
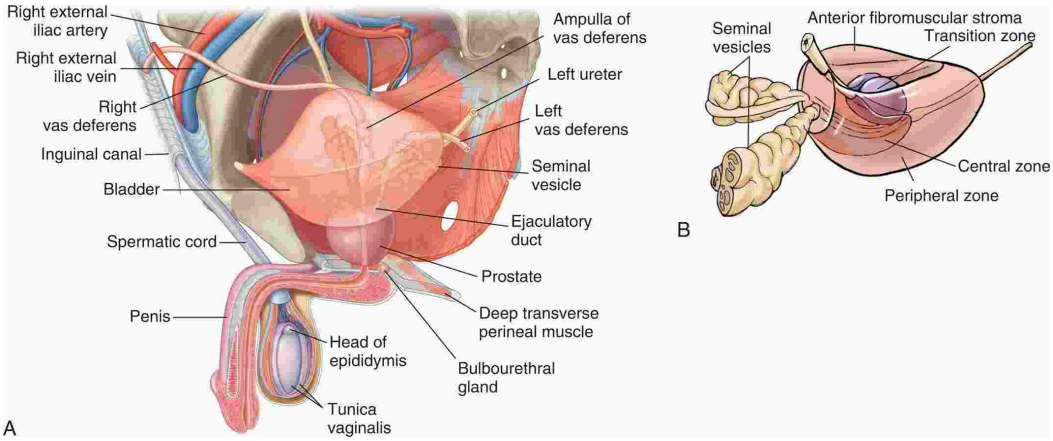

FIG. 24.16 Male Reproductive Ducts, Glands, and Seminal Vesicles. (A) Zones of the prostate. The peripheral zone, accounting for 70% of the prostate gland, is the site of origin of ≤70% of prostate cancers; the central zone, approximately 25% of the prostate gland, gives rise to only 1% to 5% of prostate cancers; and the transition zone, approximately 5% to 10% of the prostate gland, gives rise to 20% of prostate cancers and is the site of origin of benign prostatic hyperplasia (BPH) **(B)**, Glands and ducts within the male reproductive system. (A, From Drake R, et al. *Gray's atlas of anatomy*, 3rd edition. Philadelphia: Elsevier; 2020. B, Copyright Baylor College of Medicine, Houston, TX.)

"Illustration A shows and labels the following structures of the male reproductive organs, clockwise from the top: ampulla of vas deferens, left ureter, left vas deferens, seminal vesicle, ejaculatory duct, prostate, deep transverse perineal muscle, bulbourethral gland, head of epididymis, tunica vaginalis, penis, spermatic cord, bladder, inguinal canal, right vas deferens, right external iliac vein, and right external iliac artery. Illustration B shows and

labels the following structures of the male reproductive organs: anterior fibromuscular stroma, transition zone, central zone, peripheral zone, and seminal vesicles."

Fig. 24.14 shows a sagittal section of a mature testis. The adult testis is oval and varies considerably in length (3 to 6 cm), width (2 to 3.5 cm), depth (3 to 4 cm), and weight (10 to 40 g). The testis is almost entirely surrounded by an outer covering called the tunica vaginalis, which separates the testis from the scrotal wall, and an inner covering called the tunica albuginea. Inward extensions of the tunica albuginea form septa that separate the testis into about 250 compartments, or lobules, each of which contains several tortuously coiled ducts called seminiferous tubules. The seminiferous tubules constitute the bulk (80%) of testicular volume and are the site of sperm production. (Sperm production is described in the Spermatogenesis section.) The tissue surrounding these ducts contains blood and lymphatic vessels, fibroblastic support cells, macrophages, mast cells, andLeydig cells, which occur in clusters and produce androgens, chiefly testosterone.

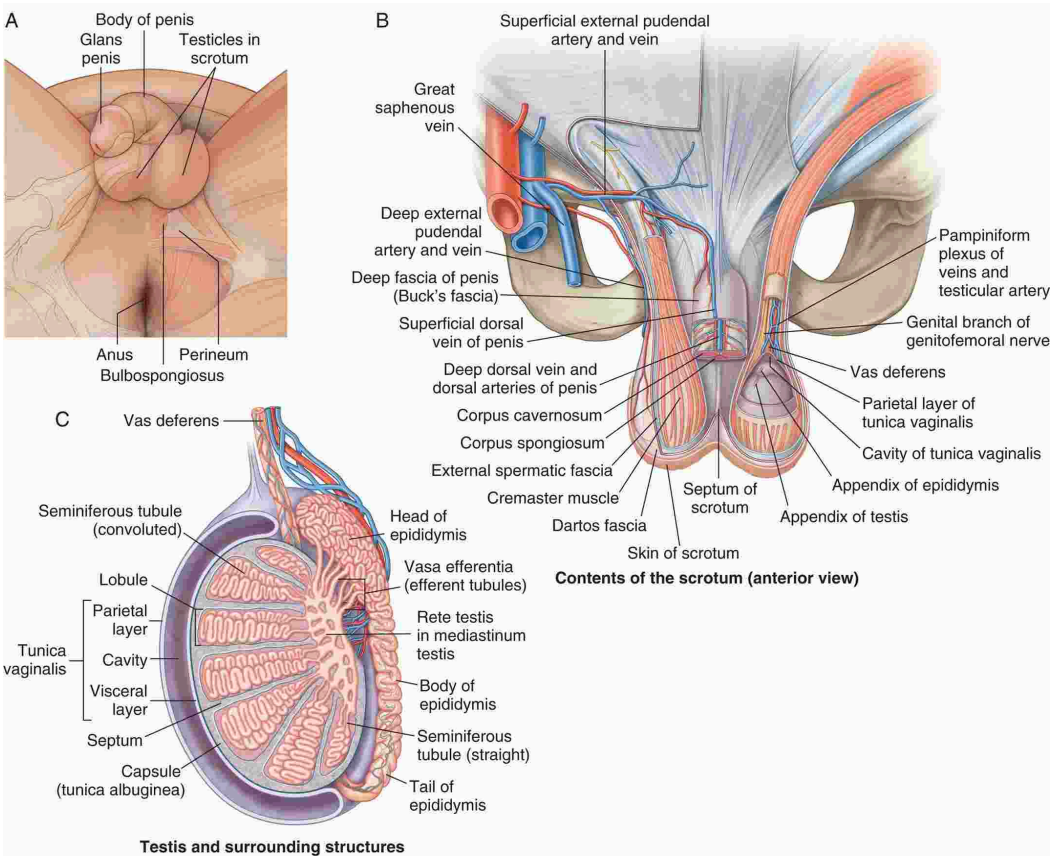

FIG. 24.14 Male Genitalia: (A) External, (B) Internal, and (C) Sagittal Views of the Scrotum and Testes. (Modified from Drake R, Vogl AW, Mitchell A, et al. *Gray's atlas of anatomy*, 3rd edition. Philadelphia: Churchill Livingstone; 2020.)

"Illustration A is an inferior view of the external male genitalia. The following structures on the genitalia are labeled from the top to the bottom: glans penis, body of penis, testicles in scrotum, perineum, bulbospongiosus, and the anus. Illustration B is an anterior view of the male genitalia, with the scrotum. The following structures are labeled, clockwise from the right: pampiniform plexus of veins and testicular artery, genital branch of genitofemoral nerve, vas

deferens, parietal layer of tunica vaginalis, cavity of tunica vaginalis, appendix of epididymis, appendix of testis, septum of scrotum, skin of scrotum, dartos fascia, cremaster muscle, external spermatic fascia, corpus spongiosum, corpus cavernosum, deep dorsal vein and dorsal arteries of penis, superficial dorsal vein of penis, deep fascia of penis (buck's fascia), deep external pudendal artery and vein, great saphenous vein, and superficial external pudendal artery and vein. Illustration C is the sagittal view of the testis and surrounding structures. The following structures on the genitalia are labeled, clockwise from the top: vas deferens, head of epididymis, vasa efferentia (efferent tubules), rete testis in mediastinum testis, body of epididymis, seminiferous tubule (straight), tail of epididymis, capsule (tunica albuginea), septum, tunica vaginalis (parietal layer, cavity, visceral layer), lobule, and seminiferous tubule (convoluted)."

The two ends of each seminiferous tubule join and leave the lobule through the tubulus rectus, which leads to the central portion of the testis, the rete testis. The sperm then move through the efferent tubules, or vasa efferentia, to the epididymis, where they mature.

The testes are innervated by adrenergic fibers whose sole function is to regulate blood flow to the Leydig cells. Arterial blood from the internal spermatic and differential arteries flows over the surface of the testes before entering the parenchyma (functional tissues). Surface flow cools the blood to temperatures to approximately 35°C to 36°C, which promotes spermatogenesis.[15] Additionally, the testes are suspended outside the pelvic cavity to facilitate cooling.

Epididymis

The epididymis (pl., epididymides) is a comma-shaped structure that curves over the posterior portion of each testis (see Fig. 24.14). It consists of a single, densely packed, and markedly coiled duct measuring 5 to 7 cm in length (but about 6 meters in length when uncoiled). The epididymis has structural and physiologic functions. Its structural function is to conduct sperm from the efferent tubules to the vas deferens, whereas physiologic functions include sperm maturation, mobility, and fertility. When sperm enter the head of the epididymis, they are not fully mature or motile, nor can they fertilize an ovum. During the 12 or more days sperm take to travel the length of the epididymis, they receive nutrients and testosterone, and their capacity for fertilization is enhanced.[16] After traveling the length of the epididymis, sperm are stored in the epididymal tail and vas deferens. The vas deferens is a duct with muscular layers capable of powerful peristalsis that transports sperm toward the urethra (see Fig. 24.14). The vas deferens enters the pelvic cavity through the spermatic cord.

Scrotum

The testes, epididymides, and spermatic cord are enclosed and protected by the scrotum, a skin-covered, fibromuscular sac homologous to the female labia majora (see Fig. 24.2). The skin of the scrotum is thin and has rugae (wrinkles or folds), which enable it to enlarge or relax away from the body. At puberty, the scrotal skin darkens, develops active sebaceous glands, and becomes sparsely covered with hair. Just under the skin lies a layer of connective tissue (fascia) and smooth muscle, the tunica dartos (see Fig. 24.14). The tunica dartos also forms a septum that separates the two testes. Exposure to cold temperatures causes the tunica dartos to contract, pulling the testes close to the warm body. In warm temperatures, the tunica dartos relaxes, suspending the testes away from body heat. These mechanisms promote optimal temperatures for spermatogenesis. In addition, scrotal sensitivity to touch, pressure, temperature, and pain protects the testes from potential harm. During sexual excitement, the scrotal skin and tunica thicken, the scrotum tightens and lifts, and the spermatic cords shorten, partially elevating

the testes toward the body. As excitement plateaus, the engorged testes increase 50% in size, rotate anteriorly, and flatten against the body, signaling impending ejaculation.

Penis

The penis has two main functions: delivery of sperm to the female vagina and elimination of urine. Embryonically, the penis is homologous to the female clitoris (see Fig. 24.2).

Fig. 24.12 shows a sagittal section of the adult penis and its anatomic relation to other urogenital structures, and Fig. 24.15 shows a cross section of the shaft of the penis. Internally, the penis consists of the urethra and three compartments or sinusoids: two corpora cavernosa (sing., corpus cavernosum) and the corpus spongiosum separated by Buck fascia. Like the testes, these compartments are enclosed by the fibrous tunica albuginea. The urethra passes through the corpus spongiosum and ends at a sagittal slit in the glans.

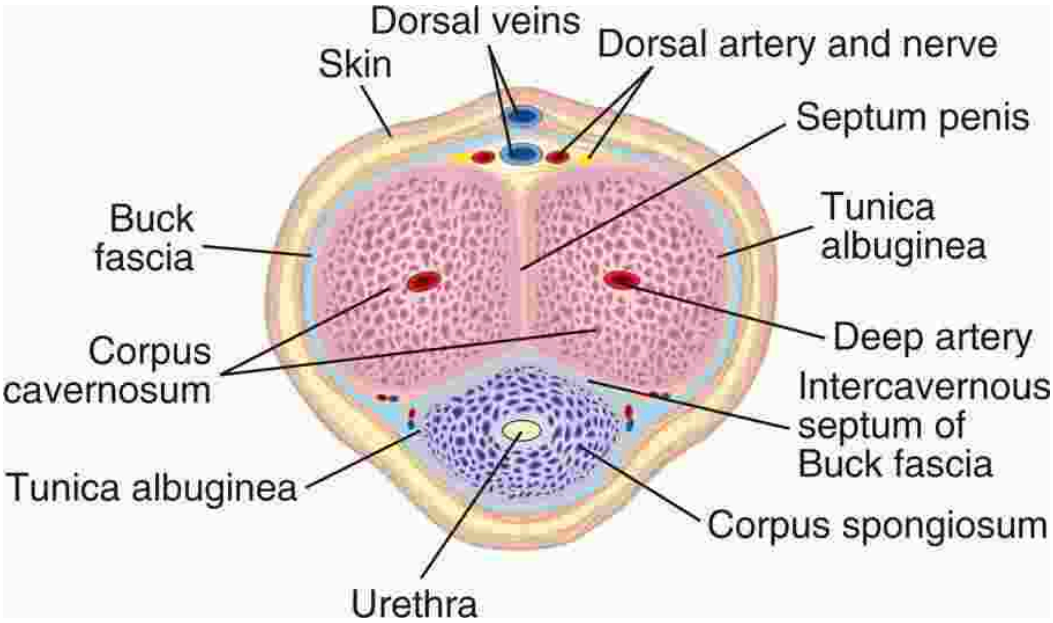

FIG. 24.15 Cross Section of the Penis.
The Buck fascia is the blue layer separating the corpora cavernosa from the corpus spongiosum.
(From Thompson JM, et al., eds. *Mosby's clinical nursing*, 5th edition. St. Louis: Mosby; 2002.)

An illustration of the cross-section of the penis shows and labels the following structures, clockwise from the top: dorsal veins, dorsal artery and nerve, septum penis, tunica albuginea, deep artery, intercavernous septum of Buck fascia, corpus spongiosum, urethra, tunica albuginea, corpus cavernosum, buck fascia, and skin.

Externally, the penis consists of a shaft with a tip (the glans) that contains the opening of the urethra (see Fig. 24.14). The skin of the glans folds over the tip of the penis, forming the prepuce, or foreskin. At birth, the foreskin is adhered to the glans. Penile erections, which commonly occur, cause the adhesions to break so that by age 3 years, the foreskin becomes completely retractable. The skin of the penis is

continuous with that of the groin, scrotum, and inner thighs. It is hairless, movable, and darker than the surrounding skin.

Penetration of the female vagina is made possible by the erectile reflex, a process in which erectile tissues within the corpora cavernosa and corpus spongiosum become engorged with blood, generally 20 to 50 mL. The erectile tissues consist of vascular spaces, or chambers, supplied with blood by arterioles (small arteries). Usually, the arterioles are constricted so that not much blood flows through the erectile tissues. Sexual stimulation, however, causes the arterioles to dilate and fill with blood, expanding the erectile tissues and causing an erection. The corpora cavernosa increases in length and width and becomes rigid. Erection apparently is maintained by compression or constriction of veins that drain the corpora cavernosa and corpus spongiosum. When sexual stimulation ceases, or orgasm and ejaculation occur, these veins open, blood flows out of the arterioles, and the penis becomes flaccid (soft and pendulous). Erection is under the control of the autonomic nervous system but can be stimulated or inhibited by CNS input.

Stimulation of the glans, which is endowed with copious sensitive nerve endings, provides maximum erotic sensation. With sexual arousal, skin color deepens, the glans doubles in size, and the urethral meatus dilates. Ejaculation occurs with frequent, strong contractions of the vas deferens, epididymis, seminal vesicles, prostate, urethra, and penis. Erection and ejaculation can occur independently of each other, but it is not common.[17]

Erections begin in utero and continue throughout life, but ejaculation does not occur until sperm production begins at puberty. Growth of the penis and scrotal contents continues well past puberty, however, and may not be complete until the late teens or early twenties. Penis size, when flaccid, varies considerably; with an erection, the difference in penis size diminishes.

Internal Genitalia

Fig. 24.12 shows the anatomy of the internal genitalia and their relation to other pelvic organs. The internal genitalia consist of ducts and glands.

- *Ducts* consist of two vasa deferentia, the ejaculatory duct and the urethra. They conduct sperm and glandular secretions from the testes to the urethral opening of the penis.
- *Glands* consist of the prostate gland, two seminal vesicles, and two Cowper (bulbourethral) glands. They secrete fluids that serve as a vehicle for sperm transport and create a nutritious alkaline medium that promotes sperm motility and survival. Together the sperm and the glandular fluids compose semen.

Sperm leaves the epididymides and travels rapidly through the internal ducts (emission). Emission occurs just seconds before ejaculation, at the moment when sexual arousal peaks. It always leads to ejaculation.

Emission occurs as smooth muscle in the walls of the epididymides and vasa deferentia begins to contract rhythmically, pushing sperm and epididymal secretions through the vasa deferentia. Each vas deferens is a firm, elastic, fibromuscular tube that begins at the tail of the epididymis, enters the pelvic cavity within the spermatic cord, loops up and over the bladder, and ends in the prostate gland (Fig. 24.16). Sperm are conducted by peristaltic contractions of smooth muscle in the walls of the vas deferens.

The seminal vesicles are glands about 4 to 6 cm long that lie behind the urinary bladder and in front of the rectum. As sperm leave the ampulla (wide portion) of the vas deferens, the seminal vesicles secrete a nutritive, glucose-rich fluid into the ejaculate (semen). The seminal vesicles provide fructose as a source of energy for ejaculated sperm and secrete prostaglandins that promote smooth muscle contraction, assisting with sperm transport. The ducts of the seminal vesicles join the ampulla of the vas deferens to become the ejaculatory duct, which contracts rhythmically during emission and ejaculation. As seen in Figs. 24.12 and 24.16B, the ejaculatory duct joins the urethra, where both pass through the prostate gland. During emission and ejaculation, a sphincter (muscle surrounding a duct) closes, preventing urine from entering the prostatic urethra.

The prostate gland is about the size of a walnut, surrounds the urethra, and is composed of glandular alveoli and ducts embedded in

fibromuscular tissue. The prostate gland has three zones (see Fig. 24.16A), which are significant in the study of prostate cancers. Prostate growth, development, and function are regulated by androgens and the androgen receptor. Nerves required for penile erection travel along the posterolateral surface of the prostate.

Included in prostate epithelial secretions are prostate-specific antigen (PSA), cytokeratins, prostate-specific membrane antigen (PSMA), and prostate-specific acid phosphatase. Prostate secretions contribute to the ejaculate. While semen moves through the prostatic portion of the urethra, the prostate gland contracts rhythmically and secretes prostatic fluid (a thin, milky substance with an alkaline pH that helps sperm survive in the acidic environment of the female reproductive tract) into the mixture. In addition, clotting enzymes and fibrinolysin in prostatic fluids help to mobilize sperm after ejaculation.

Bulbourethral glands (Cowper glands) are the last pair of glands to add fluid to the ejaculate; their ducts secrete mucus into the urethra near the base of the penis. Ejaculation occurs as semen reaches the base of the penis, where muscles rhythmically contract and expel semen. Normally a male ejaculates between 2 and 6 ml of semen, containing 75 million to 400 million sperm. About 98% of the ejaculate consists of glandular fluids, 60% to 70% of the volume originates from the seminal vesicles, and 20% from the prostate. The ejaculate of a man who has undergone a vasectomy (a surgical procedure that prevents sperm from entering the vas deferens) is reduced by about 2%.

Spermatogenesis

Spermatogenesis (the production of sperm) begins at puberty and continues for life. In this respect, spermatogenesis differs markedly from oogenesis (production of primordial ova), which occurs during fetal life only. Spermatogenesis takes place within the seminiferous tubules of the testes (Fig. 24.17). The basement membrane of each seminiferous tubule is lined with diploid (46-chromosome) germ cells called spermatogonia (sing., spermatogonium). These cells undergo continuous mitotic division. Some spermatogonia move away from the basement membrane and mature, becoming **primary spermatocytes**. These undergo meiosis, cell division that results in two haploid (23-

chromosome) cells called secondary spermatocytes. The secondary spermatocytes also undergo meiosis, resulting in four spermatids. Spermatids then differentiate into spermatozoa, or sperm, each of which contains 23 chromosomes (Fig. 24.18).

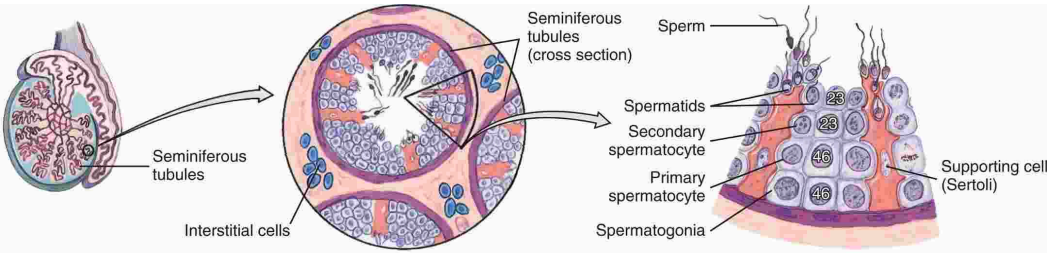

FIG. 24.17 Seminiferous Tubule and Spermatogenesis.
Cross section of a seminiferous tubule showing the different cell types. Interstitial cells that produce testosterone are between the seminiferous tubules. Spermatids in the lumen become sperm by a process called spermiogenesis. The numbers in white represent the number of chromosomes. (From Applegate E. *The anatomy and physiology learning system*, 4th edition. St. Louis: Saunders; 2011.)

"A series of illustration demonstrates spermatogenesis. Left panel. The illustration shows a cross-section of testis with seminiferous tubules. Middle panel. The illustration shows an enlarged view of cross-section of seminiferous tubules with interstitial cells in between the tubules. Bottom panel. The illustration shows an enlarged cross-sectional view of portion of seminiferous tubule and labels the following structures from the top: sperm, spermatids, secondary spermatocyte, primary spermatocyte, supporting cell (Sertoli), and spermatogonia."

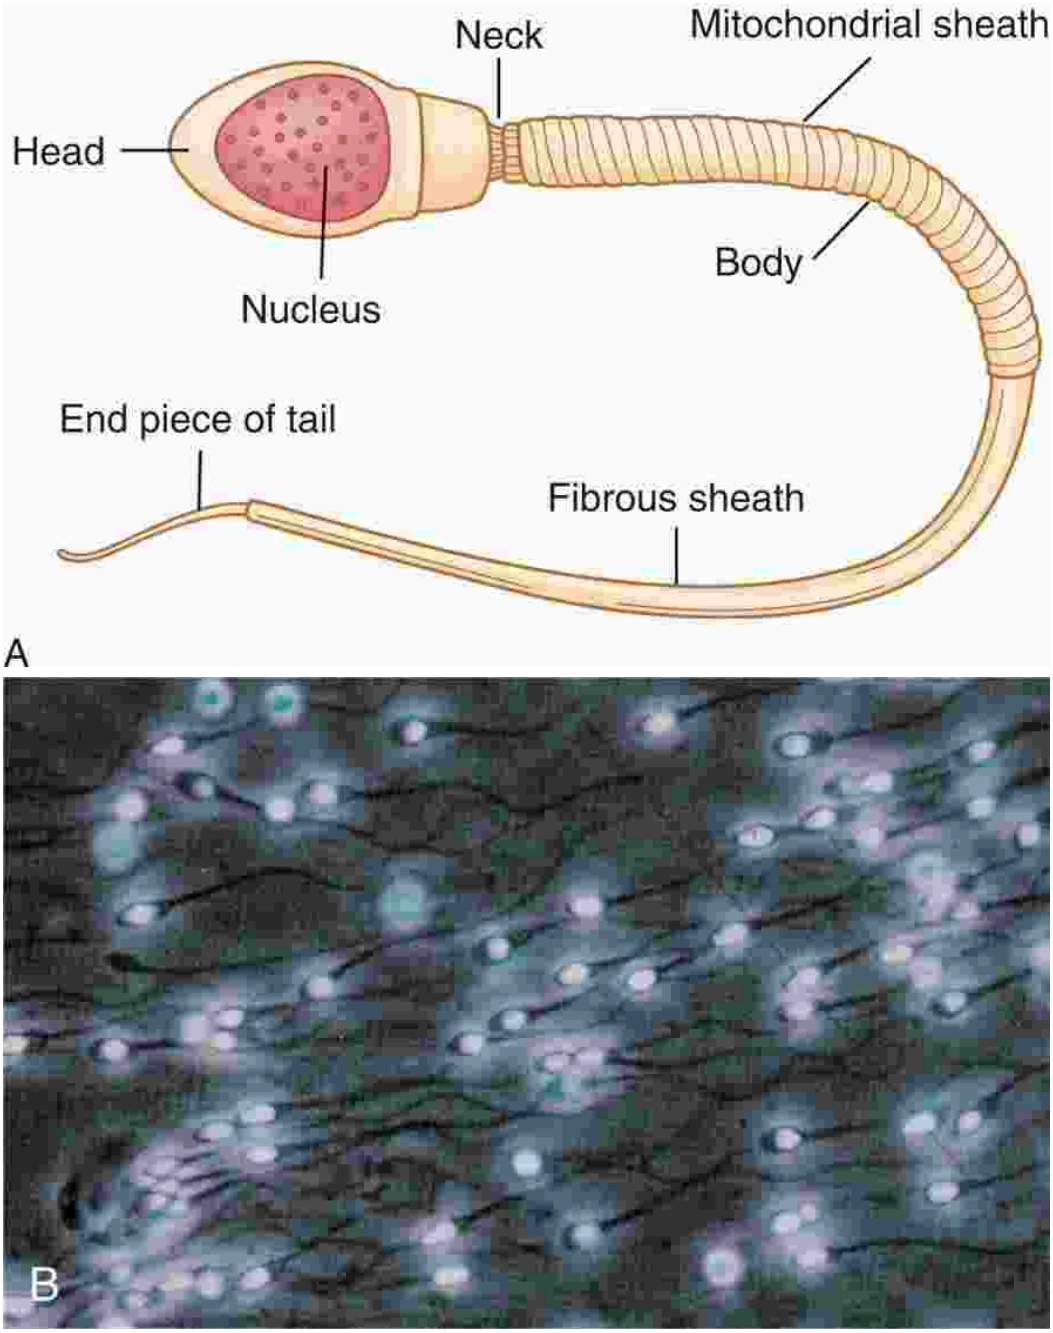

FIG. 24.18 Mature Sperm Cell (Spermatozoon). **(A)** Anatomy of mature sperm cell. **(B)** Human sperm with nuclear material glowing with a fluorescent dye. (B From Lennart Nilsson.)

"Illustration A shows and labels the following structures of a mature sperm: head, nucleus, neck,

mitochondrial sheath, body, fibrous sheath, and end piece of tail. Photomicrograph B shows a cluster of sperms swimming."

The development of spermatids into sperm depends on the presence of Sertoli cells (nondividing support cells) within the seminiferous tubules. Spermatids attach themselves to the Sertoli cells (see Fig. 24.17), where they receive nutrients and hormonal signals (e.g., testosterone) necessary to develop into sperm.

The process of spermatogenesis, from the mitotic division of a spermatogonium to the maturation of the spermatids, takes about 70 to 80 days. Mature sperm migrate from the seminiferous tubules to the epididymides, where their capacity for fertilization continues to develop. Although they are completely mature by the time they are ejaculated, the sperm do not become motile (capable of movement) until they are activated by biochemicals in the epididymis and in the female reproductive tract (known as sperm capacitation).

Male Sex and Reproductive Hormones

The male sex hormones are androgens. Testosterone, the primary male sex hormone, and other androgens are produced mainly by Leydig cells of the testes, but they are also produced by the adrenal glands in both males and females and by the ovary in females (see Table 24.1). In males, sex hormone production is relatively constant and does not occur in a cyclic pattern, as it does in females.

The physiologic actions of androgen are related to the growth and development of male tissues and organs. Androgens are responsible for the fetal differentiation and development of the male urogenital system and have some effects on the fetal brain. After birth, the Leydig cells become dormant until activated by the gonadotropins during puberty. Then androgens cause the sex organs to grow and secondary sex characteristics to develop.

Testosterone affects nervous and skeletal tissues, bone marrow, skin and hair, and sex organs. It has an anabolic effect on skeletal muscle

tissue, thereby contributing to the difference in body weight and composition between males and females. Testosterone also stimulates the growth of the musculature and cartilage of the larynx, causing a permanent deepening of the voice. Testosterone directly stimulates the bone marrow and indirectly stimulates renal erythropoietin production to achieve increased hemoglobin and hematocrit levels. Because sebaceous gland activity is stimulated by testosterone, acne may develop. Hair becomes coarser in texture, and facial, axillary, and pubic hair grows in male patterns. Testosterone is required for spermatogenesis and for the secretion of fluid by the prostate gland, seminal vesicles, and bulbourethral glands. Testosterone is also associated with libido (sex drive). Other, less-understood effects of testosterone include regulatory proteins involved in glycolysis, glycogen synthesis, insulin action, and lipid and cholesterol metabolism.

The regulation of androgen production and spermatogenesis is achieved by a complex feedback system involving the extrahypothalamic CNS, the hypothalamus, the anterior pituitary, the testes, and the androgen-sensitive end organs. These make up the hypothalamic-pituitary-testicular (HPT) axis (Fig. 24.19). These relationships are essentially the same in females (see Fig. 24.3). Extrahypothalamic influences include such variables as physiologic and psychologic stress, which may inhibit or augment hypothalamic activity. In the hypothalamus, neurotransmitters regulate GnRH synthesis and pulsatile release (about every 3 hours) into the hypophyseal portal veins. Norepinephrine stimulates GnRH secretion, and serotonin and dopamine inhibit GnRH secretion. GnRH is transported by portal flow to the median eminence of the pituitary gland, where it binds to receptors and stimulates the synthesis and secretion of the gonadotropins LH and FSH. These gonadotropins are named for their effects in the female reproductive system but have important effects on the male system as well. LH acts on the Leydig cells to regulate testosterone secretion. FSH acts on the seminiferous tubule Sertoli cells to promote spermatogenesis. FSH secretion is inhibited by inhibin secreted by the Sertoli cells. Similar to their action in the female gonad, inhibin functions as an autocrine/paracrine

regulator in the male gonad. Inhibin inhibits the proliferation of spermatogonia by regulating pituitary FSH levels. In addition, inhibin facilitates LH stimulation of androgen biosynthesis in Leydig cells.[18]

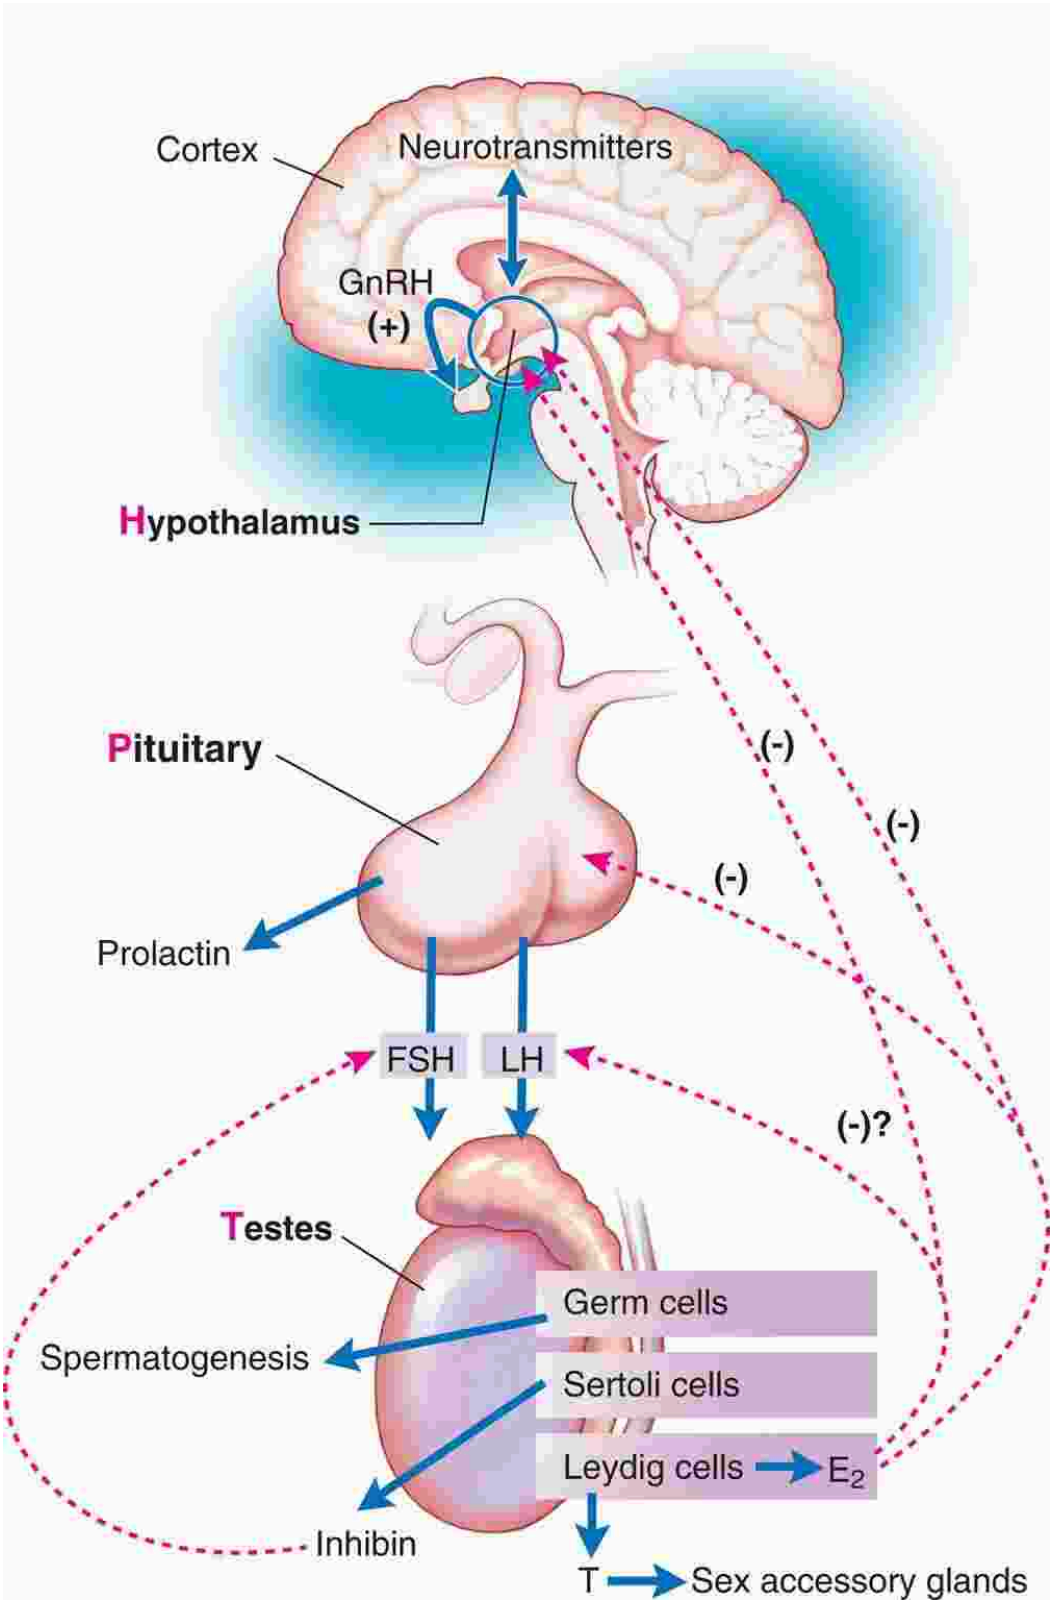

FIG. 24.19 **Schematic Representation of Activity Along the Hypothalamus-Pituitary-Testicular**

***(HPT)* Axis.**
E_2, Estrogen; *FSH*, follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *T*, testosterone.

"An illustration represents the activity along the hypothalamus-pituitary-testicular axis. The illustration shows a brain. There are neurotransmitters in the cortex. The hypothalamus releases G n R H. G n R H stimulates pituitary. The pituitary releases prolactin, F S H, and L H. The F S H and L H impact the testes. Germ cells trigger spermatogenesis. Sertoli cells releases inhibin that provide positive feedback to the F S H. Leydig cells release E 2 which provides negative feedback to L H, the pituitary, and the hypothalamus. Leydig cells also release testosterone which acts on sex accessory glands."

Ninety-eight percent of testosterone, the major steroid hormone produced by the testes, binds to either sex hormone-binding globulin (SHBG) (50%) or albumin (48%). The remaining 2% remains unbound in the plasma and is free to enter cells and wield its metabolic effects. Changes in the amount of available SHBG affect the amount of testosterone within tissues. The testes secrete only 25% of circulating estrogen (estradiol). The majority is produced by the peripheral conversion of testosterone and androstenedione. Estrogens help regulate GnRH and LH secretion. Peripheral conversion of testosterone also produces dihydrotestosterone (DHT), another potent androgen. DHT is necessary for external virilization during embryogenesis and androgen activity beginning at puberty and continuing throughout adulthood. Prolactin, a polypeptide synthesized and secreted from the pituitary, helps maintain the

biosynthesis of testosterone. However, elevated prolactin levels are associated with low levels of testosterone.[19]

In summary, hormones secreted at each level of the HPT axis control and coordinate testicular function (see Fig. 24.19). This control is exerted through positive and negative feedback signals by (1) sex steroids that inhibit hypothalamic GnRH secretion and pituitary LH responsiveness to GnRH; and (2) testicular inhibin that inhibits pituitary FSH and, possibly, circulating estrogens (E_2). Any disruption along the HPT axis may lead to hypogonadism or infertility.

Tests of Reproductive Function

Diagnostic tests of the male and female reproductive systems may be performed to detect the presence of endometriosis or cancerous lesions or identify the presence of sexually transmitted infections. Most commonly, however, tests of reproductive function are performed when infertility exists. In cases of infertility, both partners are examined, and several diagnostic evaluations may be completed. The types of tests available to assess reproductive function and fertility are summarized in Table 24.4. A list of serum hormone tests and normal values is found in Table 24.5. The male is evaluated for number, amount, structure, and motility of sperm and obstruction along the reproductive tract. Tests for females determine whether (1) the reproductive tract (cervix, uterus, fallopian tubes) is adequately patent to allow for the passage of ovum and sperm, (2) ovulation occurs normally, (3) the endometrium is responding normally to hormones, and (4) reproductive tissues are free of tumors or infections. Hormonal assays evaluate the adequacy of pituitary function and target organ response. The position and size of organs or the presence of tumors can be detected by direct observation procedures using a laparoscope or by ultrasound, radiographic, and other imaging studies.[20]

Table 24.4

Tests of Reproductive Function/Fertility

Test	Description	
Basic Assessment		
Semen analysis (two samples at least 2 weeks apart)	Determines number, motility, and structure of sperm cells	
Sperm DNA fragmentation	Determines the percentage of sperm DNA strand breaks and likelihood of infertility	
White blood cells	Determines presence of bacteria/leukocytes	
Immunologic tests	Detects antibody to sperm	
Other Assessments		
Basal body temperature	Determines whether ovulation has occurred	
FSH level	Day 2–3 of cycle to measure ovarian reserve	
Estradiol	Day 2–3 of cycle to measure ovarian reserve	
Progesterone	Midluteal phase—1 week before menses	
Prolactin	Day 3 of cycle	
TSH level	Day 3 of cycle	
Urinary LH	Day 11 of cycle	
Cervical mucus	Evaluates presence of ovulation from estrogenic effects at ovulation;	

Test	Description	
	mucus also may be examined for pH, glucose, or proteins or cultured for presence of infection	
Postcoital cervical mucus (Sims-Huhner test)	Tests ability of sperm to penetrate and maintain motility in cervical mucus 2–4 hours after coitus approximately 1 day before ovulation	
Zona binding test or hamster penetration test	Nonliving oocytes are surgically removed and bisected; sperm added to the hemi-oocyte to test fertilizing capability	
Ultrasound vaginal scanning	Provides superior quality resolution of the uterine, fallopian, and ovarian structures; also can be used to study folliculogenesis, ovulation, and luteogenesis to detect abnormalities	
More Specialized Tests		
Endometrial biopsy	Determines whether ovulation has occurred by obtaining endometrial tissue on day 26 of 28-day menstrual cycle (or postovulatory day 12)	
Hysterosalpingogram	Assessment of uterus and fallopian tubes for obstructions using transuterine injection of contrast material and radiography; performed 1–2 days after cessation of menses	

Test	Description	
Laparoscopy (pelvic endoscopy)	Visualization of reproductive organs using a laparoscope inserted within the pelvic cavity through the abdomen to assess structure or determine presence of adhesions, endometriosis, tumors, or infection	
Hysteroscopy	Visualization of uterine cavity using modified cystoscope inserted through cervical os; best done during first 14 days of cycle	
Transvaginal ultrasound	Identifies endometrial development	

Test	Description	
Basic Assessment		
Semen analysis (two samples at least 2 weeks apart)	Determines number, motility, and structure of sperm cells

Transvaginal ultrasound	Identifies endometrial development	

FSH, Follicle-stimulating hormone; *TSH*, thyroid-stimulating hormone; *WBC*, white blood cell.

Table 24.5

Serum Hormone Values

Hormone	Value
Serum progesterone	Normal = >10 ng/dL, presumptive evidence of ovulation; draw level between days 20 and 25 of 28-day cycle or 6–10 days postovulation
	<10 ng/mL = inadequate luteal function
	<3 ng/mL suggests anovulation
Serum testosterone	Normal = 300–1200 ng/dL; must be interpreted with serum LH and FSH levels
Resulting from diurnal and pulsatile pattern, need serial blood draws	Low values in male hypogonadism
Serum FSH and LH	FSH = <22 international units/L
Resulting from diurnal and pulsatile pattern, need serial blood draws	LH = 4–24 international units/LHigh levels in males indicate primary testicular disease; low levels in males indicate hypogonadism caused by hypothalamic-pituitary dysfunction

FSH, Follicle-stimulating hormone; *LH*, luteinizing hormone.

Aging and Reproductive Function

Aging and the Female Reproductive System

Menopause is the cessation of ovulation and menses caused by ovarian failure. It is a normal developmental and transitional event that is universally experienced by the average age of 51 years with a range of

40 to 60 years. Premature menopause is the cessation of ovulation before 40 years of age. A number of factors are thought to influence the age of menopause, including genetics, socioeconomic status, race, parity, oral contraceptive use, early menarche, and lifestyles such as smoking or weight.[21] The term "climacteric" refers to gradual changes of ovarian function that start before menopause and result in the symptoms associated with loss of ovarian function.[22] For clarity, the term *menopause* will be used here. Reproductive changes are caused primarily by declining ovarian function and a resulting decrease in ovarian hormone secretion.

