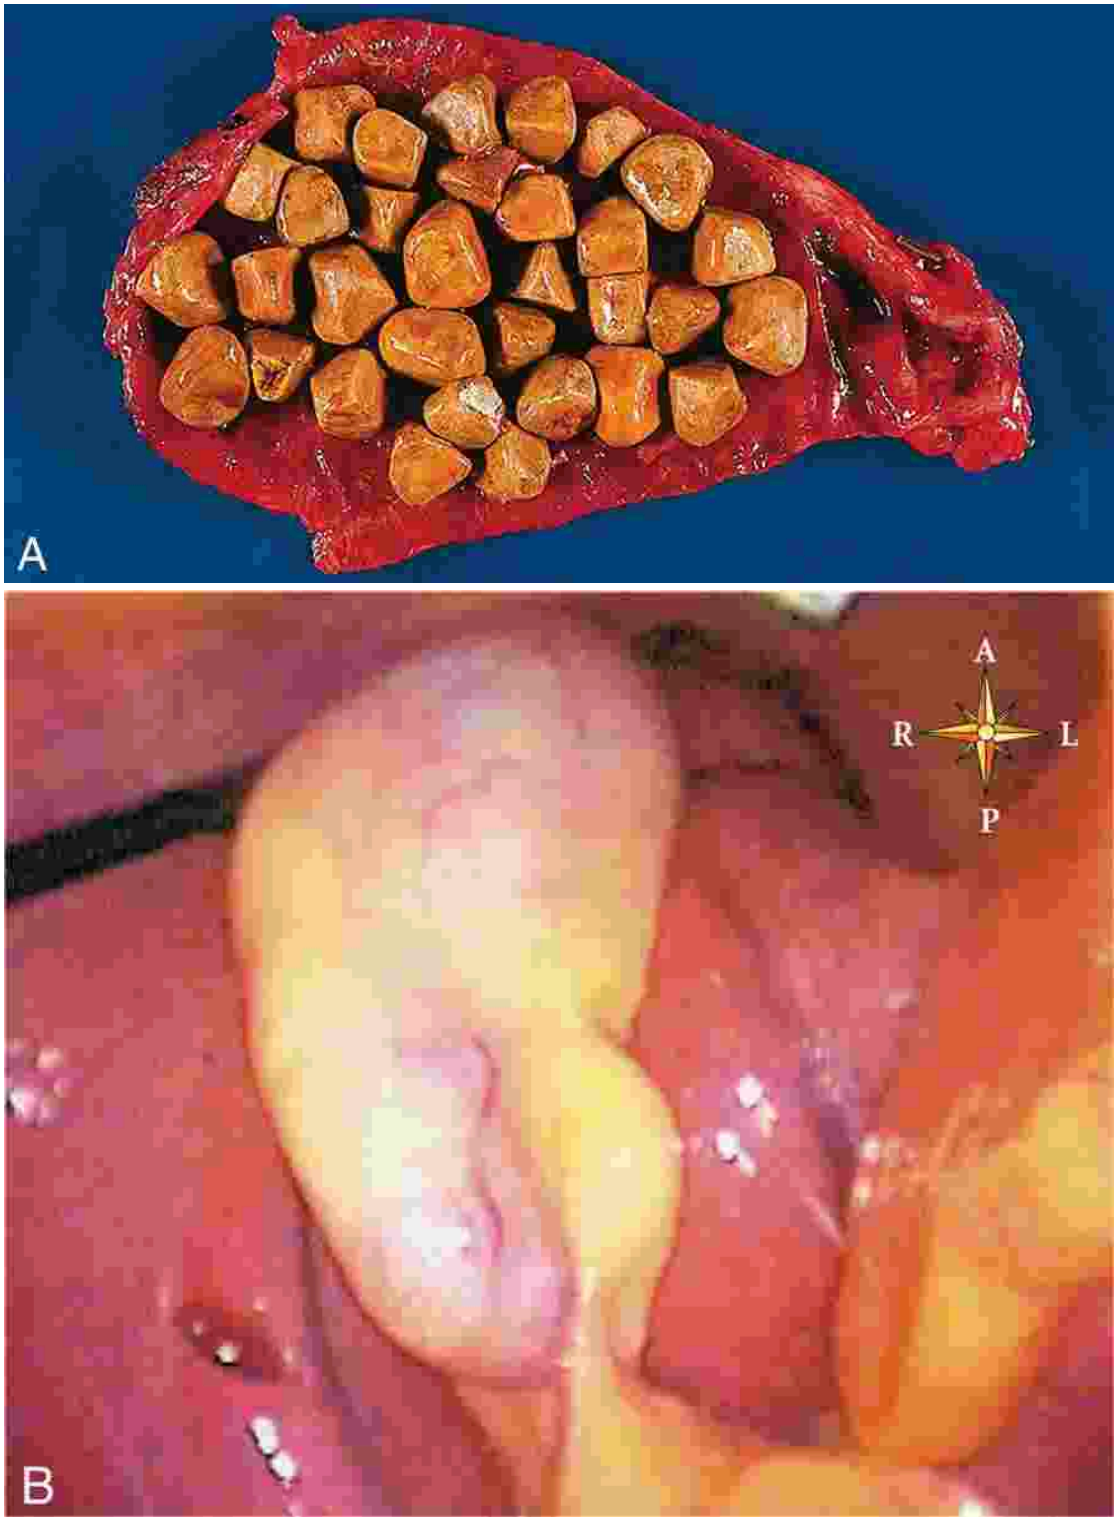

FIG. 41.20 **(A)** Resected gallbladder containing mixed gallstones. **(B)** Gallbladder before removal. (Courtesy Thompson JM, Wilson SF. *Health assessment for nursing practice*, St. Louis: Mosby, 1996.)

BOX 41.4

Possible Mechanisms of Hepatic Supersaturated Cholesterol Formation

- An enzymatic defect (e.g., increased 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase) increases hepatocyte synthesis of cholesterol;
- Diminished secretion of bile acids (BAs), which normally promote cholesterol solubility;
- Decreased resorption of bile salts from the ileum, which decrease the bile acid pool;
- Slower intestinal motility and increased cholesterol absorption;
- Gallbladder smooth muscle hypomotility and stasis (prolonged exposure to supersaturated bile can decrease motility with incomplete postprandial emptying, biliary stasis and time for cholesterol nucleation);
- Increased secretion of gallbladder epithelial procrystallizing agents mucin and biliary calcium;
- Genetic predisposition (*Lith* genes)—population studies suggest a 25%–30% genetic predisposition is associated with alterations in mucin secretion, hepatic cholesterol metabolism and transport, with variations among different populations (higher among Hispanic and American Indian ancestry);
- Insulin resistance increases cholesterol secretion with a higher prevalence of gallstones among obese individuals and those with metabolic syndrome and type 2 diabetes mellitus;
- Estrogen stimulates biliary cholesterol section and decreases bile acid synthesis, accounting for the increased incidence of gallstones among some women during years of reproduction and when taking estrogen supplements;
- Rapid weight loss dieting and bariatric surgery for treatment of obesity enhances hepatic secretion of cholesterol into bile caused by increased metabolism of lipid stores, reduced gallbladder emptying, and biliary stasis;
- Vitamin C deficiency as vitamin C modulates the hepatic and biliary pathways of cholesterol homeostasis by promoting the conversion of cholesterol into BAs through liver 7α-hydroxylation and prolongs cholesterol nucleation and crystallization time;
- Low fiber has a negative effect on colonic motility and increased production of secondary [lithogenic] BAs and is associated with high saturated fat and refined sugar diet;
- Some combination of the above mechanisms.

Clinical Manifestations

Cholelithiasis is often asymptomatic as it takes years for gallstones to develop, and they may be found incidentally on imaging for another condition or disease. Manifestations of disease are caused by occlusion of the ducts by sludge or gallstones. Epigastric and right hypochondrium pain and intolerance to fatty foods are the cardinal manifestations of cholelithiasis. Vague symptoms include heartburn, flatulence, epigastric discomfort, and food intolerances, particularly to fats, and they occur long before the development of complications. The pain, oftentimes referred to as biliary colic, occurs 30 minutes to several hours after eating a fatty meal. It is caused by the lodging of one or more gallstones in the cystic or common duct during contraction of the gallbladder (a physiologic response to cholecystokinin) with increases in intraluminal pressure and distention of the gallbladder wall. It can be intermittent or steady

and usually occurs in the right upper quadrant, radiating to the midupper area of the back. Jaundice indicates that the stone is located in the common bile duct.

Evaluation and Treatment

The diagnosis is based on the medical history, physical examination (including circumscribed pain over the gallbladder on direct pressure), laboratory tests (leukocytosis differentiates biliary colic from acute cholecystitis), and imaging evaluation. Transcutaneous sonography identifies the gallbladder and stone(s) and outlines the intrahepatic and extrahepatic bile ducts. CT or MRI can be helpful if there are complications. Other imaging options including endosonography are used if choledocholithiasis is suspected. Acute episodic biliary colic is managed with pain control.[134] Oral BA (UDCA or chenodeoxycholic acid) may prevent or dissolve cholesterol stones, particularly when there is gallstone sludge, but the stones may recur when the drug is discontinued. Dietary factors may prevent the development of gallstones, including increasing the intake of polyunsaturated fat, monounsaturated fat, and caffeine, vitamin C, and consumption of fiber. Exercise and maintenance of normal body weight with gradual weight loss are important. Laparoscopic cholecystectomy is the preferred treatment for uncomplicated gallstones causing obstruction of the bile ducts. Large stones may be managed by extracorporeal shock wave lithotripsy prior to endoscopic removal.[135]

Cholecystitis

Cholecystitis is inflammation of the gallbladder and typically develops after a gallstone becomes lodged in the cystic duct. This disorder may have either an acute or chronic presentation. The obstruction of the cystic duct causes the gallbladder to become distended and inflamed. The pain is similar to that caused by gallstones. Pressure against the distended wall of the gallbladder decreases blood flow and may result in ischemia, necrosis, and perforation. Fever, leukocytosis, rebound tenderness, and abdominal muscle guarding are common findings. Serum bilirubin and alkaline phosphatase levels may be elevated. Cholescintigraphy (a radiotracer scan of the gallbladder) is the most sensitive imaging for cholecystitis. The acute abdominal pain of cholecystitis must be differentiated from that caused by pancreatitis, myocardial infarction, and acute pyelonephritis of the right kidney. Narcotics may be required to control pain not responding to NSAIDs, and antibiotics are prescribed to manage bacterial infection in severe cases. Acute attacks usually require laparoscopic cholecystectomy. Obstruction also may lead to reflux of bile into the pancreatic duct, causing acute pancreatitis.[136]

Disorders of the Pancreas

Pancreatitis, or inflammation of the pancreas, is a relatively rare disease and potentially serious disorder. The incidence is about equal in men and women, is more common between 50 and 60 years of age and is more likely to occur in Blacks. Risk factors include obstructive biliary tract disease (particularly cholelithiasis), alcoholism, obesity, peptic ulcers, trauma, hyperlipidemia, hypercalcemia, smoking, certain drugs, and genetic factors (hereditary pancreatitis, cystic fibrosis). The cause is unknown in 15% to 25% of cases. Pancreatitis can be acute or chronic.

Acute Pancreatitis

Acute pancreatitis is usually a mild disease and resolves spontaneously, but approximately 20% of those with the disease develop a severe, acute pancreatitis requiring hospitalization, with more than 300,000 emergency department visits per year in the United States.[137] Pancreatitis develops because of obstruction to the outflow of pancreatic digestive enzymes caused by bile and pancreatic duct obstruction. Gallstones are the leading cause of acute obstructive pancreatitis. Acute pancreatitis also results from direct cellular injury from alcohol, drugs, or viral infection.

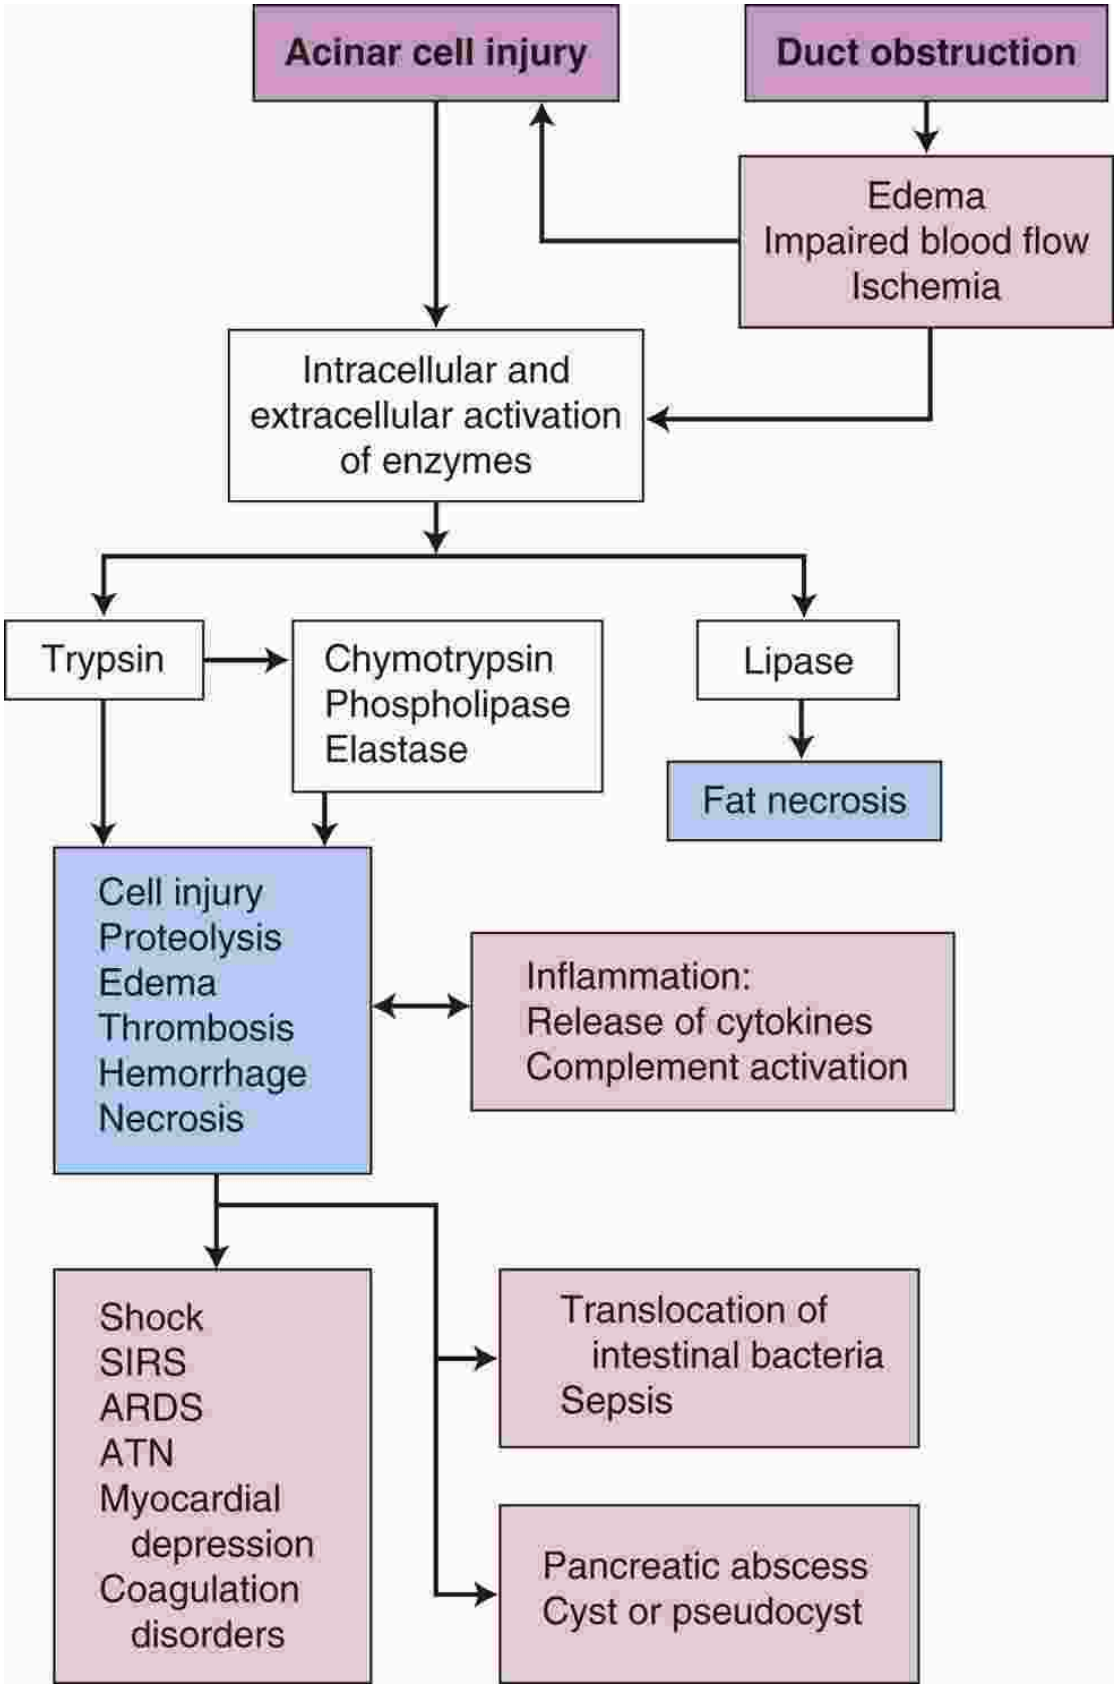
Pathophysiology

Acute pancreatitis has an unclear pathophysiologic trigger. Both intracellular and systemic events are proposed to contribute to the disease process. Reflux of BA into the pancreatic duct from gallstone obstruction of the common bile duct and ethanol metabolites within the pancreas promote intracellular

pancreatic injury, including calcium overload, alterations in heat shock proteins (HSPs), and injury to the mitochondria and endoplasmic reticulum. Intracellular calcium overload is proposed as a primary mechanism of cell injury in acute pancreatitis. Ethanol metabolites and BAs stimulate sustained pathologic calcium release from acinar endoplasmic reticulum stores, increased entry of extracellular calcium, and defects in calcium extrusion and reuptake mechanism. Intracellular calcium overload causes inappropriate intracellular trypsin activation, impaired fluid and $HCO3^-$ secretion in ductal cells, activation of the nuclear factor (NF)-κB proinflammatory pathway, and cell necrosis. Cellular injury leads to recruitment of neutrophils with release of inflammatory mediators and the formation of neutrophil extracellular traps, which further ductal obstruction and systemic inflammatory responses.[138] Trypsin activation causes autodigestion, while the activation of proinflammatory pathways leads to release of inflammatory cytokines with amplification of injury within the pancreas and systemic inflammatory responses.

Severe acute pancreatitis is also associated with sustained hypercalcemia in cases of primary hyperparathyroidism.[139] Sustained hypercalcemia increases the content of calcium in the pancreatic secretions, resulting in an accelerated transformation of trypsinogen to trypsin with cell injury, inflammation, and necrosis. HSPs are cytoprotective. They stabilize protein folding, are antioxidative and antiinflammatory, downregulate intra-acinar activation of trypsinogen and the NF-κB pathway, and are released in response to cellular stress and injury. BA and alcohol metabolites depress HSP function, contributing to the injury and inflammation of acute pancreatitis. There are increased demands for protein synthesis, and the endoplasmic reticulum is important for protein synthesis and transport, protein folding, and calcium storage. Mitochondria supply the adenosine triphosphate (ATP) for metabolism and protein synthesis. Alterations in mitochondrial function and stress to the endoplasmic reticulum contribute to the pathophysiology of acute pancreatitis. Synthesis of needed proteins and failure to recycle unneeded proteins and refold proteins (autophagy) fail and result in apoptosis (programmed cell death) and inflammation.[140–143] Paradoxically hypocalcemia is common in acute pancreatitis and is associated with severity of disease. Hypocalcemia develops from the autodigestion of mesenteric fat by pancreatic enzymes and release of free fatty acids, which form calcium salts (soaps). Transient hypoparathyroidism, and hypomagnesaemia can also contribute to hypocalcemia associated with pancreatitis.[144]

Activated trypsin activates other enzymes (chymotrypsin, lipase, and elastase) within the pancreatic acinar cells, causing autodigestion of pancreatic cells and tissues, resulting in inflammation. The autodigestion causes vascular damage, coagulation necrosis, fat necrosis (see Chapter 2), and the formation of pseudocysts (walled-off collections of pancreatic secretions). Edema within the pancreatic capsule causes compression and leads to ischemia and can contribute to necrosis (Fig. 41.21). Chronic alcohol use may also cause formation of protein plugs in pancreatic ducts and spasm of the sphincter of Oddi, resulting in obstruction. The obstruction leads to further intrapancreatic release of activated enzymes, autodigestion, inflammation, and pancreatitis.



Acinar cell injury

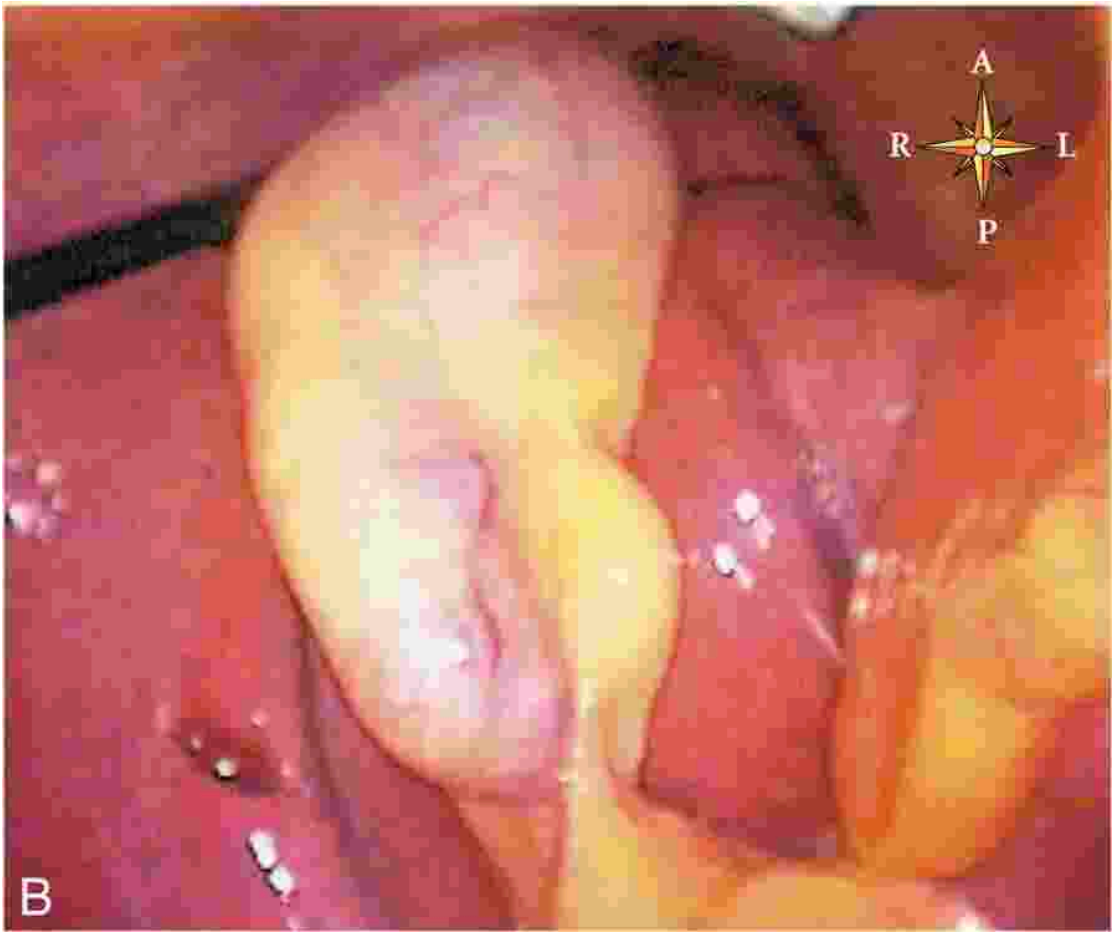

FIG. 41.21 Pathophysiology of Acute Pancreatitis.
ARDS, Acute respiratory distress syndrome; *ATN*, acute tubular necrosis; *SIRS*, systemic inflammatory response syndrome.

A flow diagram illustrates the pathophysiology of acute pancreatitis. The diagram begins as follows. • Acinar cell injury leads to intracellular and extracellular activation of enzymes. • Duct obstruction leads to edema, impaired blood flow, and ischemia, causing intracellular and extracellular activation of enzymes. • Intracellular and extracellular activation leads to trypsin, chymotrypsin, phospholipase, elastase, and lipase. • Trypsin, chymotrypsin, phospholipase, and elastase cause cell injury, proteolysis, edema, thrombosis, hemorrhage, and necrosis. • Lipase leads to fat necrosis. • Cell injury, proteolysis, edema, thrombosis, hemorrhage, necrosis causes shock, SIRS, ARDS, ATN, myocardial depression, coagulation disorders due to inflammation, the release of cytokines, complement activation, translocation of intestinal bacteria, sepsis, pancreatic abscess, cyst or pseudocyst.

Systemic effects of acute pancreatitis are related to the release of proinflammatory cytokines and digestive enzymes into the bloodstream. There is activation of leukocytes and complement, injury to vessel walls, and coagulation abnormalities, with the development of vasodilation, hypotension, and

shock. Complications can include acute respiratory distress syndrome (ARDS), heart failure, renal failure, coagulopathies, splenic vein obstruction, intra-abdominal hypertension, and systemic inflammatory response syndrome (SIRS). Paralytic ileus from release of toxic fluid into the peritoneum and GI bleeding can occur. Translocation of intestinal bacteria to the bloodstream may cause peritonitis or sepsis. Recurrent inflammation activates pancreatic stellate cells, which transdifferentiate into fibrogenic myofibroblasts, causing pancreatic fibrosis, strictures, and duct obstruction, which can all lead to chronic pancreatitis.

Clinical Manifestations

The cardinal manifestation of acute pancreatitis is epigastric or midabdominal constant pain ranging from mild abdominal discomfort to severe, incapacitating pain. The pain may radiate to the back. Pain is caused by (1) edema, which distends the pancreatic ducts and capsule, (2) chemical irritation and inflammation of the peritoneum, (3) irritation or obstruction of the biliary tract, and (4) inflammation of nerves. Fever and leukocytosis accompany the inflammatory response. Nausea and vomiting are caused by paralytic ileus secondary to the pancreatitis or peritonitis. Jaundice can occur from obstruction of the bile duct (e.g., a gallstone) or from pancreatic edema pressing on the duct. Abdominal distention accompanies bowel hypomotility and the accumulation of fluids in the peritoneal cavity. Hypovolemia, hypotension, tachycardia, myocardial insufficiency, and shock occur because plasma volume is lost as inflammatory mediators released into the circulation increase vascular permeability and dilate vessels. Tachypnea and hypoxemia develop secondary to ascites, pulmonary edema, atelectasis, or pleural effusions. Hypovolemia can decrease renal blood flow sufficiently to impair renal function and can cause renal failure. Tetany may develop as a result of hypocalcemia when calcium is deposited in areas of fat necrosis or as a decreased response to parathormone. Transient hyperglycemia also can occur if glucagon is released from damaged alpha cells in the pancreatic islets. In severe acute pancreatitis, some individuals develop flank or periumbilical ecchymosis, a sign of a poor prognosis. Multiple organ failure or SIRS accounts for most deaths of those with severe acute pancreatitis (Fig. 41.22).

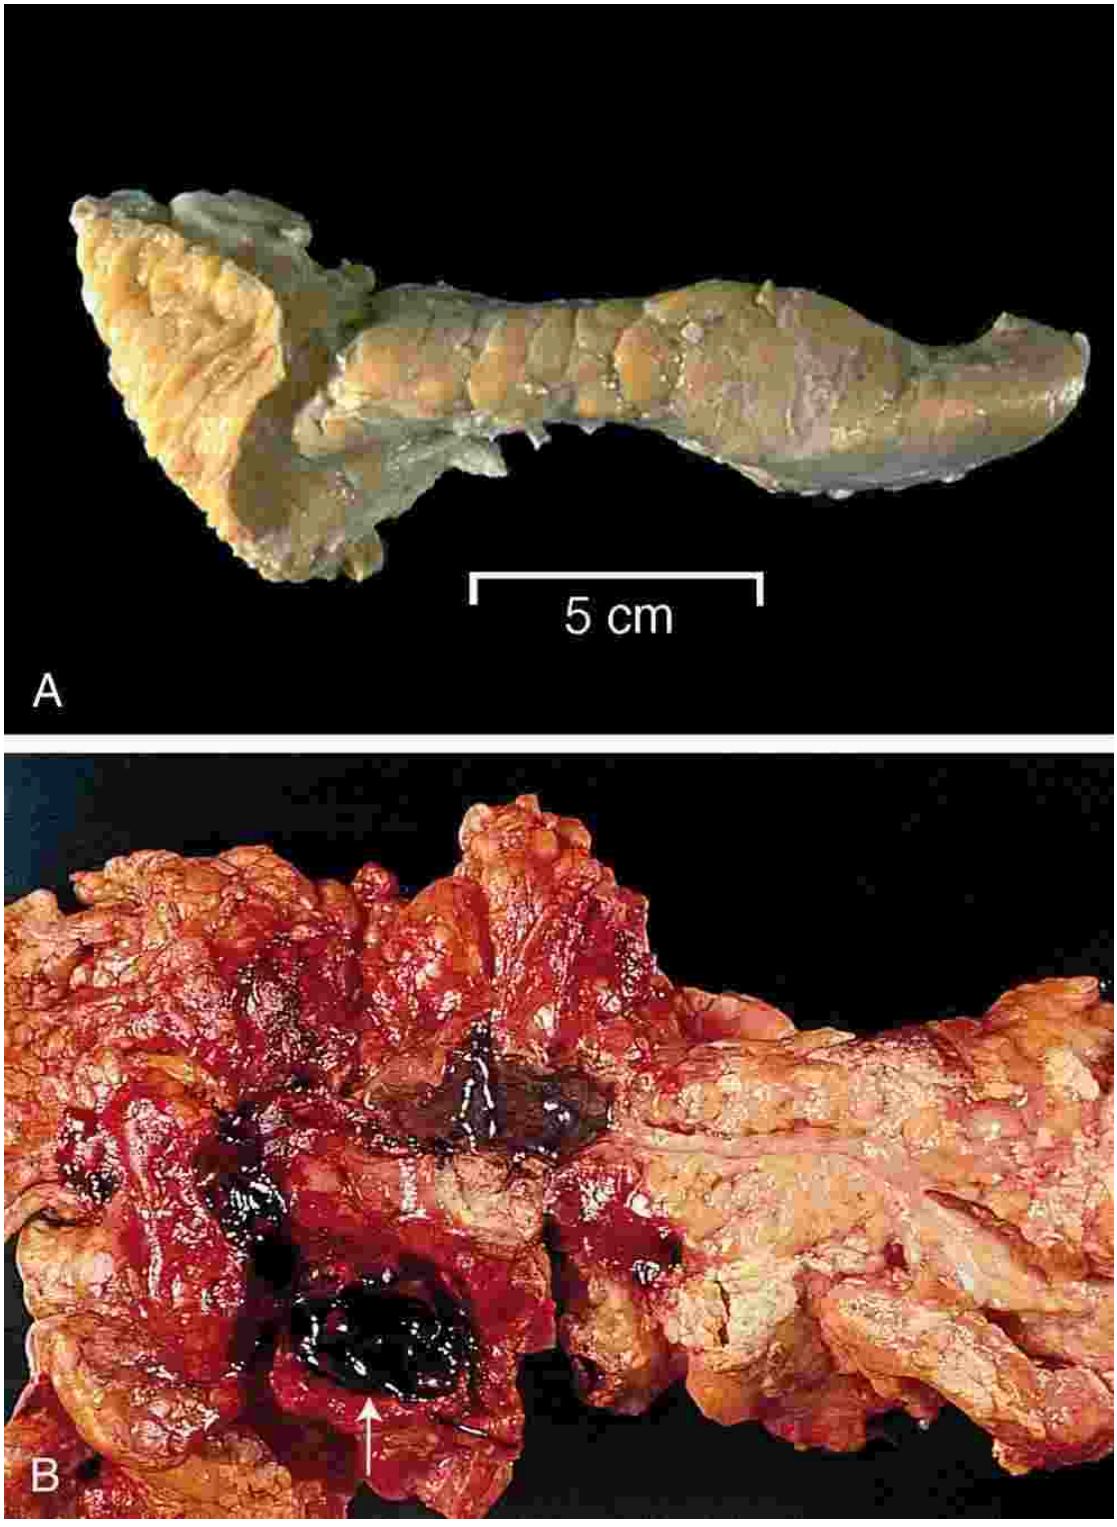

FIG. 41.22 Acute Severe Pancreatitis With Hemorrhage.
(A) Normal pancreas. **(B)** Acute hemorrhagic pancreatitis. The pancreas has hemorrhage, fat necrosis *(white patches)*, and a pseudocyst filled with blood *(white arrow)*. (A, From Klatt EC. *Robbins and Cotran atlas of pathology*. Philadelphia: Elsevier; 2021. B, From Damjanov I, Linder J, eds. *Pathology: A color atlas*. St. Louis: Mosby; 2000.)

Evaluation and Treatment

The diagnosis is based on clinical findings, identification of associated disorders, laboratory studies, and imaging results. The revised Atlanta classification (RAC) is used to guide diagnosis and requires two of the three following criteria be present: (1) abdominal pain suggestive of pancreatitis, (2) serum amylase and/or lipase greater than 3 times the upper limit of normal, and (3) and cross-sectional imaging (CT or MRI) findings consistent with acute pancreatitis.[145] An elevated direct bilirubin and/or alkaline phosphatase level or transabdominal ultrasound may indicate the presence of an obstructing gallstone.

The goal of treatment for acute pancreatitis is to stop the process of autodigestion and prevent systemic complications. Parenteral fluids are essential to restore blood volume, maintain perfusion, and prevent hypotension and shock. Narcotic medications may be needed to relieve pain. Epidural anesthesia was used successfully with reduced mortality in one multicenter study, but more evaluation is needed before use as routine care.[146] To decrease pancreatic secretions, oral food and fluids may be withheld initially and continuous gastric suction instituted. Nasogastric suction may not be necessary with mild pancreatitis, but it helps to relieve pain and prevent paralytic ileus in individuals who are nauseated and vomiting. Enteral feeding is usually initiated within 24 to 72 hours if ileus is not present. In severe pancreatitis, enteral nutrition with use of nasogastric or nasojejunal feeding usually is well tolerated, may decrease pancreatic enzyme secretion, prevents gut bacterial overgrowth, and maintains gut barrier function. In the presence of ileus, parenteral nutrition is started within 72 hours.[147] Drugs that decrease gastric acid production (e.g., H_2 receptor antagonists) can decrease stimulation of the pancreas by secretin. Antibiotics are used if there is documented infection.[148] Research is in progress to develop agents that target the intracellular mechanism of pancreatic injury, particularly intracellular calcium regulation.[139] The risk of mortality increases significantly with the development of infection or pulmonary, cardiac, and renal complications.

Chronic Pancreatitis

Chronic pancreatitis is a process of progressive fibrotic destruction and irreversible scarring of the pancreas. Multiple forms of the disease exist, but chronic alcohol abuse is the most common cause due to chronic changes in the structure of the pancreas related to repeated exacerbations of pancreatitis. Obstruction from gallstones, smoking, hypertriglyceridemia, and genetic factors increase the risk of chronic pancreatitis[149]; however, the disease may also be idiopathic. Toxic metabolites and chronic release of inflammatory cytokines contribute to the destruction of acinar cells and islets of Langerhans. The pancreatic parenchyma is destroyed and replaced by fibrous tissues, strictures, calcification, ductal obstruction, and pseudocysts. The cysts are walled-off areas or pockets of pancreatic juice, necrotic debris, or blood within or adjacent to the pancreas.

Continuous or intermittent abdominal pain and weight loss are common and reduce quality of life. The pain is difficult to manage, involves both peripheral and central pain sensitization (see Chapter 16), and is associated with inflammation induced by increased intraductal pressure, acinar cell injury, and parenchymal ischemia.[150] There are elevations in serum and urine pancreatic amylase and lipase, and imaging findings show pseudocysts and alterations in pancreatic structure. Manifestations of pancreatic enzyme deficiency, such as steatorrhea or a malabsorption syndrome, are present in late stages of chronic pancreatitis. To correct enzyme deficiencies and prevent malabsorption and malnutrition, oral enzyme replacements are taken before and during meals. Loss of islet cells can cause insulin-dependent diabetes and requires treatment. Osteoporosis is common in chronic pancreatitis and is related to smoking, alcohol abuse, low vitamin D, maldigestion, and malnutrition.[151] Hypocalcemia can develop from the autodigestion of mesenteric fat by pancreatic enzymes and release of free fatty acids, which form calcium salts (soaps). Transient hypoparathyroidism, and hypomagnesaemia can also contribute to hypocalcemia associated with pancreatitis.[144] Cessation of alcohol intake and smoking is essential for the management of both acute and chronic pancreatitis. Endoscopic or surgical drainage of cysts or partial resection of the pancreas may be required to relieve pain and to prevent cystic rupture. Total pancreatectomy with autologous islet cell transplant (TPAIT) may be considered for relief of intractable

pain and to prevent postoperative diabetes mellitus.[152] Chronic pancreatitis is a risk factor for pancreatic cancer and requires screening.[153,154]

Cancer of the Digestive System

Cancer of the Gastrointestinal Tract

Table 41.10 presents information on the various GI cancers by organ, percentage of deaths compared with all cancer deaths, risk factors, type of cell, and common manifestations. The biology of cancer is presented in Chapter 12.

Table 41.10

Cancer of the Gut, Liver, and Pancreas

Organ	Proportion of All Cancer Deaths[a]	Risks	Cell Type	Common Manifestations
Esophagus	2.6%	Malnutrition Alcohol Tobacco Chronic reflux	Squamous cell Adenocarcinoma	Chest pain Dysphagia
Stomach	1.8%	Salty food Fried red meat Nitrates-nitrosamines	Adenocarcinoma Squamous cell	Anorexia Malaise Weight loss Upper abdominal pain Vomiting Occult blood
Colon/rectum	8.7%	Polyps Long-term inflammatory bowel disease Diverticulitis Diets high in fat and refined carbohydrates; low in fiber	Adenocarcinoma (left colon grows as ring; right colon grows as mass)	Pain Mass Anemia Bloody stool Obstruction Distention
Liver	5.0%	HBV, HCV, HDV Cirrhosis Intestinal parasite Aflatoxin from moldy peanuts and corn	Hepatomas Cholangiomas	Pain Anorexia Bloating Weight loss Portal hypertension

Organ	Proportion of All Cancer Deaths[a]	Risks	Cell Type	Common Manifestations
				Ascites Jaundice
Pancreas	7.9%	Chronic pancreatitis Cigarette smoking Alcohol (?) Diabetic women	Adenocarcinoma (exocrine part of gland, ductal epithelium)	Weight loss Weakness Nausea Vomiting Abdominal pain Depression ± jaundice May have insulin-secreting tumors with symptoms of hypoglycemia

Organ	Proportion of All Cancer Deaths[a]	Risks	Cell Type	Common Manifestations
Esophagus	2.6%	Malnutrition Alcohol Tobacco Chronic reflux	Squamous cell Adenocarcinoma	Chest pain Dysphagia
Stomach	1.8%	Salty food Fried red meat Nitrates-nitrosamines	Adenocarcinoma Squamous cell	Anorexia Malaise Weight loss Upper abdominal pain Vomiting Occult blood
Colon/rectum	8.7%	Polyps Long-term inflammatory bowel disease Diverticulitis Diets high in fat and refined carbohydrates; low in fiber	Adenocarcinoma (left colon grows as ring; right colon grows as mass)	Pain Mass Anemia Bloody stool Obstruction Distention
Liver	5.0%	HBV, HCV, HDV Cirrhosis Intestinal parasite Aflatoxin from moldy peanuts and corn	Hepatomas Cholangiomas	Pain Anorexia Bloating Weight loss Portal hypertension Ascites Jaundice

Cancer of the Esophagus

Carcinoma of the esophagus is a rare type of cancer with an estimated incidence of 17,650 new cases and 16,080 deaths in the United States in 2019.[155]

Risk factors are summarized in the box Risk Factors: Esophageal Cancer.

Risk Factors

Esophageal Cancer

- Age older than 50 years
- Male
- White race
- Tobacco use
- Alcoholism
- Dietary factors: deficiencies of trace elements and vitamins
- Malnutrition associated with poor economic conditions or special dietary habits (e.g., very hot drinks, fish preserved in lye; diet deficient in fruits and vegetables)
- Gastroesophageal reflux with dysplasia
- Sliding hiatal hernia
- Obesity
- Family history of barrett esophagus or esophageal adenocarcinoma

Pathophysiology

Carcinoma of the esophagus includes squamous cell carcinoma and adenocarcinoma, which is more prevalent in the United States. Squamous cell carcinomas are more common in the thoracic and cervical areas of the esophagus and are associated with smoking tobacco and chronic alcohol consumption. Adenocarcinomas are associated with chronic GERD.[156]**BE** is the known precursor to adenocarcinoma. Normal squamous epithelium of the distal esophagus is replaced by specialized columnar epithelium with intestinal metaplasia, the precancerous lesion. The disease then progresses through stages from intestinal metaplasia (nondysplastic BE [NDBE]), to low-grade dysplasia (LGD), to high-grade dysplasia (HGD), to intramucosal carcinoma, and finally to invasive adenocarcinoma.[157] Both genomic and epigenomic events are associated with esophageal cancers, and mutation of the *TP53* gene and aberrant DNA methylation are early events, although the genetic landscape is diverse. The *CagA*-positive strain of *H. pylori* may be protective against esophageal carcinoma.[158] The tendency for early metastasis is related to the superficial nature of the esophageal lymphatics and the lack of symptoms until late stages of tumor progression.

Clinical Manifestations

The two frequent symptoms of esophageal carcinoma are chest pain and dysphagia. The most common type of pain is heartburn. It is initiated by eating spicy or highly seasoned foods and by assuming the recumbent position. Odynophagia (pain on swallowing) may be initiated by the swallowing of cold liquids. Some individuals with esophageal cancer complain of a constant retrosternal pain that radiates to the back. Dysphagia (difficulty swallowing) is usually pressure-like and may radiate posteriorly between the scapulae. Dysphagia usually progresses rapidly. Esophageal carcinoma is asymptomatic during the early stages and presents at an advanced stage. Esophageal cancer metastasizes rapidly and therefore has a poor prognosis.

Evaluation and Treatment

The stepwise progression of BE underlies the rationale for screening. Individuals who have BE risk factors are screened with an endoscopic evaluation, with biopsy if the endoscopic appearance of the distal esophagus is consistent with BE.[159] Noninvasive screening procedures have been developed, including the use of a cytosponge on a string combined with a biomarker for use in primary care

settings (Cytosponge-TFF3 test).[160] Endoscopic ablative therapy is recommended for individuals with BE and LGD or HGD. Endoscopic ultrasound and CT studies of the thorax are also used for diagnosis and staging. Prevention of gastroesophageal reflux and removal of HGD are essential to the management of BE. Once-daily PPIs are recommended for chemoprevention of BE. Aspirin, and nonaspirin antiinflammatory drugs and statins may be used in selected cases to prevent HGD and adenocarcinoma.[161] It is impossible to remove all lymph nodes with the tumor, but removal of the primary lesion and the local lymph nodes can benefit the individual with esophageal cancer. If the malignancy has not spread beyond these sites, cure is likely. However, if metastasis has occurred, an incomplete resection is of little survival benefit. Treatment is combined radiation and chemotherapy.

Cancer of the Stomach

The incidence of gastric cancer is estimated at 27,510 new cases and 11,140 deaths in the United States in 2019.[155] Most cases are adenocarcinoma. Squamous cell carcinoma is very rare and accounts for only a small percentage of all gastric carcinomas. Nonenvironmental risk factors include a family history of gastric adenocarcinoma; mutations in tumor suppressor and DNA repair genes, epigenetic modulation, type A atrophic gastritis (autoimmune); pernicious anemia, which is associated with atrophy of the gastric mucosa in the same locations where gastric tumors arise. Environmental factors include *H. pylori* infection, diet, alcohol consumption, smoking, and Epstein-Barr virus (EBV)-associated gastric carcinoma in some individuals; however, the mechanism is unknown.

Pathophysiology

Gastric adenocarcinomas are associated with the many virulence factors associated with *H. pylori* infection and progresses from chronic gastritis to atrophic gastritis, intestinal metaplasia to dysplasia and intestinal-type gastric cancer. *H. pylori* generally colonizes the pyloric antrum. *H. pylori* also causes gastric B-cell mucosa-associated lymphoid tissue lymphoma (see Box 41.1). Most adenocarcinomas are sporadic and associated with consumption of heavily salted and preserved foods (e.g., nitrates in pickled or salted foods such as bacon), a low intake of fruits and vegetables, and the use of tobacco and alcohol. Dietary salt enhances the conversion of nitrates to carcinogenic nitrosamines in the stomach. Salt and nitrates converted to nitrites are caustic to the stomach, delay gastric emptying, and can cause chronic atrophic gastritis. Insufficient acid secretion by the atrophic mucosa creates a relatively alkaline environment that permits bacteria to multiply and act on nitrates. The resulting increase in nitrosamines damages the DNA of mucosal cells, further promoting metaplasia and neoplasia. Gastric adenocarcinoma usually begins in the glands of the proximal or distal stomach mucosa. Different cell types, tumor locations, and molecular subtypes contribute to the heterogeneity of gastric adenocarcinoma.[162] Duodenal reflux also may contribute to an intestinal-like metaplasia. The reflux contains caustic bile salts that destroy the mucosal barrier that normally protects the stomach. There are two types of gastric cancer, intestinal and diffuse. Intestinal is associated with the inflammation of *H. pylori* infection and other environmental factors, and diffuse is related to familial gene mutations.[163,164]

Clinical Manifestations

The early stages of gastric cancer are generally asymptomatic or produce vague symptoms such as loss of appetite, malaise, and indigestion. Later manifestations of advanced gastric cancer include unexplained weight loss, upper abdominal pain, vomiting, change in bowel habits, and anemia caused by persistent occult bleeding. The prognosis is poor because symptoms do not occur until the tumor has spread and caused distant metastases, particularly to the liver and peritoneal structures. In general, the first manifestations of carcinoma are caused by distant metastases, and the disease is already in an advanced stage (Fig. 41.23).

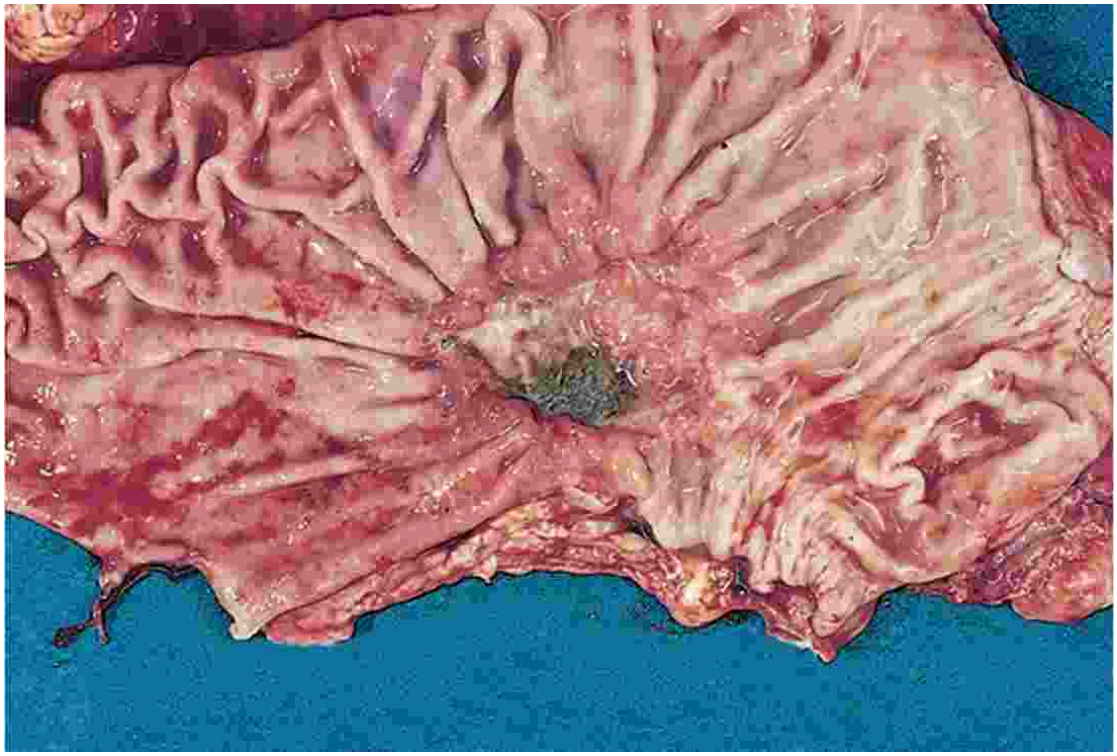

FIG. 41.23 Stomach Cancer. (From Patton KT. *Anatomy & physiology*, 10th edition. Elsevier; 2019.)

Evaluation and Treatment

No specific biomarkers have been identified for gastric cancer, and often it is at an advanced stage when diagnosed. Direct endoscopic visualization, lavage, and cellular examination or biopsy and imaging are used to establish the diagnosis and for staging. Screening and treatment for *H. pylori* infection constitute the best preventive approach to gastric cancer but must be done before dysplasia and metaplasia develop. Eradication of *H. pylori* has been shown to significantly reduce the risk of gastric cancer.[165] Chemotherapy and endoscopic resection are the usual treatment for early stages of disease, including lymphadenectomy, although recurrence is common. Staging is determined by histologic findings after resection. Liquid biopsy identifies molecular characteristics of the tumor and guides therapy.[164] Early diagnosis and chemotherapy, combined with radiation, improve the postsurgical outcomes. Because of the diverse cell types and molecular mechanisms involved in gastric cancer, there is resistance to the effectiveness of chemotherapy treatment (see Box 41.5). Survival at 5 years for localized disease is approximately 70% and for distant metastasis is approximately 6%.[166]

Box 41.5

Mechanisms of Drug Resistance in Gastric Adenocarcinoma

Mechanisms proposed to reduce the effectiveness of chemotherapy for the treatment of gastric adenocarcinoma include:

- Reduced cellular drug uptake
- Enhanced drug efflux from cancer cells
- Impaired drug activation or active drug inactivation
- Spontaneous changes in molecular targets sensitive to anticancer drugs,

- Enhanced ability of cancer cells to repair drug-induced DNA damage
- Decreased function of proapoptotic factors versus upregulation of antiapoptotic genes
- Changes in the tumor cell microenvironment (blood vessels, immune cells, extracellular matrix) reducing the efficacy of antitumor agents
- Phenotypic transformations, including epithelial-mesenchymal transition (EMT) and the appearance of stemness characteristics (an ability of cells to transform into other cell types)

Data from Marin J, Perez-Silva L, Macias R, et al. Molecular bases of mechanisms accounting for drug resistance in gastric adenocarcinoma. *Cancers*, 2020;12(8):2116. https://doi.org/10.3390/cancers12082116.

Cancer of the Small Intestine

Small intestine carcinoma is rare, with 11,790 estimated new cases and 1960 estimated deaths in 2022.[155] Adenocarcinoma is the most common tumor type usually occurring in the duodenum, followed by well-differentiated neuroendocrine tumors (most common in the ileum), sarcomas, and lymphomas. Carcinoma occurs more frequently in **Familial adenomatous polyposis** and CD. Symptoms are nonspecific and develop when there is obstruction (anorexia, nausea and vomiting, abdominal distention, weight loss). Tumors are usually found incidentally during abdominal surgery or with imaging for other reasons. Screening includes imaging and endoscopic surveillance. Urinary evaluation of 5-hydroxyindoloacetic acid can assist with diagnosis of well-differentiated neuroendocrine tumors. Treatment is surgical resection followed by tumor type–specific treatment.[167,168]

Cancer of the Colon and Rectum

CRC is the third most common cause of cancer and cancer death. An estimated 106,180 new cases of colon cancer and 54,040 new cases of rectal cancer, and 44,850 deaths, occurred in the United States in 2022.[155] The number of deaths has been declining over the past several years because of successful screening programs and diagnosis and treatment of *H. pylori* infection. CRC tends to occur in individuals older than 50 years, although the incidence is increasing in those younger than 50 years[169] and is rare in children. Risk factors for CRC can be reviewed in the box Risk Factors: Cancer of the Colon and Rectum. Regular use of aspirin and cyclooxygenase 2 (COX-2) selective inhibitors are associated with a decreased risk of CRC.[170]

Risk Factors

Cancer of the Colon and Rectum

- Advanced age
- Diet high in fat (especially egg consumption) and red and processed meats, low in fiber
- High consumption of alcohol
- Cigarette smoking
- Obesity
- Familial polyposis or family history of colorectal cancer
- Low levels of physical activity
- Inflammatory bowel disease
- Type 2 diabetes mellitus
- Black-American race/ethnicity

Pathophysiology

Most CRCs are sporadic (acquired) or associated with a family history of CRC (approximately 5% to 10%). They are caused by multiple gene alterations and environmental interactions (see Chapter 6 for epigenetics and Chapter 12 for mechanisms of oncogenesis). **Familial adenomatous polyposis (FAP)** is

a mutation of the *APC* gene (adenomatous polyposis coli, a tumor-suppressor gene) and is the most common hereditary cause of CRC. **Hereditary nonpolyposis CRC (HNPCC)**, or **Lynch syndrome**, is associated with several DNA mismatch repair (MMR) genes. Both FAP and HNPCC have a rare, family-linked autosomal dominant inheritance trait that accounts for approximately 3% to 5% of CRCs.[171] Sporadic tumors are thought to involve the loss of function or mutation of tumor-suppressor genes and epigenetic modifiers. Understanding the molecular events associated with CRC is allowing more targeted detection, diagnosis, and prognosis prediction and more specific and personalized treatment approaches.[172] CRC begins with the formation of an adenoma, termed "tumor initiation." The progression to carcinoma is termed "tumor progression" and is a multistep process of genetic mutations that may take 8 to 10 years.

Colorectal polyps are closely associated with the development of cancer. A polyp, or papilloma, is a projection arising from the mucosal epithelium. The most common types of polyps are benign. However, adenomatous polyps are neoplastic (Fig. 41.24). The larger the polyp, the greater the risk of CRC. Although lesions larger than 1.5 cm occur less often, they are more likely to be malignant than those smaller than 1 cm. Thus screening colonoscopy with polypectomy is performed when polyps are found **Neoplastic polyps** are premalignant lesions that arise from aberrant crypt epithelial stem cells and grow and progress to CRC (Fig. 41.25). Over a period of 10 to 15 years there is progressive multistep cascade of genetic and epigenetic alterations that inactivate tumor-suppressor genes and activate oncogenes that lead to carcinoma and metastasis with a long preinvasive phase (Box 41.6 and Table 41.11).[173] There are distinct precursor lesion pathways, and they are summarized in Fig. 41.26. Because the lymphatic channels are located under the submucosae, the lesions must traverse this layer before the multistep process of metastasis can occur. Once the malignant cells of an adenoma traverse the submucosae, tumor cells enter the bloodstream and lymphatics and become invasive, spreading to other organs. However, adenomas can be detected early because the submucosa may not be penetrated for several years.

A. Seven illustration depicts the development of colon cancer from polyps. The first illustration depicts an adenomatous polyp with root, stalk, base, body and tip. The second illustration depicts the focal atypia or cancer in situ. The third illustration depicts focal cancer or malignant adenoma. The fourth illustration depicts focal cancer invading stalk with some benign polyp still in the body. The fifth illustration depicts invasive cancer containing a piece of the polyp. The sixth illustration depicts the polypoid invasive cancer without polyp remnant. The seventh illustration depicts the ulcerated invasive cancer without polyp remnant. B. A close shot of endoscopic image showing pedunculated polyp along the distal descending colon.

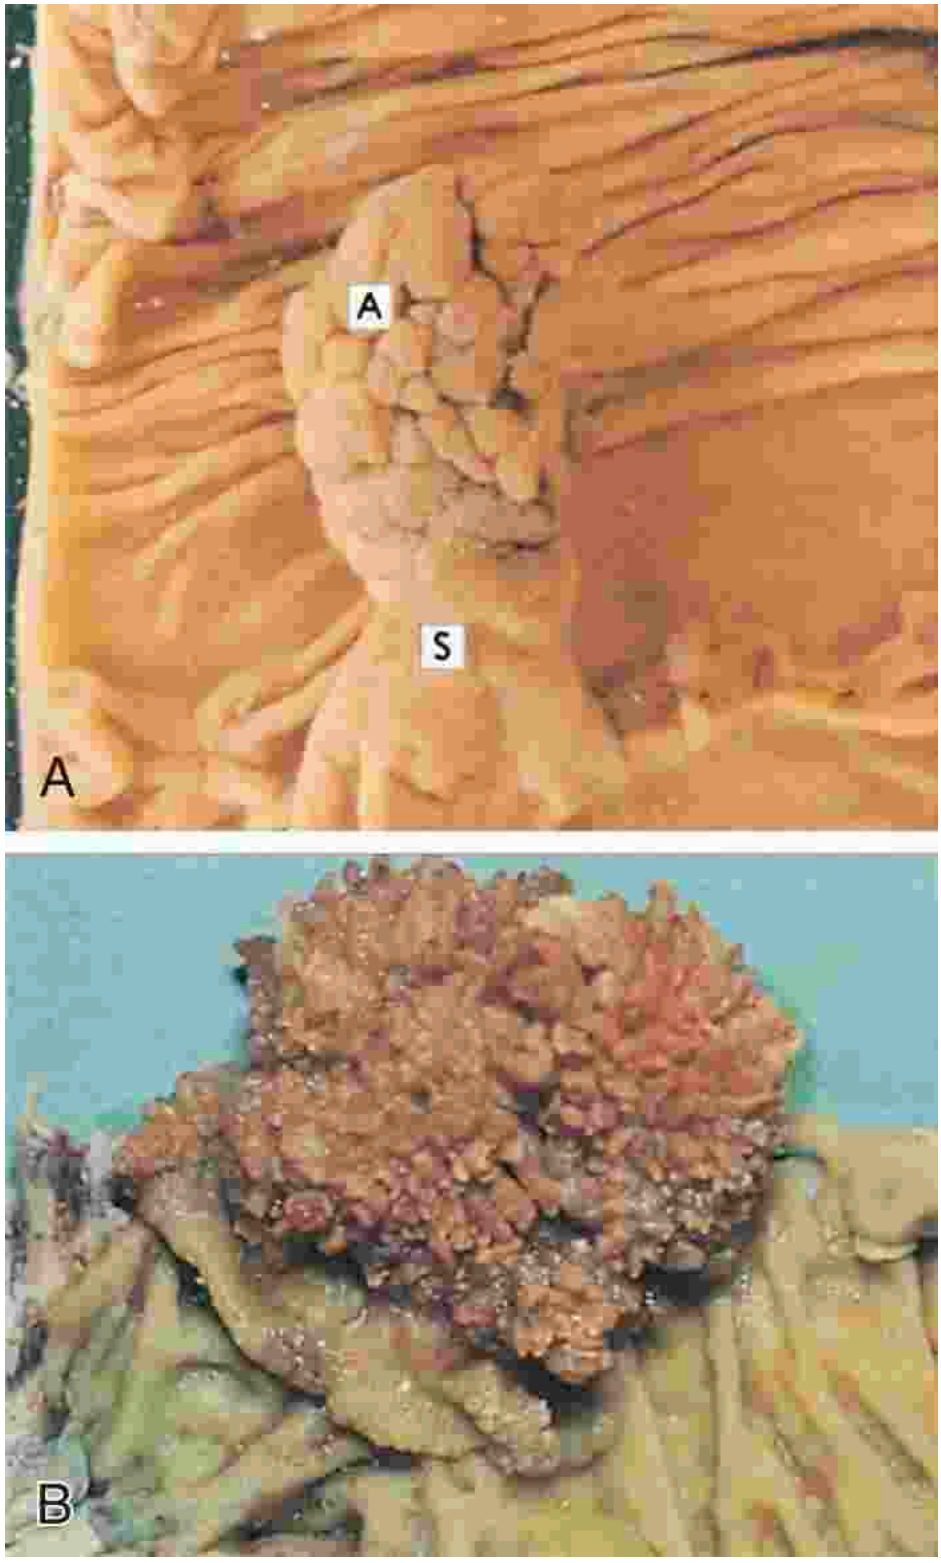

FIG. 41.25 Neoplastic Polyps.
(A) Tubular adenomata *(A)* are rounded lesions 0.5 to 2 cm in size that are generally red and sit on a stalk *(S)* of normal mucosa that has been dragged up by traction of the polyp in the bowel lumen. **(B)** Villous adenomata are velvety lesions about

0.6 cm thick that occupy a broad area of mucosa generally 1 to 5 cm in diameter.
(From Stevens A, et al. *Core pathology*, 3rd edition. London: Mosby; 2009.)

BOX 41.6

Common Genes Associated With Colorectal Cancer

APC (adenomatous polyposis coli): tumor suppressor; suppresses cell growth
TP53 (tumor protein 53): prevents gene mutations; a tumor suppressor gene
KRAS (V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog, proto-oncogene): promotes cell proliferation
BRAF (B-Raf proto-oncogene serine/threonine kinase): promotes cell proliferation
DCC (deleted in colon cancer): located at chromosome *18q*; tumor suppressor and apoptosis regulation
SMAD4 (Mothers against decapentaplegic homolog 4, proto-oncogene): promotes cell growth through TGF-β
TGF-β (transforming growth factor-beta): activates signaling pathways that facilitate tumor growth
EGFR (epidermal growth factor receptor): activates signaling pathways that facilitate tumor growth
COX-2 (cycloocygenase-2): promotes cell growth and inflammation.
BAX: promotes apoptosis and normal cell life cycle
DNA: (mismatch repair genes [hereditary nonpolyposis colorectal cancer/Lynch syndrome and some sporadic colorectal cancers]):
- *hMLH1* (human mutator homolog 1)
- *hMSH2* (human mutator S protein homolog 2)
- *hMSH6* (human mutator S homolog 6)
- *PMS2* (postmeiotic segregation increased 2)

LOH (loss of heterozygosity): loss of entire genome and surrounding chromosomal region

Table 41.11

Conditions Commonly Confused With Colorectal Cancer

Condition	Significant Characteristics
Diverticulitis	Left-sided pain similar to that of appendicitis; tender lower left quadrant; associated findings: nausea, vomiting, fever, obstruction, anorexia, and leukocytosis; mucosa is intact, and perforation, peritonitis, and abscesses occur more often than in cancer; ultrasound, CT scan, MRI, and proctosigmoidoscopy are used to distinguish from cancer
Ulcerative colitis	Younger individuals with chronic attacks of bloody diarrhea, crampy abdominal pain, fever, malnutrition, and dehydration; usually involves the left colon and rectum; endoscopy, barium enema, and biopsy performed for definitive diagnosis
Crohn disease (granulomatous colitis)	Generally involves the right colon; chronic diarrhea with abdominal cramps, fever, weight loss, and often a palpable abdominal mass; difficult at times to distinguish Crohn disease from ulcerative colitis; endoscopic examination and CT scan used to distinguish from cancer
Appendicitis	Vague abdominal symptoms, often with a tender or nontender mass in the lower right quadrant; associated symptoms: mild fever and leukocytosis; CT scan used to distinguish cancer of the cecum from appendiceal abscess
Thrombosed hemorrhoids	Examination shows a tender, swollen, bluish painful mass in the anus; individual has a history of hemorrhoids

CT, Computed tomography; *MRI*, magnetic resonance imaging.

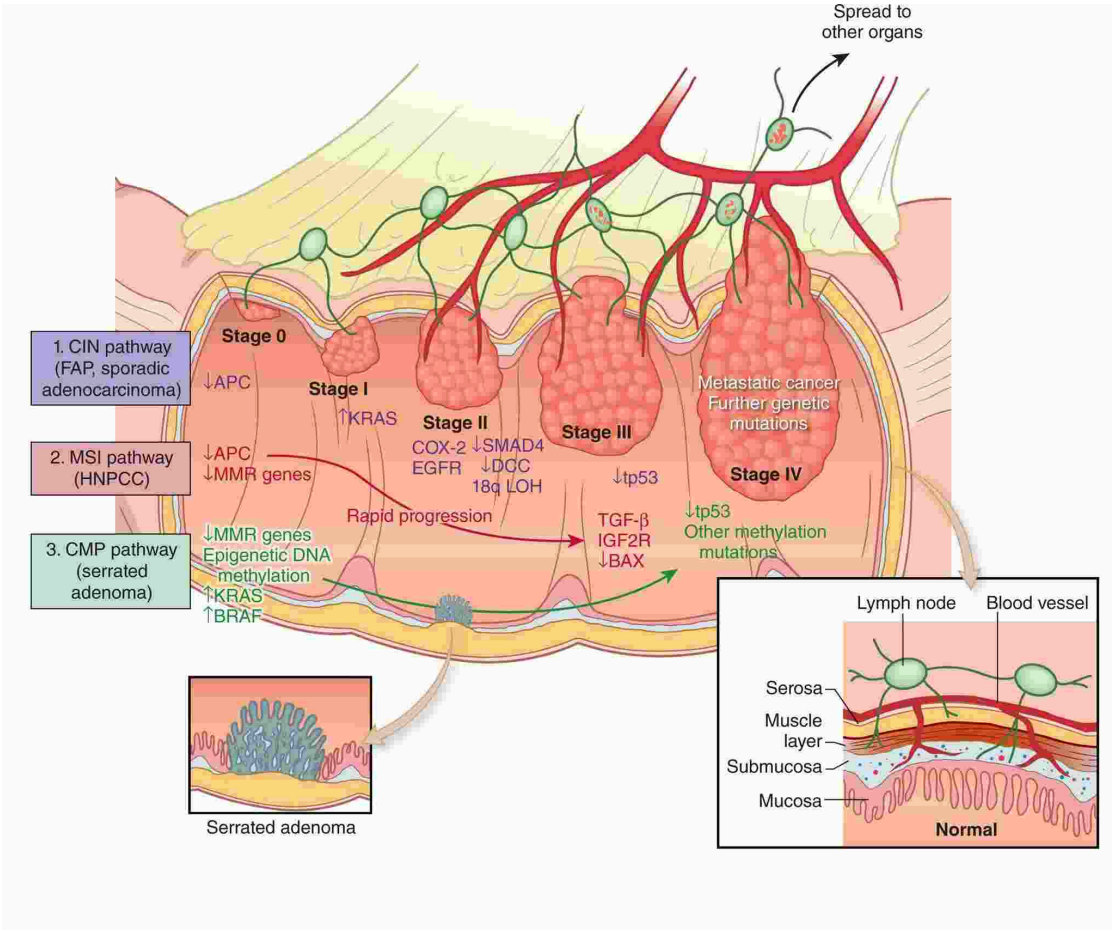

FIG. 41.26 Multistage Development of Colonic Cancer.
Colorectal carcinoma develops from the sequential progression of genetic abnormalities in different pathways. These pathways overlap in many tumors. *1*, Most colonic cancers arise in the chromosomal instability (CIN) pathway with imbalances in chromosomal numbers (aneuploidy) and loss of heterozygosity. Abnormalities in oncogenes and tumor-suppressor genes activate the pathways for CRC initiation and progression. Mutations in the APC gene are the earliest known event and inactivation of APC accelerates cell cycle progression. K-ras (proto-oncogene) overexpression leads to loss of other tumor-suppressor genes SMAD4, DCC, and tp53 and transforms an adenoma into a metastatic carcinoma. tp53 loss occurs in about 35% to 45% of colorectal carcinomas and occurs less frequently in benign lesions. Growth factors cyclooxygenase 2 and epidermal growth factor receptor promote tumor growth and angiogenesis in response to inflammatory cytokines and proto-oncogenes. *2*, The microsatellite instability (MSI) pathway involves the epigenetic mutation of DNA mismatch repair (MMR) genes that encode key molecules that repair DNA, resulting in replication errors and deactivation of proteins from other downstream mutations (transforming growth factor-β, IGF2R, BAX). *3*, The epigenetic pathway, CpG island methylator phenotype (CIMP), involves early hypermethylation of DNA with gene silencing of MMR (i.e., MLH1, MSH2, MSH6). Proto-oncogenes KRAS and BRAF also are involved in this pathway. This pathway also can transform into the MSI pathway. NOTE: definitions for all abbreviations are listed in Box 41.4. (Adapted from Collins FC. *Advances in colorectal cancer research*. Bethesda, MD: National Institutes of Health; 2010. https://www.nih.gov/research-training/advances-colorectal-cancer-research.)

An illustration depicts the cross-section of the colon, summarizing the distinct precursor lesion pathway involved in the multistage development of colonic cancer. 1. C I N pathway (F A P, sporadic adenocarcinoma) involves a decrease in A P C in stage 0; increase in K R A S in stage one; decrease in C O X-2, E G F R; S M A D A, DC C, L O H in stage two; decrease tp 53 in stage three and transformation to metastatic cancer further genetic mutations during stage four. 2. M S I pathway involves a decrease in A P C, M M R genes during stage 0 and, with rapid progression, transforms T G F beta, I G F 2 R, and decreases B A X during stage three. 3. C M P pathway involves a decrease in M M R genes, epigenetic D N A methylation, increase in K R A S and B R A F leading to the transformation of Tp 53 other methylation mutations during stage four. An inset depicts the enlarged view of serrated adenoma. Another inset depicts the normal view of the colon with labels indicating lymph node, blood vessel, serosa, the muscle layer, submucosa, and mucosa.

Clinical Manifestations

Symptoms of CRC depend on the location, size, and shape of the lesion and are silent in the early stages (Fig. 41.27). Tumors of the right (ascending) colon and left (descending) colon evolve into two distinct tumor types.[173] On the right side (proximal colon), the lesions extend along one wall of the cecum and ascending colon. These tumors may be silent, evolving to pain, a palpable mass in the lower right quadrant, iron deficiency anemia, fatigue, and dark red or mahogany-colored blood mixed with the stool. These tumors can become large and bulky with necrosis and ulceration, contributing to persistent blood loss and anemia. Obstruction is unusual because the growth does not readily encircle the colon. These tumors are more common in women and have a poorer prognosis with the occurrence of metastasis.

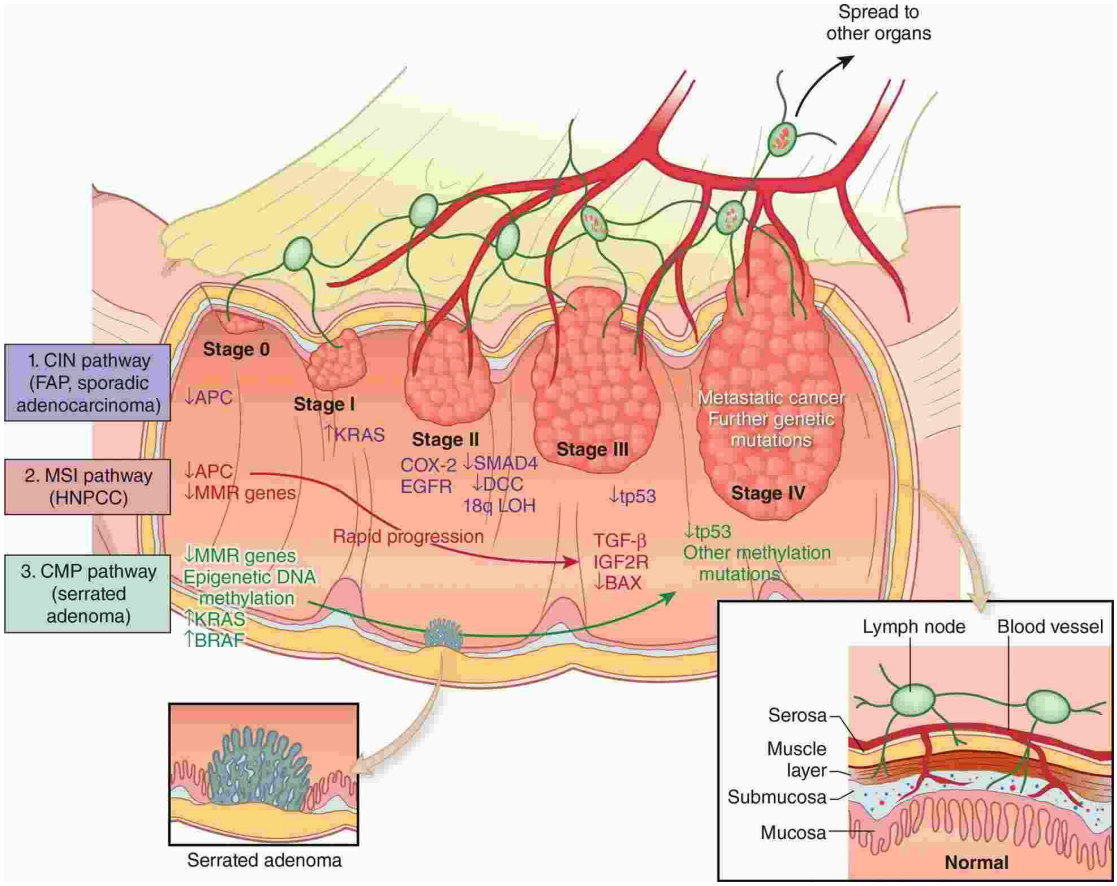

FIG. 41.27 Signs and Symptoms of Colorectal Cancer by Location of Primary Lesion.
Clinical manifestations are listed under the order of frequency for each region.

An illustration of the intestine depicts the symptoms of colorectal cancer depending on the location as follows. Transverse colon ten percent: Pain, obstruction, change in bowel habits, and anemia. Descending colon 15 percent: Pain, change in bowel habits, bright red blood in stool, and obstruction. Rectum 20 percent and sigmoid colon 25 percent: Blood in stool, change in bowel habits, and rectal discomfort. Ascending colon 30 percent: Pain, mass, change in bowel habits, and anemia.

Tumors of the left, or descending, colon (distal colon) start as small, elevated, button-like masses and are more common in men. This type grows circumferentially, encircling the entire bowel wall and eventually ulcerating in the middle of the tumor as the tumor penetrates the blood supply. Obstruction is common but occurs slowly, and stools become narrow and pencil shaped. Manifestations include progressive abdominal distention, pain, vomiting, constipation, a need for laxatives, cramps, and bright red blood on the surface of the stool.

Systematic lymphatic distribution occurs along the aorta to the mesenteric and pancreatic lymph nodes. Liver metastasis is common and follows invasion of the mesenteric veins (left colon) or superior veins (right colon), which drain into the portal circulation.

Rectal carcinomas (approximately 20% of CRCs) are defined as tumors occurring up to 15 cm from the anal opening. Tumors of the rectum can spread through the rectal wall to nearby structures: the

prostate in men and the vagina in women. Penetration occurs more readily in the lower third of the rectum because it has no serosal covering. Systemic and pulmonary metastases occur through the hemorrhoidal plexus, which drains into the vena cava.

Evaluation and Treatment

Individuals with hereditary polyposis should begin screening at an early age (10 to 12 years); colonoscopy should be used, with the removal of polyps when they are found. Specific, sensitive, and affordable molecular markers are being evaluated using liquid biopsy to assist with early diagnosis and evaluation of therapy. Carcinoembryonic antigen (CEA) is evaluated during and after cancer treatment.[174] Screening procedures for the detection of nonhereditary CRC are summarized in Box 41.7. Aspirin and celecoxib may reduce the incidence of CRC in the general population, but the risk of GI bleeding must be considered. Vitamin D, calcium, fiber, folate, dietary modification, weight control, exercise, and other nondietary lifestyle changes can reduce the risk of CRC.

Box 41.7

Screening for Colorectal Cancer

Beginning at age 45, both asymptomatic men and women of average risk should follow one of these testing schedules:

- Yearly fecal occult blood test (gFOBT) with at least 50% sensitivity* *or*
- Yearly fecal immunochemical test (FIT) with at least 50% sensitivity,*
- Every 3 years: multitarget stool DNA test
- Flexible sigmoidoscopy every 5 years,

Flexible sigmoidoscopy every 10 years + FIT every year

- Colonoscopy every 10 years

Data from US Preventive Services Task Force, Davidson KW, et al. Screening for colorectal cancer: US preventive services task force recommendation statement. *JAMA*, 2021;325(19):1965–1977.

The staging of CRC involves imaging and operative exploration. Physical examination of the abdomen detects liver enlargement and ascites; appropriate lymph nodes are palpated. Imaging is useful for pretreatment staging. Operative staging consists of careful exploration during surgery and biopsy of possible metastases. The National Cancer Institute's[175] tumor-node-metastasis (TNM) classification system is widely used for staging CRC (also see Chapter 12).

Treatment for all stages of cancer of the colon is surgical. Chemotherapy and radiation therapy may be given before surgery in the hope they will shrink the tumor or alter the malignant cells, or both, so that these cells will not survive after surgery. Resection and anastomosis can be performed for cancer of the ascending, transverse, descending, or sigmoid colon and upper rectum. These surgeries are performed through abdominal incisions and assisted with radiofrequency ablation. Natural defecation is preserved. Growths in the lower portion of the rectum require removal of the entire rectum with the formation of a permanent colostomy. Chemotherapy, including immunotherapy, is used to treat metastatic disease and cases with a high risk of recurrence. New therapeutic agents are improving personalized, first line therapy. Immunotherapy, vaccines, and viral vectors for the treatment of colon cancer are under continuing investigation (see Emerging Science Box: Colorectal Cancer).

Emerging Science Box

Colorectal Cancer

Colorectal cancer (CRC) is heavily researched as advancements for ways to reduce risk of CRC, early detection, and effective treatment strategies are sought. In particular, advances continue to be made in targeted therapy for CRC. Targeted therapy drugs affect cancer cells specifically as opposed to general chemotherapy drugs that target healthy cells as well. Targeted therapy drugs are already being used to treat CRC, but researchers continue to examine new-targeted therapy drugs that are indicated after common gene mutations are tested. If there is a specific mutation in the *BRAF* gene; the drugs cetuximab and panitumumab may be helpful if administered with other targeted drugs. Some CRCs that have no gene mutations in *KRAS*, *NRAS*, and *BRAF* genes may respond well to treatment with targeted drugs trastuzumab and lapatinib or trastuzumab or pertuzumab. Vaccines for prevention of CRC are under investigation including those that target tumor cells, loading immune cells with immunostimulatory adjuvants, and genetic-based vaccines that allow antigen-presenting cells to carry antigen-specific fragments to cancer cells. Dendritic cell vaccines which prime T cells to release antiangiogenic mediators within tumor tissue are holding promise for advanced stages of CRC. Research is continuing for the advancement of these therapies and their use for the treatment of CRC.

Data from American Cancer Society. What's new in colorectal research? 2020. Obtained from www.cancer.org/cancer/colon-rectal-cancer/about/new-research.html); Chudasama R, et al. Vaccines in gastrointestinal malignancies: From prevention to treatment. *Vaccines*, 2021;9(6):647. https://doi.org/10.3390/vaccines9060647; Wooster AL, et al. Resection of liver metastases or hepatic intra-arterial chemotherapy may prolong survival.

Cancer of the Accessory Organs of Digestion

Cancer of the Liver

Cancer of the liver is a leading cause of cancer death worldwide. The estimated number of new cases is 41,260 with 30,520 deaths in the United States in 2022.[155] Primary liver cancer is rare before the age of 40 years and is most common after 60 years. Cancer in the liver is usually caused by metastatic spread from a primary site elsewhere in the body. Risk factors for primary liver cancer are summarized in the box Risk Factors: Primary Liver Cancer. Risks associated with HBV and HCV infection are decreasing with antiviral therapy and HBV vaccination.

Risk Factors

Primary Liver Cancer

1. Infection and inflammation associated with HBV, HCV, and HDV, particularly in conjunction with cirrhosis, act either as a carcinogen or as a cocarcinogen in chronically infected hepatocytes;
2. Chronic alcoholic liver disease and nonalcoholic fatty liver disease that results in cirrhosis
3. Exposure to mycotoxins (e.g., aflatoxins), particularly those produced by *Aspergillus flavus*, a mold found on spoiled corn, peanuts, and grain; aflatoxins cause mutation of the *TP53* suppressor gene and activation of WNT signal transduction pathway
4. Long duration of heavy smoking (>20 years)
5. Hepatic iron overload (hemochromatosis)

Pathophysiology

Primary carcinomas of the liver are hepatocellular or cholangiocellular. **HCC** is the most common (approximately 90% of liver cancers) and develops in hepatocytes. It can be nodular (consisting of multiple, discrete nodules), massive (consisting of a large tumor mass having satellite nodules), or diffuse (consisting of small nodules distributed throughout most of the liver) (Fig. 41.28).[176] Chronic

hepatitis B and hepatitis C and cirrhosis give rise to HCC repetitive cellular proliferation that occurs in the inflamed liver in response to alterations in immunity, growth factor and cytokine stimulation, oxidative stress–induced DNA damage, and incorporation HBV DNA in or near cancer-related genes. Numerous genetic and epigenetic alterations, including activation of oncogenes, failure of tumor-suppressor genes, and signaling pathways, combine to promote carcinogenesis.[177] NAFLD progressing to cirrhosis is a risk for HCC and may be related to metabolic syndrome, lipotoxicity, and chronic inflammation that promotes tumor angiogenesis.[178] There is extensive heterogeneity among individual risk factors and within tumor intrinsic factors, including numerous gene mutations, epigenetic modifications, and signaling molecule subclasses affecting growth and proliferation. This significant variability contributes to difficulty in prevention, early diagnosis, identification and selection of targeted treatment, and survival prognosis.[179] Because carcinoma of the liver invades the hepatic and portal veins, it often spreads to the heart and lungs. Other sites of metastases are the brain, kidney, and spleen.

FIG. 41.28 Primary Hepatocellular Carcinoma.
Macroscopically, hepatocellular carcinomas may be single or multifocal. They usually develop in a liver already affected by cirrhosis as shown in this image. Tumor appears as the light-colored mass within the top part of the liver. (From Connolly AJ, et al., eds. *Autopsy pathology: A manual and atlas*, 3rd edition. Philadelphia: Saunders; 2016.)

Cholangiocellular carcinoma (cholangiocarcinoma) is rare (less than 1% of liver cancers) and develops in the bile ducts. It is associated with primary sclerosing cholangitis (a rare autoimmune disease often associated with UC) and is geographically associated with areas where parasitic liver fluke infestation is prevalent, such as Southeast Asia. Cholangiocellular carcinoma can occur anywhere along the bile duct and is often classified by where it is found (common bile duct, intrahepatic ducts, and in small ductules) and extend directly into the liver, usually as a solitary lesion. A combined form of HCC is known as combined (mixed) hepatocellular-cholangiocellular carcinoma. Chronic inflammation from autoimmune processes and parasitic fluke infestations are drivers of dysplasia and metaplasia. It is difficult to distinguish an invasion of cholangiocellular carcinoma from a metastatic adenocarcinoma except by neoplastic changes found in nearby ducts.[180]

Clinical Manifestations

HCC is usually asymptomatic. Manifestations are often nonspecific, can develop slowly or abruptly, and include vague abdominal symptoms, such as nausea and vomiting, fullness, pressure, a dull ache in the right upper abdominal area, and weight loss. In individuals with cirrhosis, deepening jaundice or abrupt lack of appetite is a sign of HCC. Obstruction by the tumor can cause sudden worsening of portal hypertension and development of ascites. As the tumor enlarges, it causes pain. Cholangiocellular carcinoma is often silent in early stages and presents insidiously as pain, loss of appetite, weight loss, and gradual onset of jaundice. Some carcinomas of the liver rupture spontaneously, causing hemorrhage. Others are discovered accidentally during laboratory evaluation, imaging, or surgery for other diseases or trauma.

Evaluation and Treatment

There is no specific test for the diagnosis of liver cancer. For high-risk individuals, α-fetoprotein associated with HBV infection and abdominal ultrasound are common screening tools. Imaging is required for diagnosis supported by clinical manifestations, laboratory findings, and exploratory laparotomy. In individuals without cirrhosis, CT or ultrasonography is used to detect solid tumors, but neither can distinguish benign from malignant tumors. Biopsy is generally not performed because of risk for tumor seeding and bleeding. Several staging systems are available for HCC, including the TNM system and those that include liver function.[181]

Primary prevention may be achieved by vaccinating against HBV, preventing and treating HBV and HCV infection, screening all donated blood for the presence of HBV, and reducing contamination of food with aflatoxins.

Surgical resection for HCC and cholangiocarcinoma is possible only if the tumor is localized to a removable lobe of the liver. Surgery is hazardous and usually not undertaken if the individual has cirrhosis. Percutaneous or laparoscopic ablation and transplantation are effective for early stages of disease. Most individuals develop metastases after surgical resection, but long-term survival is possible. Chemoembolization, immunotherapy, and radiotherapy are treatment options. Targeted molecular therapy for HCC includes multikinase inhibitors (sorafenib is standard of care), anti-vascular endothelial growth factor (VEGF) antibodies (ramucirumab for second line therapy), immune checkpoint inhibitors, and combination therapies. Gene therapy and epigenic modulators are under investigation.[182] Cholangiocarcinoma is usually diagnosed at late stages and is unresectable. Systemic chemotherapy is palliative.[180] The prognosis for those with symptomatic liver cancer is poor.

Cancer of the Gallbladder

In 2022 in the United States, there were an estimated 12,130 new cases and 4400 deaths attributable to gallbladder cancer.[155] Risk factors include biliary reflux, gallstones, advancing age, female sex (2:1), obesity, anomalous pancreaticobiliary ductal junction, bacterial infection, and exposure to heavy metals. It occurs rarely before the age of 40 years and is most common between the ages of 65 and 75 years. Primary carcinoma of the gallbladder is the most common cancer of the biliary tree but is rare in the United States and associated with gallstones. Approximately 85% of people who develop gallbladder cancer have gallstones.[183] Most gallbladder cancer is caused by metastasis.