Perimenopause is the transitional period between reproductive and nonreproductive years and can last 1 to 8 years. About 5 to 10 years before menopause, approximately 90% of females note mild to extreme variability in frequency and quality of menstrual flow. Changes in hormones occur during this time, including erratically higher estradiol levels, decreased progesterone levels (in normal ovulatory, short luteal phase, or anovulatory cycles), and a disturbed ovarian-pituitary-hypothalamic feedback relationship with higher LH levels. A decrease in the sensitivity of the target tissue receptors and the development of perimenopausal symptoms are commonly experienced. Symptoms usually begin with a lengthening of the menstrual cycle, which correlates with anovulatory cycles. Unpredictable or irregular ovulation uniformly precedes menopause. The perimenopause experience varies among females and from cycle to cycle in the same person.

Menopause is defined by the point that marks 12 consecutive months of amenorrhea. This means that it is determined retrospectively after a female has not had a menstrual period for 1 year. It is characterized by loss of ovarian function, low estrogen and progesterone levels, and high FSH and LH levels (Fig. 24.20). Early menopause is the 5 years after menopause onset. Late menopause follows and continues until death.

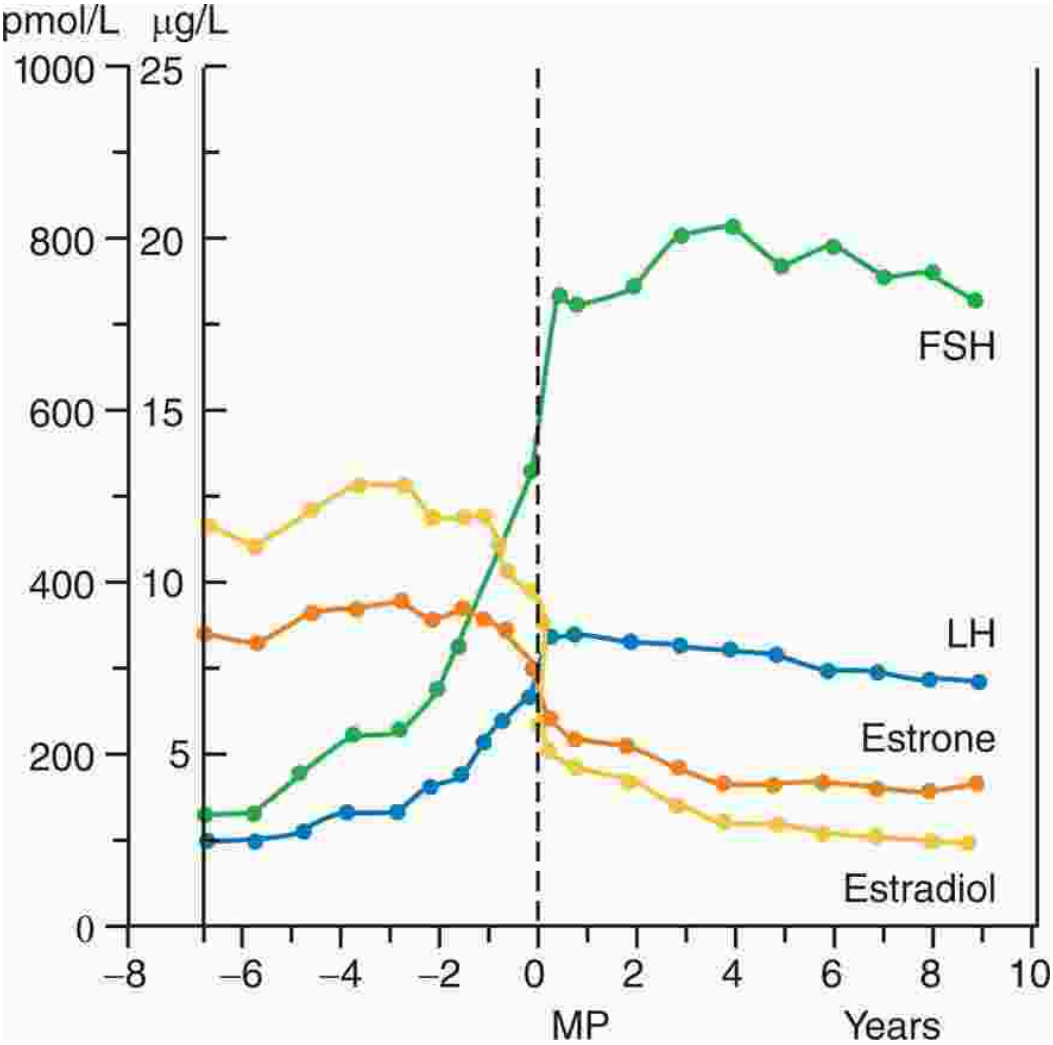

FIG. 24.20 Perimenopausal Hormone Transition. Mean circulating hormone levels. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone; *MP*, menopause.

“A graph plots the mean circulating hormone levels. The vertical axis represents picomoles per liter (0 through 1000, in increments of 200) and micrograms per liter (0 to 25, in increments of 5). The horizontal axis represents M P (negative 8 to 0, in increments of negative 2) and years (0 to 10, in increments of 2). The graph plots curves for F S H, L H, estrone, and

estradiol. A vertical dashed lined is plotted at 0. F S H. The line rises from (negative 6.5 M P, 100 picomoles per liter or 2.5 micrograms per liter) to (10 years, 700 picomoles per liter or 18 micrograms per liter), passing through (0, 500 picomoles per liter or 12.5 micrograms per liter). L H. The line rises from (negative 6.5 M P, 120 picomoles per liter or 3 micrograms per liter) to (10 years, 300 picomoles per liter or 7.5 micrograms per liter), passing through (0, 350 picomoles per liter or 8 micrograms per liter). Estrone. The lines falls from (negative 6.5 M P, 350 picomoles per liter or 7.5 micrograms per liter) to (10 years, 200 picomoles per liter or 5 micrograms per liter), passing through (0, 300 picomoles per liter or 7.5 micrograms per liter). Estradiol. The line falls from (negative 6.5 M P, 480 picomoles per liter or 12 micrograms per liter) to (10 years, 100 picomoles per liter or 2.5 micrograms per liter), passing through (0, 200 picomoles per liter or 5 micrograms per liter).”

The primary changes of perimenopause and menopause are as follows:

- *Ovarian changes:* Beginning in utero, the number of follicles steadily decreases through activation, maturation, and atresia. Around 37 to 38 years of age, females experience accelerated follicular loss, which ends when the supply of follicles is depleted at menopause. This accelerated loss is correlated with increased FSH stimulation, declining inhibin production, slightly elevated estradiol levels, and decreasing amounts of

anti-müllerian hormone (normally decreases FSH effects) (see Fig. 24.20). Attenuated LH surges are associated with impaired hypothalamic responses to estradiol positive feedback. The ovarian response to high FSH level recruits increasing numbers of follicles (Box 24.2); these follicles only partially develop, with a net effect of irregular ovulation, lower progesterone levels, depleted follicle reserve, and infertility. The ovaries begin to decrease in size around age 30; this decrease accelerates after age 60. Of the 500,000 follicles present at the onset of puberty, the number dwindles to between 100 and 1000 with menopause.[31] Table 24.6 summarizes endocrine events occurring during perimenopause. Table 24.7 provides a template to visualize the complex physiology of perimenopause and the dynamic changes that occur during this time.

- *Uterine changes:* The increase in anovulatory cycles allows for proliferative growth of the endometrium. With this longer exposure to unopposed estrogen and greater thickness of the endometrium, 50% of perimenopausal females will experience dysfunctional uterine bleeding that is heavy and unpredictable. Increased endometrial bleeding is correlated with a change from ovulatory to anovulatory cycles and is associated with unopposed high estrogen levels the week before menses. Estrogen causes endometrial tissue to thicken. However, without corresponding stromal support from progesterone, estrogen production leads to heavier periods, menometrorrhagia (excessive bleeding often caused by submucosal myomas and endometrial polyps), or metrorrhagia (midcycle bleeding) (Table 24.8). In the past, this has put females at high risk for hysterectomy or endometrial ablation. Medical and hormonal management is the first line of therapy if the uterus is normal.[23]
- *Breast tissue changes:* Breast tissue becomes involuted, fat deposits and connective tissue increase, and breasts are reduced in size and firmness. There can be an increase in white

adipose tissue inflammation with elevated aromatase levels (increases circulating estrogen), particularly in obese women.[24]

- *Genitourinary tract changes:* The ovaries shrink; the uterus atrophies; and the vagina shortens, narrows, and loses some elasticity. Lubrication of the vagina diminishes, and vaginal pH increases, creating a higher incidence of vaginitis. The cervix atrophies; the cervical os shrinks; vaginal epithelium atrophies; labia majora and minora become less prominent; some pubic hair is lost; urethral tone declines along with muscle tone throughout the pelvic area; urinary frequency or urgency, urinary tract infections, and incontinence may occur. Regular sexual activity and orgasm may diminish some of these changes. Sexually active females have less vaginal atrophy.
- *Skeletal changes:* Bone mass is reduced, leading to increased brittleness and porosity, which increases the risk of osteoporosis and fracture, particularly in the lumbar spine and femoral neck.[25]
- *Cardiovascular changes:* The risk of cardiovascular disease increases significantly and is the leading cause of death in postmenopausal females. Blood pressure and total LDL cholesterol increase, and HDL cholesterol decreases. There is an increased risk for metabolic syndrome.[26]
- *Systemic changes:* Vasomotor flushes are characterized by a rise in skin temperature, dilation of peripheral blood vessels, increased blood flow in the hands, increased skin conductance, and a transient increase in heart rate followed by a temperature drop and profuse perspiration over the area of flush distribution. This usually occurs in the face and neck and may radiate into the chest and other parts of the body. Night sweats, dizziness, nausea, headaches, or palpitations may accompany the flush. These flushes can vary in frequency, intensity, and duration and are experienced by up to 85% of perimenopausal to postmenopausal females from 1 to 15 years. The physiology of vasomotor flushes is poorly understood. Interestingly, emerging evidence shows that the intensity of

vasomotor flushes may be associated with an increased risk for cardiovascular disease.[27]

- *Other changes:* Emotional stress with unpredictable mood swings, weight gain, migraine headaches, insomnia, and depression often accompany the change in estrogen levels. Lower estrogen levels decrease skin thickness and diminish skin elasticity, thereby causing increased skin dryness, wrinkling, and poor wound healing. Alopecia and unwanted facial hair are common.[28] Hormone replacement therapy can relieve the symptoms of menopause, but risks and benefits must be evaluated for each person.

Box 24.2

Changes in Ovarian Follicle Maturation

Changes in ovarian folliculogenesis during perimenopause leads to endogenous overstimulation

- ↑ FSH → ovarian hyperstimulation → ↑ number of follicles recruited (net effect of follicular depletion) → ↑ estradiol
- ↓ Follicular reserve → ↓ inhibin and ↑ activin in FP and LP → ↑ FSH → ↑ number of follicles recruited, partial development, infrequent ovulation → ↑ estrogen (E_2) and ↓ progesterone

FP, Follicular phase; *FSH*, follicle-stimulating hormone; *LP*, luteal phase

Table 24.6

Endocrine Events Associated With Perimenopause

Hormone Changes	Effects
Estradiol (E_2) levels	Erratic and intermittent increase
Mean FP level 1 greater than mean FP level in younger women	First in FP (inverse relationship between length of FP and estradiol level)
FP level may be greater than midcycle peak level in fertile women	Later during premenstrual phase
Ovulatory cycles	Short or insufficient LP (decreased fertility)
Progesterone levels	Decreased in ovulatory cycle; minimal during anovulatory cycles
Anovulatory cycles	Increased to about 50%; perhaps more in later perimenopause
FSH levels	Variable, then increased
LH levels	Normal initially, then increased
Inhibin levels	Correlate with progesterone levels

FP, Follicular phase; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *LP*, luteal phase.

Table 24.7

Postulated Perimenopausal Transition Time Line

Phase	Menstrual Physiology	Hormonal Changes	Symptomatology
A	Regular, ovulatory cycles Short cycles, short FP	Intermittent ↑ E_2 FSH usually normal Intermittent ↑ FP FSH Low inhibin	Increased breast tenderness, mood swings, fluid retention, premenstrual symptoms Early morning night sweats (vasomotor symptoms) Weight gain, migraine headaches, heavy flow
B	Regular cycles with disturbances in ovulation Short LP Insufficient LP Anovulatory cycles	Intermittent ↑ FP FSH E_2 often ↑ Inhibin inappropriately low	Heavy flow ↑ Premenstrual symptoms ↑ Dysmenorrhea Predictable or ↑ vasomotor symptoms before flow

Phase	Menstrual Physiology	Hormonal Changes	Symptomatology
C	Onset of perimenopause Alternating short, long, or skipped cycles	E_2 often quite ↑ E_2 normal or low ↑ FSH (slight) ↑ LH Low inhibin	Vasomotor symptoms during waking hours Vasomotor symptoms more persistent, remain cyclic before flow
D	Onset of oligomenorrhea 50% of cycles anovulatory Heavy flow may predict onset of oligomenorrhea	↑ Progesterone with ovulation Persistent ↓ FSH ↑ LH ↑ E_2 Low inhibin	↑ Vasomotor symptoms ↑ Signs/symptoms of high estrogen after long periods without flow Flow light but unpredictable
E	Final menstrual period plus 1 year	↑ FSH and LH ↓ or normal E_2 Consistent low inhibin ↓ Progesterone	↑ Intensity and frequency of vasomotor symptoms (although vasomotor symptoms may disappear)

Phase	Menstrual Physiology	Hormonal Changes	Symptomatology
			↓ Cramps and premenstrual-type symptoms without subsequent flow ↓ Breast, mood, and fluid symptoms

Phase	Menstrual Physiology	Hormonal Changes	Symptomatology
A	Regular, ovulatory cycles Short cycles, short FP	Intermittent ↑ E_2 FSH usually normal Intermittent ↑ FP FSH Low inhibin	Increased breast tenderness, mood swings, fluid retention, premenstrual symptoms Early morning night sweats (vasomotor symptoms) Weight gain, migraine headaches, heavy flow
B	Regular cycles with disturbances in ovulation Short LP Insufficient LP Anovulatory cycles	Intermittent ↑ FP FSH E_2 often ↑ Inhibin inappropriately low	Heavy flow ↑ Premenstrual symptoms ↑ Dysmenorrhea Predictable or ↑ vasomotor symptoms before flow
C	Onset of perimenopause Alternating short, long, or skipped cycles	E_2 often quite ↑ E_2 normal or low ↑ FSH (slight) ↑ LH Low inhibin	Vasomotor symptoms during waking hours Vasomotor symptoms more persistent, remain cyclic before flow
D	Onset of oligomenorrhea 50% of cycles anovulatory Heavy flow may predict onset of oligomenorrhea	↑ Progesterone with ovulation Persistent ↓ FSH ↑ LH ↑ E_2 Low inhibin	↑ Vasomotor symptoms ↑ Signs/symptoms of high estrogen after long periods without flow Flow light but unpredictable
E	Final menstrual period plus 1 year	↑ FSH and LH ↓ or normal E_2 Consistent low inhibin ↓ Progesterone	↑ Intensity and frequency of vasomotor symptoms (although vasomotor symptoms may disappear) ↓ Cramps and premenstrual-type symptoms without subsequent flow ↓ Breast, mood, and fluid symptoms

E_2, Estradiol; *FP*, follicular phase; *FSH*, follicle-stimulating hormone; *LP*, luteal phase.

Table 24.8

Impact of High Estrogen Levels on Menstrual Cycle and Symptomatology

Associated Physiologic Change	Signs/Symptoms
Short follicular phase (FP)	Short cycles
Long FP	Long cycles
Thickened endometrium	Heavy, long, or unpredictable flow (including clotting and flooding)[a]
Increase in glandular cells without stromal support produced by progesterone → unstable endometrium	Midcycle spotting Menorrhagia
Possible increased production of prostaglandins within endometrial tissue	Metrorrhagia Dysmenorrhea Breast tenderness, modularity, enlargement Water retention Emotional stress; new or unpredictable mood swings Weight gain Vasomotor symptoms

Associated Physiologic Change	Signs/Symptoms
	New onset of migraine headaches; exacerbation of headaches Increased premenstrual symptoms

Associated Physiologic Change	Signs/Symptoms
Short follicular phase (FP)	Short cycles
Long FP	Long cycles
Thickened endometrium	Heavy, long, or unpredictable flow (including clotting and flooding)[a]
Increase in glandular cells without stromal support produced by progesterone → unstable endometrium	Midcycle spotting Menorrhagia
Possible increased production of prostaglandins within endometrial tissue	Metrorrhagia Dysmenorrhea Breast tenderness, modularity, enlargement Water retention Emotional stress; new or unpredictable mood swings Weight gain Vasomotor symptoms New onset of migraine headaches; exacerbation of headaches Increased premenstrual symptoms

[a]Symptoms aggravated by anovulatory cycles; leads to dysfunctional uterine bleeding.

Menopause increases the risk of ovarian, breast, and uterine cancers. The risk is greater in females who began menstruating before age 12 or experience menopause after age 55. Females who menstruate longer than normal during a lifetime are exposed to more estrogen and have more ovulations. A longer exposure to estrogen increases the risk of uterine and breast cancers and having more ovulations than normal increases the risk of ovarian cancer.

Aging and the Male Reproductive System

Males maintain reproductive capacity longer than females. There is no known discrete event comparable to menopause that characterizes

aging of the male reproductive system, although the term andropause is sometimes used to describe the changes associated with male aging and lower levels of testosterone. Gradual changes do occur, and aging in the male reproductive system is characterized by hypogonadism, testosterone deficiency, erectile dysfunction, and proliferative disorders of the prostate gland (see Chapter 26). Aging changes are also influenced by chronic diseases and the use of medications.[29]

Components of male sexual behavior include both sexual drive and erectile and ejaculatory capacity. Libido, or sexual drive, is a complex phenomenon that is influenced significantly by health status and environmental, social, and psychological factors. In males older than 40 years, organic factors and chronic disease (e.g., vascular, endocrine, and neurologic disorders) are involved in more than half of the cases of male sexual dysfunction. Aging causes specific physical changes that may influence erectile and ejaculatory capabilities. Alterations in sexual response include the need for longer stimulation to achieve a full erection; slower and less forceful ejaculation, with less pelvic muscle involvement; decreased vasocongestive response; and longer refractory period (time during which erection and ejaculation are not possible), up to 24 hours in some men.

The testes undergo several age-related structural changes, including decreased weight, atrophy, and softening. Degenerative changes in the seminiferous tubules may include thickening of the basement membrane; increase in lumen size; germ cell (spermatogonium) arrest and a decrease in spermatogenic activity; and collapse of tubules, followed by complete obstruction caused by sclerosis and fibrosis. Areas of mild to severe degenerative change may be interspersed with areas having intact tubules. These morphologic changes may result from atherosclerosis (arterial clogging) in the testicular vascular bed. Alterations of the seminiferous tubules do not appear to diminish sperm counts (20 million sperm per milliliter of semen is estimated as the minimum concentration for fertility), but they do reduce fertility because a greater percentage of the sperm lack motility or have structural abnormalities.

About 20% of healthy males more than 60 years of age and 30% to 50% older than 80 years of age have testosterone levels below the

reference range, and about 2% have hypogonadism. Aging can cause changes in the production of male sex hormones, levels of SHBG, and responsiveness of target tissue receptors. Hormone synthesis by the testes and testicular responsiveness to the gonadotropins (FSH and LH) are diminished, and pituitary secretion of these gonadotropins is elevated. The reduced levels of testosterone may be related to alterations in the Leydig cells, the testosterone producers of the testes. The number of Leydig cells and their function decrease as age increases, perhaps because of decreased arterial perfusion of the testes, and varicoceles and decreased LH or responsiveness to LH. Decreases in testosterone with advancing age and symptoms of libido loss, erectile dysfunction, loss of muscle mass, increased body fat, anemia, osteoporosis, depressed mood, decreased vitality, sweating, and hot flushes are described as late-onset hypogonadism.30

Even if testosterone levels are not decreased, older males may have less unbound testosterone in their blood, decreasing the amount of unbound hormone available to stimulate target tissues. Decreased testosterone levels have several effects, including functional deterioration of the accessory sex organs (the prostate gland, seminal vesicles, epididymis, and ductus deferens); loss of muscle mass, strength, and endurance; increased visceral fat, osteopenia, and cognitive decline; and, in many men, decrease in libido. This last effect also may be caused by alterations in other variables that affect libido. Modifiable risk factors for low testosterone levels and symptoms of androgen deficiency include health status and waist circumference.

Summary Review

Development of the Reproductive Systems

1. Differentiation of female and male genitalia begins around 7 to 8 weeks of embryonic development when the gonads of genetically male embryos begin to secrete male sex hormones, primarily testosterone, under the influence of *SRY* gene expression and testosterone-determining factor (TDF). Female gonadal development occurs in the absence of *SRY* gene

expression. Until that time, the primitive reproductive organs of males and females are homologous (the same).
2. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of male gametes (sperm) begins at puberty; after that, millions are produced daily, usually for life.
3. Puberty is the onset of sexual maturation. Adolescence is a stage of human development between childhood and adulthood and includes social, psychological, and biologic changes.
4. The structure and function of both male and female reproductive systems depend on interactions among the central nervous system (hypothalamus), the endocrine system (anterior pituitary), the gonads (ovaries, testes), and the hypothalamic-pituitary-gonadal axis. A set of complex neurologic and hormonal interactions accelerate at puberty and lead to sexual maturation and reproductive capability.
5. One year before puberty, secretion of gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH) stimulate the gonads (ovaries and testes) to secrete female (estrogen and progesterone) or male sex hormones (testosterone). These stimulate the maturation of the gonads, reproductive organs, and breasts (in females). Puberty is complete in females with the first ovulatory menstrual period and is complete in males with the first ejaculation that contains mature sperm.

The Female Reproductive System

1. The function of the female reproductive system is to produce mature ova and, when they are fertilized, to protect and nourish them through embryonic and fetal life and expel them at birth.
2. The external female genitalia are the mons pubis, labia majora, labia minora, clitoris, vestibule (urinary and vaginal openings),

Bartholin and Skene glands, and perineum. They protect body openings and may play a role in sexual functioning.

3. The internal female genitalia are the vagina, uterus, fallopian tubes, and ovaries. Although all these organs are needed for reproduction, the ovaries are the most essential because they produce the female gametes and female sex hormones.
4. The vagina is a fibromuscular canal that receives the penis during sexual intercourse and is the exit route for menstrual fluids and products of conception. The vagina leads from the introitus (its external opening) to the cervical portion of the uterus.
5. The uterus is the hollow, muscular organ in which a fertilized ovum develops until birth. The uterine walls have three layers: the endometrium (lining), myometrium (muscular layer), and perimetrium (outer covering, which is continuous with the pelvic peritoneum). The endometrium proliferates (thickens) and is shed in response to cyclic changes in levels of female sex hormones. The cervix is the narrow, lower portion of the uterus that opens into the vagina.
6. The two fallopian tubes extend from the uterus to the ovaries. Their function is to direct ova from the spaces around the ovaries to the uterus. Fertilization normally occurs in the distal third of the fallopian tubes.
7. From puberty to menopause, the ovaries are the site of (1) ovum maturation and release and (2) production of female sex hormones (estrogen, progesterone) and androgens. The female sex hormones are involved in sexual differentiation and development, the menstrual cycle, pregnancy, and lactation. Although they are primarily male sex hormones, androgens in females are precursors of female sex hormones and contribute to the prepubertal growth spurt, pubic and axillary hair growth, and activation of sebaceous glands.
8. Estrogen (primarily estradiol) is produced by cells in the developing ovarian follicle (the structure that encloses the ovum). Progesterone is produced by cells of the corpus luteum, the structure that develops from the ruptured ovarian follicle

after ovulation (ovum release). Androgens are produced within the ovarian follicle, adrenal glands, and adipose tissue.

9. The average menstrual cycle lasts 25 to 30 days and consists of three phases, which are named for ovarian and endometrial changes: the follicular/proliferative phase, the luteal/secretory phase, and the ischemic menstrual phase.
10. The follicular/proliferative phase is the maturation of an ovarian follicle, the proliferation of the uterine endometrium, and the release of the ovum. FSH stimulates follicle and ovum maturation, then a surge of LH causes ovulation. Estrogen causes proliferation of the endometrium.
11. During the luteal/secretory phase, the ovum transforms into the corpus luteum. LH stimulates the corpus luteum to secrete progesterone and estrogen. Progesterone stimulates blood vessel and glandular growth, and estrogen maintains the thickened endometrium. Glands in the endometrium begin to secrete a thin, glycogen-containing fluid, hence the name *secretory phase*.
12. During the ischemic/menstrual phase, the corpus luteum degenerates, production of progesterone and estrogen drops sharply, and the "starved" endometrium degenerates and is shed, causing menstruation.
13. Cyclic changes in hormone levels also cause thinning and thickening of the vaginal epithelium, thinning and thickening of cervical secretions, and changes in basal body temperature.

Structure and Function of the Breast

1. The basic functional unit of the female breast is the lobe, a system of ducts that branches from the nipple to milk-producing units called *lobules*. Each breast contains 15 to 20 lobes, which are separated and supported by Cooper ligaments. The lobules contain *acini cells*, which are convoluted spaces lined with epithelial cells. Contraction of the subepithelial cells of each acinus moves milk into the system of ducts that leads to the nipple.

2. Until puberty, the female and male breasts are similar, consisting of a small, underdeveloped nipple and some fatty and fibrous tissue. At puberty, however, a variety of hormones (estrogen, progesterone, prolactin, growth hormone, insulin, cortisol) cause the female breast to develop into a system of glands and ducts that is capable of producing and ejecting milk.
3. During the reproductive years, breast tissue undergoes cyclic changes in response to hormonal changes of the menstrual cycle.
4. Milk production occurs in response to prolactin, a hormone that is secreted in larger amounts after childbirth. Milk ejection is under the control of oxytocin, another hormone of pregnancy and lactation.
5. The male breast does not develop because of the absence of sufficiently high levels of estrogen and progesterone and antagonistic effects of androgens.

The Male Reproductive System

1. The function of the male reproductive system is to produce male gametes (sperm) and deliver them to the female reproductive tract.
2. The external male genitalia are the testes, epididymides, scrotum, and penis. The internal genitalia are the vas deferens, ejaculatory duct, prostatic and membranous sections of the urethra, seminal vesicles, prostate gland, and bulbourethral glands.
3. The testes (male gonads) are paired glands suspended within the scrotum. The testes have two functions: spermatogenesis (sperm production) and the production of male sex hormones (androgens, chiefly testosterone).
4. The epididymis is a long, coiled tube arranged in a comma-shaped compartment that curves over the top and rear of the testis. The epididymis receives sperm from the testis and stores them while they develop further. Sperm travel the length of

the epididymis and then are ejaculated into the vas deferens, which transports sperm to the urethra.

5. The scrotum is a skin-covered, fibromuscular sac that encloses the testes and epididymides, which are suspended within the scrotum by the spermatic cord. The scrotum keeps these organs at optimal temperatures for sperm survival (about 1°C to 2°C lower than body temperature) by contracting in cold environments and relaxing in warm environments.
6. The penis has two functions: delivery of sperm and elimination of urine.
7. The penis is a cylindric organ consisting of three longitudinal compartments (two corpora cavernosa and one corpus spongiosum) and the urethra. The urethra runs through the corpus spongiosum. The corpora cavernosa and corpus spongiosum consist of erectile tissue. Externally the penis consists of a shaft and a tip, which is called the *glans*.
8. Sexual intercourse is made possible by the erectile reflex, in which tactile or psychogenic stimulation of the parasympathetic nerves causes arterioles in the corpora cavernosa and corpus spongiosum to dilate and fill with blood, causing the penis to enlarge and become firm.
9. Emission, which occurs at the peak of sexual arousal, is the movement of semen from the epididymides to the penis. Ejaculation, which is a continuation of emission, is the pulsatile ejection of semen from the penis.
10. Spermatogenesis is a continuous process because spermatogonia, the primitive male gametes, undergo continuous mitosis within the seminiferous tubules of the testes. Some spermatogonia develop into primary spermatocytes, which divide meiotically into secondary spermatocytes and then spermatids. The spermatids develop into sperm with the help of nutrients and hormonal signals from Sertoli cells.
11. Production of the male sex hormones (androgens) is controlled by interactions among the hypothalamus, anterior pituitary,

and gonads. The male hormones are produced steadily rather than cyclically, however.

Tests of Reproductive Function

1. Diagnostic tests are performed to evaluate fertility and detect disease.
2. Evaluation of fertility includes reproductive hormone assays and assessment of structural alteration or infections and the determination of normal ovulation or adequate sperm motility and count.

Aging and Reproductive Function

1. Perimenopause is the transitional period between reproductive and nonreproductive years in females. During this transition, the ovaries produce erratic and high levels of estrogen that contribute to such symptoms as hot flashes, breast tenderness and nodularity, and migraine headaches. Menstrual cycles shorten and then become irregular as anovulation occurs.
2. Menopause, the point that marks 12 consecutive months of amenorrhea, includes atrophic changes in the ovaries, vagina, and breast.
3. Males maintain reproductive capacity into their later years. In some males, there are gradual changes with testosterone deficiency, hypogonadism, proliferative disorders of the prostate, erectile dysfunction, and some loss of muscle mass and strength. Andropause is an androgen deficiency in the aging male.

Emerging Science Box Gender Reassignment and Gender Affirming Hormone Therapy

Transgender individuals are much more likely to experience anxiety, depression, and suicide attempts than cisgender

individuals. Many transgender individuals choose gender-affirming hormone therapy (GAHT) to align with their gender identity and reduce gender dysphoria. Many transgender individuals also choose body modification with gender-affirming surgery, but that option is not the focus here.

Individuals choosing GAHT must demonstrate a consistent and persistent gender-variant identity that meets the criteria for gender dysphoria as categorized by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (2013 American Psychiatric Association, Washington, DC). Guidelines are available to assist clinicians with the hormonal management of individuals seeking GAHT (Hembree et al., 2017, details cited below). The goal of hormone therapy is to suppress endogenous sex hormone secretion determined by the person's genetic/gonadal sex and maintain sex hormone levels within the normal range for the person's affirmed gender. Hormone treatment is currently not recommended for prepubertal gender-dysphoric/gender-incongruent persons. Prior to beginning therapy, medical and mental health conditions that can be exacerbated by hormone depletion and treatment with sex hormones need to be evaluated and managed. Testosterone regimens are prescribed for transgender men (female to male) and estrogen (e.g., 17 beta-estradiol) augmented by antiandrogens (e.g., spironolactone) are prescribed for transgender women (male to female). Dosages are individually determined and monitored to maintain physiologic hormone levels and to achieve and maintain desired feminine and masculine characteristics. GAHT reduces fertility, and individuals desiring genetic offspring can consider oocyte/embryo or semen cryopreservation.

Hormone therapy requires ongoing preventive health care for the management of modifiable risk factors. Transgender women receiving estrogen and antiandrogens are at risk for thromboembolic disease (venous thrombosis and pulmonary embolism), cardiovascular and cerebrovascular disease, hypertriglyceridemia, osteoporosis, and breast cancer. Transgender men receiving testosterone are at risk for erythrocytosis, cardiovascular and cerebrovascular disease, dyslipidemia (low

HDL, high LDL), hypertension, and breast, cervical and uterine cancer. Research is in progress to determine the long-term effects and safety profiles of hormone therapy and on cardiovascular health as cardiovascular disease is the leading cause of death in the transgender population undergoing GAHT.

GAHT has significant positive psychological effects on both adolescents and adults. Research tends to support that GAHT reduces symptoms of anxiety and depression, lowers perceived and social distress, and improves the quality of life and self-esteem for transgendered individuals.

Chapter Outline

OUTLINE

Abnormalities of the Female Reproductive Tract 767

Alterations of Sexual Maturation 768
- Delayed or Absent Puberty 769
- Precocious Puberty 769

Disorders of the Female Reproductive System 770
- Hormonal and Menstrual Alterations 770
- Infection and Inflammation 777
- Pelvic Organ Prolapse 782
- Benign Growths and Proliferative Conditions 784
- Cancer 790
- Sexual Dysfunction 800
- Impaired Fertility 801

Disorders of the Female Breast 802
- Galactorrhea 802
- Benign Breast Disease and Conditions 803
- Breast Cancer 804

Alterations of the female reproductive system span a wide range of clinical presentations, from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common reproductive disorders carry potentially serious physiologic and psychological consequences. Sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications can affect ovulation, menstruation, sexual performance, and fertility. These individuals may also be risk factors for the development of some types of reproductive tract cancers.[1,2]

Abnormalities of the Female Reproductive Tract

Normal development of the female reproductive tract requires the absence of testosterone during embryonic and fetal life (see Chapter 24). The resulting

fusion of the two paramesonephric (müllerian) ducts produces the normal cervix and the uterus with an internal cavity. The distal portions of the paramesonephric ducts remain independent and form the two fallopian/uterine tubes. Alterations in the normal process include errors in cellular sensitivity to testosterone (androgen insensitivity) or failures of cell line migration, resulting in changes in the structure of the reproductive organs.

Androgen insensitivity occurs in its most extreme form and is discussed briefly in this chapter because of the often-resulting female phenotype, despite a male genotype. **Androgen insensitivity syndrome (AIS)** is caused by an X-linked (recessive pattern) genetic mutation in cellular androgen receptors that results in an end-organ insensitivity to testosterone, which normally acts as the catalyst for the development of the male reproductive system in embryonic development. Three types of AIS include complete androgen insensitivity syndrome (CAIS), partial androgen insensitivity syndrome (PAIS), and mild androgen insensitivity syndrome (MAIS).[3] AIS is characterized by a female phenotype or feminization (i.e., undermasculinization) of the external genitalia at birth, abnormal secondary sexual development in puberty, and infertility in individuals with a 46,XY karyotype.

Complete androgen insensitivity syndrome (CAIS) occurs when the body cannot use androgens at all.[3] Individuals with CAIS have external sex characteristics of females, but have a vagina with a short canal (sometimes called a blind-ending) with no uterus; therefore they do not menstruate and are infertile. They are typically raised as females with a female sex identity. Affected children have male internal organs or testes (which may be palpable within the labia majora, inguinal ring, or abdominal cavity) that produce testosterone (and estrogen). Breast development may be normal, but pubic and axillary hair is often sparse. CAIS and PAIS are associated with a rare but increased risk of gonadal germ cell cancer (GGCC). Issues in management include decisions on sex assignment, gonadectomy and timing, fertility, hormone replacement, psychological outcomes, and genetic counseling.[4–7] The risks of osteopenia and osteoporosis are higher in those with early gonadectomy.[8] Partial androgen insensitivity (PAIS) (also a common cause of male infertility) has a varied phenotype from the residual androgen receptor. Persons with PAIS (also called *Reifenstein syndrome*) can have genitalia that look typically female, genitalia that have both male and female characteristics, or genitalia that look typically male. These individuals are raised as males or as females and may have a male or female sex identity. Those with **mild androgen insensitivity syndrome** are born with male sex characteristics but are often infertile and may experience breast enlargement at puberty.

Other abnormalities of the uterus, cervix, and fallopian/uterine tubes have multifactorial origins, often the result of an interaction between genetic

predisposition and environmental factors. Such interactions result in müllerian duct abnormalities. Some medications, chemicals, and toxins have been implicated as a direct cause of uterine abnormalities. An example, diethylstilbestrol (DES) was prescribed from 1938 until 1971 as a drug to prevent miscarriages. DES affected cell development, causing abnormal internal reproductive structural defects, infertility, and a predisposition to cancer (see Chapter 13). Most uterine abnormalities stem from abnormal cell migration in the müllerian ducts during key moments in fetal development (Fig. 25.1). Uterine abnormalities are rarely diagnosed until the woman has trouble becoming pregnant or carrying a baby to term, because the uterus is capable of menstruation but may have difficulty supporting a growing fetus. Uterine malformations are usually diagnosed by ultrasound during pregnancy or with magnetic resonance imaging (MRI). The prognosis depends on the severity of the malformation and the location and size of the placenta and fetus. Some abnormalities can be surgically corrected to improve the outcome of subsequent pregnancies. Abnormalities of the lower genital tract also can result in women having two vaginas or a vaginal septum (a thin membrane dividing the vaginal vault). For most women this does not create functional problems, but it can be surgically corrected if needed.[9,10]

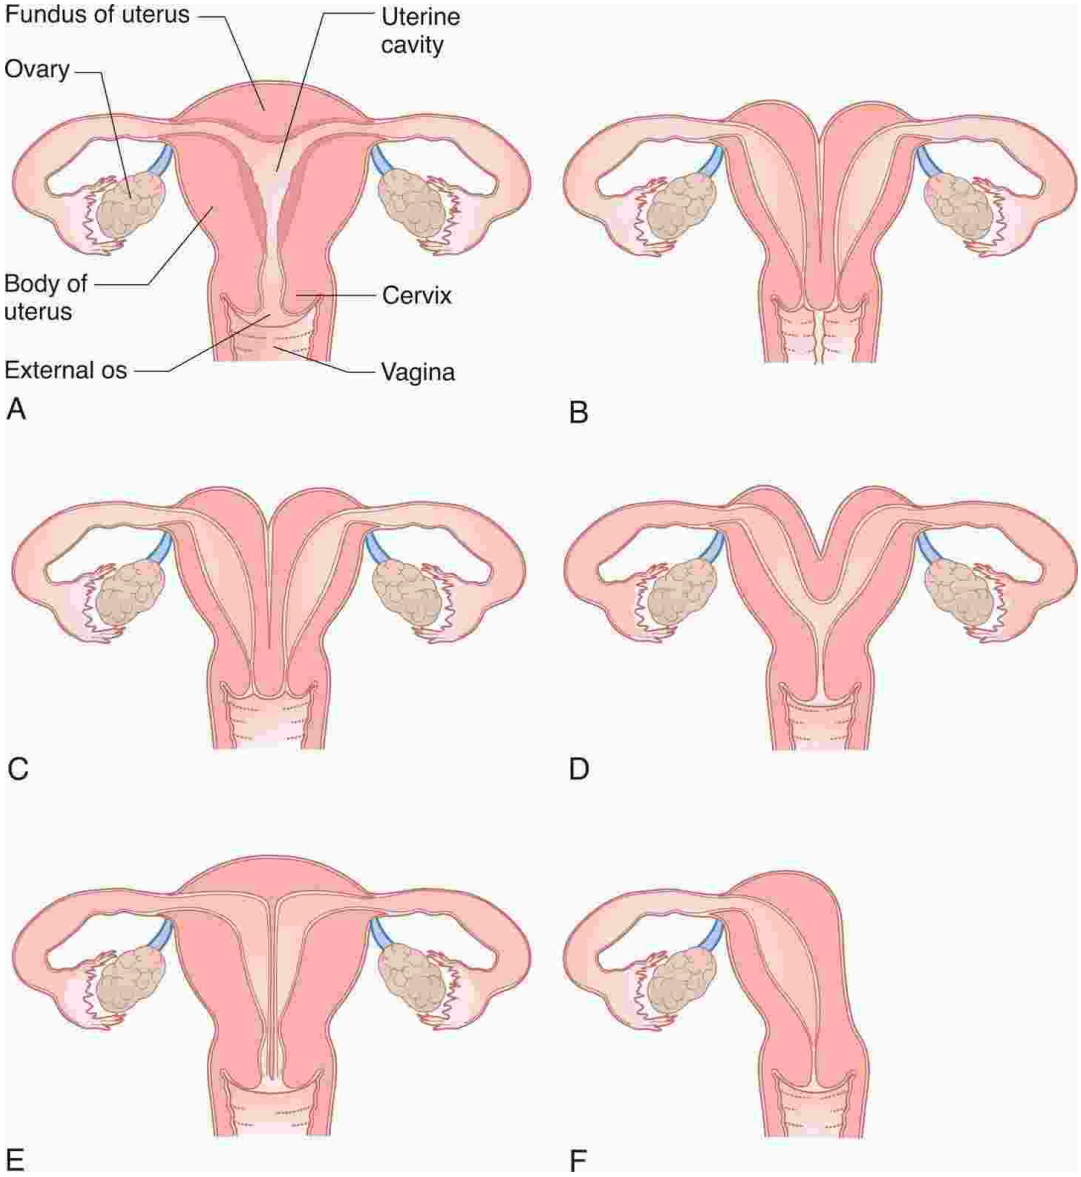

FIG. 25.1 Uterine Malformations.
Congenital uterine abnormalities. (A) The normal configuration of the uterus and the ovaries. (B) Double uterus with a double vagina. (C) A single vagina. (D) Bicornuate uterus. (E) A uterus with a midline septum. (F) Unicornuate uterus. (From de Bruyn R. *Pediatric ultrasound*, 2nd edition. London: Churchill Livingstone; 2010.)

Six illustrations of the female reproductive system, A through F, depict the classification of uterine anomalies. Illustration A shows the normal uterus and ovaries with labels indicating the fundus of the uterus, uterine cavity, cervix, vagina, the body of

the uterus, external os, and ovary. Illustration B depicts the double uterus with a double vagina. Illustration C depicts the double uterus with a single vagina. Illustration D depicts the heart-shaped uterus. Illustration E depicts the uterus with a partition in the middle. Illustration F depicts a one-sided uterus with single fallopian tube.

Alterations of Sexual Maturation

The process of sexual maturation, or **puberty**, is marked by the development of secondary sex characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty. These disorders may cause puberty to occur too late *(delayed puberty)* or too early *(precocious puberty)*. Both types involve an inappropriate onset of sex hormone production by the gonads and have potential implications for the child's social interactions and self-esteem.

The age of puberty is multifactorial, involving genetic and environmental components. The onset of puberty is 8 to 13 years of age and appears to be occurring earlier for girls. Females of African, Hispanic, and Latino descent begin puberty up to 1 year sooner than the average young female. The earlier onset appears primarily in breast development and not age of menarche. Puberty may also be accelerated by obesity.

Delayed or Absent Puberty

Delayed puberty is characterized by the absence of pubertal signs past the normal age range for the typical population. One of the first signs of puberty in girls is **thelarche**, or breast development, which typically begins by 13 years of age. In delayed puberty, these secondary sex characteristics develop later, but there are clear variations according to race and ethnicity that need consideration at the time of diagnosis. Delayed puberty is diagnosed if there is no breast development by age 13, which is 2 to 2.5 standard deviations greater than the mean age of pubertal onset. Pubic hair may be present because that is largely dependent on adrenal rather than gonadal function. Delayed puberty may have significant psychosocial implications and an increased risk for inadequate skeletal development and mineralization due to the rapid skeletal growth during that time. The majority of bone development and mineralization is achieved during adolescence. Estrogen plays a major role in this process, and a lack of

circulating estrogen puts individuals at risk for inadequate bone density in adulthood.[11]

In most cases, delayed puberty is a physiologic (constitutional) delay. Hormonal levels are normal, the hypothalamic-pituitary-gonadal (HPG) axis is intact, and maturation is slowly occurring. Often, an underlying condition or illness unrelated to gonadal function is responsible for the delayed development (Table 25.1).

Table 25.1

Frequency and Common Causes of Delayed Puberty Other Than Constitutional Delay of Growth and Puberty

Delayed Puberty	Hypergonadotropic Hypogonadism	Permanent Hypogonadotropic Hypogonadism	Functional Hypogonadotropic Hypogonadism
Male (assigned at birth)	5%–10%	10%	20%
Female (assigned at birth)	25%	20%	20%
Common causes	Turner syndrome, gonadal dysgenesis, chemotherapy, radiation therapy	Tumors or infiltrative diseases of the central nervous system, GnRH deficiency (isolated hypogonadotropic hypogonadism, Kallmann syndrome), combined pituitary-hormone deficiency, chemotherapy, or radiation therapy	Systemic illness (inflammatory bowel disease, celiac disease, anorexia nervosa, or bulimia), hypothyroidism, excessive exercise

Delayed Puberty	Hypergonadotropic Hypogonadism	Permanent Hypogonadotropic Hypogonadism	Functional Hypogonadotropic Hypogonadism
Male (assigned at birth)	5%–10%	10%	20%
Female (assigned at birth)	25%	20%	20%
Common causes	Turner syndrome, gonadal dysgenesis, chemotherapy, radiation therapy	Tumors or infiltrative diseases of the central nervous system, GnRH deficiency (isolated hypogonadotropic hypogonadism, Kallmann syndrome), combined pituitary-hormone deficiency, chemotherapy, or radiation therapy	Systemic illness (inflammatory bowel disease, celiac disease, anorexia nervosa, or bulimia), hypothyroidism, excessive exercise

GnRH, Gonadotropin-releasing hormone.

Data from Palmert MR, Dunkel L. Clinical practice. Delayed puberty. New *England Journal of Medicine*, 2012;366(5):443–453.

A delay in the production of gonadotropin-releasing hormone (GnRH) from the HPG axis further delays production of the gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which ultimately delays gametogenesis. The G protein–coupled receptor 54 (GPR54) has been identified as the gatekeeper gene for activation of the BnRH axis. GPR54 is required for the normal function of this axis, and data suggest that the ligand kisspeptin-1 may act as a neurohormonal regulator of the GnRH axis.[11–13]

Given the numerous etiologies contributing to the occurrence of delayed puberty, a thorough evaluation should be conducted that includes past medical history, birth history, family history, social history, and a physical examination. It is essential to review the child's growth curve based on appropriate age, sex, height, weight, and body mass index (BMI). If further work-up is warranted, a bone age can help to determine the child's growth status. Before ordering lab and imaging tests, the child's predicted target height should be plotted.[14] Laboratory and diagnostic work-up may consist of x-ray studies for bone age, measurement of thyroid function, determination of serum levels of prolactin, measurement of adrenal and gonadal steroids, radioimmunoassay of plasma gonadotropins, and screening for systemic disorders. Adolescents with high gonadotropin levels require a karyotype to rule out genetic causes, and those with low levels need skull imaging to rule out pituitary or central nervous system (CNS) pathology (infiltrate or tumor).[14,15]

Treatment of delayed puberty depends on the cause. The goals of treatment are the development of secondary sex characteristics and fertility (if possible) and the promotion of bone growth and mineralization.[12] The treatment for certain variations of delayed puberty requires lifelong hormone replacement therapy (HRT), synthetic GnRH, or sex hormone administration solely or in combinations.[13] This physiologic delay tends to be familial, is less common in girls than boys, and is diagnosed often retrospectively once pubertal progression is complete. Treatment is seldom needed unless the delayed puberty is causing psychosocial problems.

Precocious Puberty

Precocious puberty is the onset of sexual characteristics (breast or pubic hair development) 2 to 2.5 standard deviations below the mean age of onset of puberty in the racial and ethnic context of the individual. Precocious puberty is categorized into three groups: central precocious puberty (GnRH dependent),

peripheral precocious puberty (GnRH independent), and benign pubertal variants.[16] Premature development of secondary sex characteristics causes premature closure of the epiphysis of long bones, which results in lifelong short stature and often carry profound psychosocial consequences.[17,18] Precocious puberty can be a sign of pathologic conditions; therefore all cases of precocious puberty require thorough evaluation.

Central precocious puberty, or true precocious puberty, is GnRH dependent and occurs when the HPG axis is working normally but prematurely.[17] Central precocious puberty results from failure of the central inhibition of the GnRH pulse generator because of a CNS abnormality. Causes can be idiopathic or can include CNS lesion, genetics, previous excess of sex steroid exposure, or pituitary gonadotropin-secreting tumors.[19,20] Most cases of precocious puberty in females are idiopathic, and in males there is usually an underlying pathology. Several conditions include CNS tumors, CNS injury, genetics, certain syndromes (e.g., neurofibromatosis type 1), and environmental or familial factors.[16] Recently, mutations in the imprinted gene MKRN3 were discovered as a cause of familial central precocious puberty.[19–22]

Peripheral precocious puberty, or gonadotropin-independent precocious puberty, is an excess of estrogens secreted from the gonads or adrenal glands from exogenous sources.[16] Some causes of peripheral precocious puberty include: Ovarian cysts, ovarian tumors, primary hypothyroidism (Van Wyk and Grumback syndrome), adrenal pathology, exogenous sex steroids, endocrine-disrupting chemicals, and McCune-Albright syndrome.[16,23]**Benign pubertal variants** include isolated premature thelarche, pubarche, self-limiting vaginal bleeding, and nonprogressive precocious puberty. The etiology of benign pubertal variants is characterized by not fitting into any other category of precocious puberty and is not followed by progressive development. However, close monitoring is still important to ensure that the variant is, in fact, benign and does not progress.

The diagnosis and cause of premature development are often straightforward. A thorough history and physical examination are done to determine the impetus of the process and to rule out life-threatening CNS, ovarian, or adrenal neoplasms. A family history and social history help to exclude or include certain genetic conditions as well as environmental, medication, and hormonal exposures. Children with precocious puberty may have a tendency toward obesity. Treatment for all forms of precocious puberty is aimed to identify and remove the underlying cause. Work-up typically starts with laboratory evaluation of LH, FSH, and estradiol.[24] Urinary gonadotropins are useful in the assessment and management of precocious puberty.[25,26] Management goals include arresting maturation until developmentally appropriate, maximizing

eventual adult height, and reducing emotional problems. Because many of these children are obese and childhood obesity is predictive of morbidity in adolescence and adulthood, it is important for clinicians to include assessment and management of obesity in conjunction with the treatment of precocious puberty.[24–26]

Disorders of the Female Reproductive System

Hormonal and Menstrual Alterations

Dysmenorrhea

Primary dysmenorrhea is recurrent, painful menstruation associated with the release of prostaglandins in ovulatory cycles but not with pelvic disease. Primary dysmenorrhea begins a few days before menstruation and persists for 48 to 72 hours.[27] Women are more likely to report primary dysmenorrhea if they are younger than 30 years old; have not given birth; have a history of sexual assault, premenstrual syndrome (PMS), or sterilization; are heavy tobacco or alcohol users; have a family history of dysmenorrhea; or have a BMI less than 20.[28] In contrast, **secondary dysmenorrhea** is painful menses in the presence of a pelvic pathologic condition. Secondary dysmenorrhea manifests later in the reproductive years and may occur any time in the menstrual cycle.[29]

Pathophysiology

Primary dysmenorrhea results from excessive prostaglandin synthesis of $F_2\alpha$ ($PGF_2\alpha$), a potent myometrial stimulant and vasoconstrictor, found in secretory endometrium. Elevated levels of prostaglandins, especially PGF2α and PGE2α, increase myometrial contractions, constrict endometrial blood vessels, and enhance nerve hypersensitivity, which results in pain.[30,31] These changes can lead to ischemia and endometrial shedding. Increased synthesis of prostaglandins may result from increased cyclooxygenase (COX) enzyme activity. Inflammatory mediators produced in leukocytes (leukotrienes) also contribute to increased levels of pain. The first 48 hours of menstruation correlate with higher prostaglandin levels, which may contribute to pain.[29] Women who experience severe primary dysmenorrhea appear to have a heightened pain sensitivity and possibly an alteration in their pain modulating system which puts them at higher risk for functional pain disorders (e.g., fibromyalgia) later in life.[32] Women who are anovulatory because they use oral contraceptives rarely have primary dysmenorrhea.[28]

Secondary dysmenorrhea results from disorders such as endometriosis (most common cause), endometritis (infection), adenomyosis, pelvic inflammatory disease (PID), obstructive uterine or vaginal anomalies, inflammation, uterine

fibroids, polyps, tumors, cysts, ovarian cysts, pelvic congestion syndrome, or nonhormonal intrauterine devices (IUDs).[18]

Clinical Manifestations

The chief symptom of dysmenorrhea is pelvic pain associated with the onset of menses. The severity is directly related to the length and amount of menstrual flow. The pain often radiates into the groin and may be accompanied by fatigue, backache, anorexia, nausea, vomiting, diarrhea, syncope, insomnia, and headache. The latter symptoms are caused by the entry of prostaglandins and their metabolites into the systemic circulation. Secondary dysmenorrhea has very similar symptoms but in response to an underlying causative pathology.[29]

Evaluation and Treatment

A thorough medical history and pelvic examination can differentiate primary dysmenorrhea from secondary dysmenorrhea. Nonsteroidal antiinflammatory drugs (NSAIDs) (e.g., ibuprofen) are the treatment of choice because they reduce COX enzyme activity and thus prostaglandin production. NSAIDs are effective in the majority of women with primary dysmenorrhea and are most effective if started at the first sign of bleeding or cramping.[33] However, long-term use of NSAIDs has been associated with multiple side effects.[34] In women who desire contraception, dysmenorrhea may be relieved with hormonal contraceptives. Hormonal contraception inhibits ovulation and reduces endometrial proliferation, thereby decreasing prostaglandin synthesis and myometrial contractility. Regular exercise and stress reduction are thought to prevent or reduce symptoms. Complimentary approaches for treatment include local application of heat, herbs, yoga, relaxation, psychotherapy, massage, hypnosis, vitamins (E, B, C) and supplements (calcium and magnesium), acupressure, and acupuncture.[27]

Primary Amenorrhea

Amenorrhea is the lack of menstruation in females of reproductive age. **Primary amenorrhea** is the failure of menarche and the absence of menstruation by age 14 years without the development of secondary sex characteristics or by age 16 years regardless of the presence of secondary sex characteristics. In contrast, **secondary amenorrhea** is defined as the cessation of previous menses for more than 6 months.[35]

Pathophysiology

Normal menstruation depends on the structure and function of the genital outflow tract, including the uterus, ovaries, pituitary gland, and hypothalamus. If any of these components are nonfunctional, bleeding cannot occur.[36,37] The most

common causes of amenorrhea (aside from pregnancy) include anatomic defects, elevated FSH levels, hyperprolactinemia, hypothalamic amenorrhea, or polycystic ovary syndrome (PCOS) (Table 25.2).[38] Anatomic defects, including absence of the vagina and uterus, are a disorder associated with amenorrhea. Genetically normal females without a uterus or vagina usually have normal ovarian function. Therefore skeletal growth occurs and secondary sex characteristics develop in the proper sequence, but menstruation does not occur because the uterus is too small or malformed to produce substantial endometrium. Other disorders related to amenorrhea involve the ovary, primarily genetic disorders (e.g., Turner syndrome), and AIS. Gonadal dysgenesis includes Turner syndrome, which accounts for approximately 43% of primary amenorrhea cases.[39] The target organs (e.g., ovaries) in AIS are completely resistant to the action of androgens, resulting in a lack of estrogen. Without primitive gametes and follicles, follicular development and estrogen secretion cannot occur. Lack of estrogen accounts for failure of secondary sex characteristic development and amenorrhea, although there are high levels of circulation FSH and LH.[40] Disorders of the anterior pituitary gland, including tumors, may result in failure of signaling to the ovaries through FSH and LH secretion. Examples of such defects include hydrocephalus, craniopharyngiomas, and other space-occupying lesions of the CNS. The target (the ovary) does not receive the necessary signals, and ovulation and menstruation do not occur. In some cases, these lesions develop between the onset and conclusion of puberty. Therefore skeletal growth may occur and secondary sex characteristics may develop, but sexual maturation is interrupted before menarche. Finally, CNS disorders that primarily involve hypothalamic defects, prevent secretion of GnRH; thus there is no signaling to the pituitary to release FSH and LH. The ovary does not receive the hormonal signals required to stimulate estrogen production, and ovulation and menstruation do not occur. Because the ovarian hormones are absent, estrogen-dependent sex characteristics do not develop. CNS tumors can cause these disruptions in the hypothalamic-pituitary-ovarian axis.[41]

Table 25.2

Common Causes of Primary Amenorrhea

Anatomic Defects	The diagnosis is typically müllerian agenesis
Uterus and vagina are partially or completely lacking in the presence of otherwise normal female sexual characteristics.Other defects include imperforate hymen or transverse vaginal septum	Accounts for ~10% of cases Create a partial or complete vaginal blockage
Elevated Follicle-Stimulating Hormone	Individuals with XX chromosomes, gonadal failure refers to ovarian failure and isolated absence of the vagina or cervix
Indicate gonadal dysfunction	
Hyperprolactinemia	Involved in many reproductive functions; Prolactin secretion inhibits secretion of gonadotropin-releasing hormone (GnRH), which negatively modulates the secretion of pituitary hormones
Prolactin	
Hypothalamic Amenorrhea	Functional disorder of the hypothalamus
Cessation or absence of menses	
Polycystic Ovary Syndrome (PCOS)	Three characteristics include: hyperandrogenism, polycystic ovaries, and ovulatory dysfunction.
Most common cause of amenorrhea in females with evidence of androgen excess; common reproductive and endocrinologic disorder	
Other	
Hypopituitarism, weight loss, anorexia nervosa, GnRH deficiencyConstitutional delay of puberty, chronic systemic disease, or acute illness

Data from Gasner A, Rehman A. *Primary Amenorrhea*. StatPearls [Internet]. Treasure Island, FL: StatPearls Publishing; 2021.

Clinical Manifestations

The major clinical manifestation of primary amenorrhea is the absence of the first menstrual period. The cause of the amenorrhea determines whether secondary sex characteristics and height are affected.

Evaluation and Treatment

Diagnosis of primary amenorrhea is based on the history and physical examination. It is necessary to first rule out pregnancy. The Tanner scale should be used to stage pubertal development to determine whether secondary sexual characteristics are present. Absence of these sexual characteristics indicates that a female has never been exposed to estrogen. If ovarian steroid hormone levels are low, the individual has the appearance of an immature female. Pelvic ultrasound is used to confirm the presence or absence of a uterus.[39] Laboratory studies may be required to document abnormal levels of gonadotropins or ovarian hormones or the presence of genetic conditions. Diagnostic imaging, including ultrasonography and MRI, is used to document structural abnormalities.[42,43]

Treatment involves correction of any underlying disorders and implementation of HRT to induce the development of secondary sex characteristics. Although surgical alteration of the genitalia may be undertaken to correct structural abnormalities, it should be postponed until the individual can make a truly informed decision.[39] Hormonal manipulation or embryo transplantation may

make pregnancy possible for women with primary amenorrhea who have a normal uterus.

Secondary Amenorrhea

Secondary amenorrhea is the absence of menstruation for a time equivalent to three or more cycles in women who previously had regular menstrual cycles or 6 months in females with irregular menstrual cycles. A wide variety of disorders and physiologic conditions is associated with secondary amenorrhea.[35] Secondary amenorrhea is common during early adolescence, pregnancy, lactation, and the perimenopausal period, primarily because of anovulation.[44] The most common causes (after pregnancy) are thyroid disorders (e.g., hypothyroidism); hyperprolactinemia; hypothalamic-pituitary-ovarian (HPO) interruption secondary to excessive exercise, stress, or weight loss; and PCOS. The factors leading to secondary amenorrhea also may cause primary amenorrhea in a young woman who has not begun to menstruate.

Pathophysiology

The pathophysiology is dependent on the causes of secondary amenorrhea (Fig. 25.2). Hormonal causes include pregnancy, lactation, thyroid dysfunction, hyperprolactinemia, hyperandrogenism (including PCOS), hypogonadotropic hypogonadism (hypothalamic-pituitary dysfunction), and suppression of the endometrium by hormonal birth control. Structural causes include damage to the endometrium (Asherman syndrome) and obstruction of the outflow tract (cervical stenosis). An excess of ovarian hormones disrupts feedback relationships within the HPO axis, preventing ovulation. Depressed ovarian hormone levels also cause amenorrhea by preventing ovulation. Lack of ovulation, termed *anovulation*, may result from increased levels of prolactin, decreased levels of gonadotropins, irregular secretion of gonadotropins, or abnormally low levels of CNS neurotransmitters. Any of these variables can alter the feedback mechanism that ovarian hormones have on the hypothalamus and pituitary.

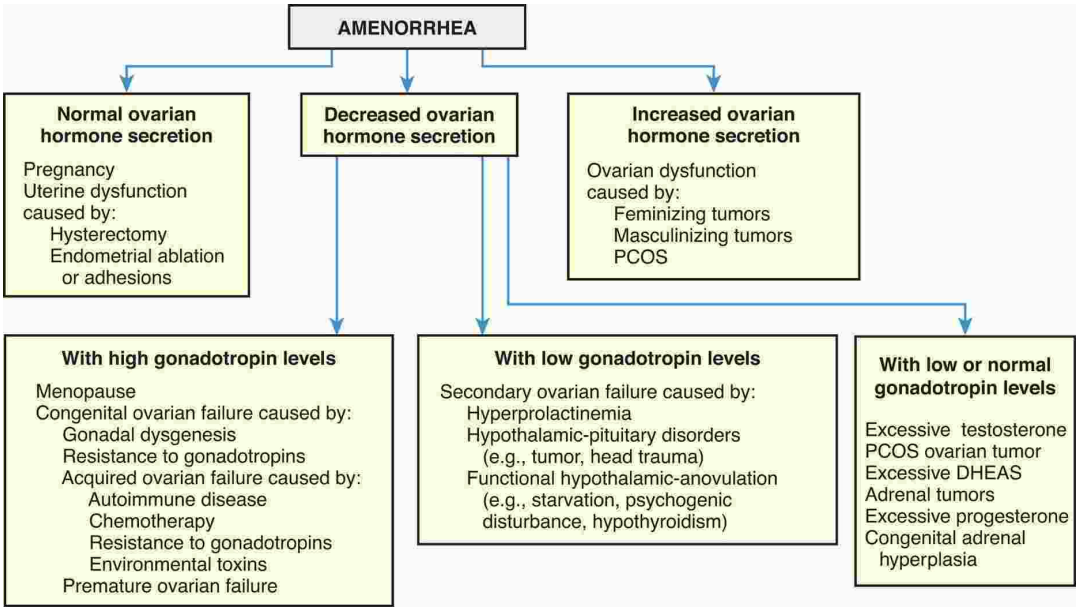

FIG. 25.2 Causes of Secondary Amenorrhea.
Of note, hypothyroidism is a relatively common condition and should be ruled out as the cause of hyperprolactinemia before more extensive evaluation (i.e., computed tomography or magnetic resonance imaging) occurs. *DHEAS*, Dehydroepiandrosterone sulfate; *PCOS*, polycystic ovary syndrome.

A flowchart summarizes the pathophysiology of secondary amenorrhea. The chart begins as follows. â€¢ Amenorrhea leads to decreased ovarian hormone secretion, normal ovarian hormone secretion, and increased ovarian hormone secretion. â€¢ Normal ovarian hormone secretion causes pregnancy; uterine dysfunction due to hysterectomy, endometrial ablation, or adhesions. â€¢ Increased ovarian hormone secretion causes ovarian dysfunction due to feminizing tumors, masculinizing tumors, P C O S. â€¢ Decreased ovarian hormone secretes with high gonadotropin levels, low gonadotropin levels, and low or normal gonadotropin levels. â€¢ High gonadotropin levels cause menopause; Congenital ovarian failure caused by: Gonadal dysgenesis; Resistance to gonadotropins. Acquired ovarian failure caused by:

Autoimmune disease; Chemotherapy; Resistance to gonadotropins; Environmental toxins; Premature ovarian failure. â€¢ Low gonadotropin levels cause Secondary ovarian failure caused by: Hyperprolactinemia; Hypothalamic-pituitary disorders, for example, tumor, head trauma; Functional hypothalamic-anovulation for example, starvation, psychogenic disturbance, hypothyroidism. â€¢ Low or normal gonadotropin levels cause Excessive testosterone; P C O S ovarian tumor; Excessive D H E A S; Adrenal tumors; Excessive progesterone; Congenital adrenal; hyperplasia.

High levels of prolactin are physiologic during lactation because it increases milk production and suppresses ovulation, preventing closely spaced pregnancies. However, high levels of prolactin not related to lactation are abnormal and will disrupt the menstrual cycle. Hyperprolactinemia (overproduction of prolactin by the pituitary) may have indirect effects that lead to decreased secretion of GnRH by the hypothalamus. The result is a reduction in FSH and LH secretion followed by anovulation and secondary amenorrhea. Hyperprolactinemia can have many causes, including medication side effects, hypothyroidism, excessive nipple stimulation, and pituitary tumors.[45]

Clinical Manifestations

The major manifestation of secondary amenorrhea is the absence of menses after previous menstrual periods, infertility, vasomotor flushes, vaginal atrophy, acne, and osteopenia. **Hirsutism** (abnormal hairiness) may also be present, depending on the underlying cause of the amenorrhea.

Evaluation and Treatment

Pregnancy is the most common cause of secondary amenorrhea and must be ruled out before any further evaluation. A thorough history and physical examination are important because the menstrual cycle may stop or become irregular in response to stress, exposure to severe emotional stress, extreme exercise, dietary changes, eating disorders, or sleep abnormalities.[46] After ruling out pregnancy and PCOS, initial laboratory evaluation includes measurement of thyroid-stimulating hormone (TSH) and prolactin levels. Elevated prolactin levels warrant further investigation, which could include performing a progestin challenge; measurement of gonadotropins (FSH), estrogen, and testosterone; and ultrasonography of the outflow tract and/or ovaries, MRI, or both.[35]

Treatment of amenorrhea depends on the cause and on the woman's psychological need for cycle stability. Treatments may include replacing deficient hormones (e.g., estrogens, thyroid hormone, glucocorticoids, gonadotropins) or correcting underlying pathologic conditions.[41] A diagnosis of PCOS may be treated with an insulin-sensitizing agent, such as metformin, as well as ovulation-inducing drugs if fertility is desired. Asherman syndrome is treated with hysteroscopic lysis of lesions, and cervical stenosis is treated with cervical dilation. The goals of therapy include correcting the underlying pathology, achieving fertility, and preventing complications of treatment.

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) is bleeding that is abnormal in duration, volume, frequency, or regularity and has been present for the majority of 6 months, outside of pregnancy.[47] AUB may be acute or chronic and is classified by the cause of bleeding using an internationally recognized PALM-COEIN acronym (**P**olyp, **A**denomyosis, **L**eiomyoma, **M**alignancy [and hyperplasia]-**C**oagulopathy, **O**vulatory disorders, **E**ndometrial, **I**atrogenic, and **N**ot otherwise classified) (Fig. 25.3). Approximately one-third of females will experience AUB in their lifetime, with irregularities most commonly occurring at menarche and perimenopause.[47]

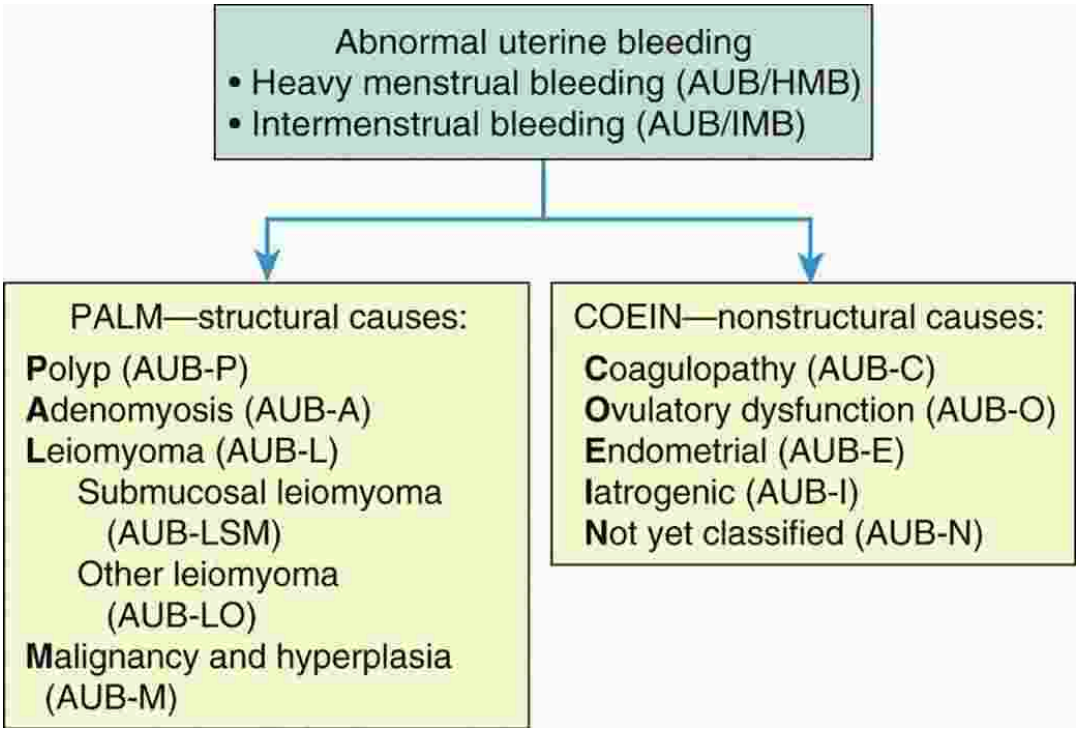

FIG. 25.3 PALM-COEIN System for Classification of Abnormal Uterine Bleeding.
AUB, Abnormal uterine bleeding. (Modified from Critchley HOD, Fraser IS. The FIGO classification of causes of abnormal uterine bleeding: Malcolm G. Munro, Hilary O.D. Crithcley, Ian S. Fraser, for the FIGO Working Group on Menstrual Disorders. *International Journal of Gynecology & Obstetrics*, 2011;113:3–13.)

A flowchart summarizes the classification of abnormal uterine bleeding recognized by the PALM-COEIN System. â€¢ Abnormal uterine bleeding includes heavy menstrual bleeding (A U M or H M B); intermenstrual bleeding (A U B or I M B) is classified into two. â€¢ One is P A L M-structural causes: Polyp or A U B-P; adenomyosis or A U B-A; leiomyoma or A U B-L; submucosal leiomyoma or A U B-L S M; other leiomyoma or A U M-L O; malignancy and hyperplasia or A U B-M. â€¢ Two are C O E I N-nonstructural causes: Coagulopathy or A U B-C; Ovulatory dysfunction or A U B-O; endometrial or A U B-E; Iatrogenic or A U B-I; Not yet classified or A U B-N.

Acute AUB is excessive bleeding that requires immediate treatment. Acute AUB can occur on its own or as a part of chronic AUB. **Chronic AUB** is irregularities in menstrual bleeding for most of the previous 6 months.[48] Some structural changes, such as endocervical polyps, endometrial polyps, or leiomyomas, may be asymptomatic and not the primary cause of AUB.[47] In the 2018, AUB secondary to anticoagulants was moved from the coagulopathy category to the iatrogenic category by the International Federation of Gynecology and Obstetrics (FIGO) system. Conditions included in the *"not otherwise classified"* were PID, chronic liver disease, and cervicitis. The prevalence of AUB among reproductive-aged women internationally is estimated as 3% to 30%, with a higher incidence occurring around menarche and perimenopause. Because many women do not seek health care for their symptoms, the exact prevalence is uncertain. In premenstrual or menopausal women, any bleeding is considered abnormal. For reproductive-aged women, normal uterine bleeding is every 28 days with variation up to 7 days. Bleeding more frequently than every 21 days, or less frequently than every 35 days, is considered abnormal. Menstrual bleeding for longer than 7 days also is considered abnormal.[49] AUB is the leading cause for hysterectomy in the United States.

Pathophysiology

The majority of AUB is associated with lack of ovulation. Normal, regular periods are the result of a complex interplay between the hypothalamus, pituitary, ovary, and uterine endometrium. Disruptions in this system can affect the amount and structure of the uterine endometrium, causing it to shed irregularly or heavily. Although anovulatory AUB may occur at any time during the reproductive years and many conditions are associated with irregular ovulation, it tends to occur in adolescents and perimenopausal women more frequently because women at the edges of their productive years are more likely to ovulate irregularly. The formation of a follicle and its rupture to release an ovum are important components of the menstrual cycle. As the follicle forms, it produces estrogen, which causes proliferation of the endometrium. Following ovulation, the remaining portions of the follicle, known as the corpus luteum, release progesterone. The progesterone acts on the proliferating endometrium to limit growth and cause changes in the vasculature of the endometrium. This limits bleeding during endometrial shedding.

If a follicle forms but never releases the ovum, the follicle may continue to produce estrogen, encouraging endometrial proliferation beyond the normal 14-day time. In addition, the lack of progesterone causes the thickened endometrium to be unable to shed in a predictable fashion without excessive blood loss. Women who fail to ovulate experience irregularities in their menstrual bleeding because of a lack of progesterone and, in some cases, an excess of estrogen.

Without ovulation, menstrual flow may become irregular, excessive, or both, resulting from the large quantity of tissue available for bleeding and the random breakdown of tissue that results in exposure of vascular channels. Derangements to the clotting pathways (coagulopathies or iatrogenic) can lead to abnormal bleeding with prolonged and excessive flow. Stasis does not occur because the normal control mechanisms (i.e., vasoconstrictive rhythmicity, tight coiling of spiral vessels, and orderly collapse) are absent from the lack of progesterone. **Unopposed estrogen** induces a progression of endometrial responses beginning with proliferation, hyperplasia, and adenomatous hyperplasia. Over a course of many years, unopposed estrogen may end with atypia and carcinoma.

Abnormal menstrual bleeding also can result from defects of the corpus luteum, resulting in progesterone deficiencies, or from abnormalities of the uterus or cervix. Examples include endometrial polyps, uterine fibroids, or even uterine or cervical cancers. Coagulation defects also can cause heavy and AUB and should be suspected in younger women with a history of extensive bruising or bleeding during dental procedures. Iatrogenic AUB can be caused by IUDs or long-acting contraceptive implants or medications, such as anticoagulants, steroids, digitalis, phenytoin, or hypothalamic depressants.[50,51]

Clinical Manifestations

AUB is characterized by unpredictable and variable bleeding in terms of amount and duration. Especially during perimenopause, dysfunctional bleeding also may involve flooding and the passing of large clots, leading to excessive blood loss. Excessive bleeding can lead to iron deficiency anemia and its associated symptoms, including fatigue or shortness of breath. AUB also may cause pain, decreased productivity, and sexual dysfunction.

Evaluation and Treatment

The first step in the evaluation of AUB is to establish the cause of bleeding. Evaluation includes a thorough history, physical examination, and transvaginal ultrasound. Laboratory evaluation includes a pregnancy test, complete blood count (CBC), ferritin, thyroid function tests, coagulation studies, gonadotropins, and prolactin if indicated. If no cause is found, it is usually assumed that the bleeding is caused by lack of regular ovulation. Based on the PALM-COEIN acronym, specific treatment goals are indicated for each category (Box 25.1). Therapeutic goals include preventing or controlling abnormal bleeding, identifying underlying disease, and inducing regular menstrual cycles. Treatment varies greatly by the age of the woman and her desire for current and future fertility.[52,53]

Box 25.1

Treatment Guidelines According to PALM-COEIN

Polyps are treated through surgical resection.

Adenomyosis is treated by hysterectomy. Less often, adenomyomectomy is performed.

Leiomyomas (fibroids) are treated according to the individual's desire, include both medical and surgical management for fertility, medical comorbidities, pressure symptoms, and distortion of the uterine cavity. Surgical options include uterine artery embolization, endometrial ablation, or hysterectomy. Medical management options include a levonorgestrel-releasing intrauterine device (IUD), GnRH agonists, systemic progestins, and tranexamic acid with nonsteroidal antiinflammatory drugs (NSAIDs).

Malignancy or hyperplasia can be treated through surgery, ± adjuvant treatment depending on the stage, progestins in high doses when surgery is not an option, or palliative therapy, such as radiotherapy.

Coagulopathies leading to abnormal uterine bleeding (AUB) can be treated with tranexamic acid or desmopressin (DDAVP).

Ovulatory dysfunction can be treated through lifestyle modification in women with obesity, polycystic ovary syndrome (PCOS), or other conditions where anovulatory cycles are suspected. Endocrine disorders, for example Cushing syndrome, are corrected using appropriate medications, such as cabergoline for hyperprolactinemia and levothyroxine for hypothyroidism.

Endometrial disorders have no specific treatment because mechanisms are not clearly understood.

Iatrogenic causes of AUB are based on offending drug(s). If a contraception method is suspected, alternative methods are considered, such as the levonorgestrel-releasing IUD, combined oral contraceptive pills (in monthly or extended cycles), or systemic progestins. If other medications are suspected but cannot be discontinued, the aforementioned methods can also help to control AUB.

Not otherwise classified causes of AUB include endometritis and arteriovenous malformations (AVMs). Endometritis can be treated with antibiotics and AVMs with embolization.Data from American College of Obstetricians and Gynecologists (ACOG) committee opinion no. 557: Management of acute abnormal uterine bleeding in nonpregnant reproductive-aged women. Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) remains one of the most common endocrine disturbances affecting women. The National Institutes of Health (NIH) criteria for the diagnosis of PCOS require at least two of these three conditions: menstrual irregularity, hyperandrogenism, and appearance of polycystic ovaries on ultrasonography. International criteria (Androgen Excess-PCOS Society Criteria, Rotterdam Criteria) also include any two of the three conditions. The Rotterdam definition is the most widely used PCOS classification.[54] Polycystic ovaries do not have to be present to diagnose PCOS, and their presence alone does not establish the diagnosis. Signs and symptoms of PCOS can vary over time, with metabolic syndrome becoming more prominent with age.[55]

Pathophysiology

No single factor fully accounts for the abnormalities of PCOS. PCOS is a heterogeneous disorder with different manifestations and phenotypes.[54]Box 25.2 summarizes the phenotypes. The more criteria met by an individual with PCOS, the more severe a particular phenotype is considered.[54] Hyperandrogenic state is a cardinal feature in the pathogenesis of PCOS. Two-thirds of cases of PCOS are due to functional ovarian hyperandrogenism (FOH). It is characterized by dysregulation of androgen secretion with an increased response of 17-hydroxyprogesterone (17-OHP) to gonadotropin stimulation. Other PCOS cases have atypical FOH detectable by testosterone elevation after suppression of adrenal androgen production. Approximately 3% of cases of PCOS have an isolated functional adrenal hyperandrogenism. The rest of the cases of PCOS are mild.[56,57]

Box 25.2

Phenotypes of Polycystic Ovary Syndrome

- Hyperandrogenism and ovulatory dysfunction.
- Hyperandrogenism and polycystic ovarian morphology.
- Oligo-ovulation and polycystic ovarian morphology.
- Hyperandrogenism, oligo-ovulation, and polycystic ovarian morphology.

Polycystic Ovary Syndrome Final Report
https://prevention.nih.gov/docs/programs/pcos/FinalReport.pdf (National Institute of Health, Bethesda MD, USA 2012).

Glucose intolerance/insulin resistance and hyperinsulinemia often occur concurrently and markedly aggravate the hyperandrogenic state, thus contributing to the severity of signs and symptoms of PCOS. A metabolic syndrome of obesity-related and/or intrinsic insulin resistance occurs in approximately half of PCOS individuals, and the compensatory hyperinsulinism has tissue specific effects that intensify hyperandrogenism.[56]

PCOS is proposed as resulting from a vicious circle of androgen excess favoring abdominal adipose tissue deposition and visceral adiposity by inducing insulin resistance and compensatory hyperinsulinism, which further allows androgen secretion by the ovaries and adrenal glands in women with PCOS (Fig. 25.4).[54] Weight gain tends to aggravate symptoms, whereas weight loss may ameliorate some of the metabolic and endocrine events. Avoidance of these epigenetic initiators and maintenance of healthy habits in women with PCOS, at least in theory, may be more protective for their fetuses and would to some extent prevent the nongenetic inheritance of PCOS and its metabolic comorbidities. Inappropriate gonadotropin secretion triggers the beginning of a vicious cycle that perpetuates anovulation. Typically, levels of FSH are low or below normal, and the LH level is elevated. Persistent LH level elevation causes an increase in the concentration of androgens (dehydroepiandrosterone sulfate [DHEAS] from the adrenal glands and testosterone, androstenedione, and dehydroepiandrosterone [DHEA] from the ovary). Androgens are converted to estrogen in peripheral tissues, and increased testosterone levels cause a significant reduction (approximately 50%) in the sex hormone–binding globulin (SHBG) level, which in turn causes increased levels of free estradiol. Elevated estrogen levels trigger a positive feedback response in LH and a negative feedback response in FSH. Because FSH levels are not totally depressed, new follicular growth is continuously stimulated but not to full maturation and ovulation. The accumulation of follicular tissue in various stages of development allows an increased and relatively constant production of steroids in response to gonadotropin stimulation. Thus PCOS is characterized by excessive production of both androgen and estrogen.

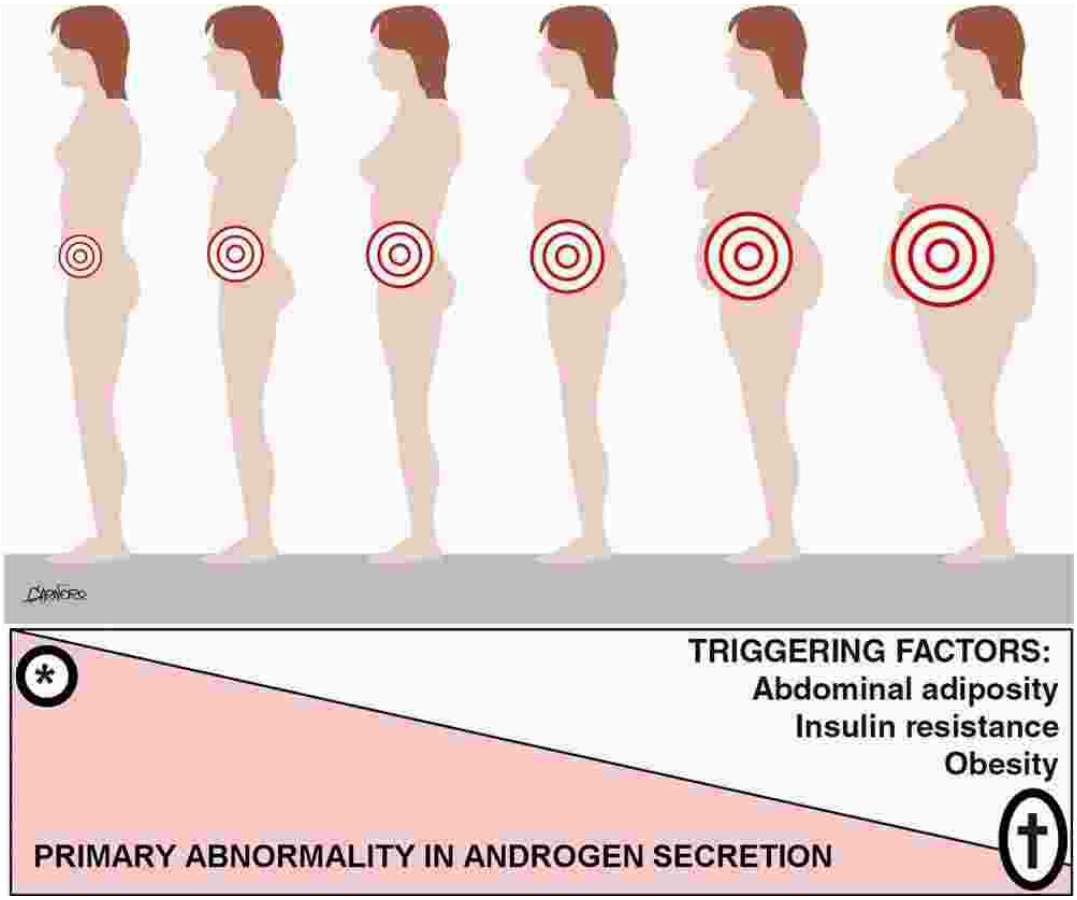

FIG. 25.4 Abdominal Adiposity and Polycystic Ovary Syndrome.

An interplay between polycystic ovary syndrome (PCOS) and abdominal adiposity At one extreme *(*)*, for some individuals, the disorder is severe enough to result in PCOS even in the absence of triggering factors. At the other extreme *(†)*, a very mild defect in androgen secretion is amplified by the coexistence of abdominal adiposity, obesity and/or insulin resistance. All individuals share a primary defect in androgen secretion. (Modified and reproduced with permission from Escobar-Morreale HF, San Millan JL. Abdominal adiposity and the polycystic ovary syndrome. *Trends in Endocrinology and Metabolism*, 2007;18:266–272, copyright Elsevier, 2007 and Escobar-Morreale HF, Santacruz E, Luque-Ramirez M, Botella Carretero JI. Prevalence of "obesity-associated gonadal dysfunction" in severely obese men and women and its resolution after bariatric surgery: A systematic review and meta-analysis. *Human Reproduction Update*, 2017;23:390–408, Copyright Oxford University Press, 2017.)

An illustration depicts the pathophysiological heterogeneity in patients with P C O S, which shows the polycystic ovary syndrome with increasing size of cystic ovary indicated by red and white targets results from the interaction of a primary abnormality in androgen secretion and other triggering factors such as abdominal adiposity, insulin resistance, and other.