Pathophysiology

Most primary carcinomas of the gallbladder are adenocarcinomas and more rarely squamous cell carcinomas. It is the most aggressive of the biliary tract cancers, with a mean survival of approximately 2 years. The pathogenesis is not clear. Chronic inflammation due to exposure to gallstones and BA or infection may trigger genomic alterations, dysplasia, and progression to metaplasia. The molecular mechanisms involve mutation of several genes, including tumor-suppressor genes and oncogenes, DNA repair genes, and alterations in the extracellular matrix. Epigenetic modification, particularly DNA hypermethylation and hypomethylation of tumor suppressor genes and oncogenes, is common in gallbladder cancer, and its exact role in tumor initiation is under investigation.[184] Invasion of the liver and lymph nodes occurs early. Direct invasion of the stomach and the duodenum can cause pyloric

obstruction, and infection often accompanies cancer of the gallbladder. Generalized peritonitis, gangrene, perforation, and liver abscesses are potential complications of infection.

Clinical Manifestations

Early stages of gallbladder carcinoma are asymptomatic, and the disease usually presents at an advanced stage. When symptoms develop, there is usually steady, upper right quadrant pain for approximately 2 months. Other manifestations include diarrhea, belching, weakness, loss of appetite, weight loss, and vomiting. Obstructive jaundice can occur if an enlarging tumor presses on the extrahepatic ducts and is a sign of an inoperable tumor.

Evaluation and Treatment

Early diagnosis of cancer of the gallbladder is rare and is often found incidentally. Therefore older adults with gallstones, particularly women, are evaluated for disease. Inflammatory disorders, such as cholangitis (bile duct inflammation) and peritonitis, often obscure an underlying malignancy. Diagnostic procedures include ultrasonography and further imaging with suspicious findings. Complete surgical resection of the gallbladder is the only effective treatment for early stages of disease, and recurrence is common. Complete removal of tumor tissue and lymph nodes with chemoradiation therapy is performed for more advanced stages. Because advanced malignancies cannot be resected, gallbladders containing stones are removed as a preventive measure. The prognosis of unresectable gallbladder cancer is extremely poor. Targeted molecular therapies, including epidermal growth factor receptor, fibroblast growth factor receptor, and VEGF receptor, and immune therapy using monoclonal antibodies are in clinical trials.[185]

Cancer of the Pancreas

Pancreatic cancer is the fourth leading cause of cancer deaths in the United States. An estimated 62,210 new cases and 49,830 deaths occurred in the United States in 2022.[155] The incidence of pancreatic cancer rises steadily with age, and it has been increasing in recent years. The cause of pancreatic cancer is not known, but there are modest risks associated with tobacco smoking, certain dietary factors (e.g., high-fat foods and processed meat), obesity, diabetes mellitus, chronic pancreatitis, family history of pancreatic cancer, Lynch syndrome gene mutation, and several oncogenic and tumor-suppressor gene mutations.[186]

Pathophysiology

Pancreatic cancer can arise from exocrine or endocrine cells. Most pancreatic tumors arise from metaplastic exocrine cells in the ducts and are called *pancreatic ductal adenocarcinomas;* they commonly arise from the head of the pancreas and are highly malignant. The *K-ras* oncogene is the most common gene mutation, and mutations also occur in tumor suppressor genes and DNA repair genes. Chronic pancreatitis and inflammatory cytokines support tumor growth. There is significant expansion of the extracellular matrix (stroma) from activation of stellate cells that contributes to therapeutic resistance. Tumors arising in small ducts invade nearby glandular tissue, penetrate the covering of the pancreas, and extend into surrounding tissues. Tumors of the head of the pancreas quickly spread to obstruct the common bile duct and portal vein (Fig. 41.29). These tumors can then infiltrate the superior mesenteric artery, the vena cava, and the aorta and form emboli. Tumors of the body and tail of the pancreas infiltrate the posterior abdominal wall. Lymphatic invasion occurs early and rapidly. Venous invasion causes metastases to the liver. Tumor implants on the peritoneal surface can obstruct veins and promote development of ascites. Tumors are staged using the TNM classification. Tumors of the endocrine pancreas are rare.

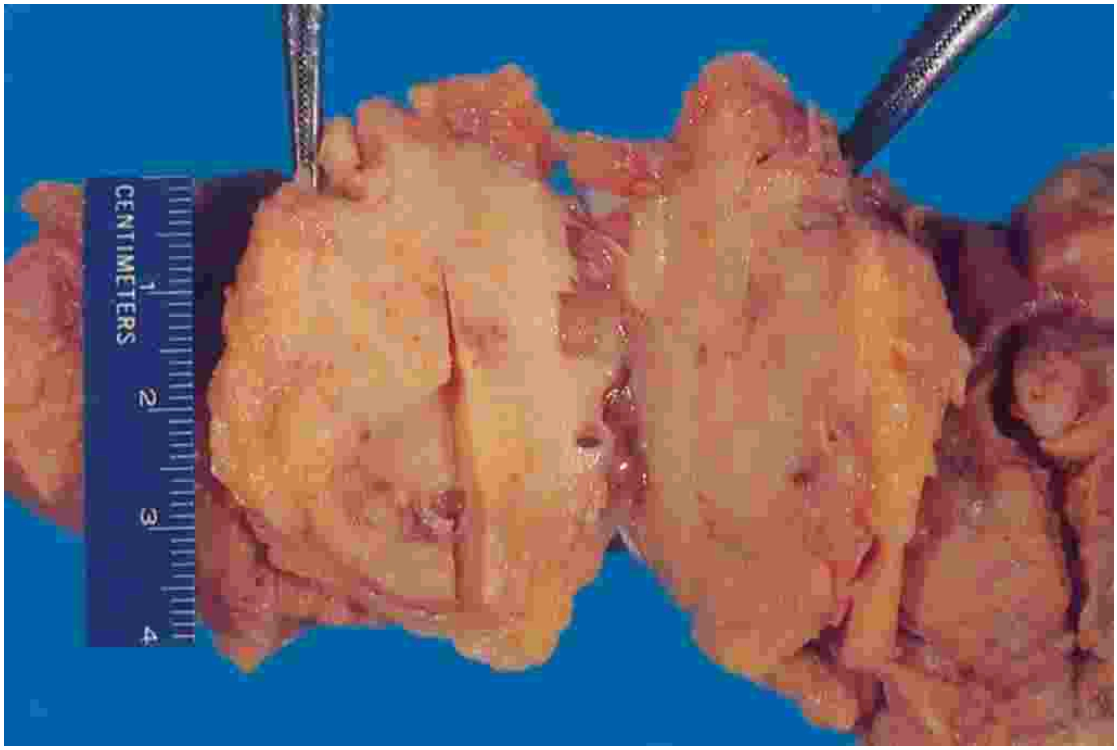

FIG. 41.29 Pancreatic Carcinoma.
Adenocarcinoma of the head of pancreas. Pancreatic adenocarcinoma may arise in the head (60%), body (15%), or tail (5%) of the pancreas; in 20% of cases there is involvement of more than one segment. (From Connolly AJ, Finkbeiner WE, Ursell PC, et al. *Autopsy pathology: A manual and atlas*, 3rd edition. St. Louis: Elsevier; 2016.)

Clinical Manifestations

Early stages of pancreatic cancer are asymptomatic. When symptoms occur, there usually has been obstruction and a malignant transformation. Typically, vague upper abdominal pain that radiates to the back or shoulder develops. Nonspecific symptoms include lethargy, nausea, vomiting, bloating, and changes in bowel habits. Jaundice arises in most cases, usually caused by obstruction of the bile duct. Because obstruction impairs enzyme secretion and flow to the duodenum, pancreatic cancer causes fat and protein malabsorption, resulting in weight loss. Distant metastases are found in the cervical lymph nodes, the lungs, and the brain. Most individuals die of hepatic failure, malnutrition, or systemic diseases.

Evaluation and Treatment

The molecular pathogenic pathways associated with pancreatic cancer are very complex, and there is no specific biomarker for pancreatic cancer. Several molecular markers are under investigation, and molecular profiling can guide targeted treatment and monitor treatment response.[187] The relative rarity of the disease and vagueness of symptoms contribute to the late diagnosis. There is no specific biomarker for pancreatic cancer. The diagnosis is usually made after the tumor has spread and is nonresectable. CT and endoscopic ultrasound are used initially for diagnosis. Laparotomy is often used to establish a definitive diagnosis, evaluate the extent of disease, and determine whether palliative bypass surgery (i.e., cholecystojejunostomy and gastrojejunostomy) is needed. Pancreaticoduodenectomy (Whipple procedure) is performed to decompress duct obstruction. Many surgeons recommend a total pancreatectomy because cancer of the pancreas seldom consists of a single lesion. However, resection is difficult as the tumor often grows into adjacent large vessels. Adjuvant chemotherapy, immunotherapy, radiochemotherapy, and combination therapy may produce favorable

controls in locally advanced cancer. There is no targeted therapy for the treatment of pancreatic cancer. Supportive therapy involves pain management, nutritional support, and an interdisciplinary team. Five-year survival is approximately 15% to 20% with resectable disease (a small subset) and less than 6% for metastatic disease. Screening is recommended for those with the highest risk factors, particularly those with a known family history. There is a need for new approaches for earlier diagnosis and more effective treatment.[188]

Summary Review

Disorders of the Gastrointestinal Tract

1. Anorexia (loss of appetite), vomiting, constipation, diarrhea, abdominal pain, and evidence of GI bleeding are clinical manifestations of many disorders and diseases of the GI tract.
2. Vomiting is the forceful emptying of the stomach effected by GI contraction and reverse peristalsis of the esophagus. It is usually preceded by nausea and retching, with the exception of projectile vomiting, which is associated with direct or indirect stimulation of the vomiting center in the brain.
3. Primary constipation is defined in three categories: functional, associated with low-residue, low-fluid diet; slow-transit, related to impaired colonic motor function; and IBS-C. Secondary constipation results from diet, neurogenic disorders and abdominal pain or muscle weakness, drugs that decrease intestinal motility, endocrine or metabolic disorders, or obstruction.
4. Diarrhea is three or more loose stools per day and can be acute, persistent, or chronic. It can be caused by excessive fluid drawn into the intestinal lumen by osmosis (osmotic diarrhea), excessive secretion of fluids by the intestinal mucosa (secretory diarrhea), or excessive GI motility (motility diarrhea).
5. Abdominal pain is caused by stretching, inflammation, or ischemia and originates in the peritoneum (parietal pain) or in the abdominal organs (visceral pain). Visceral pain is often referred to the back.
6. GI bleeding can occur in the upper or lower GI tract. Obvious manifestations of GI bleeding are hematemesis (vomiting of blood), melena (dark, tarry stools), and hematochezia (frank bleeding from the rectum). Occult bleeding can be detected only by testing stools or vomitus for the presence of blood.
7. Dysphagia is difficulty in swallowing or perception of obstruction during swallowing. It can be caused by a mechanical obstruction or a functional neuromuscular disorder of esophageal motility.
8. Achalasia is a rare form of functional dysphagia caused by loss of esophageal innervation or relaxation of the LES that may be caused by and immune response to an unknown antigen.
9. GERD is the regurgitation of chyme from the stomach into the esophagus, causing esophagitis from repeated exposure to acids, enzymes, or bile salts in the regurgitated gastric contents. GERD is related to abnormalities in lower esophageal function, esophageal motility, and gastric motility or emptying and can cause reflux esophagitis.
10. EoE is an idiopathic chronic allergic/immune disease of the esophagus characterized by infiltration of eosinophils in the esophagus with inflammation.
11. Hiatal hernia is the protrusion of the upper part of the stomach through the hiatus (esophageal opening in the diaphragm) at the gastroesophageal junction. Hiatal hernia can be sliding, paraoesophageal, or mixed.
12. Gastroparesis is delayed gastric emptying in the absence of mechanical gastric outlet obstruction and involves abnormalities of the autonomic nervous system, smooth muscle cells, enteric neurons, and GI hormones.
13. Pyloric obstruction is the narrowing or blockage of the pylorus, which is the opening between the stomach and the duodenum. It can be caused by a congenital defect, inflammation and scarring secondary to a gastric ulcer, or tumor growth.

14. Intestinal obstruction can occur in the small or large intestine and prevents the normal movement of chyme through the intestinal tract. It is usually mechanical (i.e., caused by torsion, herniation, or tumor). Functional or pseudo-obstruction is caused by paralytic ileus and can be associated with abdominal surgery, intestinal infection, cardiac dysfunction, or hypokalemia.
15. The most severe consequences of intestinal obstruction or ileus are fluid and electrolyte losses, hypovolemia, shock, intestinal necrosis, and perforation of the intestinal wall.
16. Gastritis is an acute or a chronic inflammation of the gastric mucosa.
17. Regurgitation of bile, use of NSAIDs or alcohol, *H. pylori* infection, and some systemic diseases are associated with gastritis.
18. Chronic fundal gastritis (autoimmune gastritis) is rare and associated with autoantibodies to parietal cells and intrinsic factor, resulting in gastric atrophy and causing pernicious anemia.
19. Chronic antral gastritis is the most common and is associated with *H. pylori*, which stimulates gastrin secretion, and NSAIDs.
20. Alkaline reflux gastritis is stomach inflammation caused by the reflux of bile and pancreatic secretions from the duodenum into the stomach. These substances disrupt the mucosal barrier and cause inflammation.
21. A peptic ulcer is a circumscribed area of mucosal inflammation and ulceration caused by excessive secretion of gastric acid, disruption of the protective mucosal barrier, or both.
22. The three types of peptic ulcers are duodenal, gastric, and stress ulcers. Duodenal and gastric ulcers are associated with *H. pylori* infection and chronic use of NSAIDs.
23. Zollinger-Ellison syndrome is associated with a gastrin secreting gastrinoma, chronic secretion of gastric acid, and gastric and duodenal ulcers.
24. Duodenal ulcers, the most common peptic ulcers, are associated with increased numbers of parietal (acid-secreting) cells in the stomach, elevated gastrin levels, and rapid gastric emptying. Pain occurs when the stomach is empty, and pain is relieved with food or antacids. Duodenal ulcers tend to heal spontaneously and recur frequently.
25. Gastric ulcers develop near parietal cells, generally near the antrum, and tend to become chronic. Gastric secretions may be normal or decreased, and pain may occur after eating.
26. Stress ulcer (stress-related mucosal disease) is an acute form of peptic ulcer associated with severe illness or extensive trauma.
27. Ischemic stress ulcers develop suddenly after severe illness, systemic trauma, neural injury, or burns (Curling ulcer). Ulceration follows mucosal damage caused by ischemia (decreased blood flow to the gastric mucosa and hypersecretion of acid).
28. Cushing ulcer is a stress ulcer caused by head trauma. Ulceration follows hypersecretion of hydrochloric acid caused by overstimulation of the vagal nuclei.
29. Postgastrectomy syndromes are a group of signs and symptoms that occur after gastric resection for the treatment of peptic ulcer, gastric carcinoma, or bariatric surgery for extreme obesity. Dumping syndrome causes malabsorption by the rapid emptying of hypertonic chyme from the surgically created residual stomach into the small intestine. It causes an osmotic shift of fluid from the vascular compartment to the intestinal lumen, which decreases plasma volume and increases intestinal motility. Other syndromes include alkaline reflux gastritis, afferent loop obstruction, anemia, and bone and mineral disorders.
30. Malabsorption syndromes result in disruption of absorption of nutrients, and maldigestion is failure of the chemical process of digestion.
31. Pancreatic insufficiency causes maldigestion and malabsorption associated with insufficient amounts of the enzymes that digest protein, carbohydrates, and fats into components that can be absorbed by the intestine.
32. Lactase deficiency or production in the brush border of the small intestine inhibits the breakdown of lactose. This prevents lactose absorption and causes osmotic diarrhea.
33. Bile salt deficiency causes fat malabsorption, including fat-soluble vitamins, and steatorrhea (fatty stools). Bile salt deficiency can result from inadequate secretion of bile, excessive bacterial deconjugation of bile, or impaired reabsorption of bile salts caused by ileal disease.
34. UC is an IBD associated with immune dysregulation that causes ulceration, abscess formation, and necrosis of the colonic and rectal mucosa. Cramping pain, bleeding, frequent diarrhea,

dehydration, and weight loss accompany severe forms of the disease. A course of frequent remissions and exacerbations is common.

35. CD is similar to UC, but it affects the entire GI tract, including the large and small intestines. Ulceration tends to involve all layers of the lumen. "Skip lesion" fissures and granulomas are characteristic of CD. Abdominal tenderness and pain, nonbloody diarrhea, and weight loss are the usual symptoms.
36. Microscopic colitis involves two histologic forms of the disease, lymphocytic and collagenous, with both resulting in frequent diarrhea but without ulceration.
37. IBS is a disorder of brain-gut interaction characterized by abdominal pain with altered bowel habits (diarrhea, constipation, or both).
38. Diverticula are outpouchings of colonic mucosa through the muscle layers of the colon wall. Diverticulosis is the presence of these outpouchings; diverticulitis is inflammation of the diverticula.
39. Appendicitis is caused by obstruction of the lumen leads to increased pressure, ischemia, and inflammation of the appendix. Without surgical resection, inflammation may progress to gangrene, perforation, and peritonitis.
40. Vascular insufficiency in the intestine is associated most often with acute or chronic occlusion or obstruction of the mesenteric vessels or insufficient mesenteric arterial blood flow. The resulting ischemia and necrosis produce abdominal pain, fever, bloody diarrhea, hypovolemia, and shock.

Disorders of the Accessory Organs of Digestion

1. Portal hypertension, ascites, hepatic encephalopathy, jaundice, and HRS are complications of many liver disorders.
2. Portal hypertension is an elevation of portal venous pressure to at least 10 mm Hg. It is caused by increased resistance to venous flow in the portal vein and its tributaries, including the sinusoids and hepatic vein.
3. Portal hypertension is the most serious complication of liver disease because it can cause fatal complications, such as bleeding varices, ascites, hepatic encephalopathy, and renal failure.
4. Varices are distended, tortuous, collateral veins associated with portal hypertension and can develop in the esophagus, stomach, abdominal wall, and rectum.
5. Splenomegaly is an enlargement of the spleen resulting from increased splenic vein pressure caused by portal hypertension.
6. HPS is pulmonary hypertension related to the release of vasodilators that effect pulmonary arterioles and is associated with portal hypertension and severe liver disease. PPH occurs with portal hypertension with arterial remodeling and increased arterial resistance.
7. Ascites is the accumulation and sequestration of fluid in the peritoneal cavity, often as a result of portal hypertension, decreased concentrations of plasma proteins, and sodium retention.
8. Hepatic encephalopathy (portal system encephalopathy) is impaired cerebral function caused by blood-borne toxins (particularly ammonia) not metabolized by the liver.
9. Jaundice (icterus) is a yellow or greenish pigmentation of the skin or sclera of the eyes caused by increases in plasma bilirubin concentration (hyperbilirubinemia).
10. Obstructive jaundice is caused by obstructed bile canaliculi (intrahepatic obstructive jaundice) or obstructed bile ducts outside the liver (extrahepatic obstructive jaundice). Bilirubin accumulates proximal to sites of obstruction, enters the bloodstream, and is deposited in the skin and other connective tissues.
11. Hemolytic jaundice is caused by destruction of red blood cells at a rate that exceeds the liver's ability to metabolize unconjugated bilirubin.
12. HRS is functional renal failure caused by advanced liver disease, particularly cirrhosis with portal hypertension. *Type 1 HRS-AKI* is caused by a decrease in blood flow to the kidneys that occurs in less than 2 weeks, usually as a result of massive GI hemorrhage or liver failure. *Type 2 HRS-NAKI* develops more slowly and is associated with ascites and decreased circulating blood volume. The predominant clinical manifestation is oliguria.

13. Acute liver failure can be caused by toxic overdose of acetaminophen, complications of viral hepatitis, or metabolic disorders that cause death of hepatocytes.
14. Autoimmune hepatitis may be caused by an autoimmune T cell–mediated inflammatory response with hypergammaglobulinemia, elevated transaminases, and absence of viral hepatitis. The disease may be mild or cause acute liver failure.
15. Cirrhosis is an irreversible inflammatory disease of the liver that develops slowly and causes disorganization of lobular structure, fibrosis, and nodular regeneration. Bile obstruction causes jaundice. Vascular obstruction causes portal hypertension, shunting, and varices. Cirrhosis can result from hepatitis or exposure to toxins, such as acetaldehyde (a product of alcohol metabolism). The disease causes progressive irreversible liver damage, usually over a period of years.
16. Alcoholic liver disease results from formation of acetaldehyde impairing the hepatocytes' ability to oxidize fatty acids, synthesize enzymes and proteins, degrade hormones, and clear portal blood of ammonia and toxins. The disease causes progressive fibrosis and includes steatosis, steatohepatitis, and alcoholic cirrhosis.
17. NAFLD is fat infiltration into hepatocytes, and NASH is inflammation of hepatocytes associated with obesity, hypertriglyceridemia, metabolic syndrome, and type 2 diabetes mellitus that can progress to liver failure.
18. Primary biliary cholangitis is an autoimmune disease with inflammatory destruction of intrahepatic bile ducts. Mitochondrial autoantibodies are found in this disease.
19. Secondary biliary cirrhosis develops from prolonged obstruction of bile flow (e.g., gallstones, tumors, chronic pancreatitis) with increased pressure in the hepatic bile ducts that causes pooling of bile and necrosis of tissue. Relief of obstruction alleviates symptoms of jaundice and pruritus. Continued obstruction causes cirrhosis and liver failure.
20. Viral hepatitis is an infection of the liver caused by strains of the hepatitis virus: HAV (fecal-oral transmission), HBV, HCV, HDV, and HEV (parenteral and sexual transmission). The hepatitis viruses can cause hepatic cell necrosis, Kupffer cell hyperplasia, and infiltration of liver tissue by mononuclear phagocytes. These changes obstruct bile flow and impair hepatocyte function.
21. The clinical manifestations of viral hepatitis depend on the type of virus and stage of infection. Fever, malaise, anorexia, and liver enlargement and tenderness characterize the prodromal phase (stage 1). Jaundice and hyperbilirubinemia mark the icteric phase (stage 2). During the recovery phase (stage 3), symptoms resolve. Recovery takes several weeks.
22. Chronic active hepatitis can occur with HBV and HCV with predisposition to cirrhosis and HCC.
23. Fulminant hepatitis is a complication of hepatitis B (with or without hepatitis D infection) or hepatitis C. It causes widespread hepatic necrosis and is often fatal.
24. Cholelithiasis (the formation of gallstones) is a result of bile aggregation of cholesterol crystals (cholesterol stones) or precipitates of unconjugated bilirubin (pigmented stones). Gallstones that fill the gallbladder or obstruct the cystic, or common, bile duct cause abdominal pain and jaundice.
25. Cholecystitis is an inflammation of the gallbladder. It is usually associated with obstruction of the cystic duct by gallstones.
26. Acute pancreatitis (pancreatic inflammation) is a serious but relatively rare disorder associated with biliary obstruction, toxic effects of alcohol, or unknown causes. Injury permits leakage of digestive enzymes into pancreatic tissue, where they become activated and begin the process of autodigestion, inflammation, and destruction of tissues. Release of pancreatic enzymes into the bloodstream or abdominal cavity causes damage to other organs.
27. Chronic pancreatitis is a process of progressive fibrotic destruction, irreversible scarring of the pancreas, and formation of pseudocysts resulting in functional impairment and commonly related to alcoholism or recurrent acute pancreatitis. It causes recurrent abdominal pain, digestive disorders, and malnutrition.

Cancer of the Digestive System

1. Cancer of the esophagus is rare and tends to occur in people older than 60 years. Alcohol and tobacco use, reflux esophagitis, radiation exposure, and nutritional deficiencies are associated with esophageal carcinoma. There are two types, squamous cell and adenocarcinoma, the most common. It is preceded by precancerous lesions known as BE, with progression from intestinal metaplasia to dysplasia to adenocarcinoma.
2. Dysphagia and chest pain are the primary manifestations of esophageal cancer. Early treatment of tumors that have not spread into the mediastinum or lymph nodes results in a better prognosis.
3. Gastric carcinoma is commonly an adenocarcinoma associated with *H. pylori (CagA)*, high salt intake, food preservatives (nitrates and nitrites), duodenal reflux, atrophic gastritis, and familial gene mutations.
4. Gastric cancers are commonly located in the prepyloric antrum. Clinical manifestations (weight loss, upper abdominal pain, vomiting, hematemesis, and anemia) develop only after the tumor has penetrated the wall of the stomach.
5. Cancer of the small intestine is rare and associated with FAP and CD. Tumors are usually found incidentally.
6. CRC is the third most common type of cancer and cancer death in the United States. FAP coli and HNPCC (or Lynch syndrome) are inherited forms of colon cancer. Preexisting large and numerous polyps are highly associated with sporadic (acquired) adenocarcinoma of the colon. Specific molecular pathways and gene mutations are associated with sporadic and familial CRCs.
7. Tumors of the right (ascending) colon are usually large and bulky; tumors of the left (descending, sigmoid) colon develop as small button-like masses. Manifestations of colon tumors include pain, bloody stools, and change in bowel habits.
8. Rectal carcinoma is located up to 15 cm from the opening of the anus. The tumor spreads transmurally to the vagina in women or to the prostate in men.
9. Metastatic invasion of the liver is more common than primary cancer of the liver.
10. Primary liver cancers are associated with chronic liver disease (cirrhosis and hepatitis B and C) and alterations in tumor suppressor genes and oncogenes. HCCs arise from the hepatocytes, whereas cholangiocellular carcinomas arise from the bile ducts. Primary liver cancer spreads to the heart, lungs, brain, kidney, and spleen through the circulation.
11. Cancer of the gallbladder is relatively rare and tends to occur in women older than 50 years. Adenocarcinoma is most common. Because clinical manifestations occur late in the disease, metastases to lymph channels have usually occurred by the time of diagnosis, and the prognosis is poor.
12. Cancer of the pancreas represents approximately 2.6% of all cancers in the United States. Most tumors are adenocarcinomas that arise in the exocrine cells of ducts in the head, body, or tail of the pancreas. Symptoms may not be evident until the tumor has spread to surrounding tissues. Treatment is palliative, and mortality is nearly 100% for advanced tumors.

Chapter Outline

OUTLINE

Disorders of the Gastrointestinal Tract 1375
- Congenital Impairment of Motility 1375
- Meconium Syndromes 1380
- Acquired Impairment of Motility 1381
- Impairment of Digestion, Absorption, and Nutrition 1383
- Diarrhea 1390

Disorders of the Liver 1391
- Disorders of Biliary Metabolism and Transport 1391
- Inflammatory Disorders 1392
- Portal Hypertension 1394
- Metabolic Disorders 1394

Disorders of the gastrointestinal (GI) tract and liver in children include congenital anomalies with structural and functional alterations, enzyme deficiencies, and infections. These disorders lead to impairment of normal digestive function and often affect growth and development.

Disorders of the Gastrointestinal Tract

Congenital Impairment of Motility

Congenital impairments of motility can occur throughout the GI tract. Here they are presented in order by location, starting with the mouth and esophagus, through the stomach and small intestine, and into the large intestine, rectum, and anus.

Mouth and Esophagus

Cleft lip and cleft palate

There are numerous types of congenital orofacial anomalies, the most common of which is **cleft lip (CL)** or **cleft palate (CP)**, or both (CLP). In the United States, the estimated prevalence of CL with CP is about 1 in every 1600 live births. Prevalence of CL alone was 1 in every 2800 live births, and approximately 1 in every 1700 babies are born with CP. The prevalence of CP is consistent across all ethnicities. However, the prevalence of CL alone and CL with CP is highest in American Indian or Alaska Natives and lowest in African Americans in the United States. Male to female ratio of CL/P is 2:1, while male to female ratio of CP is 1:2.[1,2] CL, CP, or CL/P can be classified

as nonsyndromic or syndromic. Overall, 70% of are **nonsyndromic** clefting disorders, which are complex genetic and environmental phenomena. Nonsyndromic occur as isolated cases without any additional physical or cognitive deficits. In contrast, 30% of clefts are syndromic. **Syndromic** clefting disorders are associated with single gene mutations or deletions and are associated with other congenital malformations.[3]

Pathophysiology

CL and CP are the most common craniofacial malformation of the newborn. CL, CP, and CL/P differ in their embryonic development, etiology, and genetic associations. There are a variety of cellular mechanisms, such as cell proliferation, cell migration, cell growth, cell fusion, apoptosis, epithelial-mesenchymal transition, and extracellular remodeling, that are involved in a coordinated manner during the development of lip and palate.[4] Disruption in the gene(s) involved in these processes during lip and palate development may lead to CL, CP, or CL/P.[4] Epigenetic and genetic influences include maternal use of tobacco, exposure to smoke, alcohol intake, medication use (such as anti-seizure agents, corticosteroids, anti-nausea drugs, and methotrexate), B vitamin deficiency (B_6, folic acid, B_{12}), maternal obesity, gene mutations of the amniotic band sequence, maternal exposure to viral illness or radiation, and chronic disease conditions such as diabetes.[5] CL and CP also may be syndromic, and therefore may be associated with other malformations (e.g., cardiac, skeletal, or central nervous system). Together the genetic and epigenetic factors reduce the amount of neural crest mesenchyme that migrates into the area that will develop into the face of the embryo.[4] Orofacial clefts are categorized by location, degree of lip involvement, and the presence or absence of a CP.[5]

Cleft lip is caused by the incomplete fusion of the nasomedial or intermaxillary process beginning the fourth week of embryonic development, a period of rapid development. The cleft causes structures of the face and mouth to develop without the normal restraints of encircling lip muscles. The facial cleft may affect not only the lip but also the external nose, nasal cartilages, nasal septum, and alveolar processes. The cleft is usually just beneath the center of one nostril. The defect may occur bilaterally and may be symmetrical or asymmetrical. The more complete the CL, the greater the chance that teeth in the line of the cleft will be missing or malformed.

Cleft palate is often associated with CL but may occur without it. The fissure may affect only the uvula and soft palate or may extend forward to the nostril and involve the hard palate and the maxillary alveolar ridge. It may be unilateral or bilateral, with the cleft occupying the midline posteriorly and as far forward as the alveolar process (the ridge of bone that holds the teeth), where it deviates to the involved side. Clefts involving the palate only are usually, but not necessarily, in the midline. In some cases, the vomer (the small, thin bone separating the left and right nasal cavities) and nasal septum are partly or completely undeveloped. When these facial bones are involved, the nasal cavity may freely communicate with the oral cavity.

Clinical Manifestations

Clefts of the lip or palate, or both, are immediately recognizable disruptions of normal facial structure (Fig. 42.1). The most common type of CL is unilateral with or without a CP.[5] Feeding difficulty is the most significant clinical manifestation because of the oronasal communication and inability to generate negative pressure needed for normal sucking. There also may be swallowing and speech difficulty. Children with any cleft abnormalities have an increased risk for middle ear infections and may have recurrent otitis media.[6] Individuals with CL, CP, or CL/P may suffer appearance-related distress secondary to the facial disfiguration.[7]

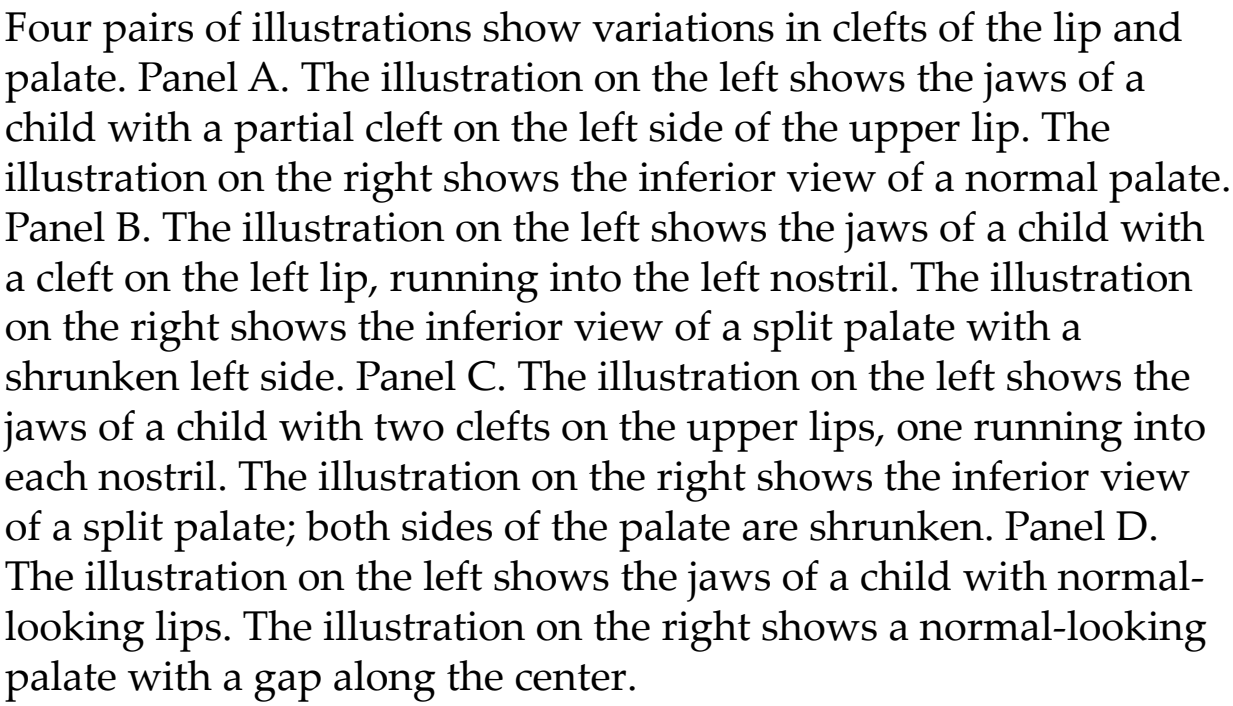
(A) Notch in the vermilion border. **(B)** Unilateral cleft lip and palate. **(C)** Bilateral cleft lip and cleft palate. **(D)** Cleft palate.



Evaluation and Treatment

Prenatal diagnosis is made by ultrasound, and postnatal imaging confirms the extent of bone deformity. Soft tissue alterations are evaluated by history and physical examination. The oral palate should be carefully examined for a translucent appearance, an elevation of the palate during phonation, and possibly a bifid uvula.[5] A speech therapist should evaluate the child's speech articulation and phonology, making note of hypernasality.[5] Children with CL, CP, or CL/P require long-term complex and coordinated care.[5] The nature and extent of the cleft, the infant's condition, and the method of surgical correction proposed determine the course of treatment. Surgical correction is planned at about the third to sixth month and may be performed in stages.

Feeding the infant with CL usually presents no difficulty if the CL is simple and the palate intact. An infant with a complete CP requires consultation with a feeding and swallowing specialist to ensure adequate and safe nutritional intake. Bottles with nipples specialized for feeding an infant with a CP are required. Breast-feeding is encouraged and recommended; therefore, a certified lactation consultant should be offered to the mother.[5,8] An orthodontic prosthesis for the roof of the mouth may facilitate sucking for some infants. Parental education and support are required for the long-term care of children with CP. Longitudinal monitoring requires a

multidisciplinary team, including an oral and maxillofacial surgeon, dentist, orthodontist, otolaryngologist, neurosurgeon, geneticist, nutritionist, speech therapist, and child development specialist.[5]

Esophageal malformations

Congenital malformations of the esophagus are rare and often occur with other congenital malformations. **Esophageal atresia (EA)**, where the esophagus ends in a blind pouch, is the most common congenital malformation involving the esophagus. **Atresia** is an absence or abnormal narrowing of a passage, in this case the esophagus, during embryonic development. EA is often accompanied by a fistula (an abnormal connection) between the esophagus and the trachea **(tracheoesophageal fistula [TEF])**. Either defect can occur alone, although isolated TEF is very rare (Fig. 42.2). Environmental risk factors include maternal exposure to methimazole (used to treat an overactive thyroid), exogenous sex hormones, infectious diseases, alcohol, or smoking; maternal diabetes; advanced maternal age; and maternal employment in agriculture or horticulture.[9] EA and TEF may be associated with congenital vertebral, anorectal, cardiovascular, renal, and limb malformations (collectively known as the VACTERL association).[10] EA and TEF also are commonly present with other birth defects, such as trisomy 13, 18, or 21.

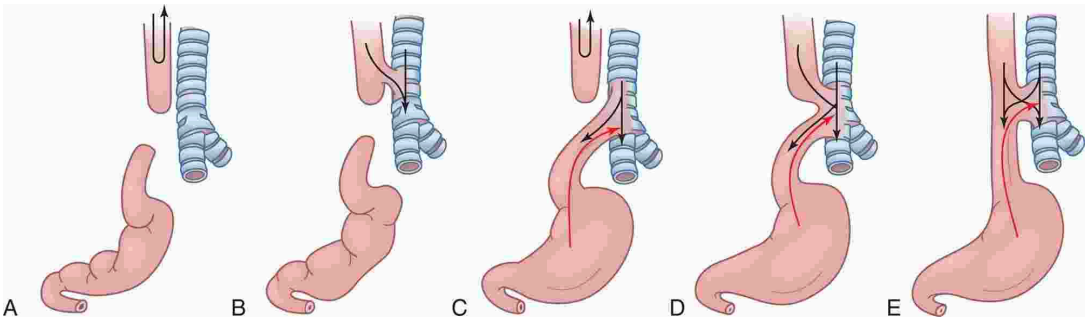


FIG. 42.2 Five Types of Esophageal Atresia and Tracheoesophageal Fistulae.
(A) Simple esophageal atresia. The proximal esophagus and distal esophagus end in blind pouches, and there is no tracheal communication. Nothing enters the stomach; regurgitated food and fluid may enter the lungs. **(B)** Proximal and distal esophageal segments end in blind pouches, and a fistula connects the proximal esophagus to the trachea. Nothing enters the stomach; food and fluid enter the lungs from the mouth. **(C)** Proximal esophagus ends in a blind pouch, and a fistula connects the trachea to the distal esophagus. Air enters the stomach; regurgitated gastric secretions enter the lungs through the fistula. **(D)** A fistula connects both proximal and distal esophageal segments to the trachea. Air, food, and fluid enter the stomach and the lungs from the mouth; regurgitated gastric secretions enter the lungs through the fistula. **(E)** A simple tracheoesophageal fistula is present between an otherwise normal esophagus and trachea. Air, food, and fluid enter the stomach and the lungs from the mouth through the fistula; regurgitated gastric secretions enter the lungs through the fistula. Of esophageal anomalies, 85% to 90% are the type shown in (C); 6% to 8% are the type shown in (A); 3% to 5% are the type shown in (E); and fewer than 1% are the types shown in (B) and (D).

Pathophysiology

The pathogenesis of esophageal abnormalities is unknown, but viral, infectious, environmental, and genetic factors have been suggested.[11] Defective growth of endodermal cells and impaired embryonic foregut development of the trachea and esophagus lead to atresia.[12]

Clinical Manifestations

The diagnosis of EA/TEF during pregnancy increases with the findings of polyhydramnios (excessive amniotic fluid) on ultrasound. Swallowed amniotic fluid is usually absorbed into the placental circulation; therefore, if the fetus cannot

swallow, amniotic fluid accumulates in the uterus. Many cases are not detected during the prenatal period. EA is diagnosed at birth on the basis of drooling, inability to swallow secretions, or choking with feeding, and respiratory distress. Confirmation is established by inability to pass a gastric tube into the stomach and radiographic evidence of the gastric tube curled up within the distal pouch. If a fistula connects the trachea with the distal esophagus, the abdomen fills with air and becomes distended, possibly interfering with breathing (see Fig. 42.2C–E). Intermittent cyanosis may result.

Pulmonary complications are compounded by reflux of air and gastric secretions into the tracheobronchial tree through the fistula, causing severe chemical irritation. Infants with EA but no fistulae have scaphoid (boat-shaped), gasless abdomens. In infants with fistulae, but without atresia (see Fig. 42.2E), the usual symptoms are recurrent aspiration, pneumonia, and atelectasis that remains unexpressed for days or even months.

Evaluation and Treatment

EA is rarely diagnosed during pregnancy and most often is detected after birth when the neonate has difficulty feeding and often has choking or vomiting. To assist the child with feeding, a tube is inserted in the baby's nose or mouth, but it cannot pass down into the stomach because of EA or TEF. An x-ray can confirm where the upper esophagus ends.[13] Infants presenting with EA are further evaluated with ultrasound, echocardiogram, and vertebral and limb radiographs.

After diagnosis, a tube should be placed into the upper pouch and continuous suction applied to reduce the risk of aspiration. The head of the bed should be elevated slightly to assist drainage of the upper pouch. The infant should not be fed orally. The surgical options for EA/TEF repair include open thoracotomy or video-assisted thoracoscopic surgery. The best radical surgical treatment for EA with TEF is primary single-staged correction comprising esophagoesophagostomy and TEF division. However, the procedure is generally performed in a staged manner for infants with unstable respiratory or cardiovascular conditions.[14]

The overall survival rate for infants with esophageal defects is greater than 90%; however, it is dependent on the extent of associated abnormalities.[15] Children will require life-long follow-up as respiratory and gastrointestinal (GI) complications occur frequently.[16,17]

Infantile hypertrophic pyloric stenosis

Infantile hypertrophic pyloric stenosis (IHPS) is an acquired narrowing and distal obstruction of the pylorus and a common cause of postprandial (after a meal) vomiting. It is the most common cause of intestinal obstruction in infancy. The etiology of IHPS is unknown, but genetic and environmental factors, bottle feeding, younger maternal age, maternal smoking, and erythromycin administration in the first two weeks of life have shown associations with the disease.[18,19]

Pathophysiology

Individual muscle fibers of the longitudinal and circular muscles thicken, so the entire pyloric sphincter becomes enlarged and inflexible.[20] The mucosal lining of the pyloric opening is folded and narrowed by the encroaching muscle. Because of the extra peristaltic effort necessary to force the gastric contents through the narrow opening, the muscle layers of the stomach may become hypertrophied as well.

Clinical Manifestations

Within 2 to 3 weeks after birth, an infant who has fed well and gained weight begins forceful, nonbilious vomiting immediately after feeding. The infant then demands to be refed. Constipation occurs because little food reaches the intestine.

In severe, untreated cases, increased gastric peristalsis and vomiting lead to dehydration and electrolyte imbalances, malnutrition, weight loss, and shock that can be life-threatening. Infants with pyloric stenosis are irritable because of hunger, and they may have esophageal discomfort caused by repeated vomiting and esophagitis. The vomitus may be blood streaked because of rupture of gastric and esophageal vessels.

Evaluation and Treatment

The diagnosis is based on the history, clinical manifestations, and findings on abdominal ultrasound. The force or "projectile" vomiting and the timing of the vomiting can help distinguish IHPS from gastroesophageal reflux (for which episodes of vomiting are not forceful and occur 10 minutes or more after a feeding). The hypertrophied pylorus is palpable as a firm, small, movable mass, approximately the size of an olive, and is felt in the right upper quadrant in 70% to 90% of infants with pyloric stenosis. A visible gastric peristaltic wave after eating is observed in some infants. The hypertrophied pyloric muscles and narrowed pyloric channel are identified with ultrasound. A fluoroscopic upper GI series may be necessary if the physical exam and ultrasound are inconclusive. Gastric decompression by nasogastric tube may be required for comfort and to clear the stomach for further evaluation and treatment.

The standard treatment for IHPS is a laparoscopic pyloromyotomy, in which the muscles of the pylorus are split and separated. Preoperative and postoperative medical management to correct fluid and electrolyte imbalance has been the key to the high success and low complication rates associated with this surgery.[21]

Obstructions of the duodenum, jejunum, and ileum

High intestinal obstruction should be considered whenever persistent vomiting occurs. With duodenal obstruction there will be upper abdominal distention, visible peristaltic waves, a decrease in the size and frequency of meconium stools, progressive weight loss, persistent vomiting, and dehydration. Congenital obstruction of the duodenum is rare and can be caused by intrinsic malformations, such as atresia (complete blockage), stenosis (partial obstruction or narrowing), or external pressure (choledochal cyst or annular pancreas). Duodenal obstruction may be partial or complete and is usually located at or near the major duodenal papilla (the opening of

the common bile duct and pancreatic duct into the duodenum). The classic "double bubble" sign is seen on imaging of the abdomen and represents dilation associated with duodenal obstruction. The larger, proximal "bubble" is air in a dilated stomach. The more distal, smaller "bubble" is air in a dilated proximal duodenum. There is usually little or no air in the bowel distal to the obstruction. Double bubble also may be seen on prenatal ultrasounds.

Congenital obstructions of the jejunum and ileum can be attributable to atresia, stenosis, meconium ileus, megacolon (Hirschsprung disease), intussusception, Meckel diverticulum, intestinal duplication, or strangulated hernia. In ileal or jejunal atresia, the intestine ends blindly, proximal and distal to an interruption in its continuity, with or without a gap in the mesentery. Stenosis (narrowing of the lumen) causes dilation proximal to the obstruction and luminal collapse distal to it.

Intestinal malrotation

Intestinal malrotation is a common congenital anomaly of the small intestine. Once thought to be a disease of infancy, newer epidemiologic evidence supports presentation of intestinal rotation in children up to 17 years of age. The majority of cases (approximately 75%) will present before the age of 5.[22] Associated abnormalities are common and include duodenal, jejunal, or biliary atresia; pancreatic malformations; and heart defects.[23]

Pathophysiology

During normal embryonic development, the ileum and cecum rotate into the lower right abdominal quadrant and are fixed there by the mesentery. In malrotation, this rotation does not occur and the small intestine lacks a normal posterior attachment (Fig. 42.3). The mobile loops of intestine can twist upon themselves (volvulus), leading to symptoms of bowel obstruction. The twisting can partly or completely occlude the superior mesenteric artery, causing infarction and necrosis of the entire midgut. Additionally, abnormal periduodenal (Ladd) bands may press against and obstruct the duodenum.

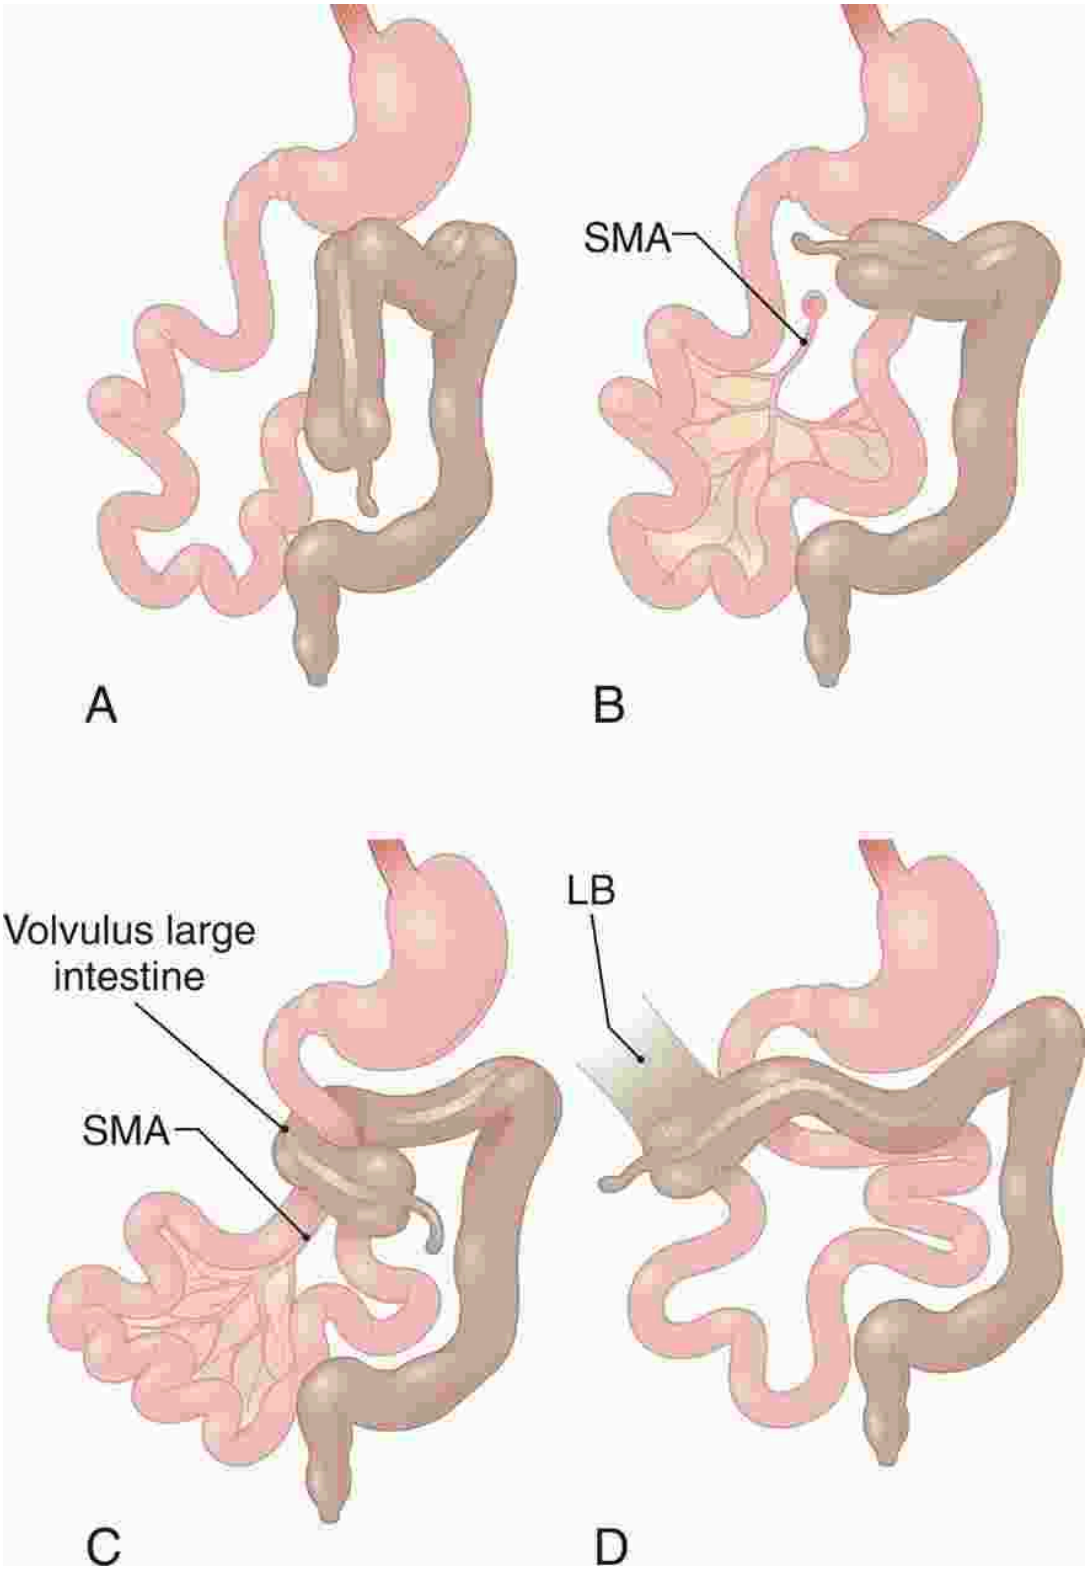

FIG. 42.3 Variations of Intestinal Malrotation.
(A) Nonrotation. **(B)** Incomplete rotation. **(C)** Midgut volvulus with duodenal obstruction and obstruction of superior mesenteric artery

blood flow. **(D)** Incomplete rotation with Ladd bands extending from the lateral and posterior abdominal wall to the subhepatic cecum. *LB*, Ladd band; *SMA*, superior mesenteric artery. (From Gilbert-Barness E, et al. *Potter's pathology of the fetus, infant and child*, 2nd edition. Philadelphia, PA: Mosby; 2007

Clinical Manifestations

Classic symptoms in infants are intermittent or persistent bile-stained vomiting after feedings and epigastric distention. Dehydration and electrolyte imbalance may occur rapidly. Fever usually ensues, with pain and scanty stools. Diarrhea and bloody stools are associated with progressive volvulus, vascular compression, and infarction of the intestine. Intermittent or partial volvulus may be seen in older children and adults. It may be asymptomatic or cause minor abdominal discomfort and be discovered during unrelated abdominal surgery.[24]

Evaluation and Treatment

The diagnosis of malrotation with volvulus and infarction is based on clinical manifestations. Radiographic films of the abdomen and barium studies show intestinal gas bubbles and distention proximal to the site of obstruction. Asymptomatic infants with complex birth defects of the heart, lungs, liver, spleen, or intestines should be screened for intestinal malrotation with a contrast upper GI study.[24] Ultrasound imaging has also been used with good success and avoids exposure to ionizing radiation.[25]

Treatment includes laparoscopic or open Ladd procedure to reduce the volvulus.[26] Necrotic bowel is resected and a primary anastomosis performed. An intestinal diversion (ostomy) may need to be created. Most children have a good outcome; however, there is risk for adhesion-related bowel obstruction in a small number of cases. Resection of large segments of the small intestine results in short bowel syndrome, a malabsorption syndrome with diarrhea, dehydration, and malnutrition.[27]

Meckel diverticulum

Diverticula are small outpouches, or sacs, that have formed and pushed outward through weak spots of the intestinal wall. **Meckel diverticulum** is a true diverticulum in that it contains all layers of the wall of the intestine, usually the ileum. It is a remnant of the embryonic yolk sac and is the most prevalent congenital abnormality of the small bowel. Ectopic (abnormal location) gastric mucosal cells are contained in the diverticula and may cause peptic ulcer and painless bleeding or mimic colonic diverticulitis. Often referred to as "the rule of 2 s," a Meckel diverticulum occurs in approximately 2% of the general population, is typically located within 2 feet of the ileocecal valve (on the antimesenteric border of the ileum), is 2 inches in length on average, and its clinical symptomatology often occurs before 2 years of age.

Although most Meckel diverticula are generally asymptomatic, symptomatic Meckel diverticula can present as obstruction of the small bowel, fever, vomiting, abdominal pain, or painless rectal bleeding. Diagnosis can be made by symptom presentation and imaging studies. Radionucleotide scintigraphy shows the gastric mucosal cells in the diverticula. Treatment for symptomatic Meckel's diverticula includes laparoscopic or open surgical resection. Treating asymptomatic Meckel's diverticula remains controversial.[28]

Obstruction of Large Intestine, Rectum, and Anus

Hirschsprung disease

Hirschsprung disease, or congenital aganglionic megacolon, is a functional obstruction of the colon. It is rare but the most common cause of colon obstruction in infants. The incidence is higher in males, siblings of children with Hirschsprung disease, and children with Down syndrome or other congenital malformations.[29]

Pathophysiology

The exact cause of Hirschsprung disease is unknown, but it is associated with multiple interacting factors, including gene mutations and epigenetic mechanisms. The congenital malformation results from failure of neural crest cells to migrate into the GI tract. There is an absence of parasympathetic plexuses (Meissner and Auerbach plexuses) along variable lengths of the colon. Lacking neural stimulation, muscle layers fail to propel feces through the colon, leading to functional obstruction. This causes the proximal colon to become distended, hence the term *megacolon* is often used (Fig. 42.4). In most cases, the aganglionic segment is limited to the rectal end of the sigmoid colon. In rare cases, the entire colon lacks ganglion cells and the ileum may be involved.[30]

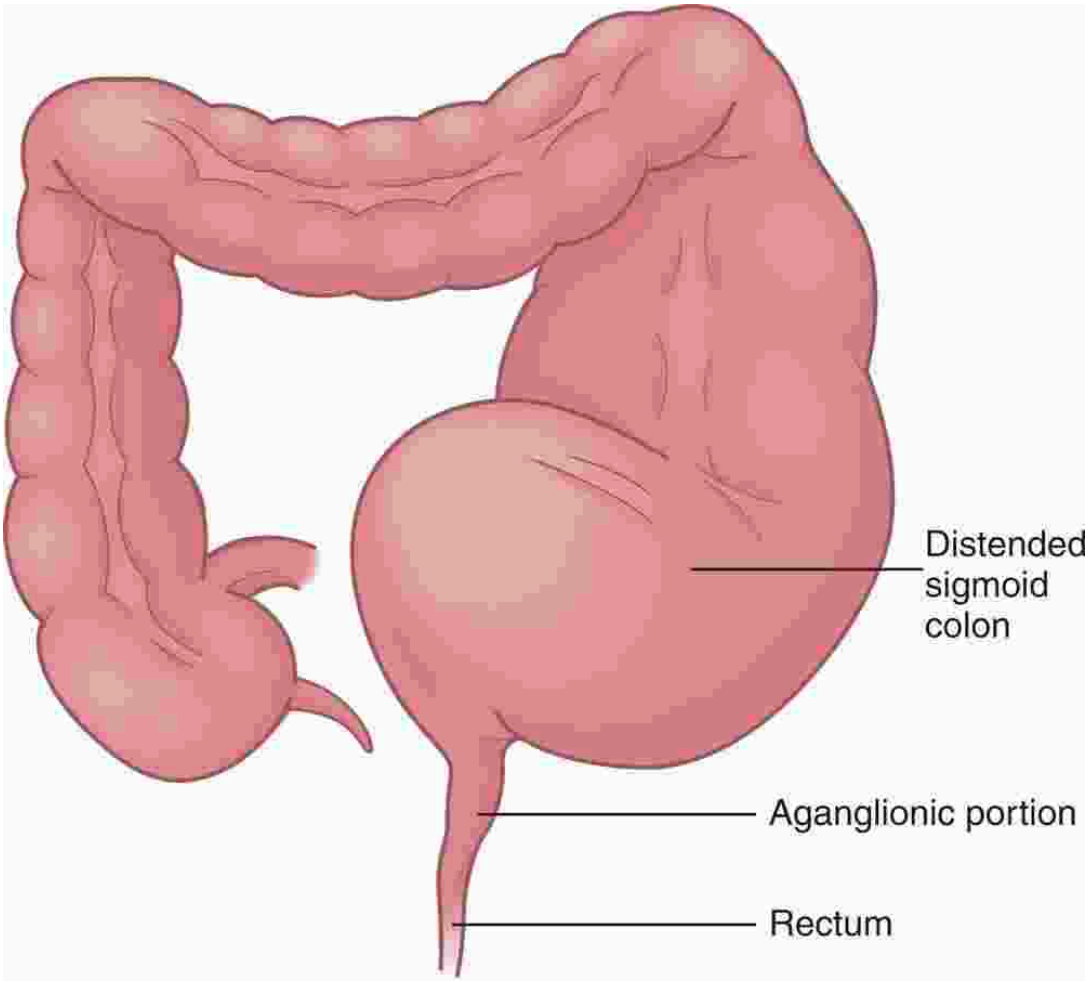

FIG. 42.4 Hirschsprung Disease.

Clinical Manifestations

The infant typically becomes symptomatic during the first 48 hours after birth with delayed passage of meconium. Children with less severe disease may not be diagnosed until 3 years of age. Mild to severe constipation is the usual manifestation accompanied by poor feeding, poor weight gain, and progressive abdominal distention. However, diarrhea may be the first sign because only water can travel around the impacted feces.[31]

The most serious complication in the neonatal period is enterocolitis related to fecal impaction. This presents with sepsis-like symptoms of fever, abdominal distension, vomiting, and diarrhea. The intestinal inflammation is related to fecal impaction, alterations in intestinal microbiota, impaired mucosal barrier function, and innate immunity with bacterial translocation.[32,33]

Bowel dilation stretches and partly occludes the encircling blood and lymphatic vessels, causing edema, ischemia, infarction of the mucosa, and significant outflow of fluid into the bowel lumen. Copious liquid stools result. Infarction and destruction of

the mucosa enable enteric microorganisms to penetrate the bowel wall and gram-negative sepsis can occur. Severe and rapid fluid and electrolyte changes may take place, causing hypovolemic or septic shock or death.

Evaluation and Treatment

Radiocontrast enema and anorectal manometry are screening tools for the diagnosis of Hirschsprung disease. The definitive diagnosis is made by rectal biopsy, showing an absence of ganglion cells in the submucosa of the colon. Surgery is the definitive treatment in all cases of Hirschsprung disease. In general, the prognosis of congenital megacolon is satisfactory for children who undergo surgical treatment. Bowel training may be prolonged; most children achieve bowel continence before puberty, but some have long-term constipation or fecal incontinence that can adversely affect their quality of life.[34]

Distal intestinal obstruction syndrome**Distal intestinal obstruction syndrome (DIOS)**, formerly called *meconium ileus equivalent*, is the partial or complete obstruction of the terminal ileum and proximal colon by abnormally viscous intestinal contents. The condition is unique to children with cystic fibrosis (CF).

Pathophysiology

The epithelium of the intestine secretes chloride and inhibits sodium absorption, which will force fluid into the lumen. This is a similar mechanism as is seen in the epithelium of the lungs. Defective CF transmembrane conductance regulator (CFTR) function disrupts this fluid homeostasis resulting in intestinal fluid imbalance.[35] This is coupled with insufficient pancreatic enzyme activity, causing malabsorption of fat. This leads to impaired motility that causes slow intestinal transit and altered viscosity of the bowel contents.[36] The terminal ileum or proximal colon becomes plugged with thick, sticky meconium resulting from the formation of abnormal mucus. The segment of the ileum proximal to the obstruction is distended with liquid contents, and its walls may be hypertrophied. The segment distal to the obstruction is collapsed and filled with small pellets of pale-colored stool. Meconium in the obstructed segment has the consistency of thick syrup or glue. Peristalsis fails to propel this sticky material through the ileum, so it becomes impacted.

Clinical Manifestations

Abdominal distention usually develops during the first few days after birth. The distention increases as air is swallowed. The infant does not pass meconium and begins to vomit bile-stained material within hours or days of birth. Infants with CF may have signs of pulmonary involvement, such as tachypnea, intercostal retractions, and grunting respirations. The distended abdomen shows patterns of dilated intestinal loops that feel dough-like when palpated. Some of the loops contain scattered, firm, movable masses. Despite hyperactive peristalsis, the rectal ampulla is empty.

Evaluation and Treatment

Radiologic examination confirms the presence of meconium in the ileum or ileocecum and is typically described as "bubbly" or granular in appearance. The sweat test, which measures the amount of chloride in the sweat, is performed to detect or rule out CF and is accurate in 90% of infants. In cases not complicated by volvulus or perforation, the obstruction is relieved by intestinal lavage and administration of oral laxatives. If this is not possible, the meconium is removed surgically. Survival of infants with simple meconium ileus is improving, with rates approaching 100%. Mortality of infants increases if the obstruction is complicated by peritonitis. DIOS is treated with hydration and stool softeners.[37]

Anorectal malformations

Anorectal malformations (ARMs) represent a spectrum of rare anomalies of the anus and rectum (Fig. 42.5). ARMs include anorectal stenosis, imperforate anus, anorectal atresia, and rectal atresia. Persistent cloaca (an embryonic component of the hind gut) is the most severe type of anorectal malformation and occurs exclusively in girls. The rectum, urethra, and vagina fail to develop separately; instead, they drain through a single, common channel onto the perineum.[38] Infants with anorectal malformations may have other developmental anomalies (e.g., Down syndrome, Hirschsprung disease, duodenal atresia, neurogenic bladder, and spinal malformations).

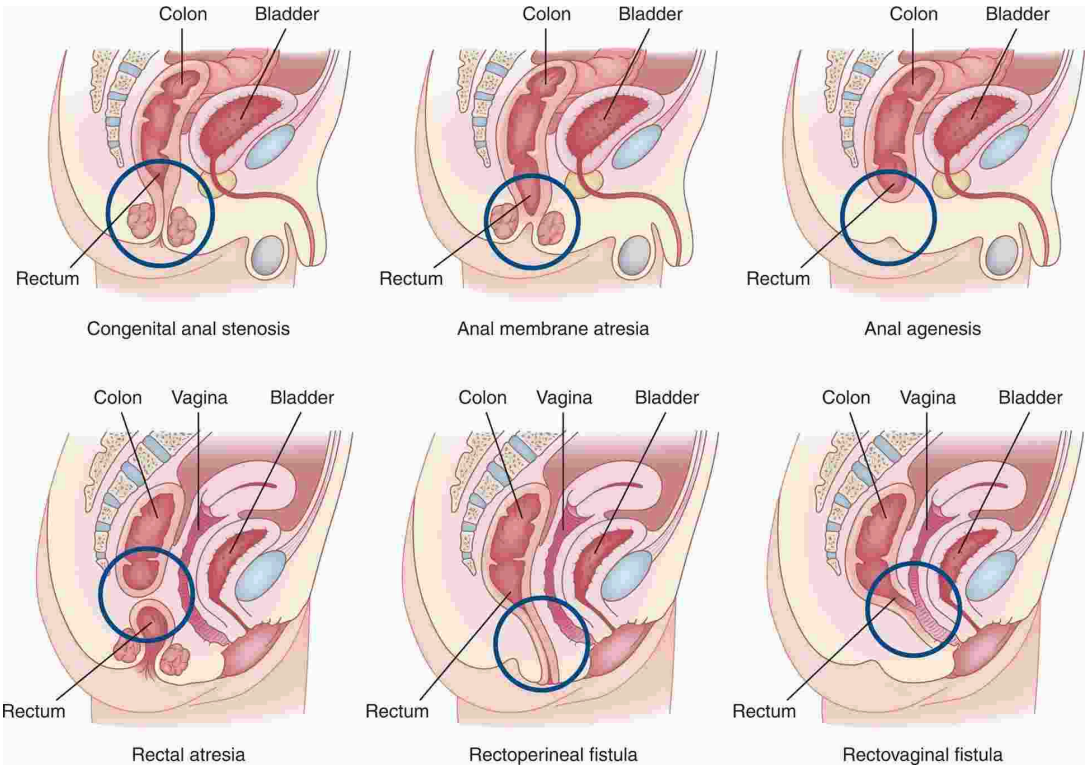

FIG. 42.5 Anorectal Stenosis and Imperforate Anus. Except for the rectovaginal fistula, all of the malformations shown occur in both males and females.

A series of illustrations shows anorectal stenosis and imperforate anus. Top-left panel, congenital anal stenosis. The colon, bladder, and rectum are labeled. The rectum is closed. Top-middle panel, anal membrane atresia. The colon, bladder, and rectum are labeled. The rectum rectum has a membrane closing the rectal opening. Top-right panel, anal agenesis. The colon, bladder, and rectum are labeled. The rectal sac end before the opening. Bottom-left panel, rectal atresia. The colon, vagina, bladder, and rectum are labeled. The rectum is split. Bottom-middle panel, rectoperineal fistula. The colon, vagina, bladder, and rectum are labeled. The rectum rectum is split with lower sac connected to rectal opening. Bottom-right panel, rectovaginal fistula. The colon, vagina, bladder, and rectum are labeled. The rectum connects with vaginal canal.

Most ARMs are identified in routine physical examination during the neonatal period. Ultrasound and magnetic resonance imaging (MRI) can assist prenatal diagnosis. Types of **imperforate anus** include an anal opening that is narrow or misplaced; a membrane (covering) may be present over the anal opening; the rectum may not connect to the anus; the rectum may connect to part of the urinary tract or to the reproductive system through a *fistula*; or the anal opening is not present. Treatment recommendations depend on the type of imperforate anus, the presence and type of associated abnormalities, and the child's overall health status. Infants with an imperforate anus and other anorectal malformations require surgical correction. Outcomes are affected by the type of malformation, sacral development, and presence of spinal abnormalities.[39]

Meconium Syndromes

Meconium is a substance that fills the entire intestine before birth. It is a dark greenish mass of desquamated cells, mucus, and bile that accumulates in the bowel of a fetus and is typically discharged during the first 12 to 48 hours after birth.

Meconium ileus (MI) is an intestinal obstruction in the neonatal period caused by meconium formed in utero that is abnormally thick and sticky, which leads to a partial or complete obstruction at the level of the terminal ileum. There are two forms of MI: simple and complex. In simple MI, thickened meconium accumulates and obstructs the ileum causing proximal dilatation, bowel wall thickening, and congestion. Complex MI is associated with bowel atresia, volvulus, necrosis, or perforation and is a surgical emergency. MI occurs in up to 20% of infants with CF. It is thought to result from abnormal mucus production in the intestine or impaired pancreatic enzymes, or both.[40]

Meconium plug syndrome (MPS), also termed *functional immaturity of the colon*, is a transient disorder of the newborn colon characterized by an inability to pass meconium within 24 to 48 hours following delivery along with radiographic evidence of intestinal dilation. Plugs of meconium are found in the distal ileum and proximal colon, resulting in obstruction of passage of meconium from the rectum. There may be an association with MPS in prematurity, mothers with diabetes, and mothers who received magnesium sulfate.[41]

Meconium aspiration syndrome occurs following intestinal peristalsis, meconium release, and contamination of amniotic fluid associated with fetal hypoxia. Gasping respirations cause aspiration of the contaminated amniotic fluid deep into the fetal lung. Infants present with respiratory distress with expiratory airway obstruction, air trapping, surfactant inactivation, atelectasis, and chemical pneumonitis. Meconium aspiration also predisposes to infection and the development of persistent patent ductus arteriosus and foramen ovale.[42] The presence of meconium-stained amniotic fluid and the clinical presentation help confirm the diagnosis. Treatment includes surfactant administration, oxygen, inhaled nitric oxide, and ventilator support.[43]

Acquired Impairment of Motility

Gastroesophageal Reflux and Gastroesophageal Reflux Disease

Gastroesophageal reflux (GER) is the passage of gastric contents into the esophagus with or without regurgitation and/or vomiting.[44] GER is normal and nonpathologic in healthy infants and children. Most episodes are asymptomatic and without long-term consequence. The frequency of GER is highest in premature infants and peaks at 4 months of age in healthy infants. GER will subside in 90% of cases by 12 months of age.[45]

GER disease (GERD) is different from GER and is considered pathologic. It occurs when GER induces troublesome symptoms or complications, such as esophagitis or structuring, that affect daily functioning.[44] Children at greatest risk for complicated GERD are those with other underlying medical conditions including prematurity, neurologic impairment, EA, obesity, hiatal hernia, achalasia, chronic lung diseases, and certain genetic disorders, including CF.[44]

Pathophysiology

GERD is influenced by genetic, environmental, anatomic, hormonal, and neurogenic factors. Although transient lower esophageal sphincter relaxations (TLESRs) are the most common pathophysiologic cause of GERD, inadequate adaptation of sphincter tone to changes in abdominal pressure also may be implicated. Factors that maintain lower esophageal sphincter integrity in children include the location of the gastroesophageal junction in a high-pressure zone within the abdomen, mucosal gathering within the sphincter, and the angle at which the esophagus is inserted into the stomach. Reflux persists if any one of these pressure-maintaining factors is altered. Other mediators of GERD are esophageal peristalsis or clearance, mucosal resistance that mediates the noxiousness of the refluxate, and delayed gastric emptying. Reflux of acidic gastric contents results in inflammation of the esophageal epithelium (esophagitis) and stimulation of the vomiting reflex.

Clinical Manifestations

The clinical manifestations of GERD will differ in accordance with the age of the child. Infants with GERD will present with symptoms of irritability, sleep disturbance, excessive regurgitation, hematemesis, unexplained crying, back arching, food refusal or anorexia, and failure to thrive (FTT).[44] Children may present with decreased food intake, weight loss, and abdominal or epigastric pain. Older children and adolescents will present similarly to adults with heartburn and regurgitation.[44] Esophageal complications of GERD can be significant, such as esophagitis, hemorrhage, stricture, Barrett esophagus (see Chapter 41), and, rarely, adenocarcinoma. Extraesophageal symptoms include cough, wheezing, stridor, laryngitis, pharyngitis, dental erosions, sinusitis, recurrent otitis media, and Sandifer syndrome (a neurologic disorder characterized by unusual posturing).[44] This

constellation of symptoms is often difficult to distinguish from those of cow's milk protein allergy, which may coexist with or overlap GERD.[46]

Evaluation and Treatment

The clinical manifestations are often adequate to confirm a diagnosis of GERD. Barium contrast studies may be beneficial to exclude anatomical abnormalities but are not recommended to diagnose GERD in children. There is insufficient evidence to support the use of pH metry for the diagnosis of GERD, but it can be useful to correlate troublesome symptoms and determine the efficacy of acid suppression therapy.[44]

In breast-fed babies, maternal elimination of cow's milk protein is recommended, whereas formula-fed infants may require feeding volume and frequency adjustments using extensively hydrolyzed protein or amino acid–based formulas. Using thickened feedings is recommended for treating visible regurgitation and/or vomiting in infants with GERD. Prone positioning is recommended only for infants older than 1 year of age because of the risk of sudden infant death syndrome. Lifestyle changes for children and adolescents include weight loss, smoking cessation, sleeping position changes, and avoidance of caffeine, chocolate, alcohol, and spicy foods. Medications are used to buffer or reduce gastric acid secretion, increase motility, or increase lower esophageal sphincter pressure to treat GERD. If no improvement is seen with medical management or the child has life-threatening events with reflux, an anti-reflux surgical procedure, including gastropexy and fundoplication, is performed.[44]

Eosinophilic Esophagitis

Pediatric **eosinophilic esophagitis (EoE)** is an emerging chronic, local, progressive antigen- immune-mediated relapsing disease caused by eosinophilic infiltration of the esophageal mucosa, belonging to a group of eosinophilic GI disorders.[47–49] EoE is an atopic inflammatory disease and often referred to as the "asthma of the esophagus" due to the similar clinical and pathophysiologic characteristics.[50] EoE is the most prevalent cause of esophagitis after GERD.[47] The incidence and prevalence of EoE have sharply increased globally within the last 20 years.[49]

Pathophysiology

The pathogenesis of EoE is complex and still not completely understood. The onset of disease involves a multitude of factors including genetics, immunity, the environment, as well as damaged mucosa and fibrosis mechanisms. Eosinophils are recruited to specific sites of the esophagus by cytokines and begin remodeling esophageal tissues. It is likely EoE is associated with T-helper cell-2 (Th2) type of immune response seen in other atopic conditions.[47] High levels of Th2 cytokines, mast cells, and interleukins 4, 5, and 13 have been found in esophageal biopsies of individuals with EoE.[47]

Clinical Manifestations

The symptoms associated with EoE are dependent on the age at presentation.[47] The typical clinical manifestations associated with EoE include dysphagia and food impaction.[47] Infants and toddlers may have feeding difficulties, such as prolonged feeding time, food refusal, or GERD-like symptoms, and in advanced stage can present as FTT.[49] School-aged children and adolescents may present with dysphagia, food impaction, and gagging with meals. It is important to identify any history of food or environmental allergens as this is a common trigger of mucosal inflammation and hence the recruitment of eosinophils.[47] Children may have atopic diathesis or a predisposition to develop one or more of the following: allergic rhinitis, hay fever, bronchial asthma, or atopic dermatitis.[49]

Evaluation and Treatment

A comprehensive evaluation of EoE can be performed by using one of the scoring systems developed. The Pediatric Eosinophilic Esophagitis Symptoms Score correlates with histologic activity, and the Pediatric Quality of Life Inventory EoE is a valid symptomatic measure in children.[49] Diagnosis is confirmed by the demonstration in biopsy specimens obtained through upper endoscopy of eosinophilic inflammation (more than 15 for high powered field) of the esophageal mucosa and other histologic features.[47] Endoscopic features change from childhood to adulthood. Chronic inflammation drives a progressive fibrosis and esophageal modeling.[49]

Therapeutic approaches to treatment include eliminating triggers, medications, dietary interventions, and esophageal dilation.[49,51] Identification, management, and elimination of food allergens and aeroallergen sensitivities is an important step in the prevention of flares.[47] Children with EoE should be advised to take small bites and chew food slowly and completely, making sure to consume fluids in between each bite. Foods lubricated with sauces may assist with food passage down the esophagus. Proton pump inhibitors can be used in the treatment for EoE, with about one-third of individuals responding to this therapy.[47] Corticosteroids are a mainstay therapeutic treatment for EoE because of the anti-inflammatory effects, which decrease esophageal fibrosis and remodeling and improve the integrity of the esophageal mucosal barrier.[49,51] Complications such as strictures, esophageal rings, and narrowing of the esophagus can occur if EoE is left untreated.[47] In some cases, EoE strictures require endoscopic dilation.[51]

Intussusception

Intussusception is the telescoping of a proximal segment of intestine into a distal segment, causing an obstruction. It is rare but the most common cause of small bowel obstruction in children in the United States. Most cases occur between 5 and 7 months of age. Intussusception is more common in males and can occur in children with polyps or tumors (lead points), CF, Meckel diverticulum, intestinal adhesions, or immediately after abdominal surgery. There is a small risk of intussusception

associated with rotavirus vaccination, but the health benefits of the vaccine far exceed the risk of intussusception.[52]

Pathophysiology

In intussusception, the ileum commonly telescopes into the cecum and part of the ascending colon by collapsing through the ileocecal valve, although intussusception can occur anywhere from the duodenum to the rectum. The proximal portion of the intestine (the intussusceptum) telescopes into the distal portion (the intussuscipiens) in the direction of peristaltic flow (Fig. 42.6). The intussusceptum then drags its mesentery into the enveloping lumen, causing an intussusception. Initially, the mesentery is constricted, obstructing venous return. Compression of the mesenteric vessels between the two layers of intestinal wall and at the U-shaped angle at either end of the intussusceptum leads to venous stasis, engorgement, edema, exudation, and further vascular compression within hours. The tension of the mesentery on the intussusceptum tends to arch the bowel in a curve with its center at the mesenteric root. Edema and compression obstruct the flow of chyme through the intestine. Unless the intussusception is treated, bleeding, necrosis, and bowel perforation ensue.

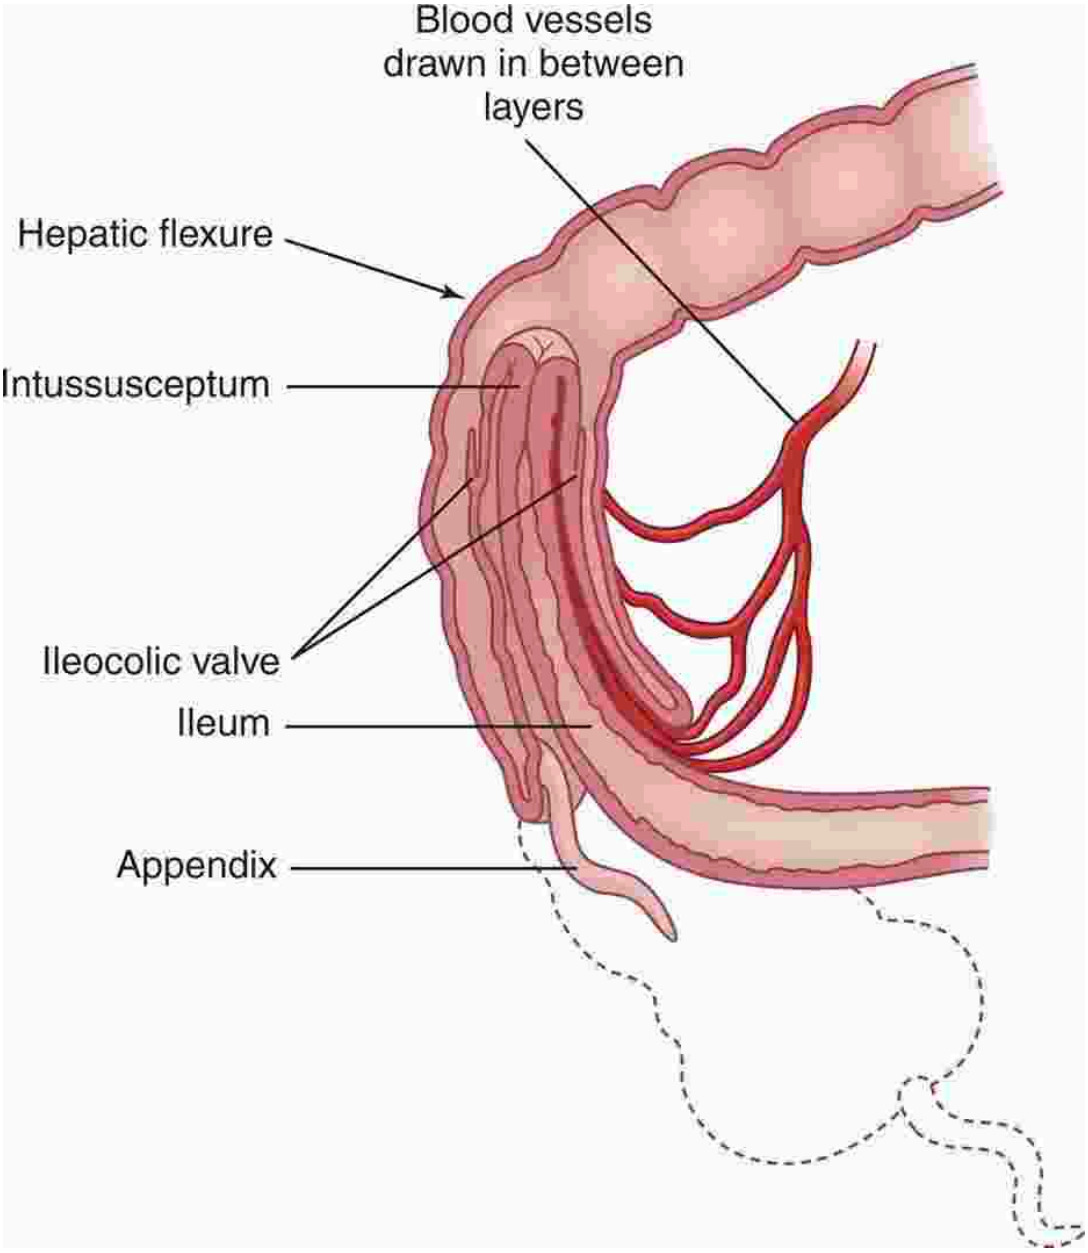

FIG. 42.6 Ileocolic Intussusception.
Dotted outline indicates normal anatomy.

Clinical Manifestations

The classic symptoms of intussusception include colicky abdominal pain, irritability, knees drawn to the chest, abdominal mass, vomiting, and bloody (currant jelly) stools. In children older than 1 year, abdominal pain is the most common symptom. In children younger than 1 year, vomiting, irritability, and bloody stools are the most common symptoms.[53]

Intussusception has been discovered incidentally by computed tomography (CT) or MRI scan for other indications. Abdominal tenderness and distention develop as intestinal obstruction becomes more acute.

Evaluation and Treatment

The diagnosis is based on clinical manifestations, the onset of symptoms, and ultrasonographic or radiologic imaging studies. Ultrasonography is highly sensitive and specific for the diagnosis of intussusception and appears to be diagnostically superior to radiographs.[53,54]

In a stable child the obstructive area can be successfully reduced with the use of an enema (air or liquid). However, if the child is unstable or presents with peritonitis, bowel perforation, or shock, then surgical intervention is necessary.

Open laparotomy with manual reduction is commonly performed. Untreated intussusception in infants is nearly always fatal. Most infants recover if the intussusception is reduced within 24 hours. Spontaneous reduction of intussusception may occur in symptomatic or asymptomatic children.[55,56]

Appendicitis

Appendicitis is the most common cause of emergency abdominal surgery in children. The mechanisms of disease, symptoms, and treatment are similar to those for adults and can be reviewed in Chapter 41. Most cases of appendicitis will occur in the second decade of life. Children typically present differently from adults, especially children under the age of 6. This puts them at greatest risk for perforation.[57]

Impairment of Digestion, Absorption, and Nutrition

Cystic Fibrosis

CF is an autosomal recessive disease of the exocrine glands that involves multiple organ systems but mostly the GI and respiratory systems. CF causes a shortened lifespan and prognosis is determined mainly by the degree of pulmonary involvement. This section focuses on GI complications of CF. (Chapter 36 discusses the epidemiology and pulmonary involvement.)

Pathophysiology

The GI presentation of CF is caused by a dysfunction of the CF transmembrane regulator (CFTR) protein, which is located on epithelial membranes and regulates chloride and sodium ion channels. It is found throughout the airways, sweat glands, digestive tract, pancreas, hepatobiliary system, and reproductive system. The hallmark pathophysiologic triad of CF is obstruction, infection, and inflammation that are evident throughout the GI tract. The full extrapulmonary spectrum of involvement is summarized in Table 42.1.