Increased androgens contribute to premature follicular failure (atresis) and persistent anovulation. Persistent anovulation causes enlarged polycystic ovaries, characterized by a smooth, pearly white capsule (Fig. 25.5). This characteristic appearance is caused by an increase of surface area along with an increased volume, growing atretic follicles, thickening of the tunica, increasing cortical stromal thickening, and an increase in subcortical stroma. With advancing age, menstrual irregularities may improve, but the incidence of metabolic syndrome and type 2 diabetes mellitus (T2DM) increases. Women with PCOS have a three times greater incidence of uterine cancer later in life than normally cycling women because of an anovulatory lack of progesterone. Without treatment for anovulation, the risk for endometrial cancers increases because of the effects of unopposed estrogen.[56,58]

Clinical Manifestations

Clinical manifestations of PCOS usually appear within 2 years of puberty but may appear after a period of normal menstrual function and pregnancy. Signs and symptoms related to anovulation and hyperandrogenism are presented in Box 25.3, including a summary of hormonal disturbances and complications of PCOS. Multiple morbidities are associated with PCOS, including metabolic syndrome, infertility, impaired glucose tolerance, T2DM, cardiovascular risk, depression, obstructive sleep apnea (OSA), endometrial cancer, and nonalcoholic fatty liver disease/nonalcoholic steatohepatitis (NAFLD/NASH).[59–61]

Box 25.3

Clinical Manifestations of Polycystic Ovary Syndrome

Obesity
Hirsutism
Menstrual disturbance
Oligomenorrhea
Amenorrhea
Regular menstruation
Hyperandrogenism
Infertility
Asymptomatic (20% of those with polycystic ovary syndrome [PCOS])

Hormonal Disturbances

Increased insulin
Decreased sex hormone–binding globulin (SHBG)
Increased androgens (testosterone, androstenedione)
Increased dehydroepiandrosterone (DHEA) (occurs in 50% of women)
Increased luteinizing hormone (LH) (genetic variant LH-β subunit)
Increased prolactin

Increased leptin, especially in obesity
Suggested decreased insulin-like growth factor 1 (IGF-1) receptors on theca cells
Possible decreased estrogen receptors (intraovarian and along hypothalamic-pituitary axis)

Possible Late Sequelae

Dyslipidemia—increased low-density lipoproteins (LDLs), decreased high-density lipoproteins (HDLs), increased triglycerides
Diabetes mellitus (30% of women with or without obesity will develop type 2 diabetes mellitus by age 30)
Cardiovascular disease; hypertension
Endometrial hyperplasia and carcinoma (anovulatory women are hyperestrogenic)

Other

Sleep apnea
Nonalcoholic fatty liver disease
Women with PCOS are at increased risk of gestational diabetes mellitus, pregnancy-induced hypertension, preterm birth, and perinatal mortality

Evaluation and Treatment

Diagnosis of PCOS is based on evidence of androgen excess, chronic anovulation, and sonographic evidence of polycystic ovaries, with at least two of the three criteria evident. As stated previously, polycystic ovaries do not have to be present and, conversely, their presence alone does not establish the diagnosis. Tests for impaired glucose tolerance are recommended. In female adolescents, evidence of hyperandrogenism in the setting of irregular menses must be present before PCOS is diagnosed. Principles of treatment for PCOS are outlined in Box 25.4. Goals of treatment include reversing signs and symptoms of androgen excess,

instituting cyclic menstruation, restoring fertility, and ameliorating any associated metabolic and/or endocrine disturbances.[62]

Box 25.4

Principles of the Treatment of Polycystic Ovary Syndrome

- No universal treatment for polycystic ovary syndrome (PCOS) exists.
- Treatment is symptom oriented.
- Other than lifestyle recommendations, individuals with mild symptoms might not require any intervention.
- No drugs are currently approved specifically for PCOS.
- Targets for pharmacologic treatment should consider androgen excess, oligo-ovulation, and insulin resistance.
- Treatment should be chronic and dynamic and adapted to the changing circumstances, personal needs, and expectations of the individual.

From Escobar-Morreale HF. Polycystic ovary syndrome: definition, aetiology, diagnosis and treatment. *Nature Reviews Endocrinology*, 2018;142:271–284.

Treatment of PCOS often includes use of combined oral contraceptives for the management of symptoms (e.g., hirsutism, acne) and to establish regular menses. Treatments for obese or overweight women with PCOS include lifestyle modifications, such as regular exercise and weight loss. Reductions in weight can dramatically improve insulin sensitivity and the return of ovulatory cycles. Women with insulin resistance or those who do not respond to contraceptive therapy may benefit from the insulin sensitizer metformin. Bariatric surgery is an alternative for women with severe obesity and PCOS.[63] Progesterone therapy is recommended to oppose estrogen's effects on the endometrium and as a means to initiate monthly withdrawal bleeding (at the expense of continued hirsutism) if combined oral contraceptives are not used and pregnancy is not desired.[58,62,64] Management of PCOS is a nearly lifelong process because the effects of the syndrome persist past childbearing years. Appropriate primary care is needed to control the systemic features of PCOS so that it has minimal impact on a woman's life and health outcomes.

Premenstrual Disorders Syndrome

Premenstrual syndrome (PMS) and **premenstrual dysphoric disorder (PMDD)** are the cyclic recurrence (in the luteal phase of the menstrual cycle) of distressing physical, psychological, or behavioral changes that impair interpersonal relationships or interfere with usual activities. Symptoms for PMS and PMDD begin after ovulation during the luteal phase and persist up to 4 days into the menstrual cycle. The prevalence of PMS and PMDD is difficult to determine, possibly because of the wide-ranging nature of accepted symptoms. It is estimated that 12% of menstruating women are significantly affected by these disorders, with 2% to 5% meeting criteria for PMDD.[65]

Pathophysiology

The psychological and physiologic changes of PMS/PMDD occur in the luteal phase of ovulatory cycles and are linked with the complex hormonal changes of the menstrual cycle. Neurotransmitters, such as serotonin (SE), gamma-aminobutyric acid (GABA), and norepinephrine (NE), have demonstrated interactions with estrogen and progesterone and have established mood and behavior effects, including negative mood, irritability, aggression, and impulse control.[66] The differential behavioral response to estrogen and progesterone in PMDD is accompanied by ovarian steroid-related alterations in the neuronal circuit activity underlying reward, social cognition, and affective states.[67] There is evidence that supports a relationship between the severity and frequency of PMS/PMDD and reports of low well-being, major affective disorder, and personal characteristics, such as increased stress, poor nutrition, lack of exercise, low self-esteem, perfectionism, history of sexual abuse, and family conflict. In turn, when PMS/PMDD is distressing, the quality of interpersonal relationships and self-image are negatively affected.[68]

In addition, neurotransmitters may have mediating or moderating roles on symptom manifestation. Sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS), which could explain some PMS/PMDD signs and symptoms (e.g., water retention, bloating, weight gain).[69] A predisposition to PMS occurs in families. Recently, expression of the ESC/E(Z) gene network was found to be systemically disturbed in PMDD.[65]

Clinical Manifestations

Nearly 300 physical, emotional, and behavioral symptoms have been attributed to PMS/PMDD. The pattern of symptom frequency and severity is more important than specific complaints. Emotional symptoms, particularly depression, anger, irritability, and fatigue, have been reported as the most prominent and the most distressing, whereas physical symptoms (abdominal bloating and fatigue) seem to be the least prevalent and problematic. PMS is characterized by the presence of both physical and behavior symptoms that

negatively affect the woman's life. PMDD is a severe form of PMS in which symptoms such as anger, irritability, and internal tension are most prominent. The presence of underlying physical or psychological disease may be aggravated in the premenstrual phase and must be diagnosed and treated independently of PMS/PMDD.

Evaluation and Treatment

Diagnosis of PMS or PMDD is based on the health history, menstrual cycle history, symptoms, and the timing of symptoms (present *only* in the week or two prior to the period) using the Daily Record of Severity of Problems (DRSP) form. PMDD is diagnosed using the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) criteria, which is presented in Box 25.5. Current management is treatment of symptoms. For many women, nonpharmacologic therapies, such as regular exercise, appropriate sleep, diet, stress reduction, acupuncture, and cognitive-behavioral therapy (CBT) with or without medication, may be effective in controlling symptoms.[70,71]

Box 25.5

Diagnostic Criteria for Premenstrual Dysphoric Disorder

A. Five or more of the symptoms listed in this box—occur in most cycles during the week before menses onset, improve within a few days after menses onset, and diminish in the week post menses
B. One (or more) of these symptoms must be present:
   a. Marked affective lability
   b. Marked irritability or anger or increased interpersonal conflicts
   c. Marked anxiety, tension
C. One (or more) of these symptoms must also be present:
   a. Decreased interest
   b. Difficulty concentrating
   c. Easy fatigability, low energy
   d. Increase or decrease in sleep
   e. Feelings of being overwhelmed
   f. Physical symptoms (e.g., breast tenderness, muscle or joint aches, "bloating" or weight gain)

Note: Criteria A through C must be present for most menstrual cycles in the preceding year.

D. Symptoms are associated with significant distress or interferences with work, school, and relationships.
E. The disturbance is *not* an exacerbation of another disorder, such as major depression, panic disorder, persistent depressive disorder, or a personality disorder.
F. Criterion A should be confirmed by prospective daily ratings in at least two symptomatic cycles.
G. The symptoms are not due to the physiologic effects of a substance or another medical condition.

Data from The American Psychiatric Association. *Diagnostic and statistical manual of mental disorders—DSM-5-TR* 5th ed. Washington: Author; 2022.

If nonpharmacologic methods fail or symptoms are severe, pharmacologic intervention is indicated. Two major forms of prescription treatment include hormonal cycle regulation and selective serotonin reuptake inhibitor (SSRI) antidepressants. SSRIs can be administered in three different dosing therapies: daily, luteal phase only (starting on cycle day 14), or symptom-onset only therapy. If a woman does not desire immediate fertility, the oral contraceptive pill containing estrogen and progesterone may regulate her menstrual cycle and decrease levels of circulating steroidal hormones.[72–74]

Infection and Inflammation

Infections of the genital tract may result from exogenous or endogenous microorganisms. Exogenous pathogens are most often sexually transmitted (see Chapter 27). Endogenous causes of infection include microorganisms that are normally resident in the vagina, bowel, or vulva. Infection occurs if these microorganisms migrate to a new location or overproliferate when the immune system and other defense mechanisms are impaired. Skin disorders that can affect the vulva include reactive dermatitis, contact dermatitis, psoriasis, and impetigo. (For a discussion of skin disorders, see Chapter 46.)

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an acute inflammatory process caused by infection. It may involve any or all organs in the upper genital tract: the uterus, fallopian tubes, or ovaries. Typically, it is an ascending infection, spreading from the lower genital tract (Fig. 25.6).[75] In its most severe form, the entire peritoneal cavity can be affected. Inflammation of the fallopian tubes is termed **salpingitis** (Fig. 25.7), and inflammation of the ovaries is called **oophoritis**. Most cases of PID are caused by sexually transmitted microorganisms, such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, that migrate from the vagina to the uterus, fallopian tubes, and ovaries. PID is very common in the United States and around the

world and carries with it immediate and long-term health implications, including infertility and increased risk of ectopic pregnancy, for women and their sexual partners.[76] Risk factors include intercourse with multiple partners, age, previous history of PID, IUD implantation, and tubal ligation.

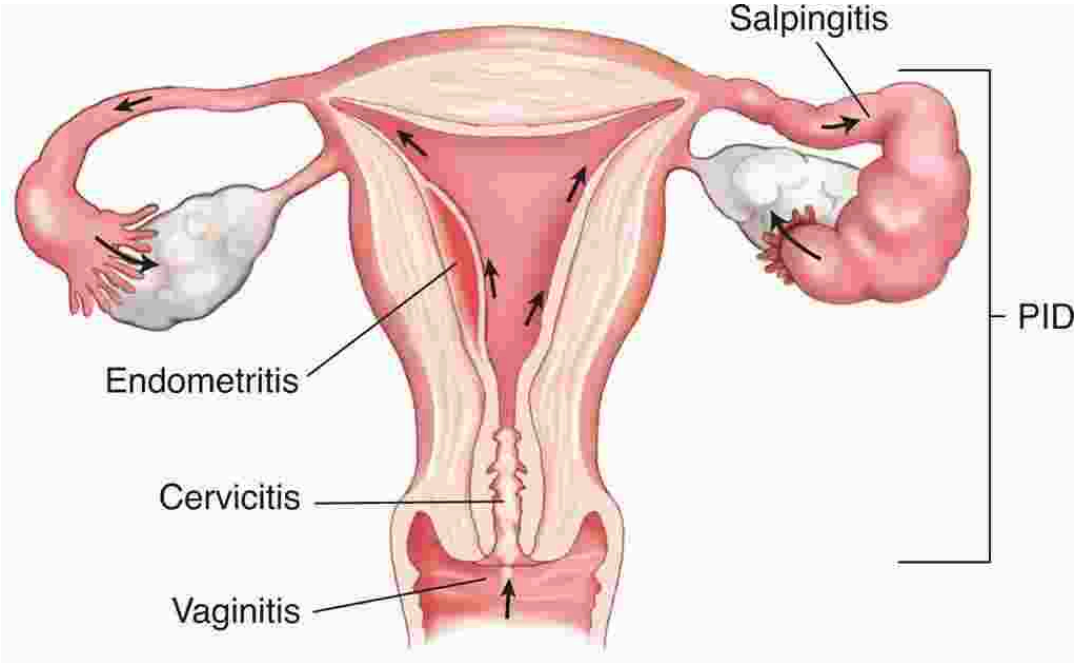

FIG. 25.6 Ascension of Pelvic Inflammatory Disease. Microorganisms from the lower genital track ascend into the endometrium, fallopian tubes, and peritoneum to cause endometriosis-salpingitis-peritonitis (pelvic inflammatory disease *[PID]*). The arrows indicate the "flow" of microorganisms from the lower genital tract to the upper genital tract. This is noted as an ascending infection in the text. (Adapted from Brooks M. *Exploring medical language*, 8th edition. St. Louis: Mosby; 2012.)

An illustration depicts the structure of the uterus and ovary with labels indicating the location of infection caused by pelvic inflammatory disease as follows: vaginitis, cervicitis, endometritis, and salpingitis. The arrow marks from the vagina moving upward through the fallopian indicates the ascending infection spreading from the lower genital tract.

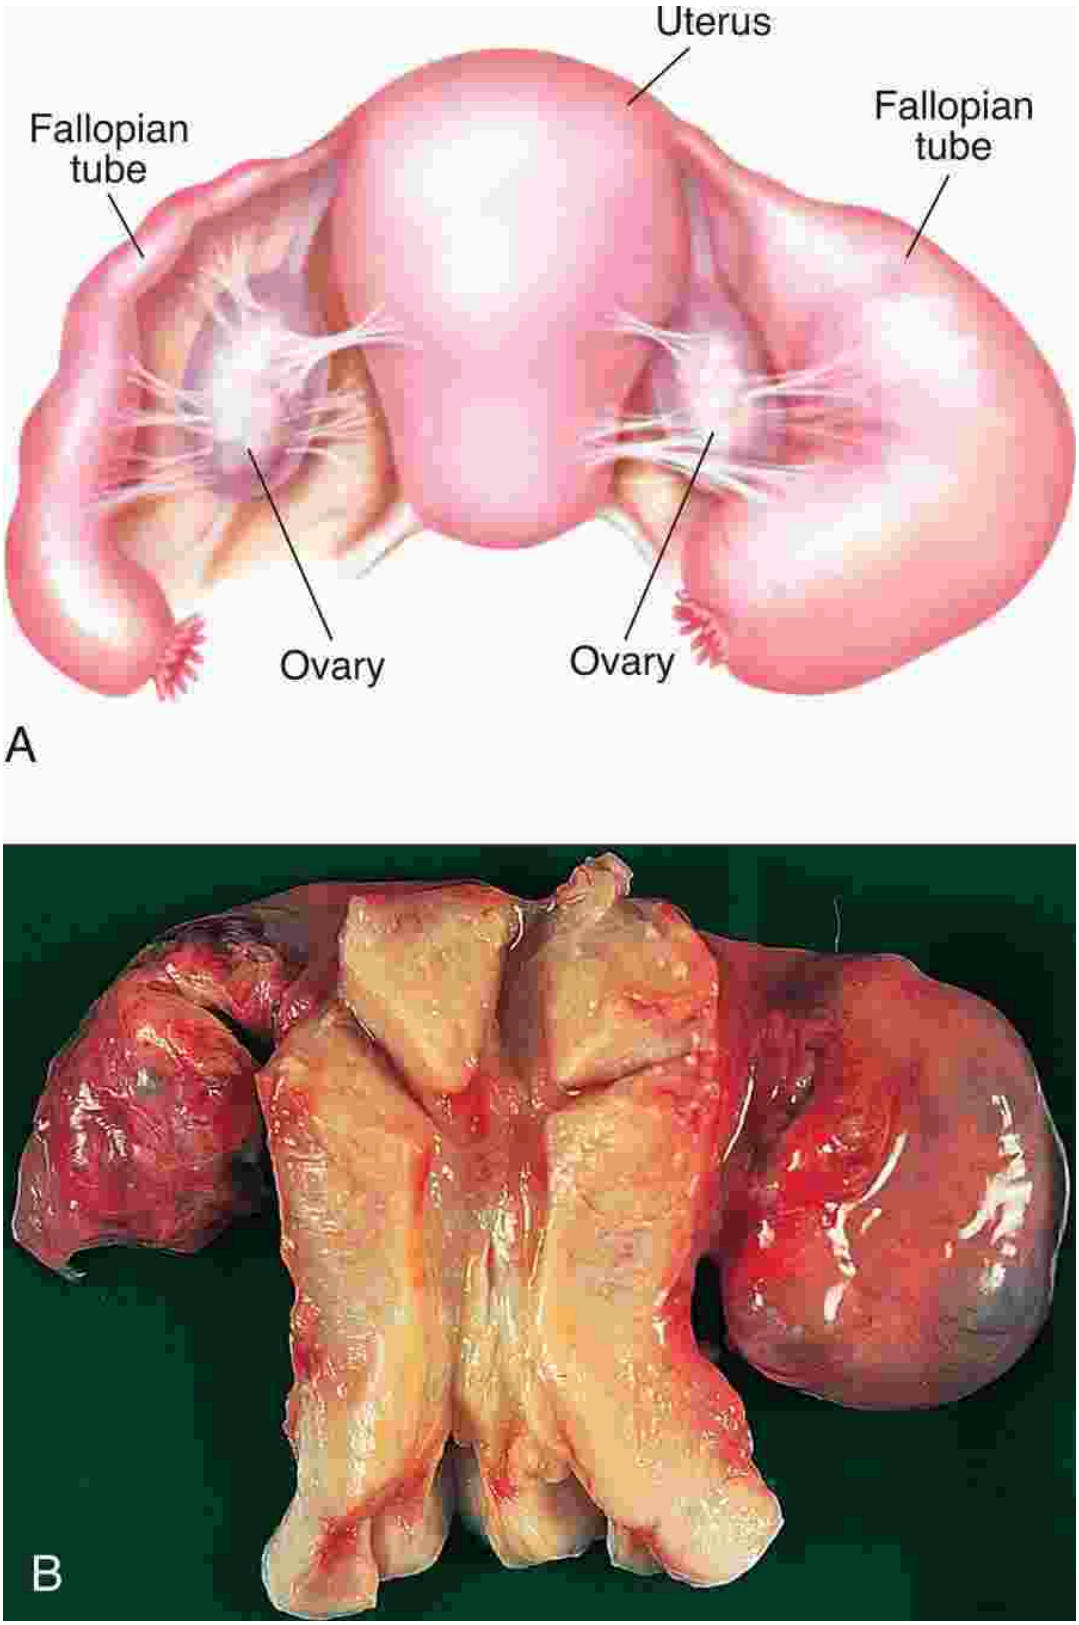

FIG. 25.7 **Salpingitis.**
(A) Advanced pyosalpinx. Note the swollen fallopian tube. (B)

Bilateral, retort-shaped, swollen, sealed tubes and adhesions of the ovaries are typical of salpingitis. (A, From Ball J, Dains JE, Flynn JA, Solomon BS, Stewart RW. *Seidel's guide to physical examination*, 8th edition. St. Louis: Mosby; 2015; B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

A. An illustration depicts the structure of the uterus and ovary with the swollen fallopian tube. The labels indicate the fallopian tubes, ovary, and uterus. B. A close shot of the uterus with both fallopian tubes and ovaries bound down in hemorrhagic adhesions that largely obscure the line on one side.

Pathophysiology

Infection of the upper female genital track leads to inflammatory damage, including scarring, adhesions, and partial or total obstruction of the fallopian tubes.[75] Loss of the ciliated epithelial cells along the fallopian tube lining results in impaired ovum transport and increases the risk for infertility, ectopic pregnancy, and adhesions that can lead to chronic pelvic pain.[77] Two sexually transmitted infectious causes of PID are gonorrhea and chlamydia. The microorganisms that cause these infections can infect the vagina and cervix, and if the normal vaginal microbial flora is disrupted, the pathogens can more easily ascend through the cervix (see Fig. 25.6).[78]

Many anaerobic bacteria have been implicated as increasing the risk of PID because they alter the pH of the vaginal environment and may decrease the integrity of the mucus blocking the cervical canal.[75] Bacterial vaginosis (BV) is present in up to 66% of women with PID. In addition, other pathogens are frequently isolated and include anaerobes (e.g., *Peptostreptococcus* species, *Bacteroides* species, *Gardnerella vaginalis*), respiratory pathogens *(Haemophilus influenzae, Streptococcus pneumonia, Staphylococcus aureus)*, genital tract mycoplasmas *(Mycoplasma hominis, Mycoplasma genitalis, Ureaplasma urealyticum)*, and enteric pathogens (*Escherichia coli*, *Bacteroides fragilis*, group B streptococci), which have been identified in acute PID and account for approximately 15% of cases.[75] Therefore, although *N. gonorrhoeae* and *C. trachomatis* are the main pathogens in PID, the disease is actually polymicrobial in origin and is treated with a broad spectrum of antibiotics to ensure that all the causative agents are eliminated.[78,79]

The infection may induce changes in the columnar epithelium lining of the upper reproductive tract, causing permanent damage. The subsequent inflammatory response causes localized edema and sometimes obstruction or necrosis of the area. Gonorrhea gonococci attach to the fallopian tubes and excrete a substance that is toxic to the tubal mucosa, increasing inflammation and damage. Chlamydia enter the tubal cells and replicate, bursting the cell membrane as they reproduce and causing permanent scarring. Scarring increases the risk of a later ectopic pregnancy because the mobility of an egg through the fallopian tubes is slowed by damaged cilia. Scarring and adhesions also can result in chronic pelvic pain and, potentially, an increased risk of uterine cancer.[80,81]

Clinical Manifestations

The clinical manifestations of PID vary from asymptomatic to sudden, severe abdominal pain with fever. It also may present with mild to moderate abdominal or pelvic pain, dysuria (difficult or painful urination), vaginal discharge, dyspareunia (pain with sexual intercourse), and/or abnormal vaginal bleeding.[75] An asymptomatic cervicitis may be present for some time before PID develops. The first sign of the ascending infection may be the onset of low bilateral abdominal pain, often characterized as dull and steady with a gradual onset. Symptoms are more likely to develop during or immediately after menstruation. The pain of PID may worsen with walking, jumping, intercourse, or other activities involving movement.

Evaluation and Treatment

PID often has limited or vague clinical symptoms, leading to undertreatment and long-term health effects. PID is a substantial health risk to a woman; therefore the Centers for Disease Control and Prevention (CDC) encourages clinicians to consider PID as a likely diagnosis when a sexually active woman has abdominal or pelvic tenderness and *one* of these conditions: cervical motion tenderness, uterine tenderness, or adnexal tenderness. Box 25.6 lists the diagnostic criteria for PID.

Box 25.6

Diagnostic Criteria for Pelvic Inflammatory Disease

Minimum Criteria (One or More Needed for Diagnosis)

Cervical motion tenderness, *or*
Uterine tenderness, *or*

Adnexal tenderness

Additional Criteria That Increase Specificity of Diagnosis

Fever >38.3°C (>101°F)
Mucopurulent cervical or vaginal discharge, or cervical friability
Numerous white blood cells on saline wet prep
Elevated C-reactive protein
Elevated erythrocyte sedimentation rate
Documented infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae*

Definitive Criteria (Not Needed for Treatment)

Transvaginal ultrasound, magnetic resonance imaging showing thickened and fluid-filled tubes, *or*
Doppler studies indicating pelvic infection, and
Laparoscopic visualization of PID-related abnormalities, or
Endometrial biopsy with evidence of endometritis

From Centers for Disease Control and Prevention (CDC). *Pelvic Inflammatory Disease (PID) Treatment and Care*. Atlanta: U.S. Department of Health and Human Services; 2022. https://www.cdc.gov/std/pid/treatment.htm

No laboratory tests or studies are needed to begin treatment; however, additional information can improve the specificity of the diagnosis. Abdominal pain in women can have many causes, and it is important to rule out other diagnoses (Fig. 25.8). This can be done while the person is being treated for PID.[61]. A pregnancy test may be done to exclude the possibility of an ectopic pregnancy as an alternate etiology of the pelvic pain.[75] If vaginal or cervical discharge is present, microscopy of the discharge is recommended along with obtaining nucleic acid amplification tests (NAATs) for *C. trachomatis* and *N. gonorrhoeae*. Testing for other sexually transmitted infections (STIs), such as human immunodeficiency virus (HIV) and *Treponema pallidum* (syphilis), is considered. Although laboratory testing may help to confirm the diagnosis, NAATs can typically take several hours to days to obtain a result. Negative results do not exclude the diagnosis. Therefore prompt and early treatment is advised.[78] Histopathologic examination from a biopsy is rarely done, but should be done if there is a doubt about the diagnosis.[75] Prompt antibiotic treatment can prevent severe damage to the reproductive organs and prevent infertility or a future ectopic pregnancy.[78]

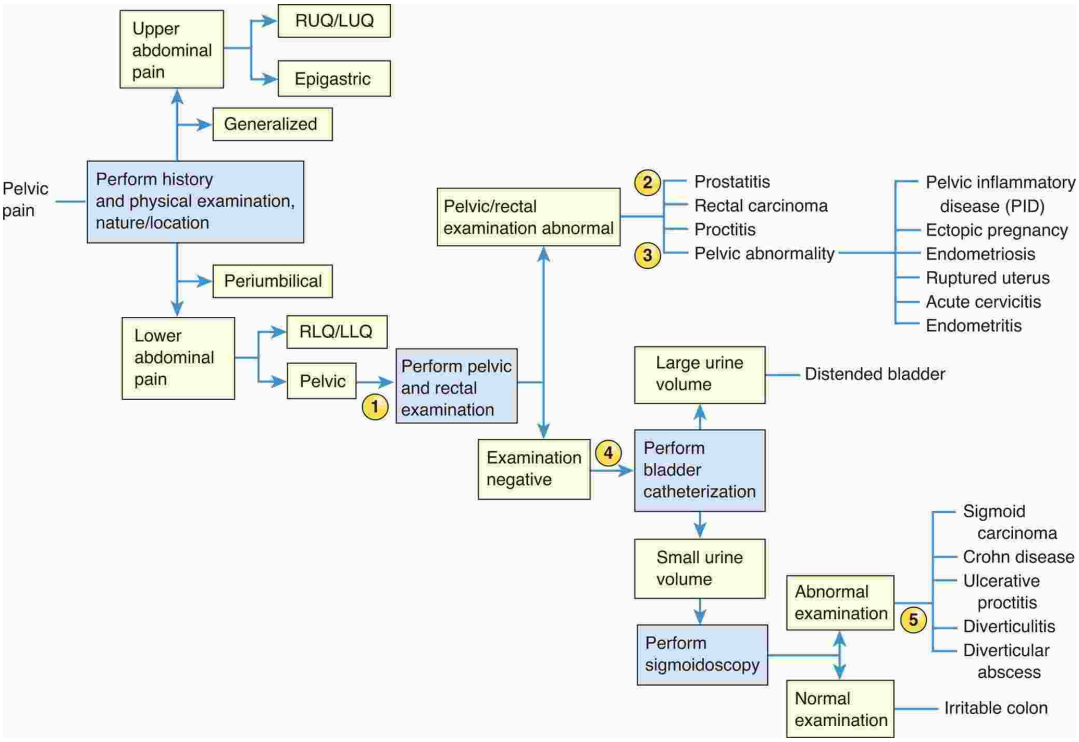

FIG. 25.8 Diagnostic Algorithm for Pelvic Pain.
LLQ, Left lower quadrant; *LUQ*, left upper quadrant; *RLQ*, right lower quadrant; *RUQ*, right upper quadrant.

A flowchart represents the algorithm for the diagnosis of pelvic pain. Perform history and physical examination, nature or location which involves generalized upper abdominal pain and periumbilical lower abdominal pain. Lower abdominal pain involves R L Q or L L Q and pelvic. Upper abdominal pain involves R U Q or L U Q or epigastric. 1. If lower abdominal pain involves in the pelvic then perform a pelvic and rectal examination. 2. If the pelvic or rectal examination is abnormal check for prostatitis, rectal carcinoma, proctitis, pelvic abnormality 3. Pelvic abnormality leads to pelvic inflammatory disease or P I D; ectopic pregnancy, endometriosis, ruptured uterus, acute cervicitis, and endometritis. 4. If pelvic or rectal examination, perform bladder catheterization. If bladder catheterization causes large urine volume that leads to a distended bladder. If bladder

catheterization causes small urine volume, then perform sigmoidoscopy. 5. Abnormal examination of sigmoidoscopy leads to sigmoid carcinoma; Crohn disease; ulcerative proctitis; diverticulitis; diverticular abscess. Normal examination of sigmoidoscopy leads to irritable colon.

The complications of PID can be significant; therefore rapid treatment is recommended even before the causative pathogen can be identified. Because treatment is empiric, it needs to be effective against a broad range of pathogens, especially chlamydia, gonococci, and anaerobic bacteria. Treatment is usually done on an outpatient basis unless the female has symptoms of advanced infection, cannot take oral medications, is pregnant, or exhibits other pathologies that cannot be excluded. The outpatient regimen recommended by the CDC is shown in Box 25.7.[78] Although alternative treatment regimens are available, the growing antibiotic resistance of gonorrhea limits antibiotic choices.

Box 25.7

CDC-Recommended Treatment for Pelvic Inflammatory Disease: Intramuscular/Oral Regimens

Ceftriaxone 500mg IM in single dosePLUS
Doxycycline 100mg PO twice a day for 14 days
WITH
Metronidazole 500mg PO twice a for 14 daysOR
Cefoxitin 2g IM in a single dose AND
Probenecid 1g administered PO concurrently in a single dose
PLUS
Doxycycline 100mg PO twice a day for 14 days
WITH
Metronidazole 500mg PO twice a for 14 days
OR
Other parenteral third-generation**Cephalosporin** (e.g., ceftizoxime or cefotaxime)
PLUS
Doxycycline 100mg PO twice a day for 14 daysWITH[a] or WITHOUT
Metronidazole 500mg PO twice a for 14 days

Data from Centers for Disease Control and Prevention (CDC). *Pelvic Inflammatory Disease (PID) Treatment and Care*. Atlanta: U.S. Department of Health and Human Services; 2021; Centers for Disease Control and Prevention (CDC). Page updated: November 9, 2021. https://www.cdc.gov/std/treatment-guidelines/pid.htm; Walker CK, Workowski KA, Washington AE, Soper D, Sweet RL. Anaerobes in pelvic inflammatory disease: Implications for the Centers for Disease Control and Prevention's guidelines for treatment of sexually transmitted diseases. Clinical Infectious Diseases, 1999;28(Supp 1):S29–S36.

These regimens provide coverage against frequent etiologic agents of PID, but the optimal choice of a cephalosporin is unclear. Cefoxitin, a second-generation cephalosporin, has better anaerobic coverage than ceftriaxone and in combination with probenecid and doxycycline has been effective in short-term clinical response in women with PID. Ceftriaxone has better coverage against *Neisseria gonorrhoeae*. The addition of metronidazole also will effectively treat BV, which is frequently associated with PID.

CDC, Centers for Disease Control and Prevention; *IM*, intramuscularly; *PID*, pelvic inflammatory disease; *PO*, orally.

[a]The recommended third-generation cephalosporins are limited in the coverage of anaerobes. Therefore, until it is known that extended anaerobic coverage is not important for treatment of acute PID, the addition of metronidazole to treatment regimens with third-generation cephalosporins should be considered.

To prevent recurrence, sexual partners of women with PID should also receive treatment, even if they are asymptomatic. Women receiving treatment should be reevaluated by their care provider in 3 days to ensure that the antibiotic treatment is effective. Because women with a history of PID are at increased risk for ectopic pregnancy, they should seek care as soon as they know they are pregnant, because ectopic pregnancy is a major cause of maternal mortality. All sexually active women younger than age 25 should receive, at minimum, annual screening for chlamydia and gonorrhea, as should women older than age 25 who have a new sexual partner, more than one sexual partner, a partner who has been diagnosed with an STI, or a partner with more than one sexual partner.[78]

Vaginitis

Vaginitis is irritation or inflammation of the vagina, typically caused by infection, irritants, pathologies, or disruption of the normal vaginal flora. Vaginitis is characterized by complaints of vaginal irritation, itching, burning, odor, or abnormal discharge. Clinically, it is characterized by an increase in white blood cells or abnormal cells, or both, observed on a saline wet prep examination. The major causes of vaginitis are overgrowth of normal flora, STIs, and vaginal irritation related to low estrogen levels during menopause (a condition known as

atrophic vaginitis). The primary forms of vaginitis are vulvovaginal candidiasis, or yeast vaginitis, and BV, or trichomoniasis. **Bacterial vaginosis (BV)** is a noninflammatory condition resulting from an overgrowth of anaerobic bacteria. The overgrowth causes a shift in the composition of the vaginal flora and produces a malodorous vaginal discharge. Pain and itching are common manifestations.[82,83]

Pathophysiology. The development of vaginitis is related to alterations in the vaginal environment. This includes changes with complications in local defense mechanisms, such as skin integrity, immune reaction, and, particularly, vaginal pH. The pH of the vagina (normally 4 to 4.5) depends on cervical secretions and the presence of normal flora that help maintain an acidic environment. A neutral or alkaline pH normally occurs before puberty, after menopause, and during pregnancy. The acidic nature of vaginal secretions during the reproductive years provides protection against a variety of sexually transmitted pathogens and establishes a healthy microflora in the vagina. Changes in the vaginal pH may predispose a woman to infection. Variables that affect the vaginal pH and therefore the bactericidal nature of secretions and the predisposition to infection include semen and the use of douches, soaps, spermicides, feminine hygiene sprays, and deodorant menstrual pads or tampons. Another variable is having a condition associated with an increased glycogen content of vaginal secretions, such as pregnancy and diabetes. Antibiotics often destroy normal vaginal flora, facilitating the overgrowth of *Candida albicans* and causing a yeast infection. Increased vaginal alkalinity also may enhance susceptibility to trichomoniasis and BV.

Clinical Manifestations. Vaginal discharge is typically clear, milky, or cloudy with a slippery or clumpy texture. It is nonirritating, has a mild smell, and may yellow after drying. Throughout the menstrual cycle, the amount and texture of a woman’s discharge change in response to hormonal fluctuation. Vaginal secretions increase at the time of ovulation, during pregnancy (because of increased estrogen levels), and with sexual arousal. Just before menstruation, vaginal discharge becomes thick and sticky. Unusual changes in the amount, color, or texture of the vaginal discharge may signal an infection, especially if the discharge is malodorous, irritating, or copious.

Evaluation and Treatment. Diagnosis is based on the history, physical examination, and examination of the discharge by wet mount. Infection is suggested by a marked change in color or by a discharge that becomes copious, malodorous, or irritating. Treatment involves developing and maintaining an acidic environment, relieving symptoms (usually pruritus and irritation), and administering antimicrobial or antifungal medications to eradicate the infectious organism. If the infection can be sexually transmitted, the woman's partner will also need to be treated. Research suggests that probiotics, especially *Lactobacillus*

rhamnosus, can encourage the proliferation of normal vaginal flora and reduce the incidence of vaginitis in women at risk for this disease.[84,85]

Cervicitis

Cervicitis is a nonspecific term used to describe inflammation of the cervix. The CDC defines cervicitis as having two major diagnostic signs: a purulent or mucopurulent (mucus and pus) discharge from the cervical os or endocervical bleeding (or both) induced by gently introducing a cotton swab into the cervix.[86] Cervicitis can have infectious or noninfectious causes; approximately half of all cases are caused by sexually transmitted pathogens. Chemicals and substances introduced into the vagina can cause cervicitis in addition to disruptions in the normal vaginal flora or microbiome. Age and risk factors are important in assessing a woman with cervicitis. Younger women are at risk for STIs and should be tested for chlamydia, gonorrhea, and trichomoniasis. More stubborn adolescent cases may involve group B streptococcus.[87] Older women with cervicitis may have STIs but are at risk for irritation from abnormal vaginal flora related to low vaginal estrogen levels. In cases where no infectious agent can be identified, pharmacologic therapy may still be effective. The CDC guidelines for the prevention and treatment include antimicrobial therapies, prevention counseling, vaccination, and contraceptive methods.[86] Surgery may be an option or necessary for unresponsive and chronic cases.[88]

Mucopurulent cervicitis (MPC) is usually caused by one or more sexually transmitted pathogens, such as *Trichomonas, Neisseria, Chlamydia, Mycoplasma*, or *Ureaplasma* parvum. Infection causes the cervix to become erythematous and edematous. A mucopurulent exudate drains from the external cervical os, and the individual may report vague pelvic pain, bleeding, or dysuria. The cervix often becomes friable, and bleeding can occur during sexual intercourse or with pelvic examinations (or both), as well as with Papanicolaou (Pap) smears. Because MPC is a symptom of PID, women at risk for STIs, especially those younger than age 26, should receive treatment for PID while awaiting the results of microbial testing. If the woman is not at risk for STIs, a thorough evaluation often reveals another cause for the inflammation.[86]

Vulvodynia

Vulvodynia (also referred to as *vulvitis*, *vestibulitis*, or *vulvovestibulitis* [VV]) is chronic pain of at least 3 months duration and inflammation of the vulva or vaginal vestibule (entrance of vagina), or both. The classification of vulvodynia is based on the location of the pain, whether it is localized or generalized, and whether the pain is provoked, unprovoked, or mixed. *Localized* is characterized by pain from a cause that usually does not cause pain (allodynia) to the vulvar vestibule area. *Generalized* is a diffuse pain pattern involving all of the pudendal

nerve distribution and beyond. *Provoked* means any touch or stimulation that elicits pain, *unprovoked* is pain that occurs in the absence of touch or stimulation, and *mixed* is pain that varies with or without touch or stimulation. Individuals describe the pain as burning, stinging, soreness, irritation, dyspareunia, throbbing, itching, or rawness.[89]

Pathophysiology. The cause of vulvodynia is unknown. Theories suggest it is multifactorial in origin, including embryonic factors, chronic inflammation, genetic immune factors, nerve pathways, increased sensitivity to environmental factors (infection, trauma, irritants), hormonal changes, human papillomavirus (HPV), and oxalates. Although the inflammation of vulvodynia may be caused by contact dermatitis (e.g., exposure to soaps, detergents, lotions, sprays, shaving, menstrual pads/tampons, perfumed toilet paper, tight-fitting clothes), the condition may be more complex and represent abnormalities in three interdependent systems: the vestibular mucosa, pelvic floor musculature, and CNS pain regulatory pathways. The condition also may represent an autoimmune reaction or genetic and psychological links.Clinical Manifestations. An important trigger is chronic inflammation caused by contact irritants, recurrent infections, hormonal changes, and chronic skin conditions. Overall, with normal sensations there is a heightened sensitivity. Vulvodynia can occur in the context of other pain conditions, such as irritable bowel syndrome, interstitial cystitis, recurrent yeast infections, and fibromyalgia.[90]

Evaluation and Treatment. Cotton swab testing is used to identify painful areas. For vulvar pain, treatment is focused on identifying and treating any infectious cause or comorbid contributor. However, laboratory tests and imaging are rarely required. Women are advised to avoid potential irritants; wear loose, cotton clothing; use mild soaps; and apply a vaginal emollient after bathing. Hot water may incite vulvar symptoms. Studies on treatments are limited but suggest that women may benefit from topical lidocaine (Xylocaine), estrogen cream, topical or systemic antidepressants, or anxiolytics; Botox injections into the affected nerve; dietary modifications; physical therapy; behavioral or sexual counseling (or both); acupuncture; or vestibulectomy. Biofeedback may help to relax the muscles of the pelvic floor and reduce pain.[91–93]

Bartholinitis

Bartholinitis, or **Bartholin cyst**, is an acute inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands (Fig. 25.9).Pathophysiology. Most lesions of the Bartholin gland are cysts or abscesses. The usual causes are microorganisms that infect the lower female reproductive tract, such as streptococci, staphylococci, and sexually transmitted pathogens. Acute bartholinitis may be preceded by cervicitis, vaginitis, or urethritis.

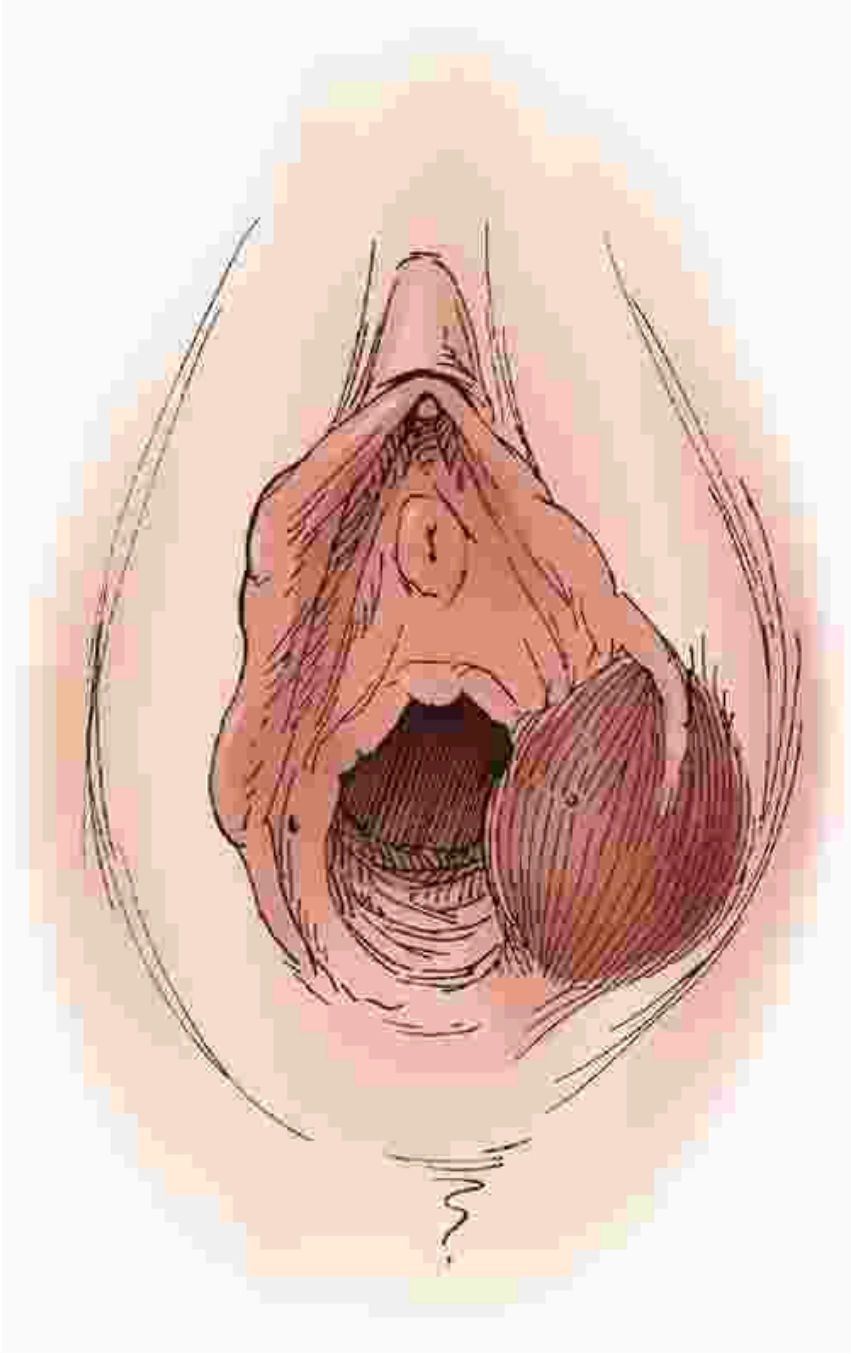

FIG. 25.9 Inflammation of Bartholin Gland. (Modified from Gershenson DM, DeCherney AH, Curry SL. *Operative gynecology*, 2nd edition. Philadelphia: Saunders; 2001. In Fuller JK. *Surgical technology*, 6th edition. Philadelphia: Saunders; 2013.)