Table 42.1

Cystic Fibrosis—Pathophysiology, Clinical Manifestations, and Complications

Organ Involved	Secretory Dysfunction	Clinical Manifestations	Complications
Sweat Glands	Elevated concentrations of sodium and chloride in sweat	Hyponatremia; hypochloremia	Heat prostration; shock
Digestive System			
Esophagus	None	Gastroesophageal reflux	Risk for aspiration events
Intestine			
Newborn	Viscid meconium	Meconium ileus with intestinal obstruction	Meconium peritonitis
Older child and adult	Inspissated (dried out) mucofecal masses (intestinal sludging)	Partial intestinal obstruction with severe cramping pains	Gastroesophageal reflux Volvulus (obstruction), intussusception (prolapse) Distal intestinal obstruction syndrome
Pancreas (enzyme deficiency)	Inspissation and precipitation of pancreatic secretions, causing obstruction of pancreatic ducts Insulin deficiency	Absence of pancreatic enzymes, causing malabsorption of food; fatty, bulky stools Decreased vitamins A, D, E, and K absorption Growth failure	Hypoproteinemia; iron deficiency anemia; malnutrition Recurrent pancreatitis, pancreatic cysts Vitamins A, D, E, and K deficiency

Organ Involved	Secretory Dysfunction	Clinical Manifestations	Complications
		Glucose intolerance	and rectal prolapse Decreased bone density and risk of fractures in adolescents and adults Diabetes mellitus
Liver	Inspissation and precipitation of bile in biliary system	Focal biliary cirrhosis; shrunken, "hobnail" liver	Portal hypertension with esophageal varices, hematemesis and hypersplenism Hepatic steatosis Focal biliary cirrhosis Steatorrhea from lack of bile salts
Salivary glands	Inspissation and precipitation of secretions in small ducts of submaxillary and sublingual salivary glands	Mild patchy fibrosis of salivary glands	None
Respiratory System			
Paranasal structures	Viscid mucus	Retention of mucus; clouding seen on sinus roentgenograms	Mucopyoceles (pus accumulations) with nasal deformity or orbital cavity extension

Organ Involved	Secretory Dysfunction	Clinical Manifestations	Complications
Nose	Nasal polyps	Obstruction of nasal airflow	None
Lungs	Viscid mucus in bronchioles and bronchi	Obstruction of bronchioles causing bronchiolectasis, bronchiectasis, and chronic lung infection	Hemoptysis; pneumothorax; cor pulmonale; atelectasis; chronic bacterial infection; respiratory failure
Reproductive System			
Male	Viscid genital tract secretions during embryologic development, causing failure of formation of normal vas deferens	Delayed puberty Sterility	None
Female	Distention of endocervical epithelial cells with cytoplasmic mucin	Delayed puberty Decreased fertility	Polypoid cervicitis (cervical inflammation) while taking oral contraceptives

Organ Involved	Secretory Dysfunction	Clinical Manifestations	Complications
Sweat Glands	Elevated concentrations of sodium and chloride in sweat	Hyponatremia; hypochloremia	Heat prostration; shock
Digestive System			
Esophagus	None	Gastroesophageal reflux	Risk for aspiration events
Intestine			
Newborn	Viscid meconium	Meconium ileus with intestinal obstruction	Meconium peritonitis
Older child and adult	Inspissated (dried out) mucofecal masses (intestinal sludging)	Partial intestinal obstruction with severe cramping pains	Gastroesophageal reflux Volvulus (obstruction), intussusception (prolapse) Distal intestinal obstruction syndrome
Pancreas (enzyme deficiency)	Inspissation and precipitation of pancreatic secretions, causing obstruction of pancreatic ducts Insulin deficiency	Absence of pancreatic enzymes, causing malabsorption of food; fatty, bulky stools Decreased vitamins A, D, E, and K absorption Growth failure Glucose intolerance	Hypoproteinemia; iron deficiency anemia; malnutrition Recurrent pancreatitis, pancreatic cysts Vitamins A, D, E, and K deficiency and rectal prolapse Decreased bone density and risk of fractures in adolescents and adults Diabetes mellitus
Liver	Inspissation and precipitation of bile in biliary system	Focal biliary cirrhosis; shrunken, "hobnail" liver	Portal hypertension with esophageal varices, hematemesis and hypersplenism Hepatic steatosis Focal biliary cirrhosis Steatorrhea from lack of bile salts
Salivary glands	Inspissation and precipitation of secretions in small ducts of submaxillary and sublingual salivary glands	Mild patchy fibrosis of salivary glands	None
Respiratory System			
Paranasal structures	Viscid mucus	Retention of mucus; clouding seen on sinus roentgenograms	Mucopyoceles (pus accumulations) with nasal deformity or orbital cavity extension
Nose	Nasal polyps	Obstruction of nasal airflow	None
Lungs	Viscid mucus in bronchioles and bronchi	Obstruction of bronchioles causing bronchiolectasis, bronchiectasis, and chronic lung infection	Hemoptysis; pneumothorax; cor pulmonale; atelectasis; chronic bacterial infection; respiratory failure
Reproductive System			
Male	Viscid genital tract secretions during embryologic development, causing failure of formation of normal vas deferens	Delayed puberty Sterility	None
Female	Distention of endocervical epithelial cells with cytoplasmic mucin	Delayed puberty Decreased fertility	Polypoid cervicitis (cervical inflammation) while taking oral contraceptives

Data from Assis DN, Freedman SD. Gastrointestinal disorders in cystic fibrosis. *Clinics in Chest Medicine*, 2016;37(1):109–118; Lavelle LP, McEvoy SH, Ni Mhurchu E, et al. Cystic fibrosis below the diaphragm: Abdominal findings in adult patients. *Radiographics*, 2015;35(3):680–695; Leeuwen L, Fitzgerald DA, Gaskin KJ. Kliegman RM, eds. *Nelson essentials of pediatrics*, 7th edition. Philadephia: Saunders; 2014; Stalvey MS, Clines GA. Cystic fibrosis-related bone disease: Insights into a growing problem. *Current Opinion in Endocrinology, Diabetes and Obesity*, 2013;20(6):547–552.

Dysfunction of the CFTR protein results in altered sodium, chloride, and potassium resorption, all of which remain external to the surface of the epithelial membrane, with reduced clearance from tubular structures lined by affected epithelia. Maldigestion of proteins, carbohydrates, fats, and fat-soluble vitamins occurs because mucus obstruction of the pancreatic ducts blocks the flow of pancreatic enzymes, causing intestinal malabsorption and degenerative and fibrotic changes in the pancreas and GI tract. **Cystic fibrosis-related diabetes (CFRD)** is the most common comorbidity of CF. Pancreatic islet cells are lost, which leads to insulin and glucagon deficiency, insulin resistance, delayed gastric emptying, and altered intestinal motility.[58]

Clinical Manifestations

Clinical manifestations are summarized in Table 42.2. Newborn screening programs have changed the standard of diagnosis for CF. Traditionally, the diagnosis of CF was based on the presence of clinical features. Early diagnosis can now be made before clinical symptoms appear, which has led to modernized and streamlined interventions.[59,60]

Table 42.2

Galactosemia, Fructosemia, and Wilson Disease

	Galactosemia	Fructosemia	Wilson Disease
Mechanism of disease	Deficiency of galactose-1-phosphate uridylyltransferase Autosomal recessive trait Cannot convert galactose to glucose Toxic accumulation of galactose in body tissues, liver, and brain	Deficiency of fructose-1-phosphate aldolase Autosomal recessive trait Cannot metabolize fructose, sucrose, or honey; occurs when breast milk is replaced with cow's milk Toxic accumulation of fructose in body tissues	Defect in copper excretion by liver Autosomal recessive: defect on chromosome 13 (ATP 7B) Impaired transport of copper into bile/blood caused by diminished transport protein (ceruloplasmin) Toxic accumulations of copper in liver, brain, kidney, corneas
Clinical manifestation	High levels of blood galactose Vomiting Hypoglycemia May have failure to thrive Symptoms of cirrhosis at 2–6 months—jaundice	High levels of blood fructose Vomiting Hypoglycemia May have failure to thrive Hepatomegaly Jaundice	Intention tremors Indistinct speech Dystonia Greenish yellow rings in cornea Hepatomegaly Jaundice

	Galactosemia	Fructosemia	Wilson Disease
	Intellectual disabilities if not treated Cataracts if not treated	Seizures	Anorexia Renal tubular defects
Evaluation	Newborn screening Presence of reducing substances in urine when infant is receiving lactose	Detailed dietary history Liver or intestinal mucosa biopsy	Low plasma ceruloplasmin level
Treatment	Galactose-free diet	Fructose-, sucrose-, honey-free diet Vitamin C supplementation	Chelation therapy to remove copper from body Decreased dietary intake of copper Liver transplantation

	Galactosemia	Fructosemia	Wilson Disease
Mechanism of disease	Deficiency of galactose-1-phosphate uridylyltransferase Autosomal recessive trait Cannot convert galactose to glucose Toxic accumulation of galactose in body tissues, liver, and brain	Deficiency of fructose-1-phosphate aldolase Autosomal recessive trait Cannot metabolize fructose, sucrose, or honey; occurs when breast milk is replaced with cow's milk Toxic accumulation of fructose in body tissues	Defect in copper excretion by liver Autosomal recessive: defect on chromosome 13 (ATP 7B) Impaired transport of copper into bile/blood caused by diminished transport protein (ceruloplasmin) Toxic accumulations of copper in liver, brain, kidney, corneas
Clinical manifestation	High levels of blood galactose Vomiting Hypoglycemia May have failure to thrive Symptoms of cirrhosis at 2–6 months—jaundice Intellectual disabilities if not treated Cataracts if not treated	High levels of blood fructose Vomiting Hypoglycemia May have failure to thrive Hepatomegaly Jaundice Seizures	Intention tremors Indistinct speech Dystonia Greenish yellow rings in cornea Hepatomegaly Jaundice Anorexia Renal tubular defects
Evaluation	Newborn screening Presence of reducing substances in urine when infant is receiving lactose	Detailed dietary history Liver or intestinal mucosa biopsy	Low plasma ceruloplasmin level

GI symptoms, such as meconium ileus, often precede pulmonary manifestations. Most of those with CF present early in life with pancreatic insufficiency (PI). PI is the cause of nutrient malabsorption and FTT in children with CF. Steatorrhea (fatty stools) and abdominal distention are common symptoms with potential sequelae that include DIOS, fibrotic colonopathy, intussusception, or focal biliary cirrhosis. Children who are pancreatic sufficient (PS) are at greater risk of developing pancreatitis.

Evaluation and Treatment

All states in the United States screen newborns for CF using a blood test to detect immunoreactive trypsinogen (IRT). Genetic screening and the sweat test are required for diagnosis. Evaluation of pancreatic sufficiency also is essential. The extent of pancreatic function is determined by 72-hour fecal fat measurements, which are not easily obtained. Therefore, the most common measurement of fat malabsorption is fecal elastase. A serum test for IRT also can be used to detect PI in children older than 8 years of age, and various combinations of tests, including IRT, deoxyribonucleic acid (DNA) CF, pancreatitis-associated protein (PAP), and CFTR-extended genetic analysis (EGA), are being used in some states and countries.[59,61]

The goal of treatment for PI is to reduce malabsorption of nutrients and improve growth. Most children with CF take pancreatic enzyme replacement therapy (PERT) for the rest of their lives. PERT is administered before or with every meal, snack, or enteral feeding supplementation. High doses of PERT are associated with DIOS; therefore, minimal effective doses are indicated. High-caloric, high-protein diets with frequent snacks and vitamin supplements are used to treat malnutrition. Nutritional status and growth should be carefully monitored, and growth hormone may be included with nutritional supplements.[62,63]

Celiac Disease

Celiac disease (CD), also known as *celiac sprue* or *gluten-sensitive enteropathy*, is an autoimmune disease that damages small intestinal villous epithelium when gluten (gliadin), the protein component of wheat derivatives, barley, or rye, is ingested. CD is a common multiorgan disease with a strong genetic predisposition. It is associated with certain human leukocyte antigens (HLAs): HLA-DQ2 and HLA-DQ8. **Nonceliac gluten sensitivity (GS)** should not be confused with CD. It presents similarly after the ingestion of products containing gluten. The individual will not have positive antibodies, nor will they exhibit the classic intestinal villous atrophy. Instead, there will be variable HLA status with similar symptoms of the disease.[64] IgE-mediated wheat allergy is a gluten-related disorder, with GI manifestation in younger children (vomiting and/or diarrhea), and dermatitis and wheezing in older children.[65]

The pathogenesis of CD is complex and involves genetic and immunologic factors. Environmental factors include early infections, gut microbiota in infants, feeding patterns, and the timing and amount of gluten. CD presents with greater frequency in children with type 1 diabetes mellitus, autoimmune thyroid or liver disease, Down syndrome, Turner syndrome, Williams syndrome, selective immunoglobulin A (IgA) deficiency, Addison disease, and in those with first-degree relatives with CD. Individuals with CD are also at greater risk for non-Hodgkin's lymphoma and, rarely, small intestinal adenocarcinoma.[66]

Pathophysiology

The major pathophysiologic characteristic of CD is an HLA-DQ2- or HLA-DQ8-induced CD4+ T-cell-mediated autoimmune injury to the small intestinal epithelial cells of genetically susceptible individuals. There are increased numbers of intraepithelial lymphocytes, atrophy and flattening of villi, crypt hyperplasia in the upper small intestine, and malabsorption of most nutrients in the presence of gluten (Figs. 42.7 and 42.8). Atrophy is caused by accelerated shedding of epithelial cells from the villi. To compensate for this loss, epithelial cell production increases, causing hypertrophy of the crypts and Lieberkühn. Increased cell production is not sufficient to keep pace with cell loss, and the cells are not mature enough to sustain absorptive functions. The microvilli and crush border disappear, leaving patches of bald mucosa. The loss of mucosal surface area and brush-border is pronounced in the duodenum

and jejunum. The ileum may be spared. The severity of the disease correlates with the length of the small intestinal mucosa involved.[67,68]

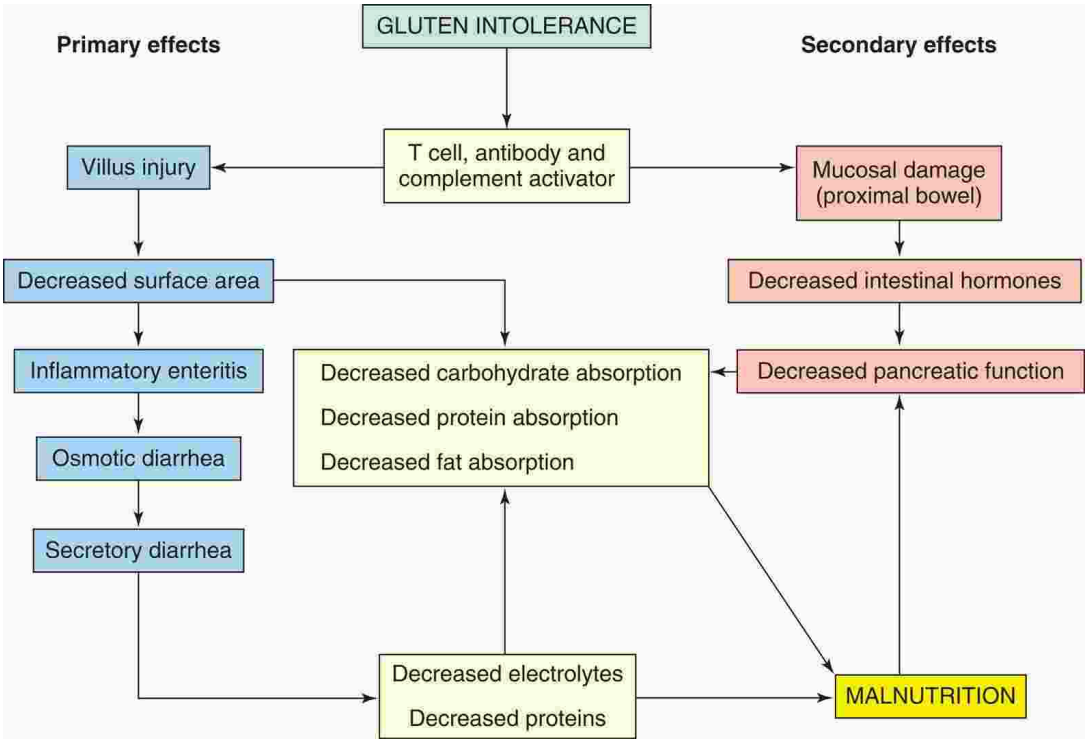

FIG. 42.7 Pathophysiology of Celiac Disease.

A flowchart shows the pathophysiology of celiac disease. 1. Gluten intolerance. Leads to 2. 2. T cell, antibody and complement activator. Leads to 5 and 10. 3. Decreased carbohydrate absorption; decreased protein absorption; and decreased fat absorption. Lead to 13. 4. Decreased electrolytes and decreased proteins. Leads to 3 and 13. 5. Villus injury. Leads to 6. 6. Decreased surface area. Leads to 3 and 7. 7. Inflammatory enteritis. Leads to 8. 8. Osmotic diarrhea. Leads to 9. 9. Secretory diarrhea. Leads to 4. 10. Mucosal damage (proximal bowel). Leads to 11. 11. Decreased intestinal hormones. Leads to 12. 12. Decreased pancreatic function. Leads to 3. 13. Malnutrition. Leads to 12.

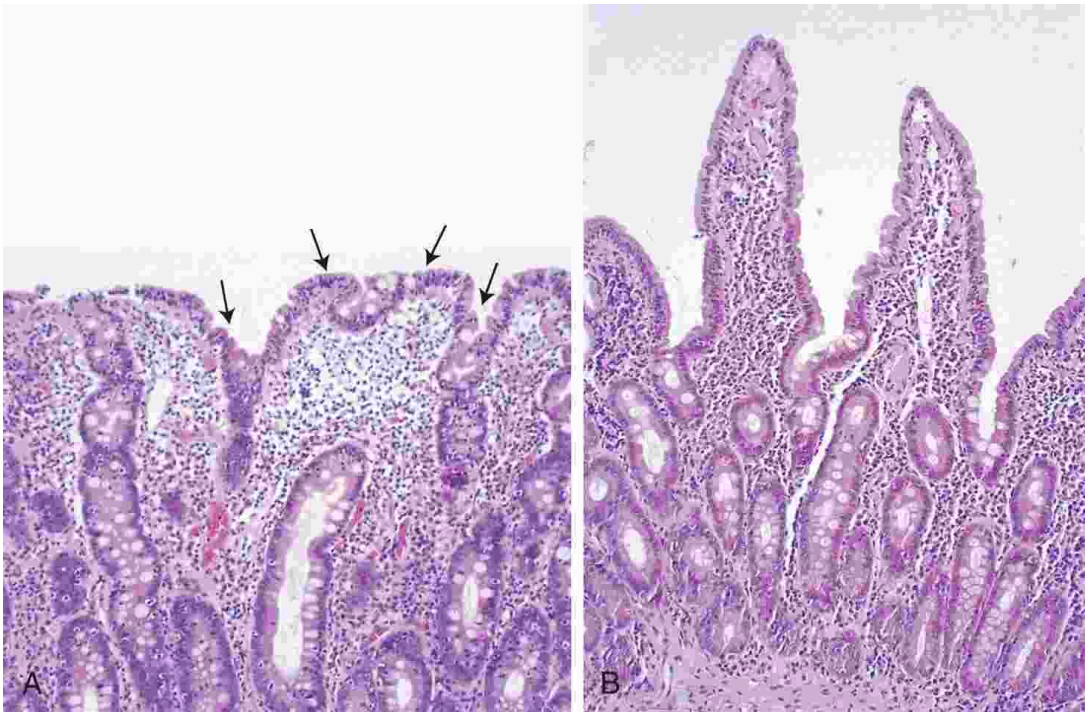

FIG. 42.8 Gluten – Sensitive Enteropathy.
(A) Atrophy of villi and elongation of crypts that result in reduced surface area, loss of digestive enzymes, and malabsorption. **(B)** Recovery of normal villous structure after 6 months of gluten-free diet. (From Damjanov I, Linder J. *Pathology: A color atlas*. St. Louis, MO: Mosby; 2000.)

Damage to the mucosa of the duodenum and jejunum exacerbates malabsorption. The secretion of intestinal hormones, such as secretin and cholecystokinin, may be diminished. Consequently, secretion of pancreatic enzymes and expulsion of bile from the gallbladder are reduced, contributing to malabsorption. Destruction of mucosal cells causes inflammation, and water and electrolytes are secreted, leading to watery diarrhea. Potassium loss leads to muscle weakness. Magnesium and calcium malabsorption can cause seizures or tetany. Unabsorbed fatty acids combine with calcium, and secondary hyperparathyroidism increases phosphorus excretion, resulting in bone reabsorption. Calcium is no longer able to bind oxalate in the intestine and is absorbed, which causes hyperoxaluria. Gallbladder function may be abnormal, and bile salt conjugation may decrease.

Fat malabsorption in the jejunum is the major cause of steatorrhea (fatty stools). Deficiencies of fat-soluble vitamins are common in children with CD. Vitamin K malabsorption leads to hypoprothrombinemia. There can be iron and folic acid malabsorption manifested as cheilosis, anemia, and a smooth, red tongue. Vitamin B_{12} absorption is impaired in those with extensive ileal disease. Because the absorption of folate and iron is greatest in the proximal small intestine, deficiencies of these substances are common.

Clinical Manifestations

The onset of clinical manifestations of CD are dependent on the age of the infant when gluten-containing substances are added to the diet. This can make diagnosis difficult. It is not uncommon for a person to be diagnosed later in life. Severity of symptoms can vary tremendously and depend on the age of the child. Abdominal pain, abdominal distention, anorexia, and diarrhea are early signs in most infants, which result in FTT and anemia. The stools are pale, bulky, greasy, and foul smelling, and many contain oil droplets. Some children present with constipation. Many untreated children older than 3 years of age present with non-GI symptoms related to malabsorption and malnutrition and the effect of autoantibodies on nonintestinal tissues.[69,70] Older children typically do not present with vomiting and abdominal pain; however, anorexia is prevalent. Extraintestinal manifestations of malabsorption, such as rickets, tetany, frank or occult bleeding, or anemia may be obvious. Some children will have increased nocturia. The tongue can be smooth and red, and the child may bruise and bleed easily. Hypomagnesemia and hypocalcemia cause irritability, tremor, convulsions, tetany, bone pain, osteomalacia, and dental abnormalities. If vitamin D deficiency is prolonged, rickets and clubbing of the terminal phalanges are likely. In older children, delayed puberty and infertility may be a manifestation of otherwise subtle gluten-sensitive enteropathy. There is an increased incidence of malignant disease, particularly T-cell lymphoma, in individuals who have refractory CD.[71]

Evaluation and Treatment

The diagnosis includes confirmation with serologic autoantibody measurement against tissue transglutaminase IgA (most sensitive and specific), antiendomysium IgA, or deaminated gliadin peptides, which are more sensitive in children younger than 2 years of age. A negative genetic screening for HLA haplotypes rules out CD. If an autoantibody or genetic screen is positive, a small duodenal biopsy sample may be obtained to check for the classic mucosal changes caused by CD.[69,72]

A wide variety of screening tests for malabsorption also may be useful. Even though very useful screening tools are available to diagnose CD, many children remain undiagnosed.[73–75]

Treatment consists of lifelong adherence to a gluten-free diet (GFD), which includes the elimination of wheat, rye, barley, and malt. Lactose (milk sugar) intolerance also may be present from damage to villi; therefore, lactose also may be excluded from the diet but should be resumed after treatment. Infants are routinely given fat-soluble vitamins, iron, and folic acid supplements to treat deficiencies. Most children have complete remission of symptoms with clearing of serologic markers and an excellent prognosis. Refractory CD, which is resistant to a GFD treatment, is rare and may require steroids or immunosuppressants. Steroid or immunosuppressants may be required in special cases.[76,77]

Malnutrition

Pediatric malnutrition is an imbalance between nutrient requirements (energy expenditure) and intake that results in energy, protein, and micronutrient deficits that impair growth and development. Malnutrition may involve impaired absorption, altered nutrient utilization, increased nutrient losses, or increased nutrient requirements (hypermetabolism). Severe or moderate acute or chronic illnesses can contribute to the development of malnutrition, including surgery, trauma, burns, and chronic diseases (e.g., CF, tuberculosis, chronic kidney disease, malignancies, congenital heart disease [CHD], GI diseases, and neuromuscular diseases). Malnutrition unrelated to illness develops from a lack of access to nutrients as a result of environmental factors (i.e., political/socioeconomic, inadequate food supplies, or food contaminated with parasites) or behavioral factors (e.g., anorexia nervosa). Malnutrition may be acute (less than 3 months' duration) or chronic (more than 3 months' duration).

Kwashiorkor (a deficiency of dietary protein) and **marasmus** (all forms of inadequate nutrient intake) are terms that have been used to describe types of malnutrition in children, particularly in developing countries. Collectively they are known as **protein-energy malnutrition (PEM**). PEM describes the effects of malnutrition but not the etiology or interactions that contribute to nutrient depletion. A definition of pediatric malnutrition that includes the etiology (illness or environmental), identification of pathogenesis and chronicity, associations with inflammation, and resulting impact on functional status is more directive for defining the risk of malnutrition, planning interventions, and assessing outcomes.[78] States of long-term starvation are often the result of widespread nutritional deficiencies among children in developing countries and economically destitute populations, particularly when associated with human immunodeficiency virus (HIV) infection. Malnutrition can occur in infants or children from 1 to 4 years of age who have been weaned from breast milk to a high-starch, protein-deficient diet or switched to overdiluted commercial formulas that lack adequate protein and carbohydrates.[79–81]

Hospitalized children are at risk for malnutrition. Acute illness, trauma, surgery, or preexisting chronic diseases contribute to malnutrition and requires assessment and intervention. Acute and chronic inflammatory states also increase nutrient requirements. Treatments, including radiation therapy, chemotherapy, and longer times on mechanical ventilation, also can contribute to malnutrition with increased hospital length of stay, and increased morbidity and mortality rates.[82]

Pathophysiology

The pathogenesis of marasmus is uncertain but includes inadequate dietary proteins, carbohydrates, fats, and micronutrients over a period of months or years. There is wasting of fat and muscle. It is the most common form of PEM. Young children are most susceptible because of increased caloric requirements. Children with marasmus demonstrate greater wasting of protein and fat stores, which is presented in the clinical manifestations.

The metabolic response in Kwashiorkor is different. Kwashiorkor is the result of inadequate protein intake, but a high carbohydrate intake, and is more common

where the diet is rice, corn, or beans. The liver swells with stored fat because no hepatic proteins are synthesized to form and release lipoproteins. Pancreatic atrophy and fibrosis may be present. Atrophy of intestinal villi and alterations in gut microbiota results in nutrient malabsorption and malnutrition. Malabsorption causes reduced bone density and impaired renal function. If the condition is not reversed, the prognosis is very poor and growth is severely retarded.

Children with malnutrition show stunting of gut microbiota maturation, which may delay normal development of the gut, depress intestinal immune function, and promote inflammation, leaky gut syndrome, and infection. Healthy gut bacteria also produce short-chain fatty acids, B vitamins, and vitamin K, and promotes the absorption of minerals important for maintaining the intestinal epithelium. Alterations in intestinal microbiota and immune dysregulation can cause leaky gut syndrome (compromised gut barrier) and intestinal inflammation. Atrophy of the thymus gland and tonsils with decreased T cell formation, synthesis of IgA, and impaired phagocytosis increase susceptibility for infection and poor tissue repair and regeneration.[83–85]

Clinical Manifestations

Children with marasmus have systemic muscle wasting and appear emaciated, and are weak and may have associated bradycardia, hypotension, and hypothermia. Anemia is common and can be severe. Their skin is wrinkled and loose from loss of subcutaneous fat. Metabolic processes, including liver function, are preserved, but growth is severely retarded; therefore, marasmus is characterized by low weight for height representation. Marasmus is not only characterized by muscle wasting, but children also may have diarrhea, dermatosis, low hemoglobin level, and infection. There is loss of subcutaneous fat and an absence of edema, whereas marked generalized edema is characteristic of Kwashiokor. Edema begins in the most dependent regions and proceeds toward the cranium as the process continues. The response to starvation includes low serum albumin (hypoproteinemia), increased cortisol, inability to activate antidiuretic hormone, and hypokalemia. The hair is dry, sparse, brittle, and depigmented, appearing reddish yellow. The skin can appear dry and shiny with areas of hyperpigmentation or hypopigmentation. Body weight may be normal and related to edema. Children also may have clinical manifestations of a distended abdomen, hepatomegaly, and almost normal weight for age (because of edema). Both conditions lead to delays in physical, behavioral, and cognitive development and academic performance. Finally, micronutrient deficiencies, especially with zinc, selenium, iron, and antioxidant vitamins, can lead to immune deficiency and infections. Severe vitamin A deficiency commonly results in blindness.[86–88]

Evaluation and Treatment

Evaluation of malnutrition is based on the nutritional history and clinical manifestations, including anthropometric measurements and use of appropriate growth charts. Laboratory monitoring is used to assess for macronutrient and

micronutrient deficiencies, aminotransaminase alterations, the presence of inflammation, and response to refeeding. Treatment of underlying disease and provision of deficient nutrients will resolve clinical symptoms in 4 to 6 weeks. Use of antibiotics has been shown to improve recovery and decrease mortality as severe caloric restriction causes an increased susceptibility to infection. This is secondary to immunodeficiency.[85]

Developmental sequelae of malnutrition may be irreversible; therefore, early intervention is recommended. Nutritional rehabilitation and adequate hydration with appropriate environmental stimulation for infants and young children has been shown to resolve or improve cerebral shrinkage, physical growth, and psychomotor development.

Faltering Growth (Failure to Thrive)

Faltering growth (previously known as FTT) is not a diagnosis but a physical sign demonstrating that a child has a slower rate of weight gain in childhood than expected for age and sex. It is manifested as a decrease in velocity in weight gain, a low weight/height or body mass index (BMI) ratio, or a low weight/height/head circumference ratio over time. Faltering growth is a common problem and can present at any time in childhood but is usually present before 18 months of age.[89]

Pathophysiology

Faltering growth is considered a multifactorial condition that includes biologic, psychosocial, and environmental contributions that may or may not be related to illness (Box 42.1). In more than 80% of cases, an underlying medical condition is never found. Categories of faltering growth include inadequate caloric intake, inadequate caloric absorption, or excessive caloric expenditure. Infants and children are at risk if their parents or primary caregivers are unable to provide nurturance.

Box 42.1

Factors Associated With Faltering Growth

Poverty (food insecurity related to lack of money)
Premature birth; low birth weight
Inadequate caloric intake or caloric absorption (infant feeding problems, underlying chronic disease or malabsorption syndromes)
Incorrect preparation of formula (too diluted, too concentrated)
Mechanical feeding difficulties (oromotor dysfunction, congenital anomalies, central nervous system disorders)
Unsuitable feeding habits (food fads, excessive juice)
Behavior problems affecting eating
Disturbed parent-child relationship; parental stress, parental lack of knowledge; child neglect

Data from Krishna A, et al: Glob Health Action 8:26523, 2015; National Guideline Alliance (UK): Faltering growth–recognition and management, London, UK; 2017, National Institute for Health and Care Excellence (UK); https://www.ncbi.nlm.nih.gov/books/NBK458459/.

Clinical Manifestations

Clinical manifestations of faltering growth are delayed growth accompanied by manifestations of malnutrition or an underlying disease (e.g., diarrhea or infectious disease, or both). Infants who present with faltering growth frequently have feeding problems. Symptoms include pallid or dry, cracked skin; sparse hair; poorly developed musculature; decreased subcutaneous fat; swollen abdomen with malabsorption, diarrhea, or anorexia; and signs of vitamin deficiencies, such as rickets. Social or emotional manifestations include reduced energy level, reduced responsiveness and interaction with the environment, social isolation, spasticity and rigidity when held or touched, inability to make eye contact or smile, refusal to eat, and rejection of foods. There may be long-term adverse effects on cognitive, behavioral, and academic performance.

Evaluation and Treatment

Faltering growth is a clinical finding as opposed to a diagnosis. Therefore, serial growth measurements over time are necessary. Underlying medical conditions should be thoroughly evaluated. If illness is ruled out, a thorough review of psychosocial, emotional, and environmental components of care is necessary. Screening tools are available to assist with evaluation of nutrition status and to guide therapy, particularly in hospitalized children.

Treatment for faltering growth includes treating an underlying illness if found, increasing volume or caloric density of formula, increasing frequency of breast-feeding (if found to be insufficient), structuring meals and snacks, and adding high-calorie foods and additives. Eliminating fruit juice, soda, or excessive milk also will improve appetite and absorption of nutrients. Medications are used to stimulate appetite. Nutrient deficiencies are supplemented. If the child is unable to gain weight, an oral enteral supplement may be added to the diet or a nasogastric or gastrostomy tube can be used to supplement oral intake.

If the cause is not medical, management involves the immediate total care of the child and measures to address (1) the psychosocial and emotional problems of the caregivers and (2) parent-child interactions. Counseling, parental modeling, and long-term family support are sometimes required. Hospital admission and evaluation are recommended if the diagnosis is unclear or the child is in nutritional or emotional jeopardy. Eating patterns, food preferences, caloric intake, and family interactions can be assessed and treatment plans implemented during the hospital stay.[89]

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is an ischemic, inflammatory condition that causes bowel necrosis and perforation. NEC is not a specific diagnosis but a constellation of signs and symptoms with several proposed etiologies. It is the most common severe

neonatal GI emergency that predominantly affects the smallest (weighing less than 1500 g) and most premature infants. The incidence and mortality of NEC have decreased over the past decade and have been attributed to improved risk assessments.[90]

Pathophysiology

The exact etiology of NEC is unclear. Factors contributing to the development of NEC include infections, abnormal bacterial colonization, intestinal ischemia, immature immune responses, exaggerated inflammatory responses, immature intestinal motility, altered microcirculatory blood flow and barrier function, perinatal stress, effects of medications, and feeding practices, including alterations in TLR4 expression (a pattern recognition receptor that triggers the NF-κB inflammatory pathway activating the innate immune system).[90]

The immature mucosal barrier delays digestion and motility is slower, allowing for the accumulation of noxious substances that damage the intestine, increase permeability, and increase the risk for infection. Translocation of intestinal bacteria and other substances contributes to injury, with inflammation, vasoconstriction of mesenteric blood flow, development of systemic inflammatory disease, multiple organ failure, and death. Immature intestinal innate immunity and an unfavorable balance between normal and pathogenic bacteria promote intestinal inflammation and release of proinflammatory cytokines. Accumulation of gas in the intestine can cause pressure that decreases blood flow, and an imbalance between vasodilator and vasoconstrictor inputs in the immature gut may lead to vasoconstriction promoting ischemia and oxidative stress, reperfusion injury, necrosis, and perforation.[91,92]

Clinical Manifestations

Manifestations of NEC usually appear suddenly and within weeks of premature birth, and sooner for term neonates. Signs and symptoms of "classic" NEC include feeding intolerance, abdominal distention and bloody stools after 8 to 10 days of age, septicemia with an elevated white blood cell count, and falling platelet levels. Unstable temperature, bradycardia, and apnea are nonspecific signs. In late preterm or term infants, NEC is more likely to be associated with other predisposing factors, such as low Apgar scores, chorioamnionitis, exchange transfusions, prolonged rupture of membranes, congenital heart defects, or neural tube defects.[93]

Evaluation and Treatment

Diagnosis is based on the clinical manifestations, laboratory results, and plain films of the abdomen. Symptoms usually progress rapidly, often within hours, from subtle signs to abdominal discoloration, intestinal perforation, and peritonitis, or even death. Abdominal radiographs show pneumoperitoneum, pneumatosis intestinalis (gas in the bowel wall), or unchanging "rigid" loops of small bowel. Systemic hypotension requires intensive medical support or bowel resection, or both. Efforts are in progress to identify predictive biologic markers for early diagnosis. Preventive strategies

include encouragement of breast milk feeding, preferential feeding of human milk, judicious fluid management to prevent vascular fluid overload, and confirmation of patent ductus arteriosus (see Chapter 33). Additional treatments include administration of amino acids (i.e., arginine and glutamine supplements) to support intestinal epithelial cell growth and enteral probiotics to support normal gut bacteria. The rapid onset of symptoms makes primary prevention difficult.[94,95]

Treatments include cessation of feeding, implementation of gastric suction to decompress the intestines, maintenance of fluid and electrolyte balance, and administration of antibiotics to control sepsis. Surgical resection is the treatment of choice for perforation, and peritoneal drainage may be used as an adjunct to laparotomy. Overall mortality is high, particularly for infants who have surgery.[96]

Diarrhea

Diarrhea is an increase in the water content, volume, or frequency of stools and can be acute or chronic. Diarrhea is usually defined as three or more watery or loose stools in 24 hours. Children with acute gastroenteritis often remain mildly symptomatic for up to 4 weeks; therefore, diarrhea that persists longer than 4 weeks is considered chronic. Diarrhea is a common GI problem during infancy and early childhood and is the leading cause of death in young children, particularly among preterm infants and children in developing countries.[97] Severe, acute infectious diarrhea occurs one to three times during the first 3 years of life. Most episodes are self-limiting and resolve within 72 hours.

The pathophysiologic mechanisms of diarrhea in children are similar to those described for adults: osmotic, secretory, intestinal dysmotility, or inflammatory (see Chapter 41). Prolonged diarrhea is more dangerous in infants and children, however, because they have much smaller fluid reserves and more rapid peristalsis and metabolism than adults. Therefore, dehydration in children can develop rapidly if any disturbance:

- increases fluid secretion into the GI lumen (secretory diarrhea).
- draws fluid into the lumen by osmosis (osmotic diarrhea).
- reduces intestinal transit time with luminal fluid retention (intestinal dysmotility).
- causes inflammation that results in malabsorption and an increased luminal osmotic load from nutrients, fluid, and blood, which may increase gut motility (inflammatory diarrhea).

There are numerous causes of diarrhea in infants and children, including viral, bacterial, and systemic infections; malabsorption syndromes; autoimmune disorders; congenital malformations; and genetic disorders. Acute infection is the most common cause of childhood diarrhea worldwide.[98] Most recently, episodes of diarrhea have been associated with the COVID-19 pandemic. See Emerging Science Box: COVID-19 and the Gastrointestinal System in Children.

Emerging Science BOXCOVID-19 and the Gastrointestinal System in Children

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is primarily a respiratory pathogen that manifests as viral infectious pneumonia. That said, the pathogen can also cause gastrointestinal (GI) and hepatic symptoms. Angiotensin converting enzyme-2 (ACE-2) receptor and transmembrane serine protease 2 (TMPRSS2) are expressed in the respiratory mucosa as well as in the enterocytes of the ileum and colon. The most common GI symptoms reported in children are diarrhea, nausea, vomiting, and abdominal pain. Aspartate transferase, alanine transferase, and total bilirubin are commonly elevated in infected individuals with these symptoms. SARS-CoV-2 is believed to be transmitted through respiratory droplet and fomite contamination. However, RT-PCR positive stool samples have been found in multiple children, which raises the concern of a possible fecal-oral transmission route.

Data from Matthai J, et al. Indian Society of Pediatric Gastroenterology, Hepatology and Nutrition; Pediatric Gastroenterology Chapter of Indian Academy of Pediatrics. Coronavirus disease (COVID-19) and the gastrointestinal system in children. *Indian Pediatrics*, 2020;57(6):533–535. https://doi.org/10.1007/s13312-020-1851-5; Cha MH, et al. Detection of Novel Coronavirus by RT-PCR in stool specimen from asymptomatic child, China. *Emerging Infectious Diseases*, 2020;26(6):1337–1339. https://doi.org/10.3201/eid2606.200301.

Acute Infectious Diarrhea

Acute infectious diarrhea in infants and young children is usually associated with viral or bacterial gastroenteritis from contaminated food or water. Viruses include rotaviruses, noroviruses, and adenoviruses. **Rotavirus** is the most common cause in young children and is associated with a higher death rate in low-income countries. It is transmitted by the fecal-oral route among humans. Rotavirus vaccination is an effective preventive strategy.[98]

Pathophysiology. Numerous bacteria or parasites can contaminate food or water and cause diarrhea. Bacterial causes of diarrhea have geographic variation, and specific bacteria can be identified using molecular analysis or stool culture. *Clostridium difficile* is often associated with previous antibiotic therapy.

Clinical Manifestations. Infectious diarrhea has a rapid onset, with watery stools sometimes mixed with blood, abdominal cramping, fever, vomiting, and weight loss. Severe dehydration, acidosis, and shock can occur quickly from diarrhea and vomiting. Hemolytic uremic syndrome and renal failure can develop when diarrhea is associated with *Shigella* toxin and *Escherichia coli* infection (see Chapter 39). Other causes of acute diarrhea in the older child include antibiotic therapy, appendicitis, chemotherapy, inflammatory bowel disease (IBD), parasitic infestation, parenteral infections, and ingestion of toxic substances.

Evaluation and Treatment. Treatment of diarrhea requires evaluation of the cause through the history, stool testing for common pathogens, and laboratory analysis.

Treatment of underlying illness is warranted when identified. Other treatments include hydration, electrolyte replacement, nutrition maintenance, and antibiotics if a pathogen is found. In certain children, antispasmodics may relieve abdominal cramping and selected probiotics can reduce the duration and improve morbidity and mortality. Intravenous solutions are used only when oral solutions are not tolerated. Prevention includes clean water, environmental sanitation, and good hygiene.[99]

Primary Lactose Intolerance

Lactose malabsorption, **lactose intolerance**, and lactase deficiency are three separate entities. Lactase deficiency refers to the lower than expected activity of lactase at the brush border of the intestine. Lactose malabsorption refers to the small bowel's inability to absorb ingested lactose due to lactase deficiency. Lactose intolerance is the clinical manifestation in which the ingestion of lactose-containing products induces symptoms. Primary lactose intolerance is an acquired deficiency and rarely manifests itself before age 5. Transient lactose malabsorption following gastroenteritis is common in children under the age of 2.[100]

The malabsorption of lactose results in osmotic diarrhea accompanied by abdominal pain, diarrhea, and flatulence. Symptoms of cow's milk allergy (CMA) are similar, which leads to misdiagnosis and inappropriate dietary modification.[101]

The diagnosis can be made through elimination of dietary lactose or by performing a hydrogen lactose breath test or an oral lactose tolerance test. Treatment consists of reducing milk consumption or supplementing the diet with oral lactase. Some children can tolerate lactose in fermented forms, such as cheese and yogurt, or by adding soy food. A diet low in fermentable oligosaccharides, disaccharides, and monosaccharides and polyols (FODMAPs) or administration of probiotics to alter intestinal flora has been found to be effective in children with lactose intolerance and irritable bowel syndrome (IBS) who have persistent symptoms. Additional sources of dietary calcium and vitamin D should be considered.[102]

Disorders Of The Liver

Disorders of Biliary Metabolism and Transport

Neonatal Jaundice

Jaundice (icterus) is a yellow pigmentation of the skin, mucus membranes, or the whites of the eyes caused by an increased level of bilirubin in the bloodstream (i.e., a total serum bilirubin [TSB] level that exceeds the 95th percentile for the infant's age in hours or greater than 20 mg/dL, except in the low birth weight population). Jaundice usually becomes clinically apparent when the serum bilirubin concentration is greater than 2 mg/dL (34 μmol/L). **Physiologic jaundice (hyperbilirubinemia) of the newborn** is a frequently encountered problem in otherwise healthy newborns caused by lack of maturity of bilirubin uptake and conjugation. Poor caloric intake or dehydration, or both, associated with inadequate breast-feeding also may contribute to the high levels of bilirubin. High bilirubin levels in the newborn period can be

associated with hemolytic disease, metabolic and endocrine disorders, anatomic abnormalities of the liver, and infections. For older infants and children, the most common causes of unconjugated hyperbilirubinemia are hemolytic processes resulting in bilirubin overproduction.

Pathologic jaundice appears within 24 hours after birth and with TSB concentration greater than 17 mg/dL in the newborn period associated with a severe illness, or a TSB level that rises by more than 5 mg/dL during the newborn period. Risk factors for development of pathologic jaundice include preeclampsia, maternal hypertension, maternal diabetes mellitus, vaginal bleeding, fetal-maternal blood type incompatibility (ABO and Rh incompatibility, hemolytic disease in the newborn), premature birth, maternal age greater than or equal to 25 years, male gender, delayed meconium passage, glucose-6-phosphate dehydrogenase deficiency, and excessive birth trauma, such as bruising or cephalohematomas.[103]

Pathophysiology

Pathologic jaundice results from the complex interaction of factors that cause (1) increased bilirubin production (e.g., hemolysis), (2) impaired hepatic uptake or excretion of unconjugated bilirubin, or (3) delayed maturation of liver bilirubin conjugating mechanisms. The most common cause is hemolytic disease of the newborn, also called erythroblastosis fetalis (ABO blood incompatibility [see Chapters 9 and 30]). All pregnant women should be tested for ABO and Rh incompatibility. Unconjugated bilirubin (indirect bilirubin) is lipid soluble and bound to albumin in the blood, and in the free form it readily crosses the blood-brain barrier in infants. Bilirubin encephalopathy **(kernicterus)** is caused by the deposition of toxic, unconjugated bilirubin in brain cells and usually does not occur in healthy, full-term infants. The mechanism of injury is not clearly known. An elevated level of conjugated bilirubin is a sign of underlying disease.[104,105]

Clinical Manifestations

Physiologic jaundice develops during the second or third day after birth and usually subsides in 1 to 2 weeks in full-term infants and in 2 to 4 weeks in premature infants. After this, increasing bilirubin values and persistent jaundice indicate pathologic hyperbilirubinemia. Manifestations include yellowing of the skin, dark urine, light-colored stools, and weight loss. Premature infants with respiratory distress, acidosis, or sepsis are at greater risk for kernicterus and the development of bilirubin-induced neurologic dysfunction (BIND) (e.g., neuromotor signs, hyperexcitable neonatal reflexes, and speech and hearing impairment).[106]

Evaluation and Treatment

Jaundice is detected by clinical assessment. Both total and direct (conjugated) bilirubin levels are monitored, and the bilirubin/albumin ratio is being evaluated as a corollary to unbound serum bilirubin level for predicting neurotoxicity, particularly in premature infants. Other causes of jaundice must be eliminated to confirm physiologic jaundice. Treatment depends on the degree of hyperbilirubinemia.

Physiologic jaundice is commonly treated by phototherapy and several techniques are available. Pathologic jaundice requires an exchange transfusion and treatment of the underlying disorder.[107]

Biliary Atresia

Biliary atresia (BA) is a rare congenital malformation characterized by the absence or obstruction of extrahepatic bile ducts resulting in neonatal cholestasis. The etiology of duct injury is not clear but is thought to be related to an embryonic (or congenital) abnormality or an acquired anomaly (e.g., perinatal viral or toxin-induced progressive inflammation with innate autoimmune destruction). Genetic associations have been reported in the following sequences: *GATA3*, *FOXA2*, *NODAL*. More research is needed in this area. The disease expression is a continuum in which the principal process is one of bile duct destruction. The atresia of the bile ducts is associated with inflammation, fibrosis, loss of epithelial cells, and obstruction of the bile canaliculi. Progressive obstruction leads to secondary biliary cirrhosis (see Chapter 39), portal hypertension, liver failure, and subsequent liver transplant.[108]

Jaundice is the primary clinical manifestation of BA, along with hepatomegaly and acholic (clay-colored) stools. Fat absorption is impaired because of the lack of bile salts. Abdominal distention caused by hepatomegaly and ascites may cause anorexia and faltering growth. Fat-soluble vitamin deficiencies (A, D, E, K) require supplementation. Manifestations of cirrhosis and liver failure include ascites, hypoalbuminemia, hypercoagulation, thrombocytopenia, pruritus, esophageal varices, and GI bleeding that may lead to death.

Early diagnosis of BA is essential; the best outcome is achieved when the infant is diagnosed and treated in the first 30 to 45 days of life. BA that is diagnosed late does not respond well to current surgical treatment. The diagnosis of BA is based on the clinical manifestations, abnormal liver function test results, liver biopsy results, and an intraoperative cholangiogram. Serum aminotransaminase and alkaline phosphatase levels are elevated, and conjugated (direct) serum bilirubin levels rise progressively. Surgical intervention removes the atretic biliary remnants and creates an intestinal conduit for bile drainage, also known as the hepatoportoenterostomy (HPE), or Kasai portoenterostomy (KPE) (Fig. 42.9). Even with initial restoration of bile flow, however, obliteration of intrahepatic bile ducts can continue and cirrhosis results. The vast majority of children will eventually need a liver transplant.[109]

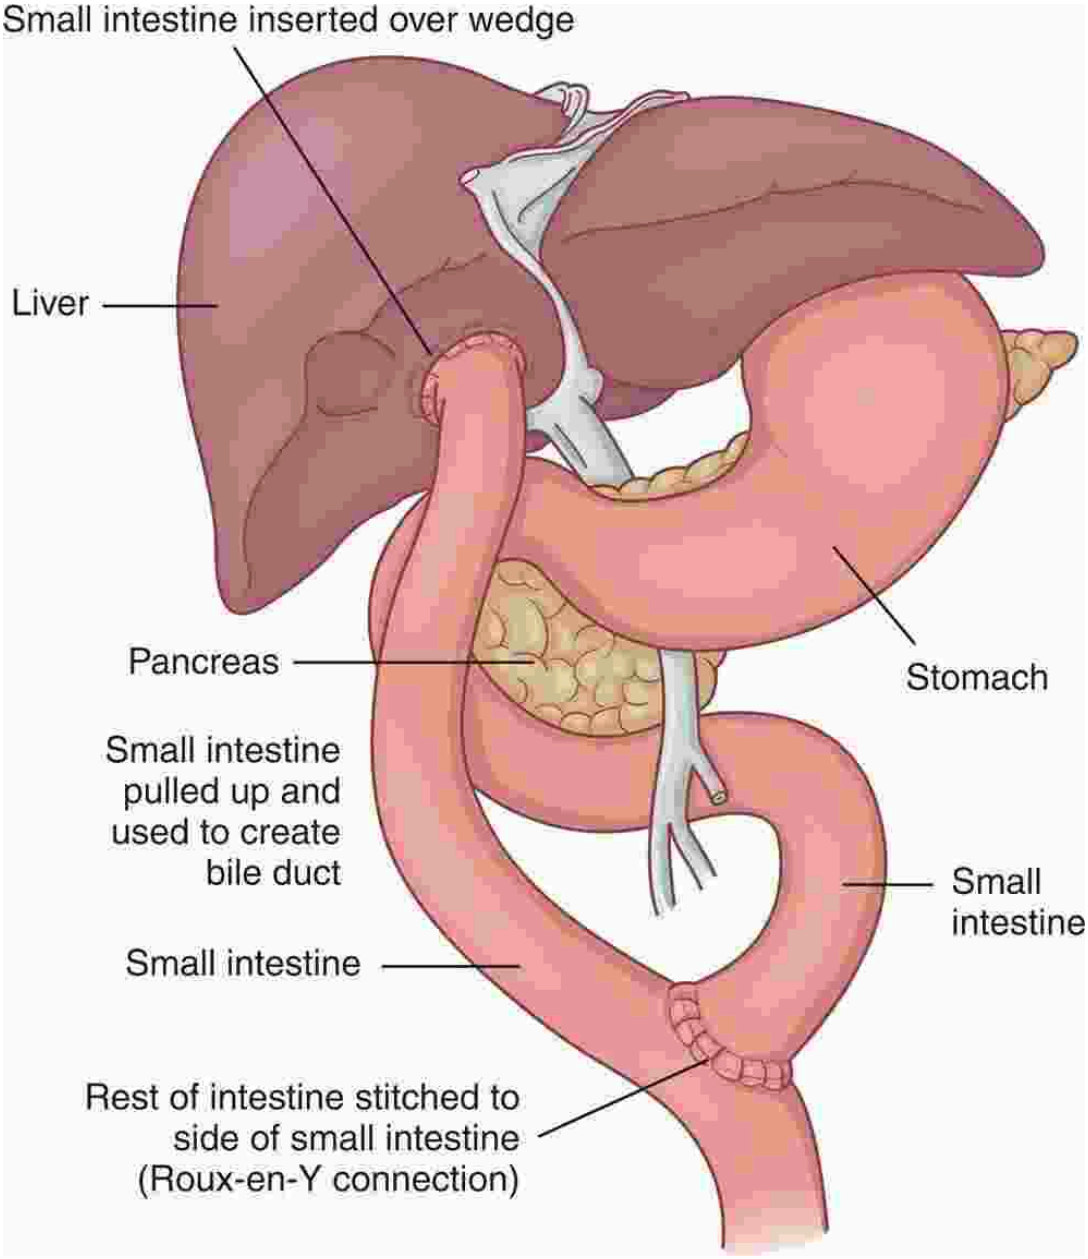

FIG. 42.9 Kasai Procedure.
Surgical correction for extrahepatic biliary atresia. The jejunal segment between the liver and the bowel may be externalized, creating a double-barrel portoenterostomy.

An illustration shows and labels the following structures liver, stomach, pancreas, and small intestine. The Kasai procedure shows the following corrections. • Small intestine inserted over wedge. • Small intestine pulled up and used to create bile duct. •

Rest of intestine stitched to side of small intestine (Roux-en-Y connection).

Inflammatory Disorders

Hepatitis

Hepatitis refers to an inflammation of the liver. The condition can be self-limiting, or it can lead to cirrhosis, liver, cancer, and even death. Etiology includes toxic substances and viral, infectious, and autoimmune diseases. There are five main types of viral hepatitis. Details are presented in Chapter 41.

Hepatitis A virus

Hepatitis A virus (HAV) is transmitted through the fecal-oral route. The incubation period is 28 days and can produce either symptomatic or asymptomatic infection, which is related to the age of the infected person. Children younger than 6 years do not present with symptoms 70% of the time, whereas older children and adults typically do present with symptoms. HAV replicates in the liver and is excreted through the biliary system into the stool. Concentration of viral shedding in the stool is highest during the 2-week period before the onset of symptoms. Children can shed longer than adults, for up to 10 weeks.

Outbreaks tend to occur in day-care centers with large numbers of children who are not toilet trained, throughout a household, and sometimes through food or water contaminated with fecal matter. Vertical transmission from mother to newborn or from a transfusion, as well as from a blood transfusion infection, is rare. HAV in children is usually asymptomatic, but if symptoms do appear, they are mild and may include nausea, vomiting, and diarrhea. Jaundice is more likely to appear in older children.[110]

Almost all children recover from hepatitis A without residual liver damage, although relapse may occur. After HAV infection, the body produces antibodies and natural immunity to prevent reinfection. Vaccination programs have successfully reduced the incidence of HAV in the United States by 95%.[111]

Hepatitis B virus

Hepatitis B virus (HBV) is a world health problem. Despite immunization programs, HBV continues to be a major cause of acute and chronic liver disease and associated population morbidity and mortality. Transmission occurs through contact of infected blood and body fluids. Risk factors for HBV include infants of mothers who are chronic hepatitis B surface antigen (HBsAg) carriers, children from families who immigrated to the United States or are adopted from endemic areas, infection from HBsAg-positive household contacts, and children who abuse parenteral drugs or engage in unprotected sex. Vertical transmission (mother-to-child) and horizontal

early childhood transmission continue to be the main routes of HBV transmission for children.[112]

Chronic hepatitis may develop more often in young children because their immune system is immature. Cirrhosis and hepatocellular carcinoma are rare. The most serious consequence of HBV infection is fulminant hepatitis, which occurs in 1% of cases. There is evidence that the risk of fulminant hepatitis is higher in individuals with combined infection with HBV, hepatitis D virus (HDV), hepatitis C virus (HCV), or HIV than in those with HBV infection alone. Aggressive HBV vaccination programs have reduced the incidence of HBV. To prevent perinatal transmission of HBV, immunoprophylaxis and HBV vaccination within the first 12 hours of birth are recommended, with close follow-up visits. Treatment is conservative, and antivirals are used for chronic disease. Children ages 2 to 17 years who are HBsAg seropositive for more than 6 months with elevated serum alanine transaminase (ALT) and HBV DNA levels for more than 3 months respond to treatment with antivirals. Maternal antiviral therapy during pregnancy and lactation reduces the HBV mother-to-child transmission rate.[113–115]

Hepatitis C virus

Hepatitis C Virus (HCV) in children is most commonly transmitted vertically and is enhanced by maternal coinfection with HIV. Risk factors for vertical transmission include internal fetal monitoring, mothers with high HCV viral load, prolonged rupture of membranes, and fetal anoxia. In older children, HCV transmission occurs more commonly through exposure to infected blood or contaminated materials (as in injection drug use or tattooing and body piercing) and after sexual encounters with individuals infected with HCV. Transmission from blood transfusions has become a negligible risk with universal HCV screening of blood. With vertical transmission, spontaneous resolution of HCV is high; otherwise, the disease is usually mild in children and cirrhosis is rare. Treatment is genotype specific, but because of adverse drug events, only children with persistently elevated serum aminotransferases or those with progressive liver disease are treated with antiviral drugs. Unfortunately, treatment seldom results in cure, and there is currently a need for further research and collaboration in order to guide pediatric management practice and policy.[116,117]

Hepatitis D virus

Hepatitis D Virus (HDV) is a single-strand RNA virus. Replication depends on the presence of HBV. Infection occurs simultaneously or as a superinfection; therefore, individuals with HVD infection are always mutually infected with HBV. Vertical transmission is uncommon. The prevalence in the United States is low, but HDV continues to affect parts of Europe and Asia and is a cause of progressive liver disease in children who are chronic hepatitis B surface antigen (HBsAg) carriers.[118] Treatment is based on genotype (genotype 1 is most common in the United States), but more research is currently underway for novel approaches to treatment.[119]

Chronic hepatitis

HBV and HCV are the main causes of **chronic hepatitis** in children. Manifestations of chronic hepatitis may include malaise, anorexia, fever, GI bleeding, hepatomegaly, edema, and transient joint pain. However, often there are no symptoms. Serum alanine aminotransferase and bilirubin levels are elevated. There may be evidence of impairment of synthetic functions of the liver: prolonged prothrombin time, thrombocytopenia, and hypoalbuminemia. The diagnosis is based on the clinical manifestations and liver biopsy results. There is no curative therapy for chronic HBV or chronic HCV. Children are treated with antiviral drugs and should continue to be monitored. Large scale clinical trials for the children with chronic hepatitis are lacking. Liver transplant may ultimately be required for these children.[120]

There is an autoimmune form of chronic hepatitis, known as *autoimmune hepatitis* (AIH) or *autoimmune primary sclerosing cholangitis* (PSC), which has an unknown etiology. The pathogenic mechanism is thought to be immunologic with loss of tolerance to hepatocyte-specific autoantigens, environmental, or genetic in nature. PSC is associated with a diagnosis of IBD. Advances are being made in identifying serologic markers to guide diagnosis and treatment. These diseases are chronic and progressive, typically presenting with elevations in the levels of bilirubin, aspartate aminotransferase-to-platelet ratio index, gamma-glutamyltransferase, and alkaline phosphatase. Children diagnosed at younger ages and those with small duct disease as compared to large duct involvement have better outcomes and less long term sequelae.[121]

Cirrhosis

Cirrhosis is fibrotic scarring of the liver, in response to inflammation and tissue damage, that results in nodular obstruction to the flow of blood and bile (see Chapter 41). Most forms of chronic liver diseases in children can progress to cirrhosis, but that is rare. The complications of cirrhosis in children are the same as those in adults: portal hypertension, the opening of collateral vessels between the portal and systemic veins, and varices. In addition, children with cirrhosis experience growth failure caused by nutritional deficits, as well as developmental delay, particularly in gross motor function because of ascites and weakness. The cause of cirrhosis may influence its severity and course (i.e., biliary atresia and hepatitis). Some types of cirrhosis can be stabilized if the cause is identified and treated early.[122]

Nonalcoholic fatty liver disease

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease in children. It is associated with obesity, insulin resistance, genetic predisposition, ethnicity, the gut microbiome, and environmental factors (diet and lack of exercise). NAFLD is associated with dyslipidemia, hypertension, and early cardiac dysfunction in children and can progress to cirrhosis and cardiometabolic syndrome within a few years if not treated. The rise in childhood obesity worldwide is contributing to the increasing prevalence of NAFLD. Circulating mRNAs may serve as important biomarkers for obesity and its comorbidities (See Emerging Science Box: The Role of miRNAs as Biomarkers of Obesity). The disease usually presents in

prepubertal children and is predominant in males and in children of Hispanic origin. The diagnosis is made by exclusion of other causes of the disease, usually by 12 to 13 years of age. Liver biopsy is required for definitive diagnosis of nonalcoholic steatohepatitis (NASH). Compared to adults, there are differences in the extent of fat, inflammation, and fibrosis in children, and there is no standard scoring system. There also is no consensus regarding treatment. Exercise and slow, consistent weight loss with a low glycemic index diet have been shown to be more effective than a low-fat diet in lowering body weight. Pharmacologic agents are being evaluated to control insulin

Emerging Science BOXThe Role of miRNAs as Biomarkers of Obesity

MicroRNAs or miRNAs are a class of small, non-coding RNAs that modulate gene expression at the post-transcription level. Several miRNAs have been found in research as overexpressed in obesity (miR199a, miR-122, miR-222, miR-142-3, miR-140-5p, and miR-143 to name a few). Two miRNAs have been identified as overexpressed in children with obesity and nonalcoholic fatty liver disease (NAFLD) and/or insulin resistance (miR-122 and miR-34). Also implicated in the pathogenesis of NAFLDA is miR-34a. Circulating miRNAs may prove to become a sensitive and specific biomarker for the development of obesity and obesity-associated diseases such as NAFLD.

Data from Oses M, et al. Circulating miRNAs as biomarkers of obesity and obesity-associated comorbidities in children and adolescents: A systematic review. *Nutrients*, 2019;11(12):2890. https://doi.org/10.3390/nu11122890; Torres J, et al. Role of microRNAs in alcohol-induced liver disorders and non-alcoholic fatty liver disease. Elevation of circulating microRNA levels in obese children compared to healthy controls. Clinical Obesity, 2017;7(4):216–221. https://doi.org/10.1111/cob.12192.

resistance, prevent the progression of liver disease, and cirrhosis. Omega-3 fatty acids, probiotics, and vitamin E may delay disease progression. Research is in progress to define the pathophysiology, noninvasive diagnostic procedures, and prevention measures.[123–125]

Portal Hypertension

Portal hypertension is an increased pressure in the portal venous system and a major cause of morbidity and mortality in children with liver disease. There are two basic causes of portal hypertension in children: (1) increased resistance to blood flow within the portal system, and (2) increased volume of portal blood flow. The second cause is rare in children and is not discussed here. Increased resistance to flow can occur anywhere in the portal circulatory system. Portal hypertension can accompany cirrhosis, intra-abdominal infections, portal vein thrombosis, congenital anomalies of the portal vein, and congenital hepatic fibrosis.

Types of Portal Hypertension

Extrahepatic portal hypertension

Extrahepatic portal hypertension causes 50% to 70% of portal hypertension in children. No specific cause can be found in approximately two-thirds of these children. Obstructions are almost always in the portal vein and are usually caused by thrombosis as a complication of abdominal trauma, pancreatitis, abdominal infections, and some systemic disorders; however, these causes are rare. Umbilical infection with or without a history of catheterization of the umbilical vein may be a cause in neonates. It also has been associated with neonatal dehydration, inflammatory bowel disease (IBD), and hypercoagulable states, such as protein C and protein S deficiencies. Life-threatening bleeding and coagulation disorders can occur. Mesoportal bypass (anastomosis of the mesenteric vein to the portal vein) restores normal physiologic portal flow to the liver and corrects portal hypertension.[126]

Intrahepatic portal hypertension

Intrahepatic portal hypertension is usually caused by fibrosis. This can lead to cirrhosis and increased resistance to portal blood flow by constricting and reducing the compliance of hepatic sinusoids. Chronic hepatitis, biliary atresia, NAFLD, and congenital hepatic fibrosis are causes of liver fibrosis in children.

The clinical manifestations of portal hypertension are (1) splenomegaly, (2) upper GI tract bleeding, (3) ascites, (4) hepatopulmonary syndrome, (5) hepatorenal syndrome, and (6) hepatic encephalopathy (see Chapter 41).

The objectives of the clinical investigation are to locate the site of the venous block and to identify the disease responsible for the portal hypertension. Thorough physical examination, laboratory evaluation, ultrasonic evaluation, endoscopic evaluation, and biopsy may be included in the diagnostic workup. Treatment in children is the same as that in adults (see Chapter 41). The outcome of portal hypertension depends almost entirely on its cause. Children with extrahepatic disease are expected to recover with little morbidity. For children with intrahepatic disease, the prognosis varies.

Metabolic Disorders

More than 5000 genetically determined metabolic pathways have been identified in liver tissue. The earliest possible identification of metabolic disorders is essential because (1) early treatment may prevent permanent damage to vital organs, such as the liver or brain; (2) precise genetic counseling may be possible with prenatal diagnosis; and (3) complications can be minimized, even if cure is not possible. **Galactosemia**, **fructosemia**, and **Wilson disease** are rare, treatable metabolic disorders that have hepatic clinical manifestations.[127–129] The mechanisms of disease, clinical manifestations, evaluation and treatment of these disorders are reviewed in Table 42.2.

Summary Review

Congenital Impairment of Motility in the Gastrointestinal Tract

1. CL and CP may occur separately or together and both defects are associated with multiple gene-environmental interactions and deficiency of B vitamins. The fissure may affect the uvula, soft palate, hard palate, nostril, and maxillary alveolar ridge, with difficulty sucking and swallowing.
2. EA, a condition in which the esophagus ends in a blind pouch, may occur with or without a TEF. As the infant swallows oral secretions or ingests milk, the pouch fills, causing either drooling, regurgitation, or aspiration into the lungs.
3. IHPS is an obstruction of the pyloric outlet caused by hypertrophy of circular muscles in the pyloric sphincter.
4. In intestinal malrotation, the small intestine lacks a normal posterior attachment during fetal development, causing volvulus (twisting of the bowel on itself) that may partly or completely occlude the GI tract and its blood vessels.
5. Meckel diverticulum is a congenital malformation of the GI tract involving all layers of the small intestinal wall. It usually occurs in the ileum.
6. Hirschsprung disease (congenital aganglionic megacolon) is caused by a malformation of the parasympathetic nervous system in a segment of the colon needed for peristalsis, resulting in colon obstruction.
7. Idiopathic intestinal pseudo-obstruction is repetitive episodes or continuous symptoms of intestinal obstruction without an obstructing lesion and may be associated with atrophy of enteric nerves and/or muscles.
8. DIOS, formerly called meconium ileus equivalent, can occur when intestinal contents become abnormally thick and obstruct the intestinal lumen. CR, pancreatic enzyme deficiency, and dehydration are common causes.
9. Malformations of the anus and rectum range from mild congenital stenosis of the anus to complex deformities.
10. MI is a newborn condition in which intestinal secretions and amniotic waste products produce a thick, sticky plug that obstructs the intestine, usually from lack of fetal digestive enzymes.

Acquired Impairment of Motility in the Gastrointestinal Tract

1. GERD is the presence of symptoms related to the return of stomach contents into the esophagus. This is caused by relaxation or incompetence of the lower esophageal sphincter that results from immaturity of the gastroesophageal sphincter. Infants are susceptible to reflux because the sphincter is not fully mature, their diet consists of liquids, and they are seldom in an upright position.
2. EoE is an emerging chronic, local, progressive antigen-immune-mediated relapsing disease caused by eosinophilic infiltration of the esophageal

mucosa.
3. Intussusception is the telescoping of a proximal segment of intestine into a distal segment, causing an obstruction. It occurs most commonly in the area of the ileocecal junction.
4. Appendicitis is common in children 10 to 11 years of age, however, presentation may differ from adults in younger children.

Impairment of Digestion, Absorption, and Nutrition

1. CF is an inherited fibrocystic disease that involves mucosal chloride and sodium ion channels in many organs, including the GI tract and pancreas; CF causes pancreatic enzyme deficiency with maldigestion.
2. CD is caused by hypersensitivity to gluten protein, with autoimmune injury and loss of the villous epithelium. It results in malabsorption and growth failure.
3. Pediatric malnutrition is an imbalance between nutrient requirements and intake that results in energy, protein, and micronutrient deficits, which impair growth and development.
4. Kwashiorkor is a severe protein deficiency. Marasmus is a deficiency of all dietary nutrients, including carbohydrates.
5. Faltering growth, or FTT, is a multifactorial condition that includes biologic, psychosocial, and environmental contributions. It may or may not be related to illness, and it results in inadequate physical growth and development of a child.
6. NEC is an ischemic, inflammatory disorder in neonates, particularly premature infants, thought to result from immaturity, infection, stress, and anoxia of the bowel wall.

Diarrhea

1. Diarrhea in infants and children is three or more watery or loose stools in 24 hours. It may last up to 4 weeks in acute cases, or longer in chronic cases. It is commonly caused by viral or bacterial enterocolitis.
2. Primary lactose intolerance is the inability to digest milk sugar because of a lack of the enzyme lactase, resulting in osmotic diarrhea.

Disorders of the Liver

1. Physiologic jaundice of the newborn is caused by mild hyperbilirubinemia that subsides in 1 or 2 weeks. Pathologic jaundice is caused by severe hyperbilirubinemia and can cause brain damage (kernicterus).
2. BA is a congenital malformation of the bile ducts that obstructs bile flow and causes jaundice, cirrhosis, and liver failure.

3. Acute hepatitis is usually caused by a virus, and hepatitis A is the most common form of childhood hepatitis. Chronic hepatitis B or C usually occurs by maternal transmission.
4. Cirrhosis is fibrotic scarring of the liver and is rare in children, but it can develop from most forms of chronic liver disease.
5. Portal hypertension in children usually is caused by extrahepatic obstruction. Thrombosis of the portal vein is the most common cause of portal hypertension in children, and splenomegaly is the most common sign.
6. The most common metabolic disorders that cause liver damage in children are galactosemia, fructosemia, and Wilson disease. All three are rare and inherited as genetic traits that allow toxins to accumulate in the liver and other body tissues.

Chapter Outline

OUTLINE

Structure and Function of Bones 1399
- Elements of Bone Tissue 1399
- Types of Bone Tissue 1406
- Characteristics of Bone 1407
- Maintenance of Bone Integrity 1407

Structure and Function of Joints 1408
- Fibrous Joints 1408
- Cartilaginous Joints 1408
- Synovial Joints 1411

Structure and Function of Skeletal Muscles 1413
- Whole Muscle 1413
- Components of Muscle Function 1418
- Tendons and Ligaments 1422

Tests of Musculoskeletal Function 1423
- Tests of Bone Function 1423
- Tests of Joint Function 1423
- Tests of Muscular Function 1423

The way an individual functions in daily life, moves about, or manipulates objects physically depends on the integrity of the musculoskeletal system. The musculoskeletal system consists of two systems: (1) the skeleton composed of bones and joints and (2) soft tissues (skeletal muscles, tendons, and ligaments). Each system contributes to mobility. The skeleton supports the body and provides leverage to the skeletal muscles so that movement of various parts of the body is possible. Contraction of the skeletal

muscles and bending or rotation at the joints facilitate movements of the various body parts.

Structure and Function of Bones

Bones give form to the body, support tissues, and permit movement by providing points of attachment for muscles. Many bones meet in movable joints that determine the type and extent of movement possible. Bones also protect many of the body's vital organs. For example, the bones of the skull, thorax, and pelvis are hard exterior shields that protect the brain, heart, lungs, and reproductive and urinary organs, respectively.

Bone marrow is one of the sources of **mesenchymal stem cells (MSCs)** (Fig. 43.1). These nonhematopoietic stem cells consist of a small proportion of the stromal cell population in the bone marrow and can generate bone cells, cartilage cells, and fat cells that support the formation of blood and fibrous connective tissue. Within certain bones, the marrow cavities serve as storage sites for the hematopoietic stem cells that form both blood and immune cells. In adults, blood cells originate exclusively in the marrow cavities of the skull, vertebrae, ribs, sternum, shoulders, and pelvis. The development of blood cells is discussed in Chapter 28. Bones have a crucial role in mineral homeostasis (storing minerals [i.e., calcium, phosphate, carbonate, magnesium]), hormone homeostasis (essential for the proper performance of many delicate cellular mechanisms), and assist in maintaining normal immunologic function.

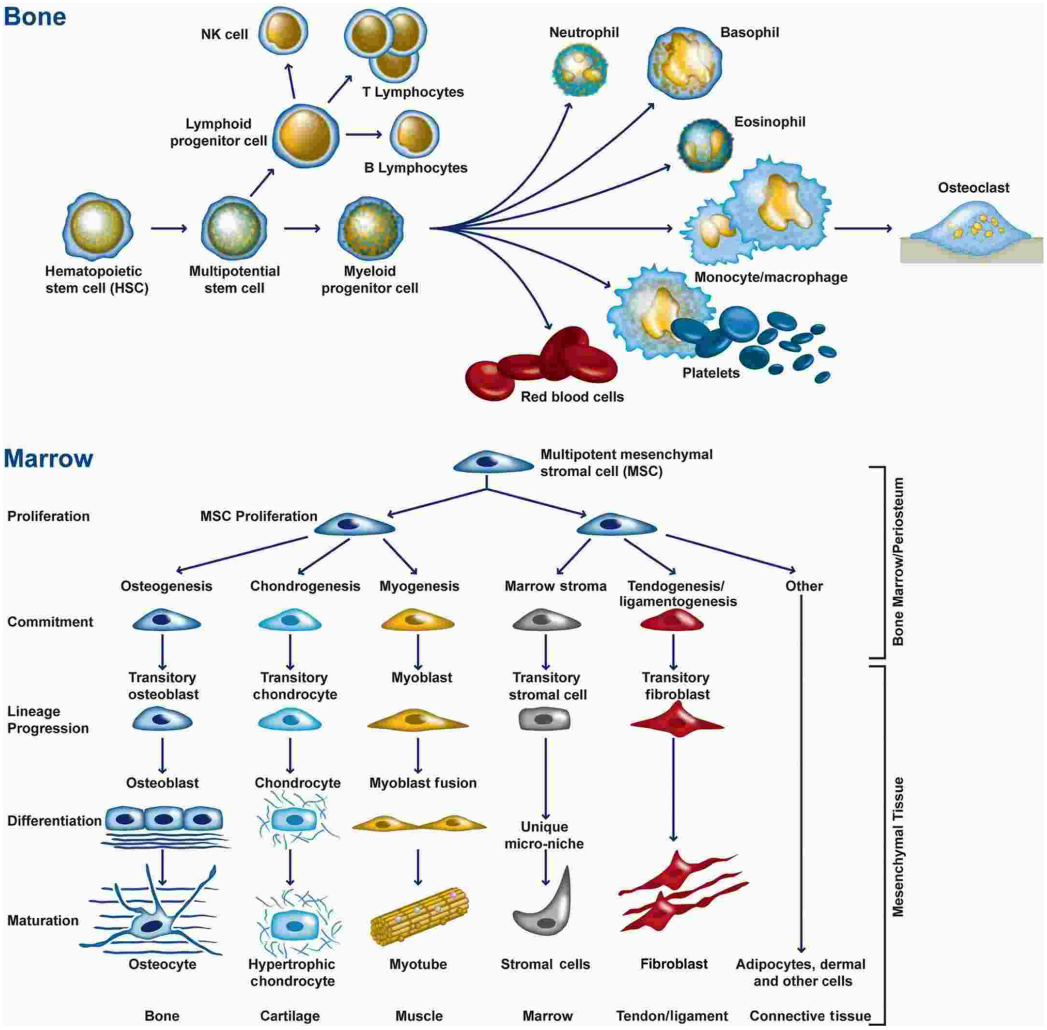

FIG. 43.1 Hematopoietic and Mesenchymal Stromal Differentiation.

The illustration on the top depicts the differentiation process of the hematopoietic cells which shows the hematopoietic stem cell differentiates into multipotential stem cells into myeloid progenitor cells. The multipotential stem cell is further classified into lymphoid progenitor cell which includes N K cell, T lymphocytes, and B lymphocytes. The myeloid progenitor cells include neutrophil, basophil,

eosinophil, monocyte or macrophage, platelets, and red blood cells. Monocyte or macrophage includes osteoclast. The illustration at the bottom depicts the differentiation process of mesenchymal stem cells which shows the multipotent mesenchymal stromal cell differentiated into M S C proliferation which includes osteogenesis, chondrogenesis, myogenesis, marrow stroma, tendogenesis or ligamentogenesis, and others. Osteogenesis commits to transitory osteoblast; chondrogenesis commits to transitory chondrocyte; myogenesis commits to myoblast fusion; marrow stroma commits to transitory stroma cell; tendogenesis commit to transitory fibroblast. The transitory osteoblast progress to osteoblast; transitory chondrocyte progress to chondrocyte; myoblast progress to myoblast fusion; transitory stroma cell progress to unique micro-niche; transitory fibroblast progress to fibroblast. Osteoblast differentiates to osteocyte which matures in bone; chondrocyte differentiates to hypertrophic chondrocyte which matures in cartilage; myoblast fusion differentiates to myotube which matures in muscle; unique micro-niche differentiates to a stromal cell which matures in marrow; fibroblast matures in tendon or ligament; adipocytes, dermal and other cells mature in connective tissue.

Elements of Bone Tissue

Mature bone is a rigid connective tissue consisting of cells; fibers; a homogenous, gelatinous medium termed **ground substance;** and large amounts of crystallized minerals, mainly calcium, that give bone its rigidity. Ground substance consists of proteoglycans and hyaluronic acid secreted by chondroblasts. The structural elements of bone are summarized in Table 43.1.

Table 43.1

Structural Elements of Bone

Structural Elements	Function
Bone Cells	
Osteoblasts	Synthesize collagen and proteoglycans; initiate new bone formation by their synthesis of osteoid; mineralize osteoid matrix; produce receptor activator of nuclear factor-κB ligand (RANKL), which in turn stimulates osteoclast resorption of bone; also produce osteoprotegerin (OPG), which inhibits osteoclast formation by binding to RANKL
Osteoclasts	Resorb bone; major role in bone homeostasis
Osteocytes	Transform osteoblasts trapped in osteoid; signal both osteoblasts and osteoclasts; maintain bone homeostasis; synthesize new bone matrix; initiate osteoclast function; mechanosensory receptors to reduce or augment bone mass; produce sclerostin (SOST), which inhibits bone growth
Bone Matrix	
Bone morphogenic proteins (BMPs)	Subfamily of transforming growth factor-β (TGF-β) cytokine growth factors; induce and regulate bone and cartilage formation; affect all other organ systems
BMP-1	Unrelated to other BMPs (is a metalloprotease); involved in cartilage development; is actually a

Structural Elements	Function
	metalloprotease; key role in extracellular matrix (ECM) formation
BMP-2	Promotes chondrogenesis, bone formation; induces bone and cartilage formation, osteoblast differentiation, bone healing; clinically used to enhance bone formation in spine surgery
BMP-3 (osteogenin)	Inhibits bone formation
BMP-4	Osteoblast differentiation; involved in cartilage repair, endochondral bone formation; enhances chondrogenesis; regulates formation of teeth, limbs, and bone
BMP5	Involved in cartilage development
BMP-6	Found in osteoblasts; helps maintain adult joint integrity; accelerates bone repair
BMP-7	Osteogenic cell formation from mesenchymal stem cells (MSCs); enhances bone formation in spine surgery; induces formation of brown fat; has a major role in osteoblast differentiation, chondrocyte formation, fracture healing; important in renal development and repair
BMP8a	Involved in bone and cartilage development; up-regulated in fracture nonunion
BMP-9	Promotes osteoblast formation from MSCs; induces osteogenesis in mature osteoblasts

Structural Elements	Function
BMP10	Plays role in development of the heart
BMP12 (cartilage-derived morphogenic protein-3; CDMP-3)	Involved in tendon and ligament formation
BMP-13	Inhibits bone formation by reducing calcium mineralization; involved in cartilage development; tendon and ligament repair
BMP14	Assists in bone and tendon healing; cartilage formation
Collagen fibers	Lend support and tensile strength
Proteoglycans	Control transport of ionized materials through matrix
Glycoproteins	
Albumin	Transports essential elements to matrix; maintains osmotic pressure of bone fluid
α-Glycoproteins	Promote calcification
Laminin	Stabilizes basement membranes in bones
Osteocalcin	Vitamin K–dependent protein present in bone; inhibits calcium phosphate precipitation (attracts calcium ions to incorporate into hydroxyapatite crystals); serum osteocalcin is a sensitive marker of bone formation
Osteonectin	Binds calcium in bone; necessary for normal bone formation

Structural Elements	Function
Sialoprotein	Promotes calcification, osteoblast formation
Minerals	
Calcium	Crystallizes, providing bone rigidity and compressive strength
Phosphate	Balance of organic and inorganic phosphate required for proper bone mineralization; regulates vitamin D, promoting mineralization
Alkaline phosphatase	Promotes mineralization
Vitamins	
Vitamin D	Assists with differentiation, mineralization of osteoblasts
Vitamin K	Increases bone calcification; reduces serum osteocalcin

Data adapted from Caetano-Lopes J, Canhão H, Fonseca JE. Osteoblasts and bone formation. *Arthritis Research and Therapy*, 2007;9(suppl 1):S1; Hojo H, Ohba S, Yano F, et al. Coordination of chondrogenesis and osteogenesis by hypertrophic chondrocytes in endochondral bone development. *Journal of Bone and Mineral Metabolism*, 2010;28(5):489–502; Fajardo M, Liu C-J, Egol K. Levels of expression for BMP-7 and s veral BMP antagonists may play an integral role in a fracture nonunion: A pilot study. *Clinical Orthopaedics and Related Research*, 2009;467(12):3071–3078; Li Y, Shen H, Burczynski FJ, et al. Prospect of bone morphogenetic protein 13 in liver diseases. *Zhong Nan Da Xue Xue Bao Yi Xue Ban*, 2012;37(1):1–5.

Bone cells enable bone to grow, repair itself, change shape, and continuously synthesize new bone tissue and **resorb** (dissolve or

digest) old tissue. The fibers in bone are made of collagen, which gives bone its tensile strength (the ability to hold itself together). Ground substance acts as a medium for the diffusion of nutrients, oxygen, metabolic wastes, biochemicals, and minerals between bone tissue and blood vessels.

Bone formation begins during embryonic development when MSCs begin differentiating into either chondrocytes or preosteoblasts. Endochondral ossification and intramembranous ossification are the two major mechanisms responsible for normal bone development.

Endochondral ossification occurs when mesenchymal (**mesenchyme**, or loose tissue found during embryonic development) stem cells begin differentiating into chondrocytes (see Fig. 43.1), which in turn develop a mineralized cartilage scaffold that allows the formation of osteoblasts. Long bones and most other bone elements are formed this way. **Intramembranous ossification** is responsible for the development of skull and flat bones.[1] With intramembranous ossification, MSCs differentiate into a preosteoblast line that forms osteoblasts without any cartilage framework.[2]

Multiple factors influence normal bone formation, maintenance, and remodeling. Bone morphogenic proteins (BMPs) are members of the transforming growth factor-β (TGF-β) superfamily and play a major role in bone formation. This group is primarily responsible for the initiation, differentiation, and commitment of precursor cells into osteoblasts. TGF-β signals are transmitted across the plasma membrane, combine with certain proteins that act as transcription factors (Smads) and then form specific receptors known as *R-Smads*.[3] These receptors, in turn, initiate intracellular signaling, interact with other transcription factors, and regulate other factors that are important in osteoblast formation, function, and maintenance. Crosstalk between signaling pathways is critical in regulating osteoblasts.

BMPs have multiple crucial functions in the skeletal system. BMP activities are regulated at different molecular levels. The Bones

Matrix section in Table 43.1 summarizes the function of several important BMPs.

***Wnt*genes** belong to a large family of protein-signaling factors that are required for the development of body systems, including the musculoskeletal system. They play a significant role in forming bone, developing bone mass, remodeling bone, and healing fractures. Wnt signaling regulates the production and differentiation of osteoblasts and osteoclasts and affects bone mass and density, joint formation, fracture repair, bone remodeling, and some bone diseases. Other important elements responsible for bone formation and homeostasis are presented in Table 43.2.

Table 43.2

Selected Factors Affecting Bone Formation, Maintenance, and Remodeling

Factor	Function
Transforming growth factor-beta (TGF-β)	Superfamily of polypeptides; regulates bone formation, many other cellular processes through signaling
Platelet-derived growth factor (PDGF)	Increases number of osteoblasts
Fibroblast growth factor (FGF)	FGF-2 increases osteoblast population, but not function; inhibits alkaline phosphatase activity, osteocalcin, type I collagen, and osteopontin
Insulin-Like Growth Factor (IGF)	
IGF-1	Increases peak bone mass during adolescence; decreases osteoblast apoptosis; maintains bone matrix
IGF-2	Increases BMP-9–induced endochondral ossification
Smad proteins	Mediate signaling cascade of TGF-β, especially in embryonic bone development; play role in crosstalk between BMP/TGF-β and Wnt signaling pathways
Bone morphogenic proteins (BMPs)	Members of TGF-β superfamily of polypeptides; have many functions outside skeletal system; stimulate endochondral bone and cartilage formation and function, promote

Factor	Function
	osteoblast maturation; augment bone remodeling by affecting both osteoblasts and osteoclasts
Tumor necrosis factors (TNFs)	Superfamily of cytokines; play major role in regulating bone metabolism, especially osteoclast function
Osteoprotegerin (OPG)	Inhibits bone remodeling/resorption; produced by several cells, including osteoblasts; is a decoy receptor for RANKL (binds to RANKL, inhibiting RANK/RANKL interactions, suppressing osteoclast formation and bone resorption); also may directly interfere with ability of osteoclasts' podosomes to attach to bone matrix
Receptor activator of nuclear factor-κB (RANK)	Stimulates differentiation of osteoclast precursors; activates mature osteoclasts
Receptor activator of nuclear factor-κB ligand (RANKL)	Promotes osteoclast differentiation/activation; inhibits osteoclast apoptosis
BMP antagonists	Prevent BMP signaling
Noggin	Binds BMP-2 and -4, reducing osteoblast function
Gremlin	Multiple effects in and out of skeletal system, but also binds BMP-2, -4, and -7, thus reducing BMP signaling; may play role in development of osteoporosis

Factor	Function
Twisted gastrulation	Acts as either a BMP agonist or a BMP antagonist
Activin (a BMP-related protein)	Affects both osteoblasts and osteoclasts; may promote bone formation and fracture healing; expressed by both osteoblasts and chondrocytes; helps regulate bone mass
Annexins	Class of calcium-binding proteins; help mineralize matrix vesicles; may influence bone formation
Inhibin	Dominant over activin and BMPs; helps regulate bone mass and strength by affecting formation of osteoblasts and osteoclasts
Leptin	Plays role in bone formation and resorption
Wnt Antagonists	
Dickkopf family (Dkk)	Disrupt Wnt signaling, leading to reduced bone mass
Sclerostin	A protein secreted by osteocytes, osteoblasts, and osteoclasts; binds to BMP-6 and BMP-7; interferes with Wnt signaling pathway, inhibiting bone formation by osteoblasts
Transcription Factors	
β-Catenin pathway	Protein with multiple functions; one of most important is activation of genetic transcription factors;

Factor	Function
	balance between Wnt/β-catenin signaling promotes normal bone formation/resorption
Wnts (complex signaling pathway)	Important in differentiating osteoblasts, bone formation; has overlapping effects with BMPs, helps regulate bone formation and remodeling; crosstalks with other signaling pathways
Nuclear factor of activated B cells (NF-κB)	Affects embryonic osteoclastogenesis; plays role in certain osteoclast, osteoblast, and chondroblast functions
Matrix Metalloproteinases (MMPs)	
Family of endopeptidases (enzymes) that includes collagenases, gelatinases, stromelysins, matrilysins	Help maintain equilibrium of extracellular matrix (ECM); breakdown almost all components of ECM
A disintegrin and metalloproteinase (ADAM)	Proteolytic enzymes; also have cell-signaling functions, usually linked to cell membrane
A disintegrin and metalloproteinase with thrombospondin motifs (ADAMTs)	Similar to ADAMs but are secreted into circulation, are found around cells; various subgroups affect multiple tissues

Factor	Function
Cysteine protease	Cathepsin K expressed by osteoclasts; assists in bone remodeling by cleaving proteins, such as collagen type I, collagen type II, and osteonectin
MMP Inhibitors	
Tetracyclines (especially doxycycline), bisphosphonates	Block enzymatic function of MMPs
Tissue inhibitors of metalloproteinases (TIMPs)	Balance effect of MMPs in maintaining ECM equilibrium

In mature bone, the formation of new tissue begins with the production of an organic matrix by the bone cells. This **bone matrix** consists of ground substance, collagen, and other proteins (see Table 43.1) that take part in bone formation and maintenance.