Clinical Manifestations. Infection or trauma causes inflammatory changes that narrow the distal portion of the duct, leading to obstruction and stasis of glandular secretions. The obstruction, or cyst, varies from 1 to 8 cm in diameter

and is located in the posterolateral portion of the vulva. The affected area is usually red and painful, and pus may be visible at the opening of the duct. The exudate should be cultured, specifically for gonorrhea and chlamydia. The individual may have fever and malaise.

Evaluation and Treatment. The diagnosis is based on the clinical manifestations reported and examined, and the identification of infectious microorganisms. Most cases of Bartholin cysts require no treatment. However, to prevent abscess formation, treatment is advised if the cysts are uncomfortable, large, or show signs of infection. Treatment has no consensus but may involve broad-spectrum antibiotics. Some clinicians attempt to drain the cyst using hot soaks, needle aspiration, insertion of a catheter, or marsupialization (cutting a slit and suturing the edges) of the infected gland.[94] No single treatment has proven superior for both relief and prevention of recurrence. Lesions in the form of carcinomas are a rare type of gynecologic tumor and are carefully monitored among postmenopausal women, who are more prone to Bartholin malignancy.[95]

Pelvic Organ Prolapse

The bladder, urethra, and rectum are supported by the endopelvic fascia and perineal muscles, particularly the levator ani group. This muscular and fascial tissue loses tone and strength with aging and may fail to maintain the pelvic organs in the proper position. Weak support of the bladder and rectum tends to cause movement toward the vagina and vaginal wall. The increased pressure causes the area becomes increasingly weaker. Progressive descent of the pelvic support structures may cause pelvic floor disorders, such as urinary and fecal incontinence, and pelvic organ prolapse.

Pelvic organ prolapse (POP) is the descent of one or more of these structures: the vaginal wall, uterus, or apex of the vagina (after a hysterectomy). Although more than 50% of women have some version of POP on physical examination, most women have no symptoms. When prolapse becomes severe, the function of the surrounding organs can be altered. POP is thought to be caused by direct trauma (e.g., childbirth), pelvic floor surgery, obesity, constipation, pelvic organ cancers, or damage to the pelvic innervation, particularly the pudendal nerve. However, risk factors in nulliparous women include occupational activities that require heavy lifting or chronic medical conditions, such as chronic lung disease or refractory constipation (chronically increased intra-abdominal pressure). The most frequently cited risk factors are aging, obesity, and hysterectomy. Other risk factors include a strong familial tendency (from family and twin studies) and possibly a multifactorial genetic component. Prolapse of the bladder, urethra, rectum, or uterus may occur many years after an initial injury to the supporting structure.[96] A list of symptoms and treatments of POP is contained in Box 25.8.

Box 25.8

Pelvic Organ Prolapse: Symptoms and Treatments

Symptoms	Treatment
Urinary	Depending on age of woman and cause and severity of condition: • Isometric exercises to strengthen pubococcygeal muscles (Kegel exercises) • Estrogen to improve tone and vascularity of fascial support (postmenopausal) • Pessary (a removable device) to hold pelvic organs in place
Sensation of incomplete emptying of bladder Urinary incontinence Urinary frequency/urgency Bladder "splinting" to accomplish voiding	
Bowel	
Constipation or feeling of rectal fullness or blockage Difficult defecation Stool or flatus incontinence Urgency Manual "splinting" of posterior vaginal wall to accomplish defecation	**Surgical** Reconstructive: autologous grafts; synthetic mesh/sling Obliterative (most extreme) Weight loss Avoidance of constipation Treatment of cough/lung conditions
Pain and Bulging	
Vaginal, bladder, rectum Pelvic pressure, bulging, pain Lower back pain	
Sexual	
Dyspareunia	

Symptoms	Treatment
Decreased sensation, lubrication, arousal

Uterine prolapse is descent of the cervix or entire uterus into the vaginal canal, and in severe cases the uterus falls completely through the vagina and protrudes from the introitus, creating ulceration and obvious discomfort. Fig. 25.10 illustrates the different degrees (grades) of uterine prolapse, showing descent of the cervix or the entire uterus into the vaginal canal. Grade 1 prolapse is not treated unless it causes discomfort. Grades 2 and 3 prolapse usually cause feelings of fullness, heaviness, and collapse through the vagina. Symptoms of other pelvic floor disorders also may be present.[97]

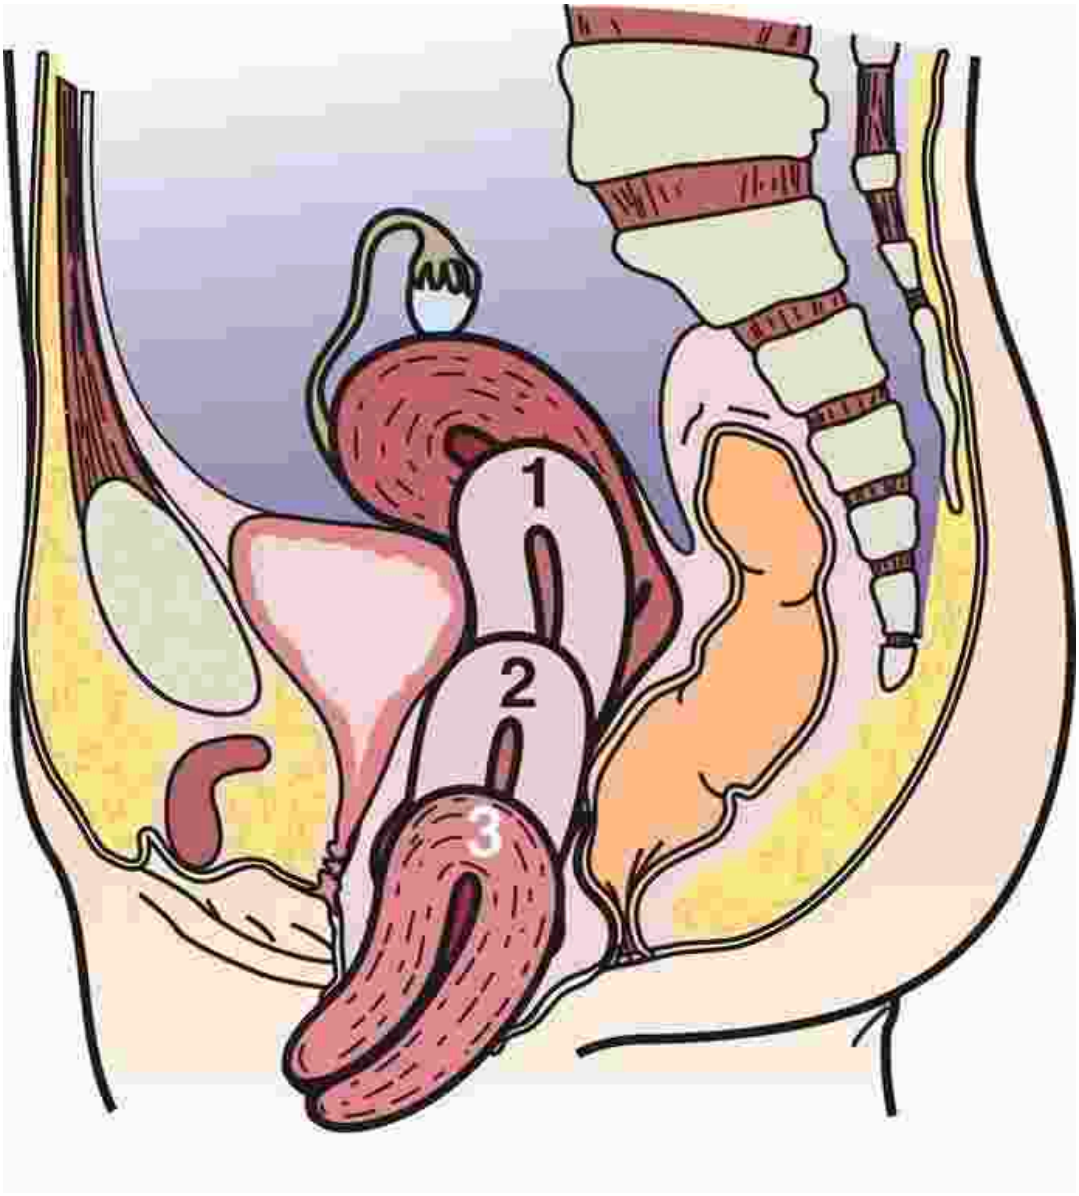

FIG. 25.10 Degrees of Uterine Prolapse.
Grade 1 prolapse is minimal and rarely requires correction. **Grade 2** prolapse has moderate symptoms. **Grade 3** prolapse is severe. The uterus is so low the cervix protrudes from the vagina. (From Phillips N. *Berry & Kohn's operating room technique*, 12th edition. Philadelphia: Mosby; 2013.)

Cystocele is descent of a portion of the posterior bladder wall and trigone into the vaginal canal and is usually caused by childbirth (Fig. 25.11). In severe cases, the bladder and anterior vaginal wall bulge outside the introitus. Symptoms are usually insignificant in mild to moderate cases. Increased bulging and descent of the anterior vaginal wall and urethra can be aggravated by vigorous activity,

prolonged standing, sneezing, coughing, or straining and can be relieved by rest or by assumption of a recumbent or prone position. If the prolapse is large, women may complain of vaginal pressure.A **rectocele** is the bulging of the rectum and posterior vaginal wall into the vaginal canal. Childbirth may increase damage, ultimately leading to a rectocele, but symptoms may not appear until after menopause. Genetic and familial predisposition and bowel habits contribute to rectocele development. Lifelong chronic constipation and straining may produce or aggravate a rectocele. A large rectocele may cause vaginal pressure, rectal fullness, and incomplete bowel evacuation. In severe cases, defecation may be difficult and can be facilitated by applying manual pressure to the posterior vaginal wall (see Fig. 25.11).

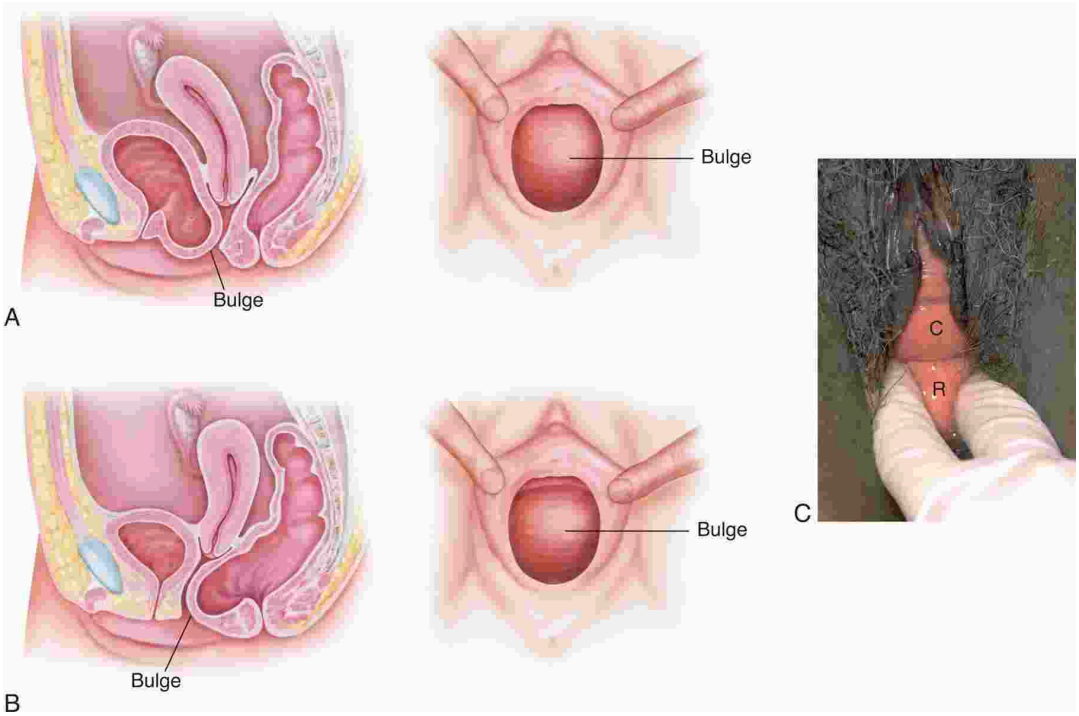

FIG. 25.11 Cystocele and Rectocele.
(A) Grade 2: anterior vaginal wall prolapse. (B) Grade 2: posterior wall prolapse. (C) Photo slowing cystocele *(C)* and rectocele *(R)*. B. An illustration depicts the sagittal section of the female genital tract indicating a bulge in the posterior vaginal wall, accompanied by an example of the perineal view of the vagina representing a bulge in the rear vaginal wall C. A close shot of the vagina opened by the two fingers of the physician representing the cystocele and rectocele.

An **enterocele** is a herniation of the rectouterine pouch into the rectovaginal septum (between the rectum and the posterior vaginal wall). It can be congenital

or acquired. Congenital enterocele rarely causes symptoms or progresses in size, but an acquired enterocele can result from muscular weakness caused by previous surgery, especially those through the vagina, or from pelvic relaxation disorders, such as uterine prolapse, cystocele, and rectocele. Most large enteroceles are found in grossly obese and older adults.

Treatment of POP depends on the severity of symptoms and the physical condition of the female. Treatment is often progressive with least invasive treatments tried first. Maintaining a healthy BMI, preventing constipation, and treating chronic cough or constipation will help. The pelvic floor muscles can be strengthened through Kegel exercises. Estrogen therapy may be necessary in postmenopausal women. A common first line treatment is a **pessary**, which is a removable device that, when placed into the vagina, holds the uterus in position. Surgical repair with or without hysterectomy is the treatment of last resort (see Box 25.8).[98]

The US Food and Drug Administration (FDA) has advised the cessation of any sale of transvaginal synthetic mesh products for the repair of POP.[99]

Benign Growths and Proliferative Conditions

Benign Ovarian Cysts

Benign cysts of the ovary may occur at any time during the life span but are most common during the reproductive years and, in particular, at the extremes of those years (Fig. 25.12). An increase in benign ovarian cysts occurs when hormonal imbalances are more common (e.g., during puberty and menopause).[100]**Benign ovarian cysts** are quite common, comprising one-third of gynecologic hospital admissions. Two common causes of benign ovarian enlargement in ovulating women are follicular cysts and corpus luteum cysts. These cysts are called *functional cysts* because they are caused by variations of normal physiologic events. Follicular and corpus luteum cysts are unilateral. They are typically 5 to 6 cm in diameter but can grow as large as 8 to 10 cm. Most women are asymptomatic.

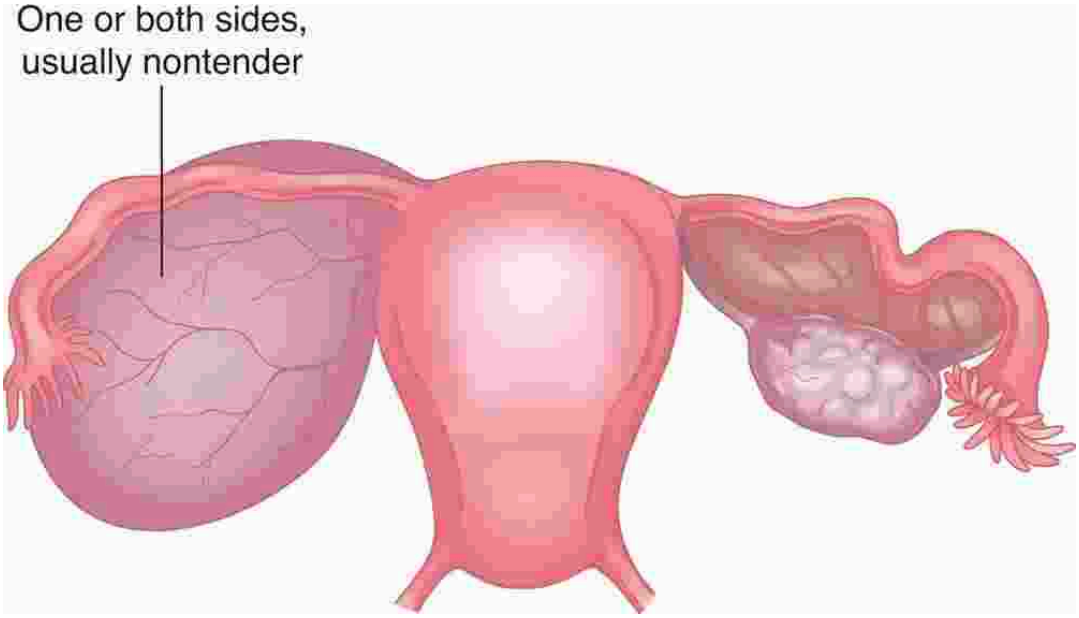

FIG. 25.12 Ovarian Cyst.

Benign cysts of the ovary are produced when a follicle or a number of follicles are stimulated but no dominant follicle develops and completes the maturation process. Every month approximately 120 follicles are stimulated, and in general, only 1 succeeds in ovulation of a mature ovum. Normally, in the early follicular phase of the menstrual cycle, follicles of the ovary respond to hormonal signals from the pituitary gland. The pituitary gland produces FSH to mature follicles in the ovary. As the follicles enlarge, granulosa cells in the follicle multiply and secrete estradiol. A dominant follicle will develop, and it secretes higher levels of estradiol, which stimulate the LH surge from the pituitary. A small cyst on the ovary during the follicular phase is normal. The LH surge stimulates the follicle to rupture, releasing the ovum and transforming the granulosa cells of the dominant follicle into the corpus luteum. If the dominant follicle develops properly before ovulation, the corpus luteum becomes vascularized and secretes progesterone. Progesterone arrests development of other follicles in both ovaries in that cycle. LH, proteolytic enzymes, and prostaglandins trigger follicular rupture and release of the ovum.

Follicular cysts are filled with fluid and can be caused by a transient condition in which the dominant follicle fails to rupture or one or more of the nondominant follicles fail to regress. This disturbance is not well understood. It may be that the hypothalamus does not receive or send a message strong enough to increase FSH levels to the degree necessary to develop or mature a dominant follicle. The hypothalamus monitors blood levels of estradiol and progesterone; when the FSH level is low, the estradiol concentration does not increase enough to stimulate LH. Research indicates that when progesterone is not being produced,

the hypothalamus releases GnRH to increase the FSH level.[101] FSH continues to stimulate follicles to mature; the granulosa cells grow, and, presumably, the estradiol level increases. This abnormal cycle continues to stimulate follicular size and causes follicular cysts to develop. Although individuals may experience no symptoms, some have pelvic pain, a sensation of feeling bloated, tender breasts, and heavy or irregular menses. After several subsequent cycles in which hormone levels once again follow a regular cycle and progesterone levels are restored, cysts usually are absorbed or regress. Follicular cysts can be random or recurrent events.

Follicular cysts can vary in size and symptoms from one episode to the next and often can recur. Most are fluid filled. The more solid an ovarian cyst, the greater the change of malignancy. Follicular cysts can be treated with combined estrogen-progestin oral contraceptives because they block the HPG axis, effectively quieting the ovary. However, progestin-only contraceptives increase the likelihood of developing follicular cysts because ovarian function is diminished but not suppressed, leading to an increased number of immature follicles.[100]

A *corpus luteum cyst* may normally form by the granulosa cells left behind after ovulation. This cyst is highly vascularized but usually limited in size, and with the normal menstrual cycle it spontaneously regresses. With an imbalance in hormones, low LH and progesterone levels may cause an abnormal or hemorrhagic cyst. In some cases, large cysts can rupture and cause hemorrhage.[102]

Corpus luteum cysts are less common than follicular cysts, but luteal cysts typically cause more symptoms, particularly if they rupture. Manifestations include dull, unilateral pelvic pain and amenorrhea or delayed menstruation, followed by irregular or heavier than normal bleeding. Rupture occasionally occurs and can cause massive bleeding, with excruciating pain; immediate surgery may be required. Corpus luteum cysts usually regress spontaneously in nonpregnant women. A persistent corpus luteum cyst is a normal finding within the first trimester of pregnancy because the corpus luteum produces progesterone to support the pregnancy until the placenta is established.[100] Following the development of a large, painful, or hemorrhagic cyst, oral contraceptives can be used to prevent cysts from forming in the future.

Dermoid cysts are ovarian teratomas that contain elements of all three germ layers; they are common ovarian neoplasms. These growths may contain mature tissue including skin, hair, sebaceous and sweat glands, muscle fibers, cartilage, and bone. Dermoid cysts are usually asymptomatic and are found incidentally on pelvic examination. Dermoid cysts have malignant potential and need careful evaluation for removal.[100]

Torsion of the ovary is a rare complication of ovarian cysts or tumors or enlargement of the ovary and can occur at any age in females. If a cyst is sufficiently large, it can cause the ovary to twist on its ligaments, pinching the blood supply to the ovary and causing extreme pain. *Ovarian torsion* is rare, but it is a gynecologic emergency. It usually presents with acute, severe, unilateral abdominal or pelvic pain and is treated surgically.[103]

Endometrial Polyps

An **endometrial polyp** is a benign mass of endometrial tissue that contains a variable number of glands, stroma, and blood vessels. Endometrial polyps are usually solitary and can occur anywhere within the uterus. Polyps are structurally diverse and are usually classified as hyperplastic, atrophic (or inactive), or functional. Hyperplastic polyps are often pedunculated (stalk- or mushroom-like) and may be mistaken for endometrial hyperplasia or, if large, for adenosarcoma (Fig. 25.13). Although polyps most often develop in women between the ages of 40 and 50 years, they can occur at all ages. Risk factors include advancing age, obesity, nulliparity, early menarche or late menopause (or both), diabetes, estrogenic states (i.e., anovulatory cycles and unopposed estrogen), treatment with tamoxifen, and hypertension. The coexistence of a separate endometrial atypical hyperplasia (AH) or adenocarcinoma is possible, but malignancy is extremely rare.

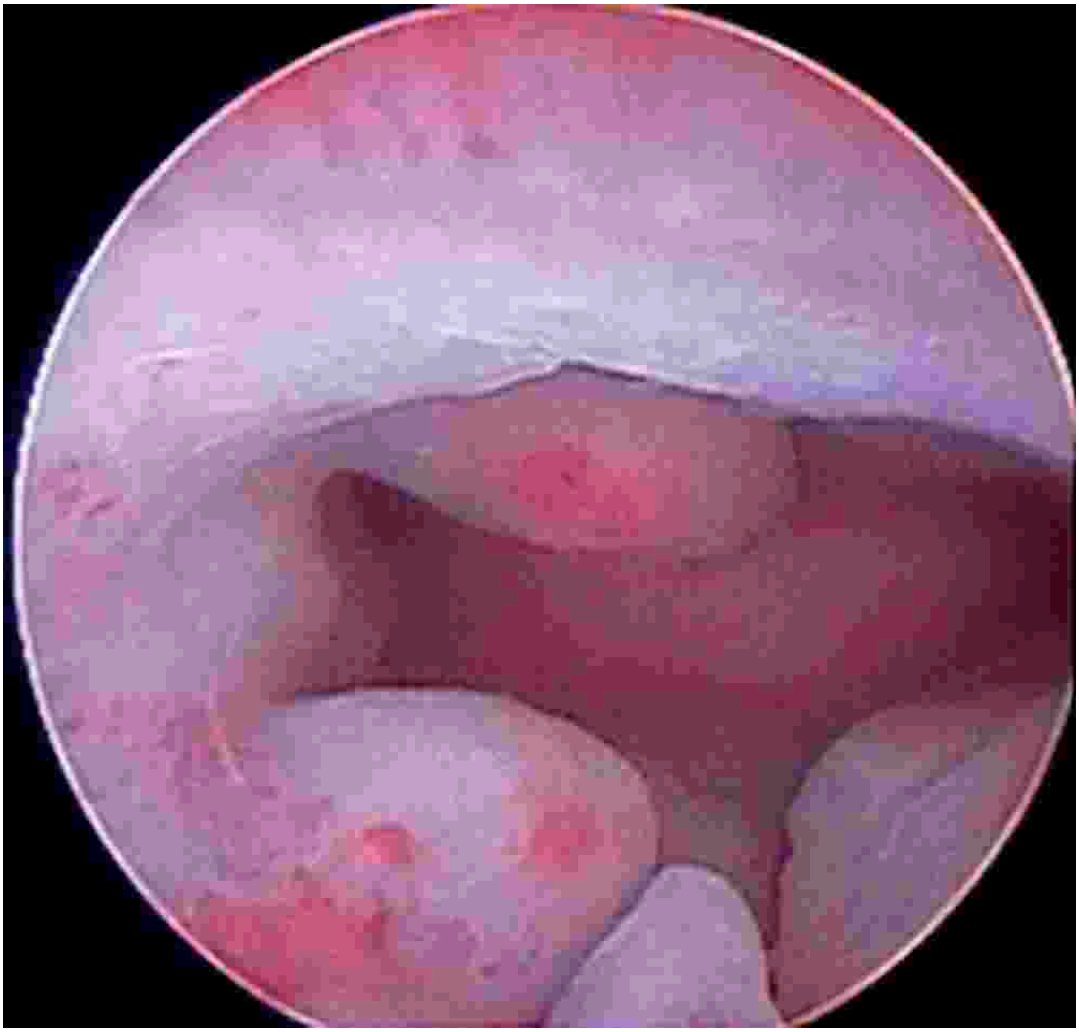

FIG. 25.13 Uterine Polyps Visible Through Hysteroscopy. (From Cheng C, Zhao T, Xue M, Wan Y, Xu D. Use of suction curettage in operative hysteroscopy. *Journal of Minimally Invasive Gynecology*, 2009;16(6):739–342.)

Endometrial polyps are a common cause of intermenstrual bleeding or even excessive menstrual bleeding and suboptimal fertility. Polyps resulting in abnormal bleeding have twice the rate of malignancy of asymptomatic polyps. The diagnosis is made by transvaginal sonography or hysteroscopy. The lesions can be removed with small, curved forceps, but there is a high rate of spontaneous resolution. Polypectomy can be performed through hysteroscopy for symptomatic women, for those at risk for malignancy, or for women who are struggling to conceive.[104]

Leiomyomas

Leiomyomas, commonly called **myomas** or **uterine fibroids**, are benign tumors that develop from smooth muscle cells in the myometrium (Fig. 25.14). Leiomyomas are the most common benign tumors of the uterus, affecting 70% to 80% of all females, and most remain small and asymptomatic. The prevalence increases in females ages 30 to 50 years but decreases with menopause. The incidence of leiomyomas in Black and Asian females is two to five times higher than that in White females. On average, the age of onset for Black females is 10 years earlier than it is for White females.[105]

FIG. 25.14 Leiomyomas.
(A) Uterine section showing the whorl-like appearance and locations of leiomyomas (also called *uterine fibroids*). (B) Sagittal section showing multiple leiomyomas. Typical, well-circumscribed, solid, light gray nodules distort the uterus. (B, From Damjanov I, Linder J. Pathology: *A color atlas*. St. Louis: Mosby; 2000.)

A. An illustration depicts the sagittal section of the uterine with labels indicating the location of uterine fibroids as follows, subserous, submucous, and intramural. B. A close shot of a sagittal section of the uterus with well-circumcised, solid nodules of various sizes.

The cause of uterine leiomyomas is unknown, although their size appears to be related to estrogen and progesterone, growth factors, angiogenesis, and apoptosis. An increase in familial aggregation may indicate genetic factors as important, and leiomyomas exhibit nonrandom chromosomal abnormalities.[106] Because leiomyomas are estrogen and progesterone sensitive, uterine leiomyomas are not seen before menarche, are common during the reproductive years, and generally shrink after menopause. Tumors in pregnant females enlarge rapidly but often decrease in size after the end of the pregnancy. Risk factors include Black race, age, family history, nulliparity, time since last birth, obesity, postmenopausal hormone use, and hypertension. Lifestyle risk factors include diet, food additive consumption, soybean milk consumption, caffeine and alcohol consumption, smoking, lack of physical activity, and stress.[105,106] Conversely, the use of oral contraceptives or the injectable contraceptive depot medroxyprogesterone acetate, smoking, low BMI, and parity reduce fibroid risk.[105]

Pathophysiology

The formation and growth of uterine leiomyomas is not well understood; however, genetics, environmental factors, steroid hormones (estrogen and progesterone), and angiogenesis all play a role.[107] Fibroid development begins with a single uterine smooth muscle cell (myometrium). Leiomyomas are benign monoclonal neoplasms that occur as a single fibroid or multiples throughout the uterus. Leiomyomas are classified as subserous, submucous, or intramural, according to their location within the various layers of the uterine wall (see Fig. 25.14). Mutations in the mediator subcomplex 12 *(MED12)* gene have been

identified in approximately 70% of uterine leiomyomas.[108] Degeneration and necrosis may occur when the leiomyoma outgrows its blood supply, which is more common in larger tumors and is frequently accompanied by pain.

Clinical Manifestations

The major clinical manifestations of leiomyomas are abnormal vaginal bleeding, pain, and symptoms related to pressure on nearby structures. Fibroids also may contribute to infertility and subfertility, as well as obstruction during birth if the fibroids are large enough. The leiomyoma can make the uterine cavity larger, thereby increasing the endometrial surface area. This enlargement may account for the increased menstrual bleeding associated with leiomyomas. Although pain is not an early symptom, it occurs with the devascularization of larger leiomyomas and is associated with blood vessel compression that limits the blood supply to adjacent structures. Because the fibroid is relatively slow growing, enabling adjacent structures to adapt to pressure, symptoms of abdominal pressure develop slowly. Pressure on the bladder may contribute to urinary frequency, urgency, and dysuria. Pressure on the ureter may cause it to become distended "upstream" from the pressure point. Ectosigmoid pressure may lead to constipation. Larger fibroids may cause a sensation of abdominal or genital heaviness.

Evaluation and Treatment

Uterine leiomyomas are suspected when bimanual examination discloses irregular, nontender nodularity of the uterus. Transvaginal ultrasound is the gold standard for imaging and confirming the diagnosis, but current recommendations do not require serial imaging.[109] Treatment depends on the symptoms, tumor size, individual's age, reproductive status, preference, and overall health. Most leiomyomas are asymptomatic, with surveillance being the preferred management.

Hormonal contraceptives, GnRH agonist (Leuprolide), and NSAIDs are used in the medical management to decrease the severity of bleeding, relieve pain, and shrink the myoma. A progestin-only IUD may be helpful for women who wish to reduce their bleeding and decrease the size of the tumors if their uterine cavity is not completely blocked by large fibroids. GnRH agonists are usually a temporary management for those close to menopause or as a presurgical treatment. Side effects are similar to those of decreased levels of estrogen and include hot flashes and osteoporosis. Various selective estrogen receptor modulators have been studied alone and in conjunction with GnRh agonists and appear effective, although more research is needed, especially because these agents may decrease bone density.[110] Nonpharmalogic therapies include green tea extract, curcumin (the active ingredient in turmeric), vitamin D, and herbal preparations used in

Chinese medicines.[111] Prevention of fibroids involves lifestyle factors and includes exercise, reducing obesity, and diet.[105]

Surgical treatments may include endometrial ablation, uterine artery embolization (UAE), myomectomy, MRI-guided focused ultrasound surgery, and hysterectomy. The most commonly performed procedure for fibroid-related bleeding and pain is a hysterectomy. Endometrial ablation is an alternative to surgery in those with heavy or abnormal bleeding. However, with submucosal fibroids, there is a larger risk of a failed procedure because the fibroids cause disruption of the uterine cavity, which can prevent proper cauterization.[109] UAE is a minimally invasive procedure for those who want to preserve fertility. The procedure is effective to control bleeding; however, there are limited studies to show preservation of fertility.[109,112] Myomectomy is an invasive option for those who want to preserve fertility and avoid hysterectomy. The outcome is highly dependent on the location and size of the fibroid, and there is no large randomized trial showing that it can improve fertility.[109] MRI-guided focused ultrasound surgery uses MRI and ultrasound to focus the fibroid and then cauterize. It is a new treatment that needs clinical evidence to support long-term effectiveness.[109] Benefits and risks of all treatments should be carefully considered, as should the desire for future pregnancy.

Adenomyosis

Adenomyosis is the presence of endometrial tissue within the uterine myometrium. Migration of endometrial cells into the myometrial layers occurs as a result of an unknown mechanism. Estrogen and progesterone likely play a role and, perhaps, metaplasia of müllerian tissue. Unlike endometriosis, the tissue does not respond to cyclic hormone changes.[113] Diagnosis of adenomyosis often is made during the late reproductive years; however, because it is commonly diagnosed after hysterectomy, the time of diagnosis may not be associated with the onset. Risk factors include conditions leading to increased estrogen exposure (increased parity, early menarche, short menstrual cycles, elevated BMI, oral contraceptive pill (OCP) use, tamoxifen use) and prior uterine surgery (e.g., dilation and curettage, cesarean section, myomectomy).[114,115]

Pathophysiology

Adenomyosis is the presence of endometrial stroma and glandular tissue within the smooth muscle of the myometrium. Endometrial proliferation, driven by estrogen, leads to the symptoms from different mechanisms. Adenomyosis leads to increased prostaglandins and results in dysmenorrhea. Heavy menstrual bleeding involves increased vascularization, abnormal uterine contractions, and increased cell-signaling molecules, such as prostaglandins, eicosanoids, and estrogen.[114,115]

Clinical Manifestations

Adenomyosis may be asymptomatic or may be associated with abnormal menstrual bleeding, anemia, dysmenorrhea, uterine enlargement, uterine tenderness during menstruation, chronic pelvic pain, dyspareunia, and infertility. Secondary dysmenorrhea becomes increasingly severe as the disease progresses.[114]

Evaluation and Treatment

On bimanual exam, the uterus is enlarged (two to three times the expected size), globular, and most tender just before or after menstruation. The enlarged uterus is often referred to as "boggy."[115] The diagnosis is confirmed by two-dimensional (2D) and three-dimensional (3D) ultrasonography as well as MRI.[116]

Treatment decisions are based on managing symptoms and preserving future fertility. Medical management includes NSAIDs for pain, hormonal contraceptives (e.g., levonorgestrel IUD) to reduce the estrogenic effects, androgenic hormones (e.g., danazol) to shrink the displaced tissue, and aromatase inhibitors (e.g., Arimidex).[115] Surgical options include endometrial ablation, hysteroscopic endometrial and adenomyoma resection, laparoscopic resection of adenoma, high-intensity focused ultrasonography (HIFU), and UAE.[117] Treatment decisions are based on managing symptoms and preserving future fertility.

Endometriosis

Endometriosis is the presence of functioning endometrial tissue or implants outside the uterus. The definition is limited because the disorder is complex and heterogenous involving pathobiologic, symptomatic, and multisystemic changes.[118] The ectopic (out of place) endometrium responds to the normal hormonal fluctuations of the menstrual cycle. Common sites of implantation of ectopic tissue include the ovaries, uterine ligaments (mostly broad and uterosacral), pouch of Douglas, and fallopian tubes.[119,120] Endometriotic implants are found outside of pelvic locations and include the gastrointestinal tract, lungs, diaphragm, abdomen, and pericardium.[121] Endometriosis primarily affects younger (premenopausal) women, with a peak incidence in the third decade. However, the incidence of endometriosis is difficult to determine, especially in asymptomatic adolescent and fertile women.[118,122,123] Endometriosis is the most common cause of chronic pelvic pain in women. It is the third most common reason for hysterectomy and is associated with a higher risk for infertility and cancers, especially ovarian cancer.[124]

The cause of endometriosis is multifaceted. In 1927, researchers found that endometriosis was linked to the implantation of endometrial cells during

retrograde menstruation, in which menstrual fluids move through the fallopian tubes and into the pelvic cavity.[125] Women with obstructed menstrual flow do have a higher incidence of endometriosis. However, it is now known that retrograde menstruation occurs in almost all women but not all women develop endometriosis. Intracaitary endometriaum and extrauterine endometriotic tissue are composed of mesenchymal progenitor/stem cells with alternate programming. GATA-binding factor-6 overexpression transforms endometrial stromal cells, and steroidogenic factor-1 overexpression causes excessive production of estrogen. This excess estrogen drives the inflammation especially in the presence of pathologically high levels of estrogen receptor-B. Progesterone receptor (PR) deficiency causes progesterone resistance. A genetic predisposition to endometriosis has been documented, and genetic polymorphisms have been identified. These altered cells have been found to harbor multiple cancer-causing mutations, such as KRAS, which has been associated with ovarian cancer.[124]

Pathophysiology

Endometrial implants can occur throughout the body but generally occur in the pelvic and abdominal cavities. The most common sites of implantation are the ovaries, uterine ligaments, rectovaginal septum, and the pelvic peritoneum (Fig. 25.15). Other sites of implantation are the sigmoid colon, small intestine, rectum, appendix, bladder, uterus, vulva, vagina, cervix, lymph nodes, extremities, pleural cavity, lungs, laparotomy scars, and hernial sacs.

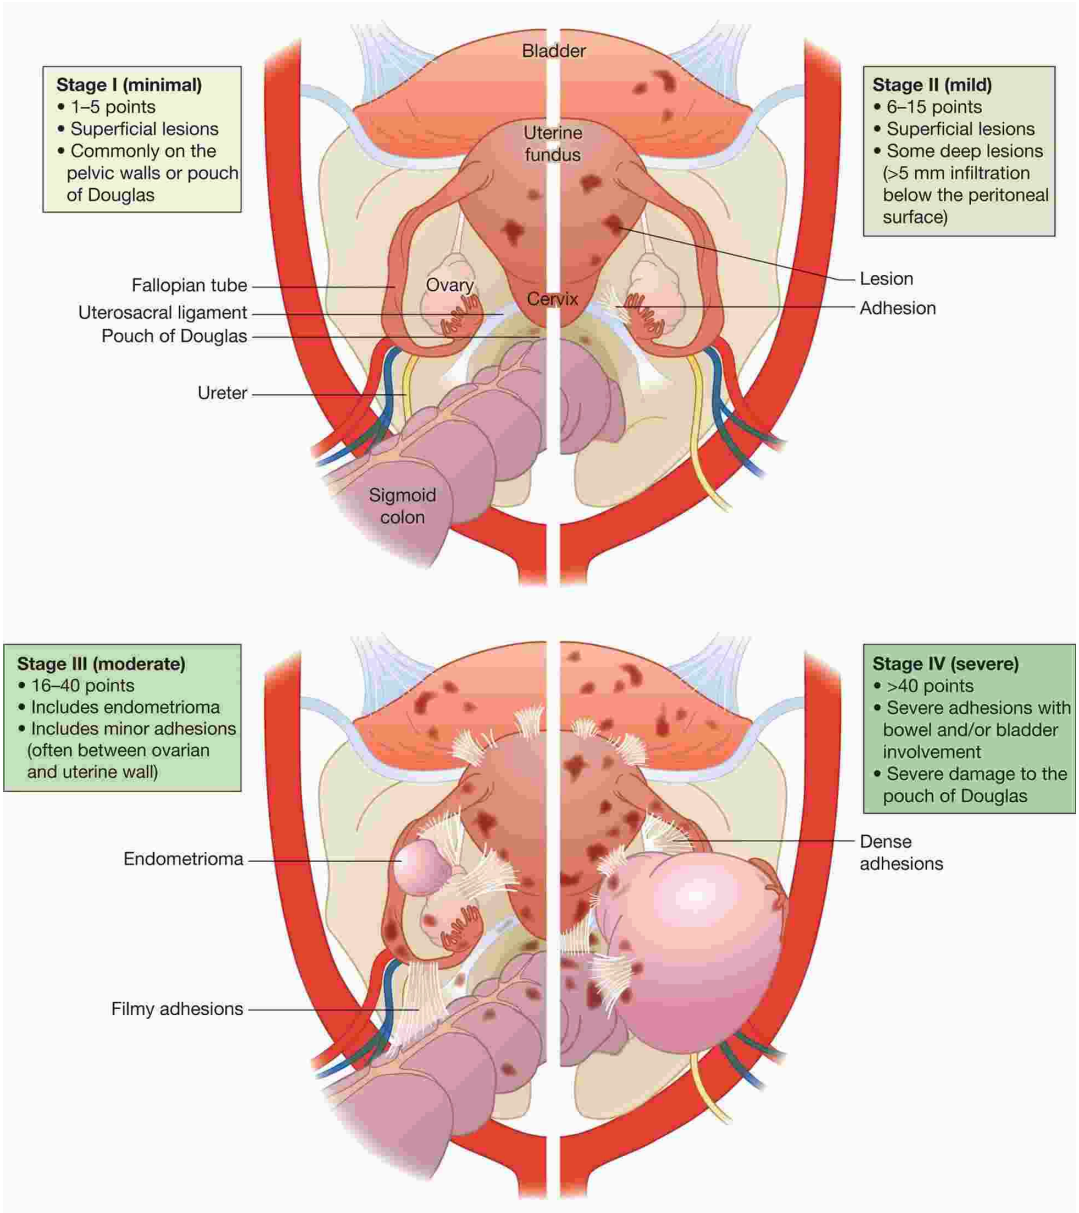

FIG. 25.15 Staging of Endometriosis.
The revised American Fertility Society and American Society of Reproductive Medicine staging system of endometriosis is a points system based on location, extent, and depth of disease in relation to pelvic structures. The uterus, fallopian tubes, ovaries, ovarian fossae (the shallow depression on the lateral wall of the pelvis where the ovary lies), uterosacral ligaments, rectovaginal septum, and pouch of Douglas (portion of the peritoneal cavity between the rectum and the posterior wall of the peritoneum between the uterus and bladder) are often affected. The stages are shown as stage I, stage II, stage III, and stage IV. Critical is the severity of the

disease according to this system and does not correlate with the severity and location of symptoms. For example, women with stage I (mild) disease may experience severe pain and/or infertility, whereas women with stage IV (severe) may be asymptomatic. (Adapted from Zondervan KT, Becker CM, Koga K, Missmer SA, Taylor RN, Viganò P. Endometriosis. *Nature Reviews Disease Primers*, 2018;4:9. Available at https://doi.org/10.1038/s41572-018-0008-5.)

Two illustrations of the female pelvic region depict the four stagings of endometriosis. The illustration on the top with labels indicating bladder, uterine fundus, cervix, ovary, lesion, adhesion, sigmoid colon, fallopian tube, uterosacral ligament, and pouch of Douglas and the ureter depicts the stage 1 and stage 2 endometriosis. The illustration at the bottom with labels indicating endometrioma, filmy adhesions, and dense adhesions shows the phase 3 and stage 4 endometriosis. Stage 1 or minimal involves 1 to 5 points; superficial lesions, commonly on Douglas's pelvic walls or pouch. Stage two or mild involves 6 to 15 points; superficial lesion, some deep lesions with greater than 5 millimeters infiltration below the peritoneal surface. Stage three moderate involves 16 to 40 points, includes endometrioma, and includes minor adhesions often between ovarian and uterine walls. Stage four or severe involvement of greater than 40 points, severe adhesions with bowel and or bladder involvement, severe damage to the pouch of Douglas.

The growth of endometrial lesions depends on estrogen. Endometrial lesions are affected by various ovarian hormones. Endometrial remodeling is a cyclical process during which time the endometrium responds to estrogenic stimulation in a uniformed manner. Endometrial hyperplasia results from continuous estrogen stimulation that is unopposed by progesterone. The cyclic changes are influenced by blood supply and the presence of glandular and stromal cells. With an adequate blood supply, the ectopic endometrium proliferates, breaks down, and bleeds with the normal menstrual cycle. The proliferative response is

regulated by progestogenic effects. The bleeding causes inflammation, triggering a cascade of cellular inflammatory mediators, including cytokines, chemokines, growth factors, and protective factors (leukocyte protease inhibitor and superoxide dismutase). Eventually, the inflammation leads to fibrosis, scarring, adhesions, and pain.

Infertility is common in women with endometriosis. The exact mechanism is unknown but may result from mechanical interference with ovulation or ovum transport through the fallopian tube because of adhesions and the effects of inflammation and cytokine activity. However, the infertility also could be a result of the underlying autoimmune disorder that caused the endometriosis in the first place. The overactive response to estrogen and the underactive response to progesterone seem to impair the endometrial receptivity to blastocyst implantation, which decreases the chance of successful pregnancy. Women with endometriosis who achieve pregnancy naturally or through in vitro fertilization (IVF) also seem to be at higher risk for poor obstetric outcomes, including preterm birth, small-for-gestational-age newborns, and placental complications.[126]

Clinical Manifestations

The clinical manifestations of endometriosis vary in frequency and severity and can mimic other pelvic diseases (e.g., PID, ovarian cysts, and irritable bowel syndrome). Heterogeneity of symptoms is high. Individuals may be asymptomatic or present with symptoms, which include infertility, pelvic pain, dyschezia (pain on defecation), dyspareunia, and, less commonly, constipation and abnormal vaginal bleeding. If implants are located within the pelvis, an asymptomatic pelvic mass having irregular, movable nodules and a fixed, retroverted uterus are found on examination. Most symptoms can be explained by the proliferation, breakdown, and bleeding of the ectopic endometrial tissue, with subsequent formation of adhesions. However, in most instances, the degree of endometriosis is not related to the frequency or severity of symptoms. For example, dysmenorrhea does not appear to be related to the degree of endometriosis. With involvement of the rectovaginal septum or the uterosacral ligaments, dyspareunia develops. Dyschezia, a hallmark symptom of endometriosis, occurs with bleeding of ectopic endometrium in the rectosigmoid musculature and subsequent fibrosis. Approximately 25% to 40% of women with infertility have endometriosis. The relationship between endometriosis and infertility is strong; however, the *degree* of disease is not as closely associated. More simply, women with untreated minimal to mild disease may have high pregnancy rates or may experience infertility.

Evaluation and Treatment

A presumptive diagnosis is based on the previously described symptoms, but pelvic laparoscopic visualization (ideally, with histologic verification) is the standard for diagnosis.[118] Less invasive testing includes imaging, genetic tests, biomarkers, or micro ribonucleic acid (miRNA), but further research is required before they can be recommended in routine clinical care. Ovarian endometrioma and deep nodular forms of disease can be detected through ultrasound and MRI.[127–129] Different classification systems have been introduced to categorize endometriosis. Some focus more on surgical findings and other with symptoms. It appears that the major drawback of all existing classification systems is that not one of them links the severity of the pain with the disease findings. As of now, no single global classification system exists.[130,131]

Treatment is based on preventing progression of the disease, alleviating pain, and restoring fertility. A multidisciplinary team approach using medical therapies that suppress systemic or local estrogen, decrease tissue proliferation, and reduce inflammation are the most common modalities. The combination of estrogen and progesterone or progestin-only oral birth control pills is a first line, widely used approach for dysmenorrhea or chronic pelvic pain, with or without presumed endometriosis.[132] GnRH agonists (i.e., leuprolide acetate, goserelin acetate, and nafarelin acetate) are a second line treatment to suppress systemic estrogen levels. Other treatment may include GnRH antagonists (e.g., Elagolix), which decrease hormones and reduce endometriosis-associated pelvic pain.[133] Aromatase inhibitors are used as off-label treatment for women resistant to hormone therapy (HT). However, long-term use is restricted because of bone-density loss, vasomotor side effects (flushing and hot flashes), and increased multiple-pregnancy rates.[118] Overall, hormonal treatments are contraindicated for women with endometriosis who wish to conceive.[118] Endometriosis-associated pain is treated with analgesics, acetaminophen, and NSAIDs. Complementary therapies may include pelvic physical therapy and cognitive therapy. In women with hormone-resistant pain, surgical treatment is considered.[118] Conservative surgical treatment includes laparoscopic removal of endometrial implants with conventional or laser techniques. Endometriosis-associated pain is the leading indication for hysterectomy in females 30 to 34 years of age and accounts for 18% of all hysterectomies.[134] All treatments have risks or side effects, and recurrent symptoms develop in most females within a few years, even with surgical treatments. Females should be fully informed of all options and understand the risk-to-benefit ratio of treatments, especially nonreversible treatments.[135]

Cancer

Malignant tumors of the female reproductive system are common. Because the pelvis and abdomen are poorly innervated and designed to accommodate a growing fetus, cancers of the female reproductive tract can often grow large before causing pain. Reproductive cancers are likely to be diagnosed early if there are symptoms; for example, vaginal bleeding prompts the individual to seek treatment. Clear screening guidelines and techniques have proven beneficial in early detection and intervention, resulting in lower mortality.[1]

Cervical Cancer

Each year more than a half a million women are diagnosed with cervical cancer.[136] Globally, cervical cancer is the fourth most common cancer among women, causing more than 300,000 deaths worldwide.[137,138] Cervical cancer incidence rates declined by more than half between 1975 (14.8 per 100,000) and 2014 (6.9 per 100,000). The decline is attributed to the widespread use of screening, primarily with the Pap test, immunization efforts, and hand-held technology accessibility.[139] Estimated new cases for 2021 in the United States are 14,480, with 4290 deaths.[140] High-risk subtypes of HPV are the main cause of cervical cancer. HPV screening and vaccination programs are effective methods in disease prevention.[136]Box 25.9 summarizes the major risk factors for cervical cancer.

Box 25.9

Risk Factors for Cervical Cancer

Chronic infection by high-risk oncogenic types of human papillomavirus (HPV).

Risk factors are those associated with acquiring HPV and impaired immune response to HPV, or both.

Risk Factors include:

Early age of sexual intercourse
Multiple sexual partners or a high-risk partner
Immunosuppression (e.g., organ transplantation, immunodeficiency disorders [HIV])
History of sexually transmitted infection
History of HPV-related vulvar or vaginal dysplasia
Lack of screening and underscreening
Tobacco smoke and cessation of smoking reduced risk by twofold

Data adapted from Cohen PA, Jhingran A, Oaknin A, Denny L. Cervical cancer. *The Lancet*, 2019;393:169–182.

Pathophysiology

Human papillomavirus (HPV) is a necessary condition in the development of almost all precancerous and cancerous cervical lesions. HPVs are DNA viruses grouped into high and low risk based on their genotypes. There are 15 high-risk HPVs currently identified. HPV-16 accounts for approximately 60% of cervical cancer cases, HPV-18 accounts for another 10%, and the other HPV types account for less than 5%.[141] Genital HPV infections are very common, and it is estimated that most sexually active women will contract HPV at some point in their lifetime. Most of these infections are asymptomatic, do not cause tissue changes detected on the Pap test, and resolve spontaneously. However, high-risk HPV may persist, increasing the risk of developing cervical precursor lesions (cervical intraepithelial neoplasia [CIN]) and eventual carcinoma (Fig. 25.16). It is unknown as to why some females are able to clear HPV infection and others cannot. Women with multiple sexual partners, a male partner with multiple previous or current sexual partners, young age at first sexual intercourse, high parity, immunosuppression, a long history of the use of oral contraceptives, certain human leukocytic antigen (HLA) subtypes, and use of nicotine are more likely to be infected.

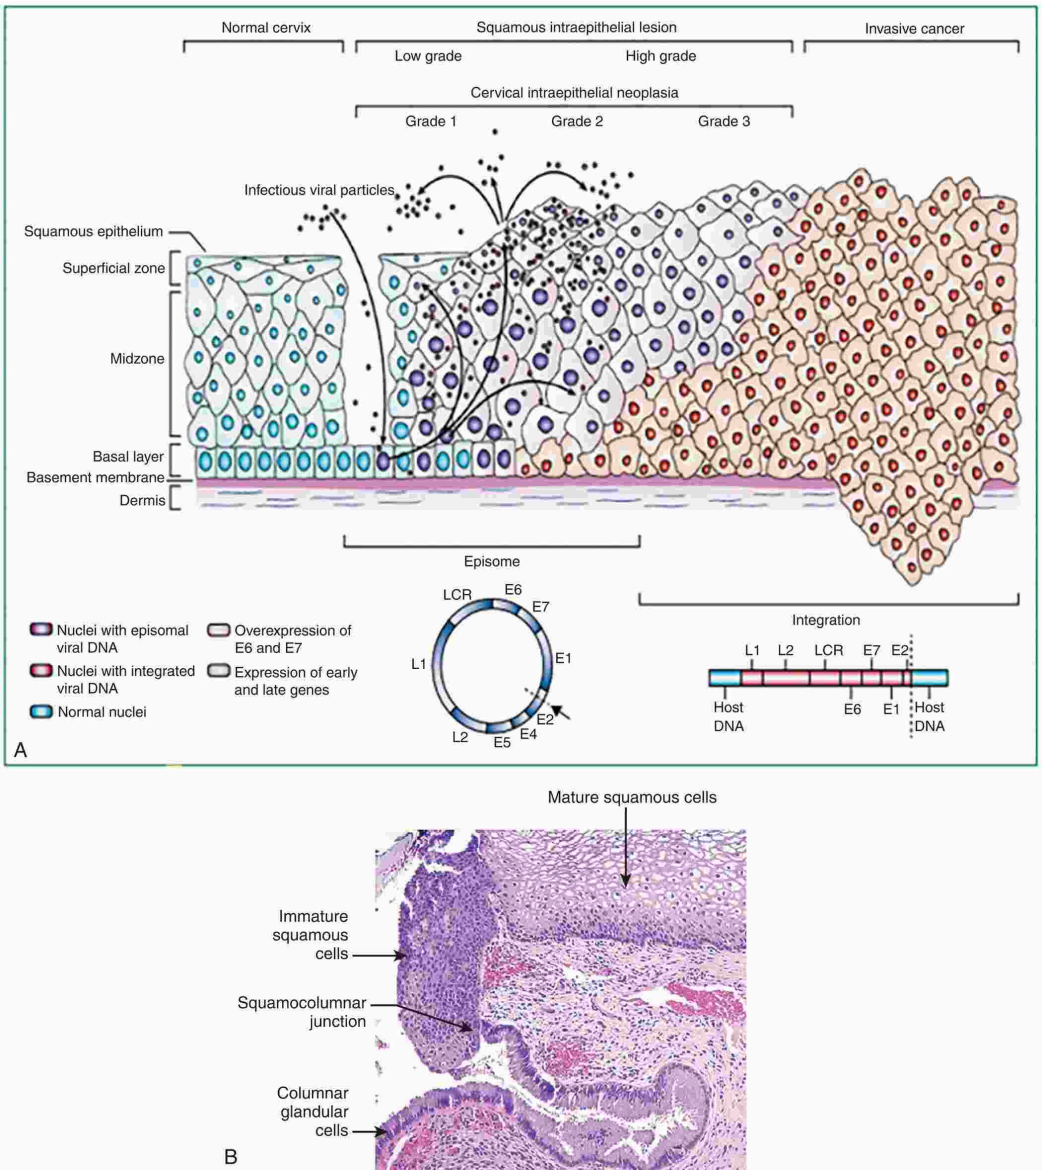

FIG. 25.16 Pathogenesis of Cervical Cancer. (A) Normal cervix and progression of cervical intraepithelial neoplasia (CIN) to invasive cervical cancer from persistent human papillomavirus (HPV) infection. The ability of HPV to act as a carcinogen depends on viral E6 and E7 proteins. These proteins interfere with the activity of key tumor suppressor proteins, p53 and RB, respectively. The overall effect of E6 and E7 proteins is increased proliferation of host cells now prone to acquire additional mutations and

lead to carcinogenesis. (B) Normal epithelium, then HPV infection progressing to CIN stage I. With more time, persistent HPV infections progress to precancerous lesions CIN II and CIN III and eventually to cervical cancer. Most cervical lesions do not progress to cervical cancer. (A, Reprinted with permission from Elsevier. From Crosbie EJ, et al: *Lancet* 2013;382:889-899 with permission in Cohen PA, et al: *Lancet* 2019;393:169-82; B, From Symonds EM, Macpherson MBA. *Color atlas of obstetrics and gynecology*. London: Mosby; 1994.)

An illustration depicts the schematic representation of the development of cervical cancer, which shows the transverse section of epithelial on the top with labels indicating the layers from lower to upper as follows. The dermis, basement membrane, basal layer, midzone, superficial zone, and squamous epithelium. The development of cervical cancer involves a progression of the normal cervix, low-grade squamous intraepithelial lesion, high-grade intraepithelial lesion, and invasive cancer. Cervical intraepithelial neoplasia involves grade 1, grade 2, and grade 3. The interpretation of the progression of cervical intraepithelial neoplasia and invasive cervical cancer from normal cervix involves nuclei with episomal viral D N A, nuclei with integrated viral D N A, normal nuclei, overexpression of E 6 and E 7, and expression of early and late genes. The nuclei with episomal viral D N A in the bottom

depict a cyclic structure with expressions labeled clockwise as follows. E 6, E 7, E 1, E 2, E 4, E 5, L 2, L 1, L C R. The nuclei with integrated viral D N A depicts the horizontal bar with labels from left to right as follows. Host D N A, L 1, L 2, L C R, E 7, E 2, and host D N A. B. A microscopic image of normal epithelium indicates the mature squamous cells, immature squamous cells, squamocolumnar junction, and columnar glandular cells.

The cervix is lined by two types of epithelial cells: squamous cells at the outer aspect and columnar glandular cells along the inner canal. The site of the cellular **transformation zone**, called the *squamocolumnar junction*, is illustrated in Fig. 25.17. The transformation zone is most susceptible to the oncogenic effects of HPV. Squamous cervical cancer accounts for most cervical precursor lesions and cancer and originates in the transformation zone or the glandular epithelium above the transformation zone.[141,142] In this zone, columnar epithelium is constantly being replaced by squamous epithelium in a process known as metaplasia (see Chapter 2). Metaplasia may be affected by hormonal levels. Because metaplastic cells are at increased risk of incorporating foreign or abnormal genetic material, neoplastic changes are most common in the transformation zone.

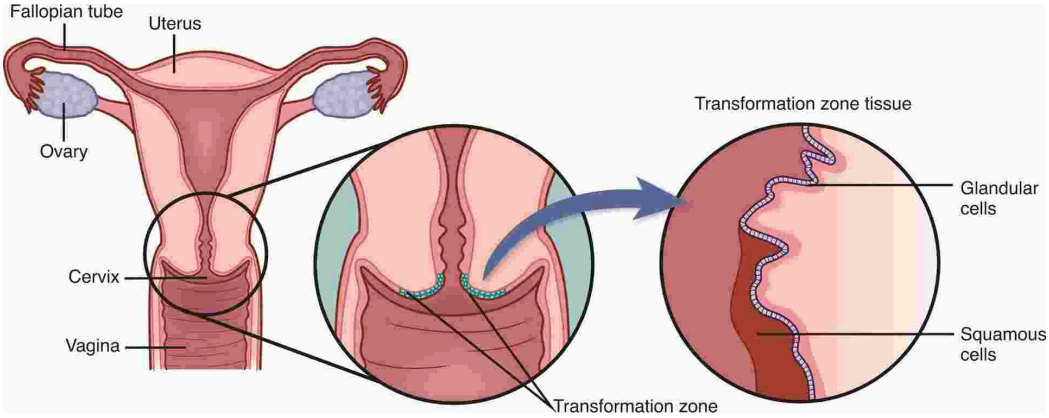

FIG. 25.17 Cervical Squamocolumnar Junction. Showing a transition from mature, glycogenized squamous epithelium, immature squamous metaplastic cells, and columnar endocervical glandular epithelium. The two types of epithelial cells lining the cervix: squamous cells and columnar glandular cells. (From Kumar V, Abbas AK, Aster JC, Cotran RS, Robbins SL. Robbins & Cotran pathologic basis of disease, 10th edition. Philadelphia: Elsevier; 2021.)

The illustration on the left depicts the female genital tract with labels indicating the fallopian tube, uterus, ovary, cervix, and vagina. The illustration in the middle shows the enlarged view of the cervix, revealing the transformation zone on the cervix epithelium. The illustration on the right depicts the enlarged view of the transformation zone tissue showing glandular cells and squamous cells.

Young females are especially vulnerable to HPV because of their cervical anatomy. Squamous epithelial cells in older females cover the portions of the cervix that protrude into the vagina, and columnar epithelial cells line the inner portions of the cervical canal.

The location of the transformation zone changes as females age and in response to estrogen and vaginal pH changes. In adolescent and mature females, a large portion of their cervix is covered with columnar epithelium, a condition known as squamous metaplasia. Hence the younger a female is when she contacts HPV, the more sensitive cervical cells are exposed. This is one reason vaccinations against HPV are aimed at individuals before the initiation of sexual activity.

Many chromosomes may contain genes that relate to HPV-linked cervical cancer. Like other cancers, cervical cancer requires the accumulation of genetic alterations for carcinogenesis to occur. Several genetic mutations have been identified, including some that have not been seen in other cancers. Several chromosome regions with recurrent loss of heterozygosity (LOH) have been identified. In addition, other genes may influence a female's receptivity to HPV. HPV may upregulate the E6 and E7 oncoproteins in certain gene sequences, causing a greater production of vascular epidermal growth factor, which allows the tumor to promote blood vessel growth toward the proliferating cells, fueling growth (see Fig. 25.16A). These viral proteins impair the ability to repair DNA damage or to regulate telomerase, which leads to cellular immortalization. Overall, these alterations promote increased proliferation of cells prone to acquire more mutations that can lead to carcinogenesis.[143]

Clinical Manifestations

Cervical cancer in the early stages is often asymptomatic. Symptoms in advancing cervical cancer may include postcoital or abnormal vaginal bleeding or discharge.[144] Vaginal discharge is a less common presenting symptom and may be serosanguineous or yellowish in color with a foul odor. Bleeding and discharge are subtle and are likely to be disregarded by premenopausal females. Postmenopausal females are more likely to seek medical attention if these signs appear. Advanced disease may cause urinary (e.g., passage of urine

through the vagina) or rectal (e.g., feces through the vagina) symptoms and pelvic or back pain along with anemia.

Evaluation and Treatment

Females should be screened for cervical cancer and their risk for future cervical cancer through Pap and HPV testing.

A Pap test involves the noninvasive collection of cellular samples from the surface of the cervix during a pelvic examination. Cervical cytologic examination is most accurate if cells are obtained from both the endocervix and the ectocervix (the transformation zone), which involves placing the collection device into the cervical os. Diagnosis is based on histopathologic assessment of a cervical biopsy. A colposcopy with biopsy is performed in symptomatic women with cytology suggestive of invasion without visible lesions.[136] A cone biopsy is necessary if cancer is suspected either clinically or on cervical cytology but is not confirmed on histopathologic review of cervical biopsies (Fig. 25.18).[136] If invasive carcinoma is found, lymphangiography, CT scan, MRI, ultrasonography, or radioimmunodetection methods are used for staging according to the FIGO guidelines, but it is not necessary to use all modalities on every individual.[136] The FIGO staging system was revised in 2018 and now includes lymph node status, similar to the system used by the American Joint Committee on Cancer (Table 25.3).[136,145]

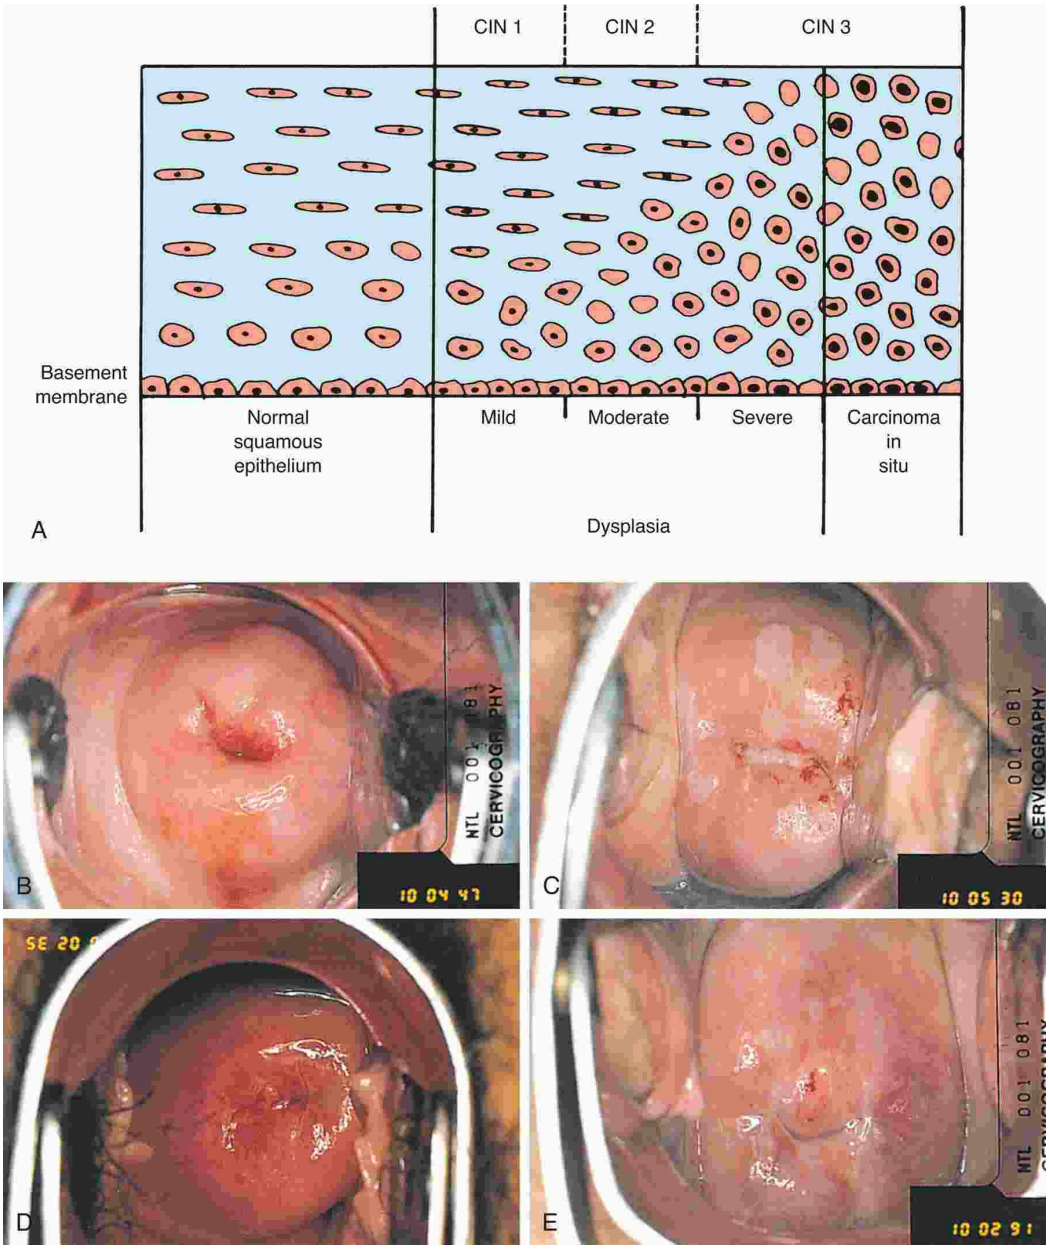

FIG. 25.18 Cervical Intraepithelial Neoplasia. (A) Diagram of cervical endothelium showing progressive degrees of cervical intraepithelial neoplasia *(CIN)*. (B) Normal multiparous cervix. (C) CIN stage 1. Note the white appearance of part of the anterior lip of the cervix associated with neoplastic changes. (D) CIN stage 2. Lesions reflected in distant capillaries. (E) CIN stage 3. Lesion predominantly around the

external os. (A, From Herbst AL, et al. *Comprehensive gynecology*, 2nd edition. St. Louis: Mosby; 1992. B–E, From Symonds EM, Macpherson MBA. *Color atlas of obstetrics and gynecology*. London: Mosby-Wolfe; 1994.)

A. An illustration of the squamous epithelium of the cervix depicts the schematic interpretation of the progression of cervical intraepithelial neoplasia from normal squamous epithelium through carcinoma in situ, which shows the squamous epithelium of the cervix divided into normal squamous epithelium, dysplasia which includes C I N 1: mild; C I N 2: moderate; and C I N 3: severe, and carcinoma in situ. B. Colonoscopic view of the normal multiparous cervix with round or oval cervical os. C. Colonoscopic view of the cervix represents the white appearance on the cervixâ€™s anterior lip, which has a slit-like cervical os. D. Colonoscopic view of the cervix represents the lesion in the distant capillaries. E. Colonoscopic view of the cervix represents the lesion around the external os.

Table 25.3

Staging of Cervical Tumors Staging of Cancer

	TNM	FIGO
Primary tumor cannot be assessed	TX	..
No evidence of primary tumor	T0	..
Carcinoma in situ (preinvasive)	Tis	..
Cervical carcinoma confined to the cervix (without extension to uterine corpus)	T1	I
Invasive carcinoma diagnosed only by microscopy, stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium, and horizontal spread of 7.0 mm or less; vascular space involvement, venous or lymphatic, does not affect classification	T1a	IA
Measured stromal invasion no greater than 3.0 mm and lateral spread no greater than 7.0 mm	T1a1	IA1
Measured stromal invasion greater than 3.0 mm and no greater than 5.0 mm, and horizontal spread no greater than 7.0 mm	T1a2	IA2
Clinically visible lesion confined to the cervix or microscopic lesion greater than Tla or IA2	T1b	IB
Clinically visible lesion no greater than 4.0 cm in greatest dimension	T1b1	IB1
Clinically visible lesion greater than 4.0 cm in greatest dimension	T1b2	IB2
Cervical carcinoma invades beyond the uterus but not the pelvic wall or lower third of vagina	T2	II

	TNM	FIGO
Tumor without parametrial invasion	T2a	IIA
Clinically visible lesion no greater than 4.0 cm in greatest dimension	T2a1	IIA1
Clinically visible lesion greater than 4.0 cm in greatest dimension	T2a2	IIA2
Tumor with parametrial invasion	T2b	IIB
Tumor extends to pelvic wall, involves lower third of vagina, causes hydronephrosis, or a combination of all symptoms, or non-functioning kidney	T3	III
Tumor involves lower third of vagina, without extending to the pelvic wall	T3a	IIIA
Tumor extends to pelvic wall, causes hydronephrosis or non-functioning kidney, or both	T3b	IIIB
Tumor invades mucosa of bladder or rectum, extends beyond the true pelvis, or both (bullous oedema is not sufficient to classify a tumor as T4 or IV)	T4	IV
Tumor invades mucosa of bladder or rectum (bullous oedema is not sufficient to classify a tumor as T4 or IV)	T4a	IVA
Tumor extends beyond the true pelvis	T4b	IVB
TNM is a cancer staging system, where T is associated with the size of the primary tumor. N with the nodal involvement, and M with metastatic disease		

	TNM	FIGO
Primary tumor cannot be assessed	TX	..
No evidence of primary tumor	T0	..
Carcinoma in situ (preinvasive)	Tis	..
Cervical carcinoma confined to the cervix (without extension to uterine corpus)	T1	I
Invasive carcinoma diagnosed only by microscopy, stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium, and horizontal spread of 7.0 mm or less; vascular space involvement, venous or lymphatic, does not affect classification	T1a	IA
Measured stromal invasion no greater than 3.0 mm and lateral spread no greater than 7.0 mm	T1a1	IA1

Tumor with parametrial invasion	T2b	IIB
Tumor extends to pelvic wall, involves lower third of vagina, causes hydronephrosis, or a combination of all symptoms, or non-functioning kidney	T3	III
Tumor involves lower third of vagina, without extending to the pelvic wall	T3a	IIIA
Tumor extends to pelvic wall, causes hydronephrosis or non-functioning kidney, or both	T3b	IIIB
Tumor invades mucosa of bladder or rectum, extends beyond the true pelvis, or both (bullous oedema is not sufficient to classify a tumor as T4 or IV)	T4	IV
Tumor invades mucosa of bladder or rectum (bullous oedema is not sufficient to classify a tumor as T4 or IV)	T4a	IVA
Tumor extends beyond the true pelvis	T4b	IVB
TNM is a cancer staging system, where T is associated with the size of the primary tumor. N with the nodal involvement, and M with metastatic disease		

Treatment depends on the degree of neoplastic change, stage of tumor, location of the lesion, and the extent of metastatic spread. Treatment includes surgery (hysterectomy), radiation therapy, chemotherapy, and targeted treatment. The prognosis is excellent with early detection and treatment.

The prevention of HPV infection through HPV vaccines is the key to substantially reducing the risk of cervical cancer. HPV also can cause anal cancer and mouth/throat (oropharyngeal) cancer, as well as cancer of the vulva, vagina, and penis. HPV vaccination is recommended for preteen individuals at age 11 or 12 through the age of 26. HPV vaccine recommendations are outlined in Table 25.4 and in Chapter 27, Box 27.5.[146]

Table 25.4

Human Papillomavirus Vaccine Recommendations

Eligible individual: Girls and boys ages 11–12 years old are eligible for the HPV vaccine series. However, the vaccination series can be started at age 9. Some adults age 27 through 45 who were not already vaccinated may wish to receive the vaccination after speaking with their health care provider. HPV vaccination in this age range provides less benefit because more people have already been exposed.	
Age	Recommendation
9–14 years old	• 2-dose schedule is recommended for people who get the first dose before 15 years old. The second dose should be given 6–12 months after the first dose. • If the second dose is administered after a shorter interval, a third dose should be administered at a minimum of 12 weeks after the second dose.
15–26 years old	• 3-dose schedule • The second dose should be given 1–2 months after the first dose, and the third dose should be given 6 months after the first dose • The minimum intervals are 4 weeks between the first and second dose,

	12 weeks between the second and third doses and 5 months between the first and third dose.
Immunocompromised, aged 9–26	• 3-dose schedule
27–45 years old	• Some adults may decide to get the HPV vaccine (just starting sexual encounters, not previously adequately vaccinated)

Eligible individual: Girls and boys ages 11–12 years old are eligible for the HPV vaccine series. However, the vaccination series can be started at age 9. Some adults age 27 through 45 who were not already vaccinated may wish to receive the vaccination after speaking with their health care provider. HPV vaccination in this age range provides less benefit because more people have already been exposed.	
Age	Recommendation
9–14 years old	• 2-dose schedule is recommended for people who get the first dose before 15 years old. The second dose should be given 6–12 months after the first dose. • If the second dose is administered after a shorter interval, a third dose should be administered at a minimum of 12 weeks after the second dose.
15–26 years old	• 3-dose schedule • The second dose should be given 1–2 months after the first dose, and the third dose should be given 6 months after the first dose • The minimum intervals are 4 weeks between the first and second dose, 12 weeks between the second and third doses and 5 months between the first and third dose.
Immunocompromised, aged 9–26	• 3-dose schedule
27–45 years old	• Some adults may decide to get the HPV vaccine (just starting sexual encounters, not previously adequately vaccinated)

Vaginal Cancer

Primary cancer of the vagina is the rarest of the female genital cancers, accounting for 1% to 2% of all female reproductive cancers.[147] It is rare because most of these lesions (80% to 90%)

represent metastases from another primary site.[148] The metastases come from other reproductive organs such as the cervix, endometrium, or ovary but also can come from distant sites such as the colon, breast, and pancreas.[148]Pathophysiology. **Vaginal cancer** is a heterogenous disease. Estimated new cases in the United States for 2021 are 8180 and estimated deaths 1530.[140] Vaginal and cervical cancers are thought to have a similar epidemiology. They both start as intraepithelial lesions, occur in females who have been sexually active, and are associated with HPV infection. Although HPV is an established carcinogen for vaginal cancer, not all vaginal cancers are caused by HPV.[149] Like cervical cancer, the high-risk subtypes of HPV are responsible for cancers of the head and neck and vulva or vagina. As with cervical cancer, the HPV-16 subtype accounts for most of the HPV-positive females for both cancers.[150] Other risk factors include increasing age, smoking, previous cervical cancer, exposure to DES, history of radiotherapy, or hysterectomy.[147,151,152]

More than 90% of women with vaginal cancer have squamous cell carcinoma. The remaining 10% are adenocarcinomas, sarcomas (rare), and melanomas (rare). Nonsquamous types of cancer are more common in younger women. Vaginal sarcomas can develop in children younger than 5 years, and adenocarcinomas are the most common in females younger than age 30 years.[152,153]

Clinical Manifestations. Vaginal cancer can be asymptomatic until late in the progression. The main clinical manifestations include abnormal vaginal bleeding or bloody discharge. Other manifestations include dyspareunia, pelvic pain, vaginal mass, vaginal discharge, vulvar pruritus, constipation, or dysuria.[148]

Evaluation and Treatment. Diagnosis of vaginal cancer includes history and physical examination, pelvic exam, cervical cytology (Pap smear), and HPV test. Other testing may include rectovaginal exam, a speculum exam, palpation of inguinal nodes, colposcopy, and biopsy. Biopsy is still the gold standard to diagnose vaginal cancer. Table 25.5 contains the stages of vaginal cancer. There are no specific laboratory tests in diagnosing vaginal cancer.[148] Once the

diagnosis of cancer is known and the size and extent of the lesion are determined, FIGO encourages using CT, MRI, or positron emission tomography (PET) scan to guide therapy.[148] Treatment depends on these findings and on the age of the individual. Three main types of treatment are surgery, radiation therapy, and chemotherapy. New treatments being tested in clinical trials include immunotherapy and radiosensitizers. Vaginal cancer can recur after it has been treated.[154] Recurrence and survival rates vary greatly by stage, size of the tumor, grade of the tumor, whether the cancer is within the vagina, whether there are signs and symptoms at diagnosis, and whether the cancer has just been diagnosed or has recurred. Once the diagnosis of vaginal carcinoma is made, coordinated care needs to be prompt. The involvement of social workers, nurses, radiation oncologists, and gynecologic oncologists is critical.[148]

Table 25.5

FIGO Carcinoma of the Vagina

FIGO Nomenclature	
Stage I	The carcinoma is limited to the vaginal wall.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edemas as such does not permit a case to be allotted to stage IV.
	IVa—tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis.
	IVb—spread to distant organs

Vulvar Cancer

Cancer of the vulva most often affects the labia majora and less often the labia minora, clitoris, or vaginal glands. The incidence of vulvar cancer over the past 30 years has steadily increased. Age-adjusted rates for new vulvar cancer cases have been increasing 0.6% each year from 2008 through 2017.[155] Estimated number of new cases is 6330 and estimated deaths 1560 in 2022.[155]Pathophysiology. The majority (90%) are squamous cell carcinomas. Melanoma subtypes are also common, whereas basal cell carcinoma and Paget disease of the vulva are rare. A history of HPV infection is related to 20% to 80% of vulvar cancers, depending on type; however, HPV-related lesions have a better prognosis than those that are not positive for HPV.[156] Previous squamous dysplasia of the vagina or cervix is a major risk factor, as are HPV infection, HPV-associated vulvar intraepithelial neoplasia, smoking, and HIV infections. Other risk factors include increased age, coexisting autoimmune conditions, organ transplant recipients, immunosuppressed individuals, many sexual partners, first sexual intercourse at a young age, and a history of abnormal Pap test results.[154,157]

Clinical Manifestations. Females in their 60 s typically present with symptoms and are more likely to present with advanced disease as opposed to other malignant conditions. The most common symptoms are vulvar irritation, pruritis, and vulvar lesions, which may be a hard ulcerated area of the vulva, large cauliflower lesions, or lesions similar to those of chronic dermatitis. There also may be abnormal bleeding and pain. Early detection is critical.Evaluation and Treatment. Biopsy confirms the diagnosis. Diagnosis and staging of vulvar cancer include physical examination and history, pelvic examination, Pap smear, HPV test, biopsy (may be examined under anesthesia), colposcopy, and imaging studies (MRI, CT,

PET/CT).[154] The main treatment for vulvar cancer is ablative or excisional surgery. Radiation and chemotherapy may be used if the cancer cannot be removed with surgery. Prognosis depends on the lesion size and location, histology, and lymph node involvement. Risk of metastasis increases with tumor size. The 5-year survival rate depends on the extent of the lesion, treatment, and overall health of the woman. Cancer caught in the early stages has a greater 5-year survival rate, with progressively poorer prognosis with advancing stages.

Endometrial Cancer

Endometrial cancer begins in the cells lining the uterus or endometrium and is a prevalent gynecologic malignancy. Most cases occur in postmenopausal females, with a peak incidence in the late 50 s to early 60 s. It is the sixth most common cancer and the 14th leading cause of cancer death worldwide.[158] Incidence is highest in North America and Europe and lowest in middle-income countries, such as India and South Africa. Incidence rates have been increasing worldwide.[158] The rise in incidence is thought to be caused by factors that affect hormones, such as rising rates of obesity and shifting reproductive trends (e.g., having fewer children). The primary risk factor for endometrial cancer is prolonged exposure to unopposed estrogen (without progesterone). Exposure to unopposed estrogen includes estrogen-only HRT, tamoxifen use, early menarche, late menopause, nulliparous status (never having a child), and failure to ovulate (i.e., PCOS and anovulatory cycles typical of the late reproductive years). Box 25.10 summarizes the epidemiologic and genetic risk factors for endometrial cancer. Another risk factor is obesity (elevated BMI as well as waist-to-hip ratio) because it is a known source of endogenous estrogen. Although related to obesity, other risk factors include diabetes, chronic inflammation, and lack of physical activity (Fig. 25.19).[159–161] Parity (having given birth to at least one child) reduced the risk of cancer.[162]

Box 25.10

Epidemiologic and Genetic Risk Factors for Endometrial Cancer

Epidemiologic Risk Factors

Endometrioid endometrial cancer (EC) is an estrogen-dependent tumor type associated with obesity, diabetes, unopposed estrogen use, nulliparity, early menarche, and late menopause. Increasing age is a risk factor for serous and clear cell ECs. Tamoxifen use increases the risk of developing EC; histologic subtypes enhanced in users of tamoxifen are serous EC, high-grade endometrioid ECs, and carcinosarcoma.

Genetic Risk Factors

Increased genetic risk for development of EC is correlated with Lynch syndrome, polymerase proofreading-associated polyposis, and Cowden syndrome.

- Lynch syndrome autosomal dominant cancer syndrome, highly penetrant caused by germline mutation in a mismatch repair gene (*MLH1*, *MSH*2, *MSH6*, or *PMS2*), or by deletion in germline within *EPCAM* leading to epigenetic silencing of the adjacent *MSH2* gene. Mutation carriers have increased risk of EC and colorectal cancer, as well as cancers of the ovary, stomach, kidney, urinary tract, biliary tract, small intestine, and skin. Approximately 2%–6% of ECs are attributed to Lynch syndrome.
- Polymerase proofreading-associated polyposis is an autosomal dominant cancer susceptibility syndrome attributed to germline mutations of *POLD1* or *POLE*. *POLD1* mutation carriers are at increased risk of colorectal cancer. Predisposition to EC has not been established in *POLE* mutation carriers.

- Cowden syndrome is a condition with phosphatase and tensin homologue (PTEN) mutation carriers having an increased predisposition for developing multiple hamartomas and cancers of the breast, thyroid, endometrium, colorectum, kidney, and skin.

Data from Urick ME, Bell DW. Clinical actionability of molecular targets in endometrial cancer. *Nature Reviews Cancer*, 2019;19:510–521.

FIG. 25.19 Food, Nutrition, Physical Activity, and Endometrial Cancer.
(A) Overview of obesity's contribution to the progression of endometrial cancer, and preventive strategies. The T-shaped bar indicates factors that reduce the risk of endometrial cancer. (See the text for a full discussion.) (B) Convincing and probable data on reducing and increasing the

risk of endometrial cancer. (A, From Schmandt RE, Iglesias DA, Co NN, Lu KH. Understanding obesity and endometrial cancer risk: Opportunities for prevention. *American Journal of Obstetrics and Gynecology*, 2011;205(6):518–525; B, This material has been reproduced from the World Cancer Research Fund/American Institute for Cancer Research. Diet, Nutrition, Physical Activity and Cancer: a Global Perspective. Continuous Update Project Expert Report 2018. Available at dietandcancerreport.org.)

A. An illustration depicts the overview of obesityâ€™s contribution to healthy endometrium progressing to complex atypical hyperplasia and endometrial adenocarcinoma. Obesity is induced by increased estrogen, insulin, and adipokines, and the factors that inhibit obesity are diet, exercise, hormone therapy, and chemoprevention. B. A tabular format depicts the convincing and probable data on decreased and increased risk factors of endometrial cancer. Data from the table presented in the format risks: factors of convincing; probable factor, are as follows. Decrease risk: Nil; physical activity sup 2 and coffee sup 3. Increase risk: Convincing: Body fatness sup 1; glycemic load. The text for sup 1 reads, the panel interpreted B M I, including B M I at age 18 to 25 years, measures of abdominal girth, and adult weight gain as interrelated aspects of body fatness as well as fat distribution. Sup 2 reads, physical activity of all types; occupational, household, transport, and

recreational. Sup 3 reads that the effect is found in both caffeinated and decaffeinated coffee and cannot be attributed to caffeine.

Pathophysiology

Endometrial hyperplasia is associated with prolonged estrogenic stimulation of the endometrium. Endometrial hyperplasia and carcinoma share acquired genetic alterations in genes linked to carcinogenesis (Fig. 25.20).[163–165] Progesterone inhibits estrogen-driven growth in the uterus. The antagonistic effects of progesterone on the estrogen-induced proliferation and growth occur mostly during the luteal phase and are dependent on the presence of functional PR expression. The interactions between the epithelial and stromal cells of the endometrium may determine the eventual role in the actions of progesterone. The delicate balance of the PR isoforms can tip the scales to foster endometrial hyperplasia and atypia and enhance expression of uterine growth factors. Dysregulation of isoform expression can lead to abnormal function and precancerous changes.