The next step in bone formation is **calcification**, in which minerals are deposited and then crystallize. Minerals bind tightly to collagen fibers, producing tensile and compressional strength in bone and allowing it to withstand pressure and weightbearing.

Bone Cells

Bone contains three types of cells: osteoblasts, osteocytes, and osteoclasts (Fig. 43.2). Both osteoblasts and osteocytes originate from osteoprogenitor cells found in the MSC lineage. Osteoclasts originate from hematopoietic stem cells. Osteoblasts are the bone-forming cells. Osteocytes, the most numerous cells within bone, are osteoblasts that have become imprisoned within the mineralized bone matrix. They have multiple important duties in maintaining bone homeostasis, including synthesizing new bone matrix molecules and initiating osteoclast function. Osteoclasts primarily resorb (remove) bone during processes of growth and repair.

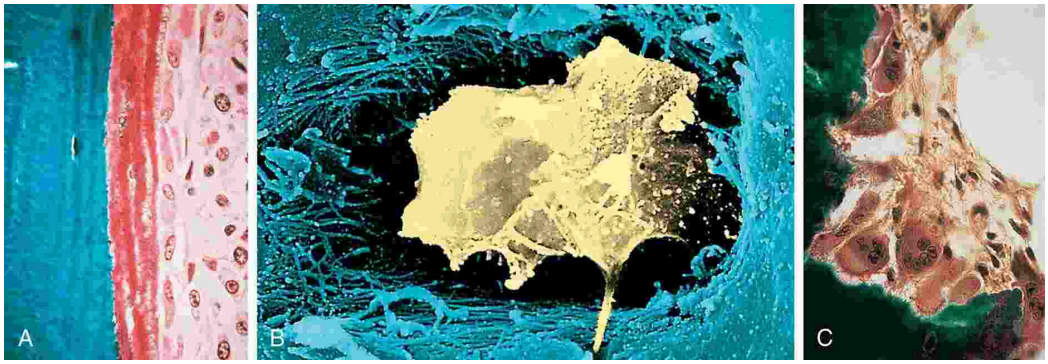

FIG. 43.2 Bone Cells.
(A) Osteoblasts are responsible for the production of collagenous and noncollagenous proteins that compose osteoid. Active osteoblasts are aligned on the osteoid. Note the eccentrically located nuclei. **(B)** Electron photomicrograph of an osteocyte. Osteocytes reside within the lacunae of compact bone. **(C)** Osteoclasts actively resorb mineralized tissue. The scalloped surface in which the multinucleated osteoclasts rest is termed *Howship lacuna*. (A and C, From Damjanov I, Linder J, eds. *Anderson's Pathology*, 10th edition. St. Louis: Mosby; 1996; B, From Wikimedia Commons, courtesy Robert M. Hunt.)

Osteoblasts

Originating from MSCs, **osteoblasts** are the primary bone-producing cells and are involved in many functions related to the skeletal system (see Table 43.1). Mature osteoblasts produce inorganic calcium phosphate, which is converted to hydroxyapatite, and an organic matrix that is composed mainly of type I collagen.[4]

Once this process is complete, osteoblasts deposit new bone in response to the bone resorbed by osteoclasts.[4] Osteoblasts are responsive to parathyroid hormone (PTH) and produce osteocalcin when stimulated by 1,25-dihydroxy-vitamin D_3. Osteoblasts are active on the outer surfaces of bones, where they form a single layer

of cells. Osteoblasts initiate new bone formation by their synthesis of **osteoid** (nonmineralized bone matrix). Osteoblasts also mineralize the newly formed bone matrix. Stimulation of new bone formation and orderly mineralization of bone matrix occur by concentrating some of the plasma proteins (growth factors) found in the bone matrix and by facilitating the deposit and exchange of calcium and other ions at the site. Enzymes, signaling proteins, and growth factors, including BMPs and other members of the TGF-β superfamily, are critical components of bone formation, maintenance, and remodeling (see Table 43.2).

Osteocytes

Osteocytes, the most abundant cells in bone, are transformed osteoblasts trapped or surrounded in osteoid as it hardens because of minerals that enter during calcification (see Fig. 43.2B). It is the final differentiation stage for an osteoblast. The osteocyte is within a space in the hardened bone matrix called a **lacuna**. Osteocytes have numerous functions, including acting as mechanoreceptors and synthesizing certain matrix molecules, playing a major role in controlling osteoblast differentiation and production of growth factors, and maintaining bone homeostasis.

As the major source of sclerostin, **receptor activator nuclear factor κ-B ligand** (RANKL), and osteoprotegerin, osteocytes are thought to be key regulators of both bone formation and bone resorption.[5] They also help concentrate nutrients in the matrix. Osteocytes obtain nutrients from capillaries in the canaliculi, which contain nutrient-rich fluids. Through exchanges among these cells, hormone catalysts, and minerals, optimal levels of calcium, phosphorus, and other minerals are maintained in blood plasma.

One of the osteocyte's primary functions is to act as a mechanoreceptor, responding to changes in weightbearing or other stressors ("loading") on bone. Lying within the lacunae are the osteocyte's primary cilia, which are likely the primary mechanoreceptors in bone. Once changes in bone, such as mechanical stress, hormonal imbalance, loading, or unloading, are

detected by the osteocyte's mechanoreceptors, multiple molecular signals are produced, and the process of bone remodeling begins. Remodeling is described in the Maintenance of Bone Integrity Section.

Osteoclasts

Osteoclasts are large (typically 20 to 100 μm in diameter), multinucleated cells that develop from the hematopoietic monocyte-macrophage lineage. Osteoclasts are the major resorptive cells of bone. They migrate over bone surfaces to resorption areas that have been prepared and stripped of osteoid by enzymes, such as collagenases produced by osteoblasts in the presence of PTH, which is necessary for the resorptive process. Osteoclasts travel over the prepared bone surfaces, creating irregular, scalloped cavities known as *Howship lacunae* or *resorption bays*, as they resorb bone areas and then acidify hydroxyapatite to dissolve it.

A specific area of the cell membrane forms adjacent to the bone surface and develops multiple infoldings to permit intimate contact with the resorption bay. These infoldings, known as the **ruffled border**, greatly increase the surface areas of cells under their scalloped or ruffled borders. Osteoclasts resorb bone by the secretion of hydrochloric acid, acid proteases (such as cathepsin K), and matrix metalloproteinases (MMPs) that help digest collagen, along with the action of cytokines (see Table 43.2). Osteoclasts also resorb bone through the action of lysosomes (digestive vacuoles) filled with hydrolytic enzymes in their mitochondria.

Osteoclasts bind to the bone surfaces through attachments called **podosomes**, which are footlike structures that cluster together along a sealing membrane that forms a "belt" containing multiple proteins, enzymes, and **integrin** receptors. Once resorption is complete, the osteoclasts retract and loosen from the bone surface under the ruffled border through the action of calcitonin. Calcitonin binds to receptor areas of the osteoclasts' cell membranes to effectively loosen the osteoclasts from the bone surfaces. Once resorption is completed, osteoclasts disappear by the process of degeneration, either by

reverting to the form of their parent cells or by undergoing cell movements away from the site, in which the osteoclast becomes an inactive or a resting osteoclast.

In addition to resorption of bone, osteoclasts assist the endocrine and renal systems in maintaining appropriate serum calcium and phosphorus levels. Osteoclasts also appear to have a role in the body's immune response.

Osteoprotegerin/Receptor Activator Nuclear Factor κ-B Ligand/Receptor Activator Nuclear Factor κ-B System

Osteoprotegerin (OPG), a glycoprotein belonging to the tumor necrosis factor (TNF) superfamily, inhibits bone remodeling and resorption, inhibiting osteoclast formation. Numerous cells, including osteoblasts and osteocytes, produce it. OPG is the key to the interaction between osteoblasts and osteoclasts. Osteoblasts and osteoclasts cooperate (a process called *coupling*) to maintain normal bone homeostasis. **RANKL** is an essential cytokine needed for the formation and activation of osteoclasts. Like an automobile's accelerator, RANKL increases bone loss. OPG, similar to an automobile's brakes, reduces bone loss because when it is activated, it promotes bone formation. When RANKL binds to its receptor (i.e., **receptor activator nuclear factor κ-B** [RANK]) on osteoclast precursor cells, it triggers their proliferation and increases bone resorption. OPG is secreted by osteoblasts and B lymphocytes and serves as a decoy by binding to RANK, preventing RANKL from binding to RANK and thus preventing bone resorption. Therefore, the overall balance between RANKL and OPG determines the amount of bone loss. The balance between RANKL and OPG is regulated by cytokines and hormones. Alterations of the RANKL/RANK/OPG system can lead to dysregulation and pathologic conditions, including primary osteoporosis, immune-mediated bone diseases, malignant bone disorders, and inherited skeletal diseases.

Bone Matrix

Bone matrix is made of the *extracellular elements* of bone tissue, specifically collagen fibers, structural proteins (e.g., proteoglycans and certain glycoproteins), carbohydrate-protein complexes, ground substance, and minerals.

Collagen fibers

Collagen fibers make up the bulk of the bone matrix. They are formed in this way:

1. Osteoblasts synthesize and secrete type I collagen and osteocalcin.
2. Collagen molecules assemble into three thin chains (alpha chains) to form **fibrils**.
3. Fibrils organize into the staggered pattern, with each fibril overlapping its nearest neighbor by about one-fourth its length. This creates gaps into which mineral crystals are deposited.
4. After mineral deposition, fibrils interlink and twist to form ropelike fibers.
5. The fibers join to form the framework that gives bone its tensile and supportive strength. Collagen is the most abundant macromolecule in the body, accounting for approximately one-third of all protein and providing the structural framework for nearly all tissues. Collagen is one of the extracellular components, along with proteoglycans and noncollagenous matrix proteins, of articular cartilage. To date, more than 20 types of collagen have been identified, though all their functions are not yet known. Cartilage-specific collagens include types II (the principal component), VI, IX, X, and XI. Type IX collagen is thought to be the "glue" that holds together the type II collagen scaffold of articular cartilage, helps maintain the structural integrity of cartilage, and resists tensile forces on joint cartilage. Type XI regulates the fibril diameter of type II cartilage. Degradation of type IX collagen by proteolytic enzymes has been seen in the early

stages of osteoarthritis and rheumatoid arthritis. Researchers have proposed that this degradation, or "unplugging," may be the mechanism for the degenerative changes seen in osteoarthritic and rheumatoid cartilage (Table 43.3).

Table 43.3

Types of Collagen in Musculoskeletal Tissues

Type of Collagen	Distribution in Musculoskeletal Tissues
I	Bone, tendon, ligament, intervertebral disk, muscle[a]
II	Cartilage, intervertebral disk
III	Skin, muscle, often with type I
IV	Basement cell membrane, muscle
V	Codistributed with type I muscle, most interstitial tissues
VI	Ubiquitous, muscle
IX	Codistributed with type II muscle
X	Cartilage growth plate
XI	Cartilage, muscle
XII	Codistributed with type I and type III muscle
XIII	Molecule has not been isolated in connective tissues to date
XIV	Codistributed with type I muscle
XV	Muscle; contains heparin sulfate proteoglycans (HSPGs)
XVII	Muscle; contains HSPGs

[a]Refers specifically to skeletal mass.

Proteoglycans

Proteoglycans are large complexes of numerous polysaccharides attached to a common protein core. They strengthen bone by forming compression-resistant networks between the collagen fibers. Proteoglycans also control the transport and distribution of electrically charged particles (ions), particularly calcium, through the bone matrix, thereby playing a role in bone calcium deposition and calcification. Proteoglycans are important constituents of ground substances.

Glycoproteins

Glycoproteins are carbohydrate-protein com-plexes that control the collagen interactions that lead to fibril formation. They also may function in calcification. Four glycoproteins are present in bone: **sialoprotein**, which binds easily with calcium; **osteocalcin**, which binds preferentially to crystallized calcium; **bone albumin**, which is identical to serum albumin and possibly transports essential nutrients to and from bone cells and maintains the osmotic pressure of **bone fluid;** and **alpha-glycoprotein (*α*-glycoprotein)**, which probably plays a significant role in calcification and also may facilitate bone resorption by activating osteoclasts (see Table 43.1).

Bone Minerals

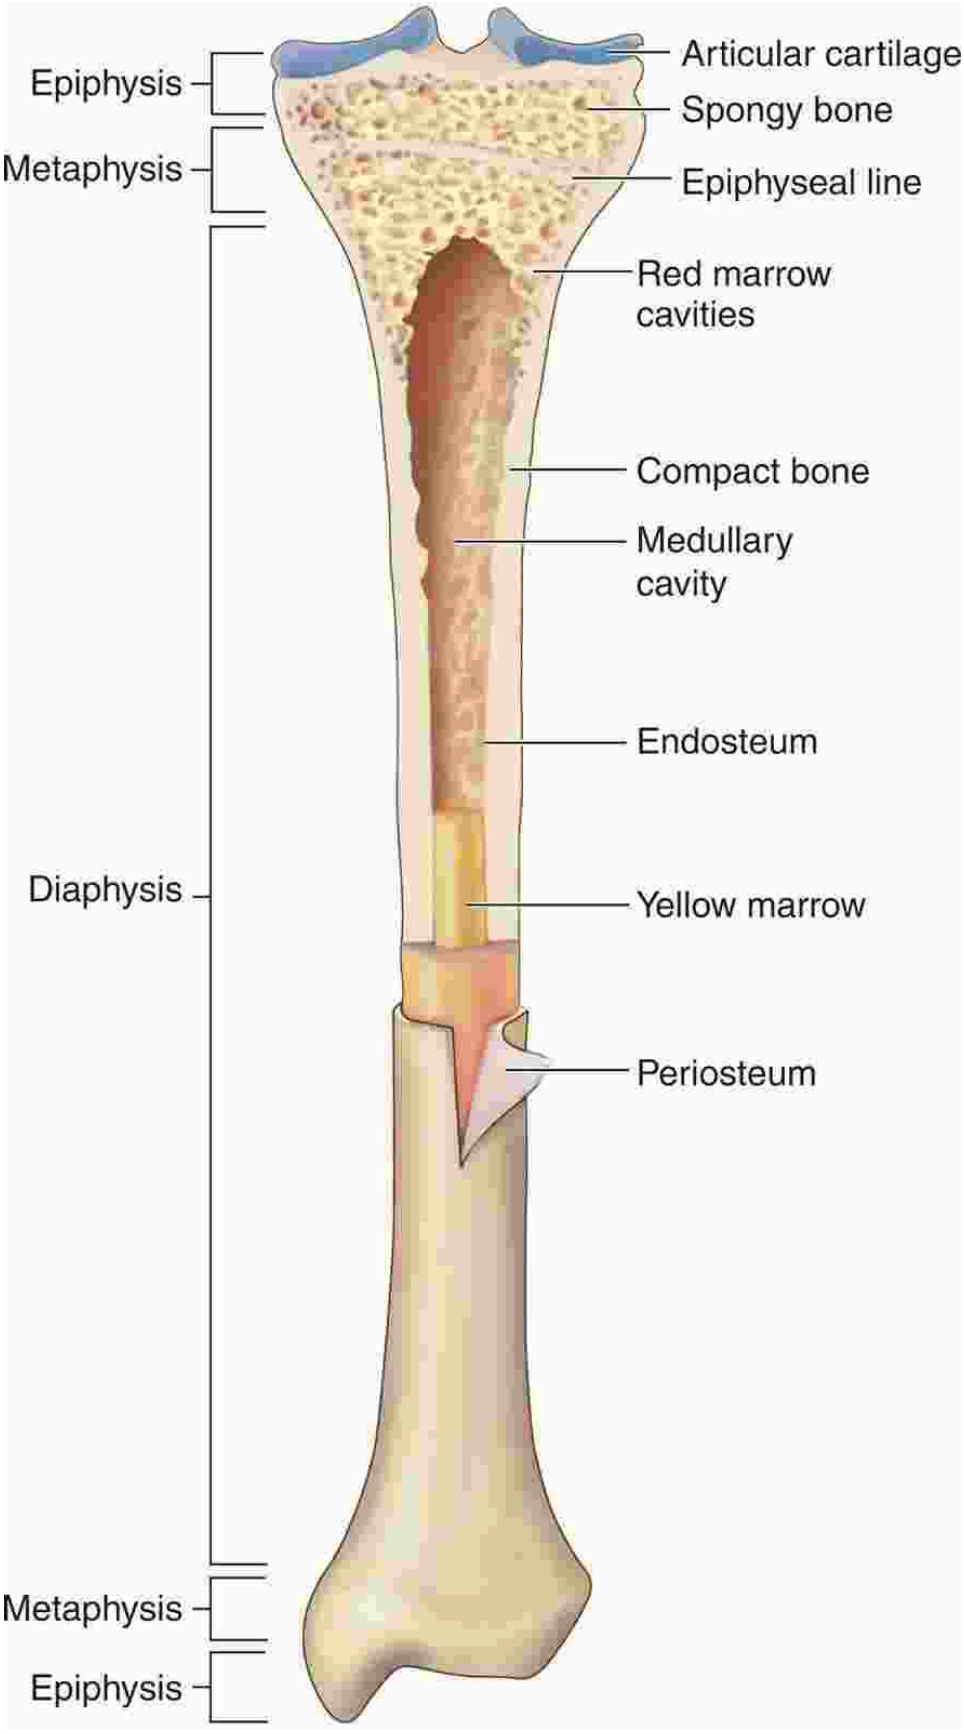
After collagen synthesis and fiber formation, the final step in bone formation is **mineralization**. Mineralization has two distinct phases: (1) formation of the initial mineral deposit (initiation) and (2) proliferation or accretion of additional mineral crystals on the initial mineral deposits (growth). The majority of the minerals in the body are analogs of the naturally occurring mineral **hydroxyapatite (HAP)**. The HAP crystals then penetrate the matrix vesicle membrane and enter the extracellular space.

As the calcium and phosphorus concentrations increase in the bone matrix, the first precipitate to form is dicalcium phosphate dihydrate (DCPD). Once DCPD precipitation begins, the remaining phases of bone crystal formation proceed until insoluble HAP is produced, with approximately 80% to 90% of the HAP incorporated

into the collagen fibers. Amorphous calcium phosphate is distributed throughout the bone matrix.

Types of Bone Tissue

Bone is composed of two types of bony (osseous) tissue: **compact bone (cortical bone)** and **spongy bone (cancellous bone)** (Fig. 43.3). Cortical bone is about 85% of the skeleton; cancellous bone makes up the remaining 15%. Both types of bone tissue contain the same structural elements, with a few exceptions. In addition, both compact tissue and spongy tissue are present in every bone. The major difference between the two types of tissue is the organization of the elements.



Epiphysis
Metaphysis

FIG. 43.3 Cross Section of Bone.
Longitudinal section of long bone (tibia) showing cancellous and compact bone. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

An illustration depicts the longitudinal section of a long bone with its components labeled from top to bottom. Epiphysis includes articular cartilage and spongy bone. Metaphysis includes an epiphyseal line. Diaphysis includes red marrow cavities, compact bone, medullary cavity, endosteum, yellow marrow, and periosteum.

Compact bone is highly organized, solid, and extremely strong. The basic structural unit in compact bone is the **haversian system**. Each haversian system consists of:

- A central canal, called the haversian canal
- Concentric layers of bone matrix, called lamellae (sing., lamella)
- Tiny spaces (lacunae) between the lamellae
- Bone cells (osteocytes) within the lacunae
- Small channels or canals, called canaliculi (sing., canaliculus)

Spongy bone is less complex and lacks haversian systems. In spongy bone, the lamellae are not arranged in concentric layers but in plates or bars termed **trabeculae** (sing., **trabecula**) that branch and unite with one another to form an irregular meshwork. The pattern of the meshwork is determined by the direction of stress on the particular bone. The spaces between the trabeculae are filled with red bone marrow. The osteocyte-containing lacunae are distributed

between the trabeculae and interconnected by canaliculi. Capillaries pass through the marrow to nourish the osteocytes.

All bones are covered with a double-layered connective tissue called the **periosteum**. The outer layer of the periosteum contains blood vessels and nerves, some of which penetrate to the inner structures of the bone through channels called *Volkmann canals*. The inner layer of the periosteum is anchored to the bone by collagenous fibers (Sharpey fibers) that penetrate the bone. Sharpey fibers also help hold or attach tendons and ligaments to the periosteum of bones.

Characteristics of Bone

The human skeleton consists of 206 bones that constitute the axial skeleton and the appendicular skeleton. The **axial skeleton** consists of 80 bones that make up the skull, vertebral column, and thorax. The **appendicular skeleton** consists of 126 bones that make up the upper and lower extremities, the shoulder girdle (pectoral girdle), and the pelvic girdle (os coxae) (Fig. 43.4). The skeleton contributes approximately 14% of an adult's body weight.

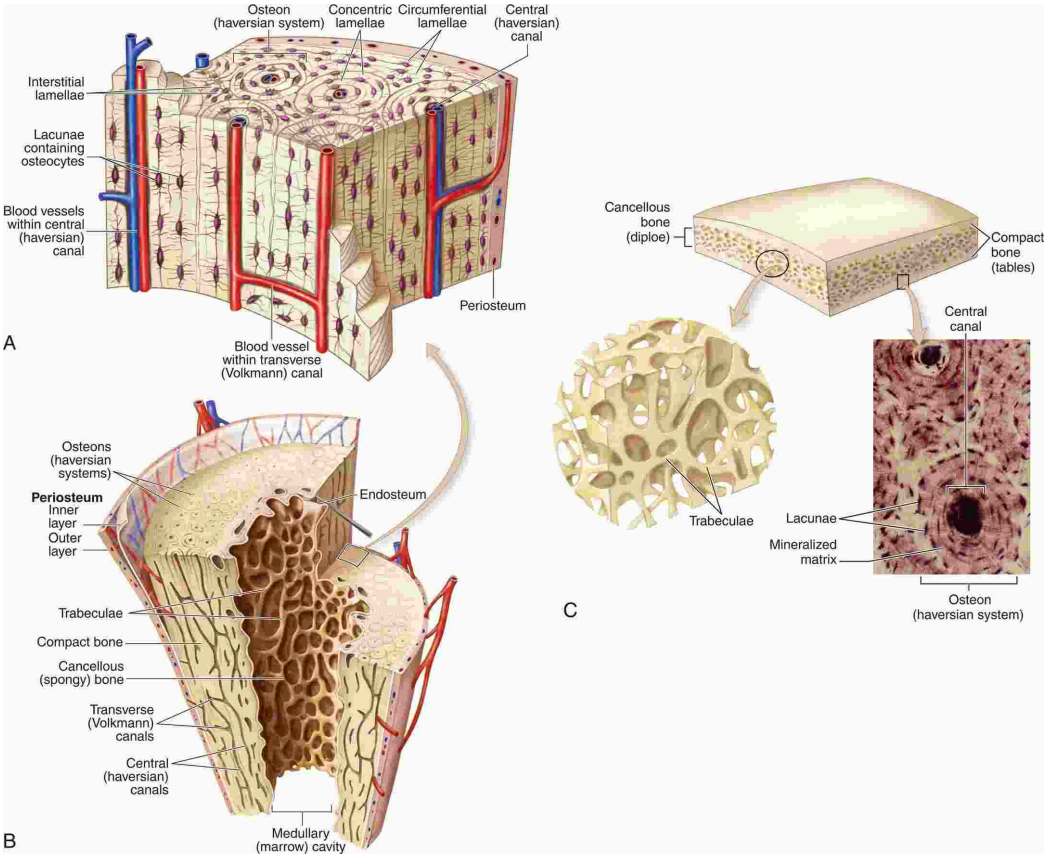

FIG. 43.4 Anterior View of the Skeleton. (From Drake R, et al. *Gray's atlas of anatomy*, 3rd edition. Philadelphia: Churchill Livingstone; 2021.)

An illustration depicts the anterior view of the skeleton its parts labeled clockwise from left as follows. Orbit, maxilla, mandible, ribs, the body of sternum, xiphoid process of sternum, ilium, sacrum, pubis, greater trochanter, femur, patella, fibula, tibia, tarsal bones, metatarsals, phalanges, less trochanter, phalanges, metacarpals, carpal bones, ulna, radius, vertebral column, humerus, scapula, manubrium of sternum, clavicle, zygomatic bone, and frontal bone.

Bones can be classified by shape as long, flat, short (cuboidal), or irregular. **Long bones** are longer than they are wide and consist of a narrow tubular midportion **(diaphysis)** that merges into a broader neck **(metaphysis)** and a broad end **(epiphysis)** (see Fig. 43.3).

The diaphysis consists of a shaft of thick, rigid compact bone that is able to tolerate bending forces. Contained within the diaphysis is the elongated marrow (medullary) cavity. The marrow cavity of the diaphysis contains primarily fatty tissue, which is referred to as *yellow marrow*. The yellow marrow assists red bone marrow in hematopoiesis only during times of stress. The yellow marrow cavity of the diaphysis is continuous with marrow cavities in the spongy bone of the metaphysis and diaphysis. The marrow contained within the epiphysis is red because it contains primarily blood-forming tissue (see Chapter 28). A layer of connective tissue, the **endosteum**, lines the outer surfaces of both types of marrow cavities.

The broadness of the epiphysis allows weightbearing to be distributed over a wide area. The epiphysis is made up of spongy bone covered by a thin layer of compact bone. In a child, the epiphysis is separated from the metaphysis by a cartilaginous **growth plate (epiphyseal plate)**. After puberty, the epiphyseal plate calcifies and the epiphysis and metaphysis merge. By adulthood, the line of demarcation between the epiphysis and metaphysis is undetectable.

In **flat bones**, such as the ribs and scapulae, two plates of compact bone are nearly parallel to each other. Between the compact bone plates is a layer of spongy bone. **Short bones**, such as the bones of the wrist or ankle, are often cuboidal. They consist of spongy bone covered by a thin layer of compact bone.

Irregular bones, such as the vertebrae, mandibles, or other facial bones, have various shapes that include thin and thick segments. The thin part of an irregular bone consists of two plates of compact bone surrounding spongy bone. The thick part consists of spongy bone surrounded by a layer of compact bone.

Maintenance of Bone Integrity

Remodeling

The internal structure of bone is maintained by **remodeling**, a three-phase process in which existing bone is resorbed and new bone is laid down to replace it. Clusters of bone cells, termed **basic multicellular units**, implement remodeling. The basic multicellular units are made up of bone precursor cells that differentiate into osteoclasts and osteoblasts. Precursor cells are located on the free surfaces of bones and along the vascular channels (especially the marrow cavities).

In phase 1 (activation) of the remodeling cycle, a stimulus (e.g., hormone, drug, vitamin, physical stressor) activates the cytokine system, particularly the TNF superfamily, to form osteoclasts. Osteoclasts attach to the bone matrix by actin microfilaments and multiple other proteins that form footlike structures called *podosomes*. Once attached, the osteoclasts' integrin receptors anchor their microfilaments to the extracellular matrix, thus providing receptor pathways between the osteocyte and bone matrix. Lysosomal enzymes produced by osteoclasts "digest" bone; the osteoclasts then release the degraded bone products into the vascular system. After bone is resorbed, the osteoclast leaves behind an elongated cavity termed a *resorption cavity*. The resorption cavity in compact bone follows the longitudinal axis of the haversian system, whereas the resorption cavity in spongy bone parallels the surface of the trabeculae.

New bone formation begins as osteoblasts lining the walls of the resorption cavity express osteoid and alkaline phosphatase, forming sites for calcium and phosphorus deposition. As the osteoid mineralizes, new bone is formed. Successive layers (lamellae) in compact bone are laid down, until the resorption cavity is reduced to a narrow haversian canal around a blood vessel. In this way, old haversian systems are destroyed and new haversian systems are formed. New trabeculae are formed in spongy bone. The formation phase takes 4 to 6 months in humans.

Repair

The remodeling process can repair microscopic bone injuries, but gross injuries, such as fractures and surgical wounds (osteotomies), heal by the same stages as soft tissue injuries, except that new bone, instead of scar tissue, is the final result (see Chapter 7). The stages of bone healing are listed here and shown in Fig. 43.5:

1. *Hematoma formation:* This process occurs if vessels have been damaged, causing hemorrhage. Fibrin and platelets within the hematoma form a meshwork that is the initial framework for healing with the help of hematopoietic growth factors such as platelet-derived growth factor and TGF-β (see Table 43.2).
2. *Procallus formation:* Fibroblasts, capillary buds, and osteoblasts move into the wound to produce granulation tissue called **procallus**. Cartilage is formed as a precursor of bone, and types I, II, and III collagen are formed. Enzymes and growth factors, such as insulin and insulin-like growth factors, plus BMP and osteogenin, aid in this stage of healing.
3. *Callus formation:* Osteoblasts in the procallus form membranous or **woven bone (callus)**. Enzymes increase the phosphate content and permit the phosphate to join with calcium to be deposited as a mineral to harden the callus.
4. *Replacement:* Basic multicellular units of the callus are replaced with lamellar bone or trabecular bone (see Fig. 43.5)
5. *Remodeling:* The periosteal and endosteal surfaces of the bone are remodeled to the size and shape of the bone before injury. Synthesis of other types of collagen recedes in favor of type I, which is the collagen found in bone. This final stage of healing, or **remodeling**, is vital because bone that has not been remodeled does not have good mechanical properties for weightbearing and mobility.

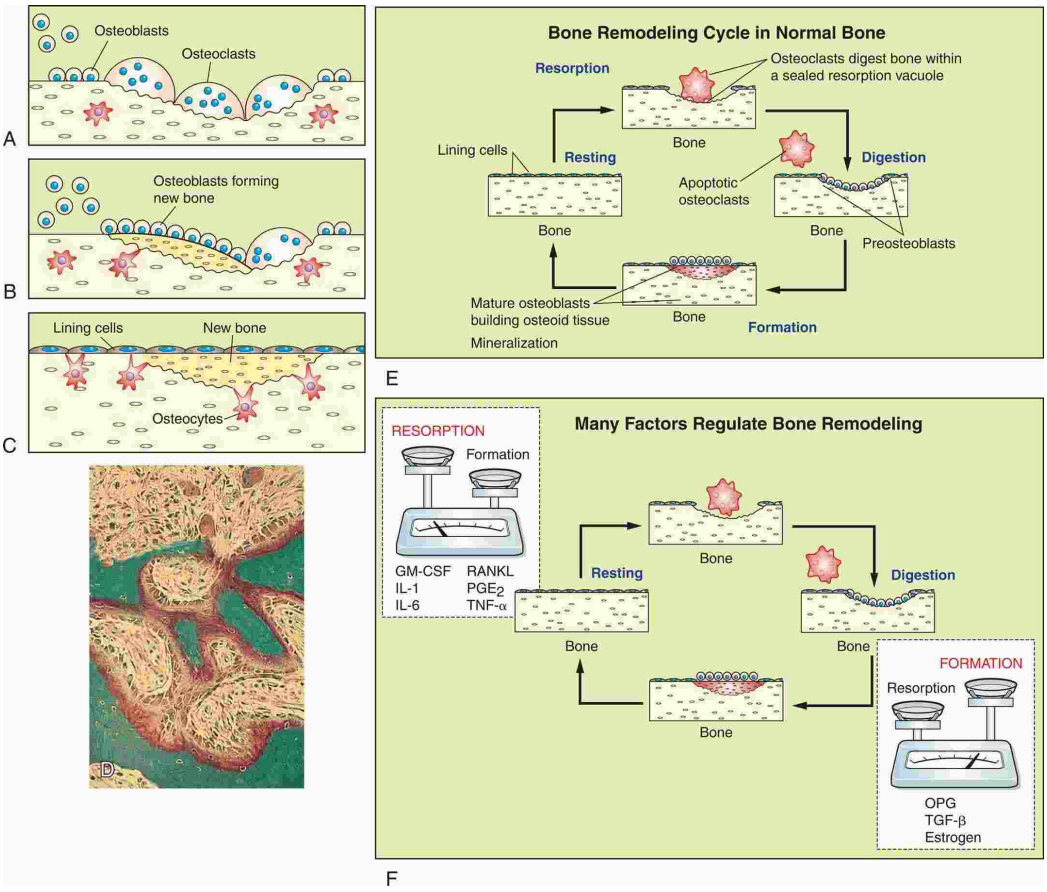

FIG. 43.5 Bone Remodeling.
All bone cells participate in bone remodeling. In the remodeling sequence, bone sections are removed by bone-resorbing cells (osteoclasts) and replaced with a new section laid down by bone-forming cells (osteoblasts). Bone remodeling is necessary because it allows the skeleton to respond to mechanical loading, maintains quality control (repair and prevent microdamage), and allows the skeleton to release growth factors and minerals (calcium and phosphate) stored in the bone matrix to the circulation. The cells work in response to signals generated in the environment (see F). Only the osteoclastic cells mediate the first phase of remodeling. They are activated, scoop out bone **(A)**, and resorb it; then the work of the

osteoblasts begins **(B)**. They form new bone that replaces bone removed by the resorption process **(C)**. The sequence takes 4 to 6 months. **(D)** Micrograph of active bone remodeling seen in the settings of primary or secondary hyperparathyroidism. Note the active osteoblasts surmounted on red-stained osteoid. Marrow fibrosis is present. **(E)** Bone remodeling cycle in normal bone with (F). Numerous signaling factors are necessary for remodeling. Factors most important for resorption include granulocyte macrophage-colony stimulating factor *(GM-CSF)*, interleukin-1 *(IL-1)* and IL-6, receptor activator for nuclear factor-κB ligand *(RANKL)*, prostaglandin E_2*(*PGE_2*)*, and tumor necrosis factor-α *(TNF-α)*. Important factors for bone formation include osteoprotegerin *(OPG)*, transforming growth factor-beta *(TGF-β)*, and estrogen. (Adapted from Nucleus Medical Art. D, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Illustration A depicts the first phase of bone remodeling which shows the activation of osteoclasts. Illustration B depicts the second phase of bone remodeling which shows the osteoblasts forming new bone. Illustration C depicts the third phase of bone remodeling which shows the new bone is replaced by the resorption process. Illustration D depicts the photomicrograph of active bone remodeling. Illustration E depicts the bone remodeling cycle in the normal bone which involves

digestion, formation, resting, and resorption. Illustration F depicts the factors regulating bone remodeling which include O P G, T G F beta, estrogen, G M C S F, I L 1, I L 6, P G E 2, T N F alpha, and R A N K L.

The speed with which bone heals depends on the severity of the bone disruption; the type and amount of bone tissue that need to be replaced (spongy bone heals faster). (See Emerging Science Box: Factors Affecting Bone Healing.)

Structure and Function of Joints

The site where two or more bones are attached is called a **joint**, or an **articulation** (Fig. 43.6). The primary function of joints is to provide stability and mobility to the skeleton. A joint's function depends on both its location and its structure. Generally, joints that stabilize the skeleton have a simpler structure than those that enable the skeleton to move. Most joints provide both stability and mobility to some degree.

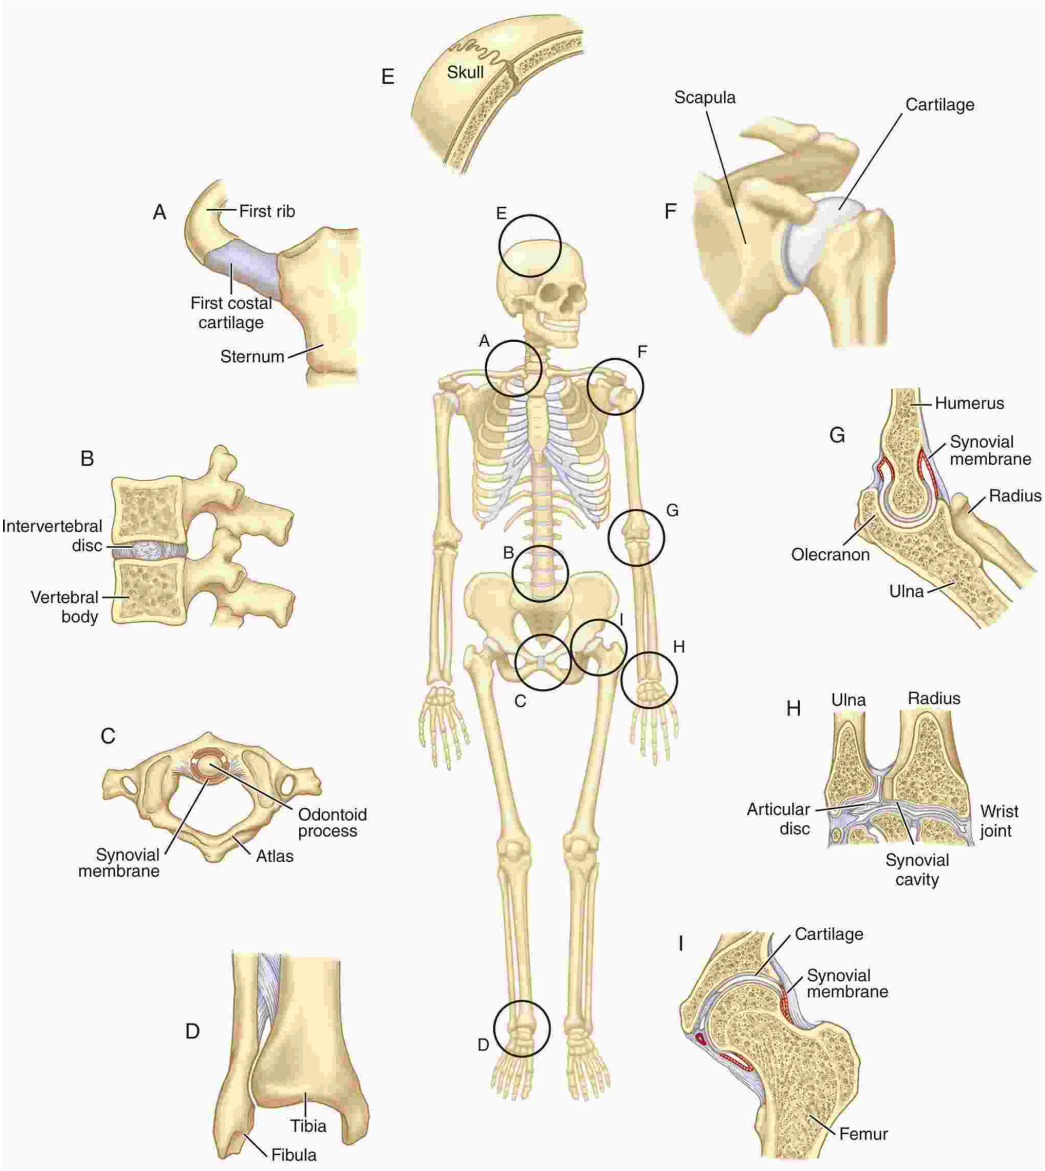

FIG. 43.6 Types of Joints. Cartilaginous (amphiarthrodial) joints, which are slightly movable, include: **(A)** a synchondrosis that attaches ribs to costal cartilage; **(B)** a symphysis that connects vertebrae; and **(C)** the symphysis that connects the two pubic bones. Fibrous (synarthrodial) joints, which are immovable, include **(D)** the syndesmosis between the tibia and fibula; **(E)** sutures that connect the skull bones; and the gomphosis (not shown), which holds teeth in their sockets. The synovial joints

include **(F)** the spheroid type at the shoulder; **(G)** the hinge type at the elbow; **(H)** the gliding joints of the hand; and **(I)** the ball and socket (hip). (Adapted from Dorland. *Dorland's medical illustrated dictionary*, 32rd edition. St. Louis: Saunders; 2012.)

Illustrations A through I depict the types of joints. Illustration A depicts the pivot joint with labels indicating the first rib, first costal cartilage, and sternum. Illustration B depicts the synchondrosis with labels indicating the intervertebral disc and vertebral body. Illustration C depicts the pubic joint with labels indicating synovial membrane, atlas, odontoid process. Illustration D depicts the plane joint with labels indicating tibia and fibula. Illustration E depicts the skull. Illustration F depicts the ball and socket joint with labels indicating scapula and cartilage. Illustration G depicts the elbow joint with labels indicating humerus, synovial membrane, radius, olecranon, ulna. Illustration H depicts the humerus joint with labels indicating ulna, radius, wrist joint, articular disc, and synovial cavity. Illustration I depicts the femoral joint with labels indicating cartilage, synovial membrane, and femur.

Joints are classified based on the degree of movement they permit or on the connecting tissues that hold them together. Based on movement, a joint is classified as a **synarthrosis (immovable joint)**, an **amphiarthrosis (slightly movable joint)**, or a **diarthrosis (freely movable joint)**. From connective structures, joints are classified

broadly as fibrous, cartilaginous, or synovial. Each of these three structural classifications can be subdivided according to the shape and contour of the articulating surfaces (ends) of the bones and the type of motion the joint permits.

Fibrous Joints

A joint in which bone is united directly to bone by fibrous connective tissue is called a **fibrous joint**. These joints have no joint cavity and allow little, if any, movement.

Fibrous joints are further subdivided into three types: sutures, syndesmoses, and gomphoses. A **suture** has a thin layer of dense fibrous tissue that binds together interlocking flat bones in the skulls of young children. Sutures form an extremely tight union that permits no motion. By adulthood, the fibrous tissue has been replaced by bone. A **syndesmosis** is a joint in which the two bony surfaces are united by a ligament or membrane. The fibers of ligaments are flexible and stretch, permitting a limited amount of movement. The paired bones of the lower arm (radius and ulna) and the lower leg (tibia and fibula) and their ligaments are syndesmotic joints. A **gomphosis** is a special type of fibrous joint in which a conical projection fits into a complementary socket and is held in place by a ligament. The teeth held in the maxilla or mandible are gomphosis joints.

Cartilaginous Joints

There are two types of cartilaginous joints: symphyses and synchondroses. A **symphysis** is a cartilaginous joint in which bones are united by a pad or disk of fibrocartilage. A thin layer of hyaline cartilage usually covers the articulating surfaces of these two bones, and the thick pad of fibrocartilage acts as a shock absorber and stabilizer. Examples of symphyses are the symphysis pubis, which joins the two pubic bones, and the intervertebral disks, which join the bodies of the vertebrae. A **synchondrosis** is a joint in which hyaline cartilage, rather than fibrocartilage, connects the two bones.

The joints between the ribs and the sternum are synchondroses. The hyaline cartilage of these joints is called *costal cartilage*. Slight movement at the synchondroses between the ribs and the sternum allows the chest to move outward and upward during breathing.

Synovial Joints

Structure

Synovial joints (diarthroses) are the most movable and the most complex joints in the body (Fig. 43.7). A synovial joint consists of the following parts:

1. A fibrous joint capsule (articular capsule)
2. A synovial membrane that lines the inner surface of the joint capsule
3. A joint cavity (synovial cavity), a space formed by the capsule
4. Synovial fluid, which fills the joint cavity and lubricates the joint surface
5. Articular cartilage, which covers and pads the articulating bony surfaces

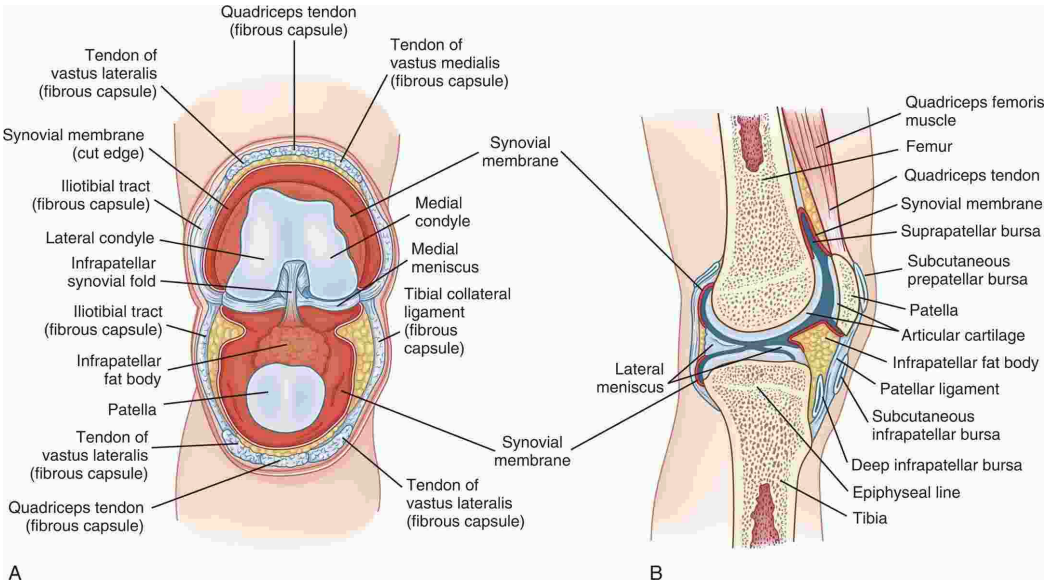

FIG. 43.7 Knee Joint (Synovial Joint).
(A) Frontal view. **(B)** Lateral view.

Illustration A depicts the frontal aspect of a longitudinal section of the knee joint with its components labeled clockwise from left as follows. Quadriceps tendon (fibrous capsule), tendon of vastus medialis (fibrous capsule), synovial membrane, medial condyle, medial meniscus, tibial collateral ligament (fibrous capsule), tendon of vastus lateralis (fibrous capsule), quadriceps tendon (fibrous capsule), patella, infrapatellar fat body, iliotibial tract (fibrous capsule), infrapatellar synovial fold, lateral condyle, iliotibial tract (fibrous capsule, synovial membrane (cut edge). Illustration B depicts the lateral aspect of a longitudinal section of the knee joint with its components labeled from top to bottom as follows. Quadriceps femoris muscle, femur,

quadriceps tendon, synovial membrane, suprapatellar bursa, subcutaneous prepatellar bursa, patella, articular cartilage, infrapatellar fat body, patellar ligament, subcutaneous infrapatellar bursa, deep infrapatellar bursa, epiphyseal line, tibia, lateral meniscus.

Joint (articular) capsule

The **joint (articular) capsule** is fibrous connective tissue that covers the ends of bones where they meet in a joint. Sharpey fibers firmly attach the proximal and distal capsule to the periosteum, and ligaments and tendons also may reinforce the capsule. It is composed of parallel, interlacing bundles of dense, white fibrous tissue richly supplied with nerves, blood vessels, and lymphatic vessels. Nerves in and around the joint capsule are sensitive to the rate and direction of motion, compression, tension, vibration, and pain.

Synovial membrane

The **synovial membrane (synovium)** is a smooth, delicate inner lining of the joint capsule found in the nonarticular portion of the synovial joint and any ligaments or tendons that traverse this cavity (Fig. 43.8). It is composed of two layers: the vascular subintima and the thin cellular intima. The vascular subintima merges with the fibrous joint capsule and is composed of loose fibrous connective tissue, elastin fibers, fat cells, fibroblasts, macrophages, and mast cells; the cellular intima consists of rows of synovial cells embedded in a fiber-free intercellular matrix and contains two types of cells—A and B. **A cells (macrophages)** ingest and remove (phagocytose) bacteria and particles of debris in the joint cavity; **B cells (fibroblasts)** are the most numerous and secrete hyaluronate, which gives synovial fluid its viscous quality. The synovial membrane is

richly supplied with blood and lymphatic vessels and is capable of rapid repair and regeneration.

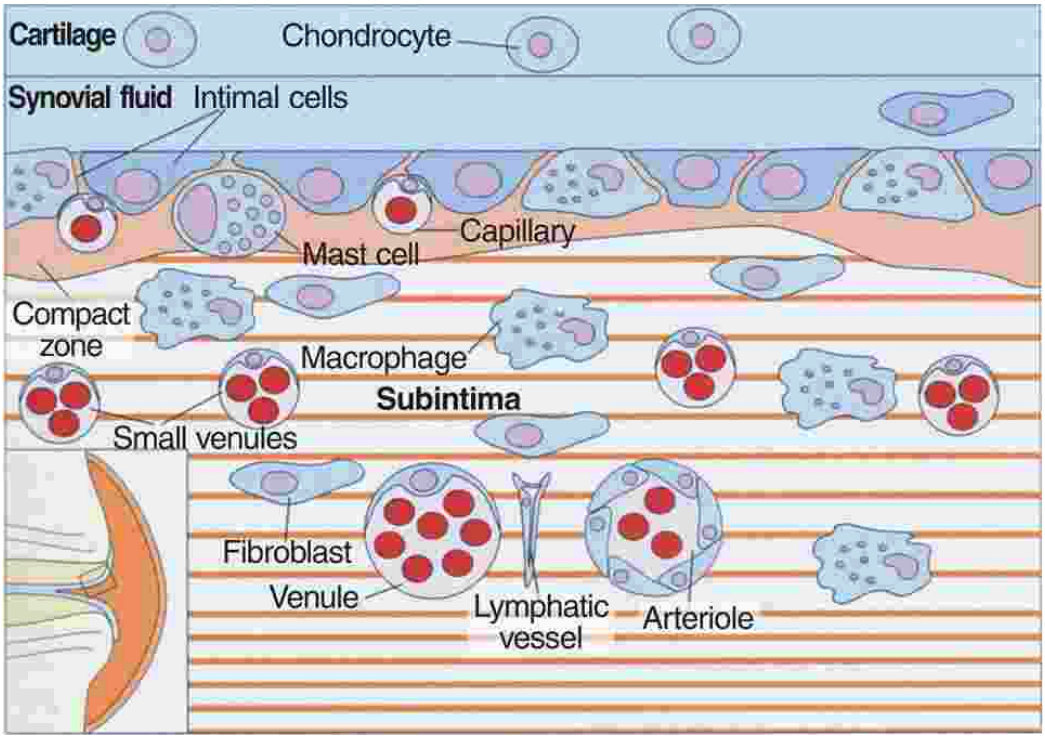

FIG. 43.8 Synovium.
Note the delicate synovial lining resting on a fibroadipose subintimal lining rich in capillaries, lymphatics, and nerve endings. (Modified from Hochberg MC, et al. *Rheumatology*, 4th edition. Philadelphia: Mosby; 2008.)

An illustration depicts the layered structure of the synovium with labels indicating cartilage, chondrocyte, synovial fluid, compact zone, mast cell, capillary, small vessels, macrophage, subintima, fibroblast, venule, lymphatic vessels, and arteriole.

Joint (synovial) cavity

The **joint (synovial) cavity** is an enclosed, fluid-filled space between articulating surfaces of two bones, also called *joint space*. It enables two bones to move "against" one another and is surrounded by synovial membrane and filled with synovial fluid.

Synovial fluid

Synovial fluid is superfiltrated plasma from blood vessels that lubricates the joint surfaces, nourishes the pad of the articular cartilage, and covers the ends of the bones. Hyaluronic acid in the synovial fluid gives it important biomechanical properties. It also contains free-floating synovial cells and various leukocytes that phagocytose joint debris and microorganisms. Loss of synovial fluid leads to rapid deterioration of articular cartilage.

Articular cartilage

Articular cartilage is a layer of hyaline cartilage that covers the end of each bone; it may be thick or thin, depending on the size of the joint, the fit of the two bone ends, and the amount of weight and shearing force the joint normally withstands. The function of articular cartilage is to reduce friction in the joint and to distribute the forces of weightbearing. Articular cartilage is composed of **chondrocytes** (cartilage cells) and an intercellular matrix consisting of type II collagen, proteoglycans, and water. The water content ranges from 60% to almost 80% of the net weight of the cartilage, and individual molecules rapidly enter or exit the articular cartilage to contribute to the resiliency of the tissue.

At the surface of articular cartilage, the collagen fibers run parallel to the joint surface and are closely compacted into a dense, protective mat. In the middle layer (the proliferative zone) of the cartilage, the fibers are arranged tangential to the surface, allowing them to deform and absorb some of the weightbearing (Fig. 43.9). In the bottom layer (the hypertrophic zone) of the cartilage, the fibers are perpendicular to the joint surface, allowing them to resist shear forces, and are embedded in a calcified layer of cartilage called the

tidemark. The **tidemark** anchors the collagen fibers to the underlying (subchondral) bone. Collagen fibers are important components of the cartilage matrix because they account for approximately 60% of the dry weight and because they (1) anchor the cartilage securely to underlying bone, (2) provide a taut framework for the cartilage, (3) control the loss of fluid from the cartilage, and (4) prevent the escape of protein polysaccharides (proteoglycans) from the cartilage. The proteoglycans give articular cartilage its stiff quality and regulate the movement of synovial fluid through the cartilage. The proteoglycans are macromolecules consisting of proteins, carbohydrates (glycosaminoglycans), and hyaluronic acid. The proteoglycans give articular cartilage its stiff quality and regulate the movement of synovial fluid through the cartilage. Without proteoglycans, normal weightbearing would rapidly and completely press all the synovial fluid out of the cartilage. Proteoglycans act as a pump, permitting enough fluid to be pressed out to ensure that a fluid film is always present on the surface of the cartilage, even after hours of weightbearing. The pumping action of proteoglycans also draws synovial fluid back into the cartilage after a weightbearing load is released. Mobility and weightbearing are necessary for the pumping action of proteoglycans to occur. Nonuse of a joint quickly reduces the pumping action, changing the composition of the matrix and interfering with the nutrition of the chondrocytes. Normal articular cartilage has no blood vessels, lymph vessels, or nerves. Therefore, it is insensitive to pain and regenerates slowly and minimally after injury.[6] Regeneration occurs primarily at sites where the articular cartilage meets the synovial membrane, where blood vessels and nutrients are available. In general, it has been difficult to enhance cartilage repair, but that may be changing (see Emerging Science Box: Progress in Rebuilding Cartilage). Synovial joints are described as uniaxial, biaxial, or multiaxial according to the shapes of the bone ends and the type of movement occurring at the joint (Fig. 43.10). Usually, one of the bones is stable and serves as an axis for the motion of the other bone. The body movements made possible by various synovial joints are either circular or angular (Fig. 43.11).

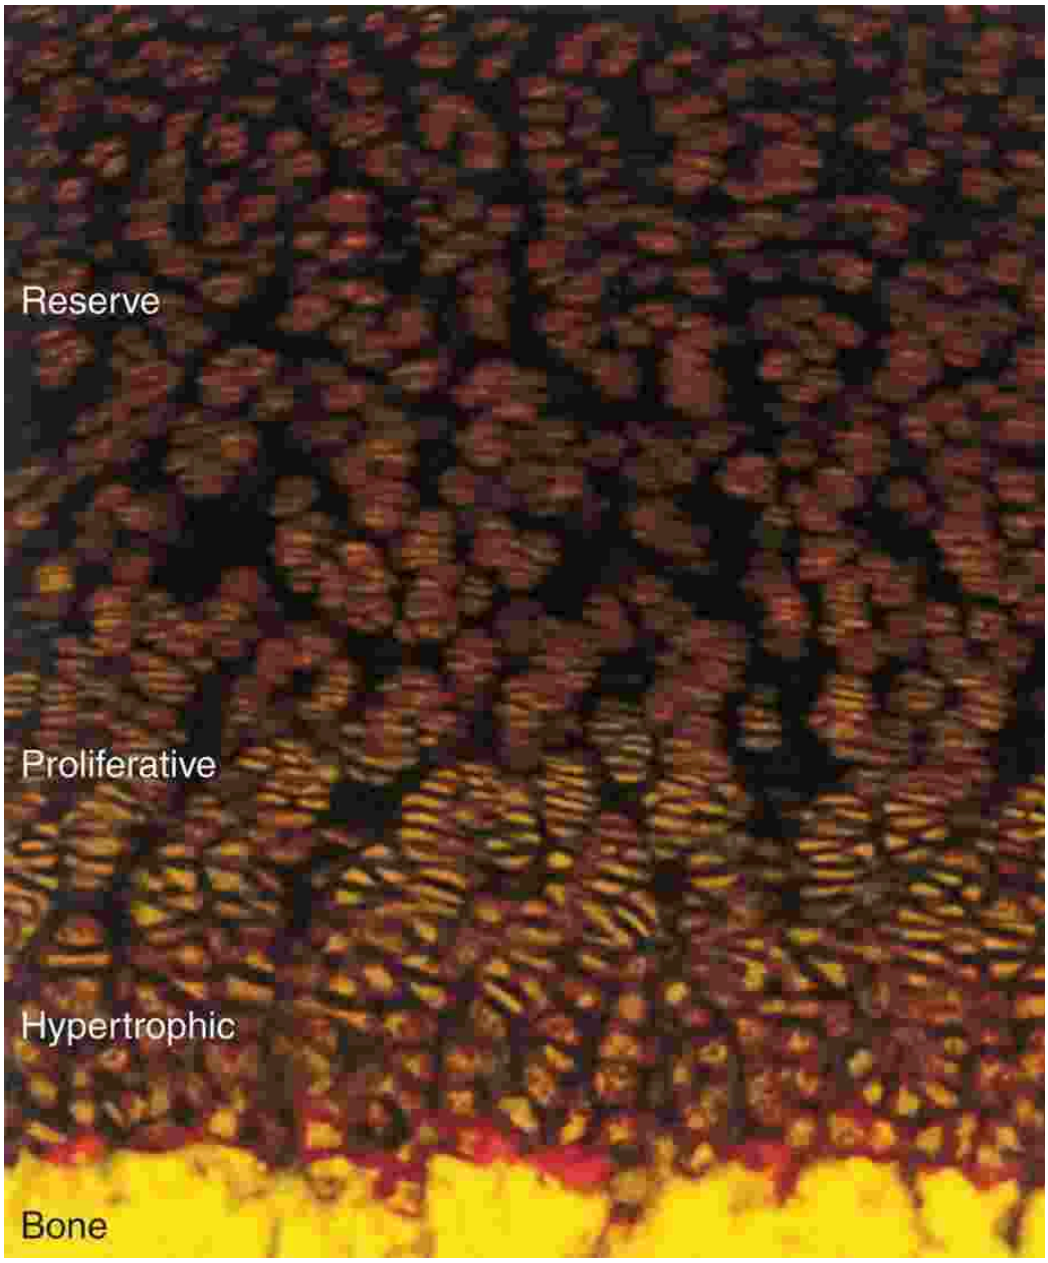

FIG. 43.9 Collagen Zones.
The three collagen zones (reserve, proliferative, and hypertrophic) are distinctly shown in a growth plate. (From Hjorten R, Hansen U, Underwood RA, et al. Type XXVII collagen at the transition of cartilage to bone during skeletogenesis. *Bone*, 2007;41[4]:535.)

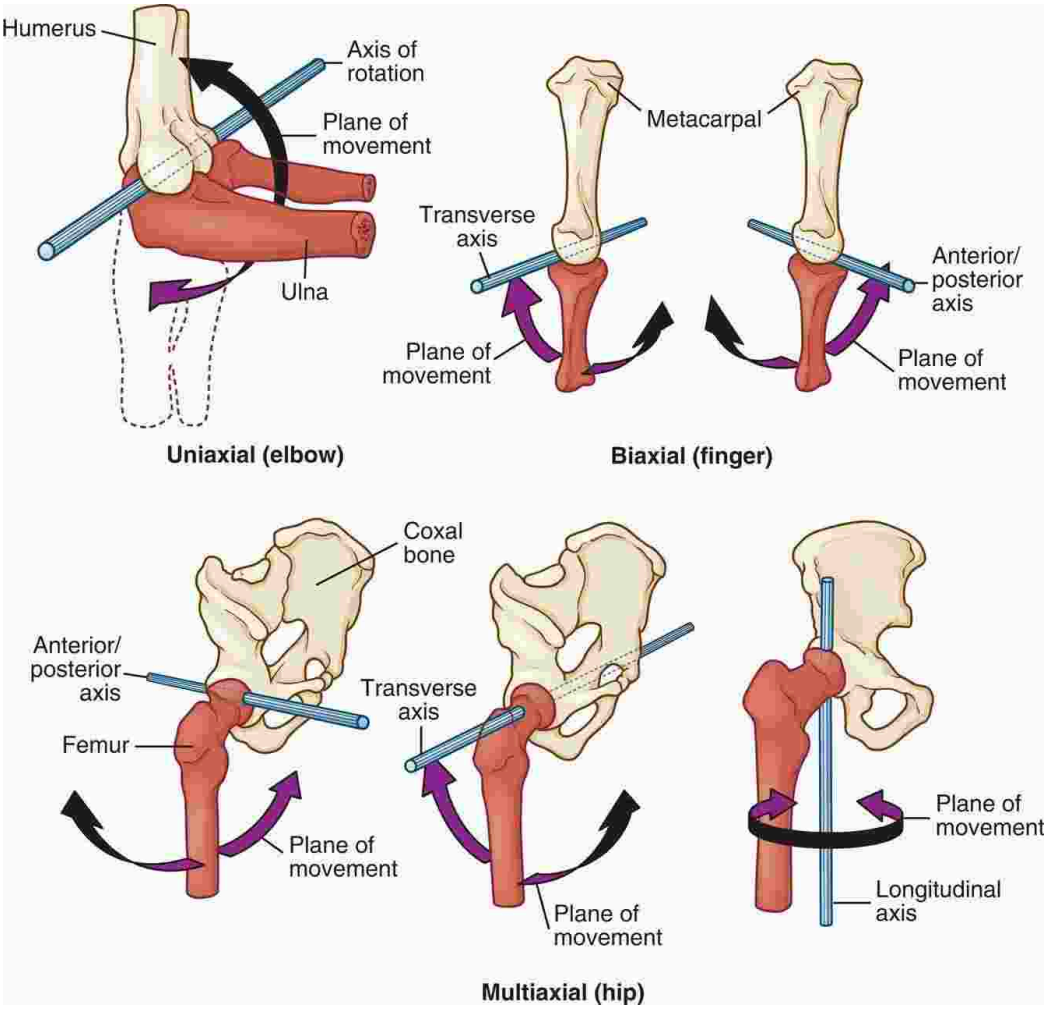

FIG. 43.10 Movements of Synovial (Diarthrodial) Joints.

Three illustrations depict the various movements of synovial joints. The first illustration depicts the uniaxial (elbow) movement of the synovial joint in the elbow which shows the sagittal plane of movement along the axis of rotation occurs. The second illustration depicts the biaxial (finger) movement of the synovial joint in the finger which shows the sagittal plane of movement along the transverse axis and the frontal plane of movement

along the anterior or posterior axis. The third illustration depicts the multiaxial (hip) movement of the synovial joint in the hip which shows the sagittal plane of movement around the transverse axis, the frontal plane of movement along the anterior or posterior axis, and the transverse plane of movement along the longitudinal axis.

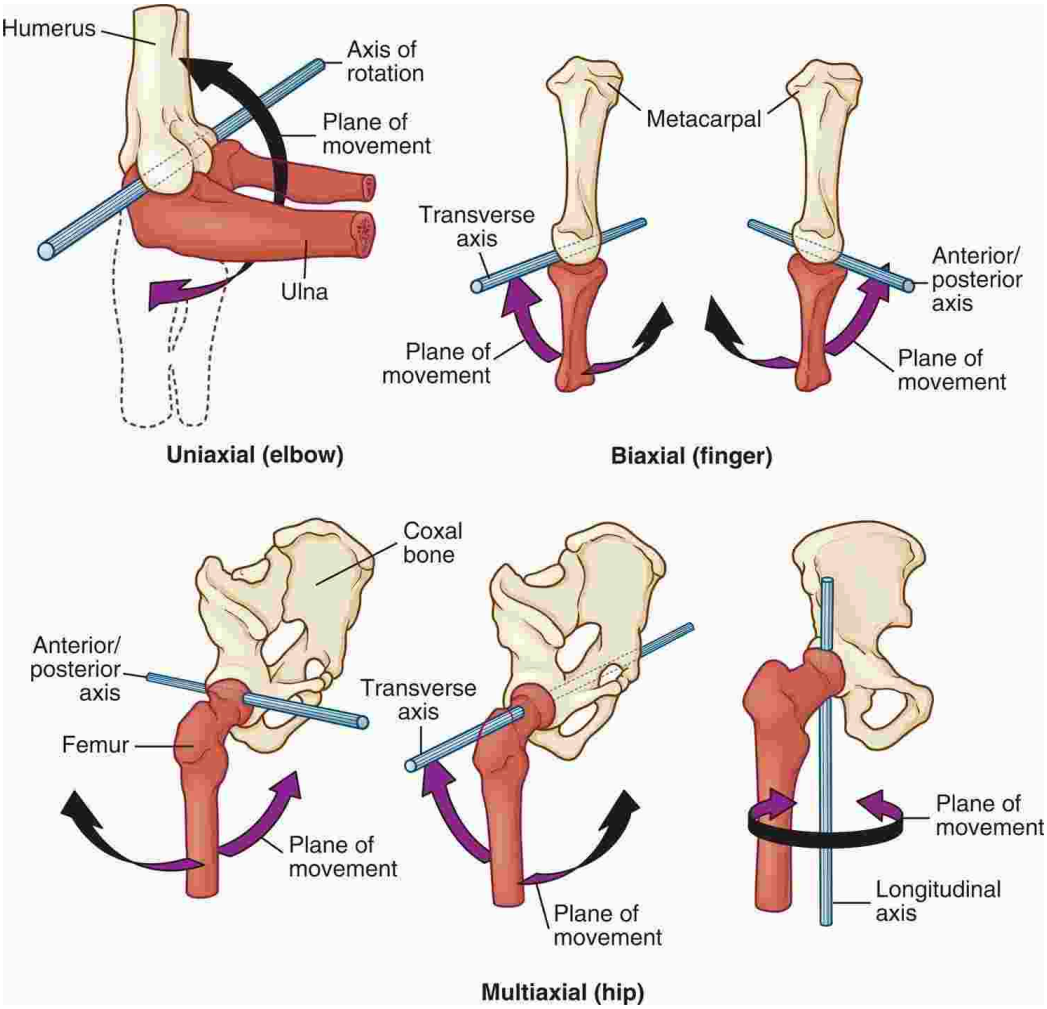

FIG. 43.11 Body Movements Made Possible by Synovial (Diarthrodial) Joints.

An illustration depicts the various types of body movements at synovial joints indicated by arrow marks. The body movements from top to bottom are as follows. Arm or hand involves circumduction, an extension of the elbow, supination, and adduction. The hip or leg involves abduction, hip and knee flexion, hyperextension, and extension. Head involves flexion or hyperflexion, rotation. Foot

involves dorsiflexion, plantar flexion, and eversion, or inversion.

Structure and Function of Skeletal Muscles

Skeletal muscles arise from mesodermal progenitor cells; the most numerous are the somites. Actual formation of skeletal muscle is a complex process controlled by multiple signaling factors. A critical component of successful embryonic muscle formation (myogenesis) is protein kinase, an enzyme that adds phosphate groups to substrate proteins, thereby directing cell processes.[7] In muscle, these factors direct the formation of myoblasts. Once myoblasts are formed, they fuse with other myoblasts and form myotubes, eventually developing into muscle fibers. At birth, the muscle fibers have completed development from myoblasts. Final muscle type is determined by transcription factors that regulate both pre- and postnatal muscle development.[8]

The millions of individual fibers of skeletal muscle contract and relax to perform the work necessary to move the body (Fig. 43.12). Muscle constitutes 40% of an adult's body weight and 50% of a child's weight. Muscle is 75% water, 20% protein, and 5% organic and inorganic compounds. Thirty-two percent of all protein stores for energy and metabolism are contained in muscle. Between the ages of 30 and 60, muscle mass decreases by about 0.5 pound of muscle each year. For each 0.5 pound of muscle lost, almost 1 pound of fat typically is gained.

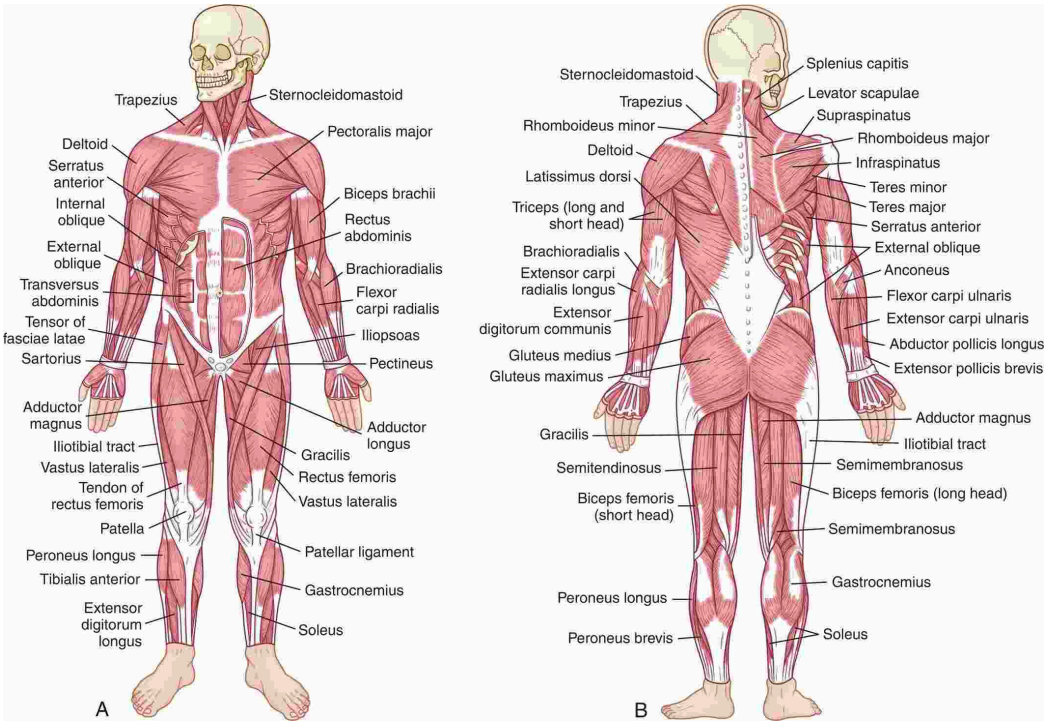

FIG. 43.12 Skeletal Muscles of the Body.
(A) Anterior view. **(B)** Posterior view.

Illustration A depicts the anterior view of the body with skeletal muscles labeled as follows. Trapezius, deltoid, serratus anterior, internal oblique, external oblique, transverse abdominis, tensor of fasciae latae, sartorius, adductor Magnus, iliotibial tract, vastus lateralis, tendon of rectus femoris, patella, peroneus longus, tibialis anterior, extensor digitorum longus, soleus, gastrocnemius, patellar ligament, vastus lateralis, rectus femoris, gracillis, adductor longus, pectineus, iliopsoas, flexor carpi radialis, brachioradialis, rectus abdominis, biceps brachii, pectoralis major, sternocleidomastoid. Illustration B depicts the posterior view of the body with skeletal

muscles labeled as follows. Sternocleidomastoid, trapezius, rhomboideus minor, latissimus dorsi, deltoid, triceps (long and short head), brachioradialis, extensor carpi radialis longus, extensor digitorum communis, gluteus Medius, gluteus maximus, gracilis, semitendinosus, biceps femoris (short head), peroneus longus, peroneus brevis, splenius capitis, levator scapulae, supraspinatus, rhomboideus major, infraspinatus, teres minor, teres major, serratus anterior, external oblique, anconeus, flexor carpi ulnaris, abductor pollicis longus, extensor pollicis brevis, adductor magus, iliotibial tract, semimembranosus, gastrocnemius, and soleus.

Whole Muscle

There are more than 350 named muscles in the body. The body's muscles vary dramatically in size and shape. They range from 2 to 60 cm in length and are shaped according to function. **Fusiform muscles** are elongated muscles shaped like straps that can run from one joint to another. The biceps brachii and psoas major are examples of fusiform muscles. **Pennate muscles** are broad, flat, and slightly fan shaped, with fibers running obliquely to the muscle's long axis. The multipennate deltoid muscle, which flexes and extends the arm, is a good example of a muscle shaped according to its function.

Each skeletal muscle is a separate organ, encased in a three-part connective tissue framework called **fascia**. The layers of connective tissue protect the muscle fibers, attach the muscle to bony

prominences, and provide a structure for a network of nerve fibers, blood vessels, and lymphatic channels. The layers are:

1. The outermost layer, the **epimysium**, which is located on the surface of the muscle and tapers at each end to form the tendon (Fig. 43.13); also see the Tendons and Ligaments Section for a discussion of tendons. Tendons allow short muscles to exert power on a distant joint, whereas a thick muscle would interfere with the joint's mobility.
2. The **perimysium**, which further subdivides the muscle fibers into bundles of connective tissue, or **fascicles**.
3. The **endomysium**, which surrounds the muscle. It is the smallest unit of muscle visible without a microscope.

Fasciculi

FIG. 43.13 Levels of Organization Within a Skeletal Muscle Showing Muscle Fibers and Their Coverings. (From Standring S. *Gray's anatomy*, 40th edition. Edinburgh: Churchill Livingstone; 2008)

An illustration depicts the level of organization within a skeletal muscle fiber which shows the muscle consists of fasciculi. Fasciculi consist of fibers. An enlarged view of fiber consists of myofilaments, sarcomere, myofibril, and nucleus.

The ligaments, tendons, and fascia are made up of connective tissue that also buffers the limbs from the effects of sudden strains or changes in speed. The rapid recovery necessary for strenuous exercise is supported by the elastic property of muscle and its connective tissue.

Skeletal muscle has been designated as **voluntary** (controlled directly by the nervous system), **striated** (has a striped pattern when viewed under a light microscope), or **extrafusal** (to distinguish from other contractile fibers in the sensory organ of the muscle). Components that are visible on gross inspection of the whole muscle include the motor and sensory nerve fibers. These function together with the muscle, innervating portions of it and providing the electrical impulses needed for motor function.

Motor Unit

From the anterior horn cell of the spinal cord, the axons of motor nerves branch to innervate a specific group of muscle fibers. Each anterior horn cell, its axon (part of the lower motor neuron; see Chapter 15), and the muscle fibers innervated by it are called a **motor unit** (Fig. 43.14). The motor units are composed of lower motor neurons, which extend to skeletal muscles. Often termed the *functional unit* of the neuromuscular system, the motor unit behaves

as a single entity and contracts as a whole when it receives an electrical impulse.

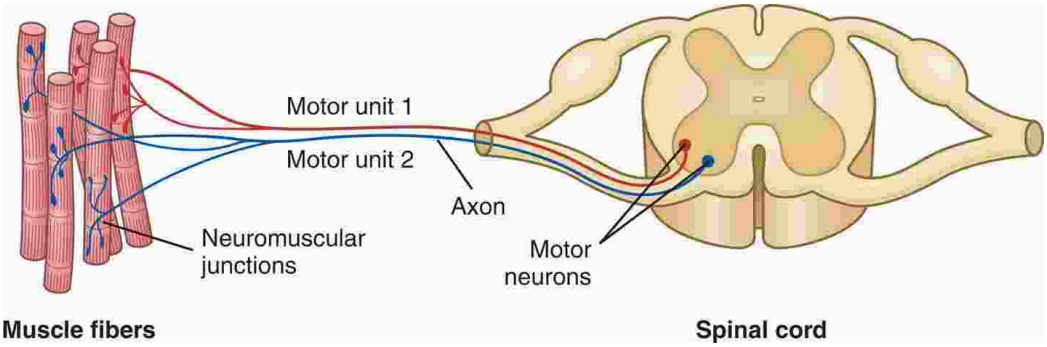

FIG. 43.14 Motor Units of a Muscle.
Each motor unit consists of a motor neuron and all the muscle fibers (cells) supplied by the neuron and its axon branches.

The whole muscle may be controlled by several motor nerve axons. These branch to innervate many motor units within the muscle. The whole muscle then may be made up of many motor units. The number of motor units per individual muscle varies greatly. In the calf, for example, 1 motor axon innervates approximately 2000 muscle fibers, out of a total of 1.2 million muscle fibers. This is a high innervation ratio of muscle fibers to axons, and it contrasts markedly with the low innervation ratio found in laryngeal muscles, where two to three muscle fibers constitute each motor unit and the innervation ratio can be of great functional significance. The greater the innervation ratio of a particular organ, the greater its endurance. Higher innervation ratios prevent fatigue, whereas lower innervation ratios allow for precision of movement.

Sensory receptors

Although muscles function as effector organs, they also contain sensory receptors and are involved in sending different signals to the central nervous system. Among these are the muscle spindles and Golgi tendon organs. **Spindles** are mechanoreceptors that lie parallel

to muscle fibers and respond to muscle stretching. **Golgi tendon organs** are dendrites that terminate and branch to tendons near the neuromuscular junction. The muscle spindles, Golgi tendon organs, and free nerve endings provide a means of reporting changes in length, tension, velocity, and tone in the muscle. This system of afferent signals is responsible for the muscle stretch response and maintenance of normal muscle tone.

Muscle fibers

Each **muscle fiber** is a single **muscle cell** that is cylindrical in structure and surrounded by a membrane capable of excitation and impulse propagation. The muscle fiber contains bundles of **myofibrils**, the fiber's functional subunits, in a parallel arrangement along the longitudinal axis of the muscle (Fig. 43.15). At birth, the muscle fibers have completed development from precursor cells called *myoblasts*. All **voluntary muscles** are derived from the mesodermal layer of the embryo. Genetic transcription factors, most notably MyoD, induce skeletal muscle differentiation. **Myoblasts** are the main cells responsible for muscle growth and regeneration. Myoblasts are termed *satellite cells* when in a dormant state. **Satellite cells** are crucial in muscle growth, maintenance, repair, and regeneration. Once muscle is injured, satellite cells become activated and increase the number of transcriptional factors necessary to form myoblasts and assist in repair.

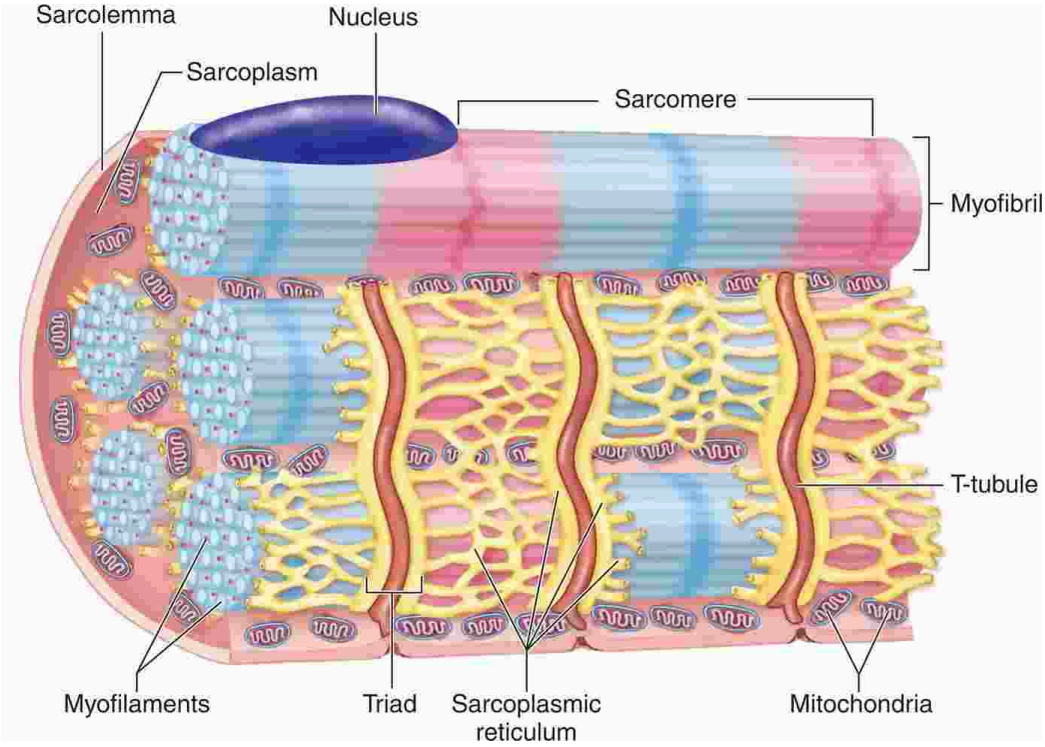

FIG. 43.15 Myofibrils of a Skeletal Muscle Fiber (Cell) and Overall Organization of Skeletal Muscle. (From Patton KT, Thibodeau GA. *Anatomy & physiology*, 9th edition. St. Louis: Mosby; 2016.)

An illustration depicts the cutaway section of muscle fiber with its major components labeled clockwise from the left. Sarcolemma, sarcoplasm, nucleus, sarcomere, myofibril, T-tubule, mitochondria, sarcoplasmic reticulum, triad, and myofilaments.

The type of peripheral nerve influences the muscle fiber and motor unit considerably. Whether motor nerves are fast or slow determines the type of muscle fibers in the motor unit. **White muscle (type II fibers [white fast-twitch fibers])** is innervated by relatively large type II alpha motor neurons with fast conduction velocities. These fibers rely on a short-term anaerobic glycolytic system for rapid energy transfer. **Red muscle (type I fibers [slow-twitch fibers])**

depends on aerobic oxidative metabolism. Table 43.4 describes the specific characteristics of type I and type II fibers.

Table 43.4

Characteristics of Human Skeletal Muscle Type I and Type II Fibers

Characteristics	Type I (Red) (Oxidative Fibers [OFs])	Type II (White)
		Type II-1A (Fast Oxidative Glycolic Fibers [FOGs])
Anatomic location	Deep axial portion of muscle	Surface portion of muscle
Fiber diameter	Small	Large
Motor neuron size	Small	Large
Contraction speed	Slow	Fast
Motor neuron type	Type I, α	Type II-A, II-B, II-X, and II-D II-A: fatigue resistant; II-B: fast fatigable; II-X and II-D: intermediate fatigability
Glycogen content (at rest)	Low	High
Oxidative capacity	High	High (for short periods)

Characteristics	Type I (Red) (Oxidative Fibers [OFs])	Type II (White) Type II-1A (Fast Oxidative Glycolic Fibers [FOGs])
Myosin-ATPase activity	Low	High
Metabolism	Oxidative (also most effective in removing glucose from bloodstream)	Some oxidative pathways, mostly glycolysis
Used for	Maintaining body posture, skeletal support, aerobic activity	Short, intense activity (e.g., sprinting)
Aerobic metabolic capacity	High	Low
Fatigue resistance	High	Intermediate to low
Myoglobin content	High	Low
Capillary supply	Profuse	Intermediate to low
Mitochondria	Many	Few
Intensity of contraction	Low	High
Example (most muscles are mixed)	Soleus muscle	Laryngeal
Satellite cell	High	Low

Characteristics	Type I (Red) (Oxidative Fibers [OFs])	Type II (White)
		Type II-1A (Fast Oxidative Glycolic Fibers [FOGs])

Data from Schiaffino S, Reggiani C. Fiber types in mammalian skeletal muscles. *Physiological Reviews*, 2011;91:1447–1531; Verdijk LB, Snijders T, Drost M, et al. Satellite cells in human skeletal muscle; from birth to old age. *Age*, 2014;36(2):545–547.

The overlap of muscle fibers that appears with staining gives a checkerboard appearance to muscle biopsy specimens. This overlap provides an equal distribution of fiber types throughout the muscle and helps to compensate for muscle fiber loss and fatigue of individual motor units during activity. Despite this, some muscles contain proportionally more of one fiber type than another. Postural muscles have more type I fibers, allowing them the high resistance to fatigue that is necessary to maintain the same position for extended periods. The ocular muscles have more type II muscle fibers, allowing them to respond rapidly to visual changes.

The number of muscle fibers varies according to location. Large muscles, such as the gastrocnemius, have more fibers (1.2 million) than smaller muscles, such as the lumbrical muscles in the hand (10,000). The diameter of muscle fibers also varies. The closely packed polygons are small (10 to 20 μm) until puberty, when they attain the normal adult diameter of 40 to 80 μm. Women usually have smaller diameter fibers than men. Small muscles, such as the ocular muscles, are 15 μm in diameter; larger, more proximal muscles are 40 μm in diameter. Fiber size can have functional significance, such as the association of larger fiber diameter with the generation of greater forces.

The major components of the muscle fiber include the muscle membrane, sarcoplasm, mitochondria, sarcotubular system, and myofibrils (see Fig. 43.15). The **muscle membrane** is a two-part

membrane. It includes the **sarcolemma**, which contains the plasma membrane of the muscle cell, and the cell's **basement membrane**. The sarcolemma is 7.5 μm thick and is capable of propagating electrical impulses to initiate contraction. At the motor nerve end plate, where the nerve impulse is transmitted, the sarcolemma forms the highly convoluted synaptic cleft. The sarcolemma is made up of lipid molecules and protein systems. The protein systems perform special functions, such as transport of nutrients and protein synthesis. They also provide the sodium-potassium pump and include the cell's cholinergic receptor. The basement membrane is 50 μm thick and is composed primarily of proteins and polysaccharides. It also serves as the cell's microskeleton and maintains the shape of the muscle cell. The basement membrane also may function to restrict further diffusion of electrolytes once they have crossed the sarcolemma.

The **sarcoplasm** is the cytoplasm of the muscle cell and contains myoglobin plus the intracellular components that are common to all cells (see Chapter 1). **Myoglobin** is a protein found primarily in skeletal and heart muscle. Related to hemoglobin in the blood, myoglobin stores oxygen and iron in the muscle. The sarcoplasm is an aqueous substance that provides a matrix that surrounds the myofibrils. It contains numerous enzymes and proteins that are responsible for the cell's energy production, protein synthesis, and oxygen storage. The mitochondria house enzyme systems for energy production, particularly those that regulate processes such as the citric acid cycle and adenosine triphosphate (ATP) formation. Many other structures are present in the sarcoplasm. The ribosomes are composed of primarily ribonucleic acid (RNA) and participate in protein synthesis. The cell nucleus, satellite cells, glycogen granules, and lipid droplets are suspended in the sarcoplasmic matrix. Blood vessels, nerve endings, muscle spindles, and Golgi tendon organs are also directly located within this structure.

Unique to the muscle is the **sarcotubular system**, a network that includes the transverse tubules and the sarcoplasmic reticulum, which crosses the interior of the cell. The **sarcoplasmic reticulum** is constructed like the endoplasmic reticulum in other cells. The

sarcoplasmic reticulum is composed of tubules that run parallel to the myofibrils. The longitudinal tubules are termed **sarcotubules**. In muscle cells, the sarcoplasmic reticulum contains a network of intracellular receptors known as ryanodine receptors (RyRs). In response to a nerve impulse, RyR1 (found in skeletal muscle cells) releases intracellular calcium and initiates muscle contraction at the **sarcomere**, a portion of the myofibril. The **transverse tubules**, which also contain calcium release channels and are closely associated with the sarcotubules, run across the sarcoplasm and communicate with the extracellular space. Together, the tubules of this membrane system allow for uptake and regulation of intracellular calcium, release of calcium during muscle contraction, and storage of calcium during muscle relaxation.

Myofibrils

Myofibrils, the most abundant subcellular muscle component (85% to 90% of the total volume), are the functional units of muscle contraction. Each myofibril contains sarcomeres, which appear at intervals (see Fig. 43.15). Sarcomeres are composed of several proteins. The two most abundant are actin and myosin, but three other giant, muscle-specific proteins (titin, nebulin, and obscurin) play important roles in myofibril formation and function (Table 43.5).

Table 43.5

Contractile Proteins of Skeletal Muscle Sarcomere

Protein	Location	Function
Actinin	Z disk	Attaches actin to Z disks; helps coordinate sarcomere contraction; cross-links thin filaments in adjacent sarcomeres
Actin	I band (thin filaments)	Contraction; activates myosin-ATPase; interacts with myosin
α-Actin	Z disk	Main ligand of titin; links and controls filament length
β-Actin	Z disk	Regulatory and structural function; links filaments, controls filament length
Myosin	A band (thick filament)	Contraction force; two distinct types: myosin heavy chain (MyHC) and myosin light chain (MyLC); hydrolyzes ATP and develops tension
Titin[a] (largest and third most abundant muscle protein)	Half of sarcomere (from Z disk to M band)	Coordinates assembly of proteins that comprise sarcomere; regulates resting length of sarcomere; important for myofibril assembly, stabilization, and maintenance

Protein	Location	Function
Nebulin[a]	I band (with α-actin)	Interacts with myosin to produce contraction; binding site for actin, desmin, titin, other proteins; stabilizes and regulates length of actin filaments; plays role in assembly, structure, and maintenance of Z disks
Obscurin[a]	Surrounds sarcomere (mainly at Z disk and M band)	May mediate interaction of sarcoplasmic reticulum and myofibrils; plays role in muscle response to injury; has role in formation and stabilization of M bands and A band

ATP, Adenosine triphosphate; *ATPase*, adenosine triphosphatase.

[a]Also may function as molecular scaffolds for myofibril formation.

Data from Herzog JA, Leonard TR, Jinha A, et al. Titin (visco-) elasticity in skeletal muscle myofibrils. *Molecular and Cellular Biomechanics*, 2014;11(1):1–17; Luther PK. The vertebrate muscle Z-disc: sarcomere anchor for structure and signalling. *Journal of Muscle Research and Cell Motility*, 2009;30:171–185; Pappas CT, Krieg PA, Gregorio CC. Nebulin regulates actin filament lengths by a stabilization mechanism. *Journal of Cell Biology*, 2010;189(5):858–870; Schiaffino S, Reggiani C. Fiber types in mammalian skeletal muscles. *Physiological Reviews*, 2011;91:1447–1531.

On cross section, they are seen to be irregular polygons with a mean diameter of less than 1 μm. Each myofibril is composed of serially repeating sarcomeres, separated by Z bands, which give the

muscle its striped, cross-striated appearance. Each sarcomere has a dark A band and is flanked by two light I bands (Fig. 43.16). The A band is 1.5 to 1.6 μm long and contains the thick myosin filaments. Included in the A band is a lighter zone called the *H band*, and in the center of the H band is the dark *M band*, or *M line*. The *I band*, which contains actin, is divided at the midpoint of each sarcomere by the *Z band*. Its length varies with the start of muscle contraction. The *Z disk* (made up of different layers of Z bands, depending on muscle type) marks the boundaries of the sarcomere.

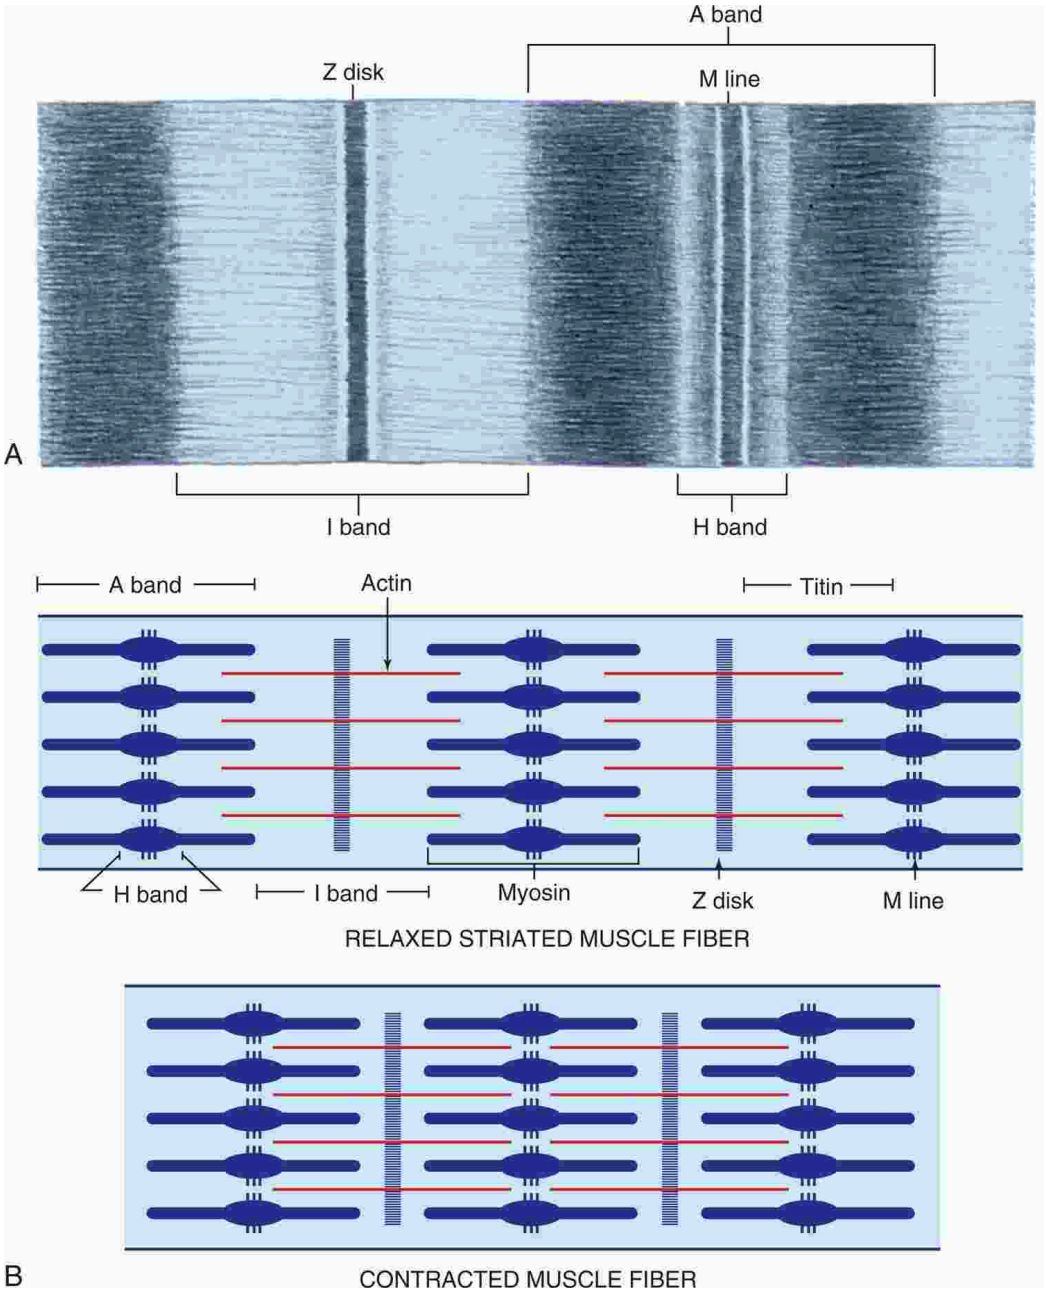

FIG. 43.16 Muscle Fibers.
(A) The Z disks define the end of an individual sarcomere. The M line (which lies within the H band) is made of cross-connecting elements of the cytoskeleton. **(B)** Actin is the primary protein of the I band (thin filament). Nebulin also extends along the I band and contains binding sites for actin and myosin. Myosin (thick filament) extends

through the A band. Titin extends from the Z disk to the M band, binding with myosin; strong titin anchoring within the I band is necessary for proper muscle function. During contraction, the I bands and H bands shorten, moving the Z disks closer together. (A, Modified from Thompson JM, et al. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002.)

Three illustrations depict the sarcomere of muscle fibers. Illustration A depicts the micrographic view of skeletal muscle sarcomere showing the Z-disk, M line, I band, H band, A band accompanied by the schematic representation of relaxed striated muscle fiber sarcomere showing the actin-based thin filaments, myosin-based thick filaments, and titin. Illustration B depicts the schematic representation of contracted muscle fiber sarcomere.

Myofibrils are composed of myofilaments. Each myofilament is structured in a closely packed hexagonal arrangement, with two thin filaments for every thick filament. The thick filament, along with C protein and M line protein, is made up of myosin. Myosin has two subunits—heavy and light meromyosin, which resemble twisted golf club shafts. The thin filaments are twisted double strands consisting of actin, troponin, and tropomyosin (see Chapter 31).

Muscle proteins

Table 43.6 summarizes muscle protein distribution, location, and possible functional significance. The contractile and regulatory functions of actin, myosin, and the troponin-tropomyosin complex (associated with actin) are the most known. They also account for

most of the protein found in the myofibril. The structural and regulatory processes of muscle proteins are less well understood. Alpha actin and beta actin are known to link the filaments. M protein contains the enzyme creatine kinase (CK). Creatine is released when muscle cells are damaged, making the serum creatine value an important measurement of pathologic conditions of muscles.

Table 43.6

Contractile Proteins of Skeletal Muscle Fibrils

Name	Approximate Percentage of Myofibrillar Protein	Location	Function
Myosin	55	A band (thick filament)	Contraction; hydrolyzes ATP and develops tension
Actin	20	I band (thin filament)	Contraction; activates myosin ATPase and interacts with myosin
Troponin	7	Thin filament	Regulatory protein; in presence of Ca^{++}, promotes actin-myosin activation
Tropomyosin	5–7	Thin filament	Regulatory and structural function; links filaments, controls filament length
Alpha (α) actin	10	Z band	Regulatory and structural function; links filaments,

Name	Approximate Percentage of Myofibrillar Protein	Location	Function
			controls filament length
Beta (β) actin	2	Z band	Regulatory and structural function; links filaments, controls filament length
M protein	2	M line (center of thick filaments)	Regulatory and structural function; provides enzyme creatine kinase
C protein	2	A band (thick filaments)	Possible structural role
Titin	Unknown	Z line (thick filament)	Interconnects thin filaments in Z line
Creatine kinase	Unknown	M line	Catalyzes the phosphorylation of ADP to form ATP
Desmin	Unknown	Z line	Interconnects thin filaments in Z line
Filamin[a]	Unknown	Z line	Interconnects thin filaments in Z

Name	Approximate Percentage of Myofibrillar Protein	Location	Function
			line; stabilizes membrane
Nebulin[a]	Unknown	Z line	Determines filament length

ADP, Adenosine diphosphate; *ATP*, Adenosine triphosphate; *ATPase*, adenosine triphosphatase.

[a]Data from Ma K, Wang K: *Fed Eur Biochem Soc Lett* 532(3):273–278, 2002; Sampson LJ, Leyland ML, Dart D: *J Biol Chem* 278(43):41988–41997, 2003.

The most abundant proteins, actin and myosin, are also found in other cells, particularly motile cells such as platelets. The complete amino acid sequences of actin and myosin have been identified. Noteworthy is the presence of the amino acid 3-methylhistidine, found only in the thin filament, actin; 85% to 90% of 3-methylhistidine is found in skeletal muscle.

Nonprotein constituents of muscle

Nitrogen, creatine, creatinine, phosphocreatine, purines, uric acid, and amino acids all serve in the complex process of muscle metabolism. Energy is provided by glycogen and its derivatives.

Creatine metabolism and creatinine metabolism have been used to measure muscle mass. Plasma creatine is taken up by muscle and converted into the high-energy phosphate compound phosphocreatine by the enzyme CK. Creatinine is formed in muscle from creatine at a constant rate of 2% per day. Creatine excretion is increased in muscle wasting. This change reflects the reduction in total body creatine stores and the loss of muscle mass.

Inorganic compounds, anions (phosphate, chloride), and cations (calcium, magnesium, sodium, potassium) are important in the regulation of protein synthesis, muscle contraction, and enzyme systems, as well as in the stabilization of cell membranes. The total

body potassium (TBK) level, measured by the K40 method, has been used to measure muscle mass, also called *lean body mass*. TBK levels reflect changes in muscle mass seen during growth, malnutrition, and muscle wasting.

Components of Muscle Function

The ultimate function of muscle is to accomplish work. Although variously expressed in such measures as foot-pounds or kilogram-meters, work usually refers to the amount of energy liberated, or force exerted over a distance (Work = Force × Distance). Muscles usually contract or tense while doing work. Muscle contraction occurs on the molecular level and leads to the observable phenomenon of muscle movement.

Muscle Contraction at the Molecular Level

The four steps of muscle contraction are (1) excitation, (2) coupling, (3) contraction, and (4) relaxation. The process involves the electrical properties of all cells and the movement of ions across the plasma membrane (see Chapter 1). The muscle fiber is an excitable tissue. At rest, an electrical charge of −90 mV is continually maintained across the sarcolemma. This resting potential, generated by the separation of positive and negative charges on either side of the membrane, creates an electrochemical equilibrium caused by the selective permeability of the sarcolemma to electrolytes in the intracellular and extracellular fluids, particularly potassium and sodium.

Excitation, the first step of muscle contraction, begins with the spread of an action potential from the nerve terminal to the neuromuscular junction. The rapid depolarization of the membrane initiates an electrical impulse in the muscle fiber membrane called the **muscle fiber action potential**. As the action potential advances along the sarcolemmal membrane, it spreads to the transverse tubules. A receptor on the transverse tubule opens, allowing calcium to enter the cell.

The second stage, **coupling**, follows the depolarization of the transverse tubules. This triggers the release of calcium ions from the

sarcoplasmic reticulum through RyR1 channels into the sarcoplasm. The calcium then binds to a protein on the actin filament. (Calcium affects troponin and tropomyosin, muscle proteins that bind with actin when the muscle is at rest.) In the presence of calcium, however, both these proteins are attracted to calcium ions, leaving the actin free to bind with myosin. The release of intracellular calcium ions is the critical link between a nerve impulse (electrical excitation) and muscle contraction.

Contraction begins as the calcium ions combine with troponin, a reaction that overcomes the inhibitory function of the troponin-tropomyosin system. Myosin binds to actin, forming cross-bridges. The myosin heads attach to the exposed actin-binding sites, pulling actin (the thin filament) inward. The thin filament, actin, then slides toward the thick filament, myosin. The two ends of the myofibril shorten after contraction when the myosin heads attach to the actin molecules, forming a cross-bridge that constitutes an actin-myosin complex. ATP, located on the actin-myosin complex, is released when the cross-bridges attach. Contraction was first described by A.F. Huxley in the 1950s. It is commonly known as the **cross-bridge theory** because the actin and myosin proteins form cross-bridges as they contract. The useful distance of contraction of a skeletal muscle is approximately 25% to 35% of the muscle's length.

The last step, **relaxation**, begins as calcium ions are actively transported back into the sarcoplasmic reticulum, removing ions from interaction with troponin. The cross-bridges detach, and the sarcomere lengthens. (The cross-bridge theory of muscle contraction is discussed in Chapter 31.)

Muscle Metabolism

Skeletal muscle requires a constant supply of ATP and phosphocreatine. These substances are necessary to fuel the complex processes of muscle contraction, driving the cross-bridges of actin and myosin together and transporting calcium from the sarcoplasmic reticulum to the myofibril. Other internal processes of the muscular system that require ATP include protein synthesis,

which replenishes muscle constituents and accommodates growth and repair. The rate of protein synthesis is related to hormone levels (particularly insulin), the presence of amino acid substrates, and overall nutritional status. At rest, the rate of ATP formation by oxidation of glucose or acetoacetate is sufficient to maintain internal processes, given normal nutritional status. During activity, the need for ATP increases 100-fold. The metabolic pathways for muscle activity in Table 43.7 show reactions to the immediate need for increased ATP caused by contraction. Activity lasting longer than 5 seconds expends the available stored ATP and phosphocreatine.

Table 43.7

Energy Sources for Muscular Activity

Sources	Reactions
Short-term (anaerobic) sources	$ATP \rightarrow ADP + P_i + Energy$
	$Phosphocreatine + ADP \rightleftharpoons Creatine + ATP$
	$Glycogen/glucose + P_i + ADP \rightarrow Lactate + ATP$
Long-term (aerobic) sources	$Glycogen/glucose + ADP + P_i + O_2 \rightarrow H_2O + CO_2 + ATP$
	$Free\ fatty\ acids + ADP + P_i + O_2 \rightarrow H_2O + CO_2 + ATP$
	Creatine kinase catalyzes reversible reaction of ATP to ADP: Creatine phosphate + ATP Creatine + ATP

ADP, Adenosine diphosphate; *ATP*, adenosine triphosphate; CO_2, carbon dioxide; H_2O, water; O_2, oxygen; *Pi*, inorganic phosphate.

From Spence AP, Mason EE. *Human anatomy and physiology*, 4th edition. St. Paul, Minn: West Publishing; 1992.

Stored glycogen and blood glucose are converted anaerobically to sustain brief activity without increasing the demand for oxygen. Anaerobic glycolysis is much less efficient than aerobic glycolysis, using six to eight times more glycogen to produce the same amount of ATP. With increased activity, such as intense exercise, or with ischemia, an increase in the amount of lactic acid occurs because of the breakdown of glycogen, thus causing a shift in muscle pH (see Table 43.7). This short-term mechanism buys time by allowing ATP formation despite inadequate energy stores or oxygen supply. When

the anaerobic threshold is reached and more oxygen is required, physiologic changes occur, including an increase in lactic acid level and increases in oxygen consumption, heart rate, respiratory rate, and muscle blood flow.

Strenuous exercise requires oxygen, which activates the aerobic glycogen pathway for ATP formation. During maximal exercise, free fatty acid mobilization and the aerobic glycogen pathways provide ATP over an extended time. These pathways require oxygen both to maintain maximal activity and to return the muscle to the resting state. Maximal exercise increases oxygen uptake by 15 to 20 times over the resting state. When this system becomes exhausted or inadequate to respond to the need for ATP, fatigue and weakness finally force the muscle to reduce activity, with a resultant buildup of lactic acid in muscle fibers.

Sustaining maximal muscular activity accumulates an **oxygen debt**, which is the amount of oxygen needed to oxidize the residual lactic acid, convert it back to glycogen, and replenish ATP and phosphocreatine stores. For example, after running at maximal speed for 10 seconds, the average person has consumed 1 L of oxygen. At rest, oxygen consumption for the same period is approximately 40 mL. As the person recovers, the measured oxygen debt is 4 L greater than the amount used during activity.

Oxygen consumption is measured to calculate the metabolic cost of activity in normal and diseased muscles. It is an indirect measure of energy expenditure, along with timed tests of activity, heart rate, and respiratory quotient (ratio of carbon dioxide to expired oxygen consumed). Energy expenditure is measured directly by heat production because heat is released whenever work is accomplished.

Another factor that changes energy requirements is muscle fiber type. Type II fibers rely on anaerobic glycolytic metabolism and fatigue readily. Type I fibers can resist fatigue for longer periods because of their capacity for oxidative metabolism.

Muscle Mechanics

Muscle contraction cannot be viewed in isolation. Several factors determine how force is transmitted from the cross-bridges on individual muscle fibers to accomplish whole-muscle contraction. First, when a motor unit responds to a single nerve stimulus, it develops a phasic contraction, also called a *twitch*. Because the motor unit contracts in an all-or-nothing manner, the contraction that is generated will be a maximal contraction. The central nervous system smoothly grades the force generated by recruiting additional motor units and varying the discharge frequency of each active motor unit. This adding of motor units within the muscle is called **repetitive discharge**.

Recruitment and repetitive discharge of motor units allow the muscle to activate the number of motor units needed to generate the desired force. The total force developed is the sum of the force generated by each motor unit. If the motor units are stimulated again and the muscle unit has not been able to relax between stimulation and the next contraction, the second contraction will fuse with the first, causing **physiologic tetanus** (not to be confused with the disease tetanus).

Other variables, such as fiber type, innervation ratio, muscle temperature, and muscle shape, influence the efficiency of muscular contraction. The two muscle fiber types differ in their responses to electrical activity. Tetanus and duration of phasic contractions, which take microseconds to accomplish, are achieved more rapidly in type II (white fast-twitch) than in type I (red slow-twitch) muscle fibers. Low innervation ratios promote control and coordination, whereas high ratios promote strength and endurance. Muscles work best at normal body temperature, or 37°C (98.6°F). Finally, muscles with a large cross-sectional area, such as the fan-shaped pennate muscles, develop greater contractile forces than smaller diameter muscles. The initial length of a muscle and the range of shortening that occur when the muscle contracts also determine the force it can generate. The long fusiform muscles have a greater range of shortening and can contract up to 57% of their resting length. A certain amount of elongation is necessary to generate sufficient tension and muscular force. The elongation that occurs during the

swing of a golf club or tennis racket is an example of how stretch improves contractile force.

Types of Muscle Contraction

During **isometric** (or **static**) **contraction**, the muscle maintains constant length as tension is increased (Fig. 43.17). Isometric contraction occurs, for example, when the arm or leg is pushed against an immovable object. The muscle contracts, but the limb does not move. Isometric contraction is also called **static (holding) contraction**.

FIG. 43.17 Isotonic and Isometric Contraction. **(A)** In isotonic contraction, the muscle shortens, producing movement. **(B)** In isometric contraction, the muscle pulls forcefully against a load but does not shorten. (From Patton KT, Thibodeau GA. *Structure & function of the body*, 15th edition. St. Louis: Mosby; 2016.)

Two illustrations, A and B, depict the two types of contractions of the muscle. Illustration A depicts the isotonic contraction involving the same tension, changing length showing the arm lifting a movable object where the muscle lengthens during eccentric and the muscle shortens during concentric. Illustration B depicts the isometric contraction involving the same length, changing tension showing the arm lifting an immovable object, where the muscle relaxed during eccentric and contracting during concentric.

During **dynamic** (formerly known as **isotonic**) **contraction**, the muscle maintains a constant tension as it moves. Isotonic contractions can be **eccentric (lengthening)** or **concentric (shortening)**. Positive work is accomplished during concentric contraction, and energy is released to exert force or lift a weight. In contrast, during an eccentric contraction, the muscle lengthens and absorbs energy (e.g., extending the elbow while lowering a weight). Eccentric contraction requires less energy to accomplish and has been said to result in the development of pain and stiffness after unaccustomed exercise.

Movement of Muscle Groups

Muscles do not act alone but in groups, often under automatic control. When a muscle contracts and acts as a prime mover, or **agonist**, its reciprocal muscle, or **antagonist**, relaxes. To illustrate this, hold the right arm in the horizontal position in front of the body and bend the elbow; use the other hand to feel the biceps on the top and the triceps on the bottom of the arm. When the elbow is bent, the biceps are firm, and the triceps are soft. As the arm is extended, the muscles change. When the elbow is completely extended, the biceps is soft and the triceps firm. Completing this movement causes the agonist and antagonist to change automatically; only the movement is commanded, not the alternate contraction and relaxation of the specific muscle groups.

Other associated actions occur with walking; as the foot leaves the ground, the paravertebral and gluteal muscles on the opposite sides of the body contract to maintain balance. Paralysis offsets this process and decreases balance.

Tendons and Ligaments

Tendons are important musculoskeletal structures that attach muscle to bone at a site called an **enthesis. Ligaments** attach bone to bone, helping to form joints, as well as stabilizing them against excessive movement. Both tendons and ligaments are primarily composed of types III, IV, V, and VI collagen and fibroblasts (called *tenocytes* in tendons).

The fibroblasts in tendons are arranged in parallel rows; fibroblasts appear less organized in ligaments. Collagen fibers and fibroblasts form fascicles, with multiple fascicles then forming a whole tendon or ligament. In the proteoglycan matrix of tendons, collagen oligomeric matrix protein (COMP) assists in providing gliding and viscoelastic properties. Compared with tendons, ligament fibers typically contain a greater proportion of elastin.

Two main functions of tendons are (1) transferring forces from muscle to bone and (2) as a type of biologic spring for muscles to enable additional stability during movement. Ligaments stabilize joints by restricting movement. Although both tendons and

ligaments can withstand significant distraction (stretching) force, they tend to buckle when compressive force is applied.

Both tendons and ligaments have complex structures at the attachment site of two dissimilar tissues. These complex structures and differences in mechanical and structural characteristics (either tendon and bone or ligament and bone) make healing and repair of damaged tissue complicated (see Emerging Science Box: Understanding Tendon and Ligament Repair).

Tests of Musculoskeletal Function

Tests of Bone Function

Diagnostic procedures to evaluate bone function include gait analysis, measurement of serum calcium and phosphorus levels, and imaging studies. Most imaging techniques provide morphologic rather than functional information about bone. Plain radiographs (x-rays) remain the standard initial imaging tool for bone evaluation because bone absorbs x-ray beams better than soft tissue. Computed tomography (CT) provides multiple images that are then processed into single (two-dimensional) or multiple images taken around a single axis to form (three-dimensional) pictures. Dual-energy computed tomography (DECT) utilizes x-ray beams at two different energy levels to determine different chemical compositions of tissues, thereby expanding CT imaging to include soft tissues, bone marrow, and crystals.[9] Advances in CT technology allow for detailed visualization of bone microstructure.[10]

Magnetic resonance imaging (MRI) provides detailed anatomic information and is useful for evaluating primary or metastatic bone lesions, infection, marrow edema, bony erosions, osteonecrosis, fractures, and other pathologic changes of bone. Magnetic resonance arthrography (MRa) involves the injection of a contrast agent into the area of interest but allows better visualization of small abnormalities. Detailed functional imaging of bone can be attained with positron emission tomography (PET) scanning. A relatively

new technology, MRI-PET combines MRI with functional imaging of molecular events seen with PET.

Nuclear medicine studies also provide imaging about metabolic activity in bone and soft tissue. After a small amount of radioactive tracer is injected, a special camera is used to identify bone absorption of the tracer. Bone scanning is very sensitive, but not specific about the cause of increased metabolic activity.

Dual-photon absorptiometry (DXA) is often used to measure the density of bones in the extremities and the fracture risk of vertebral bodies, femoral neck, and distal radius. Dual-photon absorptiometry allows the soft tissue components to be subtracted. New technology promises more accurate evaluation of bone.

Serum bone-specific alkaline phosphatase (BAP) is a marker of bone formation. Bone resorption is evaluated with urinary and serum measurements of cross-linked N-terminal telopeptides (NTx), a product of osteoclast bone resorption. NTx is specific for bone because the cross-links assessed are characteristic of bone collagen alone. Urine NTx is a more sensitive and specific biochemical marker of bone resorption than serum NTx.[11]

Tests of Joint Function

Procedures used to diagnose joint function include arthrography, arthroscopy, MRI, and synovial fluid analysis. **Arthrography** (the injection of dye into the joint) is particularly useful to diagnose tears in the fibrocartilage of the knee (meniscus) and the rotator cuff of the shoulder. **Arthroscopy** is the direct visualization of a joint through an arthroscope. **Magnetic resonance imaging (MRI)** produces images of body tissues through electromagnetic (radio) waves that alter the atoms (hydrogen ions) in the nuclei of cells being examined. When the polarized radio waves are stopped, the nuclear atoms return to their original positions, emitting energy as signals as they move back. The signals produce visible images for examination and diagnosis. MRI produces excellent contrast of soft tissues for the evaluation of musculoskeletal conditions. MRa is injection of contrast into a joint, followed by MRI evaluation.

Analysis of synovial fluid may reveal inflammatory, septic, and noninflammatory joint diseases, which cause characteristic changes in the color, clarity, viscosity, and cellular elements of the fluid. The presence of blood in the joint fluid (hemarthrosis) usually indicates joint trauma. Normal synovial fluid is sterile, so the presence of bacteria in the fluid always indicates disease. Cell fragments and fibrous tissue in the fluid are the result of inflammation or wear-and-tear on the articular surfaces.

Tests of Muscular Function

When the individual's history and physical examination disclose abnormalities, such as weakness, atrophy, muscle tenderness, cramps, and stiffness, specific tests of muscle function are in order. One of the most useful tests is the serum CK concentration. CK is found in large quantities in the muscle fibers, and when these fibers are diseased or damaged, CK leaks into the serum. Myoglobin is also detectable in the urine after acute muscle damage caused by crush injury, ischemic disorders, extreme exertion, and some inherited diseases.

Because the muscle membrane tissue is excitable and carries an electrical charge, its capacity to function can be assessed by electromyography. Using sensitive needle electrodes, the **electromyogram (EMG)** records the summation of action potentials of the muscle fibers in each motor unit. The EMG is often compared with the electrocardiogram (ECG), but the activity recorded on the EMG is on a much smaller scale. The amplitude of the ECG is measured in volts, the duration of impulse is recorded in seconds, and both are recorded as the heart rate (e.g., 80 V/60 seconds). EMG amplitude is recorded in millivolts and the duration is measured in milliseconds, with a frequency of about 5 to 50 action potentials per second. Motor unit potentials are measured to determine rate of firing, duration, and amplitude. Abnormalities in EMG and nerve conduction velocities help differentiate muscle diseases (myopathy) from peripheral nerve (neuropathy) and neuromuscular junction disorders. The muscle biopsy (using histologic, histochemical, and

electron microscopic studies) is used to further define the presence of myopathic and neuropathic disorders, many of which can be diagnosed only by muscle biopsy. Complex myography, a relatively new technique, allows a noninvasive way to gather information on the mechanical characteristics of muscle.

A new area of evaluation is genetics. Recent advances in molecular genetics, deoxyribonucleic acid (DNA) libraries, genetic probes, and gene localization techniques have enhanced the knowledge of neuromuscular diseases, including types of muscular dystrophy, Charcot-Marie-Tooth disease, and familial amyotrophic lateral sclerosis.

Geriatric Considerations

Aging and the Musculoskeletal System

Aging of BonesAging is accompanied by the loss of bone tissue. Bones become less dense, less strong, and more brittle with aging. The bone remodeling cycle takes longer to complete, and the rate of mineralization also decelerates. With aging, women experience loss of bone density, accelerated by rapid bone loss during early menopause from increased osteoclastic bone resorption, fewer osteocytes, and decreased numbers of osteoblasts. By age 70 years, susceptible women have, on average, lost 50% of their peripheral cortical bone mass (see Chapter 44). Bone mass losses can lead to deformity, pain, stiffness, and high risk for fractures. Men also experience bone mass loss but at later ages and much slower rates than women. Also, initial bone mass in men is approximately 30% higher than in women; therefore, bone loss in men causes less risk of disability than that found in women. Men's peak bone mass is related to race, heredity, hormonal factors, physical activity, and calcium intake during childhood. Bone loss in both sexes is related to smoking, calcium deficiency, alcohol intake, and physical inactivity. Bone mass can be gained in healthy young women up to the third decade through participation in physical activity, intake of dietary calcium and other minerals, and use of oral contraceptives. Height is

also lost with aging because of intervertebral disk degeneration and, sometimes, osteoporotic spinal fractures.

Stem cells in the bone marrow perform less efficiently with aging, predisposing older persons to acute and chronic illnesses. Such illnesses cause weakness and confusion in older persons and may increase the risk of injury or falling.

Aging of Joints

With aging, cartilage becomes more rigid, fragile, and susceptible to fraying because of increased cross-linking of collagen and elastin, decreased water content in the cartilage ground substance, and reduced concentrations of glycosaminoglycans. Decreased range of motion of the joint is related to the changes in ligaments and muscles. Bones in joints develop evidence of osteoporosis, with fewer trabeculae and thinner, less dense bones, making them prone to fractures. Intervertebral disk spaces decrease in height. The rate of loss of height accelerates at age 70 years and beyond. Tendons shrink and harden.

Aging of Muscles

The function of skeletal muscle depends on many influences that are affected by cellular factors, such as reduced mitochondrial volume associated with aging. Other influences include the nervous, vascular, and endocrine systems. In the young child, the development of muscle tissue depends greatly on continuing neurodevelopmental maturation. Muscle loss begins at about age 50; however, muscle function remains trainable even into advanced age. Maintaining musculoskeletal fitness at any age can improve overall health.

Age-related loss in skeletal muscle is referred to as **sarcopenia** and is a direct cause of the age-related decrease in muscle strength. As the body ages, muscle mass and strength decline slowly; thus, strength is maintained through the fifth decade, with a slow decline in dynamic and isometric strength evident after age 70. The amount

of type II fibers also decreases. There is reduced synthesis of RNA, loss of mitochondrial function, and reduction in the size of motor units. The regenerative function of muscle tissue remains normal in aging persons. As much as 30% to 40% of skeletal muscle mass and strength may be lost from the third to ninth decades. Muscle fatigue also may contribute to loss of function with aging. Sarcopenia is thought to be secondary to progressive neuromuscular changes and diminishing levels of anabolic hormones. There is an age-related decline in the synthesis of mixed proteins, myosin heavy chains, and mitochondrial protein. Changes in these muscle proteins are related to reduced levels of insulin-like growth factor-1 (IGF-1), testosterone, and dehydroepiandrosterone (DHEA) sulfate.

Maximal oxygen intake declines with age. The basal metabolic rate is reduced, and lean body mass decreases in the aged population.

Summary Review

Structure and Function of Bones

1. Bones provide support and protection for the body's tissues and organs and are important sources of minerals and blood cells. Bones permit movement by providing points of attachment for muscles.
2. Mature bone is a rigid connective tissue consisting of cells (growth, repair, synthesis, and resorption of old tissue); collagen fibers (tensile strength); a homogenous gelatinous medium called *ground substance* (diffusion); and large amounts of crystallized minerals, mainly calcium (rigidity).
3. Bone formation begins with the production of an organic matrix by bone cells. Bone minerals crystallize in and around collagen fibers in the matrix, called *calcification*, giving bone its characteristic hardness and strength.
4. Bone contains three types of cells: osteoblasts, osteocytes, and osteoclasts. These allow bone tissue to be continuously synthesized, remodeled, and resorbed.

5. Osteoblasts are cells derived from osteogenic mesenchymal stem cells; they are the primary bone-producing cells and are involved in many functions related to the skeletal system. Osteoblasts initiate new bone formation by their synthesis of osteoid (nonmineralized bone matrix).
6. Osteocytes are transformed osteoblasts that are trapped or surrounded in osteoid as it hardens. They are the most numerous cells in bone. Though imbedded in the bone matrix, osteocytes have important functions in directing bone remodeling.
7. Osteoclasts are large, multinucleated cells that develop from the hematopoietic monocyte-macrophage lineage. Osteoclasts are the major resorptive cells of bone.
8. Bone matrix is made of the extracellular elements of bone tissue, specifically collagen fibers, structural proteins (e.g., proteoglycans and certain glycoproteins), carbohydrate-protein complexes, ground substance, and minerals.
9. Bones in the body are made up of compact (cortical) bone tissue and spongy (cancellous) bone tissue.
10. Compact bone is highly organized, solid, and extremely strong. The basic structural units are the haversian systems that consist of concentric layers of crystallized matrix called *lamellae*, surrounding a central canal that contains blood vessels and nerves. Dispersed throughout the concentric layers of crystallized matrix are small spaces, called *lacunae*, containing osteocytes. Smaller canals, called *canaliculi*, interconnect the osteocyte-containing spaces.
11. The crystallized matrix in spongy bone is arranged in bars or plates called *trabeculae*. Spaces containing osteocytes are dispersed between the bars or plates and interconnected by canaliculi.
12. Bone morphogenic proteins are part of the transforming growth factor-β superfamily and are involved in multiple crucial functions in the skeletal system.
13. There are 206 bones in the body, divided into the axial skeleton and the appendicular skeleton. Bones are classified

by shape as long, short, flat, or irregular. Long bones have a broad end (epiphysis), broad neck (metaphysis), and narrow midportion (diaphysis) that contains the medullary cavity.

14. The internal structure of bone is maintained by remodeling, a process in which existing bone is resorbed and new bone is laid down to replace it. Clusters of bone precursor cells, called *basic multicellular units*, implement remodeling.
15. Bone injuries are repaired in stages: (1) hematoma formation occurs within hours of fracture or surgery, (2) procallus formation by osteoblasts occurs within days, (3) callus formation occurs within weeks, and (4) replacement and (5) remodeling occur within years. Remodeling restores the original shape and size to the injured bone.

Structure and Function of Joints

1. A joint, or articulation, is the site where two or more bones attach. Joints provide stability and mobility to the skeleton. Joints help move bones and muscles.
2. Joints are classified as synarthroses (immovable), amphiarthroses (slightly movable), or diarthroses (freely movable), depending on the degree of movement they allow.
3. Joints are also classified by the type of connecting tissue holding them together. Fibrous joints are connected by dense fibrous tissue, ligaments, or membranes. Cartilaginous joints are connected by fibrocartilage or hyaline cartilage. Synovial joints are connected by a fibrous joint capsule that contains a small fluid-filled space. The fluid in the space nourishes the articular cartilage that covers the ends of the bones meeting in the synovial joint.
4. Articular cartilage is a highly organized system of collagen fibers and proteoglycans. The fibers firmly anchor the cartilage to the bone, and the proteoglycans control the loss of fluid from the cartilage.

Structure and Function of Skeletal Muscles

1. *Myoblasts* are precursor cells that become muscle cells.
2. Skeletal muscle is the largest organ in the body and is made up of millions of individual fibers.
3. Whole muscles vary in size (2 to 60 cm) and shape (fusiform, pennate). They are encased in a three-part connective tissue framework, called *fascia*, that protects the muscle fibers, attaches the muscle to bone, and provides a structure for a network of nerve fibers, blood vessels, and lymphatic channels.
4. The fundamental concept of muscle function is the motor unit, defined as the muscle fibers innervated by a single motor nerve, its axon, and anterior horn cell.
5. Satellite cells are dormant myoblasts; however, when activated, they can regenerate muscle.
6. Skeletal muscle is made up of millions of individual muscle fibers, each of which is a single, cylindrical muscle cell. Muscle fibers contain bundles of myofibrils arranged in parallel along the longitudinal axis and include the muscle membrane, myofibrils, sarcotubular system, sarcoplasm, and mitochondria.
7. There are two types of muscle fibers, type I and type II, determined by motor nerve innervation.
8. Myofibrils and myofilaments contain the major muscle proteins actin and myosin, which interact to form cross-bridges during muscle contraction. The nonprotein muscle constituents provide an energy source for contraction and regulate protein synthesis and enzyme systems, as well as stabilize cell membranes.
9. Muscle contraction includes (1) excitation, (2) coupling, (3) contraction, and (4) relaxation.
10. Skeletal muscle requires a constant supply of adenosine triphosphate (ATP) and phosphocreatine to fuel muscle contraction and for growth and repair. ATP and

phosphocreatine can be generated aerobically or anaerobically.

11. Motor units contract in an all-or-nothing manner, so the contraction generated will be the maximal contraction. The efficiency of muscle contraction is affected by muscle fiber type, innervation ratio, temperature, and muscle shape.
12. There are two types of muscle contraction. In isometric (static) contraction, the muscle maintains a constant length as tension is increased. In dynamic (formerly called isotonic) contraction, the muscle maintains a constant tension as it moves, either lengthening (eccentric contraction) or shortening (concentric contraction).
13. Muscles act in groups. When a muscle contracts and acts as a prime mover, or agonist, its reciprocal muscle, or antagonist, relaxes.
14. Tendons attach muscle to bone at sites called *entheses*. Ligaments attach bone to bone, helping to form joints and stabilizing them against excessive movement. Both tendons and ligaments are mostly composed of types III, IV, V, and VI collagen and fibroblasts (called tenocytes in tendons).

Tests of Musculoskeletal Function

1. Procedures used to evaluate bone function include analysis of gait, evaluation of urinary bone resorption markers, measurement of serum calcium and phosphorus levels and serum bone-specific alkaline phosphatase (BAP) level, x-ray films, angiography, bone scanning, and MRI.
2. Procedures used to evaluate joint function include arthrography, arthroscopy, MRI, and synovial fluid analysis.
3. Serum creatine kinase concentration is useful in detecting muscle damage. Electromyography is used to assess the muscle membrane's capacity to function. Genetic evaluation is useful in detecting, diagnosing, and developing specific

treatment for certain inheritable muscle diseases such as muscular dystrophy.

Aging and the Musculoskeletal System

1. Bones become less dense, less strong, and more brittle with aging. The bone remodeling cycle takes longer to complete, and the rate of mineralization also decelerates.
2. With aging, cartilage becomes more rigid, fragile, and susceptible to fraying. Decreased range of motion of the joint is related to the changes in ligaments and muscles.
3. The regenerative function of muscle tissue and the trainability of muscle function remains normal in elderly persons.
4. Sarcopenia, or age-related loss of skeletal muscle, is a direct cause of decrease in muscle strength. A slow decline in dynamic and isometric strength is evident after age 70 years.
5. As much as 30% to 40% of skeletal muscle mass and strength may be lost from the third to ninth decades. Muscle fatigue also may contribute to loss of function with aging. A reduced basal metabolic rate and decreased lean body mass are also noted in the elderly population.

Emerging Science BoxFactors Affecting Bone Healing

Among the many factors affecting bone healing are the condition of local vasculature and surrounding soft tissues; the availability of effective treatment, including immobilization and the prevention of complications such as infection; chronic diseases (such as diabetes and cardiovascular disorders); age; gender; nutritional status; stimulants; and drugs.[1,2] Drugs administered due to an injury, such as analgesic drugs are the most controllable factor because their impact on bone healing can be taken into account with respect to choice and dosage. Primarily because of their analgesic efficacy and anti-inflammatory effect, nonsteroidal

antiinflammatory drugs (NSAIDS) are at the forefront in terms of frequency of use. However, NSAIDS have been shown to have negative effects on bone healing by limiting osteogenesis and should be used for the least amount of time (up to seven days).

Data from Lisowska B, et al. Positives and negatives of nonsteroidal anti-inflammatory drugs in bone healing: The effects of these drugs on bone repair. Drug Design, Development and Therapy, 2018;12:1809–1814; Loi F, et al. Inflammation, fracture and bone repair. Bone, 2016;86:119–130.

Emerging Science BoxProgress in Rebuilding Cartilage

Although much research is needed, recent evidence suggests that mesenchymal stem cell therapies may be a potential solution to rebuilding articular cartilage. Multipotent adult stem cells are largely available and accessible. It is theorized that bone marrow mesenchymal stem cells secrete proliferative and regenerative factors in the lesion site of articular cartilage (AC), thereby retarding osteoarthritis progression and promoting AC regeneration locally by trophic effects. Gene therapy (GT) also represents a novel approach to managing joint degradation. The principle of GT is the overexpression of desired gene products. GT can support AC generation by targeting different genes involved in different cellular processes, such as inhibiting inflammatory and catabolic pathways, stimulating anabolic pathways, or preventing cell senescence and apoptosis. Candidate transgene studies are currently in the exploratory phases, generally using animal models. Candidate transgenes with anti-inflammatory action include interleukin-1 (IL-1) receptor antagonist and soluble tumor necrosis factor (sTNF). GT strategies also may target the catabolic effect of matrix metalloproteinases by the delivery of tissue inhibitor of metalloproteinase.

The overexpression of growth factors has been shown to enhance matrix formation. TGF-β, in particular, was reported to

aid cartilage regeneration and enhance meniscal tissue healing in vitro. GT shows promise for the future; however, to ensure safety and efficacy, thorough evaluation of the technique is necessary.

Mesenchymal stem cell related therapies for cartilage lesion and osteoarthritis. *American Journal of Translational Research*, 2019;11(10):6275–6289; Kim GB, et al. Current perspectives in stem cell therapies for osteoarthritis of the knee. *Yeungnam University Journal of Medicine*, 2020;37(3):149–158.

Emerging Science BoxUnderstanding Tendon and Ligament Repair

Injury of tendons and ligaments is one of the greatest challenges in musculoskeletal rehabilitation. When these types of structures are damaged, attempts to engineer suitable tissue replacements have proved disappointing. The structures and intricate protein composition of tendons and ligaments are the basis for their complex biomechanical properties. One reason for a poor clinical outcome in synthetic tendon structures has been the inability to replicate any material that can bear the high mechanical stresses that occur at the interface between two dissimilar materials (i.e., either tendon and bone or ligament and bone). One promising area of investigation is finding or engineering a biodegradable material, or "scaffold," implanted with specific cells that would regenerate into a normal tendon or ligament. The scaffold must be strong enough to withstand the forces at the tissue/bone interface and then gradually break down as it is completely replaced by new cells. Currently, investigators are using synthetic polymers, silk, and collagen as scaffolds, with tendon or ligament fibroblasts and mesenchymal stem cells as the implanted cells. Once these biochemical hurdles have been overcome, the repair of damaged tendons and ligaments will be revolutionized.

Musculoskeletal injuries include fractures, dislocations, sprains, and strains. Metabolic disorders, infections, inflammatory or non-inflammatory diseases, or tumors may cause alterations in bones, joints, and muscles. The most common disease affecting bone is osteoporosis; much attention and debate has been focused on its risk factors and pathophysiology. Soft tissue disorders—including muscle, tendon, and ligament injuries; tumors; and metabolic derangements—also affect the musculoskeletal system.

Musculoskeletal Injuries

Trauma is referred to as the "neglected disease." It is the leading cause of death in people ages 1 to 44 years of all races and socioeconomic levels. Each year, more than 120,000 persons in the United States die from unintentional injuries.

Musculoskeletal injuries have a major impact on the affected individuals, families, and society in general because of the physical and psychological effects of limitation on mobility and daily activities, pain, and decreased quality of life. In addition, there are direct costs of diagnosis and treatments and indirect economic costs related to loss of employment and decreased productivity.

Skeletal Trauma

Fractures

A **fracture** is a break in the continuity of a bone. A break occurs when force is applied that exceeds the tensile or compressive strength of the bone. The incidence of fractures varies for individual bones according to age and sex with the highest incidence of fractures in young males (between the ages of 15 and 24 years) and older persons (65 years of age or older). Fractures of healthy bones, particularly the tibia, clavicle, and lower humerus, tend to occur in young persons as the result of trauma. Fractures of the hands and feet are often caused by accidents in the workplace. The incidence of fractures of the upper femur, upper humerus, vertebrae, and pelvis is highest in older adults and often is associated with osteoporosis

(see the Osteoporosis section). Hip fractures, the most serious outcome of osteoporosis, have a wide variation in geographic occurrence.

Classification of fractures

There are numerous classification systems for various types of fractures, but the simplest systems describe the basic features of the broken bone. Fractures can be classified as complete or incomplete, and as open or closed (Fig. 44.1). In a **complete fracture** the bone is broken entirely, whereas in an **incomplete fracture** the bone is damaged but is still in one piece. Complete and incomplete fractures also can be called **open** (formerly referred to as *compound*) if the skin is open and **closed** (formerly referred to as simple) if skin remains intact. A fracture in which a bone breaks into more than two fragments is termed a **comminuted fracture**. Fractures are also classified according to the direction of the fracture line. A **linear fracture** runs parallel to the long axis of the bone. An **oblique fracture** occurs at a slanted angle to the shaft of the bone. (see Fig. 44.1) A **spiral fracture** encircles the bone, and a **transverse fracture** occurs straight across the bone.

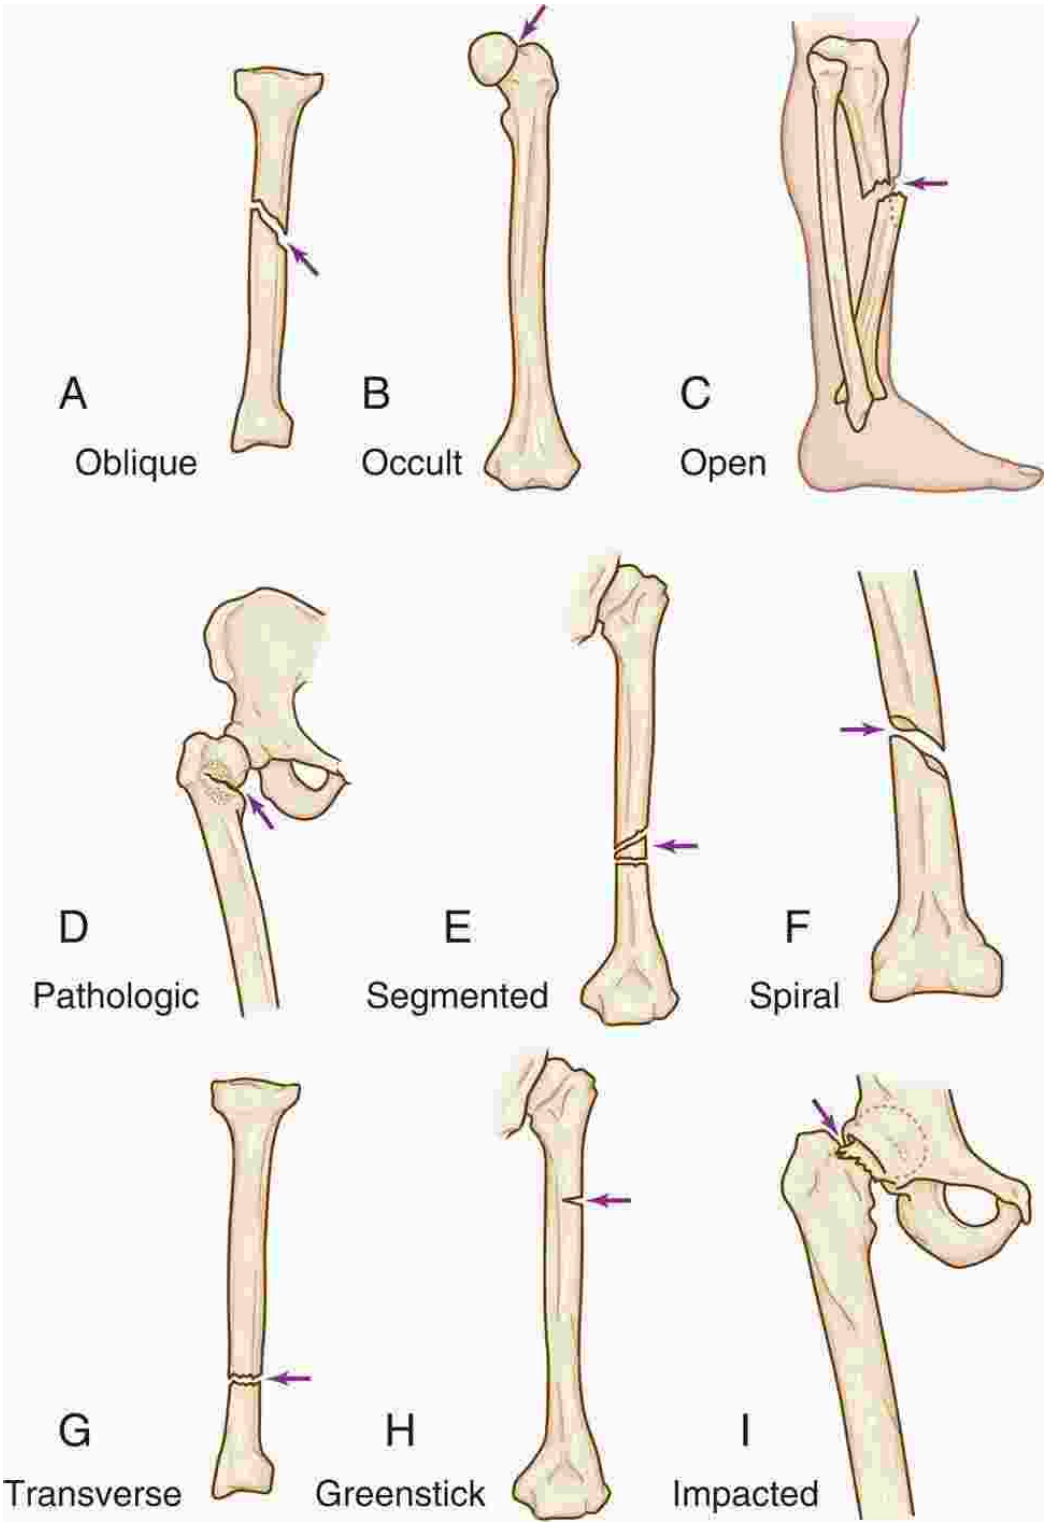

FIG. 44.1 Examples of Types of Bone Fractures.

(A) *Oblique:* Fracture at oblique angle across both

cortices. *Cause:* Direct or indirect energy, with angulation and some compression. **(B)***Occult:* Fracture that is hidden or not readily discernible. *Cause:* Minor force or energy. **(C)***Open:* Skin broken over fracture; possible soft tissue trauma. *Cause:* Moderate to severe energy that is continuous and exceeds tissue tolerance. **(D)***Pathologic:* Transverse, oblique, or spiral fracture of bone weakened by tumor pressure or presence. *Cause:* Minor energy or force, which may be direct or indirect. **(E)***Segmented:* Fracture with two or more pieces or segments. *Cause:* Direct or indirect moderate to severe force. **(F)***Spiral:* Fracture that curves around cortices and may become displaced by twist. *Cause:* Direct or indirect twisting energy or force with distal part held or unable to move. **(G)***Transverse:* Horizontal break through bone. *Cause:* Direct or indirect energy toward bone. **(H)***Greenstick:* Break in only one cortex of bone. *Cause:* Minor direct or indirect energy. **(I)***Impacted:* Fracture with one end wedged into opposite end of inside fractured fragment. *Cause:* Compressive axial energy or force directly to distal fragment.
(Redrawn from Mourad L. Musculoskeletal system. In: Thompson JM, et al., eds. *Mosby's clinical nursing*, 7th edition. St. Louis: Mosby; 2002.)

Nine illustrations of bones A through I depict the major fracture types found in bones. Illustration A depicts the oblique fracture. Illustration B depicts occult fracture. Illustration C depicts open fracture. Illustration D depicts the pathologic fracture. Illustration E depicts a segmented fracture.

Illustration F depicts a spiral fracture. Illustration G depicts transverse fracture. Illustration H depicts a Greenstick fracture. Illustration I depict impacted fracture.

Incomplete fractures tend to occur in the more flexible, growing bones of children. The three main types of incomplete fractures are greenstick, torus, and bowing fractures. A **greenstick fracture** perforates one cortex and splinters the spongy bone. The name is derived from the damage sustained by a young tree branch (a green stick) when it is bent sharply. The outer surface is disrupted, but the inner surface remains intact. Greenstick fractures typically occur in the metaphysis or diaphysis of the tibia, radius, and ulna. In a **torus fracture**, the cortex buckles but does not break. **Bowing fractures** usually occur when longitudinal force is applied to bone. This type of fracture is common in children and usually involves the paired radius-ulna or the fibula-tibia. A complete diaphyseal fracture occurs in one of the bones of the pair, which disperses the stress sufficiently to prevent a complete fracture of the second bone, which bows rather than breaks. A bowing fracture resists correction **(reduction)** because the force necessary to reduce it must be equal to the force that bowed it. Treatment of bowing fractures is also difficult because the bowed bone interferes with reduction of the fractured bone. Types of fractures are summarized in Table 44.1.

Table 44.1

Types of Fractures

Type of Fracture	Definition
Typical Complete Fractures	
Closed	Noncommunicating wound between bone and skin
Open	Communicating wound between bone and skin
Comminuted	Multiple bone fragments
Linear	Fracture line parallel to long axis of bone
Oblique	Fracture line at an angle to long axis of bone
Spiral	Fracture line encircling bone (as a spiral staircase)
Transverse	Fracture line perpendicular to long axis of bone
Impacted	Fracture fragments pushed into each other
Pathologic	Fracture at a point where bone has been weakened by disease, for example, by tumors or osteoporosis
Avulsion	Fragment of bone connected to a ligament or tendon detaches from main bone
Compression	Fracture wedged or squeezed together on one side of bone
Displaced	Fracture with one, both, or all fragments out of normal alignment
Extracapsular	Fragment close to joint but remains outside joint capsule

Type of Fracture	Definition
Intracapsular	Fragment within joint capsule
Typical Incomplete Fractures	
Greenstick	Break in one cortex of bone with splintering of inner bone surface; commonly occurs in children and elderly persons
Torus	Buckling of cortex
Bowing	Bending of bone
Stress	Microfracture
Transchondral	Separation of cartilaginous joint surface (articular cartilage) from main shaft of bone

Type of Fracture	Definition
Typical Complete Fractures	
Closed	Noncommunicating wound between bone and skin
Open	Communicating wound between bone and skin
Comminuted	Multiple bone fragments
Linear	Fracture line parallel to long axis of bone
Oblique	Fracture line at an angle to long axis of bone
Spiral	Fracture line encircling bone (as a spiral staircase)
Transverse	Fracture line perpendicular to long axis of bone
Impacted	Fracture fragments pushed into each other
Pathologic	Fracture at a point where bone has been weakened by disease, for example, by tumors or osteoporosis
Avulsion	Fragment of bone connected to a ligament or tendon detaches from main bone
Compression	Fracture wedged or squeezed together on one side of bone
Displaced	Fracture with one, both, or all fragments out of normal alignment
Extracapsular	Fragment close to joint but remains outside joint capsule
Intracapsular	Fragment within joint capsule
Typical Incomplete Fractures	
Greenstick	Break in one cortex of bone with splintering of inner bone surface; commonly occurs in children and elderly persons
Torus	Buckling of cortex
Bowing	Bending of bone
Stress	Microfracture
Transchondral	Separation of cartilaginous joint surface (articular cartilage) from main shaft of bone

Fractures may be further classified by cause as pathologic, stress, or transchondral fractures. A **pathologic** (also known as

insufficiency or **fragility**) **fracture** is a break at the site of a preexisting abnormality, resulting from force that would not fracture a normal bone. In any bone that lacks normal ability to deform and recover, these fractures can occur with normal weight bearing or activity. Rheumatoid arthritis (RA), osteoporosis, Paget disease, osteomalacia, rickets, hyperparathyroidism, and radiation therapy all cause bone to lose its normal ability to deform and recover. Pathologic fractures are generally a result of bone weakness caused by another disease, such as cancer, metabolic bone disorders, or infection. Although usually considered insufficiency fractures, breaks in the bone attributable to osteoporosis can also be referred to as pathologic fractures. Any disease process that weakens a bone (especially the cortex) predisposes the bone to pathologic fracture.

During activities that subject a bone to repeated strain, such as certain types of sports, a **stress fracture** can occur in normal or abnormal bone. The forces placed on the bone are cumulative, eventually causing a fracture. A **fatigue fracture** is caused by repetitive, sometimes abnormal stress or torque applied to a bone with a normal ability to deform and recover. Fatigue fractures usually occur in individuals who engage in a new or different activity that is both strenuous and repetitive (e.g., joggers, skaters, dancers, and military recruits). Because gains in muscle strength occur more rapidly than gains in bone strength, the newly developed muscles place exaggerated stress on the bones that are not yet ready for the additional stress. The imbalance between muscle and bone development causes micro-fractures to develop in the cortex. If the activity is controlled and increased gradually, new bone formation catches up to the increased demands and micro-fractures do not occur.

A **transchondral fracture** consists of fragmentation and separation of a portion of the articular cartilage. (Joint structures are defined in Chapter 43.) Single or multiple sites may be fractured, and the fragments may consist of cartilage alone or cartilage and bone. Typical sites of transchondral fracture are the distal femur, the ankle, the patella, the elbow, and the wrist. Transchondral fractures are most prevalent in adolescents.

Pathophysiology

Fracture healing is a complex process that occurs primarily in one of two ways: direct or indirect healing. Both types of healing require integration of cells, signaling pathways, and various molecules. In **direct** (or **primary**) **healing**, intramembranous bone formation occurs when adjacent bone cortices are in contact with one another, such as when surgical fixation devices are used. No callus formation occurs with direct bone healing. **Indirect** (or **secondary**) **healing** involves both intramembranous and endochondral bone formation, development of callus, and eventual remodeling of solid bone. Bone formation that begins with an underlying cartilage scaffold is termed **endochondral bone formation**.

A hallmark of indirect fracture healing is the formation of callus. Indirect fracture healing is most often observed when a fracture is treated with a cast. When a bone is broken, the periosteum and blood vessels in the cortex, marrow, and surrounding soft tissues are disrupted. Bleeding occurs from the damaged ends of the bone and from the neighboring soft tissue. A clot (hematoma) forms within the medullary canal, between the fractured ends of the bone, and beneath the periosteum (Fig. 44.2). Bone tissue immediately adjacent to the fracture dies. This dead tissue (along with any debris in the fracture area) stimulates vasodilation, exudation of plasma and leukocytes, and infiltration by inflammatory leukocytes, growth factors, and mast cells that simultaneously decalcify the fractured bone ends. Within 48 hours after injury, vascular tissue from surrounding soft tissue and the marrow cavity invades the fracture area, and blood flow to the entire bone increases. Bone-forming cells in the periosteum, endosteum, and marrow are activated to produce subperiosteal procallus along the outer surface of the shaft and over the broken ends of the bone (Fig. 44.3). Osteoblasts within the procallus synthesize collagen and matrix, which becomes mineralized to form callus. As the repair process continues, remodeling occurs, during which unnecessary callus is resorbed and trabeculae are formed along lines of stress as the repair tissues align with the tissue cells of the host (Fig. 44.4).

FIG. 44.2 A fracture causes bleeding from the damaged ends of the bone and from the neighboring soft tissue. (From Nyary T, Scammell BE. Principles of bone and joint injuries and their healing. *Surgery (Oxford)*, 2018;36(1):7–14.)

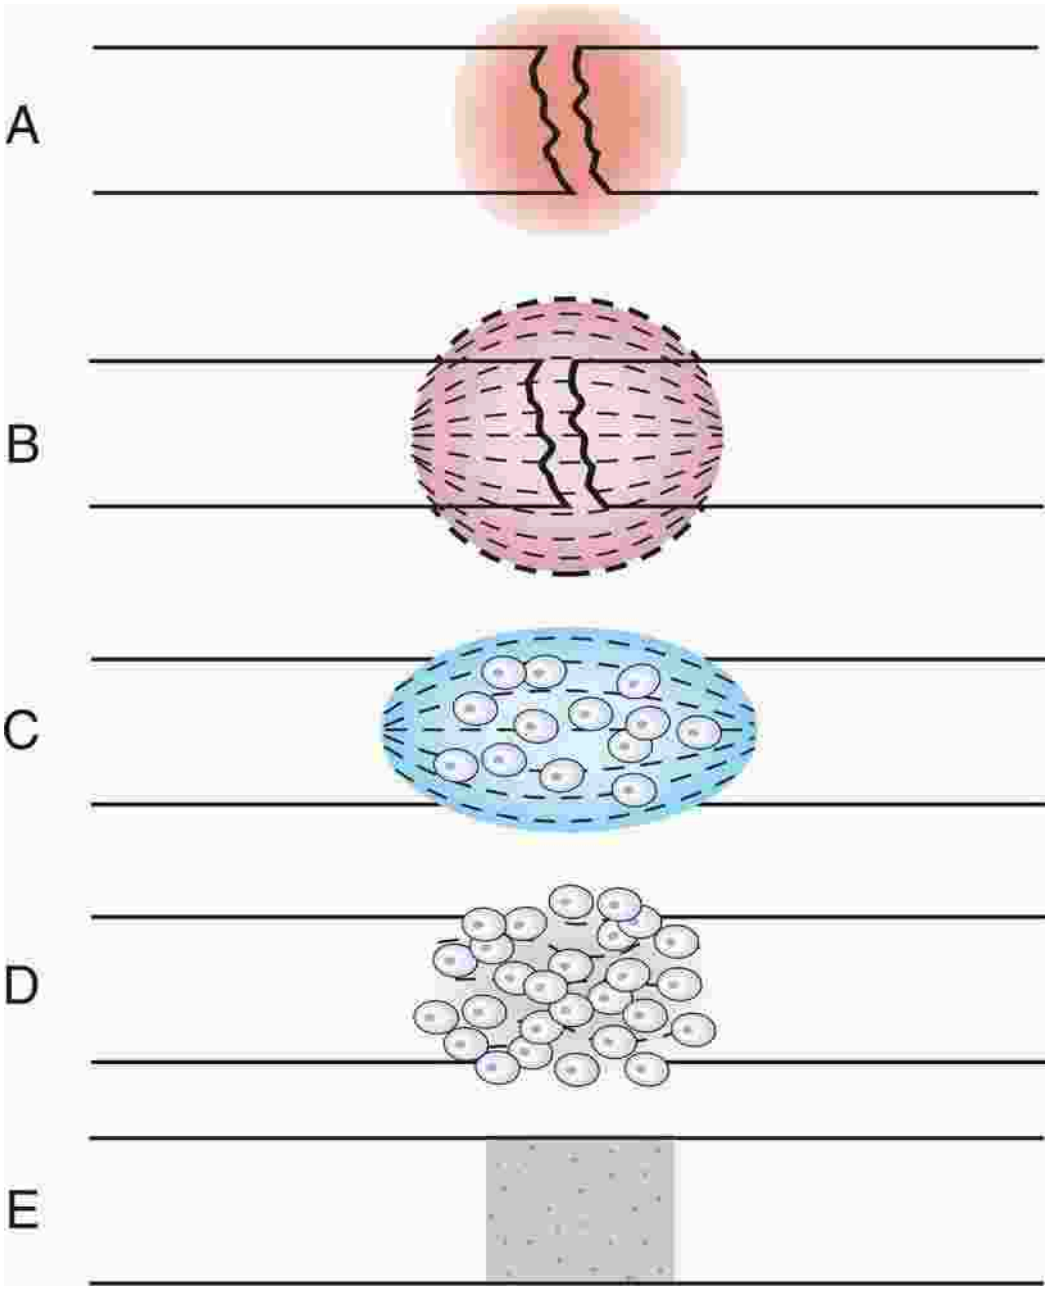

FIG. 44.3 Schematic of Bone Healing.
(A) Bleeding at broken ends of the bone with subsequent hematoma formation. **(B)** Organization of hematoma into fibrous network. **(C)** Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. **(D)** Callus formation; new bone is built while osteoclasts destroy dead bone. **(E)** Remodeling

is accomplished while excess callus is reabsorbed and trabecular bone is deposited.
(From Monahan FD, et al. *Phipps' medical-surgical nursing: Health and illness perspectives*, 8th edition. St. Louis: Mosby; 2007.)

Five illustrations, A through E, depicts the schematic representation of various phase of bone healing. Illustration A depicts the hematoma formation. Illustration B depicts the fibrous network. Illustration C depicts the invasion of osteoblast. Illustration D depicts the formation of the callus. Illustration E depicts the deposition of trabecular bone.

FIG. 44.4 Exuberant Callus Formation After Fracture. (From Rosai J. *Ackerman's surgical pathology*, 8th edition. St. Louis: Mosby; 1996.)

Clinical Manifestations

The signs and symptoms of a fracture include unnatural alignment (deformity), swelling, muscle spasm, tenderness, pain and impaired sensation, and decreased mobility. The position of the broken bone segments is determined by the pull of attached muscles, gravity, and the direction and magnitude of the force that caused the fracture.

Immediately after a bone is fractured, there often is numbness at the fracture site because of trauma to the nerve or nerves at the injury site. The numbness may last several minutes, during which time the injured person can continue to use the fractured bone. However, once the numbness dissipates, the subsequent pain is quite severe and may be incapacitating until relieved with medication and treatment of the fracture. Pain can be caused by muscle spasms at the fracture site, overriding of the fracture segments, or damage to adjacent soft tissues.

Pathologic fractures can cause angular deformity, painless swelling, or generalized bone pain. Stress fractures are painful because of accelerated remodeling; initially, pain occurs during activity and is usually relieved by rest. Stress fractures also cause local tenderness and soft tissue swelling. Transchondral fractures may be entirely asymptomatic or may be painful during movement. Range of motion (ROM) in the joint is limited, and movement may evoke audible clicking or crunching sounds (crepitus).

Evaluation and Treatment

Adequate immobilization with a splint or cast is often all that is required for healing of fractures that are *not* misaligned. Treatment of a displaced fracture involves realigning the bone fragments (reduction) close to their normal or anatomic position and holding the fragments in place **(immobilization)** so that bone union can

occur. Several methods are available to reduce a fracture: closed manipulation, traction, and open reduction. Many displaced fractures can be reduced by closed manipulation and reduction. The bone is moved or manipulated into place without opening the skin. **Closed reduction** is used when the contour of the bone is in fair anatomic alignment and can be manually placed into normal alignment, and then maintained with immobilization. Splints and casts are used to immobilize and hold a closed reduction in place.

Traction may be used to accomplish or maintain reduction. When bone fragments are displaced (not in their anatomic position) weights may be used to apply firm, steady traction (pull) and countertraction to the long axis of the bone. Traction stretches and fatigues muscles that have pulled the bone fragments out of place, more readily allowing the distal fragment to align with the proximal fragment. Traction can be applied to the skin (skin traction) or directly to the involved bone (skeletal traction). Skin traction is used when only a few pounds of pulling force are needed to realign the fragments or when the traction will be used only for a brief time, such as before surgery, or for children with femoral fractures, for 3 to 7 days before a cast is applied. In skeletal traction, a pin or wire is drilled through the bone distal to the fracture site, and a traction bow, rope, and weights are attached to the pin or wire to apply tension and to provide the pulling force required to overcome the muscle spasm and help realign the fracture fragments (Fig. 44.5). More often, surgical repair (open reduction and internal fixation) or external fixation devices are used to realign displaced fractures.

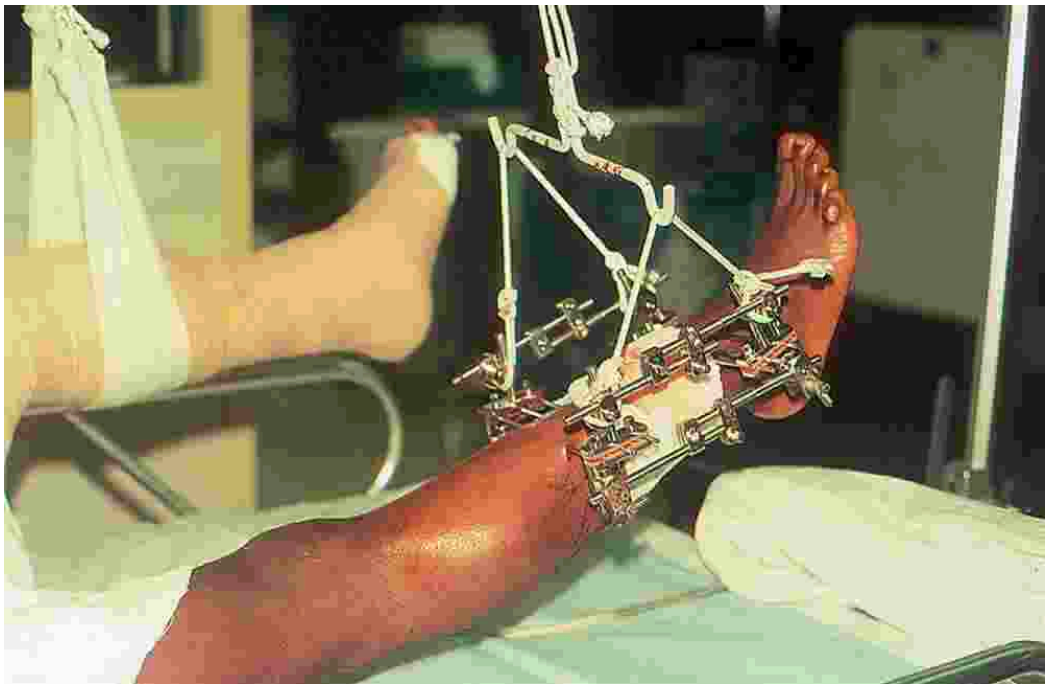

FIG. 44.5 External Fixation Device on Right Leg.

A close shot of an external fixation on a patient's right leg with screws placed into the bone above and below the fracture and a device attached to the screws from outside the skin, where it may be adjusted to realign the bone.

Open reduction is a surgical procedure that exposes the fracture site; the fragments are then manipulated into alignment under direct visualization. Some form of hardware, such as a screw, plate, nail, or wire, is used to maintain the reduction **(internal fixation)**. **External fixation**, a procedure in which pins or rods are surgically placed into uninjured bone near the fracture site and then stabilized with an external frame of bars, is another method used to treat fractures that would not be adequately stabilized with a cast (see Fig. 44.5). Bone grafts—using donor bone from the individual (autograft), a cadaver (allograft), or bone substitutes (ceramic composites, bioactive cement)—can fill voids in the bone.

Improper reduction or immobilization of a fractured bone may result in nonunion, delayed union, or malunion. **Nonunion** is failure of the bone ends to grow together. The gap between the broken ends of the bone fills with dense fibrous and fibrocartilaginous tissue instead of new bone. Occasionally, the fibrous tissue contains a fluid-filled space that resembles a joint and is termed a *false joint*, or *pseudoarthrosis*. **Delayed union** is union that does not occur until approximately 8 to 9 months after a fracture. **Malunion** is the healing of a bone in an incorrect anatomic position.

Dislocation and Subluxation

Dislocation and subluxation are usually caused by trauma. **Dislocation** is the displacement of one or more bones in a joint in which the opposing joint surfaces entirely lose contact with one another. If contact between the opposing joint surfaces is only partially lost (partial dislocation), the injury is called a **subluxation**.

Dislocation and subluxation are most common in persons younger than 20 years of age and are generally associated with fractures. However, they also may be the result of congenital or acquired disorders that cause (1) muscular imbalance, seen with congenital dislocation of the hip; (2) incongruities in the articulating surfaces of the bones, as occur with RA (see the Rheumatoid Arthritis section); or (3) joint instability.

The joints most often dislocated or subluxated are the joints of the shoulder, elbow, wrist, finger, hip, and knee (Fig. 44.6). The shoulder joint most often injured is the glenohumeral joint.

FIG. 44.6 Displaced Fracture.

In the immature skeleton, a traumatic partial dislocation of the elbow joint is common (“nursemaid's elbow”). This injury is the result of the subluxation of the radial head from under the ligament holding it in place within the elbow joint. This injury is often the result of a pulling force on the hand or forearm. In adults, however, an elbow dislocation is usually associated with a fracture of the ulna or head of the radius. Traumatic dislocation of the wrist usually involves the distal ulna and carpal bones. Any one of the eight carpal bones can be dislocated after an injury. The most common cause is a fall on the hyperextended hand. Dislocation in the hand usually involves the metacarpophalangeal (MCP) and interphalangeal joints.

This injury is also associated with a fall on the outstretched hand, which forces the joint into hyperextension. Dislocation of the interphalangeal joints of the fingers is a common injury in contact sports and caused by a hyperextension of the joint.

Considerable trauma is needed to dislocate the hip. Anterior hip dislocation is rare in healthy individuals. It is caused by forced abduction, for example, when an individual lands on their feet from a high-altitude fall. Posterior dislocation of the hip can occur as a result of an automobile accident in which the flexed knee strikes the dashboard, causing the head of the femur to be pushed posteriorly from the hip joint.

The knee is an unstable weight-bearing joint that depends heavily on the soft tissue structures around it for support. Because of the many different types of motion (flexion, extension, rotation) the knee is capable of, it is one of the most commonly injured joints. A knee dislocation can be anterior, posterior, lateral, medial, or rotary. It is often the result of a hyperextension injury that occurs during sports activities.

Pathophysiology

Dislocations and subluxations are often accompanied by fracture because stress is placed on areas of bone not typically subjected to stress. In addition, as the bone separates from the joint, it may bruise or tear adjacent nerves, blood vessels, ligaments, supporting structures, and soft tissue. Dislocations of the shoulder may damage the shoulder capsule and the axillary nerve. Damage to axillary nerves can cause anesthesia or dysesthesia in the sensory distribution of the nerve and paralysis of the deltoid muscle. Dislocations also may disrupt circulation leading to ischemia and possible permanent disability of the affected extremity. In the hip, this can develop into avascular necrosis of the femoral head.

Clinical Manifestations

Signs and symptoms of dislocations or subluxations include pain, swelling, limitation of motion, and joint deformity. Pain may be

caused by effusion of inflammatory exudate into the joint or associated tendon and ligament injury. Joint deformity is typically caused by fluid in the joint, or muscle contractions that exert pull on the dislocated or subluxated joint. Limitation of motion may also result from effusion into the joint or the displacement of bones.

Tenderness and deformity are prominent in dislocations of the fingers. Unusual muscle pull and pain often result in abnormal flexion of the fingers. A dislocated elbow is often held in a flexed position, and the joint resists active or passive movement. In most shoulder dislocations, pain is the primary symptom. Attempts to lift the arm aggravate the pain, and the ability to elevate the arm is minimal requiring the individual to support the injured arm. Pain, an abnormal gait, or an inability to bear full weight usually accompanies traumatic dislocation of the hip. The pain is constant, severe, and is felt in the thigh or inguinal region. The affected extremity may appear to be inwardly rotated, adducted, or flexed and appear shortened. In a rare anterior dislocation, the limb is not shortened, and the joint is fixed in abduction, outward rotation, and flexion.

Evaluation and Treatment

Evaluation of dislocations and subluxations is based on clinical manifestations and radiographic evaluation. Treatment consists of reduction and immobilization for 2 to 6 weeks to allow healing of damaged structures. Following the period of immobilization, exercise is necessary to restore normal ROM in the joint. Depending on the joint and severity of injury, complete healing can take months to years.

Support Structure Trauma

Sprains and Strains of Tendons and Ligaments

Tendons and ligaments support the bones and joints and can either facilitate or limit motion. Tendon and ligament injuries often accompany fractures and dislocations and can include being torn, lacerated, ruptured, or completely separated from its point of

attachment to the bone. A **tendon** is fibrous connective tissue that attaches skeletal muscle to either bone or another structure. A **ligament** is a band of fibrous connective tissue that connects bones where they meet in a joint. The structural composition of tendons and ligaments are similar with their primary difference being their anatomic function and location.

Tearing or stretching of a muscle or tendon is known as a **strain**. Major trauma can tear or rupture a tendon at any site in the body. The most commonly injured tendons are those of the hands and feet, the knee (patellar), the upper arm (biceps and triceps), the thigh (quadriceps), the ankle, and the heel (Achilles). Traumatic rupture of tendons can be caused by excessive weight or extreme flexion. Spontaneous ruptures can occur in individuals with RA or systemic lupus erythematosus (SLE), or in individuals receiving local corticosteroid injections or taking fluoroquinolones.[1,2]

Ligament tears are known as **sprains**. Ligament tears and ruptures can occur at any joint but are most common in the wrist, ankle, elbow, and knee joints. A complete separation of a tendon or ligament from its bony attachment site is known as an **avulsion**. An avulsion is the result of abnormal stress on the ligament and is commonly seen in young athletes.

Strains and sprains are classified as first degree (mild), second degree (moderate), and third degree (severe). In first-degree injuries, the fibers are stretched but the muscle (strain) or joint (sprain) remains stable. In second-degree strains or sprains, there is more tearing of the tendon or ligament fibers, resulting in muscle weakness or some joint instability and incomplete tearing of fibers. Third-degree strains and sprains result in a full tearing of fibers, creating an inability to contract the muscle normally (strain) or cause significant joint instability (sprain).

Pathophysiology

When a tendon or ligament is torn, an inflammatory exudate develops between the torn ends. Within 3 to 4 days after the injury, collagen formation begins. As the collagen fibers interweave and

connect with preexisting tendon fibers, they organize parallel to the lines of the musculotendinous unit. Eventually vascular fibrous tissue fuses the new and surrounding tissues into a single mass. Collagen fibers reconnect the tendon and bone, forming a new enthesis, or point of connection. If strong muscle contractions occur during healing, the tendon or ligament ends may separate again, which causes the tendon or ligament to heal in a lengthened shape or with an excessive amount of scar tissue, resulting in poor tendon or ligament function.[3]

Clinical Manifestations

Tendon and ligament injuries are painful and cause functional limitations. These injuries are usually accompanied by soft tissue swelling, changes in tendon or ligament contour, and dislocation or subluxation of bones. Joint swelling can typically be observed in finger and elbow sprains. Flexion deformities of a joint may be seen with extensor tendon injuries. Crepitus may also accompany tendon injuries. Pain is often the key symptom of injuries with pain radiating distal from the joint and aggravated by attempts to actively move the joint. Movement or weight bearing increases pain. Pain is generally sharp, and tenderness persists over the distribution of the tendon or ligament. Even with prompt treatment, significant injuries may result in decreased mobility, instability, and weakness of the affected joints.

Evaluation and Treatment

Evaluation is based on the mechanism of injury and the clinical manifestations. Stress radiography, x-ray, magnetic resonance imaging (MRI), arthroscopy, or arthrography may be considered. Initial treatment consists of *p*rotection, *r*est, *i*ce, *c*ompression, and *e*levation (PRICE) for the first 48 to 72 hours. Once swelling and acute pain subside, support of the affected tendon or ligament with a compression dressing or brace is often indicated to provide appropriate reinforcement while the tissues heal. Rehabilitation and early mobilization are crucial for a favorable functional outcome. In

some cases of severe (third-degree) injuries, treatment may include surgical intervention to suture the tendon or ligament ends in close approximation with one another or the enthesis.

Tendinopathy, Epicondylopathy, and Bursitis

Trauma and overuse injuries can cause painful inflammation of tendons (**tendonitis**), or inflammation in bursal sacs (**bursitis**). The term *tendinopathy* includes tendinitis, tendinosis, and paratendinitis. Microvascular and increased nerve growth often occur to these areas which increases the body's transmission of pain sensations.

A bony prominence at the end of a bone where tendons or ligaments attach is termed an **epicondyle**. Therefore, **epicondylitis** is inflammation of a tendon where it attaches to a bone at its origin (epicondyle). The histopathology of common conditions, such as lateral epicondylopathy ("tennis elbow") or medial epicondylopathy ("golfer's elbow"), is a process caused by tissue degeneration rather than inflammation and is called **tendinosis** (Fig. 44.7).[4]

FIG. 44.7 Epicondylopathy and Tendinopathy. **(A)** Lateral and medial epicondyles of the distal humerus, sites of tennis elbow (lateral) and golfer's elbow (medial). **(B)** Achilles tendon, common site of tendinopathy.

Illustration A depicts the anterior view of an elbow joint with labels indicating humerus, lateral epicondyle, annular ligament, radius, olecranon bursa, medial epicondyle, olecranon, coronoid process, and ulna. Illustration B depicts the posterior view of the superficial muscles with labels indicating gastrocnemius muscle, lateral head, medial head, soleus muscle, Achilles tendon, and calcaneus.

When force is sufficient to cause microscopic tears (microtears) in tissue, the result is known as **tendinopathy** or **epicondylopathy**. Microtears in the tendon, the presence of disorganized collagen fibers, and neovascularization indicate incomplete tissue repair. Initial inflammatory changes cause thickening of the tendon sheath, limited movements, and pain. Microtears cause bleeding, edema, and pain in the involved tendon or tendons.

Lateral epicondylopathy (tennis elbow) is caused by irritation and overstretching of the extensor carpi radialis brevis (ECRB) tendon and forearm extensor muscles, resulting in tissue degradation, loss of grip strength, and pain. **Medial epicondylopathy (golfer's elbow)** is the result of similar forces affecting the forearm muscles responsible for forearm flexion and pronation (see Fig. 44.7). Repetitive load-bearing activities or acute injuries that involve flexion, extension, pronation, or supination of the elbow and forearm can lead to either lateral or medial elbow symptoms.

Clinical manifestations of epicondylopathy are typically localized to one side of the joint. Localized pain and tenderness are more evident with active motion than with passive motion. With tendinopathy or tendonitis, the pain is localized over the involved tendon. Stressing the tendon with simple activities, such as lifting lightweight objects, can increase pain and weakness, limiting joint movement.