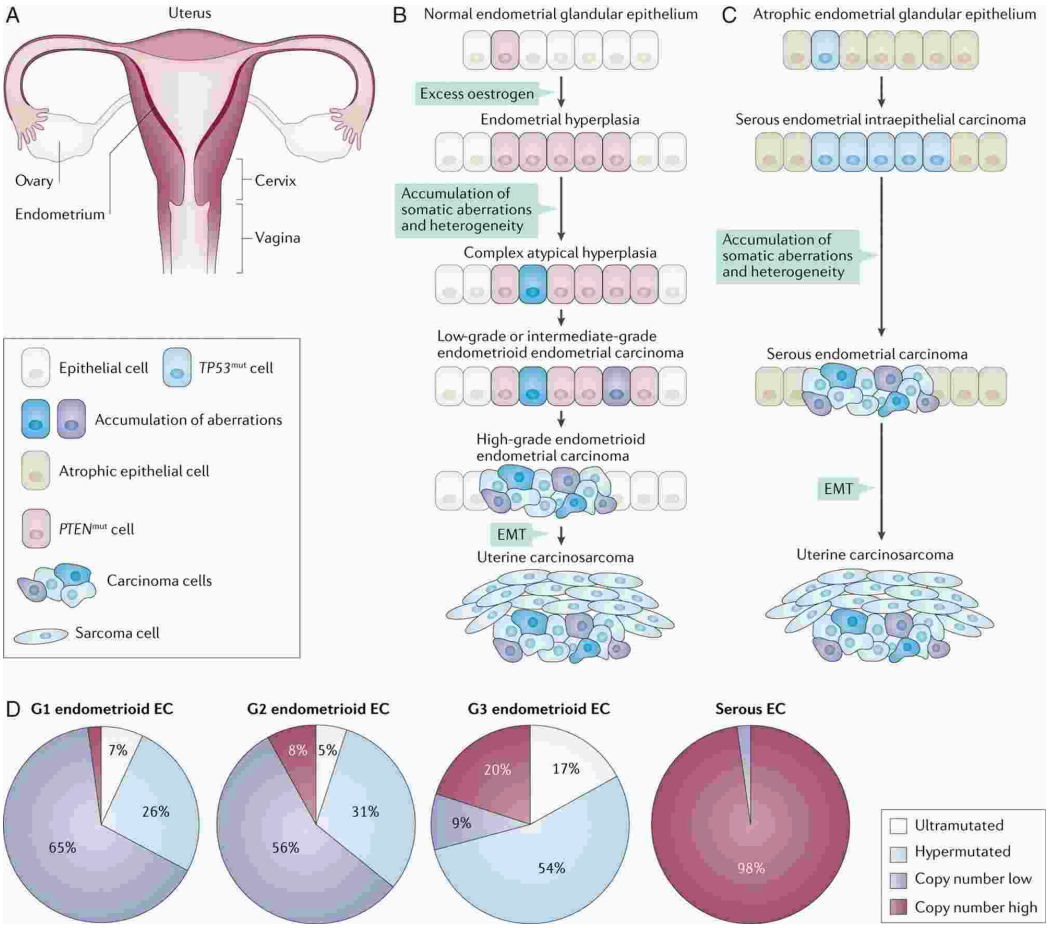

FIG. 25.20 Endometrial Hyperplasia, Complex Atypical Hyperplasia, Endometrial Carcinoma. (A) Female reproductive system showing the endometrium *(dark red)*. (B) Depictions of the initiation and progression of endometrioid and (C) serous endometrial cancers (ECs) from the normal and atrophic endometrial glandular epithelium, via precursor lesions (complex atypical hyperplasia and serous endometrial intraepithelial carcinoma). Coloring shows the columnar epithelial that have acquired somatic mutations; intratumoral heterogeneity is shown by differentially colored epithelial cells. PTEN mutation and TP53 mutation, respectively, are early events in the etiology of many endometrioid and serous ECs. In some instances, carcinomas

(especially, high-grade carcinomas, undergo epithelial-mesenchymal transition [EMT]; see Chapter 12). EMT gives rise to uterine carcinosarcomas, tumors that have epithelial carcinoma cells and sarcoma cells *(blue)*. (D) Pie charts show the distribution (% of total tumors) of low-grade or intermediate-grade (G1 and G2, respectively) endometrioid EC, high-grade (G3) endometrioid EC, and serous EC among the four molecular subgroups described in The Cancer Genome Atlas. (From Urick ME, Bell DW. Clinical actionability of molecular targets in endometrial cancer. *Nature Reviews Cancer*, 2019;19:510–521. https://doi.org/10.1038/s41568-019-0177-x.)

A. An illustration depicts the female genital track with labels indicating uterus, ovary, cervix, endometrium, and vagina. B. An illustration depicts the initialization and progression of endometrioid, which shows that normal endometrial glandular epithelium with excess estrogen leads to endometrial hyperplasia. Endometrial hyperplasia due to the accumulation of somatic aberrations and heterogeneity causes complex atypical hyperplasia. Complex atypical hyperplasia leads to low-grade or intermediate-grade endometrioid endometrial carcinoma, leading to high-grade endometrioid endometrial carcinoma causing uterine carcinosarcoma due to E M T. C. B. An illustration depicts serous endometrial cancerâ€™s initialization and progression, showing that atrophic endometrial

glandular epithelium leads to serous intraepithelial carcinoma. The serous endometrial intraepithelial carcinoma due to accumulation of somatic aberrations and heterogeneity forms serous endometrial carcinoma causing uterine carcinosarcoma due to E M T. D. Four pie charts represent the distribution of total tumors involved in the various stages of endometrial carcinoma. Data from the pie chart presented in the format, Stages of endometrial carcinoma: percentage of ultramutated; hypermutated; copy number low; copy number high, are as follows. Grade 1 endometrioid endometrial carcinoma: 7; 26; 65; 2. Grade 2 endometrioid endometrial carcinoma: 5; 31; 56; 8. Grade 3 endometrioid endometrial carcinoma: 17; 54; 9; 20. Serous endometrial carcinoma: 0, 0, 2, 98.

Clinical Manifestations and Evaluation and Treatment

AUB is the most common clinical manifestation of endometrial cancer. Females that are postmenopausal, obese, or with unopposed estrogenic conditions (i.e., anovulatory cycles) should be evaluated in the event of unscheduled or persistent, irregular vaginal bleeding.[166,167] Pain and weight loss are symptoms of more advanced disease. MRI is useful in diagnosis and locoregional spread of the tumor. Transvaginal ultrasound may be used to measure endometrial thickness, and with the rising incidence of endometrial cancer, earlier diagnosis is imperative. If the endometrium is abnormally thick (defined as >5 mm), then further testing, such as an endometrial biopsy, is done.[168] Treatment

is based on the extent of the disease and may include progestin therapy for simple hyperplasia (orally or through LNG-IUD), curettage for carcinoma in situ (CIS), total abdominal hysterectomy, chemotherapy, and radiation. Metformin is being studied as a possible strategy for preventing and treating certain cancers, including endometrial cancer.[166,169]

Ovarian Cancer

Ovarian cancer is the seventh most common cancer in women and the eighth most common cause of cancer death. Estimates for 2021 in the United States for new ovarian cancer cases are 21,410 and cancer deaths 13,770, with a 5-year survival rate just less than 45%.[1,170] The understanding of incidence patterns both within and between populations is essential to revealing potential causes of and risk factors for ovarian cancer. The highest age-adjusted incidence rates are observed in developed parts of the world, including North America and Central and Eastern Europe; the lowest such rates are seen in Asia and Africa. In the Unitted States, racial differences in epidemiology mimic the observed international variation, with rates highest in non-Hispanic whites followed by American Indians and Alaska Natives, Hispanics, non-Hispanic Blacks, and Asian and Pacific Islanders.[171,172] Migration studies show that moving from countries with low rates to those with high rates results in greater risk, demonstrating the importance of nongenetic factors. The strongest risk factor for ovarian cancer is a positive family history of breast or ovarian cancer; a personal history of cancer also increases the risk.[173] There is increased incidence, advanced stage, and lower reported survival in postmenopausal females with ovarian cancer,[171] whereas parity poses a protective role.[171,174]

Pathophysiology

The pathogenesis of ovarian cancer is not fully understood. The majority of ovarian tumors are sporadic and are not caused by inherited genetic factors. These cancers are acquired as somatic mutations in the *TP53* gene and occur in almost half of all ovarian

cancers.[175] However, in 10% to 15% of cases, a genetic predisposition is found. In cases that cluster in families, the genetic basis for the disease and the pattern of inheritance is unclear. However, there is association with the breast cancer susceptibility gene 1 *(BRCA1)* and a smaller number with mutations of *BRCA2* or mismatched repair genes (hereditary nonpolyposis colorectal cancer [HNPCC] syndrome). Females and families who are more susceptible to cancer may have errors in the ability to repair cellular DNA, related to abnormalities in several genes responsible for repair of damaged DNA.[176,177] Previously, the majority of ovarian cancers were thought to arise from just epithelial cells that cover the ovarian surface or line subserosal cysts. Newer evidence suggests that tumors arise from three ovarian components: (1) from the fimbriae of fallopian tubes and from deposits of endometriosis; (2) from germ cells, which are pluripotent and migrate to the ovary from the yolk sac; and (3) from stromal cells, including the sex cords, which precede endocrine changes of the postnatal ovary. Some ovarian tumors remain too difficult to classify.[170]

The normal ovary contains three major cell types: (1) germ cells, derived from the endoderm, which differentiate into oocytes; (2) hormone-producing cells (estrogen and progesterone) within the ovary; and (3) epithelial cells (derived from the müllerian duct) that cover the ovary and line inclusion cysts. Both benign and malignant tumors come from each of the three ovarian cell types.[178] The two major types of ovarian cancer are epithelial ovarian neoplasms and germ-cell neoplasms. Most ovarian malignancies are epithelial ovarian that develop from the surface epithelium of the ovary or the epithelium that lines cysts immediately beneath the ovarian surface or may be cells that have migrated from precursor lesions in the fallopian tubes (Fig. 25.21). Most epithelial cancers seem to arise from a single cell that is cloned. This occurs because of a loss of tumor-suppressor genes and activation of oncogenes. Ovarian cancer is heterogenous with four histologic types of epithelial ovarian cancers: serous, endometrioid, clear cell, and mucinous.[171] The histologic types also have different behaviors and characteristics.[179]

Tumors are often classified as type I (low grade) and type II (high grade) based on their cellular type. Type I tumors grow more slowly and are genetically stable.[171] Type II tumors often grow rapidly and aggressively and often have genetic mutations along with a poorer prognosis.[171] Gross appearances of serous tumors are shown in Fig. 25.22.

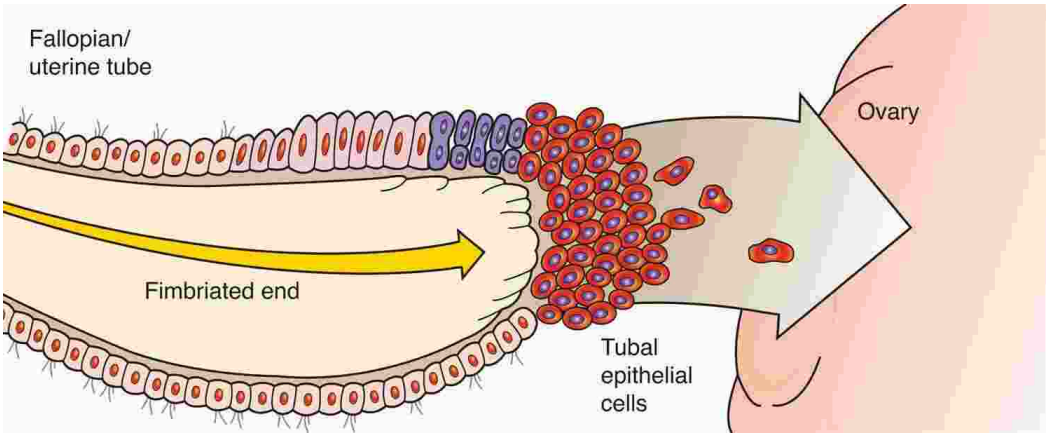

FIG. 25.21 Migration of Epithelial Cells from the Fallopian/Uterine Tubes to the Ovary. (Adapted from Kurman RJ, Shih I-M. The origin and pathogenesis of epithelial ovarian cancer: A proposed unifying theory. *American Journal of Surgical Pathology*, 2010; 34(3):433–443. https://doi.org/10.1097/pas.0b013e3181cf3d79)

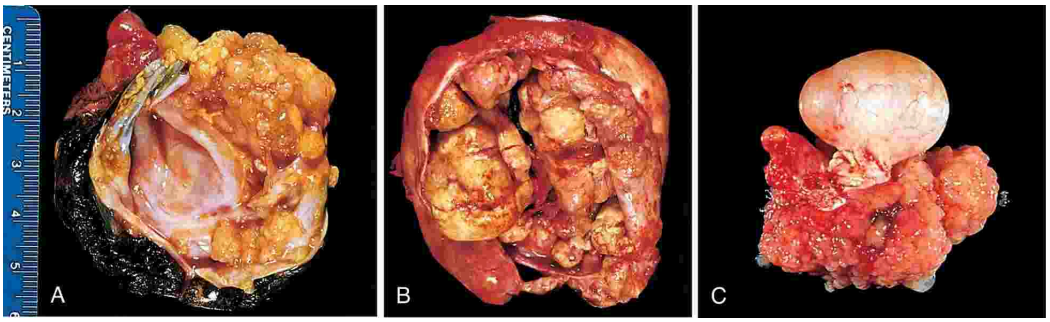

FIG. 25.22 Gross Appearances of Serous Tumors of the Ovary.
(A) Serous borderline tumor opened to display a cyst cavity lined by papillary tumor growth. (B) Carcinoma. The cyst is opened to reveal a large, bulky tumor mass. (C) Another borderline tumor growing on the ovarian surface. (From Kumar V, Abbas AK, Fausto N, Robbins SL, Cotran RS. *Robbins and Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.)

A. A close shot of a cut section of the tumor measuring around 5 centimeters displays a cyst cavity lined by deliciated papillary tumor. B. A close shot of a cut section of the tumor displays a large, bulky tumor mass. C. A close shot of the ovary with a tumor on the surface.

Germ-cell tumors are derived from the primitive germ cells (gametes) of the embryonic gonad and may be malignant or benign. The benign cystic teratoma accounts for approximately 10% of all ovarian tumors. These tumors represent an error in meiosis that results in the formation of ectoderm, endoderm, and mesoderm cell lines. Hair, teeth, and skin can be visualized within cystic teratomas. If the germ-cell tumor is malignant, it tends to be highly aggressive and rapidly growing with a poor prognosis. Cystic hygromas and

other germ-cell tumors can occur on the ovaries of females at any age. Germ-cell tumors in children can be particularly aggressive.

Clinical Manifestations

In general, individuals with ovarian cancer have no *early* symptoms. Symptoms are nonspecific and can be missed but tend to arise in the late stage (stage III or stage IV) when the tumors have grown to a very large size. Presenting symptoms include abdominal fullness, bloating, nausea, abdominal distension, early satiety, change in bowel habits, urinary symptoms, back pain, dyspareunia, and weight loss (Fig. 25.23).[171] The vague symptoms may occur months before the diagnosis.[180]

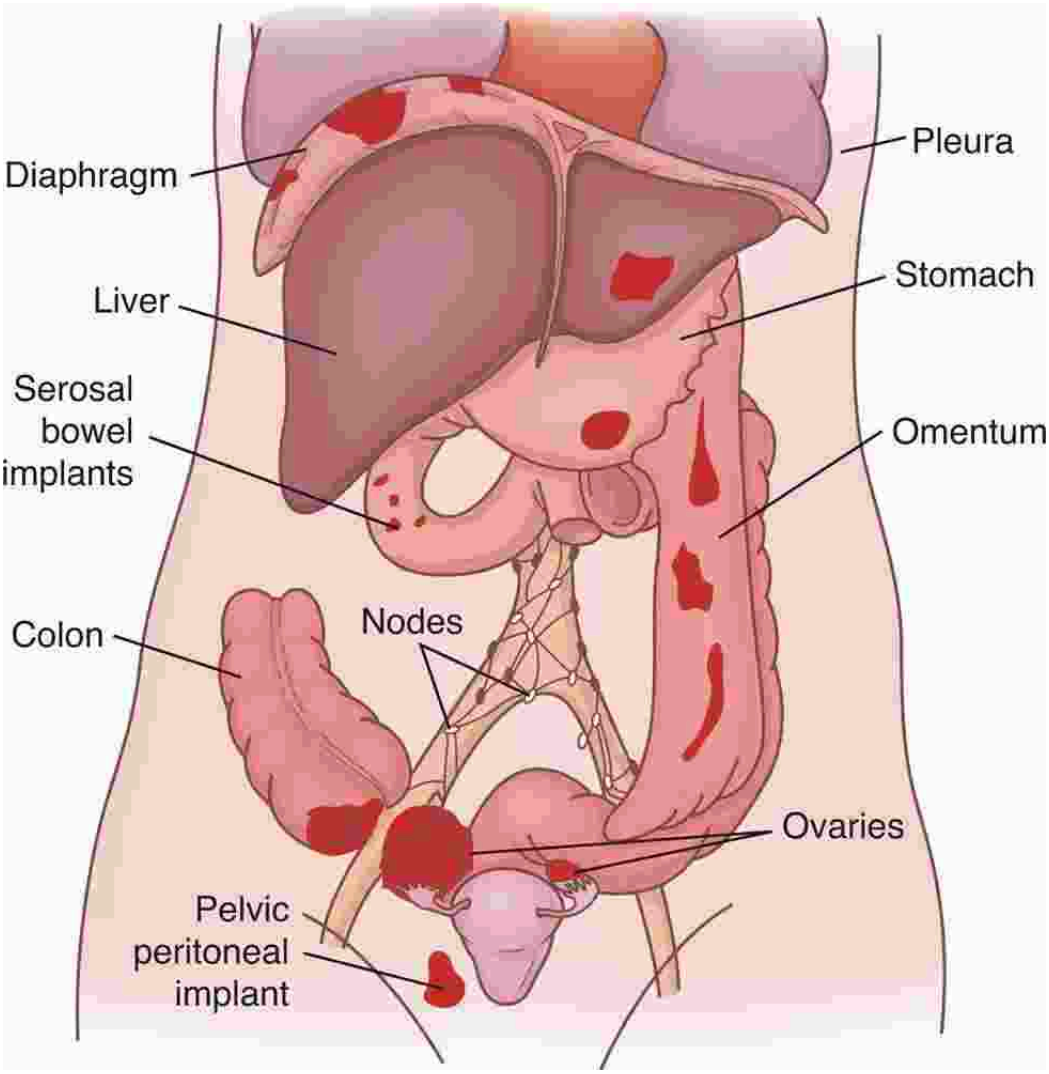

FIG. 25.23 Metastasis of Ovarian Cancer. Pattern of spread for epithelial cancer of the ovary.

An illustration depicts the metastasis of ovarian cancer which shows the anatomy of the female pelvic region with labels indicating diaphragm, liver, serosal bowel implants, colon, nodes, pelvic peritoneal implant, ovaries, pleura, stomach, and omentum.

Gastrointestinal manifestations may include dyspepsia, vomiting, and alterations in bowel habits caused by mechanical obstruction. Abnormal vaginal bleeding may occur if the postmenopausal endometrium is stimulated by hormone-secreting tumor. The tumor may cause ulcerations through the vaginal wall that result in bleeding. There can be a feeling of pressure in the pelvis or leg pain. Tumors that obstruct vascular channels can cause venous and, occasionally, arterial thrombosis. Alterations in coagulability also may occur, contributing to clot formation. Metastasis often causes pleural effusion with diminished breath sounds.

Evaluation and Treatment

A thorough physical exam, including rectovaginal examination on an empty bladder, should be performed.[171] In advanced cases, a palpable pelvic mass or ascites or diminished breath sounds may be found in the presence of pleural effusions. However, given the location of the ovaries, assessing abnormalities on routine gynecologic examination poses difficulty, especially in obese women. Minimally invasive testing should be considered in women with symptoms of disease. Initial work-up should include blood work and transvaginal ultrasound. The blood test, which measures the protein cancer antigen 125 (CA 125), is increased in approximately 80% of nonmucinous ovarian cancers. The CA 125 is an evaluative laboratory test that looks for specific cancer markers. However, CA 125 is also elevated in the presence of endometriosis, benign ovarian cysts, myomas, and pregnancy. Some types of germ cell and adenocarcinoma may be associated with increased levels of α-fetoprotein (AFP), hCG, and CA 125. A new marker, human epididymis protein 4 (HE4), is being further evaluated. HE4 has been found to be more sensitive to serous and endometrioid subtypes of ovarian cancer. A combination of higher CA 125 and HE4 levels are thought to be predictive of malignant ovarian cancer.[181]

If initial tests are suspicious for a cancerous mass, diagnosis is confirmed by biopsy and the extent of the disease is determined by ultrasound, CT, PET, MRI, or other imaging techniques. Staging of

disease may include other studies such as upper gastrointestinal series, barium enema, intravenous pyelogram (IVP), mammography, and lymphography. The FIGO staging system is described in Table 25.6.

Table 25.6

FIGO Staging of Carcinoma of the Ovary

Stage	Characteristics
I	Growth limited to ovaries
II	Growth involves one or both ovaries and also other organs (i.e., uterus, bladder, colon)
III	Cancer involves one or both ovaries, and one or both of these are present: (1) cancer has spread beyond pelvis to lining of abdomen, (2) cancer has spread to lymph nodes
IV	Growth involves one or both ovaries, with distant metastases to lungs, liver, or other organs outside peritoneal cavity
Recurrent	Cancer recurs after completion of treatment

FIGO, The International Federation of Gynecologists and Obstetricians.

The initial approach to treatment is surgery to determine the stage of disease and to remove as much of the tumor as possible. Future treatment, which requires a skilled, multidisciplinary team, is then customized based on the stage of the cancer, the woman's desires, the cell type, and the sensitivity of the cancer cells. Advanced-stage ovarian cancer is treated with primary reductive surgery, followed by platinum-based chemotherapy.[182] Radiation and chemotherapy are common adjunct treatments.[183] Even after initially effective treatment, the majority of females will relapse.[171] Prophylactic removal of the ovaries and fallopian tubes is associated with

increased survival rates among females who carry the BRCA mutation and is considered for those who do not desire fertility.

New therapies under investigation include monoclonal antibodies, epidermal growth factor receptor, gene therapy, small-molecular-weight inhibitors, and routine screening modalities. There is no sensitive and specific test for ovarian cancer for screening low-risk females. Routine screening of individuals without risk factors has not been shown to be beneficial and may cause harm because more females have unnecessary surgical procedures due to false-positives. Unfortunately, currently there are not sufficient data to support effective screening in the general population.[184,185]

However, research is ongoing for a cost-effective routine screening method.

Sexual Dysfunction

Sexual dysfunction is the lack of satisfaction with sexual function resulting from pain or a deficiency in sexual desire, arousal, or orgasm/climax. Sexual function and dysfunction result from a complex interplay of the individual, culture, and physiology.[186] Sexual issues are multifaceted and often very difficult to diagnose. Both organic and/or psychosocial disorders are implicated in sexual dysfunction. Studies show that up to 50% of adult women have some form of sexual dysfunction.[187]

The sexual response cycle is a complex process involving the brain, sympathetic and parasympathetic nervous systems, the systemic and local vascular, and local innervation. Any disruption in these systems can affect sexual response. Chronic medical conditions can greatly affect both sexual desire and sexual function (Table 25.7). Acute illness and infections also can affect the woman's desire and ability to engage in fulfilling sexual activity. Medications can disrupt the sexual response. Antihypertensives and antidepressants are commonly associated with sexual problems.[188] Surgeries near the genital area can disrupt nerve pathways, and hysterectomy may affect sexual function because the uterus, cervix, and vagina are

involved in sexual response and orgasm. The mind is a large component of sexual response, and any stressor that affects the woman can affect her sexual response, including her feelings about her sexuality and relationship, as well as past sexual abuse.[189]

Table 25.7

Possible Effects of Chronic Disease on Sexual Functioning in Women

Disease	Sexual Function
Cerebral palsy	Intact genital sensations, decreased lubrication; difficulty with sexual activity/positioning because of muscle spasticity, rigidity, or weakness; pain with positioning caused by contracture of knees and hips or because of increased spasms with arousal
Cerebrovascular accident (CVA)	Difficulties in sexual positioning and sensitivity because of impaired motor strength, coordination, or paralysis; decreased libido with stroke on dominant side of brain
Diabetes	Diminished intensity of orgasm and gradual decline in ability to achieve orgasm; decreased lubrication or recurrent vaginal infections with resultant dyspareunia
Chronic renal failure	Decreased arousal; increasingly rare and less intense orgasms; decreased lubrication
Rheumatoid arthritis (RA)	Painful sexual activity/positions because of swollen, painful joints, muscular atrophy, and joint contracture; decreased libido because of pain, fatigue, or medication; genital sensations remain intact
Systemic lupus erythematosus (SLE)	Similar to RA; decreased lubrication and vaginal lesions result in painful penetration

Disease	Sexual Function
Myocardial infarction (MI)	Most literature male oriented; problems related to medications
Multiple sclerosis (MS)	Diminished genital sensitivity; decreased lubrication; declining orgasmic ability; difficulty with sexual activity because of muscle weakness, pain, or incontinence
Spinal cord injury	Reflex sexual response with injury above sacral area; disrupted response with lesion at or below sacrum; loss of sensation, decreased lubrication; spasticity, incontinence, or pain with arousal; continued orgasmic sensations or sensations diffused in general or to specific body parts, such as breast or lips

A thorough history, including complete past medical, family, medication, and social history including any history of abuse, is needed to assess for sexual dysfunction. Testing can be appropriate to determine organic dysfunction and includes a CBC, comprehensive metabolic panel (CMP), glycated hemoglobin (HbA1c), as well as testing for STIs when indicated (Fig. 25.24). The American College of Obstetricians and Gynecologists divides sexual dysfunction into four categories: disorders of desire, arousal, orgasm, and sexual pain.[190]

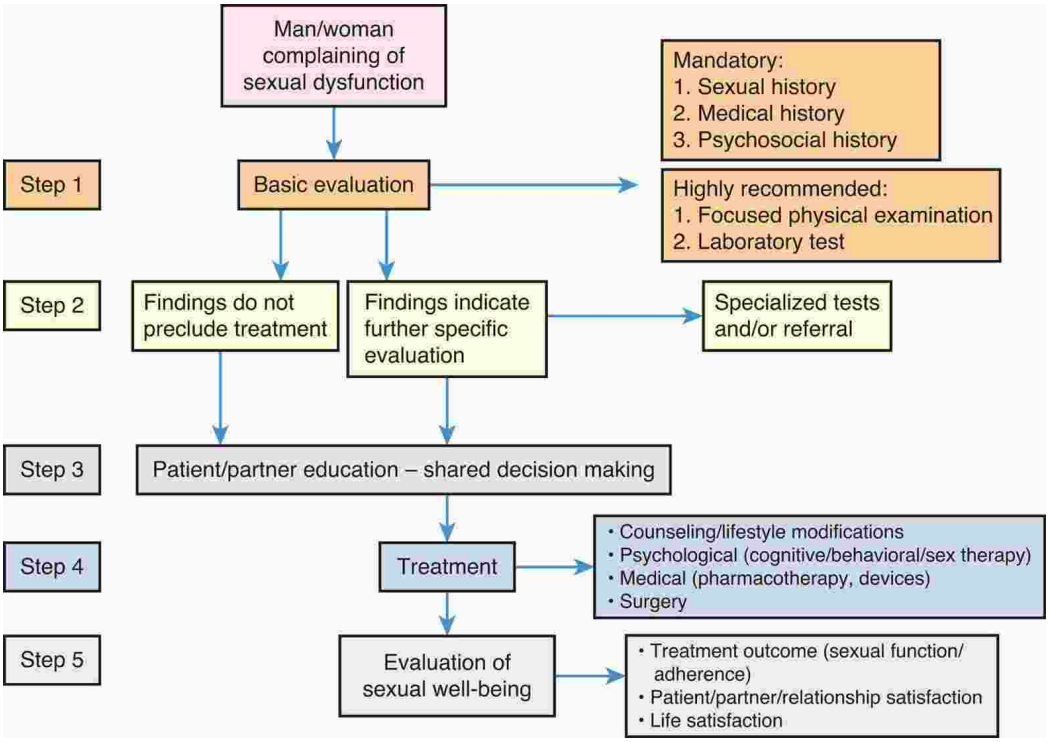

FIG. 25.24 Diagnostic and Treatment Algorithm for Sexual Dysfunction.
The International Consultation in Sexual Medicine stepwise diagnostic and treatment algorithm for sexual dysfunction in men and women. (From Hatzichristou D, Rosen RC, Derogatis LR, et al. Recommendations for the clinical evaluation of men and women with sexual dysfunction. *Journal of Sexual Medicine*, 2010;7(1pt2):337–348.)

A flowchart represents the algorithm for diagnosing and treating sexual dysfunction. The chart begins as follows. â€¢ Man or woman complaining of sexual dysfunction. â€¢ Step 1: Basic evaluation leads to mandatory and highly recommended. Mandatory includes sexual history, medical history, and psychological history. Highly recommended includes

focused physical examination and laboratory test. â€¢ Step 2: Basic evaluation leads to findings that do not preclude treatment; findings indicate further specific evaluation and specialized test and referral. â€¢ Step 3: findings do not preclude treatment; results indicate further specific evaluation leads to patient or partner education and shared decision making. â€¢ Step 4: Patient or partner education and shared decision making lead to treatment which includes counseling or lifestyle modification; psychological including cognitive, behavioral, sex therapy, medical including pharmacotherapy, devices, and surgery. â€¢ Step 5: Evaluation of sexual well-being, including treatment outcome including sexual function/adherence; Patient or partner or relationship satisfaction; life satisfaction.

Disorders of desire (hypoactive sexual desire, decreased libido) are the most common sexual dysfunction in women.[189] The prevalence of hypoactive sexual desire increases with age and may be a biologic manifestation of depression, dissatisfaction with partner relationships, a history of sexual or physical abuse, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency. Medications, such as the β-adrenergic blockers used for heart disease, may inhibit sexual desire. The medication flibanserin has been shown to activate dopamine and norepinephrine in the brain which increases sexual desire. Treatment with exogenous testosterone, the antidepressant bupropion, and sexual and psychological therapy has shown to increase sexual desire in women.[189]

Anorgasmia (orgasmic dysfunction) is the inability of a woman to reach or achieve orgasm. It ranges from difficulty in arousal to lack of orgasm. Any chronic illness may affect arousal. Specific disorders that may block orgasm are diabetes, alcoholism, neurologic disturbances, hormonal deficiencies, and pelvic disorders (e.g., infections, trauma, and surgical scarring). Narcotics, tranquilizers, antidepressants (especially SSRIs), and antihypertensive medications also can inhibit orgasm.[186]

Dyspareunia (painful intercourse) is common. Women may experience pain at any time from the beginning of arousal to after intercourse. The pain may have a burning, sharp, searing, or cramping quality and may be described as external, vaginal, deep abdominal, or pelvic. A variety of psychosocial and organic causes have been identified. Inadequate lubrication may make penetration or intercourse difficult or painful. Low estrogen levels, common with menopause and lactation, can decrease vaginal lubrication. Drugs with a drying effect (e.g., antihistamines, certain tranquilizers, and marijuana) can decrease lubrication. Infections and skin problems of the vulva and the vagina are a frequent cause of acute onset dyspareunia. The use of products such as spermicides and fragrances on the sensitive vaginal mucosa may increase the risk of irritation. Disorders of the vaginal opening, such as scarring from female genital mutilation, episiotomy, or an intact hymen, also can cause discomfort. Deep pelvic disorders such as infection, tumors, and cervical or uterine pathologies also can cause pain with intercourse.

Vaginismus is an involuntary muscle spasm in response to attempted penetration. Vaginismus is often a response to previous painful penetration. Common psychological causes include prior sexual trauma and fear of sex. Organic causes are similar to those that cause dyspareunia, including vulvodynia. Even after the underlying organic problem is detected and successfully treated, vaginismus may persist.

Sexual dysfunction may develop as a coping mechanism. Women with a history of sexual trauma—rape, incest, or molestation—often

have problems with desire, arousal, or orgasm or experience pain with sexual activity. In extreme cases, total sexual aversion may develop.[191] At other times, sexual dysfunction may be a symptom of marital or relationship problems. Because sexual dysfunction has many causes, assessment and treatment should be holistic, individualized, and culturally sensitive.[192,193]

Impaired Fertility

Infertility affects approximately 15% of all couples and is defined as the inability to conceive over 1 year of unprotected intercourse. Fertility can be impaired by factors in the male or female, or in both partners. The rate of infertility may be increasing because of increased rates of STIs, environmental exposures, delayed childbearing, or lack of previous reporting. There is a greater utilization of medical services for infertility now than ever previously recorded.[194]Pathophysiology. Causes of infertility include ovulatory disorder, abnormal semen, blockage of the fallopian tubes, endometriosis, and unexplained infertility. Most cases of infertility involve the female, caused in part by the complexity of the female reproductive cycle and tract. Ovulatory factors account for approximately 40% of female infertility. Regular ovulation occurs as a result of a functioning hypothalamic/pituitary axis. Ovulation can be disrupted by hormonal imbalances (e.g., TSH, estrogen, progesterone), chronic conditions, and stress. Age is a major factory in female fertility because the regularity of ovulation and the quality of ova decrease with age (Fig. 25.25). Approximately 20% of cases are because of abnormalities of the reproductive tract, such as tubal pathologies. Endometriosis, adhesions, and scarring from PID are major contributors to blockages within the female reproductive tract. The remaining 20% of female infertility cases are caused by rare conditions or unknown etiology.[195,196]

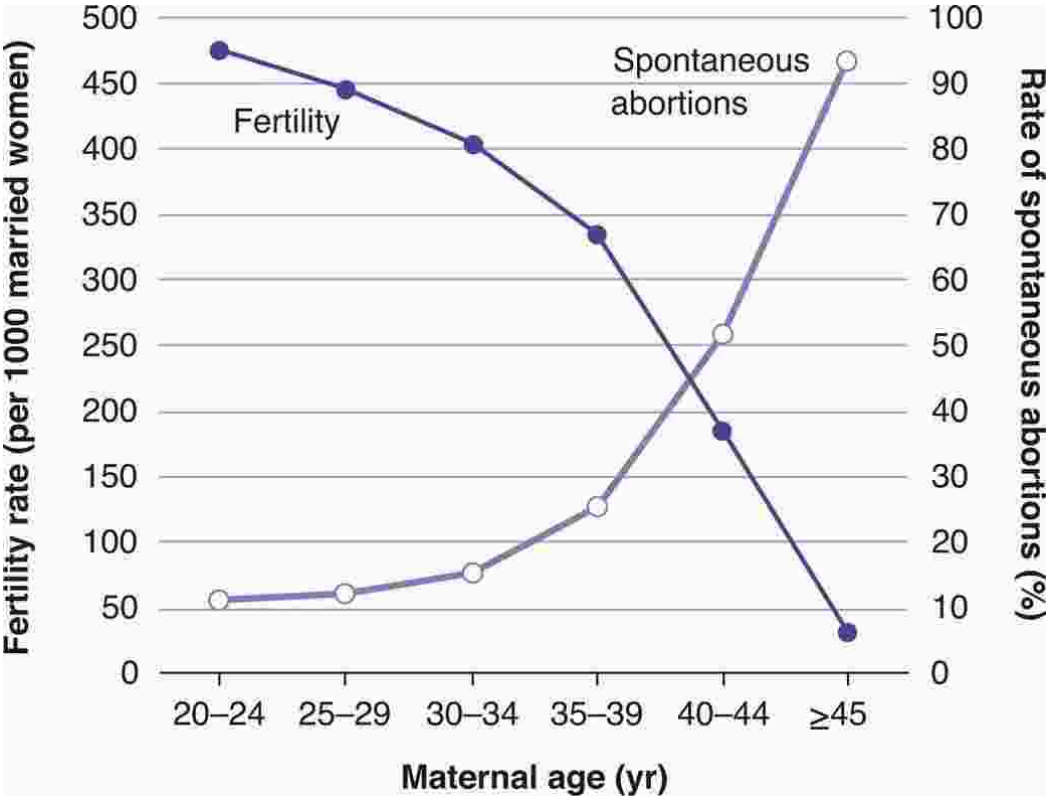

FIG. 25.25 Relationship of Fertility and Miscarriage with Maternal Age. (From Heffner LJ. Advanced maternal age—How old is too old? *New England Journal of Medicine*, 2004;351(19):1927–1929.)

A graph represents the relationship between fertility and miscarriage with maternal age. The horizontal axis represents maternal age ranging from 20 to 24, 25 to 29, 30 to 34, 35 to 39, 40 to 44, and greater than or equal to 45. The vertical axis on the left represents the fertility rate per 1000 married women, and the vertical axis on the right represents the rate of spontaneous abortion in percentage. The line graph for fertility is plotted through (20 to 24, 475), (25 to 29, 450), (30 to 34, 400), (35 to 39, 340), (40 to 44, 170),

(greater than or equal to 45, 25). The line graph for spontaneous abortion is plotted through (20 to 24, 10), (25 to 29, 11), (30 to 34, 15), (35 to 39,25), (40 to 44, 50), (greater than or equal to 92). All data are approximate.

Fallopian tube dysfunction may result from acute pelvic infections such as chlamydia or gonorrhea. Adhesions from a pelvic infection, abdominal surgery, or endometriosis may cause blockage of one or both fallopian tubes, preventing access of the sperm to the ovum. The fertilized ovum must implant on a receptive endometrium. Receptivity may be greatly diminished by fibroids or inadequate molecular or cellular preparation of the implantation site. Male infertility contributes to approximately 40% of cases of infertility (see Chapter 26).

Evaluation and Treatment. Before the performance of basic fertility tests, a complete history is obtained that includes (1) coital (sex) timing and frequency in relation to menstrual cycle, (2) an in-depth assessment and charting of the menstrual cycle, (3) a reproductive history, including previous pregnancies from both partners and their outcome, (4) a medical history of systemic disease, (5) current medications, (6) previous surgeries, (7) a sexual history, including any previous STIs, and (8) exposure to toxins. Testing starts with the least invasive test or procedure and advances in complexity and, possibly, invasiveness. The most common test for male infertility is the semen analysis. Hormonal assays may be helpful. Pelvic examination, ultrasound, and hysterosalpingogram (HSG), and MRI can help determine anatomy and fallopian/uterine tube patency. Chromosomal analyses of the couple may reveal mutations that result in early embryo loss.[197]

Treatment of infertility aims at correcting underlying pathologies or overriding the deficient system. Male infertility is discussed separately (see Chapter 26). Anovulation in the female can be

overcome with ovulation-inducing drugs. Blockages within the female reproductive tract can be bypassed with IVF.

Assisted reproductive technologies (ARTs) have enabled women and couples to conceive and bear children. However, there are questions about the health and long-term safety of infants conceived with assisted reproduction (e.g., concerns about the high rate of twins and preterm births in pregnancies conceived with ARTs). In addition, children born through ART have a higher rate of birth defects even when other variables are controlled.[198,199] Several explanations of the causes of these outcomes suggest that the birth defects may be the result of epigenetic changes that occur when the expression of the embryo's DNA is affected by the very early environment of the blastocysts, although it is not clear if damage done through the fertilization and implantation procedures themselves is caused by an underlying medical condition contributing to the infertility. Importantly, research in this area and in the field of epigenetics is ongoing.[199]

Disorders of the Female Breast

Galactorrhea

Galactorrhea (inappropriate lactation) is milk production from the breast not related to pregnancy or lactation. Milk production 1 year after cessation of breastfeeding is nonlactational and is considered galactorrhea.[200] The production of milk is affected by several hormones, including prolactin, estrogens, and thyrotropin-releasing hormone (TRH).[201] Box 25.11 includes hypothalamic-pituitary causes and non–hypothalamic-pituitary causes. Galactorrhea, which also can occur in men, may involve one or both breasts and is not usually associated with breast cancer.

Box 25.11

Etiology of Galactorrhea

Hypothalamic-Pituitary Causes

Prolactinomas

Non–prolactin-secreting pituitary tumor and infiltrative disorders of the pituitary stalk/hypothalamus

Non–hypothalamic-pituitary causes

Hypothyroidism

Medications (risperidone, clozapine, olanzapine, aripiprazole, metoclopramide, domperidone, tricyclic antidepressants, opioids, verapamil)
Renal failure
Chest wall lesions
Idiopathic hyperprolactinemia

The incidence of galactorrhea is difficult to estimate because of differences among definitions of the condition, examination techniques, and populations of women who have been studied. The prevalence ranges from 0.4% in an unselected adult population to as high as 9% to 17% in women with reproductive disorders.[200] Women with PCOS have a high reported prevalence of 17%.[202]

Pathophysiology

Galactorrhea is a manifestation of pathophysiologic processes elsewhere in the body rather than a primary breast disorder. These processes are chiefly hormone imbalances or exogenous, including drugs, estrogen, and stimulation of the nipples.[200]

Galactorrhea caused by hyperprolactinemia is manifested by the spontaneous appearance of a milky secretion from multiple duct openings, usually from both breasts. Estrogens cause hyperprolactinemia by inhibiting hypothalamic dopamine and by stimulating lactotrophs directly. High levels of estrogen in pregnancy cause lactotroph hyperplasia and can further increase the

growth of a preexisting prolactinoma. Hyperprolactinemia also is associated with excess secretion of estrogen from ovaries.[200] Unilateral, spontaneous, serous, or serosanguineous discharge from a single duct usually is caused by an intraductal papilloma. Bloody discharge suggests cancer; bilateral, sticky, multicolored discharge from multiple ducts is often caused by ductal ectasia; and purulent discharge indicates a subareolar abscess.

Clinical Manifestations

Inappropriate lactation is manifested by milky white or green breast secretions from one or both breasts of nonpregnant, nonlactating females. Most females with galactorrhea experience menstrual abnormality and changes in libido. Most males experience erectile dysfunction.[200] If a pituitary process is involved, the female usually experiences hirsutism and infertility; if a hypothalamic lesion is present, CNS symptoms may be reported, such as intractable headache, visual field disturbances, sleep disturbances, and abnormal temperature, thirst, or appetite.

Evaluation and Treatment

Galactorrhea in nulliparous or parous females who have not breast-fed for 12 months must be thoroughly evaluated. After ruling out breast pathologies, therapy is directed toward the cause of hyperprolactinemia. Evaluation includes a variety of diagnostic tests. Serum prolactin levels are measured, and at least two positive results are needed to diagnose hyperprolactinemia. Prolactin levels higher than 25 to 30 ng/mL (measured by radioimmunoassay) are considered elevated. Those in the range of 75 to 100 ng/mL are possibly caused by a pituitary tumor until proven otherwise. Serum thyroxine (T_4) and TSH levels are measured to rule out hypothyroidism, and LH and FSH levels are obtained if the individual is amenorrheic.