Bursae are small sacs lined with synovial membrane and filled with synovial fluid that are located between bony prominences, tendons, muscles, and ligaments (Fig. 44.8). Their primary function is to separate, lubricate, and cushion these structures. Bursae can be either "constant" (those formed during embryologic development) or "adventitious" (bursae that develop as a result of chronic friction and degeneration of fibrous tissue between adjacent structures). When irritated or injured, these sacs become inflamed and swell. Because most bursae lie outside joints, joint movement is rarely compromised with bursitis. Acute bursitis occurs primarily during middle age years of life and is often caused by trauma. Chronic bursitis, however, can result from repeated trauma or repetitive irritation. Septic bursitis is caused by wound infection or bacterial infection of the skin overlying the bursae. Bursitis commonly occurs in the shoulder, hip, knee, and elbow but can also affect the spine, wrist, foot, and ankle.

FIG. 44.8 Olecranon Bursitis.
Note swelling at the point of the elbow (olecranon). A smaller, rheumatoid nodule also is present. (From Hochberg MC, et al. *Rheumatology*, 6th edition. Philadelphia: Elsevier; 2015.)

Pathophysiology

In tendinitis, inflammatory fluid accumulates, causing swelling of the tendon and its enclosing sheath. Inflammatory changes cause thickening of the sheath, which limits movements and causes pain. Microtears cause bleeding, edema, and pain in the involved tendons or surrounding structures. At times, after repeated inflammations, calcium may be deposited in the tendon origin area, causing a calcific tendinitis.

Typical bursitis is due to inflammation that is reactive to overuse or excessive pressure. Bursitis can also be caused by infection, autoimmune diseases, crystal deposition, or acute trauma. The inflamed bursal sac becomes engorged, and the inflammation can spread to adjacent tissues (see Fig. 44.8). The inflammation may decrease with rest, ice, and aspiration of the fluid. (Inflammation is discussed in Chapter 7.)

Clinical Manifestations

Tendinopathy may be asymptomatic. Generally, however, there is localized pain that worsens with active motion, more than passive motion. With symptomatic tendinopathy, the pain is localized over the involved tendon and movement of the affected joint is limited. In bursitis, onset of pain may be gradual or sudden, but movement of the joint itself is normal. Shoulder bursitis impairs arm abduction due to pain and swelling of the bursa. Bursitis in the knee produces pain when climbing stairs, while crossing the legs is painful in bursitis of the hip. Furthermore, lying on the side of the inflamed trochanteric bursa is also very painful. Signs of infectious bursitis may include the presence of pain, warmth and erythema, severe inflammation, or an adjacent source of infection, such as from total joint replacement surgery. Prior corticosteroid injections or evidence of a puncture site at the joint increases the potential for infectious bursitis. Table 44.2 summarizes common sites of bursitis.

Table 44.2

Common Sites and Causes of Bursitis

Site	Common Causes
Shoulder (subacromial)	Repetitive overhead activities
Elbow (olecranon)	Rheumatoid arthritis (RA), gout, tuberculosis, leaning on elbow
Hip (greater trochanter)	Acute trauma, chronic stress
Ischial (weaver's bottom)	Overuse (runner, ballet dancers), lumbosacral disease, RA, osteoarthritis (OA)
Knee	
Prepatellar (housemaid knee)	Trauma, frequent kneeling, infection
Pes anserine (medial knee)	Obesity, long-distance runner, OA, type 2 diabetes
Heel (calcaneal)	Poorly fitting footwear, Achilles tendinitis

Evaluation and Treatment

Diagnosis of tendinopathy, epicondylopathy, and bursitis is primarily based on the clinical history and physical examination. Other advanced imaging, such as arthroscopy, arthrography, ultrasound, or MRI, may be used to evaluate the severity of the condition. Treatment may include temporary immobilization of the joint with a sling, splint, or cast; administration of systemic analgesics; application of ice or heat; or local injection of an anesthetic and/or a corticosteroid to reduce inflammation. Bursitis

may require aspiration to drain excess fluid. Physical therapy to prevent loss of function begins after acute inflammation subsides.

Muscle Strains

Muscle strain is a general term for local muscle damage. Mild muscle strain is usually seen after traumatic or sports injuries. It is often the result of sudden, forced motion causing the muscle to become stretched beyond normal capacity. Strains often involve the tendon as well. Muscle strain may be chronic when the muscle is repeatedly stretched beyond its usual capacity. Hemorrhage into the surrounding tissue and signs of inflammation also may occur. Penetrating injuries, such as knife and gunshot wounds, can cause traumatic rupture. The incidence of muscle rupture is greater in young people. However, tendon rupture occurs with greater frequency in the older population. Regardless of the cause of trauma, muscle cells usually can regenerate. Regeneration may take up to 6 weeks, and the affected muscle should be protected during this time. Types of muscle strain, together with their manifestations and treatment, are summarized in Table 44.3.

Table 44.3

Muscle Strain

Type	Manifestations	Treatment
First degree (example: bench press in untrained athlete)	Muscle overstretched, pain but no muscle deformity	Ice should be applied 5 or 6 times in first 24–48 hours; complete rest for up to 2 weeks, followed by gradual resumption of full weight bearing 3 times per week and range of motion daily
		Exercises individualized to specific injury
Second degree (example: any muscle strain with bruising and pain)	Muscle intact with some tearing of fibers, pain, swelling, mild bruising; fascia is intact	Treatment similar to that for first-degree strains, with added mild analgesia; cryokinetics (a treatment system of alternating applications of cold with progressive exercise)
Third degree (example: traumatic injury)	Caused by tearing of fascia, muscle rupture palpable, bleeding present, marked weakness, deformity	Surgery to approximate ruptured edges; immobilization and non–weight bearing status for 6 weeks, followed by an individualized rehabilitation regimen

Type	Manifestations	Treatment
		of strengthening exercises

First degree (example: bench press in untrained athlete)	Muscle overstretched, pain but no muscle deformity	Ice should be applied 5 or 6 times in first 24–48 hours; complete rest for up to 2 weeks, followed by gradual resumption of full weight bearing 3 times per week and range of motion daily
		Exercises individualized to specific injury
Second degree (example: any muscle strain with bruising and pain)	Muscle intact with some tearing of fibers, pain, swelling, mild bruising; fascia is intact	Treatment similar to that for first-degree strains, with added mild analgesia; cryokinetics (a treatment system of alternating applications of cold with progressive exercise)
Third degree (example: traumatic injury)	Caused by tearing of fascia, muscle rupture palpable, bleeding present, marked weakness, deformity	Surgery to approximate ruptured edges; immobilization and non–weight bearing status for 6 weeks, followed by an individualized rehabilitation regimen of strengthening exercises

Muscle healing occurs in three phases:

1. Destruction: the myofibers of the damaged muscle contract and necrose, beginning an inflammatory reaction; the gap between torn fibers is filled by a hematoma.
2. Repair: monocytes phagocytize the dead tissue which activate satellite cells, becoming myoblasts; myoblasts infiltrate the scar tissue; and new capillary formation begins at the site of injury.
3. Remodeling: myofibers mature, forming contractile tissue, and attach to the ends of scar tissue; regeneration may take up to 6 weeks, and the affected muscle should be protected during that time.

A late complication of localized muscle injury is abnormal bone formation in soft tissue, often called **myositis ossificans** or **heterotopic ossification (HO)**. Although its exact pathophysiology remains unknown, evidence suggests the fundamental cause is the inability of mesenchymal cells to differentiate into osteoblastic stem cells, resulting in an inappropriate differentiation of fibroblasts into bone-forming cells. Though uncommon, HO may also be associated with burns, joint surgery, and trauma to the musculoskeletal system or central nervous system (CNS). HO may involve the muscle or

tendons, ligaments, or bones near the muscle causing stiffness or deformity of an extremity. Radiographic evidence of HO may be seen as soft tissue calcification on plain radiographs.

Rhabdomyolysis

Once used interchangeably with the term *myoglobinuria*, **rhabdomyolysis** is the rapid breakdown of muscle that causes the release of intracellular contents, including the protein pigment myoglobin, into the extracellular space and bloodstream. Physical interruptions in the sarcolemma membrane, called *delta lesions*, are the route by which muscle constituents are released. (The sarcolemma membrane, the plasma membrane of the muscle cell, is described in Chapter 43.) **Myoglobinuria** refers to the presence of the muscle protein myoglobin in the urine.

Pathophysiology

The term rhabdomyolysis may be incorrectly used interchangeably with *crush injury* (a description of injuries resulting from the crushing of a body part), *compartment syndrome* (the consequences of increased intracompartmental pressures (ICPs) of a muscle), or *crush syndrome* (the systemic pathophysiologic events caused by rhabdomyolysis, primarily involving the kidneys and coagulation syndrome).[5] Rhabdomyolysis has many causes and can result in serious complications, including hyperkalemia (due to the release of intracellular potassium into the circulation), metabolic acidosis (from liberation of intracellular phosphorus and sulfate), acute renal failure (myoglobin precipitation in the renal tubules, obstructing flow through the nephron), and even disseminated intravascular coagulation (DIC) (likely caused by activation of the clotting cascade by sarcolemma damage and the release of intracellular components from the damaged muscles).

Clinical Manifestations

A *classic triad* of muscle pain, weakness, and dark urine is considered typical of rhabdomyolysis. Abnormally dark urine caused by

myoglobinuria may be the first and only symptom; however, the presence of myoglobin in urine alone is not a reliable test to diagnose rhabdomyolysis. The renal threshold for myoglobin is low (approximately 0.5 mg/dL of urine); therefore, only 200 g of muscle need to be damaged to cause visible changes in the urine. Myoglobin is rapidly cleared, and levels may return to normal within 24 hours of injury. Along with the release of myoglobin, creatine kinase (CK) and other serum enzymes are released in massive quantities. The efflux of intracellular proteins and enzymes also includes loss of potassium, phosphate, nucleotides, creatinine, and creatine. Serum hypocalcemia is seen early during myoglobinuria and is followed by late hypercalcemia. The risk of renal failure increases proportionately to the increase in the levels of serum CK, potassium, and phosphorus.

Evaluation and Treatment

The most important and clinically useful measurement in rhabdomyolysis is the serum CK level.[6] With normal CK serum levels of 5 to 25 international units/L for women and 5 to 35 international units/L for men, a level of 1000 international units/L is used to identify rhabdomyolysis. Once CK levels exceed 15 to 20,000 international units/L, acute kidney injury is likely. Other laboratory tests may include the evaluation for hyperkalemia, which can cause life-threatening cardiac arrhythmias, and a blood urea nitrogen (BUN) to creatinine ratio, which can be decreased from a release of creatine from damaged muscle being converted to creatinine. Additional laboratory tests—such as measurement of the hemoglobin, hematocrit, and platelet levels and determination of the activated partial thromboplastin time—may be indicated in the presence of other trauma or suspected bleeding.

Maintaining adequate urinary flow and prevention of kidney failure are goals of treatment. Rapid intravenous hydration maintains adequate kidney perfusion. Other complications, such as hyperkalemia, may require temporary hemodialysis. Treatments such as using mannitol to cause an osmotic diuresis or bicarbonate to

alkalinize the urine have not been shown to consistently improve outcomes.

Compartment Syndrome

Compartment syndrome is the result of increased pressure within a closed osteofascial compartment resulting in impaired circulation, decreased arterial inflow, ischemia, and edema.[7] These skeletal muscle compartments are surrounded by several layers of fibrous fascia which are not able to expand (Fig. 44.9). Common causes of compartment syndrome include conditions that increase the contents of the compartment (such as bleeding or interstitial edema after an injury), a decrease in the compartment's volume (e.g., a tight bandage or cast), or a combination of these two conditions that results in a disturbance of the muscle's microvasculature.[8] After fractures, the most common cause of compartment syndrome is soft tissue injuries. Other causes include burns, vascular injuries, crush injuries, drug overdoses, reperfusion injuries, thrombosis, bleeding disorders, infections, improperly placed casts or splints, tight circumferential bandages, penetrating trauma, intense athletic activity, and poor positioning during surgery.[7] Greater risk is found in hemophilia cases and in those with pediatric leukemia (without acute trauma).[8,9]

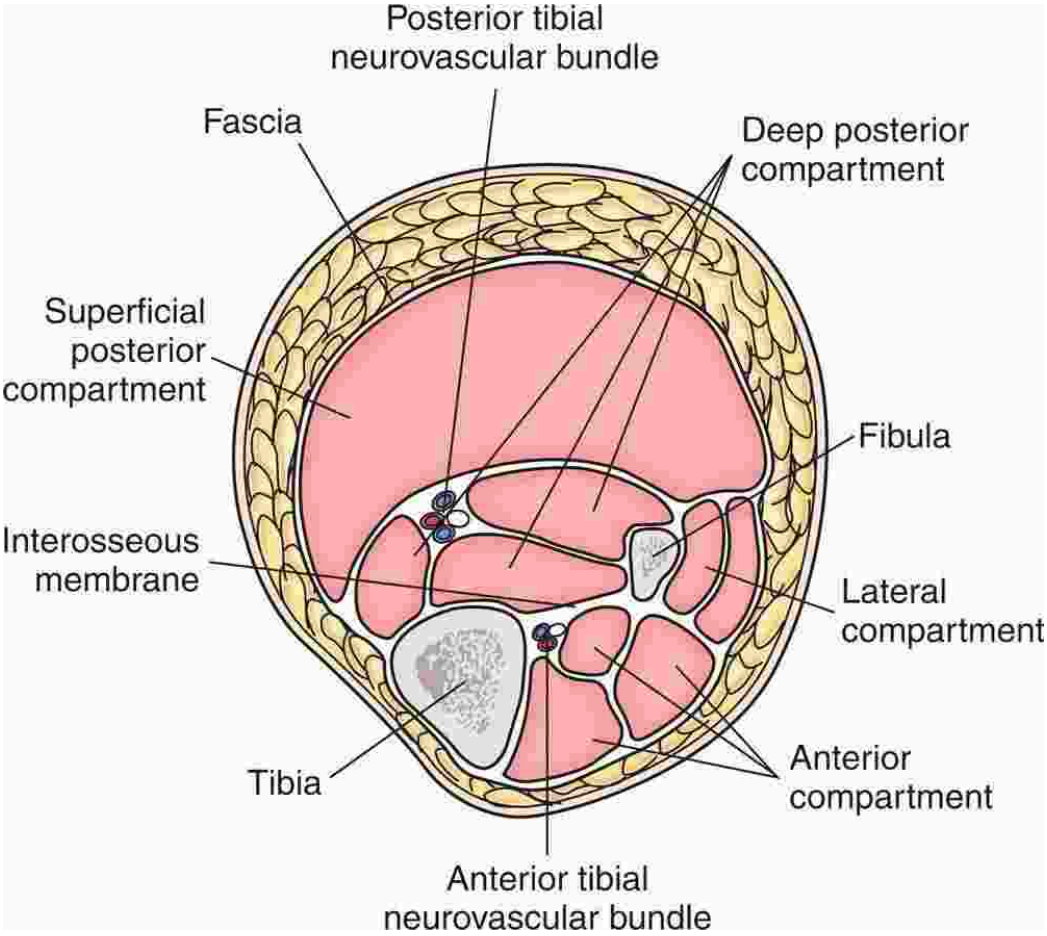

FIG. 44.9 Muscle Compartments of the Lower Leg. (From Mohahan FD, et al. *Phipps' medical-surgical nursing: Health and illness perspectives*, 8th edition. St. Louis: Mosby; 2007.)

An illustration depicts the cross-section of the lower leg with labels indicating the posterior tibial neurovascular bundle, deep posterior compartment, fibula, lateral compartment, anterior compartment, anterior tibial neurovascular bundle, tibia, interosseous membrane, superficial posterior compartment, and fascia.

Pathophysiology

Any condition that disrupts the vascular supply to an extremity can cause increased pressure within the muscle compartments. This may also include prolonged pressure on a muscle compartment, such as external compression. The weight of a limb extremity can generate enough pressure to produce muscle ischemia. The increased pressure within these compartments leads to diminished capillary blood flow, edema, rising compartment pressure, and tamponade, resulting in local tissue hypoxia and necrosis (Fig. 44.10). Normal pressure within a compartment is less than 10 mmHg; acute compartment syndrome occurs when pressures reach 30 mmHg or greater. A normal **intracompartmental pressure (ICP**) reading, however, does not exclude acute compartment syndrome, thus ICP should be monitored serially or continuously.[10–12]

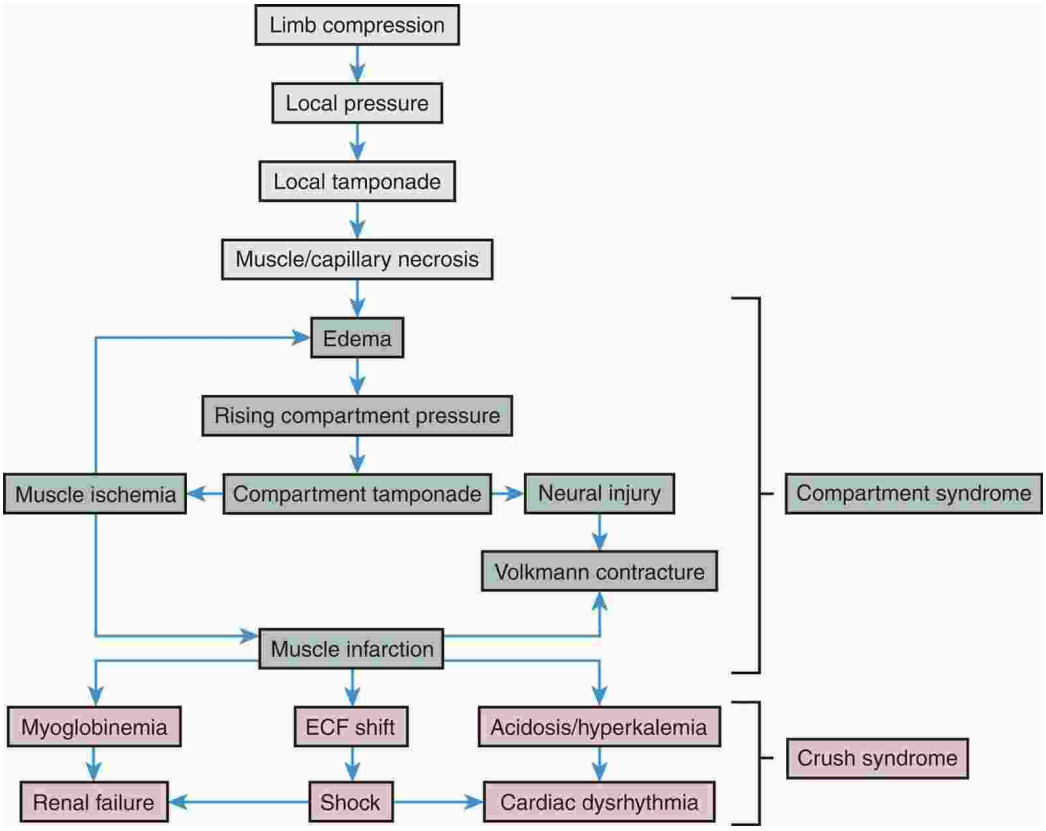

FIG. 44.10 Pathogenesis of Compartment Syndrome and Crush Syndrome Caused by Prolonged Muscle Compression.
ECF, Extracellular fluid.

A flow chart summarizes the pathogenesis of compartment syndrome and crush syndrome. • Limb compression leads to local pressure. • Local pressure leads to local tamponade. • Local tamponade leads to muscle or capillary necrosis. • Muscle or capillary necrosis to edema. • Edema leads to rising compartment pressure. • Compartment syndrome: Edema leads to rising compartment pressure. • Rising compartment pressure leads to compartment tamponade which

leads to muscle ischemia and neural injury. Neural injury leads to Volkmann contracture. • Crush syndrome: Muscle infarction leads E C F shift that leads to shock. • Shock leads to renal failure and cardiac dysrhymia. • Muscle infarction leads to myoglobinemia and acidosis and hyperkalemia. • Myoglobinemia leads to renal failure. Acidosis or hyperkalemia leads to cardiac dysrhythmia.

Clinical Manifestations

The compartments often affected are the anterior compartments of the leg.[7] Other common locations include the forearm, thigh, buttock, shoulder, hand, and foot.[7] It is uncommon in the abdomen.[7] Diagnosis is initiated by clinical examination with the earliest objective finding being pressure or tense feeling (swelling and rigidity) of the affected compartment. The classic symptoms of compartment syndrome are referred to as the "5 Ps": *p*ain (out of proportion to the injury); *p*allor (pale appearance); *p*aresthesia (impaired or altered sensations to the area, or both); *p*aresis (impaired function of the involved extremity); and *p*ulselessness (loss of a pulse to the area). None of these signs are truly dependable, although pain with passive extension of the fingers or toes in the affected extremity and paresthesia tend to be most suggestive of compartment syndrome.[7,13]

A condition known as **Volkmann ischemic contracture** can develop when compartment syndrome goes unrecognized or is not adequately treated.[14] Irreversible neurovascular damage can occur. Contracture deformities of the fingers, hand, and wrist can lead to partial or complete disability of the affected limb.

Evaluation and Treatment

Compartment syndrome is a clinical diagnosis that requires immediate treatment and surgical consultation. Delayed treatment can cause loss of limb.[15] The individual's history and physical examination findings alone can provide the necessary information to make a diagnosis of compartment syndrome. When clinical evaluation is inconclusive, the rising ICP can be directly measured by using a manometer or an electronic transducer, to confirm the diagnosis. Laboratory tests, ultrasonography, and imaging studies may help exclude other conditions but, generally, are not helpful in diagnosing compartment syndrome. Once the diagnosis is confirmed, immediate surgical intervention is warranted to relieve pressure within the compartment. Surgical intervention consists of performing an immediate fasciotomy and debridement of the affected area to decompress the compartment and allow the return of a normal blood supply. Skin grafts are often required to close the resultant opening, but vacuum-assisted wound closure devices also have been used successfully in accelerating wound closure. With delayed treatment, the limb may require amputation.[7]

Malignant Hyperthermia

Malignant hyperthermia (MH) is a potentially life-threatening hereditary musculoskeletal disorder characterized by a hypermetabolic reaction to certain volatile anesthetics or certain depolarizing muscle relaxants (e.g., succinylcholine). Nitrous oxide and xenon, although inhaled, are not halogenated or implicated in MH.[16] Other disorders associated with MH are the rare central core disease (CCD) and King-Denborough syndrome.[17]

Pathophysiology

MH is an autosomal dominant inherited disorder. The gene for the ryanodine receptor RYR1 is the location for mutations. Other genetic loci have been identified. The main concern is uncontrolled release of calcium from skeletal muscle sarcoplasmic reticulum which leads to sustained muscle contraction, depletion of adenosine triphosphate (ATP), and notably increases oxygen consumption, carbon dioxide

production, and heat.[16] Depletion of ATP stores leads to membrane integrity failure and leakage of cellular potassium, CK, and myoglobin into the circulation.[18,19] The sustained elevation of calcium concentration allows excessive stimulation of aerobic and anaerobic glycolytic metabolism, causing a hypermetabolic state resulting in extremely high body temperature, respiratory and metabolic acidosis, muscle rigidity, altered cell permeability, and hyperkalemia. Rhabdomyolysis and death may result if this condition is not quickly identified and treated.

Clinical Manifestations

Common signs and symptoms are tachycardia, tachypnea, hypoxemia, hypercarbia, metabolic and respiratory acidosis, hyperkalemia, cardiac dysrhythmias, hypotension, skeletal muscle rigidity, and hyperthermia.[16]

Evaluation and Treatment

Careful and thorough preoperative assessment by the anesthesia team will help to alert care providers to the possibility of an individual being susceptible to MH. A family history of anesthetic problems and previous untoward anesthetic experiences (muscle cramping, unexplained fevers, dark urine) are criteria that require further clarification before administration of a volatile anesthetic, such as halothane, or the muscle relaxant succinylcholine. The caffeine halothane muscle contracture test is considered the most sensitive and definitive predictor of an individual developing MH. A muscle biopsy is obtained from the individual and then separately exposed to standardized amounts of halothane and caffeine. If the muscle bundles exhibit a contracture at specified limits, the individual is considered susceptible to MH. Common signs and symptoms are tachycardia, masseter muscle and skeletal muscle spasm, and elevated body temperature.

Priorities in the treatment of MH include identifying and treating the underlying disorder and preventing life-threatening renal failure. Dantrolene, a skeletal muscle relaxant, which inhibits

calcium release from the sarcoplasmic reticulum and reverses the effects of MH, should be administered immediately. Once MH is suspected, all triggering agents must be discontinued, the person hyperventilated with 100% oxygen with non-triggering anesthetic agents used for patient care, and surgery ended as quickly as possible.[16] The management algorithm is presented in Box 44.1.[16,20,21] Secondary problems to be monitored and treated include electrolyte imbalance, volume depletion, acidosis, hyperuricemia, hyperkalemia, and calcium imbalance. Short-term dialysis also may be necessary. The mortality rate of MH is 3% to 5%, even when properly treated.[16]

Box 44.1

Critical Management Algorithm for Malignant Hyperthermia

- **Stop** the triggering agent.
- **Call** for help.
- **Administer** dantrolene 2.5 mg/kg every 5 minutes until the reaction subsides up to a maximum of 10 mg/kg.
- **Increase** ventilation to lower end-tidal CO_2.
- **Cooling** measures (cool or cold isotonic crystalloid IV fluids (20 to 30 mL/kg and ice packs to exposed surfaces).
- **Treat** arrhythmias (e.g., amiodarone; avoid calcium channel blockers).
- **Laboratory** studies include arterial blood gas, electrolytes (especially potassium), creatinine kinase (CK), serum and urine myoglobin, and coagulation profile.
- **Continue** dantrolene at 1 mg/kg every 4 hours for 24–48 hours.

- **Ensure** urine output of 2 mL/kg/h (mannitol 3 g are included in each vial of dantrolene)

Disorders of Bones

Metabolic Bone Diseases

Metabolic bone disease is characterized by abnormal bone strength caused by abnormalities of minerals, vitamin D, bone mass, or bone structures. Individuals of all ages may be affected by this disease. Causes of these conditions are attributed to genetics, poor diet, or hormone influence leading to altered or inadequate biochemical reactions.

Osteoporosis

Osteoporosis, or **porous bone**, is characterized by low bone mineral density caused by altered bone microstructure and leads to an increased risk of fractures.[22] It is a complex, multifactorial, chronic disease that often progresses silently causing impaired structural integrity of the bone, and decreased bone strength. Bone tissue can be normally mineralized in osteoporosis, but the density of bone is decreased and the structural integrity of trabecular bone is impaired. Cortical bone becomes more porous and thinner, making bone weaker and prone to fractures (Figs. 44.11 and 44.12; Box 44.2). It is the most common disease that affects bone. The World Health Organization (WHO) has defined osteoporosis as "a systematic skeletal disease characterized by low bone density and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility."[23] Incidence of osteoporosis increases with age and affects over 200 million people.[22] Over 70% of those affected are over 80 years old. In the developed world, those affected are 2% to 8% of males and 9% to 38% females. Globally, osteoporosis causes approximately 9 million fractures per year.[22]Box 44.3 presents risk

factors for osteoporosis. Over 50% of postmenopausal white women will have an osteoporotic-related fracture. Only about 33% of senior women who have a hip fracture will be able to return to independent living.[22] The risk of an osteoporotic fracture is 20% in white men, however, their 1-year mortality is twice that of women.[22] Osteoporotic fractures significantly decrease quality of life, increasing morbidity, mortality, and disability.[24] Black males and females have a decreased incidence of osteoporosis compared to white individuals but have similar fracture risks. The aging of the American population is expected to triple the number of osteoporotic fractures.[22,25,26] Due to lower exposure to sunlight and consequent lower synthesis of vitamin D, individuals who live at higher latitudes have higher fracture rates than those who live closer to the equator.[22,27]

Box 44.2

Causes of Secondary Osteoporosis

- Medications such as glucocorticoids, anti-epileptics, chemotherapy, proton pump inhibitors, possibly thiazolidines
- Hyperparathyroidism
- Overtreatment of hypothyroidism
- Chronic kidney disease
- Cushing disease
- Diseases related to long-term immobilization
- Secondary amenorrhea duration longer than one year (non-estrogen hormonal therapy,
- Low body weight, excessive exercise

Box 44.3

Risk Factors for Osteoporosis

- Increasing age
- Body weight under 128 pounds
- Smoking
- Positive family history of osteoporosis
- White or Asian race
- Early menopause
- Low levels of physical activity
- Personal history of a fracture from a ground-level fall or minor trauma after the age of 40
- Conditions affecting mobility, such as spinal cord injuries

Highest Risk for Fracture

- Advanced age
- Prior history of a fracture
- Female gender
- Use of corticosteroids
- Low body mass index
- Smoker
- Secondary osteoporosis
- Intake of alcohol

There are two types of osteoporosis: *primary* or *idiopathic osteoporosis*, which is more common, and secondary osteoporosis. Primary osteoporosis is related to the aging process associated with decreasing sex hormones.[22] *Secondary osteoporosis* is caused by other

conditions, including endocrine diseases (hormone imbalances, diabetes, hyperparathyroidism, hyperthyroidism), medications (such as heparin, corticosteroids, phenytoin, barbiturates, lithium), and other substances (including tobacco and ethanol) (see Box 44.2). Other conditions (including rheumatoid disease, human immunodeficiency virus [HIV], malignancies, malabsorption syndromes, liver or kidney disease) also increase the risk for developing osteoporosis (see Box 44.3).

Bone quality is not defined by bone mass alone (as measured by BMD) but also by the microarchitecture of the bone. Other variables include crystal size and shape, brittleness, vitality of bone cells, structure of the bone proteins, water volume, integrity of the trabecular network, vascular supply, and the ability to repair tiny cracks. Because bone density relates to the *quantity* of bone, the *quality* of bone is not accurately identified by bone density testing alone. As a result, bone density testing may not accurately identify those who will eventually be susceptible to fractures.

Postmenopausal osteoporosis is bone loss that occurs in middle-aged and older women. It can occur because of estrogen deficiency, as well as estrogen-independent age-related mechanisms (e.g., secondary causes such as hyperparathyroidism and decreased mechanical stimulation). Increased oxidative stress and intracellular reactive oxygen species play a significant role in the development of age-related bone loss and other age-related changes in the body. Estrogen deficiency can also increase with stress, excessive exercise, and low body weight. Postmenopausal changes result in a substantial increase in bone turnover—that is, an imbalance between the remodeling activity of osteoclasts (bone destroyers) and osteoblasts (bone formers). Increased formation and activity of osteoclasts result in increased bone resorption and is associated with a cascade of proinflammatory cytokines. Increased cytokine activation, especially tumor necrosis factor (TNF), can occur with declining estrogen levels. In addition, estrogen helps to protect against the effects of oxidative stress and osteoclast apoptosis (programmed cell death). A decrease in estrogen levels is therefore associated with *survival* of the bone-removing osteoclasts.

Biologically, these processes involve the receptor activator nuclear factor κβ ligand (RANKL), transcription factors such as Forkhead proteins the Wnt and osteoprotegerin (OPG) signaling pathways, and insulin-like growth factor (IGF) (Fig. 44.13; also see Chapter 43). Other causes may include a combination of inadequate dietary calcium intake and lack of vitamin D, possibly decreased magnesium levels, lack of exercise, low body mass, and family history. IGF is known to help in fracture healing and collagen synthesis and improves conditions for bone mineralization. IGF levels significantly decline by age 60. Excessive phosphorus intake, chiefly through the intake of highly processed foods, hampers the calcium/phosphorus balance by interfering with parathyroid hormone and fibroblast growth factor 23 (FGF-23).

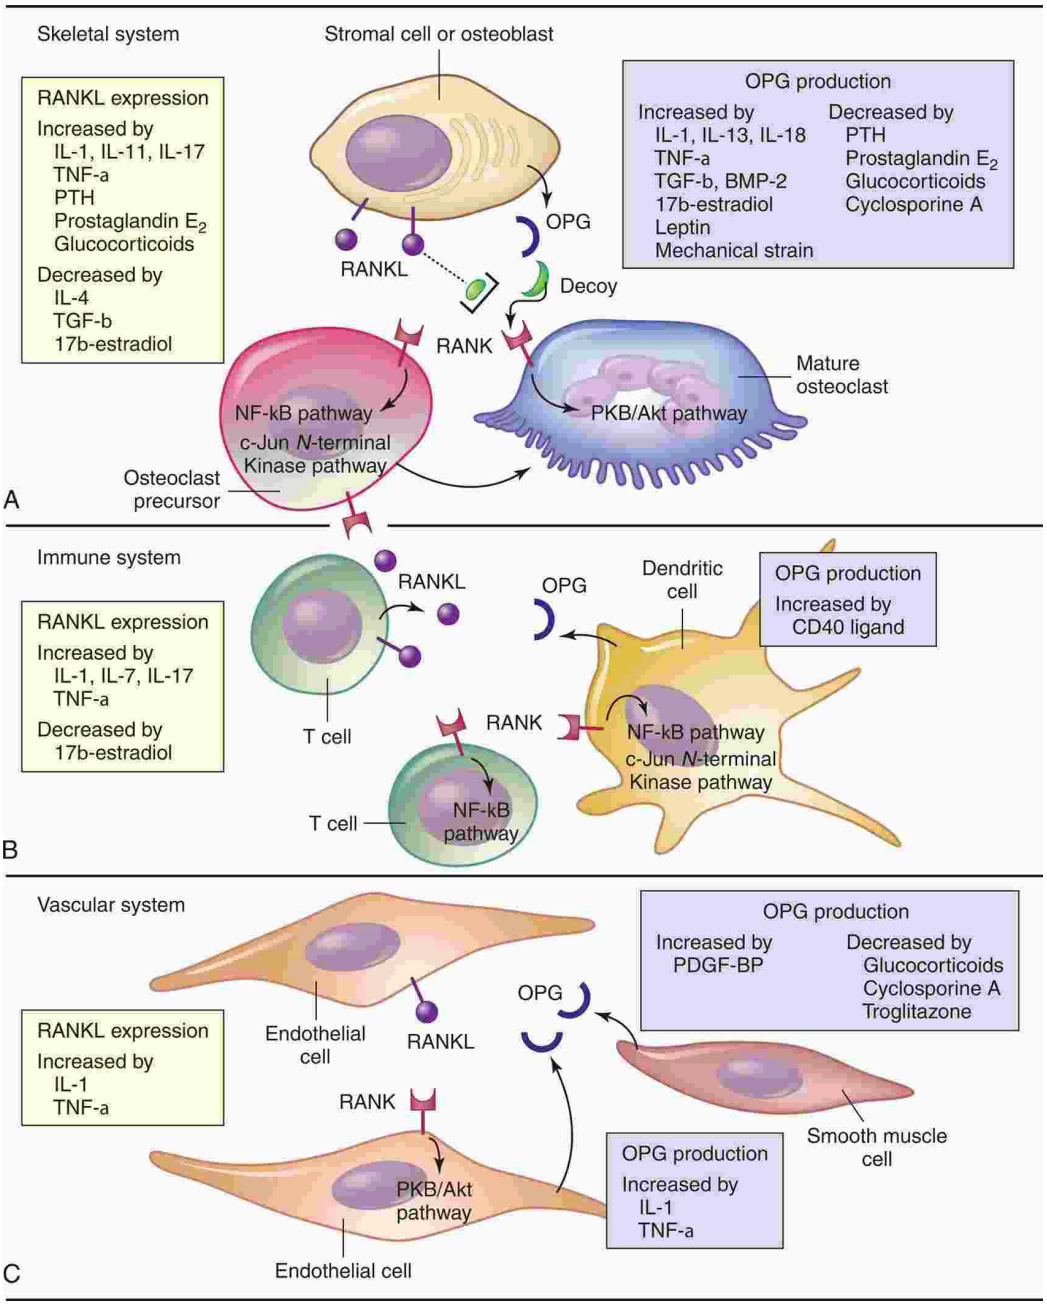

FIG. 44.13 OPG/RANKL/RANK System. Receptor activator of nuclear factor κβ ligand (*RANKL*, which is a cytokine and part of the tumor necrosis factor *[TNF]* family) and osteoprotegerin (*OPG*, which is a glycoprotein receptor antagonist) are modulated by various cytokines, hormones, drugs, and mechanical strains *(see inserts)*. **(A)** In bone, RANKL is

expressed by both stromal cells and osteoblasts. RANKL stimulates the receptor RANK on osteoclast precursor cells and mature osteoclasts, and activates intracellular signaling pathways to promote osteoclast differentiation and activation and cytoskeletal reorganization and survival *(PKB/Akt pathway)* that increase resorption and bone loss. OPG, secreted by stromal cells and osteoblasts, acts as a “decoy” receptor and blocks RANKL binding to and activation of RANK. **(B)** In the immune system, RANKL is expressed and secreted by T cells. T-cell–derived RANKL also can activate RANK on osteoclasts, T cells, and dendritic cells (antigen-presenting cells), which enhances bone loss that occurs in inflammatory bone diseases such as rheumatoid arthritis. Dendritic cells may regulate these processes by secreting OPG. **(C)** In the vascular system, endothelial cells express RANKL and the RANK receptor. RANKL/RANK interactions contribute to endothelial and smooth muscle cells and can block RANKL binding. The physiologic significance of the OPG/RANKL/RANK system in endothelial and smooth muscle cells is being studied. *BMP-2*, Bone morphogenic protein 2; *IL*, interleukin; *PDGF-BP*, platelet-derived growth factor-beta polypeptide; *PTH*, parathyroid hormone; *TGFα*, tumor necrosis factor-alpha; *TGFβ*, transforming growth factor-beta. (Adapted from Hofbauer LC, Schoppet M. Clinical implications of the osteoprotegerin/RANKL/RANK system for bone and vascular diseases. *JAMA*, 2004;292(4):490–495.)

Illustration A depicts the OPG, RANKL, RANK expression in the skeletal system, which shows the RANKL expression is increased by I L 1, I L 11, I L 17, T N F alpha, P T H, prostaglandin E 2, glucocorticoids and decreased by I L 4, T G F b, 17 b estradiol. O P G production increased by I L 1, I L 13, I L 18, T N F alpha T G F b, B M P, 17b estradiol, Leptin, mechanical strain and decreased by P T H, prostaglandin E 2, glucocorticoids, cyclosporin A. Illustration B depicts the OPG, RANKL, RANK expression in the immune system, which shows the RANKL expression is increased by I L 1, I L 11, I L 17, T N F alpha, and decreased by 17 b estradiol. O P G production increased by C D 40 ligand. Illustration C depicts the OPG, RANKL, and RANK expression in the vascular system, which shows the RANKL expression is increased by I L 1, T N F alpha. O P G production increased by P D G F-B P and decreased by glucocorticoids, cyclosporin A, and Troglitazone. O P G production increased by I L-1 and T N F-alpha.

The levels of sex hormones, particularly estradiol (estrogen) and testosterone, are major determinants of bone density in both females and males. When estrogen levels drop after menopause, circulating androgens (i.e., testosterone and dihydrotestosterone) become significant effectors on bone metabolism through their influence on the stimulation of bone formation. Other factors, such as inadequate dietary calcium intake, decreases in weight-bearing exercise, and

sarcopenia, also are associated with osteoporosis. (Other risk factors are identified in Box 44.3.)

Poor nutrition, insufficient intake, or malabsorption of dietary minerals (in particular calcium) are factors in the development of osteoporosis. Calcium intake and absorption from the intestine decreases with age and has also been associated with malnutrition following bariatric surgery.[28] Decreased serum levels of trace elements (zinc, copper, iron, magnesium, and manganese) have also been associated not only with lower peak bone mass in developing bone, but also with later development of osteoporosis. Vitamin deficiencies, particularly vitamins C, D, E, and K, as well as either deficiencies or excesses of protein, also contribute to bone loss.

Skeletal homeostasis depends on a very narrow range of plasma calcium and phosphate concentrations, which are maintained by the endocrine system. Therefore, endocrine dysfunction ultimately can cause metabolic bone disease. In addition to declining levels of sex steroids, the hormones most commonly associated with osteoporosis are parathyroid hormone, cortisol, thyroid hormone, and growth hormone. Excessive intake of caffeine, phosphorus, alcohol, and nicotine, along with lower body mass index has also been shown to lower bone mineral density.

Secondary osteoporosis is osteoporosis caused by other conditions, including hormonal imbalances (endocrine disease, diabetes, hyperparathyroidism, hyperthyroidism), medications (e.g., heparin, corticosteroids, phenytoin, barbiturates, and lithium), and other substances (e.g., tobacco, ethanol). Other conditions, including rheumatoid disease, HIV, malignancies, malabsorption syndrome, and liver or kidney disease, also increase the risk for developing osteoporosis (see Box 44.3*Risk Factors:* Osteoporosis).[29] Secondary osteoporosis caused by heparin therapy is due to reduced osteoblast formation and increasing bone resorption by reducing OPG, thus increasing osteoclast formation. These effects usually resolve when therapy stops. Other medications that increase the risk of osteoporosis include glucocorticoids, proton pump inhibitors,

aromatase inhibitors, lithium, methotrexate, anticonvulsants, cyclophosphamide, thiazolidinediones, and cyclosporine.

Pathophysiology

Osteoporosis develops when the remodeling cycle (coupling)—bone resorption and bone formation—is disrupted, leading to an imbalance in the coupling process. Throughout an individual's lifetime, old bone is removed (resorption) and new bone is added (formation) to the skeleton (see bone remodeling Chapter 43). In osteoporosis, old bone is being resorbed faster than new bone is being formed, causing the bones to lose density, becoming thinner and more porous. A progressive loss of bone mass may continue until the skeleton is no longer strong enough to support itself. Eventually, bones can fracture spontaneously. Studies in the field of bone biology have led to new understanding of the roles of hormones, growth and signaling factors, and cellular biology in osteoporosis.[30] Of primary importance is the osteoblast lineage, chondrocyte lineage, and osteoclast differentiation pathway, which are dependent on various processes, including proliferation, maturation, fusion, and activation. These processes, in turn, are dependent on the availability of stem cells to allow differentiation to occur and are controlled by hormones, cytokines, and paracrine stromal cell interactions. Mesenchymal stem cells (MSCs) and skeletal stem cells (SSCs) have been shown separately to give rise to osteoblasts but the relationship between these two stem cell populations needs much more study.[31]

Although hormonal influences remain important in maintaining bone health, genetic/ epigenetic factors and the role of oxidative stress are receiving increased attention as critical determinants of bone homeostasis. Thus, proper intracellular communication within bone among its molecular regulators is necessary for normal bone homeostasis. Numerous interleukins, TNF, TGF-β, prostaglandin E_2, and hormones interact to control osteoclasts (see Fig. 44.13). Normal bone homeostasis is dependent on the balance between the cytokine **receptor activator of nuclear factor κβ ligand (RANKL);** its **receptor**

activator nuclear factor κβ (RANK); and its decoy receptor **osteoprotegerin (OPG)**, a glycoprotein (see Chapter 43).[32,33]

Postmenopausal osteoporosis results from estrogen deficiency. It is characterized by increased bone resorption relative to the rate of bone formation, leading to sustained bone loss. This phenomenon can also be seen in men, as circulating estrogen, though in lower levels compared to women, is essential for modulating libido, erectile function, and spermatogenesis. Therefore, bone loss in men may be a result of male estrogen deficiency.

Increased bone resorption results from enhanced development of osteoclasts and decreased osteoclast apoptosis (see Fig. 44.13). Estrogen stimulates OPG secretion and down-regulates RANKL; drugs known as *selective estrogen response modifiers (SERMs)* also stimulate OPG production. Postmenopausal women express higher levels of RANKL on bone marrow stromal cells, T cells, and B cells than premenopausal women. Importantly, RANKL expression is increased when estrogen levels are decreased, leading to increased formation of osteoclasts while reducing osteoclast apoptosis.

Sex steroids (e.g., estrogens) exert antiapoptotic effects on osteoblasts but exert proapoptotic effects on osteoclasts. The difference in activity is determined by the length of time **extracellular signal regulated kinases (ERKs)** remain in the nucleus. Estrogen activates ERKs outside the nucleus; ERKs then accumulate in the nucleus and activate downstream transcription factors. Prolonged nuclear accumulation of activated ERKs converts the antiapoptotic effect of estradiol to proapoptotic. In addition to ERKs, RANKL promotes the antiapoptotic effects on osteoclasts, thus increasing their life span. Wnt signaling induces a biochemical series of events that increases osteoblast and bone formation. Alterations in Wnt signaling account for critical pathophysiologic changes in most acquired metabolic bone diseases including postmenopausal osteoporosis, aging effects, and glucocorticoid (i.e., cortisone) excess. Agents such as parathyroid hormone and bisphosphonates, used for treatment of bone loss, exert their positive effects by altering the

formation of osteoblasts or osteoclasts or by inducing osteoclast apoptosis.

Glucocorticoid-induced osteoporosis (e.g., prednisone, cortisone) is the most common type of secondary osteoporosis and is characterized by increased bone resorption and decreased bone formation. Glucocorticoids have a direct impact on bone quality by improving osteoclast survival, inhibiting osteoblast formation and function, and increasing osteocyte apoptosis. Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts (see Fig. 44.13). The use of immunosuppressive drugs (e.g., cyclosporine A) to reduce rejection of transplanted organs also alters the OPG/RANKL/RANK system and can lead to post-transplantation osteoporosis. Overall, these alterations result in decreased thickness of the bone cortex and fewer, thinner, and more widely spaced trabeculae in the marrow. Other conditions affected by OPG/RANKL/RANK include RA, myeloma, vascular diseases, and skeletal metastases from neoplastic disorders.

Age-related bone loss begins in the third to fourth decade for women but later for men.[24,34] Trabecular bone loss begins in young adult women and men at all skeletal sites, continues throughout life, and accelerates during perimenopause in women.[34] Late onset of cortical bone loss is associated with sex steroid deficiency.[22,34] Loss of trabecular bone in men proceeds in a linear fashion with thinning of trabecular bone rather than complete loss, as is noted in women (Fig. 44.14A and B). Men have approximately 30% greater bone mass than women, which may be a factor in their later involvement with osteoporosis (Fig. 44.15). Secondary osteoporosis occurs more frequently in men than women.[22] Androgens promote OPG production, thus inhibiting the osteoclastic effect of RANKL. Since men typically have a more gradual decrease in the levels of testosterone and estradiol (and possibly progesterone), bone mass is maintained longer than in women. Reduction in physical activity in older persons also may be a major factor in the degree of bone loss. Preservation of bone mass depends on skeletal stress (mechanical) through muscle contraction and weight-bearing.

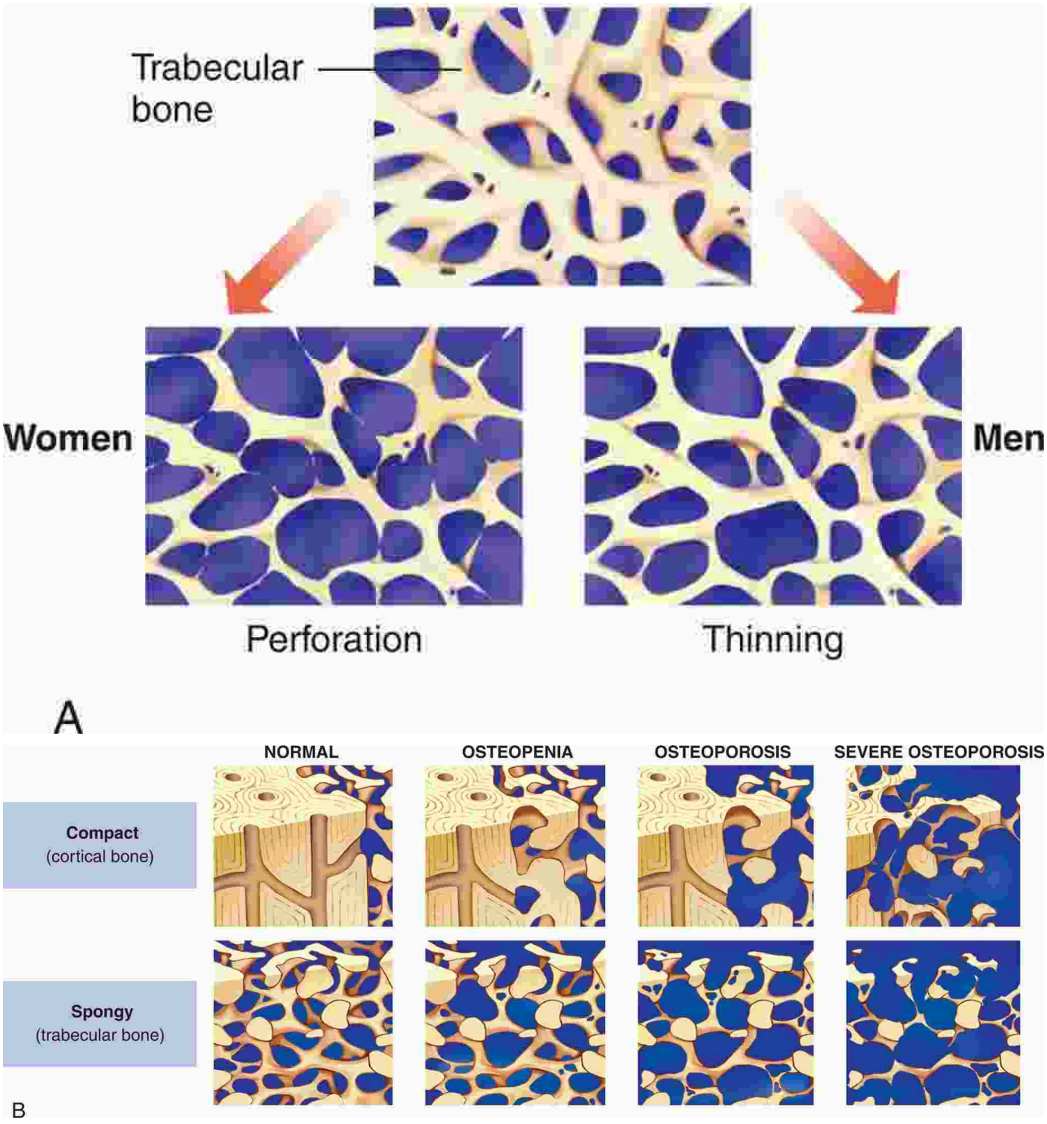

FIG. 44.14 Osteoporosis.
(A) Osteoporosis in Cortical and Trabecular Bone. **(B)** Mechanism of Loss of Trabecular Bone in Women and Trabecular Thinning in Men. Bone thinning predominates in men because of reduced bone formation. Loss of connectivity and complete trabecular loss predominate in women.

A. An illustration depicts the gender differences in the pattern of trabecular bone loss resulting in trabecular thinning in men and trabecular

perforation in women. B. An illustration depicts the pattern of trabecular bone and cortical bone under various conditions. The upper panel of illustrations depicts the pattern of cortical bone loss of normal bone, osteopenia, osteoporosis, severe osteoporosis. The lower panel of illustrations depicts the pattern of trabecular bone loss of normal bone, osteopenia, osteoporosis, severe osteoporosis.

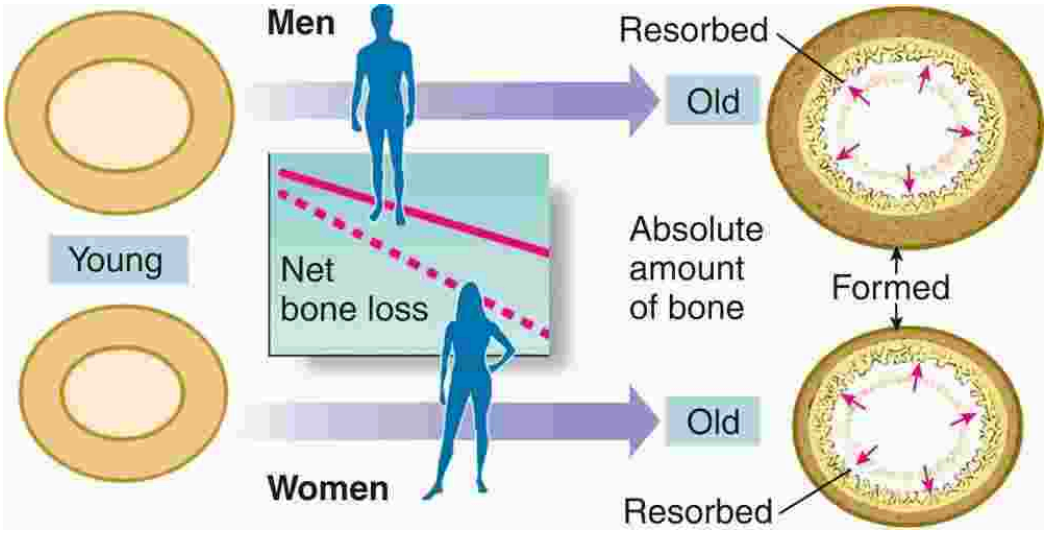

FIG. 44.15 Bone Loss in Men and Women. With aging, the absolute amount of bone resorbed on the inner bone surface and formed on the outer bone surface is greater in men than in women.

An illustration depicts the absolute amount of bone loss in women and men with aging which shows the absolute amount of bone resorbed on the inner bone surface by the men with aging is greater compared to the absolute amount of bone resorbed on the inner bone surface by the men with aging. A line graph represents the net bone loss for men is greater than women.

Clinical Manifestations

The specific clinical manifestations of osteoporosis depend on the bones involved. The most common manifestation, however, is bone deformity. Pain tends to occur only when there is a fragility fracture. Fractures are likely to occur because the trabeculae of spongy bone

become thin and sparse, and compact bone becomes porous. As bone becomes more fragile, falls or bumps which would not have caused a fracture previously may now cause bone to break; this is referred to as a fragility fracture. The most common sites for osteoporosis-related fractures are the spine, femoral neck, and wrist. As the bones lose volume, they become brittle and weak and may collapse or become misshapen. Vertebral collapse causes **kyphosis** (**hunchback**) and diminishes height. Fractures of the long bones (particularly the femur and humerus), distal radius, ribs, and vertebrae are most common. The most serious fractures associated with osteoporosis are hip fractures and spinal fractures, which have a high incidence of chronic pain, disability, diminished quality of life, and premature death.[22] Fracture of the neck of the femur (intertrochanteric fracture) tends to occur in older women with osteoporosis. Fatal complications of fractures include fat or pulmonary embolism, pneumonia, hemorrhage, and shock. Approximately 20% of persons with a hip fracture die as a result of surgical complications. Osteoporosis in men, as in women, also may be related to hypogonadism, with estradiol levels being more clinically important than testosterone levels in both genders.

Evaluation and Treatment

A thorough history and physical examination helps to define risk factors from secondary causes of bone loss. Emphasis on social history includes smoking and chronic alcohol habits. A family history is obtained as is a history of previous fractures. The physical exam rarely reveals alterations until osteoporosis is advanced.[22] The USPSTF current recommendations include screening for osteoporosis with bone measurement testing to prevent osteoporotic fractures in postmenopausal women younger than 65 years at increased risk of osteoporosis, but the USPSTF does not recommend screening in men.[35]

Generally, osteoporosis is detected radiographically as increased radiolucency of bone. By the time abnormalities are detected by x-ray examination, up to 25% to 30% of bone tissue may have been

lost. The best test for assessing bone mineral density is the dual x-ray absorptiometry (DXA) tests scans of the central skeleton.[36] In bones not at high risk, peripheral DXA tests and ultrasound measure density, but do not correlate well to the standard DXA scan of the hip and spine and are not as useful in diagnosis or treatment decisions.[22]

Bone density is based on the number of standard deviations that differ from the mean bone mineral density of a young-adult reference population (a T-score) (Table 44.5). When BMD measurement is not available, fracture prediction can be determined using an assessment tool developed by the WHO called Fracture Risk Assessment (FRAX) (Fig. 44.16). This tool incorporates clinical risk factors with BMD at the femoral neck to predict an individual's 10-year risk of fracture. This tool is available at http://www.shef.ac.uk/FRAX and is a downloadable computer-based questionnaire that has been developed for use in Europe, North America, Asia, and Australia.

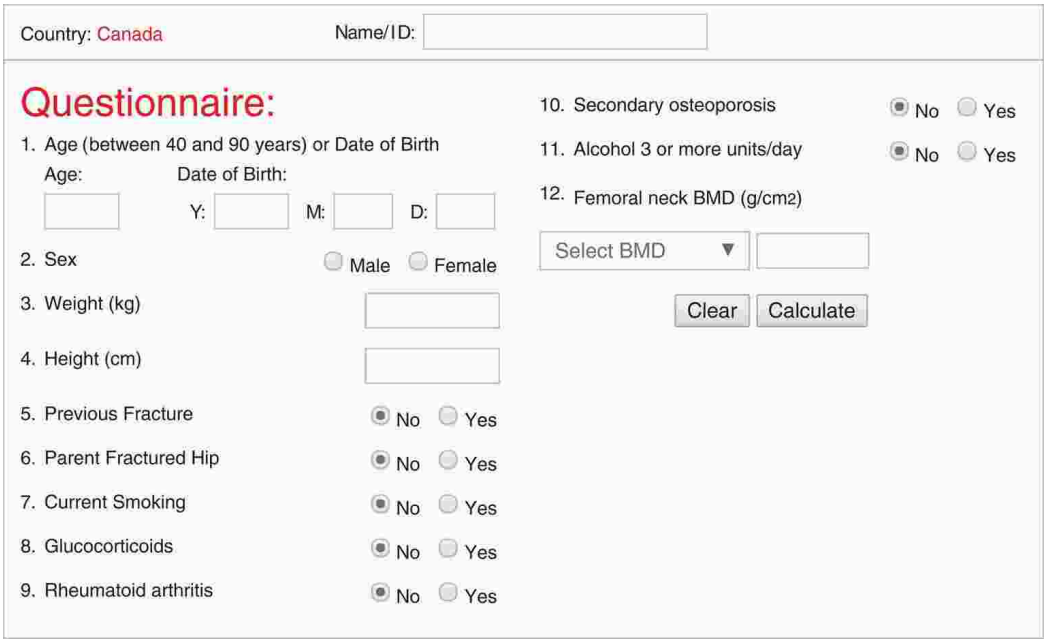

FIG. 44.16 Fracture Risk Assessment Tool: FRAX.

An image represents the questionnaire for fracture risk calculation using a web-based fracture risk assessment tool. The questionnaire includes the following questions. 1. Age (between 40 and 90 years) or date of birth age. 2. Sex. 3. Weight in kilogram. 4. Height. 5. Previous fracture. 6. Parent fractured hip. 7. Current smoking. 8. Glucocorticoids. 9. Rheumatoid arthritis. 10. Secondary osteoporosis. 11. Alcohol 3 or more units per day. 12. Femoral neck B M D.

Osteopenia is categorized as a bone density score between negative 1.0 and negative 2.5 standard deviations below normal.[22] The diagnosis of osteoporosis is made with scores below negative 2.5.[22] Severe or established osteoporosis is identified when there has been a fragility fracture associated with low bone density. The

disease can be generalized as involving major portions of the axial skeleton or regional loss that involves one segment of the appendicular skeleton.

Other evaluation procedures include tests for measuring levels of serum calcium, phosphorus, and alkaline phosphatase, protein electrophoresis, as well as urinary biochemical markers to monitor bone turnover (Box 44.4). Body calcium levels also can be measured by neuron activation analysis, a procedure involving use of radioactive calcium-49, whose gamma activity can be measured with a whole-body counter. Evaluation tools are summarized in Table 44.4.

Box 44.4

Biochemical Markers of Bone Turnover

Biochemical markers of bone turnover are useful in monitoring osteoporosis treatment. Markers of resorption include urinary N-telopeptide (NTx), C-telopeptide (CTx), and deoxypyridinoline. Markers of bone formation include bone-specific alkaline phosphatase (BSAP) and osteocalcin. However, these tests have diurnal variability within the same individual, so there must be significant changes in levels to indicate a difference in bone turnover.

Table 44.5

T-Score Classification

T-Score	Classification
T ≥ −1.0	Normal bone density
T between −1.0 and −2.5	Osteopenia or low bone density
T ≤ −2.5	Osteoporosis

[a]The World Health Organization's T-score classification scale for the diagnosis of osteoporosis. *T*, T-score.

Data from National Osteoporosis Foundation. *Clinician's Guide to Prevention and Treatment of Osteoporosis*. Washington, DC: Author; 2017.

Fracture prevention and maintaining optimal bone function is a primary goal of osteoporosis treatment. Several pharmacologic treatments are available. These agents are either antiresorptive or anabolic. In women diagnosed with known osteoporosis, the recommendations to reduce the risk of fracture are to start treatment with risedronate, alendronate, zoledronic acid, or denosumab.[22] These treatments reduce fracture both at vertebral and non-vertebral sites. The FDA has approved bazedoxifene, a selective estrogen receptor modulator combined with conjugated estrogen, for the prevention, not treatment, of osteoporosis.[22] Men should be offered bisphosphonates as first-line therapy.[22] Bisphosphonates are a class of inorganic pyrophosphate derivatives that primarily work through inhibition of hydroxyapatite breakdown and reducing bone resorption by binding bone mineral. They improve osteoblast and osteocyte survival while promoting osteoclast apoptosis, thus slowing the bone remodeling process. With low tolerance of these medications, individuals can use medications such as teriparatide. Those medications shown to reduce vertebral fractures only, such as

raloxifene and ibandronate, are reserved for individuals who cannot tolerate any previously mentioned medications. For both groups, secondary causes should be treated.

Adequate dietary intake of calcium, vitamin D, magnesium, and other trace minerals; adherence to a regular regimen of weight-bearing exercise; and avoidance of alcohol, tobacco, and glucocorticoids help to prevent primary osteoporosis. The role of calcium intake to prevent and treat osteoporosis is controversial. It is well accepted that oral calcium intake sufficient to maintain normal calcium balance is necessary during adolescence to ensure development of peak bone mass, and that calcium-deficient diets can aggravate bone loss associated with menopause and aging. Although recommendations have been established for young women of 1000 mg of calcium daily (particularly from dietary sources) and for postmenopausal women of 1500 mg daily (with vitamin D), it has been difficult to translate these recommendations into clear-cut clinical outcomes. A significant relationship has been observed between an individual's lifetime history of calcium intake and peak bone mineral density. Diets with higher fruit and vegetable intake correlate with higher BMD. Other nutrients that appear to have a positive impact on bone health include magnesium, vitamin K_2, and docosahexaenoic acid or DHA (from purified fish oil).

Magnesium (Mg^{++}), another mineral important for skeletal development, is an essential mineral in many biochemical and physiologic functions, including activation of enzymes, involvement in ATP synthesis and protein synthesis, regulation of membrane channels, and contraction of muscle. Mg^{++} is important to bone quality because it helps control hydroxyapatite crystal growth and thereby prevents formation of brittle bones. It seems reasonable that Mg^{++} is required for normal calcium (Ca^{++}) absorption because severe Mg^{++} deficiency results in hypocalcemia.

Regular, moderate weight-bearing exercise can slow the rate of bone loss and, in some cases, reverse demineralization because the mechanical stress of exercise stimulates bone formation. It is important to reduce the risk of falls and enhance bone quality.

Therefore, an exercise program to enhance muscle strength and balance has the added benefits of reducing the risk of falls and promoting bone quality.

Osteomalacia

Osteomalacia is a metabolic disease characterized by inadequate and delayed mineralization of osteoid in mature compact and spongy bone. The remodeling cycle proceeds normally through osteoid formation, but mineral calcification and deposition do not occur. Bone volume remains unchanged, but the replaced bone consists of soft osteoid instead of rigid bone. The result is abnormal bone matrix mineralization. Rickets is similar to osteomalacia in pathogenesis, but it occurs in the growing bones of children, whereas osteomalacia occurs in adult bone. (Rickets is described in Chapter 45.)

Both osteomalacia and rickets are rare in the United States and Western Europe but are significant health problems in Great Britain, Ethiopia, Pakistan, Iran, and India. Concomitant diseases, such as HIV, chronic kidney or liver disease, certain cancers, and impaired nutrient absorption from bariatric surgery, can result in vitamin D deficiency and secondary osteomalacia. In the United States, these conditions occur in older adults, premature infants of very low birth weight, and in individuals adhering to rigid macrobiotic vegetarian diets. Breast-fed black infants who do not receive vitamin D supplementation have been shown to be at risk for developing nutritional rickets.

Many factors contribute to the development of osteomalacia, but the most important is a deficiency of vitamin D. The major risk factors in vitamin D deficiency are diets deficient in vitamin D, decreased endogenous production of vitamin D, intestinal malabsorption of vitamin D, renal tubular diseases, certain types of tumors (particularly of mesenchymal origin), and anticonvulsant therapy. Classic vitamin D deficiency is rare in the United States because of the addition of synthetic vitamin D to dairy products and bread. Still, disorders of the small bowel, kidneys, hepatobiliary

system, and pancreas are causes of vitamin D deficiency in the United States. In malabsorptive disease of the small bowel, both vitamin D and calcium absorption are decreased, causing vitamin D to be lost in feces. Liver disease interferes with the metabolism of vitamin D to its more active form, and diseases of the pancreas and biliary system cause a deficiency of bile salts, which are necessary for normal intestinal absorption of vitamin D.

Pathophysiology

Crystallization of minerals in osteoid requires adequate concentrations of calcium and phosphate. When the concentrations are too low, crystallization, and hence ossification, does not proceed normally.

Vitamin D deficiency disrupts mineralization because vitamin D normally regulates and enhances the absorption of calcium ions from the intestine. A lack of vitamin D causes the plasma calcium concentrations to fall. Low plasma calcium levels stimulate increased synthesis and secretion of PTH. Although the increase in circulating PTH level raises the plasma calcium concentration, it also stimulates increased renal clearance of phosphate. When the concentration of phosphate in the bone decreases below a critical level, mineralization cannot proceed normally.

Abnormalities occur in both spongy and compact bone. Trabeculae in spongy bone become thinner and fewer, whereas haversian systems in compact bone develop large channels and become irregular. Because osteoid continues to be produced but not mineralized, abnormal quantities of osteoid accumulate, coating the trabeculae and the linings of the haversian canals. Excessive osteoid also can accumulate in areas beneath the periosteum. The excess of osteoid leads to gross deformities of the long bones, spine, pelvis, and skull.

Clinical Manifestations

Osteomalacia causes varying degrees of diffuse musculoskeletal pain and tenderness. Bone pain is typically between joints, rather than

within them. Pain is noted particularly in the hips, and the individual may be hesitant to walk. Muscular weakness, particularly of the proximal muscles, is common and may contribute to a waddling gait. Facial deformities and bowed legs or "knock-knees" may be present. Bone fractures and vertebral collapse occur with minimal trauma. Low back pain may be an early complaint, but pain may also involve ribs, feet, other areas of the vertebral column, and other sites. Fragility fractures may occur. Uremia may be present in renal osteodystrophy.

Evaluation and Treatment

Laboratory data may include elevated BUN and creatinine levels, normal or low serum calcium levels, and a serum inorganic phosphate level that is usually higher than 5.5 mg. Alkaline phosphatase and PTH levels are usually elevated. Radiographic findings may show symmetric bowing deformities and fractures with callus formation, particularly in the lower extremities. These types of fractures, known as *pseudofractures*, appear as radiolucent bands perpendicular to the surface of involved bones. Bone biopsy is used in determining bone structure and remodeling.

Treatment of osteomalacia may vary, depending on its etiology, but these general principles are followed:

- Adjustment of serum calcium and phosphorus levels to normal
- Suppression of secondary hyperthyroidism
- Chelation of bone aluminum if needed
- Administration of calcium carbonate to reduce hyperphosphatemia
- Administration of vitamin D supplements (oral or infusion)
- Administration of bisphosphonate
- Implementation of renal dialysis, if indicated
- Considering renal transplant for renal osteodystrophy

Paget Disease

Paget disease of bone (**PDB**, or **osteitis deformans**), the second most common bone disease after osteoporosis, is a state of increased metabolic activity in bone characterized by abnormal and excessive bone resorption and formation (remodeling). Genetic manipulations involving the RANK–NF-κβ signaling pathways are significant in the development of Paget disease, resulting in increased osteoclast activity. Chronic accelerated remodeling eventually enlarges and softens the affected bones, causing bowing deformity, fracture, or neurologic problems.

Classic PDB arises as a consequence of disorderly bone resorption and formation. This process can occur in any bone but most often affects the axial skeleton, especially the vertebrae, skull, sacrum, sternum, pelvis, and femur. The disease process may occur in one or more bones without causing significant clinical manifestations.

Paget disease occurs with equal frequency in men more than 55 years of age and women older than 40 years of age. Its incidence almost doubles each decade after age 50 and affects men more than women in a proportion of 1.8:1. Because it is often asymptomatic, PDB is often unrecognized, making few epidemiologic data available. Autopsy data from England and Germany indicate that approximately 3% to 4% of the population older than 40 years of age has Paget disease. It is most prevalent in Australia, Great Britain, New Zealand, and the United States. Paget disease affects several members of the same family in 5% to 25% of individuals.

The cause of PDB is not yet fully known, but studies have implicated both genetic and environmental factors. About 10% to 30% of individuals with PDB have mutations of a specific gene, sequestosome-1. Researchers have identified variations in three genes associated with PDB: *SQSTM1*, *TNFRSF11A*, and *TNFRSF11B*. Implicated environmental factors include viruses, particularly the paramyxovirus family (that includes mumps, parainfluenza, and measles viruses), but no definitive microorganism has yet been identified. Interaction between genetic and environmental factors appears to increase osteoclast activity in PDB.

Pathophysiology

Paget disease begins with excessive resorption of spongy bone and deposition of disorganized bone. The trabeculae diminish, and bone marrow is replaced by extremely vascular fibrous tissue. The resorption phase of Paget disease is followed by the formation of abnormal new bone at an accelerated rate. The collagen fibers are disorganized, and glycoprotein levels in the matrix decrease. Mineralization may extend into the bone marrow. Bone formation is excessive around partially resorbed trabeculae, causing them to thicken and enlarge. Paget disease eventually progresses to an inactive phase, in which abnormal remodeling is minimal or absent. The net result of this accelerated remodeling process is increased bone fragility and an increased risk for bone tumors.

Clinical Manifestations

In the skull, abnormal remodeling is first evident in the frontal or occipital regions; then it encroaches on the outer and inner surfaces of the entire skull. The skull thickens and assumes an asymmetric shape (Fig. 44.17). Thickened segments of the skull may compress areas of the brain, producing altered mentation and dementia. Impingement of new bone on cranial nerves can cause sensory abnormalities, impaired motor function, deafness, atrophy of the optic nerve, and obstruction of the lacrimal duct. Headaches are commonly noted.

B

FIG. 44.17 Paget Disease of the Skull. **(A)** Active Paget disease of the skull with marked cortical thickening and an area of osteoporosis circumscripta (*arrows*). **(B)** The same individual several years later (after biphosphonate treatment) with the lytic lesion largely replaced by sclerotic bone. (From Walsh JP; *Med J Aust* 181[5]; 263, 2004).

A. Radiograph of the lateral aspect of the skull representing lytic lesion in the inner and outer surface of the skull indicated by arrow marks. B. Radiograph of the lateral aspect of the skull representing cotton appearance in the inner and outer surface of the skull.

Extensive alterations of the facial bones are rare except in the jaw, where sclerosis and thickening of the maxilla and mandible displace teeth and produce malocclusion. In long bones, resorption begins in the subchondral regions of the epiphysis and extends into the metaphysis and diaphysis. Warmth over the affected area, bone and joint pain, and bone deformity may be appreciated as the condition progresses. Occasionally, Paget disease affects both ends of a tubular bone. In the femur, Paget disease produces an exaggerated lateral curvature and in the tibia, anterior curvature is also exaggerated. Stress fractures are common in the lower extremities.

Clinical manifestations of Paget disease in the vertebral column depend on the level of involvement and are caused by compression of adjacent structures. In the cervical spine, cord compression can lead to spastic quadriplegia. Approximately 1% of persons with Paget disease develop osteogenic sarcoma which carries a poor prognosis.

Evaluation and Treatment

PDB is suspected when an elevated serum alkaline phosphatase level is recognized along with abnormal x-ray films that demonstrate characteristic radiographic changes. These changes include thickened cortices marked by tunneling, and accentuated trabeculae. Plain films obtained earlier in the course of illness may show bone lesions that appear lytic in nature. Radioisotope bone scan, x-rays, and CT are used to confirm the diagnosis. Serum plasma procollagen-1 N-peptide (PINP) is another serum marker that may provide a more accurate diagnosis. Evaluation of Paget disease is made on the basis of radiographic findings of irregular bone trabeculae with a thickened and disorganized pattern. Early detection and diagnosis of the extent of Paget disease is readily obtained by bone scanning which shows increased uptake of bone radionuclides. A typical V-shaped lesion in long bones and rounded areas of thinning bone in the skull are often seen on plain x-rays. Serum total alkaline phosphatase and urinary hydroxyproline levels are elevated.

Many individuals require no treatment if the disease is localized and does not cause symptoms. Treatment during active disease is focused on pain relief and prevention of deformity or fracture. Bisphosphonates (alendronate, risedronate, and pamidronate) and calcitonin (salmon and human) are the treatment of choice; a one-time infusion of zoledronic acid can provide long-term reduction of biochemical markers and even remission. Surgery is indicated if there are neurologic complications or severe bony deformities.

Infectious Bone Disease: Osteomyelitis

Osteomyelitis is a bone infection most often caused by bacteria; however, fungi, parasites, and viruses also can cause bone infection (Fig. 44.18). Multiple classification systems have been used to describe osteomyelitis; the simplest refers to the mode of infection. **Exogenous osteomyelitis** is an infection that enters from outside the body. Direct contamination of bones with bacteria can occur in open fractures or dislocations with an overlying skin wound. Exogenous

osteomyelitis can be caused by human bites or fist blows to the mouth. Superficial animal or human bites inoculate local soft tissue with bacteria that later spread to underlying bone. Deep bites can introduce microorganisms directly onto bone. The most common infecting organism in human bites is S. aureus. In animal bites, the most common infecting organism is Pasteurella multocida, which is part of the normal oral flora of cats and dogs. In exogenous osteomyelitis, infection spreads from soft tissues into adjacent bone. Individuals that receive large doses of corticosteroids or immunosuppressive medications are particularly susceptible to chronic exogenous osteomyelitis or recurring episodes of this disease. **Endogenous osteomyelitis** is caused by pathogens carried in the blood from sites of infection elsewhere in the body. In **hematogenous osteomyelitis**, infection spreads from bone to adjacent soft tissues. Hematogenous osteomyelitis is commonly found in infants, children, and older adults. Acute hematogenous osteomyelitis is more often seen in children and is characterized by fever, pain, and voluntary immobility of the affected limb. (Osteomyelitis in children is discussed in Chapter 45.) In adults, hematogenous osteomyelitis is more common in the spine, pelvis, and small bones. Microorganisms reach the vertebrae through arteries, veins, or lymphatic vessels. The primary origin of bacteria entering the body is from cutaneous, sinus, ear, or dental infections. However, soft tissue, genitourinary, and respiratory tract infections also are sources of bacterial contamination. The spread of infection from pelvic organs (vaginal, uterine, ovarian, bladder, and gastrointestinal infections) to the vertebrae has been shown to cause iliac or sacral osteomyelitis.

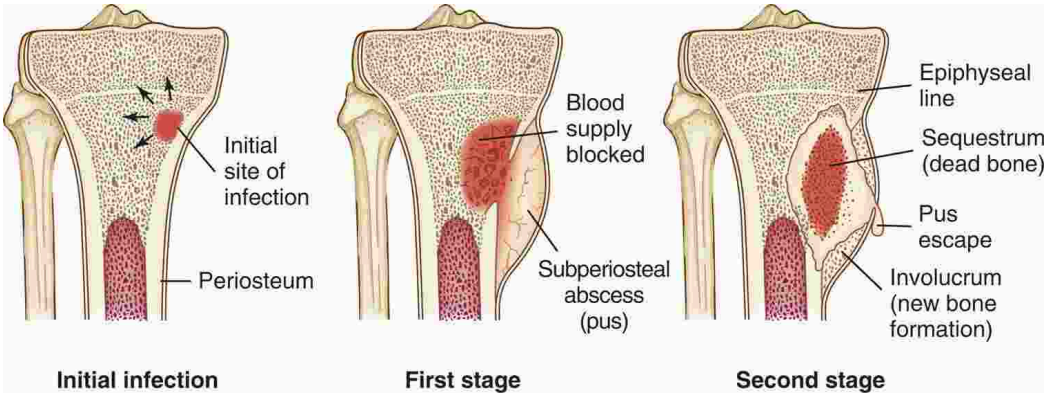

FIG. 44.18 Osteomyelitis Showing Sequestration and Involucrum.

Three illustrations of bone depict the developmental stage of osteomyelitis. The first illustration depicts the initial infection, which shows the initial site of infection in the periosteum. The second illustration depicts the first stage of infection, which shows the blockage of blood supply and subperiosteal abscess (pus). The third illustration depicts the second stage of infection, which shows the epiphyseal line, sequestrum (dead bone), pus escape, and involucrum (new bone formation).

Contiguous osteomyelitis occurs when infection spreads from one adjacent structure to another. The pathogens may enter the body through an exogenous route (open fractures, penetrating wounds, or surgical procedures). Intervertebral disk surgery and operative procedures involving implantation of large foreign objects, such as metallic plates can result in contiguous osteomyelitis. In addition, infections following total joint replacement surgeries can lead to osteomyelitis. The vulnerability of specific bone depends on the anatomy of its vascular supply. Other causes of osteomyelitis include

metabolic and vascular diseases (diabetes, peripheral vascular disease), lifestyle risks (smoking, alcohol or IV drug abuse), and advanced age.A new category of autoimmune, noninfectious osteomyelitis, known as chronic nonbacterial osteomyelitis (CNO), has recently been identified as a cause of chronic bone pain in children.

Staphylococcus aureus (including methicillin-resistant *Staphylococcus aureus* [MRSA]) is the primary microorganism responsible for hematogenous osteomyelitis. Other microorganisms include group B streptococcus, *Haemophilus influenzae, Salmonella*, and gram-negative bacteria. Group B streptococcus and *H. influenzae* tend to infect young children; *Salmonella* infection is associated with sickle cell anemia; and gram-negative infections are most common in older adults and individuals with impaired immunity. Mycobacterial, viral, and fungal infections occur in immunocompromised individuals.

Pathophysiology

Regardless of the source of the pathogen, the pathologic features of bone infection are similar to those in any other body tissue (see Chapter 7). First, the invading pathogen provokes an intense inflammatory response. Inflammation in bone is characterized by vascular engorgement, edema, leukocyte activity, small blood vessel thrombosis, and abscess formation. When *S. aureus* is the invading pathogen, in addition to producing toxins that destroy neutrophils, it forms colonies of microorganisms, called *biofilms*. They adhere to surfaces (such as surgical implants) and increase antibiotic resistance. Biofilms alter the normal balance between osteoblast and osteoclast activity by reducing the duration of osteoblast activity, enhancing osteoclast activity, and promoting inflammation (also see Chapter 10).

Once inflammation is initiated, the small terminal vessels thrombose and exudate seals the bone's canaliculi. Inflammatory exudate extends into the metaphysis and the marrow cavity and through small metaphyseal openings into the cortex. In children,

exudate that reaches the outer surface of the cortex forms abscesses that lift the periosteum of underlying bone. Lifting of the periosteum disrupts blood vessels that enter bone through the periosteum, which deprives underlying bone of its blood supply. This leads to necrosis and death of the area of bone infected, producing **sequestrum**, an area of devitalized bone (Fig. 44.19). Lifting of the periosteum also stimulates an intense osteoblastic response. Osteoblasts laying down new bone can partially or completely surround the infected bone. This layer of new bone surrounding the infected bone is called an **involucrum**. Openings in the involucrum allow the exudate to escape into surrounding soft tissue and ultimately through the skin by way of sinus tracts. Involucrum in adults is rare because the periosteum is firmly attached to the cortex and resists displacement. Instead, infection disrupts and weakens the cortex, which predisposes the bone to pathologic fracture.

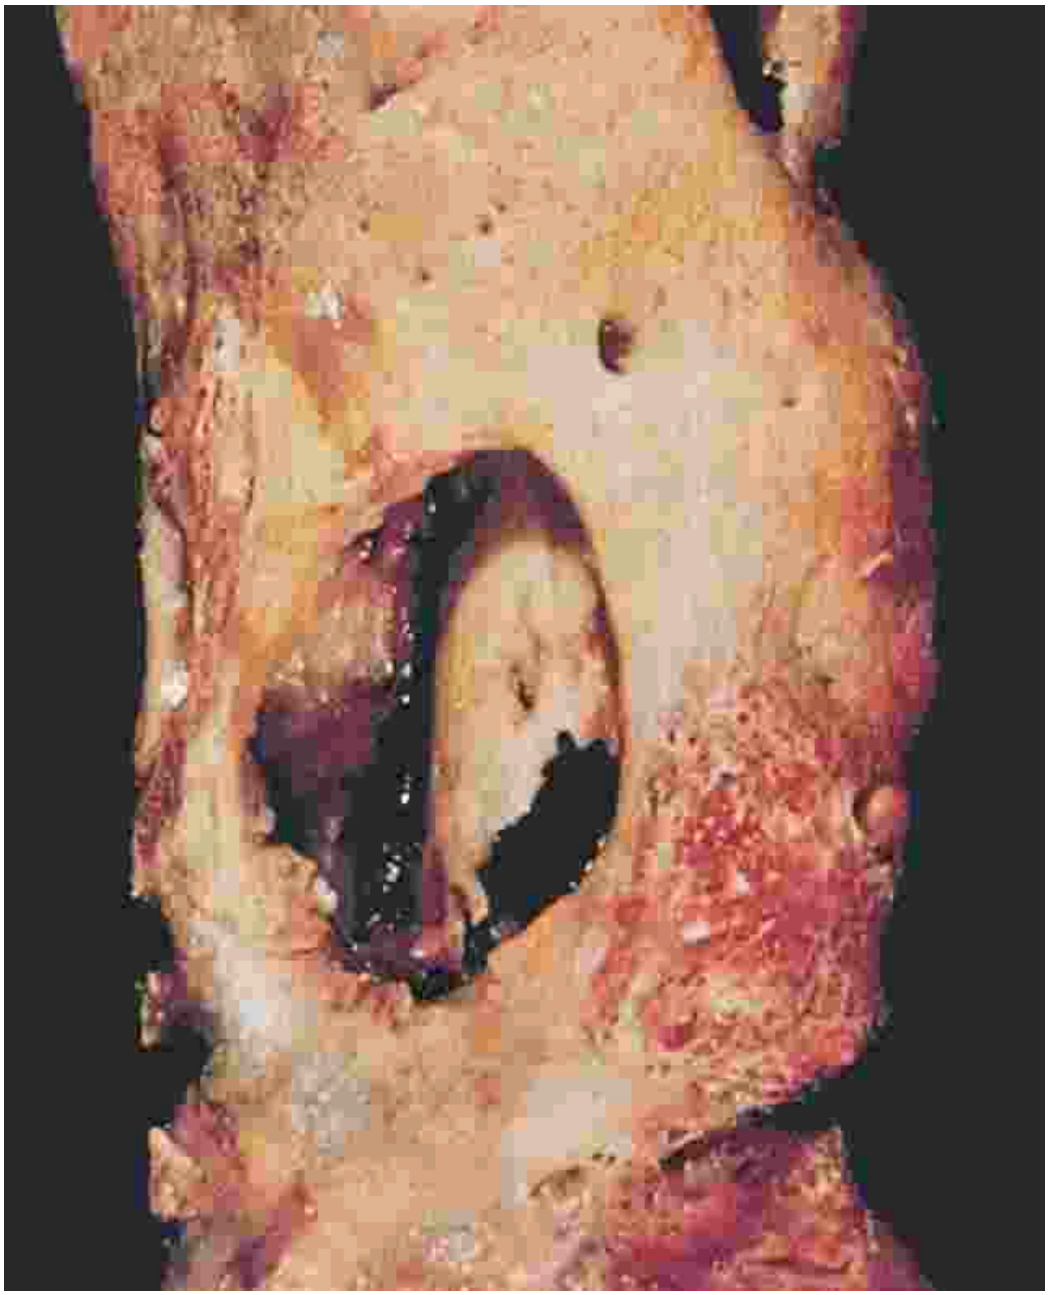

FIG. 44.19 Resected Femur in a Person With Draining Osteomyelitis.
The drainage tract in the subperiosteal shell of viable new bone (involucrum) reveals the inner native necrotic cortex (sequestrum). (From Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.)

Clinical Manifestations

Clinical manifestations of osteomyelitis vary with the age of the individual, the site of involvement, the initiating event, the infecting organism, and whether the infection is acute, subacute, or chronic. Osteomyelitis is generally considered acute if diagnosed within 2 weeks after symptom onset and is associated with an abrupt onset of inflammation (see Fig. 44.19). Subacute osteomyelitis is disease that has been present from one to several months, while chronic osteomyelitis is that which has been present for many months to even years.

If an acute infection is not eliminated, the disease may become subacute or chronic. In subacute osteomyelitis, signs and symptoms are usually vague. In the chronic stage, infection is silent between exacerbations. The microorganisms persist in small abscesses or fragments of necrotic bone and produce occasional exacerbations of acute osteomyelitis. The progression from acute to subacute osteomyelitis may be the result of inadequate or inappropriate therapy, or the development of drug-resistant microorganisms.

In the adult, hematogenous osteomyelitis has an insidious onset. The symptoms are usually vague and include fever, malaise, anorexia, weight loss, and pain in and around the infected areas. Edema may or may not be evident. Recent infection (urinary, respiratory, cutaneous) or instrumentation (catheterization, cystoscopy, myelography, diskography) usually precedes onset of symptoms.

Back pain is the primary symptom in vertebral osteomyelitis. Pain may be intermittent or constant, aggravated by motion, and throbbing at rest. It may radiate in a radicular distribution and is commonly accompanied by spinal tenderness and rigidity. Hip contracture can occur in the presence of soft tissue inflammation as a result of irritation of the psoas muscle.

Signs and symptoms of sacroiliac osteomyelitis are generally severe and include local pain, tenderness, and a limp. The pain may radiate to the buttock or the abdomen.

Single or multiple abscesses (Brodie abscesses) characterize subacute or chronic osteomyelitis. Brodie abscesses are painless, circumscribed lesions 1 to 4 cm in diameter, usually in the ends of long bones and surrounded by dense ossified bone matrix. The abscesses are thought to develop when the infectious microorganism has become less virulent or the individual's immune system is resisting the infection somewhat successfully.

In exogenous osteomyelitis, signs and symptoms of soft tissue infection predominate. Inflammatory exudate in the soft tissues disrupts muscles and supporting structures and forms abscesses. Low-grade fever, lymphadenopathy, local pain, and swelling usually occur within days of contamination by a puncture wound. Osteomyelitis in the hand causes exquisite tenderness over the course of tendon sheaths. The fingers are usually in a semiflexed position, and extension usually causes severe pain. Palmar swelling or symmetrical swelling of the fingers may be present.

Evaluation and Treatment

Laboratory data show an elevated white cell count and an elevated level of noncardiac C-reactive protein (CRP). Radiographic studies include radionuclide bone scanning, CT, functional imaging using a combination of radionuclide scanning (using fluorodeoxyglucose [FDG]) and single photon emission computed tomography (SPECT), positron emission tomography (PET), and MRI. MRI scanning with gadolinium contrast shows both bone and soft tissue, providing more accurate assessment of infection. MRI also shows early changes of bone marrow edema. FDG-SPECT imaging is highly sensitive for evaluating osteomyelitis of the extremities.

Treatment of osteomyelitis includes bone biopsy to identify the causative organism, use of antimicrobial agents, and surgical debridement of infected bone. Initial antibiotic therapy should be intravenous. Chronic conditions may require surgical removal of the inflammatory exudate or any involved implanted hardware followed by continuous wound irrigation with antibiotic solutions in addition to systemic treatment with antibiotics. **Hyperbaric oxygen**

therapy of 100% oxygen, given at 2 atmospheres of pressure for 2 hours' duration per day for 30 treatments, is also beneficial for chronic refractory osteomyelitis. This therapy has been shown to stimulate healing by suppressing proinflammatory cytokines and prostaglandins.

Bone Tumors

Primary bone cancer is rare and metastatic disease commonly affects bone. Many different types of tumors involve the skeleton. Based on the tissue of origin, **bone tumors** are classified as osteogenic, chondrogenic, collagenic, or myelogenic. Each of the four types arises from one of the four stem cells that are ultimately derived from the primitive mesoderm (Fig. 44.20) In addition, bone tumors may be classified as being of histiocytic, notochordal, lipogenic, and neurogenic origins (Box 44.5). Chondrogenic tumors contain chondroblasts and produce an intercellular substance similar to chondroid (cartilage). Collagenic tumors contain fibrous tissue cells and produce an intercellular substance similar to the type of collagen found in fibrous connective tissue.

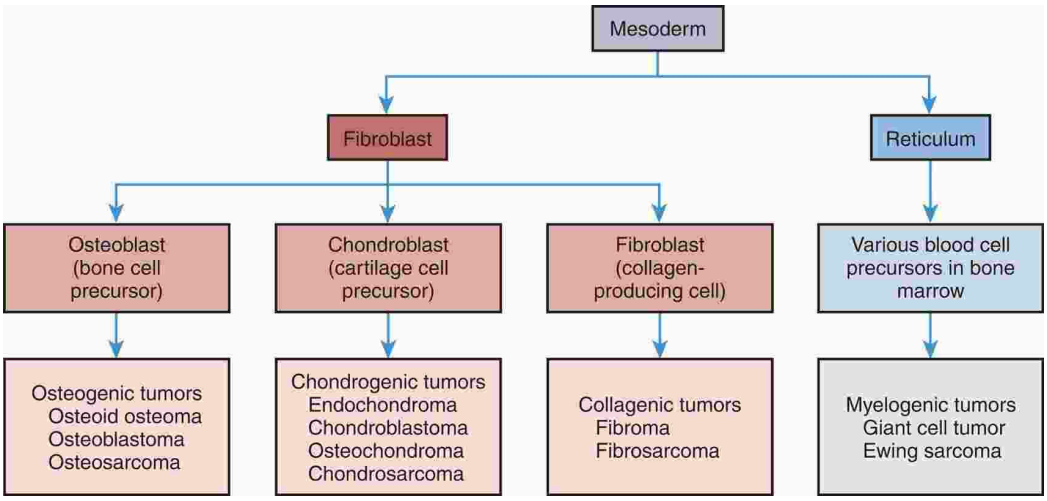

FIG. 44.20 Derivation of Bone Tumors.

A chart summarizes the derivation of the bone tumors. The chart begins as follows. • Mesoderm is divided into fibroblast and reticulum. • Fibroblast derives into osteoblast, the bone cell precursor; chondroblast, cartilage cell precursor; fibroblast, collagen-producing cell. • The reticulum derives various blood cell precursors in the bone marrow which leads to myelogenic tumors, giant cell tumors, and Ewing sarcoma. • Osteoblast derives osteogenic tumors, osteoid osteoma, osteoblastoma, osteosarcoma. Chondroblast derives chondrogenic tumors, enchondroma, chondroblastoma, osteochondroma, and chondrosarcoma. • Fibroblast derives collagenic tumors, fibroma, and fibrosarcoma.

Box 44.5

World Health Organization Classification of Bone Tumors

Cartilage Tumors

Chondrosarcoma (M)
Chondroma (B)
Osteochondroma (B; but may become malignant)
Chondroblastoma (B)

Osteogenic Tumors

Osteoblastoma (B)
Osteoid osteoma (B)
Osteosarcoma (M)

Fibrogenic Tumors (Often Produce Collagen; Do Not Have a Mineralizing Matrix)

Fibrosarcoma (M)

Fibrohistiocytic Tumors (Comprised of Fibroblasts)

Benign fibrous histiocytoma (B)
Malignant fibrous histiocytoma (M)

Ewing Sarcoma

Ewing sarcoma (M)

Hematopoietic Tumors

Plasma cell myeloma (M)
Malignant lymphoma (M)

Giant Cell Tumor

Giant cell tumor (B, but can grow aggressively)
Malignancy in giant cell tumor (M; very rare tumor)

Smooth Muscle Tumors

Leiomyoma (B)
Leiomyosarcoma (M)

Miscellaneous Tumors

Adamantinoma (M; almost exclusively found in tibia)
Metastatic malignancy (M; most common skeletal malignancy)

Miscellaneous Lesions

Aneurysmal bone cyst (B)
Simple cyst (B)
Fibrous dysplasia (B; rarely can become malignant)
Osteofibrous dysplasia (B)
Langerhans cell histiocytosis (B, but can aggressively grow)
Chest wall hamartoma (B; is excessive growth of mesenchymal tissue [mostly cartilage])

Joint Lesions

Synovial chondromatosis (B; rarely becomes M)
B, Benign lesion; *M*, malignant lesion.

Data from Dorfman HD, et al. WHO classification of tumours of the bone: introduction. In: Christopher EM, et al., eds. *World Health Organization classification of tumors, International Agency for Research on Cancer (IARC) Pathology and Genetics of Tumours of Soft Tissue and Bone*. Lyon, France: IARC Press; 2002:226.

Tumors also are classified as benign or malignant. The criteria used to identify tumor cells as malignant are (1) an increased nuclear/cytoplasmic ratio, (2) an irregular nuclear border, (3) an excess of chromatin, (4) a prominent nucleolus, and (5) an increase in the number of cells undergoing mitosis. However, many young, rapidly growing, normal cells and cells subjected to inflammation and change in their blood supply also exhibit many of these same characteristics. (Tumor biology is described in Chapter 12.)

Epidemiology

The incidence of bone tumors varies with age. Osteosarcoma is the most common primary malignant bone tumor in children and young adults. Adolescents have the highest incidence of bone tumors, and adults between 30 and 35 years of age have the lowest incidence. After age 35, the incidence slowly increases until, at age 60, it equals the incidence in adolescents, primarily related to metastatic tumors.

Patterns of Bone Destruction

The general pathologic features of bone tumors include bone destruction, erosion or expansion of the cortex, and periosteal response to changes in underlying bone. The least amount of pathologic damage occurs with benign bone tumors that push against neighboring tissue. Because they usually have a symmetrical, controlled growth pattern, benign bone tumors tend to compress and displace neighboring normal bone tissue, which weakens the bone's structure until it is incapable of withstanding the stress of ordinary use, leading to pathologic fracture. Other tumors invade and destroy adjacent normal bone tissue by producing substances that promote resorption by increasing osteoclast activity or by interfering with a bone's blood supply. Three patterns of bone destruction by bone tumors have been identified: (1) the geographic pattern, (2) the moth-eaten pattern, and (3) the permeative pattern (Table 44.6).

Table 44.6

Patterns of Bone Destruction by Bone Tumors

Type of Destruction	Pattern Seen
Geographic	Well-defined margins separated from surrounding normal bone; well-defined lytic area in affected bone
Moth-eaten	Less-defined margin not easily separated from normal bone; areas of partially destroyed bone adjacent to completely lytic areas
Permeative	Poorly demarcated margins; abnormal lytic bone merges imperceptibly with surrounding normal bone

Tumors that erode the cortex of the bone usually stimulate new bone formation at the interface between the surface of the bone and the periosteum. Slow erosion of the cortex usually stimulates a uniform periosteal response. Additional layers of bone are added to the exterior surface of the bone to buttress the cortex. Eventually the additional layers expand the bone's contour. Aggressive penetration of the cortex elevates the periosteum and stimulates erratic patterns of new bone formation. This may result in concentric layers of new bone, a sunburst pattern in which delicate rays of new bone radiate toward the periosteum from a single focus on the underlying surface, and rays of new bone that grow perpendicularly, creating a brush or bristle pattern.

Diagnosis

Malignant bone tumors account for less than 0.2% of all cancers. A tumor must be identified early to allow survival of the individual and the preservation of the affected limb. However, individuals often have vague symptoms that may be attributed to minor trauma, degenerative changes, or inflammatory conditions. In addition, other conditions may obscure the diagnosis.

Thorough diagnostic studies are needed to determine the exact type and extent of bone tumor present, which also helps determine the optimal treatment regimen. Staging of any bone tumor is critical to determine future treatment and results. The American Joint Committee on Cancer (AJCC) staging system (also known as the *Enneking* or *TNM staging system*) is the most commonly used arrangement (Table 44.7). This system classifies tumors according to grade (G), tumor site (T), and metastasis (M). Benign tumors are given a numeric value of zero for their grade, whereas malignant tumors are low grade (G_1) or high grade (G_2).

Table 44.7

The Enneking Surgical Staging System for Malignant Bone Tumors

Stage	Grade	Site (T)	Metastasis (M)
IA	Low (G_1)	Intracompartmental (T_1)	None (M_0)
IB	Low (G_1)	Extracompartmental (T_2)	None (M_0)
IIA	High (G_2)	Intracompartmental (T_1)	None (M_0)
IIB	High (G_2)	Extracompartmental (T_2)	None (M_0)
IIIA	Low (G_1)	Intracompartmental or extracompartmental (T_1 or T_2)	Regional or distant (M_1)
IIIB	High (G_2)	Intracompartmental or extracompartmental (T_1 or T_2)	Regional or distant (M_1)

Stage	Grade	Site (T)	Metastasis (M)
IA	Low (G_1)	Intracompartmental (T_1)	None (M_0)
IB	Low (G_1)	Extracompartmental (T_2)	None (M_0)
IIA	High (G_2)	Intracompartmental (T_1)	None (M_0)
IIB	High (G_2)	Extracompartmental (T_2)	None (M_0)
IIIA	Low (G_1)	Intracompartmental or extracompartmental (T_1 or T_2)	Regional or distant (M_1)
IIIB	High (G_2)	Intracompartmental or extracompartmental (T_1 or T_2)	Regional or distant (M_1)

Serum alkaline phosphatase levels are elevated in bone lytic tumors, and they are significantly elevated in osteosarcoma and Ewing sarcoma. Radiologic studies include plain radiologic film, technetium-99 bone scan, CT scan, and MRI, which has become the

examination of choice for the local staging of bone tumors, especially the staging of peripheral osteosarcomas (see Table 44.7). MRI is also used to monitor the response of osteosarcomas to radiation or chemotherapy and to detect recurrent disease. A CT scan can evaluate involvement of osteosarcoma in flat bones when the tumor is not well-defined on a plain film, can assist in differentiating the tumor, and can locate pulmonary metastases. Radionucleotide bone scans show an increased uptake at the tumor site. Before any surgical procedure, placement of bone biopsy is critical.

Additional diagnostic studies performed for specific bone tumors include a complete blood count and erythrocyte sedimentation rate (to rule out infection, myeloma, or Ewing sarcoma) and measurement of serum levels of calcium and phosphorus to detect hypercalcemia. Serum glucose levels may be elevated in chondrosarcoma. Acid phosphatase level may be moderately elevated in bone metastases, multiple myeloma, and advanced Paget disease. Serum protein electrophoresis and immunoelectrophoresis are done to rule out multiple myeloma. Fine-needle biopsy is done, usually at the time of surgery, to determine the exact tumor type.

Types

A large number of lesions are classified as bone tumors. Bone tumors are typically classified according to their origin—osteogenic, chondrogenic, collagenic, and myelogenic tumors.

Osteogenic tumors: Osteosarcoma

Osteogenic (bone-forming) tumors are characterized by the formation of bone or osteoid tissue with a sarcomatous tissue. The tissue can have the appearance of compact or spongy bone. The most common malignant bone-forming tumor is **osteosarcoma** (Fig. 44.21), which is typically found in the bone marrow. Osteosarcoma occurs mostly in adolescents and young adults; 60% of osteosarcomas occur in those younger than 20 years, and it has a slightly higher incidence in males. A secondary peak incidence for osteosarcoma occurs in the 60 and older age group, primarily in

individuals with a history of radiation therapy several years previously for pelvic or other malignancies.

FIG. 44.21 Osteosarcoma.
(A) Common locations of Ewing sarcoma and osteosarcoma. *blue*, Osteosarcoma; *red*, Ewing sarcoma. **(B)** Comparison of plain radiograph, MRI, and nuclear bone scan appearances of osteosarcoma of the distal femur. Note destruction of the bone cortex and soft tissue component. (A, Adapted from Bontrager KL, Lampignanno JP, eds. *Textbook of radiographic positioning and related anatomy*. St. Louis: Elsevier; 2013. B, From HaDuong JH, Martin AA, Skapek SX, et al. Sarcomas. *Pediatric Clinics of North America*, 2015;62:179–200.)

A. An illustration of a human skeleton depicts the common locations of Ewing sarcoma and osteosarcoma. The sites are indicated by the circle as follows. Ewing sarcoma: Left pelvic joint and left knee joint. Osteosarcoma: The right shoulder joint and right knee joint. B. Plain radiograph, M R I, and bone scan of distal femur depicts the osteosarcoma.

Pathophysiology. Osteosarcoma is aggressive and has a moth-eaten pattern of bone destruction. The borders of the tumor are indistinct and merge into adjacent normal bone. Osteosarcomas

contain osteoid and callus produced by anaplastic stromal cells, which are atypical, abnormal cells not seen in normal developing bone; they are neither normal nor embryonal. Many tumors are heterogeneous; for example, the osteosarcoma also may contain chondroid (cartilage) (e.g., chondroblastic sarcoma) and fibrinoid tissue (e.g., fibroblastic sarcoma) that may form the bulk of the tumor. The osteoid is deposited as thick masses or "streamers" which infiltrate the normal compact bone, destroy it, and replace it with masses of osteoid. Bone tissue produced by osteosarcomas never matures to compact bone.

Ninety percent of osteosarcomas are located in the metaphyses of long bones, especially the distal femoral metaphysis, with 50% around the knee area. The tumor typically impregnates the cortex, lifts the periosteum, and forms a soft tissue mass that is not covered by a smooth shell of new bone. Lifting of the periosteum stimulates bizarre patterns of new bone formation, called a *periosteal reaction*. Distinct osteosarcomas occur on the surface of long bones, called *parosteal, periosteal,* and *high-grade surface osteosarcomas*; dedifferentiated parosteal and central osteosarcomas also occur.

Clinical Manifestations. The most common initial symptoms are pain and swelling. The pain is initially slight and intermittent, but increases in severity and duration. Pain is usually worse at night and gradually requires medication. Often, a coincidental history of trauma is noted. Occasionally, the individual may present with a pathologic fracture.

Evaluation and Treatment. Systemic chemotherapy and surgery are the treatments of choice, with the location of the tumor and its size, grade, and pattern of metastasis dictating the type and extent of surgery. Preoperative chemotherapy has greatly increased the number of individuals qualifying for limb salvage surgery. Other agents under investigation include monoclonal antibodies, hormone antagonists, gene therapy, and other biologic agents.

Chondrogenic tumors: Chondrosarcoma

Chondrogenic (cartilage-forming) tumors produce cartilage or **chondroid**, a primitive cartilage or cartilage-like substance. The most common chondrogenic tumor is chondrosarcoma.

Chondrosarcoma is the second most common primary malignant bone tumor (Fig. 44.22). It is a tumor found in middle-aged and older adults, with peak incidence in the sixth decade of life. The tumor is found more commonly in men than in women. Chondrosarcomas that develop from a preexisting benign bone lesion (e.g., an enchondroma) are known as secondary chondrosarcomas. Individuals with certain conditions, such as multiple osteochondromas, may be at greater risk for developing secondary chondrosarcoma. Secondary chondrosarcomas are rare, occurring most often in young adults between 20 and 30 years of age, and are more common in men.

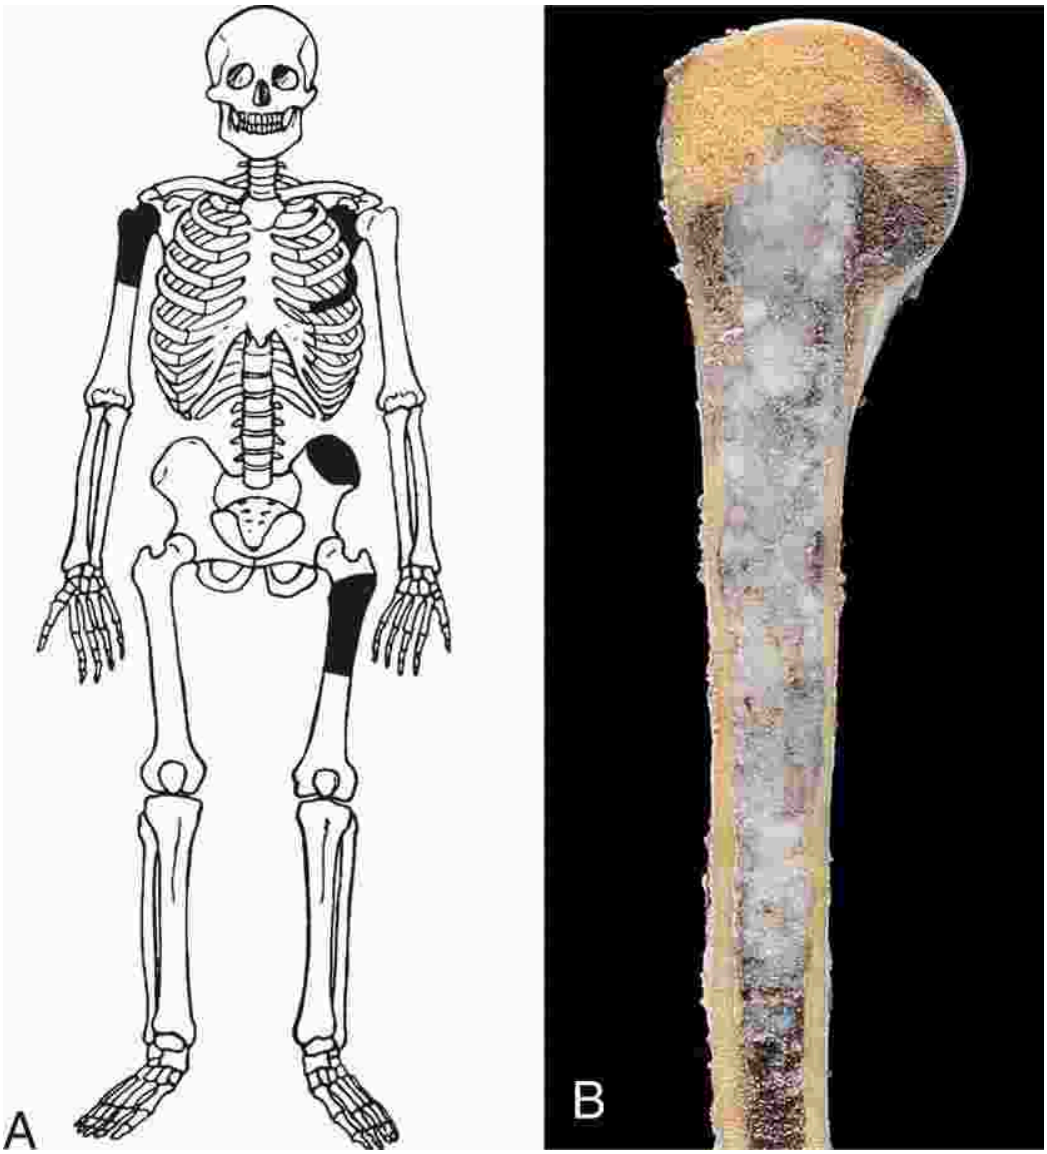

FIG. 44.22 Chondrosarcoma.
(A) Common locations of chondrosarcoma. **(B)** Chondrosarcoma of humerus. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

A. An illustration depicts the human skeleton with the shaded portions of the left arm, right rib, right pelvic, and right thigh. B. A close shot of a

longitudinal section of a long bone with chondrosarcoma of the humerus.

Pathophysiology. A chondrosarcoma is a large, ill-defined malignant tumor that infiltrates trabeculae in spongy bone. It produces cartilage-forming cells, without ossification, that occur normally in bone formation. It appears most often in the metaphysis or diaphysis of long bones, especially the femur or proximal humerus, and in the bones of the pelvis (see Fig. 44.22). Chondrosarcomas typically implant in surrounding tissue *(seeding)*.

Clinical Manifestations. Symptoms associated with a chondrosarcoma have an insidious onset. Local swelling accompanied by a dull, intermittent pain is the usual presenting symptom. The pain gradually intensifies and becomes constant, awakening the person at night.

Evaluation and Treatment. Diagnostic studies include radiographs, which must be reviewed carefully for an accurate diagnosis. Biopsy is done at the time of surgery. Performing a bone biopsy prior to surgery can result in seeding of tumor cells and metastasis. Additionally, sufficient tumor material must be obtained to facilitate an accurate diagnosis.

Surgical excision is generally regarded as the treatment of choice because chemotherapy and radiation seem to have little effect. Many surgically treated individuals demonstrate recurrences, thus amputation becomes one treatment of choice.

Collagenic tumors: Fibrosarcoma

Collagenic (collagen-forming) tumors produce fibrous connective tissue. Fibrosarcoma is the most common collagenic tumor and can affect bone or soft tissue.

Pathophysiology. Fibrosarcomas come from fibroblasts that originate from MSCs; they represent 4% of primary malignant bone tumors. The incidence has a broad age range, but this tumor type is most common in adults between 30 and 50 years of age. The

incidence is slightly greater in females. Fibrosarcoma also may be a secondary complication of radiation therapy, Paget disease, and long-standing osteomyelitis; secondary fibrosarcoma tends to be more aggressive with a poorer outcome.

Fibrosarcoma is a solitary tumor that most often affects the metaphyseal region of the femur or tibia. The tumor is composed of a firm, fibrous mass of tissue that contains collagen, malignant fibroblasts, and occasional osteoclast-like giant cells.

The tumor begins in the marrow cavity of the bone and infiltrates the trabeculae. It demonstrates a permeative growth pattern, destroys the cortex, and extends into the soft tissue. Metastasis to the lung is common.

Clinical Manifestations. Symptoms associated with the tumor have an insidious onset, which delays diagnosis. Pain and swelling are the usual presenting symptoms and usually indicate that the tumor has infiltrated the cortex. Local tenderness, a palpable mass, and limitation of motion also may be present. A pathologic fracture in the affected bone is often the reason for seeking medical help. Diagnostic studies include radiographs and MRI.

Evaluation and Treatment. Radical surgery and amputation are the treatments of choice for fibrosarcoma. Radiation therapy is generally considered ineffective treatment for this tumor.

Myelogenic tumors

Myelogenic tumors originate from various bone marrow cells. Two types of myelogenic tumors are giant cell tumor (GCT) and myeloma. Myeloma is discussed in Chapter 29.

Giant cell tumor

Giant cell tumor (GCT) is the sixth most common primary bone tumor, accounting for 4% to 5% of bone tumors. GCTs have a wide age distribution; however, they are rare in persons younger than 10 years or older than 70 years. Most GCTs are found in persons between 20 and 40 years of age. Unlike most other bone tumors, GCTs affect females more often than males.

Pathophysiology. The GCTs are generally benign, solitary, circumscribed tumors that cause extensive bone resorption because of their osteoclastic origin. There is a high rate of recurrence, but metastasis is rare. A GCT is typically located in the epiphyseal regions of the femur, tibia, radius, or humerus (Fig. 44.23). The tumor has a slow, relentless growth rate, and it is usually contained within the original contour of the affected bone. Aggressive bone resorption causes pathologic fractures. However, it may extend into the articular cartilage. When the tumor extends, it is usually covered by periosteum or periosteal bone growth; it may extend into surrounding soft tissue.

(A) Common skeletal locations. **(B)** Gross picture of cell tumor of bone (epimetaphysis). (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Clinical Manifestations. The most common symptoms associated with GCT are pain, local swelling, and limitation of movement.Evaluation and Treatment. Diagnostic studies include radiographs, CT, and MRI. Cryosurgery and resection of the tumor with the use of adjuvant polymethylmethacrylate (PMMA) for bone grafts reduce recurrence and are more successful treatments than curettage and radiation. Amputation may be necessary but is not common.

Disorders of Joints

The American College of Rheumatology (ACR) recognizes a growing body of evidence identifying and classifying joint diseases, called **arthropathies**. The two major categories of these disorders include noninflammatory joint disease and inflammatory joint disease. Current detection methods, through diagnostic imaging and serum and synovial fluid analysis, allow for a clearer delineation between the inflammatory and noninflammatory pathways once poorly understood.

Osteoarthritis

Osteoarthritis (OA) is the most common form of age-related joint disease involving the synovial joints. OA is characterized by pathologic changes in cartilage, bone, synovium, ligament, muscle, and periarticular fat (Fig. 44.24).[37] These changes lead to joint dysfunction, pain, stiffness, functional limitation, and loss of activities, such as walking for exercise.[37] Though the term OA implies an inflammatory disease, it is mostly considered a degenerative disease of cartilage.[38] Advancing disease shows first

molecular derangement or abnormal joint tissue metabolism, followed by anatomic and/or physiologic derangements. The physiologic changes include cartilage degradation, bone remodeling, **osteophyte** formation (bone spurs), joint inflammation, and loss of normal joint function, and progresses to illness.[37,39]

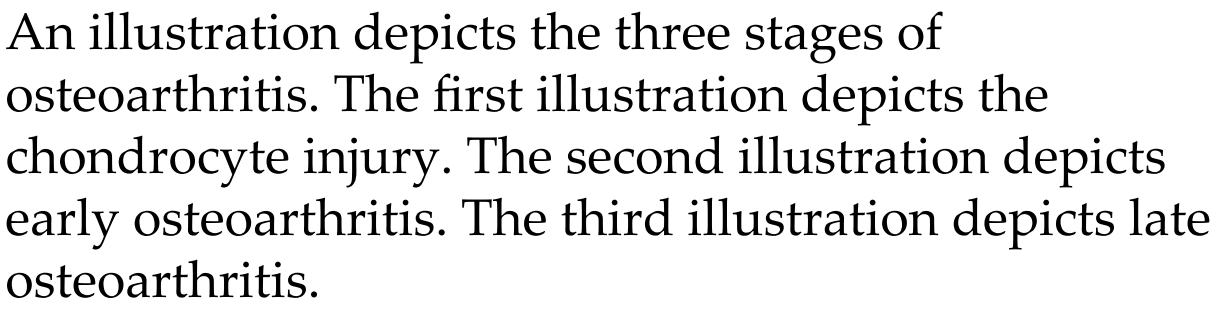
FIG. 44.24 Osteoarthritis.
(1) Osteoarthritis (OA) is initiated by biomechanical cartilage damage, it is accelerated in genetically predisposed individuals and results in changes to the extracellular matrix, *(2)* chondrocytes may proliferate to try and repair the damaged matrix, degradation exceeds repair in early OA, *(3)* Late OA has loss of both matrix and chondrocytes with subchondral bone loss (From Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.)



OA is commonly found in the knees, hips, hands, and spine.[37] Globally, OA causes moderate to severe disability in 43 million people, and in the United States it is estimated that 80% of those over 65 years old have radiographic evidence of OA. 60% of this subset has symptoms.[40] Risk factors include age (33% older than 75 years have symptomatic and radiographic knee OA), female, obesity, genetics, and previous joint injury. The level of disease severity detected radiographically does not correlate well with pain and disability.[38] Those with OA have more comorbidities and are more sedentary.[37] OA is associated with comorbidities linked to lack of physical activity, medication toxicity, and the effects of inflammatory cytokines.[37,41]

OA is a heterogenous disease process and is classified into two categories: primary and secondary. *Primary OA* or *idiopathic* is the

most common and is diagnosed in the absence of a predisposing trauma or disease and is associated with risk factors listed above. *Secondary OA* occurs with preexisting joint abnormality from conditions such as congenital joint disorders, inflammatory arthritis, avascular necrosis, infectious arthritis, Paget disease, osteopetrosis, osteochondritis dissecans, metabolic disorders (e.g., hemochromatosis, Wilson disease), hemoglobinopathy, Ehlers–Danlos syndrome, or Marfan syndrome.[42,43]

Pathophysiology

The primary defect in OA is degeneration and eventual loss and disordered repair of articular cartilage. The chondrocytes of the articular cartilage become damaged early in the disease process because of biomechanical stress, as well as genetic and biochemical factors (Fig. 44.25A and C). These changes lead to increased chondrocyte injury, altered chondrocyte signaling, and alterations of the extracellular matrix (ECM).[44,45] The progressive destruction of ECM is considered a hallmark.[46] The ECM is synthesized by chondrocytes, which have a key role in maintaining an equilibrium between anabolism and catabolism.[46] Although chondrocytes proliferate and continuously make proteoglycans, OA develops when degradation exceeds synthesis.[38] A phenotypic alteration to hypertrophic chondrocyte occurs, causing chondrocytes to proliferate and form clusters.[40] When collagen matrix is damaged, chondrocytes undergo apoptosis.[40] The ECM is essential for the biomechanical properties of cartilage because it provides critical elastic support to distribute pressure and shear stress with joint movement.[46] Chondrocytes secrete matrix metalloproteases (MMPs) that degrade type II collagen. Other involved factors include cytokines, diffusible factors from chondrocytes and synovial cells, especially TGF-β (promotes the production of MMPs), TNF, prostaglandins, and nitric oxide. Altered mineralized collagen causes subchondral bone thickening, and bone cysts infrequently occur.[40] Soft tissues are affected, such as ligaments, joint capsule, and

menisci.[40] Chronic low-level inflammation can contribute to disease progression.[38] Overall, advanced disease involves chondrocyte loss and severe matrix degradation.[38]

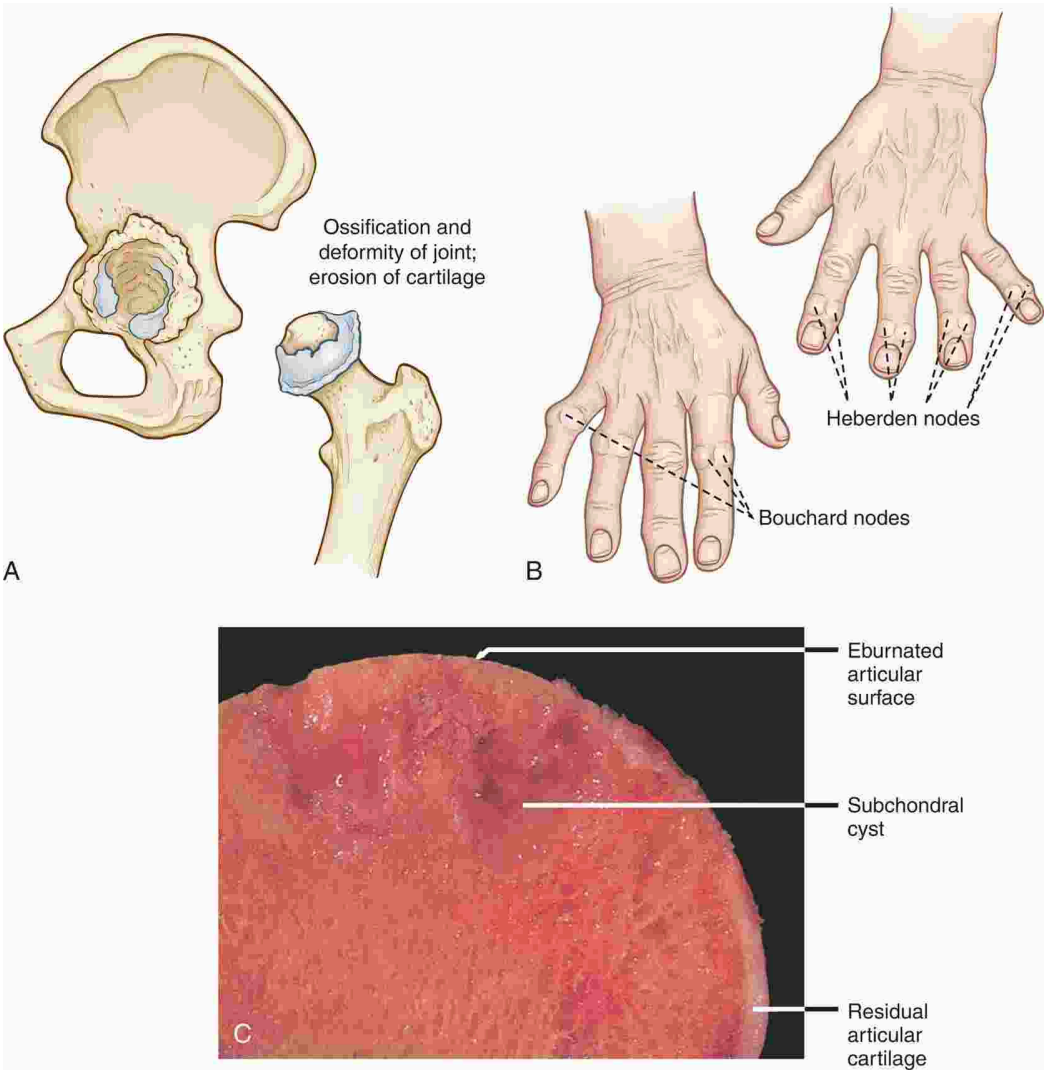


FIG. 44.25 Osteoarthritis (OA).

Heberden nodes and the right hand with Bouchard nodes. C. A close shot of a section of subchondral bone with labels indicating the location of nodes in the Eburnated articular surface, subchondral cyst, and residual articular cartilage.

Clinical Manifestations

Individuals with primary OA are usually asymptomatic until their 50 s.[38] If a younger person has manifestations of OA, it triggers a search for underlying causes. The triad of symptoms include joint pain (deep, achy) that worsens with use, morning stiffness, and motor restriction.[40] Other manifestations include muscle weakness, *crepitus* (grating sound or sensation by friction between bone and cartilage), and balance issues (Box 44.6).[40]

Box 44.6

Signs and Symptoms of Osteoarthritis

Hand

Pain on range of motion
Hypertrophic changes at distal and proximal interphalangeal joints (Heberden nodes and Bouchard nodes)
Tenderness over carpometacarpal joint of thumb

Shoulder

Pain on range of motion
Limitation of range of motion, especially external rotation
Crepitus on range of motion

Knee

Pain on range of motion
Joint effusion
Crepitus on range of motion
Sometimes presence of popliteal cyst (Baker cyst)
Lateral instability
Valgus or varus deformity

Hip

Pain on range of motion
Pain in buttock
Limitation of range of motion, especially internal rotation

Foot

Pain on ambulation, especially at first metatarsophalangeal joint
Limited range of motion of first metatarsophalangeal joint, hallux rigidus
Hallux valgus deformity

Spine

Pain on range of motion
Limitation of range of motion
Lower extremity sensory loss, reflex loss, motor weakness caused by nerve root impingement
Pseudoclaudication caused by spinal stenosis

Data from Sinusas K. Osteoarthritis: diagnosis and treatment. *American Family Physician*, 2012;85(1):49–56.

Pain is related to activity and resolves with rest, but with disease progression, pain is more constant and affects activities of daily living and eventually causes severe restrictions in function.[40] Individuals will use the following descriptors: bony swelling, joint deformity, instability, and "giving way" or "buckling," a sign of muscle weakness.[40] Joint deformities can develop with time. The types of joint deformities in the fingers are termed **Bouchard nodes and Heberden nodes**, which are typical features of OA (see Fig. 44.25B). Bouchard nodes are prominent **osteophytes** (mushroom shaped bony outgrowths) at the proximal interphalangeal (PIP) joints, whereas **Heberden nodes** are prominent at the distal interphalangeal joints.

Inflammation of the joint capsule leads to remodeling and a fibrous contraction of the capsule, causing the joint to become stiff and painful with movement (Fig. 44.26).

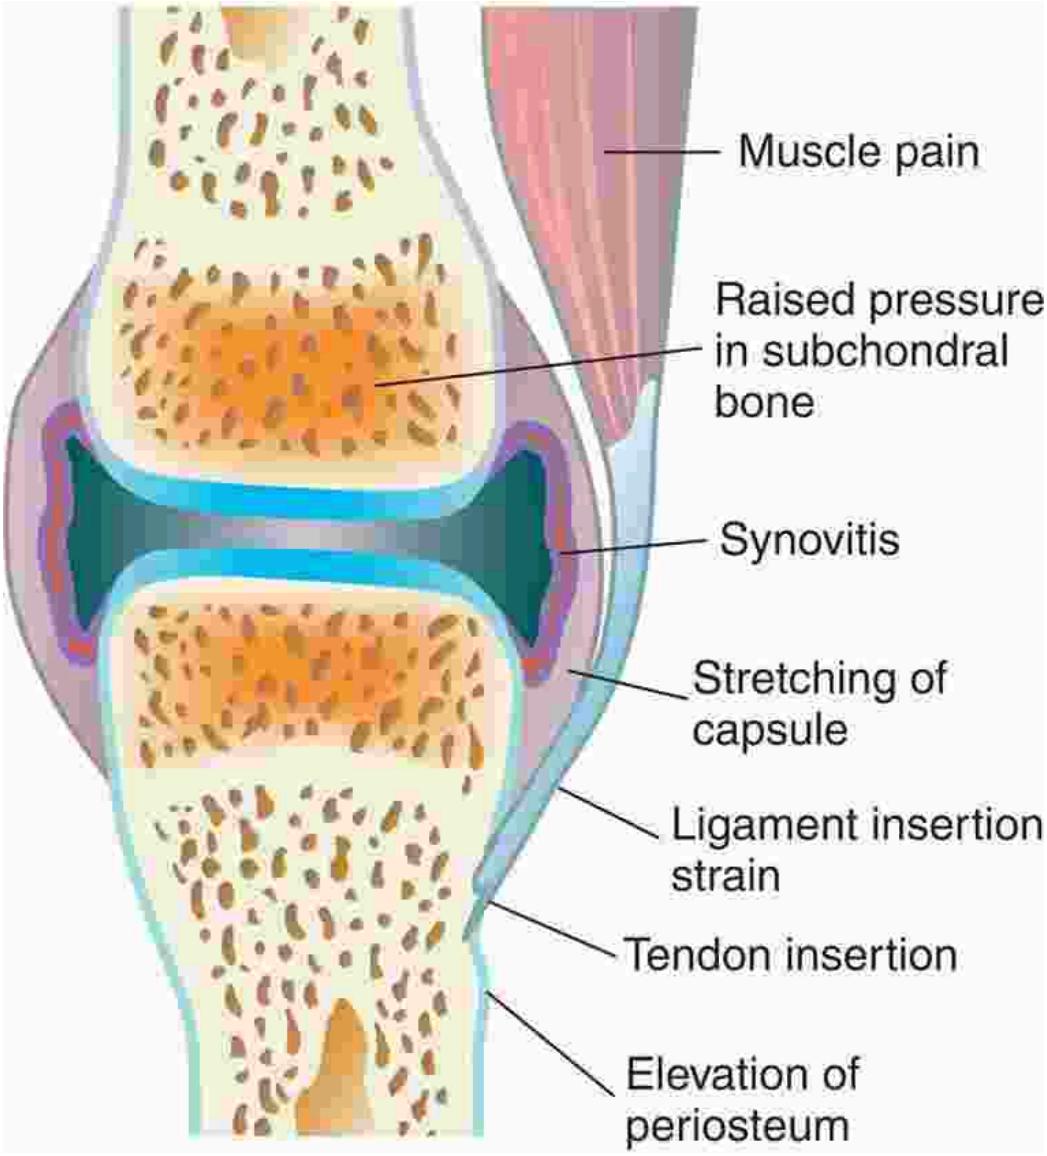

FIG. 44.26 Possible Causes of Pain in Osteoarthritis.

An illustration of a longitudinal section of the knee joint with labels depicts the causes of pain in osteoarthritis. The labels are as follows. Muscle pain, raised pressure in subchondral bone, synovitis,

stretching of the capsule, ligament insertion strain, tendon insertion, and the elevation of periosteum.

Inflammation of the joint lining, known as *synovitis*, is thought to be initiated by the release of cartilage ECM into the joint, which then activates the body's complement system. Swelling also occurs in response to tissue injury. Such injuries initiate the inflammatory cascade of cytokines and chemokines, resulting in capillary permeability and interstitial fluid collection. If inflammatory exudate or blood enters the joint cavity, the total volume of synovial fluid will be increased. This condition, termed **joint effusion**, is attributed to (1) the presence of osteophyte fragments in the synovial cavity, (2) drainage of cysts from diseased subchondral bone, or (3) acute trauma to joint structures, resulting in hemorrhage and inflammatory exudation into the synovial cavity (see Fig. 44.25C).

ROM may become limited to some degree, depending on the extent of cartilage degeneration. Frequently, joint motion is accompanied by crepitus, creaking, or grating. Abnormal knee alignment also has been shown to increase the incidence and progression of OA. The person may begin to noticeably limp as OA of the lower extremity progresses (Fig. 44.27). Either varus or valgus disorders of the knee of more than 5 degrees have been associated with increased risk of development and progression of OA.

FIG. 44.27 Typical Varus Deformity of Knee Osteoarthritis. (From Doherty M. *Color atlas and text of osteoarthritis*. London: Wolfe; 1994.)

Evaluation and Treatment

Evaluation consists primarily of individual subjective reports, clinical assessment, and radiologic studies. The ACR classification is widely used for OA.[40] A clinical diagnosis of OA is made if the following are found: (1) pain worse with activity and better with rest, (2) age greater than 45 years, (3) morning stiffness lasting less than 30 minutes, (4) bony joint enlargement, and (5) ROM limitation.[40] There may be pain upon passive movement and tenderness at joint lines.[40] Imaging may include CT scan, arthroscopy, X-rays, and MRI, however MRI is not routinely indicated for OA workup.[40] Ultrasound can identify synovial inflammation, effusion, and osteophytes. Synovial fluid may be obtained and sent for evaluation and pathology. Normal blood evaluations include CBC, ESR, rheumatoid factor (RF), and ANA.[40] Widely used is the ACR classification.[40] A clinical diagnosis of OA is made if the following are found: (1).

Treatment is often determined by the severity of pain and immobility with the goal to minimize pain and functional loss.[40] Treatment regimens span from conservative to surgical, as well as nonpharmacologic to pharmacologic.[47–49] Lifestyle modification, particularly exercise and weight reduction, is a core management approach. Both exercise and weight loss have been shown to be two of the most important nonpharmacologic treatments in improving knee OA symptoms. Exercise can reduce pain and improve physical function in individuals with OA. Exercises to improve muscle tone, ROM, and balance; stretch the joint capsule; and reduce the fear of falling also have shown promise in reducing OA symptoms.

Although the use of biomechanical devices, such as foot wedges or alignment braces, has been shown to decrease pain, the reduction of

disease progression has yet to be supported. Use of supportive devices is recommended, such as a cane, walker, brace, or other device to decrease weight bearing. Braces and foot orthoses may help correct biomechanical abnormalities, thereby reducing pain and improving mobility. Physical therapy is an important management strategy for OA. Weight loss reduces pain-associated inflammation and when combined with physical activity has a greater benefit. Dietary and nutritional recommendations include increasing intake of long-chain *n*-3 fatty acids, preferably by eating oily fish twice a week; aiming for a safe level of sun exposure; eating rich vitamin D dietary sources or taking vitamin D supplements (≤25 μg/day); and increasing vitamin K intake by eating green, leafy vegetables. Nutraceuticals, such as chondroitin and glucosamine, have also shown success in relieving OA pain in some individuals. Pharmacologic therapies may include the use of analgesic and anti-inflammatory drug therapies to reduce swelling and pain. Acetaminophen has been shown to be less effective than nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen. Because of gastrointestinal toxicity, adverse renal and cardiovascular effects, oral NSAIDs should be used very cautiously and with long-term close monitoring. Fewer systemic side effects occur with topical NSAIDs, but topical NSAIDs are less efficacious than their oral counterparts and often cause local skin irritation.[40] Intra-articular injection of corticosteroids and high-molecular-weight viscose supplements, such as hyaluronic acid, can be used as an effective treatment of acute pain. Surgical intervention may be used to improve joint movement, correct deformity or malalignment, or create a new joint with artificial implants. The key to surgery is timing because those with considerable muscle weakness may not gain postoperative functional status versus those undergoing surgery earlier.[40] Individuals with significant OA on imaging typically do poorly with partial meniscectomy.[50] For these individuals, knee arthroplasty is commonly the surgical procedure of choice.[51] More aggressive surgical procedures involve creating a new joint with artificial implants. See Emerging Science Box:

Cartilage Regeneration to learn more about future treatments for damaged and/or deteriorated cartilage. Two of the most important nonpharmacologic treatments are exercise and weight loss for improving knee OA symptoms. Also considered are complementary and alternative therapies, with Tai Chi strongly recommended in the 2019 American College of Rheumatology and Arthritis guidelines.

Emerging Science Box

Cartilage Regeneration

Active research in the area of cartilage regeneration has revealed success in both animal and human models. This process involves first causing minor injury to the joint tissue, followed by the use of chemical signals and skeletal stem cells, to facilitate cartilage growth. Cartilage inherently has very limited ability to regenerate in adults. Therefore, the use of chemical signaling and stem cells is showing great promise for individuals with damaged and/or deteriorated cartilage. Skeletal stem cells are responsible for the production of bone, cartilage, and bone marrow. Through new and innovative emerging science, these cells are being used to regrow damaged cartilage, serving as another alternative treatment rather than joint replacement for arthritis.

Data From Vaughan, C. *Researchers find method to regrow cartilage in the joints*. Medical Xpress- Arthritis & Rheumatism; August 2020. https://medicalxpress.com/news/2020-08-method-regrow-cartilage-joints.html; Murphy MP, et al. Articular cartilage regeneration by activated skeletal stem cells. Nature Medicine, 2020. DOI: 10.1038/s41591-020-1013-2.

Inflammatory Joint Disease

Inflammatory joint disease, commonly called **arthritis**, is characterized by inflammatory damage or destruction in the synovial membrane or articular cartilage and by systemic signs of inflammation (fever, leukocytosis, malaise, anorexia, hyperfibrinogenemia).

Inflammatory joint disease can be infectious or noninfectious. In infectious inflammatory joint disease, inflammation is caused by invasion of the joint by bacteria, mycoplasmas, viruses, fungi, or protozoa. These microorganisms can invade the joint through a number of ports of entry, such as a traumatic wound, surgical incision, or contaminated needle. Additionally, these pathogens can be delivered by the bloodstream from sites of entry through the body's mucous membranes, as well as infections elsewhere in the body, such as bones, heart valves, or blood vessels. Noninfectious inflammatory joint disease, such as gout, is the more common form, and is caused by immune response to the deposition of crystals of monosodium urate (MSU) in and around the joint. RA, psoriatic arthritis, and ankylosing spondylitis (AS) are other noninfectious inflammatory diseases caused by immune and hypersensitivity reactions.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory autoimmune disease distinguished by joint swelling, tenderness, and destruction of synovial joints leading to disability.[52,53] (Autoimmune disease is described in Chapter 9.) RA involves synovial inflammation, joint swelling, and ankylosis and destruction of articular cartilage. RA may cause inflammation of other tissues and organs, but predominately affects the joints. The first joint tissue to be affected is the synovial membrane, which lines the joint cavity (see Chapter 43). The two primary types of synovial cells are fibroblast-like synovial cells and macrophage-like synovial cells. The joints most commonly affected are in the fingers, feet, wrists, elbows, ankles, and knees. Other joints, such as shoulders, hips, and cervical spine, also may be involved, as well as the tissues of the lungs, heart, kidneys, and skin. In addition to joint inflammation and tissue damage, RA can cause fever, malaise, rash, lymph node or spleen enlargement, and Raynaud phenomenon (transient lack of circulation to the fingertips and toes). Internationally, the incidence and prevalence of RA ranges from 0.4% to 1.3%. The incidence of RA

increases with age and peaks at ages 65 to 74 years, with women having a greater lifetime risk than men (4% vs. 3%). The incidence and prevalence of RA have decreased in developing countries to approximately 1% of the adult population.[54,55]

Risk factors for developing RA include female sex, environmental factors, and genetics/epigenetics (Fig. 44.28). Cigarette smoking is a known risk factor for RA, and in those with anti-citrullinated peptide antibodies (ACPAs) an interaction between genes and smoking has been reported.[56,57] Another risk factor is silica. A case-control study of firefighters exposed to dust at the World Trade Center collapse found an increased risk of systemic autoimmune diseases including RA.[58] Occupational exposure to textile dust was found significantly correlated with developing RA in a group of Malaysian women.[59] Periodontal disease is associated with an increased risk of developing RA.[60] The association with periodontal disease is partly mediated by the oral microbiota, such as *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans*.[52] Importantly, the gut microbiota may have a role and needs further study.[61]

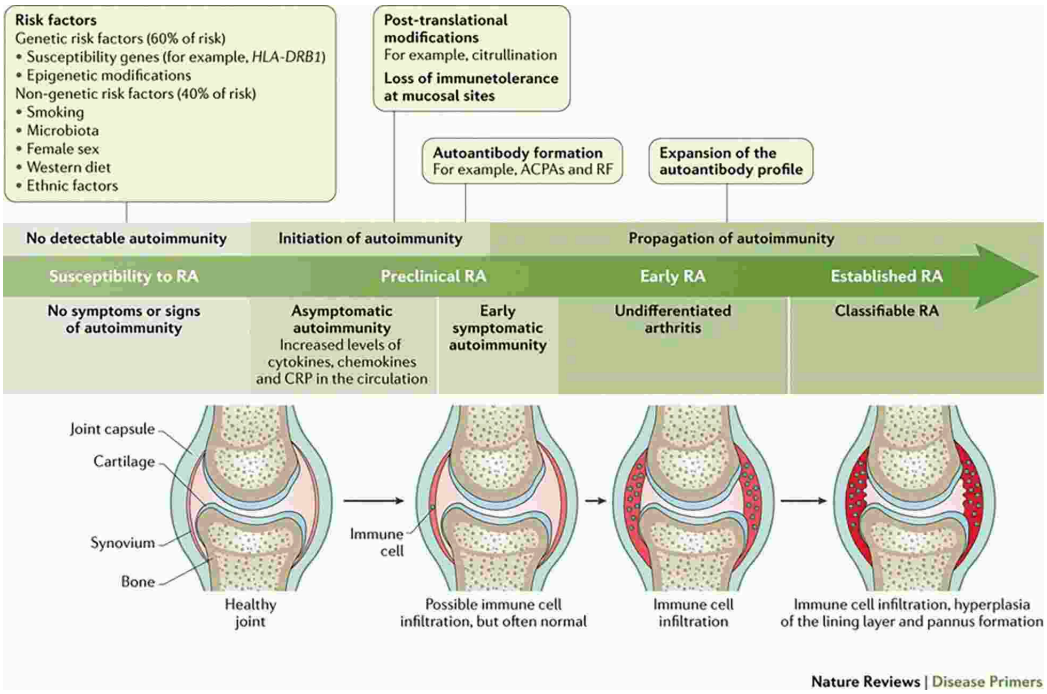

FIG. 44.28 Risk Factors, Development, and Progression of Rheumatoid Arthritis. Genetic, epigenetic, and environmental risk factors contribute to rheumatoid arthritis *(RA)*. Disease progression involves initiation and promotion of autoimmunity against modified self-proteins. These interactions can occur years before the onset of subclinical synovitis (inflammation of the synovium) and clinical symptoms. *ACPA*, Anti-citrullinated protein antibody; *CRP*, C-reactive protein; *RF*, rheumatoid factor. (From Smolen JS, Aletaha D, Barton A, et al. Rheumatoid arthritis. *Nature Reviews Disease Primers*, 2018;4:180001.)

An illustration depicts the risk factors, development, and progression of rheumatoid arthritis. Risk factors are given as follows: Risk factors: Genetic risk factor, which includes susceptibility genes, and epigenetic

modification. Non-genetic risk factors include smoking, microbiota, female sex, western diet, and ethnic factors. Post-translational modifications for example citrullination; loss of immune tolerance of mucosal sites; autoantibody formation for examples A C Ps and R F; expansion of autoantibody profile. Progression of rheumatoid arthritis accompanied by illustrations are given as follows: No detectable autoimmunity involves susceptibility to R A which shows no symptoms or signs of autoimmunity, the accompanying illustration depicts the knee joint with labels indicating joint capsule, cartilage, synovium, bone. Initiation of autoimmunity involves preclinical R A which shows asymptomatic autoimmunity and early symptomatic autoimmunity. Asymptomatic autoimmunity includes increased levels of cytokines, chemokines, and C R P in the circulation, the accompanying illustration of joint depicts the possible immune cell infiltration but is often normal. Propagation of autoimmunity involves early R A and established R A. Early R A shows undifferentiated arthritis, the accompanying illustration of the joint depicts the immune cell infiltration. Established R A shows classification R A, the accompanying illustration of the joint depicts the immune cell infiltration, hyperplasia of the lining layer, and pannus formation.

Pathophysiology

RA is a chronic autoimmune disease initiated by $CD4^+$ helper T cells (Fig. 44.29). The pathologic changes are mediated by antibodies against self-antigens, such as ACPAs detected in the serum of up to 70% of those with RA.[38] $CD4^+$ T cells promote inflammation. Acting together, T cells produce cytokines that stimulate other inflammatory cells and promote tissue injury. The most significant cytokines include interferon-gamma (IFN-γ) (activates macrophages and synovial cells), IL-17 (stimulates neutrophils and monocytes), TNF and IL-1 (stimulate synovial cells to secrete proteases that damage hyaline cartilage), and RANKL (activates bone resorption and erosion).

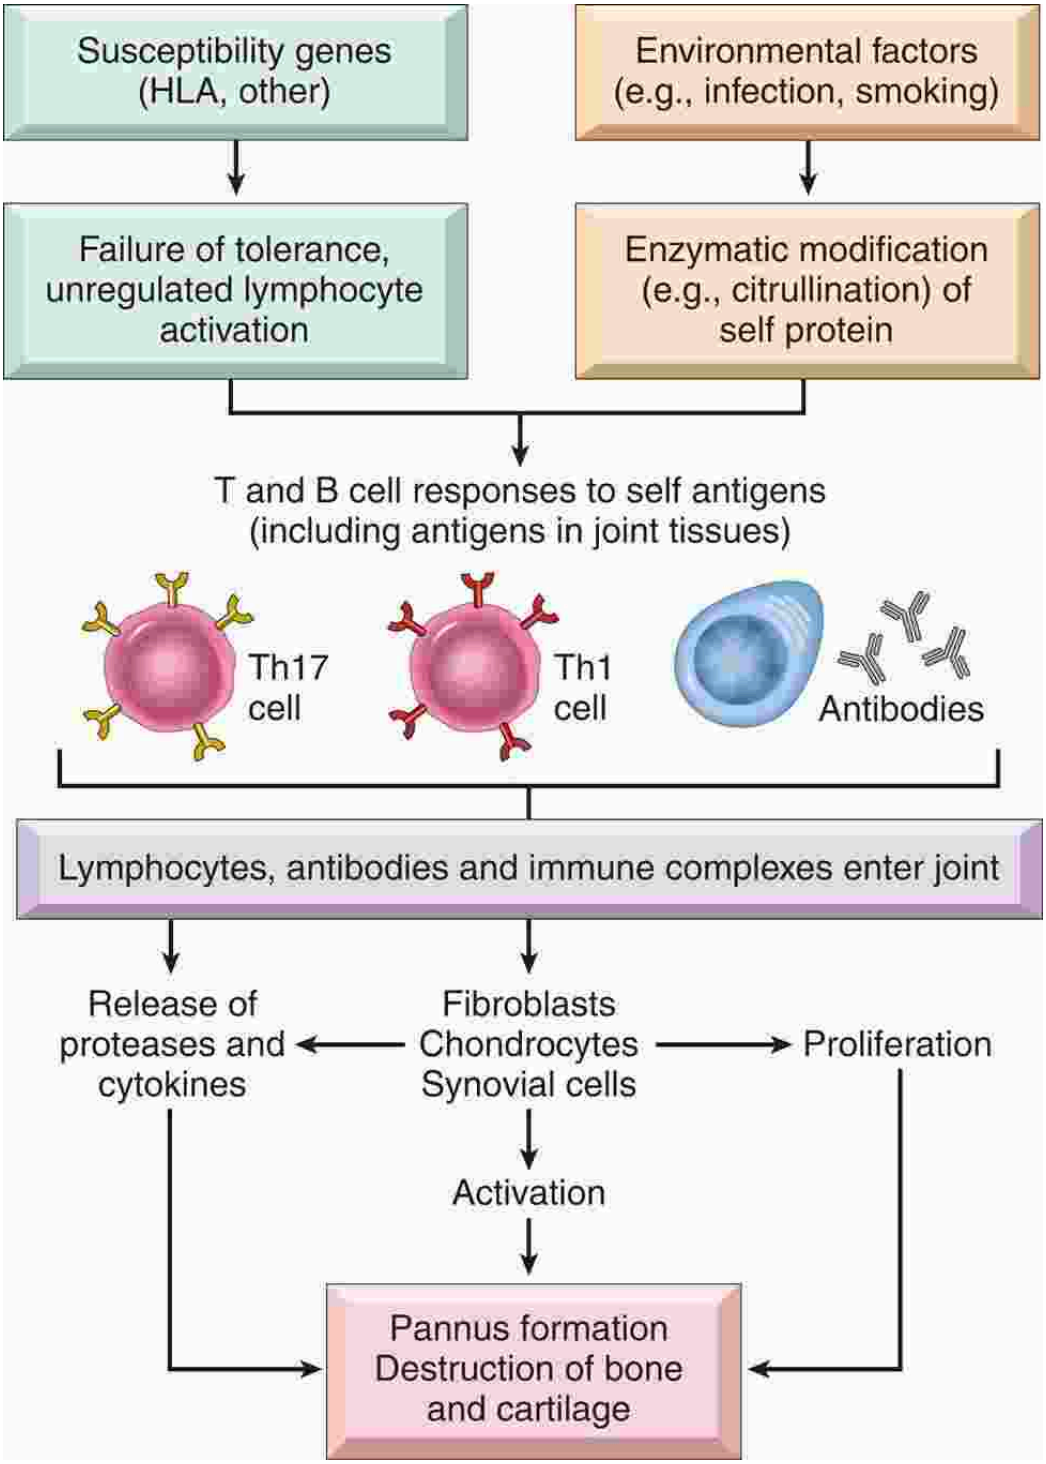

FIG. 44.29 Pathogenesis of Rheumatoid Arthritis.

HLA, Human leukocyte antigen. (From Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.)

A flow chart summarizes the pathogenesis of rheumatoid arthritis. • Susceptibility genes H L A and other cause the failure of tolerance, unregulated lymphocyte activation. • Environmental factors for example infection and smoking cause enzymatic modification for example citrullination of self protein. • Susceptibility genes and environmental factors leads T and B cell responses to self-antigen, including antigens in joint tissues. • The lymphocytes, antibodies, and immune complexes enter the joint and involves in release proteases and cytokines, fibroblasts, chondrocytes, synovial cells, and proliferation. • Fibroblasts, chondrocytes, synovial cells leads to proliferation and release of proteases and cytokines and on activation causes pannus formation, destruction of bone and cartilage.

During inflammation, arginine (an α-amino acid) can be enzymatically modified into another α-amino acid, citrulline. The process (citrullination) changes the structure and function of the protein. Other proteins, like fibrin and vimentin, can become citrullinated during cell death and tissue inflammation. In turn, the citrullinated proteins may act as new antigenic determinants or epitopes.

Given the strong genetic predisposition to developing RA, many genes have been studied as risk factors for RA, and some are involved in immune function. Genetic risk factors for RA have been localized to variations in the human leukocyte antigen (HLA) genes, particularly the HLA-DRB4 allele. The proteins produced from HLA genes assist the immune system with distinguishing self-proteins

from proteins made by invaders such as bacteria and viruses. Investigation of epigenetic factors, such as histone deacetylases, can confer the effects of environmental triggers, such as smoking or diet (e.g., *n*-3 fatty acids, or in combination with γ-linolenic acid [GLA]), or treatment on expression levels of target genes.

Chronic inflammation results from an intricate interplay of chemokines that are powerful mediators of inflammation. Chemokines attract T cells and produce inflammatory changes With long-term or intensive exposure to the antigen, normal antibodies (immunoglobulins [Igs]) become autoantibodies—antibodies that attack host tissues (self-antigens). Because they are usually present in individuals with RA, the altered antibodies are termed **rheumatoid factors (RFs)**. The RFs are mainly autoantibodies reactive with the Fc part of IgG antibodies. RFs bind with their target self-antigens in blood and synovial membrane, forming immune complexes (antigen-antibody complexes) (see Chapter 8).

The B lymphocytes are stimulated to produce more RFs, and the T lymphocytes eventually cause the release of enzymes that amplify and perpetuate the inflammatory response (see Fig. 44.29). Cartilage destruction is mediated by proteases, such as collagenase, which activates the synoviocytes to invade the synovium and cartilaginous matrix. In addition, RANKL is expressed by various cells in the synovium and induces osteoclast maturation and activation, thus producing increased bone resorption (also see Chapter 43).

Multiple immunoregulatory cytokines and inflammatory enzymes, such as interleukins, B cells, and collagenase, contribute to the development of an exaggerated immune response, resulting in leukocyte infiltration into the synovium. Once activated, synovial fibroblasts change to an invasive phenotype. Fibroblasts and inflammatory cells perpetuate the inflammatory process and thicken the synovial tissue, called "*pannus*" (Fig. 44.30; see Chapter 8). Eventually, this process leads to osteoclast generation resulting in bone destruction, the hallmark of RA. Inflammation may spread to the articular cartilage, fibrous joint capsule, bone, and surrounding ligaments and tendons, causing pain, joint deformity, and loss of function (Fig. 44.31).

(A) Schematic view of the joint lesion. **(B)** Advanced rheumatoid arthritis involving femur. There is prominent proliferation of synovium and almost complete destruction of overlying articular cartilage. (A, Modified from Feldmann M. Development of anti-TNF therapy for rheumatoid arthritis. *Nature Reviews Immunology*, 2002;2:364. B, From Rosai J. *Ackerman's surgical pathology*, 10th edition. Philadelphia: Mosby; 2011.)

A. An illustration depicts the comparison of the normal joint and rheumatoid joint. The illustration on the left depicts the normal joint with labels indicating synovial membrane and cartilage. The illustration on the right depicts the rheumatoid joint with labels indicating macrophage, plasma cell, dendritic cell, lymphocyte, pannus, immune complexes, and neutrophil. B. A close shot of femur with the complete destruction of articular cartilage.

FIG. 44.31 Rheumatoid Arthritis of the Hand. Note swelling from chronic synovitis of metacarpophalangeal joints, marked ulnar drift, subcutaneous nodules, and subluxation of metacarpophalangeal joints with extension of proximal interphalangeal joints and flexion of distal joints. Note also deformed position of thumb. (From Walker BR, et al. *Davidson's principles and practice of medicine*, 22nd edition. London: Churchill Livingstone; 2014.)

Macrophages, components of pannus (see Figs. 44.29 and 44.30), stimulate the release of IL-1, PDGF, and fibronectin. The B lymphocytes are stimulated to produce more RFs. The newly targeted self-antigens (Igs) are in relatively constant supply and can thus perpetuate inflammation and the formation of immune complexes indefinitely. Along with the swelling and damage to the synovial membrane caused by leukocyte infiltration, the synovial membrane undergoes hyperplastic thickening as its cells proliferate and become abnormally large. As synovial inflammation progresses

to involve its blood vessels, small venules become occluded by hypertrophied endothelial cells, fibrin, platelets, and inflammatory cells, which decrease vascular flow to the synovial tissue. Compromised circulation, coupled with increased metabolic needs as a result of hypertrophy and hyperplasia, causes hypoxia and metabolic acidosis. Acidosis stimulates the release of hydrolytic enzymes from synovial cells into the surrounding tissue, initiating erosion of the articular cartilage and inflammation in the supporting ligaments and tendons. Inflammation causes hemorrhage, coagulation, and fibrin deposition on the synovial membrane, in the intracellular matrix, and in the synovial fluid (see Fig. 44.30).

Clinical Manifestations

The onset of RA is usually insidious, although as many as 15% of cases have an acute onset. RA begins with general systemic manifestations of inflammation, including fever, fatigue, weakness, anorexia, weight loss, and generalized aching and stiffness. Local manifestations also appear gradually over a period of weeks or months. The joints typically become painful, tender, and stiff. Pain early in the disease is caused by pressure from swelling; later, it is caused by sclerosis of subchondral bone and new bone formation. Stiffness usually lasts for about 1 hour after arising in the morning and may be caused by synovitis. Initially, the most commonly involved joints are the MCP joints, PIP joints, and wrists, with later involvement of larger weight-bearing joints.

Widespread, symmetric joint swelling is caused by increasing amounts of inflammatory exudate (leukocytes, plasma, plasma proteins) in the synovial membrane, hyperplasia of inflamed tissues, and formation of new bone. On palpation, the swollen joint feels warm and the synovial membrane feels “boggy.” The skin over the joint may have a ruddy, cyanotic hue and may look thin and shiny.

An inflamed joint may lose some of its mobility; even mild synovitis can lead to loss of ROM. Extension becomes limited and is eventually lost if flexion contractures form. Chronic synovitis weakens ligamentous structures, leading to deformities caused by

the limited ROM and permanent deformities of the fingers, toes, and limbs, including ulnar deviation of the hands, boutonnière and swan neck deformities of the finger joints, plantar subluxation of the metatarsal heads of the foot, and hallux valgus (angulation of the great toe toward the other toes). Flexion contractures of the knees and hips are also common. Joint deformities cause the physical limitations experienced by persons with RA (see Fig. 44.31). Loss of joint motion is quickly followed by secondary atrophy of the surrounding muscles. With secondary muscle atrophy, the joint becomes unstable, which further aggravates joint pathology.

Two complications of chronic RA are caused by excessive amounts of inflammatory exudate in the synovial cavity. One complication is the formation of cysts in the articular cartilage or subchondral bone. Occasionally, these cysts communicate with the skin surface (usually the sole of the foot) and begin to drain, causing a *fistula*. The second complication is rupture of a cyst or of the synovial joint itself, usually caused by strenuous physical activity that places excessive pressure on the joint. Rupture releases inflammatory exudate into adjacent tissues, thereby spreading inflammation. Both of these complications contribute to the formation of bone erosion and worsened outcomes for the individual with RA.

Extrasynovial **rheumatoid nodules**, the most common extra-articular manifestations, are seen in areas of pressure or trauma, and occur in up to 30% of individuals with RA. Each nodule is an aggregate of inflammatory cells surrounding a central core of fibrinoid and cellular debris. T lymphocytes are the predominant leukocytes in the nodule; B lymphocytes, plasma cells, and phagocytes are found around the periphery. Nodules are most often found in subcutaneous tissue over the extensor surfaces of elbows and fingers. Less common sites are the scalp, back, feet, hands, buttocks, and knees.

Rheumatoid nodules also may invade the skin, cardiac valves, pericardium, pleura, lung parenchyma, and spleen. These nodules are identical to those encountered in some individuals with rheumatic fever and are characterized by central tissue necrosis surrounded by proliferating connective tissue. Also noted are large

numbers of lymphocytes and occasional plasma cells. Acute glaucoma may result with nodules forming on the sclera. Pulmonary involvement may result in diffuse pleuritis or multiple intraparenchymal nodules. Together, the occurrence of pulmonary nodules and pneumoconiosis (chronic inflammation of the lungs from inhalation of dust) creates **Caplan syndrome**. Diffuse pulmonary fibrosis may also occur as a result of immunologically mediated immune complex deposition.

Rheumatoid nodules within the heart may cause valvular deformities, particularly of the aortic valve leaflets. Pericardial effusion or other pericardial problems occur in almost 50% of individuals with RA. Lymphadenopathy of the nodes close to the affected joints may develop. Rheumatoid nodules within the spleen result in splenomegaly. Involvement of any blood vessel can result in the development of necrotizing vasculitis. Thromboses of such involved vessels may give rise to myocardial infarctions, cerebrovascular occlusions, mesenteric infarction, kidney damage, and vascular insufficiency in the hands and fingers (Raynaud phenomenon). Vascular changes are noted primarily in individuals receiving corticosteroid therapy; thus, there is some concern that the therapy may play a role in initiating these lesions. Changes in skeletal muscle are often noted in the form of nonspecific atrophy secondary to joint dysfunction.

Evaluation and Treatment

The presence of RF is a laboratory evaluation and is positive in about 45% to 75% of individuals with RA. Thus, it is not considered diagnostic of RA.[57] It is also present in connective tissue disease, chronic infections, and healthy individuals, mostly in low titers.[57] ACPA are detected in about 50% of individuals with early arthritis. These individuals are diagnosed with RA.[57] In the active phase of arthritis, acute-phase reactants, ESR and CRP may be elevated.[57] MRI and ultrasound of joints detect erosions earlier than an x-ray; MRI and ultrasound are more sensitive than clinical examination in identifying synovitis and joint effusion.[62–64] Disease-modifying, anti-

rheumatic drugs (DMARDS) are initiated when the diagnosis of RA is made.[57] In 2010 the ACR and the European League Against Rheumatism (EULAR) revised their classification criteria to better identify early stages of RA.[65]

Early and aggressive treatment can decrease the systemic impact of RA, leading to a decreased development of disability and joint destruction.

More recently, targeted treatment for RA has involved use of agents aimed at interrupting the pathogenesis of the disease. Known as *biologic DMARDs* (*bDMARDs*), these medications affect specific processes in the development of RA and include TNF inhibitors and monoclonal antibodies. Other agents interfere with cytokine function, inhibit T-cell activation, or deplete B cells.

Other treatments and therapies include NSAIDs, glucocorticoids, intra-articular steroid injections, physical and occupational therapy with therapeutic exercise, and use of assistive devices. Surgery is used to treat deformities or mechanical deficiencies of joints and can include synovectomy or joint replacement surgery.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a chronic inflammatory disease of the axial spine. AS is characterized by stiffening and fusion (ankylosis) of the spine, sacroiliac joints, peripheral joints, digits, entheses, and dactylitis.[66] AS is part of a group of related diseases known as **spondyloarthropathies**. The most common features of AS are chronic back pain and progressive spinal stiffness.

The primary pathologic site is the **enthesis** (the point at which ligaments, tendons, and the joint capsule are inserted into bone), and the result is fibrosis, ossification, and fusion of the joint, primarily the sacroiliac joints and the vertebral column (axial skeleton). There are two subgroups of AS: (1) mainly axial disease (involving the spine and/or sacroiliac joints); and (2) peripheral disease (involving joints and/or tendons outside the spine or sacroiliac joints).

AS ranges from 9 to 30 per 10,000 persons which are lower than previous estimates.[67] Worldwide, AS has greater prevalence in men

than women. It is typically diagnosed in those younger than 40 years and about 80% of individuals develop initial symptoms when they are younger than 30 years.[66] Although AS can occur in more than one person in a family, it is not a purely genetic disease and has multiple genetic and environmental factors.[68]

Pathophysiology

The exact cause of AS is unknown, but its high association with histocompatibility antigen HLA (*HLA-B27*) has been known for decades. Though many people with AS have the *HLA-B27* variation, most people with this version never develop the disorder.[68] Ongoing genetic studies are needed to clarify the role in AS. AS has an insidious onset and chronic inflammation. The hallmark is enthesitis with chronic inflammation, including CD4 and CD8 T lymphocytes and macrophages.[66] TNF-α and TGF-β, both cytokines, are important in the inflammatory process and promote progression to fibrosis and ossification at sites of enthesitis. The new enthesis, which forms on top of the old one, is called a **syndesmophyte**. As calcification of the spinal ligaments progresses, the vertebral bodies lose their concave anterior contour and appear square. The spine assumes the classic bamboo spine appearance of AS.

Clinical Manifestations

The most common signs and symptoms of early AS are low back pain and stiffness. Back pain typically exhibits at least four of the five following characteristics: age of onset less than 40 years, insidious onset, improvement with exercise, no improvement with rest, and pain at night with improvement upon arising.[66] Commonly seen is immobility, spinal stiffness, and postural changes, especially hyperkyphosis.[66] The thoracic spine becomes rounded, the head and neck are held forward on the shoulders, and the hips are flexed (Fig. 44.32). Complications can include chronic pain and disability, aortic regurgitation, pulmonary fibrosis, cauda equina syndrome, and mood disorders.[66]

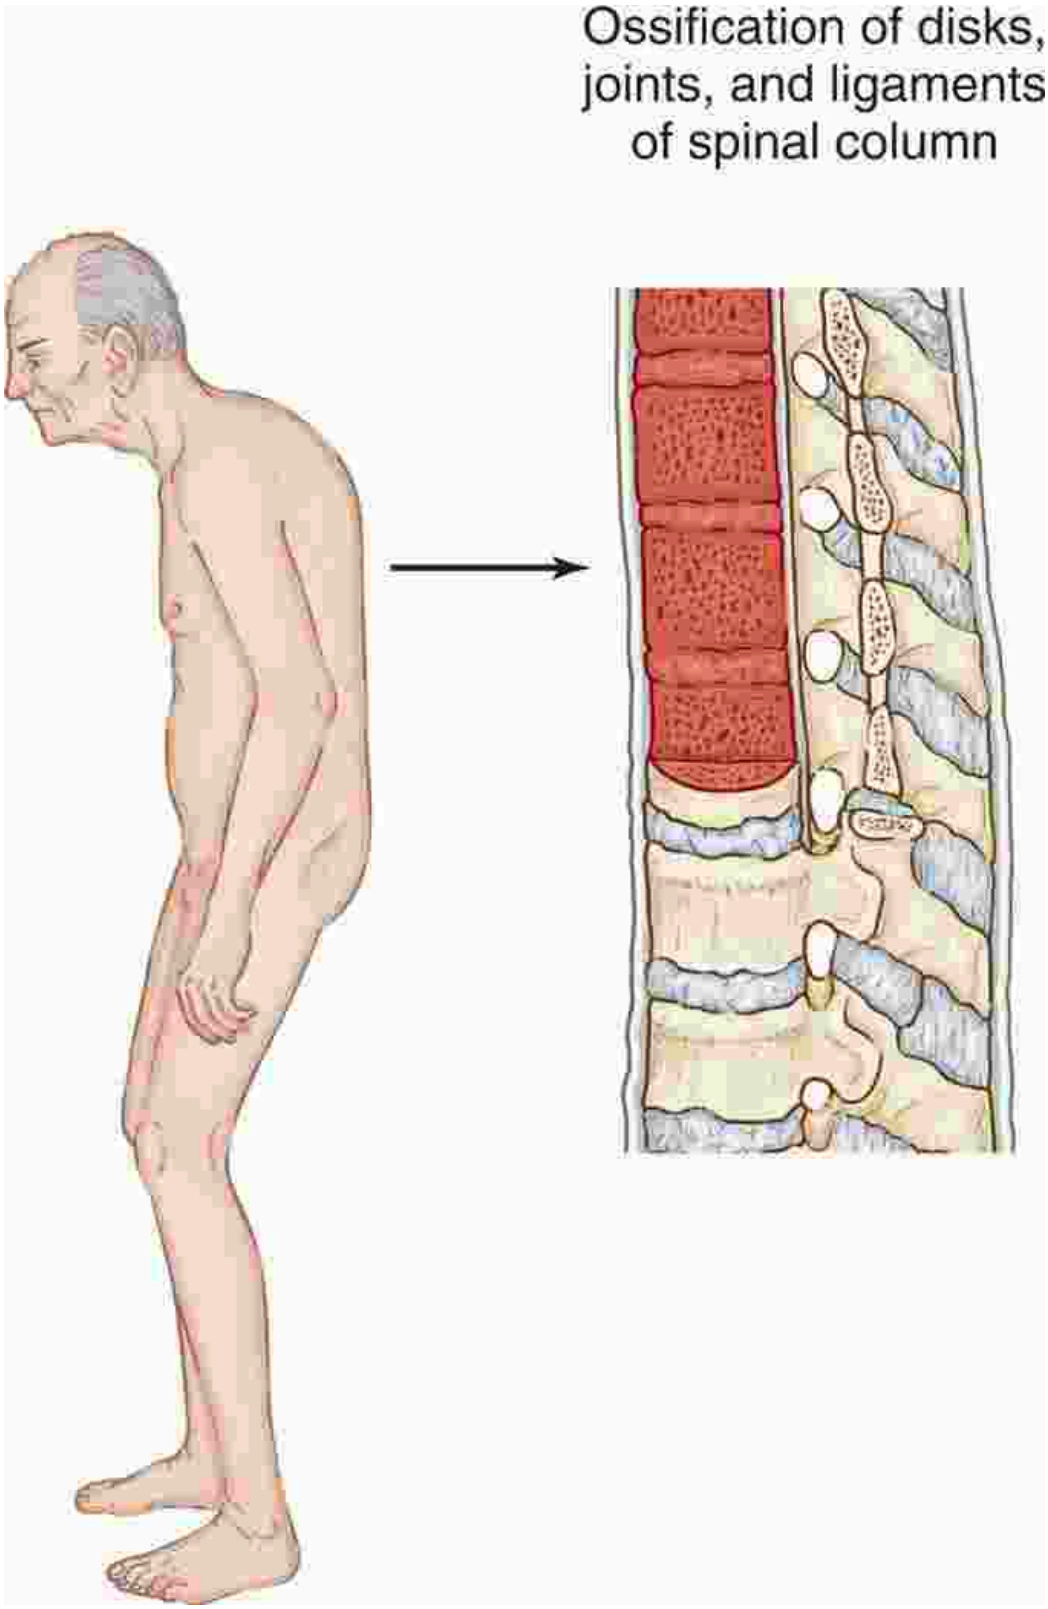

FIG. 44.32 Ankylosing Spondylitis.
Characteristic posture and primary pathologic

sites of inflammation and resulting damage.
(Redrawn from Mourad LA. *Orthopedic disorders*. St. Louis: Mosby; 1991.)

Inflammation in the tendon insertions of the many costosternal and costovertebral muscles can cause pleuritic chest pain and restricted chest movement. The pain is usually worse on inspiration. Movement of the diaphragm is normal and full. Pressure on the anterior chest wall over the sternum, ribs, and costal cartilages may cause tenderness. Tenderness over the pelvic brim may cause discomfort at night and interfere with sleep because turning onto the iliac crests causes pain. Tenderness over the ischial tuberosities may make sitting on hard seats unbearable. Tenderness in the heels may contribute to a limp or cautious placement of the feet during walking.

Evaluation and Treatment

The diagnosis of AS is made on the basis of both clinical and radiologic findings. Clinical findings include low back pain and stiffness lasting more than 3 months that improves with exercise but is not relieved by rest, limited spine ROM in both frontal and sagittal planes, and limited chest expansion relative to normal values for age and gender. Radiologic changes of the sacroiliac joint are graded according to severity of abnormality; abnormalities include sclerosis, widening, narrowing, or ankylosis. MRI can discover sacroiliitis years before there is evidence on x-rays.

Laboratory tests, including serum analysis for the presence of the histocompatibility antigen HLA-B27, elevated ESR, and elevated alkaline phosphatase levels are generally nonspecific but can assist the diagnosis. A normal ESR and CRP should not exclude the disease.[69–71] First-line treatment consists of NSAIDs. If NSAIDs do not provide adequate relief, they can be combined with or replaced with TNF inhibitors (TNF-Is) (certolizumab, golimumab) or B-cell depleting agents (rituximab). Local corticosteroid injections also may be used. Systemic glucocorticoids are not recommended.[66] Surgical

procedures, such as osteotomy, total hip replacement, and cervical spinal fusion, and radiation therapy may be utilized to provide relief for individuals with end-stage disease or intolerable deformity. Non-pharmacologic approaches include regular exercise, postural training, and physical therapy.

Gout

Gout is a systemic disease of uric acid (UA) disturbance that results from the deposition of **monosodium urate crystals (MSUs)** in tissues.[72] Increased serum uric acid (SUA) above a specific threshold leads to the formation of MSU crystals in and around joints, forming insoluble precipitates of MSU. These precipitates are then deposited in connective tissues throughout the body. Many individuals, however, with hyperuricemia do not develop gout or form UA crystals. Only about 5% of people with hyperuricemia above 9 mg/dL develop gout. Thus, other factors are important to its pathophysiology, such as genetic predisposition.[72,73] The genetic basis of progression to clinical gout needs much more investigation. Other risk factors for gout or hyperuricemia include older age, male sex, obesity, a purine diet, alcohol, medications, and comorbid diseases.[74]

In the United States, gout is the most prevalent etiology of chronic inflammatory arthritis.[73,75] Every condition that causes alterations in extracellular urate concentration has the potential to trigger an acute onset of gout "flare-up." These triggers include stress (surgical procedure, recent trauma, starvation), dietary factors (e.g., fatty food, beer, wine, spirits), and drugs (e.g., aspirin, diuretics, or even allopurinol).[74]

The disease burden of gout is substantial, increasing in Western countries and those becoming westernized analogous to the obesity epidemic. Obesity and gout are aspects of the metabolic syndrome. Estimates of gout prevalence range from 2.7% to 6.7% in countries with a Western lifestyle.[76] In the United States the most recent data

(2015 to 2016) of lifetime prevalence of gout is 3.9% which equates to 9.2 million people.[77]

Pseudogout mimics gout; however, it is caused by the formation and deposition of calcium pyrophosphate dihydrate (CPPD) crystals. CPPD crystals predominantly deposit in joint cartilage and intervertebral disks. The effect of either crystal is the same—the onset of a cytokine-mediated acute inflammatory response (see Chapter 9).

Pathophysiology

Gout develops in stages (Fig. 44.33). Crystallization in synovial fluid triggers TNF-α, causing the release of chemokines and interleukins. The result of crystallization in synovial fluid is acute, painful inflammation of the joint. This inflammatory response triggers macrophages that phagocytose MSU crystals. When macrophages phagocytize MSU crystals, they form a protein scaffold known as an *inflammasome*. Inflammasomes then convert inactive interleukins of IL-1β and IL-18 into their active forms. Prolonged accumulation results in joint damage, a condition known as **gouty arthritis**. With time, crystal deposition in subcutaneous tissues causes the formation of small, white nodules, or **tophi**, that are visible through the skin.[76]

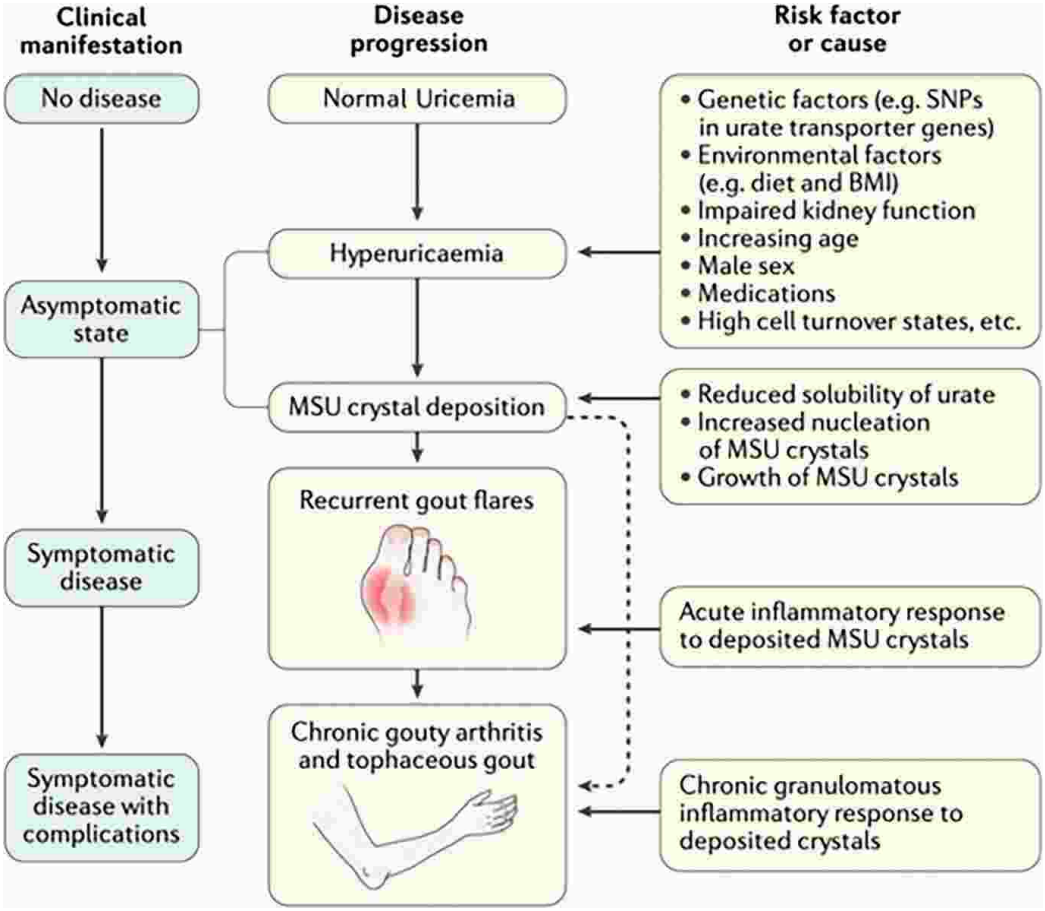

FIG. 44.33 Gout Disease Progression.
Many steps occur in the transition from normal serum uric levels to clinically evident gout. Step one is hyperuricemia, caused by both lifestyle /environmental and genetic factors. Monosodium urate (MSU) crystal deposition occurs in some individuals (see text) and the clinical manifestations of gout (gout flares, chronic gouty arthritis, tophaceous gout) occur. The transition from hyperuricemia to clinically evident gout is unclear. SNP, single-nucleotide polymorphism.
(From Dalbeth N, Choi HK, Joosten LAB, et al. Gout. *Nature Reviews Disease Primers*, 2019;5:69.)

A conceptual framework summarizes the progression of Gout disease, clinical manifestation,

risk factor, or cause. The data from the framework presented in the format, clinical manifestation; disease progression, risk factor, or cause are as follows. • No disease; normal uricemia; nil. Asymptomatic state; hyperuricemia; genetic factors in urate transporter genes; environmental factors, impaired kidney function; increasing age; male sex; medications; high cell turnover states. • Asymptomatic state; M S U crystal deposition; reduced solubility of urate; increased nucleation of M S U crystals; growth of M S U crystals. • Symptomatic disease; recurrent gout flares; acute inflammation response to deposited M S U crystals. • Symptomatic disease with complications; chronic gouty arthritis and tophaceous gout; chronic granulomatous inflammatory response to deposited crystals.

Gout flare is an acute inflammatory response to the deposited MCU crystals, and **trophus** is a chronic inflammatory granulomatous response to the deposited crystals.[76] The understanding of the pathophysiology of gout has progressed in the last decade. Although gout has been understood as a disorder of purine metabolism it has now become apparent that altered urate transport, both in the gut and the kidneys, is central in the pathogenesis of hyperuricemia and gout.[76] Genome-wide association studies (GWAS) have identified single-nucleotide polymorphisms (SNPs) in several loci and many are correlated with gout.[78,79] The urate transporter genes *SLC2A9* (encoding GLUT9), *SLC22A12* (encoding URAT1), *SLC17A1* (encoding NPT1), and *ABCG2* are

strongly correlated with urate levels.[76] Serum urate levels are mostly regulated by the activity of these four transporters in renal transport, and of *ABCG2* in intestinal transport.[76]

MSU crystals can stimulate and perpetuate the inflammatory response. The presence of MSU crystals triggers the acute inflammatory response. Initiation of the complement system activates cytokines and interleukins, which draw neutrophils out of the circulation to begin phagocytizing the crystals. Within the joint fluid, urate crystals react particularly with neutrophils and monocytes. Tissue damage occurs, principally when the neutrophils release the contents of their phagolysosomes (Fig. 44.34). These contents also perpetuate inflammation. The joint affected by gout flare has a pronounced neutrophilic infiltration in both the synovial tissue and synovial fluid.[76] At an early phase of an acute gouty attack, synovial microtophi have been demonstrated. As the process continues, numerous microtophi may be present on the synovial membrane.

FIG. 44.34 Bone Destruction of First Metatarsal Because of Gout. (From Chhana A, Dalbeth N. Structural joint damage in gout. *Rheumatic Disease Clinics of North America*, 2014;40(2):291–309.)

Clinical Manifestations

Individuals typically present with acute onset of joint pain. Often the involved joint is the first metatarsophalangeal joint.[74] Clinicians need to also inspect talar, subtalar, ankle, and knee as well as joints that may have OA. Tendons and bursa may also be affected. Pain is usually severe and mostly unresponsive to home remedies. Even touching the joint can cause excruciating pain. Gout flare-ups incite inflammation and can cause redness, swelling, and a warm joint. Other symptoms may be fever, general malaise, and fatigue.[75]

Tophaceous deposits are the characteristic diagnostic lesions of chronic gout. These deposits produce irregular swellings of the fingers, hands, knees, and feet. Tophi within the soft tissue commonly form lumps along the ulnar surface of the forearm, the tibial surface of the leg, the Achilles tendon, and the olecranon bursa.

Each tophus consists of a deposit of urate crystals, surrounded by a granuloma made up of mononuclear phagocytes (macrophages) that have developed into epithelial and giant cells. (Granuloma formation is described and illustrated in Chapter 7.) Tophi may produce marked limitation of joint movement and can eventually cause grotesque deformities of the hands and feet (see Fig. 44.34). Although the tophi themselves are painless, they often cause progressive stiffness and persistent aching of the affected joint. Tophi in the extremities can cause nerve compression, such as carpal tunnel syndrome in the wrists, or tarsal tunnel syndrome in the ankles.

Evaluation and Treatment

MSU crystal identification is the gold standard for gout diagnosis.[74] Synovial fluid or tophus aspiration analysis is done under polarizing microscopy. Arthrocentesis may be necessary to confirm the diagnosis and rule out septic arthritis, Lyme disease, or pseudogout (calcium pyrophosphate).[80] Laboratory tests may include white blood cell count, ESR, and CRP during a flare-up, but are non-specific and do not confirm a diagnosis.[74] During a flare-up, serum urate may be normal. Hyperuricemia is helpful for the clinical diagnosis of gout in symptomatic individuals, but alone does not confirm the diagnosis.[74] In the overall population, asymptomatic hyperuricemia is common (Table 44.8). Urinary studies may also be done. Not routinely used, ultrasonography and dual-energy CT (DECT) can assist in the diagnosis.

Table 44.8

Mean Urate Concentrations by Age and Sex

Characteristic	Mean Urate Levels (mg/dL)
Prepuberty	3.5
Males (at puberty)	Steep rise to 5.2
Females (puberty to after premenopause)	Slow rise to ≈4
Females (after menopause)	4.7
Hyperuricemia	
• Males	7
• Females	6

Characteristic	Mean Urate Levels (mg/dL)
Prepuberty	3.5
Males (at puberty)	Steep rise to 5.2
Females (puberty to after premenopause)	Slow rise to ≈4
Females (after menopause)	4.7
Hyperuricemia	
• Males	7
• Females	6

During an acute flare-up the goal of treatment is to decrease inflammation and pain. Treatment is usually started within the first 24 hours of onset to reduce the severity and duration of the flare-up.[81] First-line treatment for gout flares are NSAIDs, colchicine, or systemic glucocorticoids. Indomethacin is not preferred because of toxicity effects.[81] Lifestyle factors are very important, and

individuals should be counseled to lose weight if obese, avoid certain high-risk foods, avoid consumption of alcohol, and hydrate adequately.

Disorders of Skeletal Muscle

Weakness and fatigue are common symptoms of disorders of the skeletal muscles, termed **myopathies**. In many cases, neural, traumatic, and psychogenic causes provide an adequate explanation for the failure to generate force (weakness) or sustain force (fatigue) seen in myopathies. The pathophysiologic mechanisms in some of the metabolic and inflammatory muscle diseases have been explored, but the cause of many of the myopathies remains obscure. The complex interaction between muscles and nerves affects muscular function as well. Only inherited and acquired disorders of skeletal muscles are discussed here.

Secondary Muscular Dysfunction

Muscular symptoms arise from a variety of causes unrelated to the muscle itself. Secondary muscular phenomena (contracture, stress-related muscle tension, immobility) are common disorders that influence muscular function.

Contractures

Contractures are the lack of full passive ROM of a joint because of muscle, connective tissue, or other soft tissue limitations. The causes of these limitations can be *pathologic* or *physiologic*. A **physiologic muscle contracture** occurs as a result of the absence of a muscle action potential in the sarcolemma. Muscle shortening is caused by failure of the calcium pump in the presence of ATP. A physiologic contracture is seen in McArdle disease (muscle myophosphorylase deficiency) and MH. The contracture is usually temporary if the underlying pathology is reversed.

A **pathologic contracture** is a permanent muscle shortening caused by muscle spasm or weakness. Heel cord (Achilles tendon)

contractures are examples of pathologic contractures. They are associated with plentiful ATP and occur in spite of a normal action potential. Most occurrences of pathologic contractures are seen in stroke, neuromuscular disorders such as muscular dystrophy, Charcot-Marie-Tooth disease, amyotrophic lateral sclerosis (ALS), cerebral palsy (see Chapter 45), and CNS injury. Contractures of the lower extremities are more common than those in the upper extremity. Prolonged splinting in a single position or an imbalance between agonist-antagonist muscles also can cause joint stiffness and contractures. Contractures also may develop secondary to scar tissue contraction in the flexor tissues of a joint, for example, contracture of burned tissues in the antecubital area of the forearm or the palmar surface of the hand, leading to a flexion contracture.

Stress-Induced Muscle Tension

Abnormally increased muscle tension has been associated with chronic anxiety, as well as a variety of stress-related muscular symptoms, including neck stiffness, back pain, and headache. Abnormalities in the CNS, reticular activating system, and autonomic nervous system (ANS) have been implicated. The underlying pathophysiology may be related to the fact that as a muscle contracts, the muscle spindle is activated. This gamma-feedback system produces a series of impulses that are transmitted to the brain by the sensitive 1A afferent fibers. Unconscious tension is thought to increase the activity of the reticular activating system as well. This causes increased firing of the efferent loop of the gamma fibers, producing further muscle contraction which increases muscle tension. ANS function that regulates increased blood flow to the muscle during sympathetic activity may be related to increased muscle contraction tension.

Various forms of treatment have been used to reduce the muscle tension associated with stress. Progressive relaxation training, yoga, meditation, and biofeedback are examples of stress reduction therapies.

Fibromyalgia

Fibromyalgia (FM) is a chronic musculoskeletal syndrome characterized by chronic widespread pain (CWP) primarily (but not only) from the musculoskeletal system.[82] Pain can affect the whole body from head to toe.[82] The other two most frequent symptoms are fatigue (mental and physical) and sleep disturbances, particularly non-restorative sleep.[83,84] The symptoms, however, can be complex and not explained by structural or pathologically defined causes.[82] Memory deficits can be among the severe symptoms, and depression and anxiety can affect the cognitive symptoms.[82]

FM is more common in women, and its prevalence is 2% to 3% worldwide. Debated are the etiologies, pathogenesis, diagnostic criteria, classification, and treatment. Several factors, uniquely, contribute to the development of FM: genetic predisposition, personal experiences, emotional-cognitive factors, the mind-body relationship, and a biopsychological ability to cope with stress.[82] The complex symptoms also include hypersensitivity to external stimuli, somatic symptoms, and psychiatric disorders.[82] The 2016 revisions to the 2010/2011 ACR[85] highlighted the concept of "generalized pain" which is also prominent in the ACTTION-APS Pain Taxonomy diagnostic criteria published in 2018 (Fig. 44.35).[86] The main problem to FM diagnosis is the lack of biomarkers; thus it is a clinical diagnosis.[82]

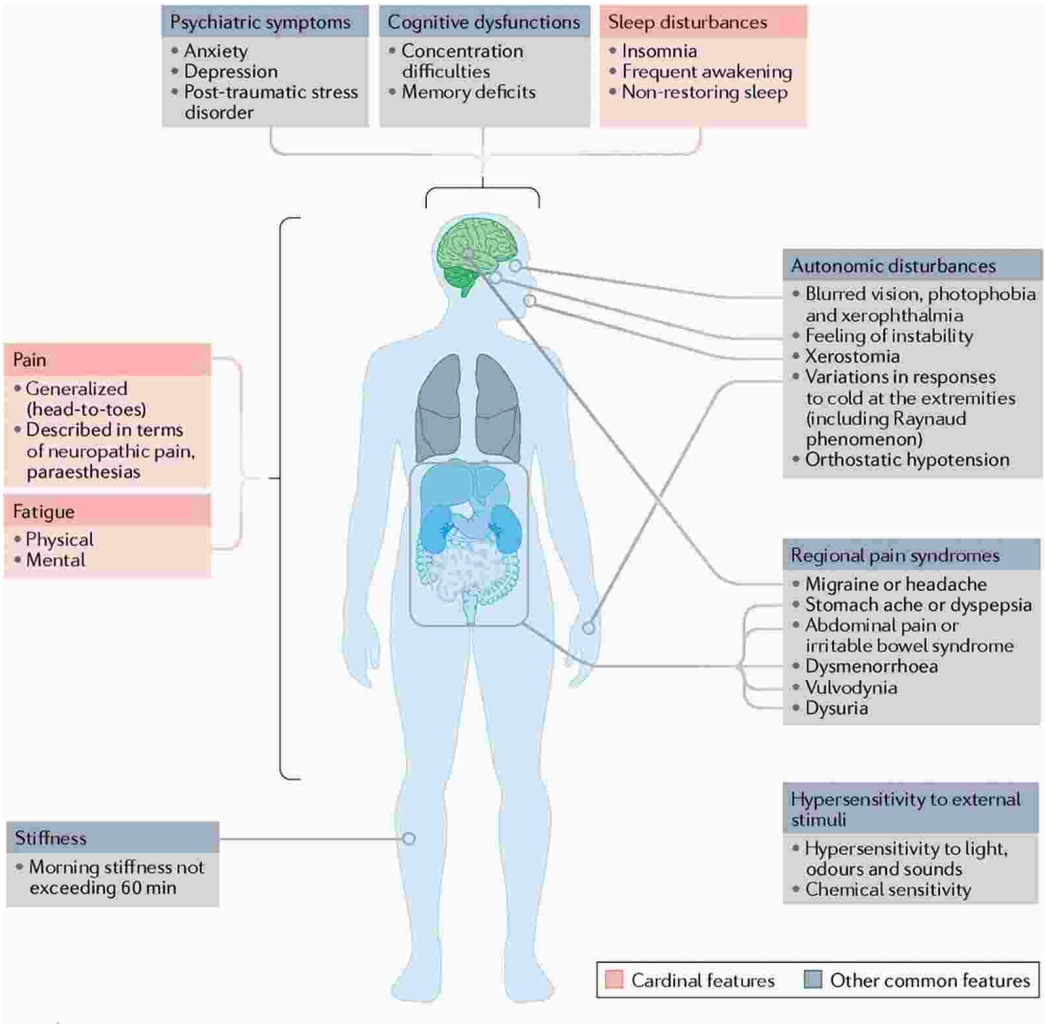

FIG. 44.35 Main Fibromyalgia (FM) Symptoms. The symptoms of FM are complex. They are divided into two groups: cardinal features (shown in pink) which are the main symptoms for achieving a diagnosis. Shown in grey are other common features. (From Sarzi-Puttini P, Giorgi V, Marotto D, et al. Fibromyalgia: An update on clinical characteristics, aetiopathogenesis and treatment. *Nature Reviews Rheumatology*, 2020;16:645–660.)

An illustration of human anatomy depicts the various symptom of fibromyalgia which are divided into cardiac features and other features. • Cardiac

features: Pain includes generalized head-to-toe and is described in terms of neuropathic pain, and para-anesthesias. • Fatigue includes physical and mental. • Sleep disturbance includes insomnia, frequent awakening, and non-resting sleep. • Other features: Stiffness includes morning stiffness not exceeding 60 minutes. • Autonomic disturbances include blurred vision, photophobia, and xerophthalmia; feeling of instability; xerostomia, variation in responses to cold at the extremities including the Raynaud phenomenon, orthostatic hypotension. • Regional pain syndrome includes migraine or headache, stomach ache or dyspepsia, abdominal pain or irritable bowel syndrome, dysmenorrhea, vulvodynia, and dysuria. • Hypersensitivity to external stimuli includes hypersensitivity to light, odors, and sounds, and chemical sensitivity. • Psychiatric symptoms includes anxiety, depression, and post-traumatic stress disorder. • Cognitive dysfunction includes concentration difficulties, and memory deficits.

Despite much debate on the classification and pathophysiology of FM, it is recognized as a disease of the musculoskeletal system and connective tissue by the WHO.

Pathophysiology

FM has an unclear pathophysiology, and many hypothetical explanations have been proposed. One hypothesis involves

nociplastic pain or pain arising from altered nociception, despite no evidence of tissue damage.[82] This type of pain conforms to FM as apart of *central sensitivity syndromes*.[82] Central sensitization is a neurophysiological process of pain amplification in the CNS. This process occurs after injuries to elicit a protective behavior and maximize the healing process. Central sensitization is also known as central hyperactivation and includes hyperalgesia, (pain perceived as hyper painful), allodynia (a normal stimulus is perceived as pain), temporal summation (perception of repetitive noxious stimulation as being increasingly painful), and hypersensitivity to external stimuli such as sounds or light.[87–90] Some studies have found diffuse pain processing in the brain is altered in FM. Individuals present with altered connectivity and a reduction in brain activity.[82,91,92] Overall, FM is becoming known as a disorder of pain regulation often classified under central sensitization.[93] Studies have suggested a link between FM and stress/stressors (such as infection including Lyme disease, psychosocial stress, sleep abnormalities, immune dysfunction, and physical or emotional trauma). The relationships continue to be researched.

Clinical Manifestations

The prominent symptom of FM is diffused, chronic pain. As discussed previously, the ACR has identified criteria for the diagnosis of FM that expand to include other non-pain symptoms not previously included. A tender point evaluation is no longer required. Instead, the use of a widespread pain index (WPI) and symptom severity inventory (SSI) is recommended. Pain often begins in one location, especially the neck and shoulders, but then becomes more generalized. Fatigue is most notable when arising from sleep and during the midafternoon. Headaches, symptoms of irritable bowel syndrome, and excess sensitivity to cold (Raynaud-like) are reported in 50% of individuals. Fatigue is profound causing a considerable effect on everyday life. Almost 25% of individuals seek psychological support for depression. Anxiety, particularly with regard to their diagnosis and future, is almost universal. Again, the

only reliable finding on examination is the presence of multiple tender points.

Evaluation and Treatment

Because the manifestations of chronic, generalized pain and fatigue are present in many musculoskeletal (e.g., rheumatic) disorders, these disorders should be considered in the differential diagnosis of FM (Tables 44.9 and 44.10). The WPI and SSI are then used for diagnostic and evaluation purposes.

Table 44.9

Differential Diagnosis of Fibromyalgia

Differential Diagnosis	Helpful Differential Features
Rheumatoid arthritis[a]	Synovitis, serologic tests, elevated erythrocyte sedimentation rate (ESR)
Systemic lupus erythematosus	Dermatitis, serositis (renal, central erythematosus,[a] nervous system, etc.)
Polymyalgia rheumatica[a]	Elevated ESR, older adults, response to corticosteroids
Myositis	Increased muscle enzymes, weakness more than pain
Hypothyroidism[a]	Abnormal thyroid function tests
Neuropathies	Clinical and electrophysiologic evidence of neuropathy

[a]Fibromyalgia may also more commonly coexist with these conditions.

Data from Klippel JH, Dieppe PA, eds. *Rheumatology*, 2nd edition. London: Mosby-Wolfe; 1998.

Table 44.10

Concomitant Conditions With Fibromyalgia

Concomitant Condition	Relationship to Fibromyalgia
Depression	Present in 25%–60% of fibromyalgia cases
Irritable bowel syndrome	Present in 50%–80% of fibromyalgia cases
Migraine	Present in 50% of fibromyalgia cases
Chronic fatigue syndrome (CFS)	70% of CFS cases meet criteria for fibromyalgia
Myofascial pain	May be a localized form of fibromyalgia

Data from Klippel JH, Dieppe PA, eds. *Rheumatology*, 2nd edition. London: Mosby-Wolfe; 1998.

No single regimen of medication has proved successful for FM. Current recommendations outline a combination of both pharmacologic and nonpharmacologic therapies. Stress reduction, sleep, and exercise remain central lifestyle modifications for individuals living with FM. Medications that improve sleep may be helpful, as well as vitamin D supplementation. The use of anti-inflammatory medications has not been effective in the treatment of FM as there is no evidence of tissue inflammation. Certain CNS-active medications, most notably pregabalin, were better than placebo in controlled trials. Other medications, designed to augment the activity of neurotransmitters and the endogenous opioid system, also have been shown to provide symptom relief. A randomized trial is needed to compare current drug regimens and cannabis.[94] Two meta-analyses have shown acupuncture efficacy in improving

stiffness and pain.[95,96] Some studies have shown benefits with neuromodulation techniques such as transcranial stimulation, occipital and C2 nerve stimulation, and transcutaneous electrical nerve stimulation.[93] Finally, the use of hyperbaric oxygen therapy has shown a promising impact in the management of FM and other chronic pain disorders.[97] The most effective approach is a combination of modalities, including education, medication, exercise, and cognitive behavioral therapy. Box 44.7 lists some of these modalities.

Box 44.7

Educating and Providing Reassurance for Individuals With Fibromyalgia

- Stress that the illness is real, not imagined.
- Explain that fibromyalgia is presumably not caused by infection.
- Explain that fibromyalgia is not a deforming or deteriorating condition.
- Explain that fibromyalgia is neither life-threatening nor markedly debilitating, although it is an irritating presence.
- Discuss the role of sleep disturbances and the relationship of neurohormones to pain, fatigue, abnormal sleep, and mood.
- Reassure that although the cause is unknown, some information is known about the physiologic changes responsible for the symptoms.
- Use muscle "spasms" and, perhaps, "low muscle blood flow" to lay the groundwork for exercise recommendations.
- Assist the individual to use aerobic exercise to reduce stress and increase rapid eye movement (REM) sleep.

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS), also known as **myalgic encephalomyelitis (ME)**, is a disabling clinical condition characterized by unexplained and persistent post-exertional fatigue and symptoms related to cognitive, immunological, endocrinological, and autonomic dysfunction.[98] Additionally, individuals may experience sore throat, headache, and tender lymph nodes. These symptoms, however, occur without a clear pathophysiologic explanation. Without a clear etiology, diagnosis of CFS is often a diagnosis of exclusion. Current research is investigating the potential impact of the immune and adrenal systems, as well as genetics and biopsychosocial involvement. As a result, CFS/ME is believed to be less of a musculoskeletal disorder and more related to hypersensitivity of the CNS, a condition known as *central sensitization*. In the WHO International Classification of Diseases version 2016, both ME and CFS were coded identically and classified as disorders of the nervous system. However, many non-expert clinicians view "fatigue syndrome" as synonymous with CFS, and classify it under mental and behavioral disorders.[98] Nonetheless, the etiology of ME/CFS is incompletely understood, complicated, and controversial.[99]

Pathophysiology

The pathophysiology of CFS remain unknown. International Consensus Criteria have recommended use of the term ME rather than CFS, because ME indicates an underlying pathophysiology. Investigators are studying alterations in the immune system. abnormal cytokine regulation, alteration of natural killer cells, B cell impairment, Igs, autoimmunity, deregulation of antiviral pathway (Oligoadenylate synthetase/RNase L pathway), neuroinflammation, changes in serotonin transmission, hypercortisolism, and genetic predisposition.[98–102] Functional MRI (fMRI) has shown lower blood perfusion to the brainstem in individuals affected by CFS supporting CNS abnormalities, immunologic dysregulation, and higher-than-

normal levels of proinflammatory cytokines. Certain points within the skeletal muscle may be affected by oxidative stress reactions (see Chapter 2), accounting for the muscle pain and fatigue associated with CFS.

Clinical Manifestations

Unrestful sleep is a hallmark of CFS. Defining symptoms include debilitating fatigue made worse by physical or mental exercise (postexertional fatigue), muscle pain, noninflammatory joint pain, headaches, flulike symptoms, and memory or concentration problems. Other common symptoms include bloating, morning joint stiffness, chest or jaw pain, chills and night sweats, visual disturbances, sore throat, and tender axillary or cervical lymph nodes. Symptoms and their consequences can be severe.

Evaluation and Treatment

ME/CFS is a diagnosis made on clinical examination and after exclusion of other possible etiologies. Diagnosis of CFS is often delayed or missed because there is no biologic marker or specific laboratory test for CFS, and many CFS symptoms are shared with other illnesses. Individuals with CFS do not necessarily appear sick, and symptoms typically have a variable course. Currently, the CDC recommends considering a diagnosis of CFS if the following two criteria are met:

1. Unexplained, persistent fatigue is not due to ongoing exertion, is not substantially relieved by rest, is of new onset (not lifelong), and results in a significant reduction of previous levels of activity.
2. Four or more of the following symptoms are present for 6 months or more:
    - Impaired memory or concentration
    - Postexertional malaise (extreme, prolonged exhaustion and exacerbation of symptoms following physical or mental exertion)

Unrefreshing sleep
Muscle pain
Multijoint pain without swelling or redness (adults)
Headaches of a new type or severity
Sore throat that is frequent or recurring
Tender cervical or axillary lymph nodes

Treatment of CFS should focus on symptom management, especially management of sleep disturbances, depression, and pain. Acknowledgement and consideration of the person's individual needs is important and involves psychosocial factors as well as symptomatic and supportive care. Professional counseling, medication, diet, and activity helps CFS sufferers deal with the limitations imposed by the disease. Alternative therapies such as acupuncture, massage, and therapeutic touch can relieve anxiety.

Disuse Atrophy

Disuse atrophy describes the pathologic reduction in normal size of muscle fibers from an accelerated degradation of myofibrillar proteins. This may be associated with the normal aging process (sarcopenia), as well as following periods of prolonged immobilization and low mechanical load, such as from inactivity during bed rest, trauma (casting), space flight, or local nerve damage seen with spinal cord trauma or poliomyelitis. Disease-induced atrophy also is seen in debilitating conditions, such as cancer, acquired immunodeficiency syndrome (AIDS), renal failure, congestive heart failure, chronic obstructive pulmonary disease, and burns. Oxidative stress from lack of muscle activity reduces muscle mass through both decreased muscle protein synthesis and increased muscle protein breakdown. The effects of muscular deconditioning associated with lack of physical activity have been seen in as few as 5 days after immobility. The normal individual on bed rest loses muscle strength from baseline levels at a rate of 3% per day. Bed rest also is associated with cardiovascular, skeletal, and other organ system changes.

The most effective restorative measure for disuse atrophy is to reapply mechanical load to the muscle group, including resistance exercises, stretching, electrical stimulation, frequent forceful isometric muscle contractions and passive lengthening exercises. Artificial gravity (fusing a *human centrifuge*) has shown benefit in maintaining muscle strength. Measures to prevent atrophy include adequate nutrition, frequent forceful isometric muscle contractions, and passive lengthening exercises. If reuse is not restored within 1 year, regeneration of muscle fibers becomes impaired.

Muscle Membrane Abnormalities

Two defects of the muscle membrane (plasma membrane of the muscle fiber) have been linked to clinical syndromes: the hyperexcitable membrane seen in myotonic disorders and the intermittently unresponsive membrane seen in periodic paralyses. Although these are infrequent disorders, research into their pathologic processes has led to an improved understanding of cell membrane channelopathies (ion channels are described in Chapter 15).

Skeletal Muscle Channelopathies

Skeletal muscle channelopathies can be divided into two primary groups: (1) those presenting with myotonia (nondystrophic myotonias) and (2) those associated with episodes of weakness (periodic paralysis [PP]). In **myotonic channelopathies**, muscle relaxation is delayed after voluntary contractions, such as handgrip or eye closure, leading to a disabling muscle stiffness and/or weakness. PP is an autosomal dominant disorder in which depolarization of the sarcolemma is severe enough that the muscle cannot be *fired* again, resulting in paralysis or even myotonia. Myotonia can be reproduced by removing extracellular chloride, thus reducing chloride conductance across the plasma membrane. The delicate balance in which sodium diffuses into the intracellular fluid, potassium diffuses out of the intracellular fluid, and chloride is in flux, is interrupted. Because the normal diffusion processes

(described in Chapter 3) stabilize the membrane, the shift in chloride ions is thought to increase membrane excitability. The chloride abnormality may explain the resting membrane hyperexcitability, but it does not explain the delayed relaxation present in myotonia and has not been detected in human myotonia. Myotonia is noted in several disorders: myotonia congenita, paramyotonia congenita, myotonic muscular dystrophy, and some forms of PP. Most are inherited disorders and are mild in symptomatology, with the exception of myotonic muscular dystrophy. Myotonia is treated by drugs that reduce muscle fiber excitability, such as sodium channel blocking agents (mexiletine, procainamide) and phenytoin.

Central core disease (CCD) is another inherited channelopathy that involves mutations in ryanodine receptors (RyR1) and affects calcium channels. In CCD, RyR1 channels are defective, and either too much or too little calcium is released from the cell's sarcoplasmic reticulum, resulting in symmetrical proximal muscle weakness. This weakness, however, is usually not progressive in nature. Classified as a neuromuscular disorder, CCD typically manifests during infancy as decreased muscle tone, delayed motor development, muscle weakness (particularly around the hip girdle), and other skeletal deformities, such as scoliosis. Thought to be the most common congenital myopathy, the pathology of CCD relates to the lack of "cores" within skeletal myofibers that do not contain mitochondria and their oxidative enzymes. Therefore, definitive diagnosis is made through muscle biopsy.

Periodic Paralysis

Periodic paralysis (PP) includes a rare group of muscle diseases caused by the inheritance of an autosomal dominant mutation of skeletal muscle calcium, sodium, or potassium channel. During an exacerbation of PP, the muscle membrane is unresponsive to neural stimuli and the resting membrane potential is reduced from −90 to −45 mV. PP can be either hyperkalemic or hypokalemic. As the name implies, PP is usually transient.

The paralysis, which leaves the individual flaccid and weak, typically affects only the skeletal muscles and not the respiratory muscles. The weakness is accompanied by a change in serum potassium levels, although in most individuals the change is negligible unless a secondary underlying condition affecting potassium distribution coexists. For this reason, cardiac dysrhythmias, although not common, have been present during attacks.

Hypokalemic PP is often triggered by thyrotoxicosis caused by alterations in potassium ion channels that are regulated by triiodothyronine (T_3). Glucose and insulin infusions and oral potassium loading are used as provocative tests; oral and intravenous potassium administration can relieve acute attacks. Treatment includes potassium-sparing diuretics and a high-salt diet. Acetazolamide, dichlorphenamide, and a low-salt diet are useful for long-term therapy.

Hyperkalemic PP is episodes of extreme muscle weakness beginning in childhood or adolescence. These episodes most often involve a temporary inability to move muscles in the arms and legs. Hyperkalemic PP is caused by an *SNC4A* genetic mutation affecting sodium channels and can be precipitated by several factors including pregnancy, alcohol, illness, exercise, and increased potassium intake. Attacks can occur without warning or can be triggered by rest after exercise, a viral illness, or certain medications, and are typically less severe than the hypokalemic form. Often a large carbohydrate-rich meal or vigorous exercise in the evening can trigger an attack upon waking the next morning. Treatment includes small carbohydrate-rich meals, light exercise, and intravenous calcium gluconate.

Metabolic Muscle Diseases

Metabolic muscle diseases are a collection of disorders caused by a genetic mutation and endocrine abnormalities that affect a muscle's metabolism. The resulting disorders in muscle metabolism lead to diseases of energy metabolism, such as glycogen storage disease,

enzyme deficiencies, and abnormalities in lipid metabolism and mitochondrial function.

Endocrine Disorders

Often the systemic effects of hormonal imbalance overshadow the individual's muscular symptoms. For example, individuals with thyrotoxicosis may have signs of proximal weakness, paresis of the extraocular muscles (exophthalmic ophthalmoplegia), and, rarely, hypokalemic PP, as discussed earlier in the previous section. Hypothyroidism is often associated with a decrease in muscle mass and strength, with weak, flabby skeletal muscles and sluggish movements.

Thyroid hormone is believed to regulate muscle protein synthesis and electrolyte balance. Changes in muscle protein synthesis and electrolyte balance may therefore explain the alterations in muscle mass and contractility seen in endocrine disorders. The muscular symptoms subside with appropriate treatment of the primary hormonal disorder.

Other endocrine disorders affecting the musculoskeletal system include Dent disease (a syndrome that causes bone deformities); rickets or osteomalacia (softening of the bone because of deficiencies in vitamin D and calcium); and osteopetrosis (also known as *Albers-Schönberg disease*) caused by failure of osteoclasts to resorb bone which thereby results in increased bone mass while causing increased bone fragility, growth abnormalities, and bone marrow failure in infants as bone marrow is replaced by bony masses. Familial hypomagnesemia is an autosomal recessive disease that primarily affects the renal system causing hypomagnesemia and secondary hypocalcemia and can result in tetany and convulsions.

Diseases of Energy Metabolism

Muscles rely on carbohydrates (e.g., glycogen) and lipids (free fatty acids) for energy. When stored glycogen or lipids cannot be used because of the lack of enzymes necessary to generate ATP for muscle contraction the individual experiences cramps, fatigue, and exercise

intolerance. Disorders of muscle metabolism can be self-limiting, such as McArdle disease and some lipid disorders, or they can cause widespread irreparable muscle destruction, as in acid maltase deficiency.

McArdle disease

McArdle disease, or glycogen myophosphorylase deficiency, is an autosomal recessive disease caused by an inability to metabolize glycogen. It was the first myopathy in which a single enzyme defect was identified (Fig. 44.36). Individuals with McArdle disease lack muscle phosphorylase, which is responsible for the breakdown of glycogen in muscle. As a result, a lack of glycogen breakdown can interfere with the function of muscle cells. The altered energy production manifests itself as exercise intolerance, fatigue, muscle pain, and cramps during the first few minutes of exercise. Some individuals describe a "second wind" phenomenon, in which exercise tolerance increases if they slow their pace once the initial sensation of fatigue commences. This is caused by the use of free fatty acids as a secondary source of energy. When exercise is carried to an extreme, muscle damage may occur, leading to the breakdown of muscle tissue (rhabdomyolysis), painful muscle contracture, and myoglobinuria.

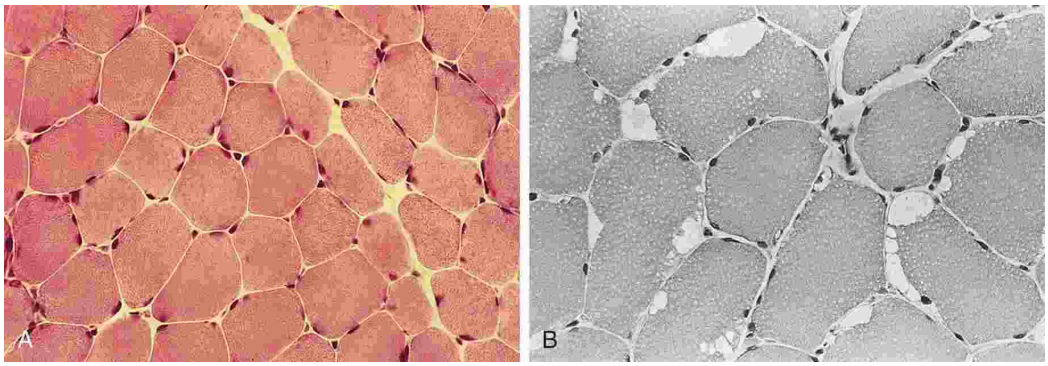

FIG. 44.36 McArdle Disease.

A. Microscopic image of cross-section of muscle fiber shows peripherally placed nuclei. B. Microscopic image of cross-section of muscle fiber shows the transversely cut muscle fibers with peripherally placed nuclei.

Acid maltase deficiency

Acid maltase deficiency is an uncommon, autosomal recessive disorder affecting glycogen storage from an accumulation of glycogen in the lysosomes of muscle and other tissue cells. The usual pathways of glycogen degradation are preserved. However, deficiency of α-glucosidase (GAA) enzyme is responsible for the abnormality in glycogen metabolism. The infantile form, **Pompe disease**, is often recognized shortly after birth because of the presence of hypotonia, respiratory weakness, dysreflexia, and physiologic abnormalities such as cardiomegaly, an enlarged tongue, and hepatomegaly. The adult form tends to be less severe than the infantile form. Hypertrophy of these tissues is thought to be the result of glycogen deposition. Diagnosis of Pompe disease can be made through the evaluation of GAA activity in blood or through muscle biopsy. Previously, children with Pompe disease often died of cardiac or respiratory failure before age 2; now enzyme replacement therapy (ERT) with recombinant human acid GAA and

physical therapy has shown a significant improvement in symptom presentation.

Myoadenylate deaminase deficiency

Myoadenylate deaminase deficiency (MDD), also referred to as *adenosine monophosphate deaminase deficiency*, is a fairly common, autosomal recessive, enzyme deficiency that causes changes in skeletal muscles and is associated with exercise intolerance accompanied by muscle pain and cramps, although the majority of individuals are asymptomatic. Because these individuals lack myoadenylate deaminase, they have a poor capacity for sustained energy production. Myoadenylate deaminase is the catalytic enzyme that forms phosphocreatine and ATP during exercise through a metabolic pathway that binds the purine and phosphate molecules that constitute ATP. Persons with MDD differ from those with McArdle disease in that during the ischemic exercise test, lactate production is normal when ATP and phosphocreatine are synthesized. Symptoms range from minimal complaints to exercise-induced muscle pain to rhabdomyolysis. Currently, there are limited reports of successful treatments. Avoidance of rigorous exercise is generally recommended.

Lipid deficiencies

Inherited disorders of lipid metabolism are uncommon but account for severe changes in muscle metabolism. These disorders are caused by abnormalities in the transport and processing of fatty acids for energy. The lipid content of muscle cells consists of free fatty acids, which are oxidized in the mitochondria. These acids require carnitine and the enzyme carnitine palmitoyltransferase (CPT) to transport long-chain fatty acids to the mitochondria. Individuals with CPT deficiency often have mild muscular symptoms but can experience bouts of renal failure caused by rhabdomyolysis. Individuals with a deficiency of carnitine alone have progressive muscle weakness and can experience sudden exacerbations. There are two types of CPT deficiency: CPT I and CPT II deficiency. **CPT I**

deficiency often appears during early childhood and is caused by mutations in the *CPT1A* gene. The gene mutation creates the deficiency of the enzyme CPT IA, which is found in the liver. Individuals with CPT I deficiency are at risk for liver failure, nervous system damage, seizures, coma, and sudden death. They often exhibit hepatomegaly, liver dysfunction, and elevated blood levels of carnitine. Carnitine is a natural substance acquired mostly from diet and is used by cells to process fats and produce energy. Affected individuals usually have hypoglycemia and a low level of ketones, which are produced from the breakdown of fats and used for energy. Viral infections or periods of fasting can trigger problems with CPT I deficiency, and the disorder is sometimes mistaken for Reye syndrome. Most cases of Reye syndrome are associated with the use of aspirin during viral infections. There are three main types of **CPT II deficiency:** a lethal neonatal form, a severe infantile hepatocardiomuscular form, and a myopathic form.[103] These three types are discussed in Table 44.11. Treatments with riboflavin, medium-chain triglycerides, oral carnitine, prednisone, and propranolol are proposed.

Table 44.11

Types of Carnitine Palmitoyltransferase II Deficiency

Lethal Neonatal Form	Becomes apparent soon after birth
	Respiratory failure, seizures, liver failure, cardiomyopathy and dysrhythmia develop
	Affected infants have hypoglycemia and low level of ketones (hypoketotic hypoglycemia)
	The brain and kidneys may be abnormal
	Infants usually live a few days to few a few months
Severe Infantile Hepatocardiomuscular Form	Affects the liver, heart and muscles
	Clinical manifestations usually appear within the first year of life
	Involves recurring episodes of hypoketotic hypoglycemia, seizures, hepatomegaly, cardiomegaly, and dysrhythmia
	Problems can be triggered by fasting or viral infections and other illnesses
	Affected infants may have liver failure, nervous system damage, coma, and sudden death
Myopathic Form	First episodes usually occur during childhood or adolescence

	Most affected individuals do not have clinical manifestations between episodes
	Include recurrent episodes of myalgia and weakness, and rhabdomyolysis
	Destruction of muscle causes the release of myoglobin by the kidneys, causing myoglobinuria
	Myoglobin causes urine to be red or brown
	Kidney failure may develop
	Myalgia and rhabdomyolysis may be triggered by exercise, stress, exposure to extreme temperatures, infections, or fasting

Lethal Neonatal Form	Becomes apparent soon after birth
	Respiratory failure, seizures, liver failure, cardiomyopathy and dysrhythmia develop
	Affected infants have hypoglycemia and low level of ketones (hypoketotic hypoglycemia)
	The brain and kidneys may be abnormal
	Infants usually live a few days to few a few months
Severe Infantile Hepatocardiomuscular Form	Affects the liver, heart and muscles
	Clinical manifestations usually appear within the first year of life
	Involves recurring episodes of hypoketotic hypoglycemia, seizures, hepatomegaly, cardiomegaly, and dysrhythmia
	Problems can be triggered by fasting or viral infections and other illnesses
	Affected infants may have liver failure, nervous system damage, coma, and sudden death
Myopathic Form	First episodes usually occur during childhood or adolescence
	Most affected individuals do not have clinical manifestations between episodes
	Include recurrent episodes of myalgia and weakness, and rhabdomyolysis
	Destruction of muscle causes the release of myoglobin by the kidneys, causing myoglobinuria
	Myoglobin causes urine to be red or brown
	Kidney failure may develop
	Myalgia and rhabdomyolysis may be triggered by exercise, stress, exposure to extreme temperatures, infections, or fasting

Carnitine Palmitoyltransferase I Deficiency. Bethesda, MD: Author; 2018.

Inflammatory Muscle Diseases: Myositis

Viral, Bacterial, and Parasitic Myositis

Viral, bacterial, and parasitic infections of varying severity are known to produce inflammatory changes in skeletal muscle, a group of conditions collectively described by the term **myositis**. In tuberculosis and sarcoidosis, chronic inflammatory changes and granulomata are found in muscle as well as in other affected tissues. In the parasitic infection trichinellosis, *Trichinella* larvae reside in the muscles of infected animals, such as pigs, horses, and other wildlife, including cougars and black bears. After ingestion, the parasites migrate to the intestinal mucosa and from there to the lymphatic and circulatory systems.

Initial symptoms occur 1 to 2 days after consumption of infected meat and present as gastrointestinal distress (e.g., nausea, diarrhea, vomiting, abdominal pain). The more traditional trichinellosis symptoms generally occur 2 to 8 weeks after ingestion and include muscle pain and stiffness, fever, rash, itching, and headaches. Treatment includes administration of corticosteroids, such as prednisone, and anti-parasitic agents, such as albendazole. Mebendazole also may be used, though it is not available in the United States. Toxoplasmosis, a common parasitic infection, also is associated with a generalized polymyositis (PM) that responds rapidly to therapy.

In the tropics, more prevalent disorders include bacterial infections with *S. aureus* and parasites such as cysticercus, the larva of the tapeworm *Taenia solium*. Viral infections can be associated with an acute myositis. Muscle pain, tenderness, signs of inflammation, and elevation of CK are common manifestations of viral myositis. The self-limiting symptoms of muscle aches and pains

during a bout of influenza may actually be a subacute form of viral myopathy.

Polymyositis, Dermatomyositis, and Inclusion Body Myositis

Idiopathic inflammatory myopathy (IIM) is a group of autoimmune disorders that typically target skeletal muscles, though cutaneous manifestations have been documented in 50% to 60% of individuals. IIMs are characterized by symmetrical proximal muscle weakness (hip and neck flexors and shoulder girdle) and myalgia that develops over weeks to months. The four principal types are PM, dermatomyositis (DM), necrotizing myopathy (NM), and inclusion-body myositis (IBM). PM and DM involve weakness of muscles such as the hips, thighs, upper arms, and neck. Although DM and PM have similar symptoms, DM is distinguished by a reddish or purplish rash on the eyelids (Fig. 44.37), elbows, knees, or knuckles. Sometimes, abnormal calcium deposits form hard bumps found under the skin (calcinosis). Inclusion body myositis involves the muscles mostly of the wrists, fingers, and the front of the thigh. Affected individuals may stumble while walking and have difficulty with grasping items. The incidence of IIM appears to be increasing, but this may simply reflect improved diagnosis. With an incidence of 5 to 22 per 100,000, it is more prevalent in nonwhite women older than age 50. The specific cause of the disorder is unknown and is thought to arise from both genetic and environmental factors. Most cases are sporadic; however, some individuals with IIM have close relatives with autoimmune disorders.

FIG. 44.37 Dermatomyositis.
Heliotrope (violaceous) discoloration around the eyes and periorbital edema. (From Habif TP. *Clinical dermatology*, 3rd edition. St. Louis: Mosby; 1996.)

Acute clinical manifestations include many of those seen in any inflammatory process: malaise, fever, muscle swelling, pain and tenderness, lethargy, and listlessness. In adults, weakness of the shoulder and pelvic girdle muscles is a primary manifestation of PM. Both PM and DM often are associated with symmetrical proximal muscle weakness and initially can be confused with other myopathies. A thorough evaluation is required to exclude other disorders. Clinical features common to both are dysphagia, reduced esophageal motility, vasculitis, Raynaud phenomenon, cardiomyopathy, and interstitial pulmonary fibrosis. Some individuals have other coexisting collagen vascular disorders, such as RA, SLE, and progressive systemic sclerosis (formerly called *scleroderma*).

Although PM and DM have similar histories of onset, DM includes cutaneous manifestations. The two most classic signs of skin involvement are (1) a heliotrope (reddish purple) rash that generally covers the eyelids and periorbital area (see Fig. 44.37) and often includes the chest; and (2) erythematous, scaly lesions (Gottron lesions) that cover joints, such as the knees and elbows. DM is slightly more common in children and older adults, with onset

before age 15 or after age 50. The adult with DM occasionally has underlying malignancies.

Additional differences between PM and DM exist. Muscle biopsy and histopathologic studies of IBM show degenerative changes of muscle, accumulation of multiple proteins within muscle fibers, and evidence of endoplasmic reticular stress with misfolding of proteins. Clinically, IBM may show weakness of the wrist and finger flexors as well as asymmetrical atrophy and quadriceps weakness. Additionally, IBM does not respond to standard pharmacologic treatment of immunosuppressants and immune-modifying agents.

The two approaches for treatment of myositis are medical treatment and lifestyle changes. Medical treatment primarily includes pharmacologic immunosuppression, although the evidence surrounding the effectiveness of this treatment is not robust. The use of pulsed intravenous glucocorticoids is followed by a 4-week oral regimen, concluding with a tapering of medication. High-dose intravenous immunoglobulin (IVIg) administration is sometimes used during active disease. Successful treatment with IVIg, azathioprine, methotrexate, mycophenolate mofetil, and cyclosporine has been reported. Lifestyle factors include exercise, rest, nutrition, and reduction of stress.

Myopathy

Myopathy is the term applied to a primary muscle disorder. Many pathologic processes affect muscles and cause loss of functional muscle cells. Myopathies affect muscle strength, tone, and bulk. Primary muscle disease is associated with marked weakness. The distribution of the weakness in myopathy is usually symmetrical and proximal, although occasionally the weakness is predominantly distal, such as in myotonic dystrophy. The weakness is associated with mild fatigue. Muscle tone is decreased, as are the tendon reflexes. Atrophy may be present. Some myopathies are associated with muscle hypertrophy as in cretinism and the familial progressive muscular dystrophies of childhood. Fasciculations are not present with myopathy because no denervation is present. No sensory

changes are found. (Specific neurologic-associated myopathies are discussed in Chapter 17.)

Toxic Myopathies

Several agents, including corticosteroids, chloroquine, alcohol, phenytoin, azathioprine, organophosphates, and reverse transcriptase inhibitors have been shown to cause muscle damage known as **toxic myopathy**. Other contributing agents may include lipid-lowering agents and opioids, such as heroin (Box 44.8).

Box 44.8

Agents That Can Cause Toxic Myopathy

Drug Induced

Alcohol
Amiodarone (and others that inhibit CYP3A4 when combined with a statin)
Amphotericin B
AZT (zidovudine)
Azathioprine
Chloroquine
Clofibrate
Cocaine
Colchicine
Ethanol
Ipecac (withdrawn from U.S. markets)
3,4-Methylenedioxymethamphetamine (MDMA, "ecstasy")
Pentachlorophenol (PCP)
Statins
Steroids (especially with prolonged high doses; doses >25 mg/day; fluorinated steroids)

Endocrine Disorders

Adrenal disorders (Addison disease, Cushing disease)
Hyperparathyroidism
Hyperthyroidism (creatine kinase may be normal)
Hypothyroidism (creatine kinase may be mildly elevated)

Infectious disorders

Coxsackie A and B viruses
Human immunodeficiency virus (HIV)
Influenza
Lyme disease
Staphylococcus aureus muscle infection (frequent cause of pyomyositis)
Toxoplasmosis
Trichinosis

Miscellaneous

Licorice
Certain edible wild mushrooms
Lead poisoning
Organophosphates
Red yeast rice
European migratory quail (quail eat toxic hemlock, hellebore seeds)
Any medication that alters serum concentrations of sodium, potassium, calcium, phosphorus, or magnesium

Data from Kuncl RW. Agents and mechanisms of toxic myopathy. *Current Opinion in Neurology*, 2009;22(5):506–515; Valiyil R, Christopher-Stine L. Drug-related myopathies of which the clinician should be aware. *Current Rheumatology Reports*, 2010;12(3):213–220.

Alcohol, specifically, has been attributed to myopathies since the mid-nineteenth century and is associated with approximately 50% of skeletal muscle myopathies. Alcoholic toxic myopathies may have

either an acute or a chronic presentation. An acute alcoholic toxic myopathy presents with muscle weakness, pain, and swelling after a large consumption of alcohol. A chronic alcoholic toxic myopathy is characterized by a progressive proximal weakness associated with long-term consumption of alcohol. The mechanisms by which alcohol affects the muscle include increasing the rate of proteolysis and amino acid oxidation and causing impaired cellular metabolism, gene dysregulation, and premature initiation of apoptosis.

Acute alcoholic myopathy can range from benign cramps and pain that resolves in a matter of hours to severe weakness and a markedly increased CK level associated with myoglobinuria and renal failure. Individuals are prone to repeated attacks after recovery. The first-line treatment remains abstinence from alcohol and improved nutrition. The individual with chronic alcoholic myopathy often has coexisting peripheral neuropathy that complicates the diagnosis.

Repeated intramuscular injections also have been associated with changes in muscle fibers. Local necrosis of muscle fiber and elevated CK concentration has been reported after intramuscular injections of certain cephalosporins, lidocaine, diazepam, and digoxin; these effects were not produced with injections of saline. When drugs are injected over long periods, a chronic focal myopathy develops. Proliferation of connective tissue both in the muscle fiber and in the overlying skin and subcutaneous tissue has been reported. Over time, segments of the muscles, particularly the deltoid and quadriceps, are converted into fibrotic bands. Pathophysiologic mechanisms for these changes include repeated needle trauma and infection, along with the nonphysiologic acidity and alkalinity of the injected material (see Box 44.8 for a list of some of the causes of toxic myopathy).

Muscle Tumors

Rhabdomyoma

Rhabdomyoma is an extremely rare benign tumor of striated muscle that generally occurs in the tongue, neck muscles, larynx, uvula,

nasal cavity, axilla, vulva, and heart. These tumors are usually treated by surgical excision and typically do not recur. When malignant, these tumors are called *rhabdomyosarcomas* (RMS).

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is a rare malignant tumor of striated muscle, which is a subgroup of sarcoma. It is the most common soft tissue sarcoma in children and adolescents, constituting 50% of all soft tissue sarcomas and 10% of all malignant tumors occurring in children. These tumors are highly malignant and metastasize rapidly. RMSs are located in the muscle tissue of the head, neck, and genitourinary tract in 75% of cases, with the remaining 25% found in the trunk, extremities, and urinary tract.

Three types of RMS are differentiated on pathologic section: pleomorphic, embryonal, and alveolar. Each type differs from the other molecularly; they are all aggressive tumors and are typically more resistant to therapy. The pleomorphic, or spindle cell, type is considered to be one of the most highly malignant tumors of the extremities seen in adulthood but has a better outcome in children. Embryonal tumors are most commonly seen in children and appear on biopsy to resemble the shape of a tadpole or tennis racquet. Alveolar-type tumors, which appear latticelike, resemble alveolar lung tissue. They are more often found in adolescents and adults and are associated with the poorest outcomes.

The diagnosis and staging of RMS are made by the history, physical examination, serologic testing, CT, and MRI. Diagnosis is confirmed by incisional biopsy with surgical resection and by examination of the specimen by a pathologist. Staging is based on the site of origin, residual disease, lymph node involvement, and distant metastases. This information allows a diagnosis of RMS to be classified into one of the following four different groups: group I, completely resected without lymph node involvement; group II, localized disease with or without complete resection, or microscopic residual disease with or without lymph node involvement; group III,

localized gross residual disease; and group IV, distant metastases. This staging is then helpful in determining prognosis and treatment.

Treatment consists of a combination of surgical excision, systemic chemotherapy, and adjunct radiation therapy. The overall survival of childhood RMS has improved over the past decades, but adult survival remains poor.

Other Tumors

Metastatic tumors in muscles are rare in spite of the extensive vascular supply of skeletal muscles. It is suggested that local pH or metabolic changes within muscles prevent metastatic involvement from other tumors. When adjacent carcinomas do cause muscle damage, it is usually related to the compression of tissue and resultant muscle atrophy.

Emerging Science Box

Invasive Therapies to Treat Musculoskeletal Conditions

The use of minimally invasive therapies to treat various musculoskeletal conditions continues to expand. This includes consolidation of skeletal tumors, palliation of painful skeletal lesions, and the treatment of symptomatic soft tissue lesions. The decision to treat individuals with percutaneous ablation is made through a team approach including radiologist, oncologist, and orthopedic/neurologic surgery. Through the use of PET, CT, MRI, and ultrasound, the individual is evaluated for optimal treatment planning. The structural characteristics of the tumor are evaluated and measured, the surrounding structures are mapped, and the metabolic characteristics determined. This allows for a more patient-specific treatment plan. Individuals may require either procedural sedation or general anesthesia depending on the extent of treatment and provider preference. Ablation options include cryoablation, radiofrequency ablation, and microwave ablation.

Cryoablation utilizes a repeated freeze-thaw cycle while radiofrequency ablation uses high-frequency alternating current to cause ionic agitation and frictional heating in tissue. Microwave ablation uses alternating electromagnetic fields to cause oscillation of water molecules in tissue, generating cytotoxic temperatures independent of tissue conductivity. All result in targeted cellular destruction of tumor cells. As these techniques continue to be developed and specialized, persons with musculoskeletal tumors have additional treatment options available to them.

Data from Parvinian A, et al. Trends in musculoskeletal ablation: emerging indications and techniques. *Techniques in Vascular and Interventional Radiology*, 23(2):100678, 2020; Kurup AN, et al. Summary Review

Musculoskeletal Injuries

1. The most common skeletal injury is a fracture. A bone can be completely or incompletely fractured. A closed fracture leaves the skin intact. An open fracture has an overlying skin wound. The direction of the fracture line can be linear, oblique, spiral, or transverse. Greenstick, torus, and bowing fractures are examples of incomplete fractures that occur in children. Stress fractures occur in normal or abnormal bone that is subjected to repeated stress. Fatigue fractures occur in normal bone subjected to abnormal stress. Normal weightbearing can cause an insufficiency fracture in abnormal bone.
2. Dislocation is complete loss of contact between the surfaces of two bones. Subluxation is partial loss of contact between two bones. As a bone separates from a joint, it may damage

adjacent nerves, blood vessels, ligaments, tendons, and muscle.

3. Tendon tears are called *strains*, and ligament tears are called *sprains*. A complete separation of a tendon or ligament from its attachment is called an *avulsion*.
4. Epicondylopathy is degeneration of a tendon where it attaches to a bone. Bursitis is inflammation of the bursae (small sacs lined with synovial membrane and filled with synovial fluid). Bursitis can be inflammatory, septic, or hemorrhagic.
5. Muscle strain can range from mild injury to severe damage that can result in loss of muscle function.
6. Rhabdomyolysis can be a life-threatening complication of severe muscle trauma wherein muscle cell contents are released into the circulation. It may result in myoglobinuria, the presence of myoglobin in the urine, and is often associated with acute renal failure.
7. Compartment syndrome is the result of increased pressure within a closed osteofascial compartment resulting in impaired circulation. These skeletal muscle compartments are surrounded by several layers of fibrous fascia which are not able to expand. After fractures, the most common cause is soft tissue injuries.
8. Malignant hyperthermia (MJ) is a potentially life-threatening hereditary musculoskeletal disorder characterized by a hypermetabolic reaction to certain volatile anesthetics or certain depolarizing muscle relaxants (e.g., succinylcholine). Rarely is MH related to exercise and heat exposure.

Disorders of Bones

1. Osteoporosis is defined as low bone mineral density caused by altered bone microstructure and leads to an increased risk of fractures. It is a complex, multifactorial, chronic disease that often progresses silently causing decreased bone strength. Bone tissue can be normally mineralized in osteoporosis, but

the density of bone is decreased and the structural integrity of trabecular bone is impaired.

2. In osteoporosis, old bone is being resorbed faster than new bone is being formed, causing the bones to lose density, becoming thinner and more porous. Postmenopausal osteoporosis results from estrogen deficiency. Estrogen stimulates osteoprotegerin (OPG) secretion and down-regulates RANKL; RANKL expression is increased when estrogen levels are decreased, leading to increased formation of osteoclasts while reducing osteoclast apoptosis.
3. Glucocorticoid-induced osteoporosis (e.g., prednisone, cortisone) is the most common type of secondary osteoporosis and is characterized by increased bone resorption and decreased bone formation. Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts, thus leading to lower bone density.
4. Osteomalacia is a metabolic bone disease characterized by inadequate bone mineralization.
5. Excessive and abnormal bone remodeling occurs in Paget disease. Sporadic Paget disease involves overexpression of RANKL.
6. Osteomyelitis is a bone infection caused most often by bacteria (e.g., *S. aureus*) that can enter bone from outside the body (exogenous osteomyelitis) or from infection sites within the body (hematogenous osteomyelitis).
7. Bone tumors originate from bone cells, cartilage cells, fibrous tissue cells, or vascular marrow cells. Each cell produces a specific type of ground substance that is used to classify the tumor as osteogenic (bone cell), chondrogenic (cartilage cell), collagenic (fibrous tissue cell), or myelogenic (vascular marrow cell). Malignant bone tumors are large, aggressively destroy surrounding bone, invade surrounding tissue, and initiate independent growth outside the site of origin. Benign bone tumors are less destructive, limit their growth to the anatomic confines of the bone, and have a well-demarcated border.

Disorders of Joints

1. Two major categories of joint diseases are noninflammatory and inflammatory joint disease. Osteoarthritis (OA) is the most common joint disease.
2. OA is an inflammatory joint disease and is characterized by pathologic changes in cartilage, bone, synovium, ligament, muscle, and periarticular fat. OA is commonly found in the knees, and less so in hips, hands, and spine. Hip and knee OA are highly prevalent and disabling.
3. The primary defect in OA is degeneration and eventual loss and disordered repair of articular cartilage. The chondrocytes of the articular cartilage become damaged early in the disease process because of biomechanical stress, as well as genetic and biochemical factors.
4. Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory autoimmune disease distinguished by joint swelling, tenderness, and destruction of synovial joints leading to disability. RA is initiated by $CD4^+$ helper T cells. The pathologic changes are mediated by antibodies against self-antigens, such as anti-citrullinated peptide antibodies (ACPAs) detected in the serum of up to 70% of those with RA. $CD4^+$ T cells promote inflammation. RA is a systemic disease that affects other organs, as well as the joints.
5. AS is a chronic inflammatory joint disease of the axial spine. AS is characterized by stiffening and fusion (ankylosis) of the spine sacroiliac joints, peripheral joints, digits, and entheses, and dactylitis. The most common features of AS are chronic back pain and progressive spinal stiffness. The hallmark is enthesitis with chronic inflammation, including CD4 and CD8 T lymphocytes and macrophages.
6. Gout is a systemic disease of uric acid disturbance that results from the deposition of monosodium urate crystals (MSU) in tissues. In the United States, gout is the most prevalent etiology of chronic inflammatory arthritis. Gout develops in

stages. Most people with hyperuricemia do not develop gout. For gout to develop it requires the deposition of MSU crystals. Altered urate transport, both in the gut and the kidneys, is central in the pathogenesis of hyperuricemia and gout. Identification of urate transporter genes are strongly correlated with urate levels.

Disorders of Skeletal Muscle

1. A pathologic contracture is permanent muscle shortening caused by muscle spasticity, as seen in CNS injury or severe muscle weakness.
2. Stress-induced muscle tension is presumably caused by increased activity in the reticular activating system and gamma loop in the muscle fiber. Progressive relaxation training and biofeedback have been advocated to reduce muscle tension.
3. Fibromyalgia (FM) is a chronic musculoskeletal syndrome characterized by chronic widespread pain (CWP) primarily (but not only) from the musculoskeletal system. Other most frequent symptoms include fatigue and sleep disturbances. Several factors, uniquely, contribute to the development of FM: genetic predisposition, personal experiences, emotional-cognitive factors, the mind-body relationship, and a biopsychological ability to cope with stress. One hypothesis for pathophysiology involves nociplastic pain or pain arising from altered nociception, despite no evidence of tissue damage. This type of pain conforms to FM as a part of *central sensitivity syndromes*. FM is becoming known as a disorder of pain regulation often classified under central sensitization.
4. Chronic fatigue syndrome (CFS), also known as myalgic encephalomyelitis (ME), is a disabling clinical condition characterized by unexplained and persistent post-exertional fatigue and symptoms related to cognitive, immunological, endocrinological, and autonomic dysfunction. The cause of

CFS/ME is hypothesized to include immunologic alterations, chronic proinflammatory cytokines, autoantibodies, neuroinflammation, central nervous system disruptions, hypercortisolism, and genetic predisposition.

5. Atrophy of muscle fibers and overall diminished size of the muscle are seen after prolonged inactivity. Isometric contractions and passive lengthening exercises decrease atrophy to some degree in immobilized persons.
6. Hyperexcitable membranes cause the physical and electrical phenomenon of myotonia. The disorder is treated with drugs that reduce fiber excitability. Periodic paralysis is caused by an unresponsive muscle membrane and is accompanied by changes in the level of serum potassium. The biochemical defect is possibly related to changes in the muscle membrane and sarcoplasmic reticulum.
7. Metabolic muscle diseases are caused by endocrine disorders, glycogen storage disease, enzyme deficiencies, and abnormal lipid function. The muscle depends on a complex system of carbohydrates and fats converted by enzymes to produce energy for the muscle cell. Abnormalities in these pathways can inhibit function or cause damage to the muscle fiber. These illnesses are rare, yet they account for significant functional abnormalities.
8. Viral, bacterial, and parasitic infections of muscles produce the characteristic clinical and pathologic changes associated with inflammation. These are usually treatable and self-limiting disorders.
9. Polymyositis (generalized muscle inflammation) and dermatomyositis (polymyositis accompanied with skin rash) are characterized by inflammation of connective tissue and muscle fibers, and muscle fiber necrosis. Cell-mediated and humoral immune factors have been implicated. Treatment with immunosuppressive agents is effective in many cases.
10. Primary disorders with weakness and atrophy are known as *myopathies*.

11. The most common toxic myopathy is caused by alcohol abuse. Direct toxic effects of alcohol-producing necrosis of muscle fibers and nutritional deficiency have been identified. The most effective treatment is abstinence and improved nutrition. The toxic effects of many drugs on muscle fibers cause local trauma to the muscle fibers from direct effects of the needle, secondary infection, and changes caused by nonphysiologic acidity and alkalinity in the fibers.
12. Sarcomas of muscle tissue are rare. Rhabdomyosarcoma is a rare malignant tumor of striated muscle. It has aggressive invasion and early, widespread dissemination.

Musculoskeletal Tumors in Children 1495
- Bone Tumors 1495
- Muscle Tumors 1497

Nonaccidental Trauma 1498
- Fractures in Nonaccidental Trauma 1498

Musculoskeletal alterations in children can be either congenital or acquired. Both pathology and treatment can cause long-term sequelae because of the growing nature of the immature skeleton. Some disorders are acute and the child can recover completely, other disorders are chronic, and some cases are terminal. The emotional trauma of an injured or malformed child is substantial and requires that careful attention be paid to both the child and family.

Musculoskeletal Development In Children

Bone Formation

Bone formation begins at about the sixth week of gestation. It involves two phases: (1) the delivery of bone cell precursors to sites of bone formation and (2) the aggregation of these cells at **primary centers of ossification**, where they mature and begin to secrete osteoid (see Chapter 44). Some of the bone cell

precursors are present in fetal connective tissues, whereas others migrate in blood to sites of bone formation after blood vessels have grown into the tissue.

Cellular aggregation and maturation occur in two types of fetal tissue, depending on which bones are being formed. The cranium, facial bones, clavicles, and part of the jawbone (classically called *flat bones*) arise from a fetal membrane termed the *mesenchyme*. Bones that develop on or within the mesenchyme grow by the process of **intramembranous formation of bone**. As the mesenchyme becomes vascularized, the immature bone cells aggregate and mature into osteoblasts that form the centers of ossification and create solid bone or osteoid.

Endochondral formation of bone is the development of new bone from cartilage (Fig. 45.1). First, mesenchymal tissue forms a **cartilage anlage**, which defines the shape of the bone. This is usually found by 6 weeks' gestation. Blood vessel invasion inside the anlage brings osteoprogenitor cells leading to primary centers of calcification by 8 weeks. Endochondral bone formation begins in the outer layer of the cartilage model, which consists of a layer of dense connective tissue call **perichondrium**. The perichondrium contains cells that develop into osteoblasts, forming a collar of bone, termed the **periosteal collar**, around the cartilage model. Cartilage enclosed within the periosteal collar degenerates, and capillaries from outside the perichondrium invade the degenerating cartilage cells, carrying with them osteoblast precursors from the inner layer of the perichondrium and osteoclast precursors from the blood itself.

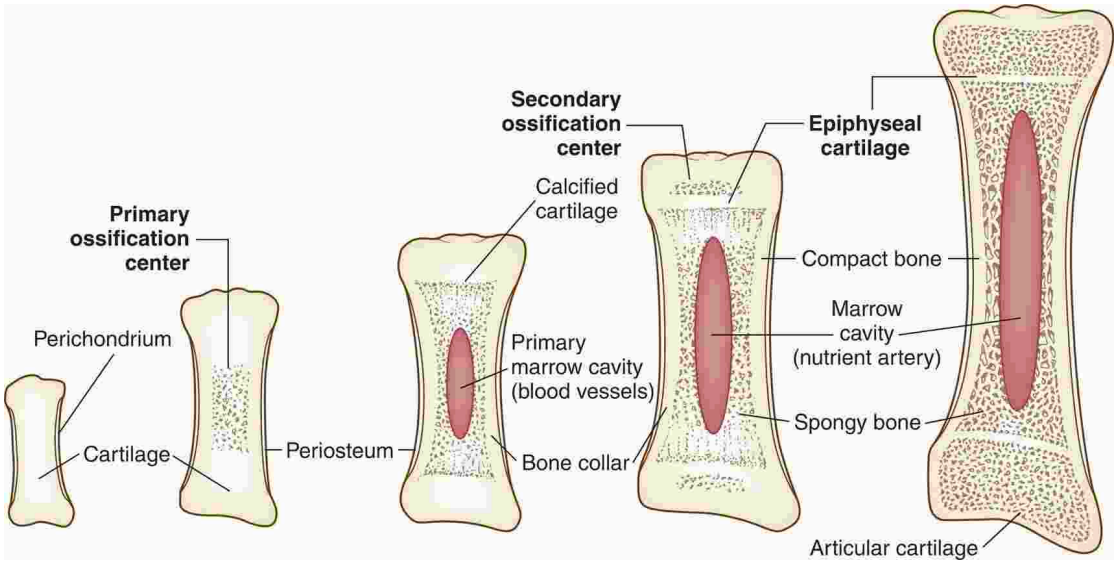

FIG. 45.1 Stages of Endochondral Bone Formation and Centers of Ossification in Long Bones.

A series of illustrations depict the longitudinal section of the long bone showing the various stage of endochondral ossification with labels. The first illustration indicates the perichondrium and cartilage. The second illustration indicates the primary ossification center, perichondrium, cartilage, and periosteum. The third illustration indicates the calcified cartilage, primary marrow cavity or blood vessels, and bone collar. The fourth illustration indicates the secondary ossification center, epiphyseal cartilage, compact bone, marrow cavity or nutrient artery, spongy bone and bone collar. The fifth illustration indicates the epiphyseal cartilage, compact bone, marrow cavity or nutrient artery, spongy bone and articular cartilage

Endochondral bone formation progresses at the primary center of ossification in the middle of the cartilage model and extends toward either end of the developing bone. At the same time, the periosteal collar thickens and becomes wider toward the epiphyses. By the end of gestation, **secondary centers of ossification** (the epiphyseal centers) begin to lay down bone at both ends of the cartilage model. Here, too, the cartilage within the periosteal collar degenerates, and blood vessels grow inward, delivering bone cell precursors. Once the osteoblasts begin to secrete osteoid, ossification spreads from the secondary centers in all directions until all the cartilage within the model is replaced by bone.

Two regions of cartilage remain at the ends of long bones: (1) articular cartilage over the free ends of the bone and (2) the physeal plate, a layer of cartilage between the metaphysis and epiphysis (see Chapter 44). The physeal plate retains the ability to form and calcify new cartilage and deposit bone until the skeleton matures approximately 1 year after sexual maturity (age 11 to 15 years in females; age 15 to 18 years in males).

Bone Growth

Until adult stature is reached, growth in the length of long bones occurs at the physeal plate through endochondral ossification. Cartilage cells at the epiphyseal side of the physeal plate multiply and enlarge. As rapidly as new cartilage cells form, cartilage cells at the metaphyseal side of the plate are destroyed and replaced by bone.

In the shaft of new bone, where growth is relatively slow, the bone produced by accretion is compact and dense. The compact bone is thickest where it has to withstand the maximal stresses, which generally occur in the middle of the shaft.

The two physes of the long bone have varying activity rates. For example, the distal physis in the femur contributes 80% of the overall length, whereas the proximal physis at the hip contributes only 20%. The more active of the two has more power to remodel deformity but also can be more sensitive to injury. The architecture of the physis also dictates its sensitivity to injury. For example, the distal femur has an undulating pattern that increases its resistance to sheer force; however, when injured, growth disturbance is highly likely. In contrast, the distal radius, which contributes 80% of overall radial length, is a flat, smooth physis that is far more resistant to traumatic injury.

Growth in the diameter of bone occurs by deposition of new bone on an existing bone surface. Bone matrix is laid down by osteoblasts on the periosteal surface and subsequently becomes calcified. At the same time, bone resorption occurs on the endosteal surface. Endosteal resorption increases the diameter of the medullary cavity, which contains marrow and spongy bone.

Many factors affect the development, physiology, and growth rate of the epiphyseal plate. Growth hormone must be secreted by the pituitary gland at a constant rate to stimulate the growth plate consistently. Other known factors affecting growth include peptide regulatory factors (e.g., fibroblast growth factor [FGF]); changes in cell-to-cell interactions through cell adhesion molecules (CAMs) and cell junctions; and complex interactions or changes in the extracellular matrix (ECM), nutrition, general health, and other hormones (e.g., thyroid hormone, adrenal and gonadal androgens, estrogens). When these factors are poorly controlled, skeletal dysplasia, such as achondroplasia, can occur.

Even after physeal closure at skeletal maturity, bone is constantly being destroyed and re-formed (see Chapter 44). This is a rapid process in young children, allowing them to heal bone injury more quickly than adults. However, by adulthood, bone turnover, or remodeling, occurs at a relatively slow rate. Peak bone mass is achieved by the middle to late 20 s and slowly decreases through life; therefore ensuring appropriate intake of calcium and phosphorus, performing weight-bearing exercise, and minimizing caffeine intake are especially important for a young female if she is to avoid osteoporosis in later life. Vitamin D plays an essential role in bone homeostasis in the pediatric population. In children, low levels of vitamin D have been associated with rickets, a higher incidence of fracture, more severe fracture, and hypocalcemia that may present as seizure or tetany.[1–4]

Skeletal Development

The axial skeleton changes shape with growth (see Chapter 44). In a newborn, the entire spine is **kyphosed**. As the infant's ability to control the head progresses in the first 3 months of life, the cervical spine begins to arch. The normal **lordotic** curve of the lumbar spine begins to develop with sitting.

The appendicular skeleton grows faster during childhood than does the axial skeleton. The newborn has a relatively large head and long spine, with disproportionately shorter limbs than an adult. By 1 year of age, 50% of the total growth of the spine has occurred and is more than 70% complete by age 8.[4a] Therefore failure of the spine to grow (spinal fusion) does not limit eventual height as much as the premature fusion of the growth plates of the lower extremities. In children with congenital curvature of the spine, growth tends to worsen the deformity rather than to increase the length of the spine.

Besides getting longer, growing bones of the extremities undergo changes in rotation and alignment. In the newborn, the proximal femur is rotated forward up to 40 degrees and the tibia is rotated inward. The femur assumes its normal alignment by age 12, and tibial rotation neutralizes at 8 years of age.[6] **Genu varum** (bowlegs) and **genu valgum** (knock knees) can be normal at certain stages of growth. At birth, the newborn's legs are bowed because of stresses in utero. Genu varum peaks by 30 months, whereas genu valgum peaks by 5 to 6 years of age. If either persists past these ages, a pathologic process rather than a physiologic phase can be present. Pathologic causes of genu varum are Blount disease, rickets, skeletal dysplasia, traumatic injury, and musculoskeletal infection. Genu valgum may also persist with skeletal dysplasia, genetic predilection, benign musculoskeletal tumor, osteogenesis imperfecta (OI), or after a traumatic injury or infection.

Muscle Growth

The composition and size of muscles vary with age. In the fetus, muscle tissue contains a large amount of water and intercellular matrix. After birth, both are reduced considerably as the muscle fibers enlarge by accumulating cytoplasm. Little information is available about the numbers of fibers in a given muscle at various ages, but the total mass of muscle in the body can be estimated from the amount of creatinine excreted in the urine. The conversion of creatine to creatinine takes place only in muscle (see Chapter 44). Between birth and maturity, the number of muscle nuclei in the body increases 14 times in males and 10 times in females. Muscle fibers reach their maximal size at approximately 10 years of age in females and 14 years of age in males. Growth in length occurs at the ends of muscles, and the increase in length is accompanied by an increase in the number of nuclei in the fibers. Muscle fibers increase in diameter as the fibrils become more numerous. The fibrils themselves do not grow where the tendon and muscle meet.

A potent stimulus to the growth of a muscle is the separation of its attachments as the skeleton grows. The length of a muscle fiber is the direct consequence of its intended range of movement. The stimulus for the formation of a tendon is probably the pull of the muscle rudiment on undifferentiated connective tissue. If the normal opponents of a muscle are paralyzed, the muscle fails to grow properly and can result in contracture of a joint.

Muscle growth during adolescence is a major factor in weight gain. Gender differences in muscle size and weight are minor in childhood but become considerable with the onset of puberty. In the infant, muscle accounts for approximately 25% of total body weight, compared with 40% in the adult. The facial muscles are well developed at birth so that the infant can perform the vital functions of breathing and sucking. Other muscle groups, such as the pelvic muscles, take several years to develop fully.

Musculoskeletal Alterations In Children

Congenital Defects

Syndactyly and Polydactyly

The most common congenital defect of the extremities is **syndactyly**, a condition characterized by webbed or conjoined fingers or toes (Fig. 45.2A). Simple webbing involves the soft tissue envelope alone and is best released surgically when the child is 6 months to 1 year of age. Complex syndactyly involves the fusion of the bones and nails as well as the soft tissues. It may be associated with an anomaly of bony or neurovascular units. Ideally, corrective surgery is deferred until the child is 1 to 2 years old and completed before the child enters school. **Polydactyly**, or supernumerary digits, is another common congenital limb anomaly. Polydactyly occurring on the hand often presents on the ulnar aspect (see Fig. 45.2B). The extra digit can vary greatly in size and shape, some appearing as fully formed digits.[7]

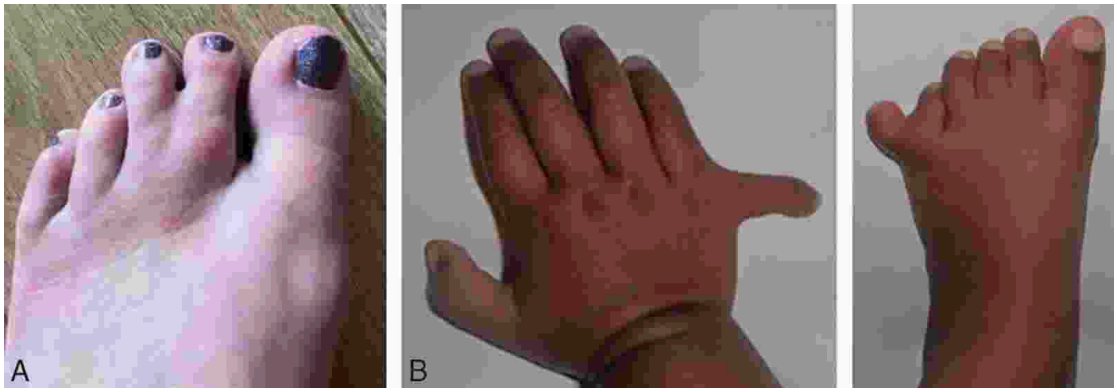

FIG. 45.2 Syndactyly and Polydactyly.
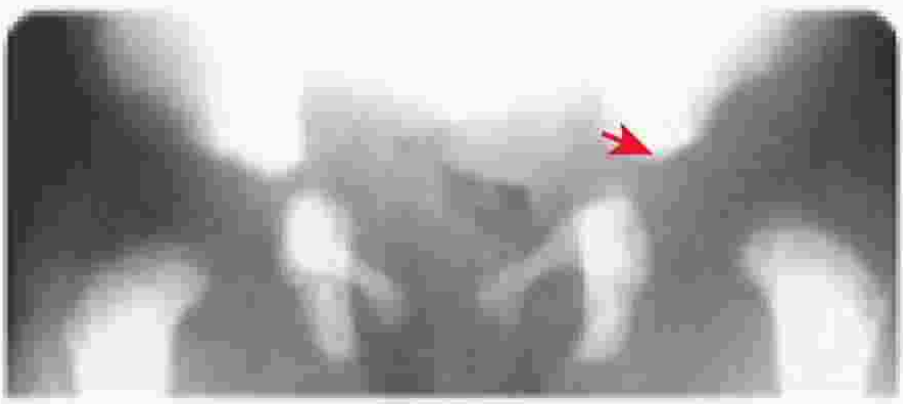
(A) Syndactyly is the fusing together or webbing of two or more fingers or toes. (B) Polydactyly is the presence of extra fingers or toes.

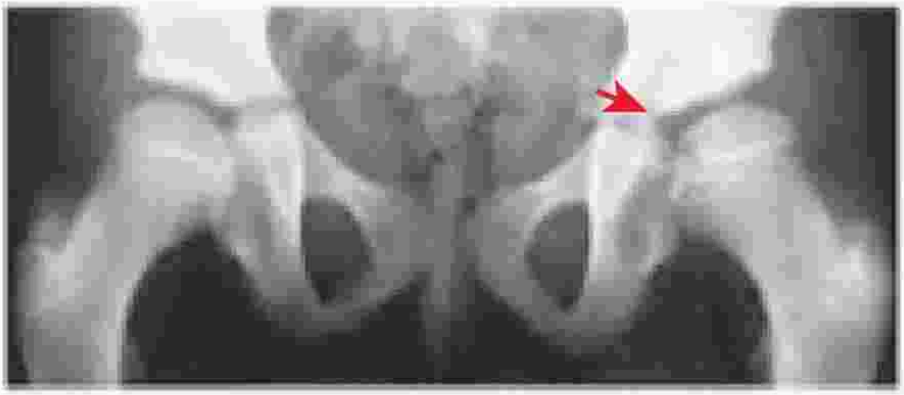
A. Close shot of syndactyly in second and third toes. B. Close shot of an infants hand with an extra digit and radially deviated fifth finger and leg with an extra toe and radially deviated the fifth toe.

Anomalies on the radial aspect of the arm, such as a foreshortened or absent radius, are often associated with abnormalities of blood, heart, or kidney. Lateral or ulnar-sided defects are less often associated with systemic anomalies and are extremely rare.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) is an umbrella term used to describe a spectrum of disorders related to abnormal development of the hip joint that affects the proximal femur, acetabulum, or both (Fig. 45.3). Although most often present congenitally, dysplasia may develop later in the newborn or infant period and can be idiopathic or teratologic. Teratologic hips (i.e., those attributable to another disorder such as cerebral palsy (CP), Down syndrome, spina bifida, or arthrogryposis) are more difficult to treat and often need operative intervention.





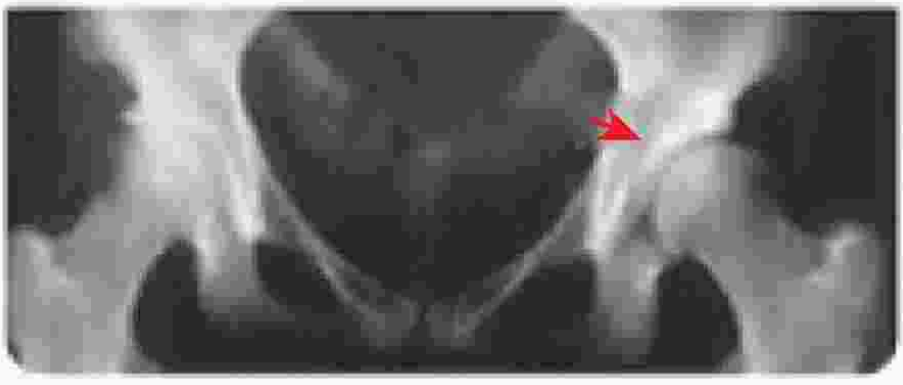


FIG. 45.3 Hip Dysplasia in Children.
Developmental dysplasia of the hip (DDH) with residual acetabular dysplasia *(red arrows)*. Radiographs at birth, 3, 10, and 19 years (top to bottom) show persisting dysphasia.

Pathophysiology

By approximately 10 weeks' gestation, the femur, acetabulum, and hip joint capsule are well developed. It appears that most hip dysplasia develops within the second and third trimesters and is often the result of positioning factors, genetics, or pathology. Risk factors for DDH include family history, female gender, oligohydramnios, first pregnancy, and breech presentation (especially 34 weeks or later gestation). First pregnancies and oligohydramnios (deficient volume of amniotic fluid) are thought to limit fetal movement. Breech presentation not only limits movement but also places the hips in a position of flexion and adduction. This creates a more shallow than normal acetabulum (socket) for the head (ball) of the femur, which results in the head of the femur sliding partially or completely out of the acetabulum.

The hip of DDH can be described as **dislocated** (no contact between the femoral head and acetabulum), **subluxated** (partial contact only, maintains contact with acetabulum but not well seated within the hip joint), and **acetabular dysplasia** (the femoral head is located properly but the acetabulum is shallow or underdeveloped) (Fig. 45.4). Some degree of acetabular dysplasia is present in almost all cases.

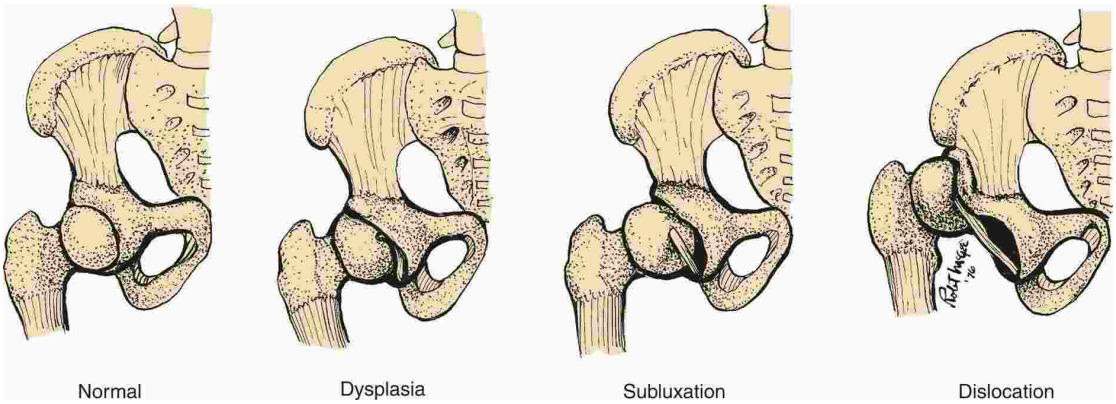

FIG. 45.4 Configuration and Relationship of Structures in Developmental Dysplasia of the Hip. (From Hockenberry MJ, Wilson DL. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

Four illustrations of the ventral view of the left pelvic region depict the configuration of the hip joint in developmental dysplasia. The first illustration depicts the normal hip joint. The second illustration depicts dysplasia. The third illustration depicts the subluxation. The fourth illustration depicts the dislocation.

Clinical Manifestations

The clinical manifestations of DDH will vary with the severity of the condition and the age of the child. Signs and symptoms that should be noted include the following:

1. Asymmetry of gluteal or thigh folds
2. Limb length discrepancy (Galeazzi sign)
3. Limitation of hip abduction
4. Positive Barlow maneuver (hip reduced, but able to be dislocated) (Fig. 45.5A)
5. Positive Ortolani sign (hip dislocated, but reducible) (see Fig. 45.5B)
6. Positive Trendelenburg gait (waddling)
7. Pain (very late)