Treatment for galactorrhea consists of identifying and treating the cause. Medical therapy is typical, and surgical or radiation therapy is rarely required.

The main treatments are bromocriptine or cabergoline.[200] Surgery or radiation therapy is rarely required.

Benign Breast Disease and Conditions

Benign breast disease (BBD) is a range of noncancerous changes in the breast. Numerous benign alterations in ducts and lobules occur in the breast, including lumps, cysts, sensitive nipples, and itching. The most common symptoms reported by women are pain, a palpable mass, or nipple discharge; the majority of these prove to have a benign cause. Major determinants of the risk of breast cancer after a diagnosis of BBD include histologic or biologic features, or both; previous biopsy; and degree of family history.[203,204] Benign epithelial lesions can be broadly classified as (1) nonproliferative breast lesions, (2) proliferative breast disease without atypia, and (3) atypical (atypia) hyperplasia. The majority of nonproliferative benign lesions are not precursors of cancer and generally are not associated with an increased risk of breast cancer.

Nonproliferative Breast Lesions

Nonproliferative epithelial breast lesions are usually not associated with an increased risk of breast cancer. The nonproliferative lesions include (1) simple breast cysts, (2) galactocele, (3) papillary apocrine change, and (4) mild hyperplasia of the usual type. Terms such as **fibrocystic changes (FCCs)** (or physiologic nodularity and cysts), fibrocystic disease, chronic cystic mastitis, and mammary dysplasia refer to nonproliferative lesions but are not clinically useful because they are a heterogeneous group of diagnoses.[204] Simple **cysts** (fluid-filled sacs) are the most common nonproliferative breast lesion and are a specific type of lump that commonly occurs in women in their 30 s, 40 s, and early 50 s. Cysts are categorized by imaging characteristics as simple, complex, or complicated. It is estimated that 50% to 80% of women normally experience some of these changes. The prevalence of fibrocystic lesions is probably related to hormonal changes, which in turn are affected by genetic

background, age, parity, history of lactation, and use of caffeine and exogenous hormones. Cysts often rupture, with release of secretory material into the adjacent tissue. The resulting chronic inflammation and scarring fibrosis contribute to the palpable firmness of the breast. Fibrous tissue increases progressively until menopause and regresses thereafter.

Simple cysts do not require medical management unless they are large and painful. In this circumstance, aspiration can be completed under ultrasound guidance. If the aspirate is bloody, the fluid should be sent for cytology. *Complicated or complex cysts* can be aspirated to complete resolution with ultrasound guidance. If complete resolution is not obtained, percutaneous biopsy of the remaining cyst should be completed. Aspiration cytology has been related to tumor cell seeding; therefore a needle gauge of 22 or less should be used.[205]

Galactoceles are cystic collections of fluid often caused by an obstructed milk duct.[204] They present as soft cystic masses on physical examination and may appear as an indeterminate mass on mammography, unless the classic fat-fluid level is seen.[204] Ultrasound may show a complex mass. Clinical history and aspiration yield a milky substance. Once the diagnosis is made, excision is not necessary, and there is no increased risk of subsequent breast cancer.[204]**Papillary apocrine change** is an increase in ductal epithelial cells that has apocrine changes or an eosinophilic cytoplasm. **Mild hyperplasia of the usual type** is an increase in the number of epithelial cells within a duct that is more than two cells, but not more than four cells, in depth.

Proliferative Breast Lesions Without Atypia

Proliferative breast lesions without atypia are characterized by the proliferation of ductal epithelium or stroma, or both, without cellular signs of abnormality (**atypia**, or deviation from normal). Five structurally diverse lesions are discussed next.

Usual ductal hyperplasia (UDH) is additional or proliferating epithelial cells that fill and distend the ducts and lobules. They are usually an incidental finding on mammography. The cells can vary

in size and shape, but they retain features of benign cells.[204] No additional treatment is needed, and chemoprevention is not recommended.[204]

Intraductal papillomas can occur as solitary or multiple lesions. *Solitary papillomas* are a monotonous (sameness) array of papillary cells that grow from the wall of the cyst into the lumen of the duct. Growth occurs within a dilated duct often near or beside the nipple, causing benign nipple discharge. These papillomas *can* harbor areas of atypia or ductal carcinoma in situ (DCIS). Newer data suggest that not all papillomas diagnosed by core needle biopsy (CNB) require surgical excision; however, surgical excision is warranted when a CNB demonstrates papilloma with atypical cells.[204]

Diffuse papillomatosis (multiple papillomas) may present as breast masses, nodules on ultrasound, or the cause of nipple discharge. Diffuse papillomatosis is defined as a minimum of five papillomas within a localized segment of breast tissue.[204] Although the breast cancer risk is small, these lesions require surgical excision.

Sclerosing adenosis is a lobular lesion with increased fibrous tissue and scattered glandular cells.[204] No treatment is needed, and chemoprevention is not indicated.

Radial scar (RS) (also called *complex sclerosing lesions*) refers to an irregular, radial proliferation of ductlike small tubules entrapped in a dense central fibrosis. RSs are usually discovered when a breast lesion or radiologic abnormality is biopsied or removed. Rarely are RSs discovered by mammography, which cannot reliably differentiate between these lesions and speculated carcinoma.[204] Although controversy exists about the need for surgical excision, there is some evidence that RSs may be premalignant lesions and can slowly progress from scar to hyperplasia to carcinoma.[204]

Simple fibroadenomas are benign solid tumors that contain glandular and fibrous lesions.[204] In approximately 20% of cases, multiple fibroadenomas can occur in the same breast or bilaterally.[204] The etiology for fibroadenomas is unknown but appears to be hormonal because they can persist during the

reproductive years and can increase in size during pregnancy or with estrogen therapy. They usually regress after menopause.[204] They are more common among women between 15 and 35 years of age. Fibroadenomas are now considered proliferative lesions, and the histologic features influence the risk of breast cancer. There is no increased risk of breast cancer in the majority of women with a simple fibroadenoma. It is not necessary to excise all biopsy-proven fibroadenomas.[204] Disadvantages of excisional surgery include scarring at the incision site, dimpling of the breast from the removal of the tumor, damage to the breast's duct system, and mammographic changes (e.g., architectural distortion, skin thickening, increased focal density).[204] If a biopsy-proven fibroadenoma is asymptomatic, it can then be left in place.[204]

Proliferative Breast Lesions With Atypia

Atypical hyperplasia (AH) is an increase in the number of cells (or proliferation) with the cells having some variation in structure (—*atypia)*. AH is associated with a moderately increased risk of breast cancer and is characterized by two forms: ductal hyperplasia and atypical lobular hyperplasia. **Atypical ductal hyperplasia (ADH)** refers to abnormal proliferating cells in breast ducts. **Atypical lobular hyperplasia (ALH)** refers to proliferation of cells in the lumen of lobular units.

Approximately 60% of the subsequent breast cancers in women with AH occur in the ipsilateral breast (same side) as the biopsy.[206–208]

It appears that menopausal status at the time of benign breast biopsy influences the magnitude of the subsequent breast cancer risk. For women who were premenopausal at the time of their breast biopsy, the risk of breast cancer was greater in those with ALH than among women with ADH.[208] Among women who were postmenopausal at the time of benign breast biopsy, the risk was similar for ALH and ADH.[208] Overall, ADH and ALH are viewed best as “markers” of a generalized, bilateral increase in breast cancer

risk.[204,208] The younger a woman is when she receives a diagnosis of AH, the higher the risk that breast cancer will develop.[209]

Evaluation and Treatment

Breast problems are diagnosed from a multimodal approach that combines physical examination, mammography, ultrasonography, possibly MRI, and biopsy. The dense breast tissue often seen in young women can make mammographic interpretation extremely difficult (Box 25.12). Surgical excision was historically recommended after a CNB identified ADH or ALH; however, newer data suggest that routine excision of all atypical lesions may not be necessary.[204]

Box 25.12

Breast Cancer Screening Mammography

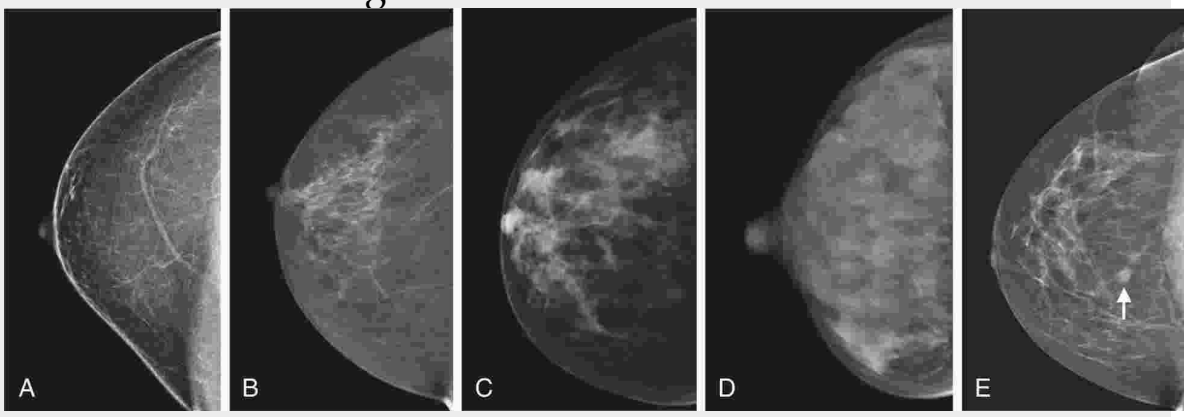
Joann G. Elmore, MD, MPH

The idea behind screening healthy individuals for disease is the hope that we can diagnose disease early, when more treatment options are available and when we can positively affect the life of the individual. Screening programs for the entire population of a country are a large undertaking and usually require careful consideration and extensive resources. Therefore we need to make certain the test has a high level of accuracy, with reasonable costs and disadvantages, the disease is not too rare, and the treatment is effective for individuals who are diagnosed because of the screening.

Women have been encouraged to undergo breast cancer screening for many decades. Early screening programs encouraged women to perform self-breast exams and also to have their clinician perform a breast exam in the office—subsequent data have shown that these screening techniques lead to false-positive exams, and no studies have shown an association of these exams with a reduction in mortality. Most guideline groups no

longer recommend breast self-exam or clinician breast exam for screening.

Breast cancer screening with mammography continues to be recommended by many groups, although the benefits are less than we had hoped and we are learning more about the harms. Mammography is an x-ray exam that takes views of each breast. The recommended age for the first mammogram and the frequency of screening vary among guidelines and countries. The US Preventive Services Task Force periodically reviews the evidence and issues guidelines to help aid discussions with women about screening.



Mammographic Views of Various Breast Densities **A**, Almost entirely fat. **B**, Scattered fibroglandular densities. **C**, Heterogeneously dense. **D**, Extremely dense. **E**, Mammogram showing invasive cancer. (From Fuller MS, Lee CI, Elmore JG. Breast cancer screening: an evidence-based update. *Med Clin North Am*. 2015;99[3]:451–468; images provided by Christoph I. Lee, MD, MSHS.)

The benefits, risks, and accuracy of mammography screening depend on numerous factors, including a woman's age and breast density (see Figure), and the time interval between screening exams. Possible risks of screening are important to consider because screening at a population level involves testing healthy individuals; we are to "first, do no harm," and screening can have potential harms.

No medical test is perfect. Approximately 10% of screening mammograms in the United States are interpreted as "abnormal,"

requiring additional testing. The great majority of women with these "abnormal" exams do not have breast cancer; this is called a *false-positive result*. The false-positive results lead to additional diagnostic testing, which can result in anxiety and morbidity for women. It is estimated that at least 50% of women in the United States who are screened annually for a decade will have experienced at least one false-positive examination.

Another harm of screening mammography is overdiagnosis—a *diagnosis* of cancer that would never have harmed the woman during her lifetime; such diagnoses can be either of a preinvasive lesion (e.g., ductal carcinoma in situ [DCIS]) or of invasive breast cancer. With more women undergoing screening with mammography, we have seen a sharp increase in the number of women *diagnosed* with DCIS and early-stage breast cancer. By definition, DCIS is not an invasive carcinoma and not an immediate life-threatening cancer—it is confined to the duct—but DCIS is often treated as if it is an invasive early-stage breast cancer. Even though women with DCIS are at increased risk of a subsequent, invasive breast cancer *diagnosis*, most women with DCIS are never subsequently diagnosed with invasive cancer and treatment of DCIS does not alter mortality. Some discussion has centered on changing the name of DCIS lesions to better differentiate preinvasive DCIS from invasive cancer because the term *carcinoma* is similar to the term *cancer*. However, it is not likely that the name will be changed because of its current common use.

Unfortunately, we are not able to identify which women with a new diagnosis of DCIS or invasive breast cancer have the type of lesion that is so low risk that it will never harm them during their lifetime. Thus most women undergo treatment, which can include either lumpectomy and radiation therapy or mastectomy. This is overtreatment if the DCIS or invasive cancer was overdiagnosed. Estimates of the prevalence of overdiagnosis vary in the literature from 10%–50%, with many groups suggesting that approximately 1 in 5 women with a new diagnosis of breast cancer are overdiagnosed; more research is clearly needed.

Women with abnormalities noted on screening mammography are often asked to return for additional diagnostic imaging and sometimes even a breast biopsy. Some women think that a breast biopsy will provide an immediate and definitive diagnosis; however, this is not always the case. Pathologists have been noted to disagree on the diagnoses of atypia and DCIS.

Balancing the benefits and harms of breast cancer screening is not an easy task for women or their clinicians. Every woman should be encouraged to make an informed decision.

Treatment of cysts consists largely of relieving symptoms. Reduction in the consumption of caffeinated beverages (e.g., cola,) and chocolate, which can cause overstimulation for some women, may reduce pain and nodularity. Given time, the cysts may disappear without treatment.

Women with AH are advised to stop oral contraceptives and avoid HRT.[204] Certain selective estrogen modulators, such as tamoxifen and raloxifene, or an aromatase inhibitor may be considered for

chemoprevention for women with AH after a thorough discussion of risks and benefits. A deficiency in iodine is hypothesized as contributing to the development of breast pathology and cancer. Therefore, although quite controversial, another preventive factor may be iodine.[210,211]

Breast Cancer

Except for skin cancer, breast cancer is the most common cancer in American females, regardless of race and ethnicity. In the United States, it is estimated that 284,200 females will be diagnosed with breast cancer, and 44,130 deaths will ensue in 2021.[1] Breast cancer is the most common cause of death from cancer among Hispanic females, and the second most common cause of death from cancer among White, Black, Asian/Pacific Islander, and American Indian/Alaska Native females.[212] The number of new cases worldwide of breast cancer in both sexes was estimated at 2.3 million and the number of deaths as 684,996 for all ages and both sexes.[213]

The causes of breast cancer have been difficult to define because each female has a different genetic profile, which is called **genetic heterogeneity**. Genetic heterogeneity is common among individuals but also at the level of the tumor itself, involving both genetic and epigenetic processes. **Phenotypic heterogeneity** is the result of tumor cell plasticity and, combined with genetic factors of the tumor, determines whether cells resist environmental stress, such as from the surrounding microenvironment (e.g., hypoxia, entering dormancy) and metastasizing.[214] The most important of the dominant genes are the breast cancer susceptibility genes *(BRCA1*, *BRCA2)* (see Pathophysiology section).

Risk

Although breast cancer is a multifactorial disease involving a complex web of interacting factors, risk is related to timing, duration, and pattern of exposures. Risk factors and possible causes of breast cancer can be divided into the following categories: age, gender,

personal and family history of breast cancer, histologic, genetic, and reproductive risk factors, exogenous hormone use, and environmental factors (Table 25.8).

Table 25.8

Factors That Increase the Relative Risk for Breast Cancer in Women

Relative Risk	Factor
>4.0	Age (65+ vs. <65 years, although risk increases across all ages until age 80) Atypical hyperplasia Lobular carcinoma in situ Pathogenic genetic variations (e.g., *BRCA1, BRCA2, PALB2, TP53*)
2.1–4.0	Ductal carcinoma in situ High endogenous hormone levels (postmenopausal) High-dose radiation to chest (e.g., Hodgkin lymphoma treatment) Mammographically dense breasts Two or more first-degree relatives with breast cancer
1.1–2.0	Alcohol consumption Early menarche (<11 years) Excess body weight

Relative Risk	Factor
	High endogenous estrogen or testosterone levels (premenopausal) Late age at first full-term pregnancy (>30 years) Late menopause (>55 years) Never breastfed a child No full-term pregnancies One first-degree relative with breast cancer Obesity (postmenopausal) Personal history of ovarian or endometrial cancer Physical inactivity Proliferative breast disease without atypia (usual ductal hyperplasia, fibroadenoma) Recent and long-term use of menopausal hormone therapy containing estrogen and progestin Recent hormonal contraceptive use Weight gain in adulthood Tall height

Relative Risk	Factor
>4.0	Age (65+ vs. <65 years, although risk increases
	across all ages until age 80)
	Atypical hyperplasia
	Lobular carcinoma in situ
	Pathogenic genetic variations (e.g., *BRCA1, BRCA2, PALB2, TP53*)
2.1–4.0	Ductal carcinoma in situ
	High endogenous hormone levels (postmenopausal)
	High-dose radiation to chest (e.g., Hodgkin lymphoma treatment)
	Mammographically dense breasts
	Two or more first-degree relatives with breast cancer
1.1–2.0	Alcohol consumption
	Early menarche (<11 years)
	Excess body weight
	High endogenous estrogen or testosterone levels (premenopausal)
	Late age at first full-term pregnancy (>30 years)
	Late menopause (>55 years)
	Never breastfed a child
	No full-term pregnancies
	One first-degree relative with breast cancer
	Obesity (postmenopausal)
	Personal history of ovarian or endometrial cancer
	Physical inactivity
	Proliferative breast disease without atypia (usual ductal hyperplasia, fibroadenoma)
	Recent and long-term use of menopausal hormone therapy containing estrogen and progestin
	Recent hormonal contraceptive use
	Weight gain in adulthood
	Tall height

Data from American Cancer Society (ACS). *Breast Cancer Facts &Figures 2019–2020*. Atlanta, GA: Author; 2020.

The Institute of Medicine reports that the two most strongly associated environmental factors are exposure to ionizing radiation and combined postmenopausal HT.[215] Ionizing radiation (e.g., x-rays, CT scans, and fluoroscopy) is a known mutagen and an established carcinogen for breast cancer. To date, only accidentally or medically induced radiation has been demonstrated to exert a carcinogenic effect on the breast.

The female reproductive hormones (estrogens, progesterone, and prolactin) have a major role and effect on mammary gland development and breast cancer (Fig. 25.26). Physiologic concentrations of estradiol increase the mitogenic activity of epithelial cells[216]; therefore increasing blood levels of estradiol increase the risk of breast cancer. Early menarche, late menopause, and short menstrual cycles all increase the risk, whereas menopause slows the *rate* of increase of breast cancer and oophorectomy reduces the risk. Environmental chemicals affect estrogen metabolism and contribute to breast cancer. **Xenoestrogens** are synthetic chemicals that mimic the actions of estrogens and are found in many pesticides, fuels, plastics, detergents, and drugs. The most significant chemicals may be polychlorinated biphenyls (PCBs), such as dichlorodiphenyltrichloroethane (DDT), pesticides (dieldrin, aldrin, heptachlor, and others), bisphenol A (pervasive in polycarbonate plastics), tobacco smoke (active and passive), dioxins (vehicle exhaust, incineration, contaminated food supply), alkylphenols (detergents and cleaning products), metals, phthalates (makes plastics flexible, some cosmetics), parabens (antimicrobials), food additives (recombinant bovine somatotropin [rBST] and zeranol to enhance growth in cattle and sheep), menopausal hormone treatment (MHT) (i.e., HRT), and others.

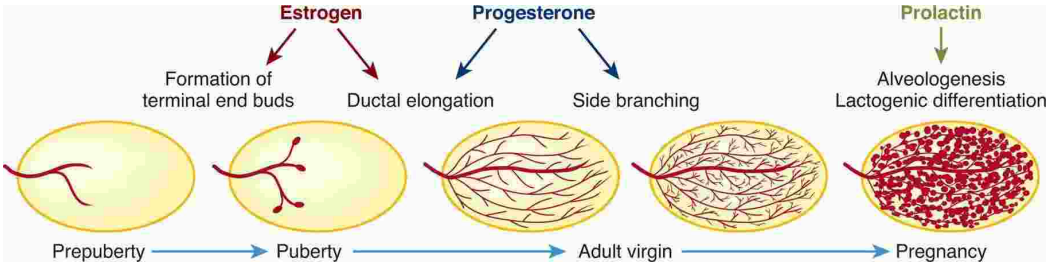

FIG. 25.26 Mammary Gland Development in the Mouse.
Schematic representation of distinct stages of postnatal mammary gland development. (From Brisken C, Hess, K, Jeitziner R. Progesterone and overlooked endocrine pathways in breast cancer pathogenesis. *Endocrinology*, 2015;156(10):3442–3450.)

An illustration depicts the various stages involved in the mammary gland development in the mouse showing the prepuberty, puberty, adult virgin, and pregnancy. Estrogen is involved in the formation of terminal end buds and ductal elongation. Progesterone affects the ductal elongation of side branching. Prolactin involves in amelogenesis and lactogenic differentiation.

Other risks associated with breast cancer include increased alcohol consumption, the use of insulin therapy, sulfonylurea medications, obesity, and weight gain after menopause.[217–220] Ethanol increases estrogen concentrations through several mechanisms: (1) increase in aromatase activity; (2) inhibition in estrogen breakdown; (3) decrease of melatonin secretion, which inhibits estrogen production; and (4) increase in hepatic oxidative stress that interferes with estrogen metabolism.[221] Excess adiposity is positively associated with breast cancer recurrence and breast cancer–specific mortality among both premenopausal and postmenopausal women. Excess adipose tissue

increases the risk from cellular pathways that involve hormonal regulation, cellular proliferation, and immunity. The increase in breast cancer risk with increasing BMI among postmenopausal females is most likely the result of increases in levels of estrogens by aromatase activity in adipose tissue. However, studies of hormones secreted by adipose tissue, *leptin* and *adiponectin*, may underlie the association between obesity and breast cancer risk. From molecular mechanism studies, leptin enhances breast cancer cell proliferation by inhibiting cell death (proapoptosis) signaling pathways and by increasing in vitro sensitivity to estrogens. A sedentary lifestyle may increase cancer risk through several mechanisms, including increased insulin resistance, increased inflammation, and decreased immune function. Epidemiologic studies demonstrate that physical activity lowered the risk of breast cancer in both premenopausal and postmenopausal women, and decreased the mortality in breast cancer survivors and improved their physiologic and immune functions.[222–224] Dietary factors also influence the risk of breast cancer.

Dietary factors also influence the risk of breast cancer. Dietary fiber may decrease the risk of breast cancer through modification of the estrogen concentration and stimulation of intestinal microflora. A recent meta-analysis revealed that every increment in dietary fiber of 10 g/day was associated with a significant reduction in breast cancer risk.[225,226]

Types

Most breast cancers are adenocarcinomas and first arise from the ductal/lobular epithelium as **carcinoma in situ (CIS)**, which is a proliferation of epithelial cells that is confined to the ducts and lobules by the basement membrane (BM). Tumors of the infiltrating (invasive) ductal type do not grow to a large size, but they metastasize early (Fig. 25.27). This type accounts for 70% of breast cancers. Table 25.9 summarizes some types of breast cancer.

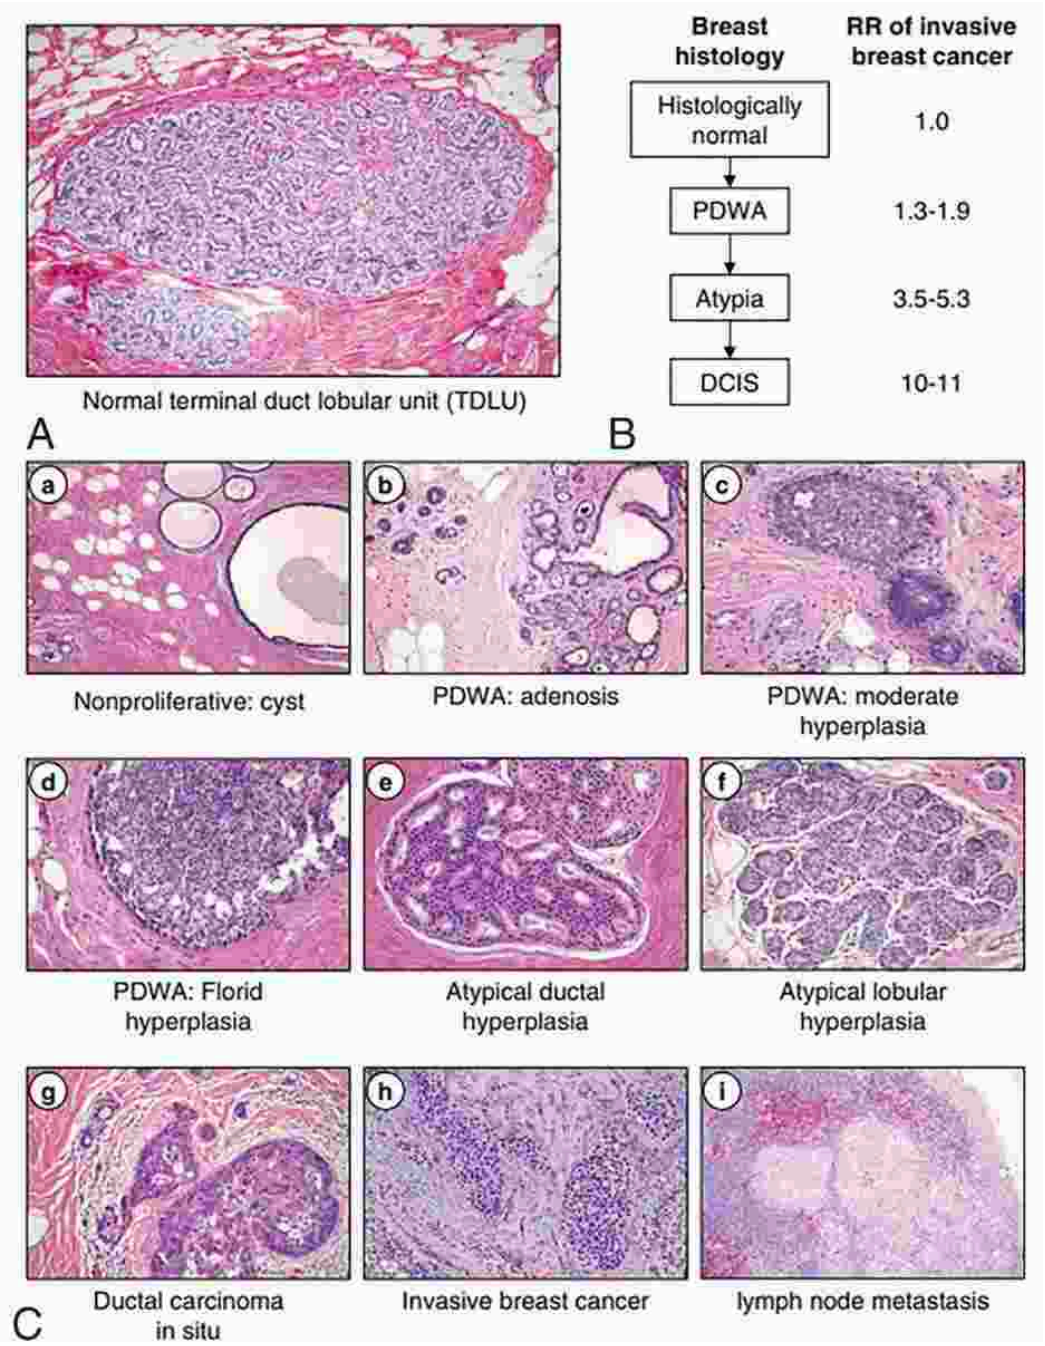

FIG. 25.27 Pathologic Characteristics Associated With Breast Cancer Progression. (A) Normal terminal duct lobular unit (TDLU), the anatomic structure where breast cancer originates, numerous acini surrounded by interlobular stroma. (B) Model of progression from normal epithelium through benign breast disease

to invasive breast cancer. Women with proliferative disease without atypia (PDWA) have an increased lifetime risk for cancer development relative risk (RR) of 1.3 to 1.9; women with atypical hyperplasia (atypia) have RR of 3.5 to 5.3; women with ductal carcinoma in situ (DCIS) have RR of 10 to 11. (C) Stages of progression from benign breast disease to invasive, metastatic breast cancer. *a*, Nonproliferative disease showing mammary cysts from TDLU. *b*, Proliferative disease without atypia (PDWA): adenosis, a proliferative lesion characterized by increased number or size of glandular structures. *c*, PDWA: moderate hyperplasia, with an increased number of epithelial cells in breast ducts and lobules with 5 or more cells above the basement membrane. *d*, PDWA: florid hyperplasia with hyperplastic cells, in solid clusters distending the lumens. *e*, Atypical ductal hyperplasia, epithelial hyperplasia and monotonous cytologic features suggesting expansion of a cell population. *f*, Atypical lobular hyperplasia with enlarged lobules some involvement with acini expanded with monotonous dyshesive epithelial cells. *g*, DCIS, a malignant proliferation of epithelial cells remaining within the basement membrane; some surrounding inflammatory infiltrate. *h*, Invasive breast cancer, malignant cells have invaded the surrounding stromal tissues. *i*, Lymph node metastasis. (From Cichon MA, Degnim AC, Visscher DW, Radisky DC. Microenvironmental influences that drive progression from benign breast disease to invasive breast cancer. *Journal of Mammary Gland Biology and Neoplasia*, 2010;15(4):389–397.)

A. A microscopic image of breast tissue represents the average terminal lobular unit. B. An illustration depicts the progression of breast cancer from normal epithelium accompanied by the relative risk of invasive breast cancer. Data is given in the format breast histology: RR of invasive breast cancer is as follows. Histologically normal: 1.0; P D W A: 1.3 to 1.9; Atypia: 3.5 to 5.3; D C I S: 10 to 11. C. Nine microscopic image of breast tissues, a through i, represents the various stages of progression of breast disease. Image a represents the nonproliferative cyst. Image b represents the P D W A: adenosis. Image c represents P D W A: moderate hyperplasia. Image d represents P D W A: Florid hyperplasia. Image e represents atypical ductal hyperplasia. Image f represents atypical lobular hyperplasia. Image g represents ductal carcinoma in situ. Image h represents invasive breast cancer. Image i represent lymph node metastasis.

Table 25.9

Types of Breast Carcinoma and Major Distinguishing Features

	Distinguishing Features
Carcinoma of the Mammary Ducts	
Papillary	Well-delineated cystic masses in multiple areas; hemorrhage often present; majority appear in 40- to 60-year age group; often involves skin
Intraductal (comedo)	Often accompanied by evidence of inflammation; well-circumscribed tumors within duct; well-differentiated tumor cells; rarely ulcerates skin
Infiltrating Carcinoma	
Ductal (no specific type [NST])	Fibrous, firm, glistening, gray-tan mass with chalky streaks, mixture of patterns; may cause discharge from nipple; represents about 70%–80% of all breast cancers
Mucinous	Usually large (>3 cm in diameter), circumscribed, and encapsulated, glistening appearance, varies in color; two types: pure and mixed; pure tumor is surrounded by mucin; infrequent; found in lateral half of breast; tends to occur in women after age 70
Medullary	Encapsulated and grows very large (7–8 cm in diameter); commonly surrounded by lymphocytic inflammatory infiltrate; occurs after age 50
Tubular	Well-differentiated with orderly tubules in center (stroma) of mass; can be associated with noninfiltrating ductal carcinoma; occurs in

Distinguishing Features	
	women about age 50; nodal metastasis infrequent; occurrence is rare
Adenoid cystic	Very rare; well-circumscribed, painless mass arising from nipple and areola
Metaplastic	Involves cartilage or bone, mixed tumors or osteogenic sarcomas
Squamous cell	Frequent in black people; originates in ductal epithelium
Carcinoma of the Mammary Lobules	
Lobular carcinoma in situ	Found in individuals with fibrocystic disease; localized to upper breast quadrants; 15%–35% risk of becoming invasive; occurs frequently in mid-40s; infiltrating variety occurs in early 50 s
Infiltrating lobular	Infiltrates from duct; firm mass with chalky streaks
Paget disease	Eczema of nipple that extends to areola; cancer usually found underneath nipple; poorly circumscribed; large Paget cells arise from duct and directly invade nipple; history of scaly, red rash spreading from nipple; lesion palpable beneath nipple, often bilateral; occurs in middle age
Inflammatory carcinoma	Not a histologic type; fairly diffuse within breast tissue, diffuse edema of overlying skin; extremely undifferentiated, very rare; most metastasize to axilla
Sarcoma of the Breast	

	Distinguishing Features
Cystosarcoma phyllodes	Usually large (>17 cm in diameter); mostly localized but can rupture through skin; rarely metastasizes to lymph nodes; history of painless nodule present for years before it forms a large mass; ulceration and bleeding of skin often present; occurs in wide age range (13–77 years)
Fibrosarcoma	Well-circumscribed, firm, and usually does not involve skin or nipple; well-differentiated to extremely undifferentiated; arises from connective tissue; extremely rare (e.g., liposarcoma, angiosarcoma)

	Distinguishing Features

Fibrosarcoma	Well-circumscribed, firm, and usually does not involve skin or nipple; well-differentiated to extremely undifferentiated; arises from connective tissue; extremely rare (e.g., liposarcoma, angiosarcoma)

Ductal and Lobular Carcinoma in Situ

Ductal carcinoma in situ (DCIS) is a heterogeneous group of proliferative lesions limited to breast ducts and lobules without invasion of the BM. When DCIS breaches the BM and invades adjacent stroma, microinvasion (MI) is said to be present. Approximately 84% of all in situ disease is DCIS; the remainder is mostly lobular carcinoma in situ. DCIS occurs predominantly in females but can occur in males. Because DCIS is almost exclusively detected by mammography, the large increase in the incidence of DCIS over the past 20 years can be attributed to screening.[227]

Approximately 49,290 cases of DCIS will be diagnosed in females in 2021.[1] Because DCIS looks like invasive cancer, the presumption was that these lesions were the precursors of cancer; therefore early removal and treatment would reduce cancer incidence and mortality.[228] However, long-term epidemiologic studies have demonstrated that the removal of 50,000 to 60,000 DCIS lesions annually has not been accompanied by a reduction in the incidence of invasive cancer; therefore low- to intermediate-grade DCIS does not need to be a target for screening or early detection.[229]

Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS) originates from the terminal duct lobular unit. Unlike DCIS, LCIS has a uniform appearance—the cells expand but do not distort involved spaces; thus the lobular structure is preserved. The cells grow in noncohesive clusters, usually because of a loss of the tumor-suppressive adhesion protein **E-cadherin**. LCIS is found as an incidental lesion from a biopsy and not from mammography because it is not associated with calcifications or stromal reactions that produce mammographic densities (MDs). LCIS has an incidence of approximately 1% to 6% of all carcinomas and does not increase with mammographic screening. With biopsies in both breasts, LCIS is bilateral in 20% to 40% of cases, compared with 10% to 20% of cases of DCIS.

The cells of AH, LCIS, and invasive lobular carcinoma are structurally identical. Loss of cellular adhesion because of dysfunction of E-cadherin results in a rounded shape without attachment to adjacent cells, increasing the risk of invasion. E-cadherin functions as a tumor-suppressor protein and may be lost in neoplastic proliferations from various mechanisms, including mutation. LCIS is a risk factor for invasive carcinoma, which develops in 25% to 35% of women over a period of 20 to 30 years. Unlike DCIS, the risk is almost as high in the contralateral breast as in the ipsilateral breast.

Pathophysiology

Breast cancer is a heterogeneous disease with diverse molecular, biologic, phenotypic, and pathologic changes. Tumor heterogeneity results from the genetic, epigenetic, and microenvironmental influences that occur as tumors progress. Most breast cancers develop due to DNA damage and genetic mutations. Inheritance factors of procancerous genes *BRCA1* and *BRCA2* play a role in the development of breast cancer. Up to 25% of hereditary cases are because of a mutation in one of the highly penetrant genes (*BRCA1, BRCA2, PTEN, TP53*, *CDHI*, and *STKII*), which confer up to an 80% lifetime risk of breast cancer.[230] An additional 2% to 3% of cases are because of a mutation in a rare, moderate penetrant gene (e.g., *CHEK2, BRIP 1*, *ATM*, and *PALB2*).[230]**BRCA1** (breast cancer 1 gene), located on chromosome 17, is a tumor-suppressor gene; therefore any mutation in the gene may inhibit or alter its suppressor function, leading to uncontrolled cell proliferation.[230]**BRCA2** (breast cancer 2 gene) is located on chromosome 13.[230]Males who develop breast cancer are more likely to have a *BRCA2* mutation than a *BRCA1* mutation (Chapter 26).

The immune system normally attacks cells with abnormal DNA or abnormal growth; however, this mechanism fails in those individuals with breast cancer, leading to tumor growth and metastatic spread. Cells communicate through paracrine or contact-dependent signaling from ligands, which is mediated from components of the microenvironment, such as blood vessels, immune cells, and fibroblasts (see Chapter 2). Cancer cells also communicate using the same system, and the cooperative behavior of these groups of cells can influence cancer progression. In advanced primary carcinomas, cancer cells recruit a variety of cell types into the surrounding stroma, including fibroblasts, myofibroblasts, granulocytes, macrophages, mesenchymal stem cells, and lymphocytes. Tissue involution involves massive epithelial cell death, recruitment and activation of fibroblasts, stromal remodeling, and immune cell infiltration, including macrophages with similarities to microenvironments present during wound healing and tumor progression.[231,232]

Once a founding tumor clone is established, genomic instability may assist through the establishment of other subclones and contribute both to tumor progression and to therapy resistance. Phenotypic plasticity is exemplified by a distinctive phenotype called **epithelial-mesenchymal transition (EMT)**. EMT is involved in the generation of tissues and organs during embryogenesis, is essential for driving tissue plasticity during development, and is an unintentional process during cancer progression. Activation of an EMT program during cancer development often requires signaling between cancer cells and neighboring stromal cells (Fig. 25.28). The EMT-associated reprogramming is involved in many cancer cell characteristics, including suppression of cell death or apoptosis and senescence, is reactivated during wound healing, and is resistant to chemotherapy and radiation therapy. Overall, interactions of cancer cells with adjacent tumor-associated stromal cells may induce malignant cell phenotypes (Fig. 25.29).

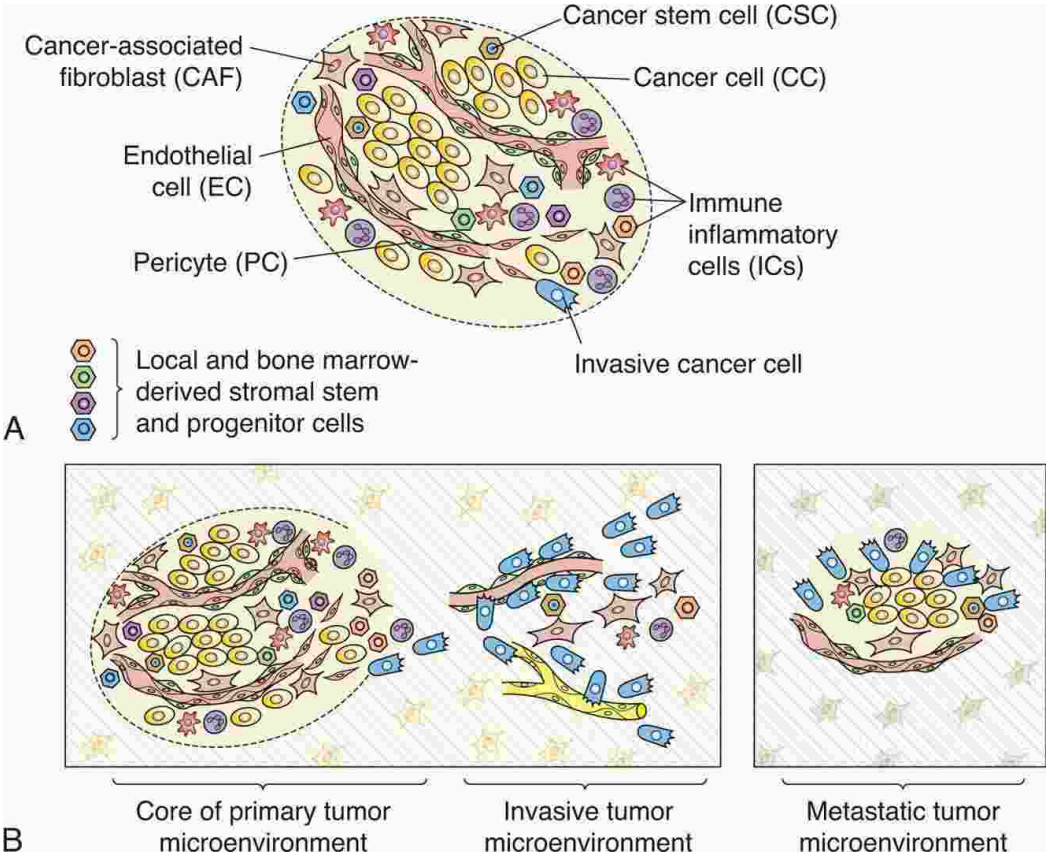

FIG. 25.28 Cells of the Tumor Microenvironment.

(A) Distinct cell types constitute most solid tumors, including breast tumors. Both the main cellular tissue, called *parenchyma*, and the surrounding tissue, or stroma, of tumors contain cell types that enable tumor growth and progression. For example, the immune-inflammatory cells present in tumors can include both tumor-promoting and tumor-killing subclasses of cells. (B) The microenvironment of tumors. Multiple stromal cell types create a succession of tumor microenvironments that change as tumors invade normal tissue, eventually seeding and colonizing distant tissues. The organization, numbers, and phenotypic characteristics of the stromal cell types and the

extracellular matrix *(hatched background)* evolve during progression and enable primary, invasive, and metastatic growth. (The premalignant stages are not shown.) (Data from Hanahan D, Weinberg R. Hallmarks of cancer: The next generation. *Cell*, 2011;144:646–674.)

A. An illustration depicts the tumorâ€™s microenvironment which shows an assemblage of distinct types of constitute most solid tumors from local and bone marrow-derived stromal stem, and progenitor cells with labels indicating the distant cell types as follows. Cancer-associated fibroblast or C A F, endothelial cell or E C, pericyte or P C, cancer stem cell or C S C, a cancer cell or C C, immune-inflammatory cells or I C S, and an invasive cancer cell. B. An illustration depicts the distinctive microenvironments of the core of primary tumor, invasive tumor, and metastatic tumor which shows multiple stromal cell types creating a succession of tumors, invading normal tissue, and thereafter seeding and colonizing distant tissues.

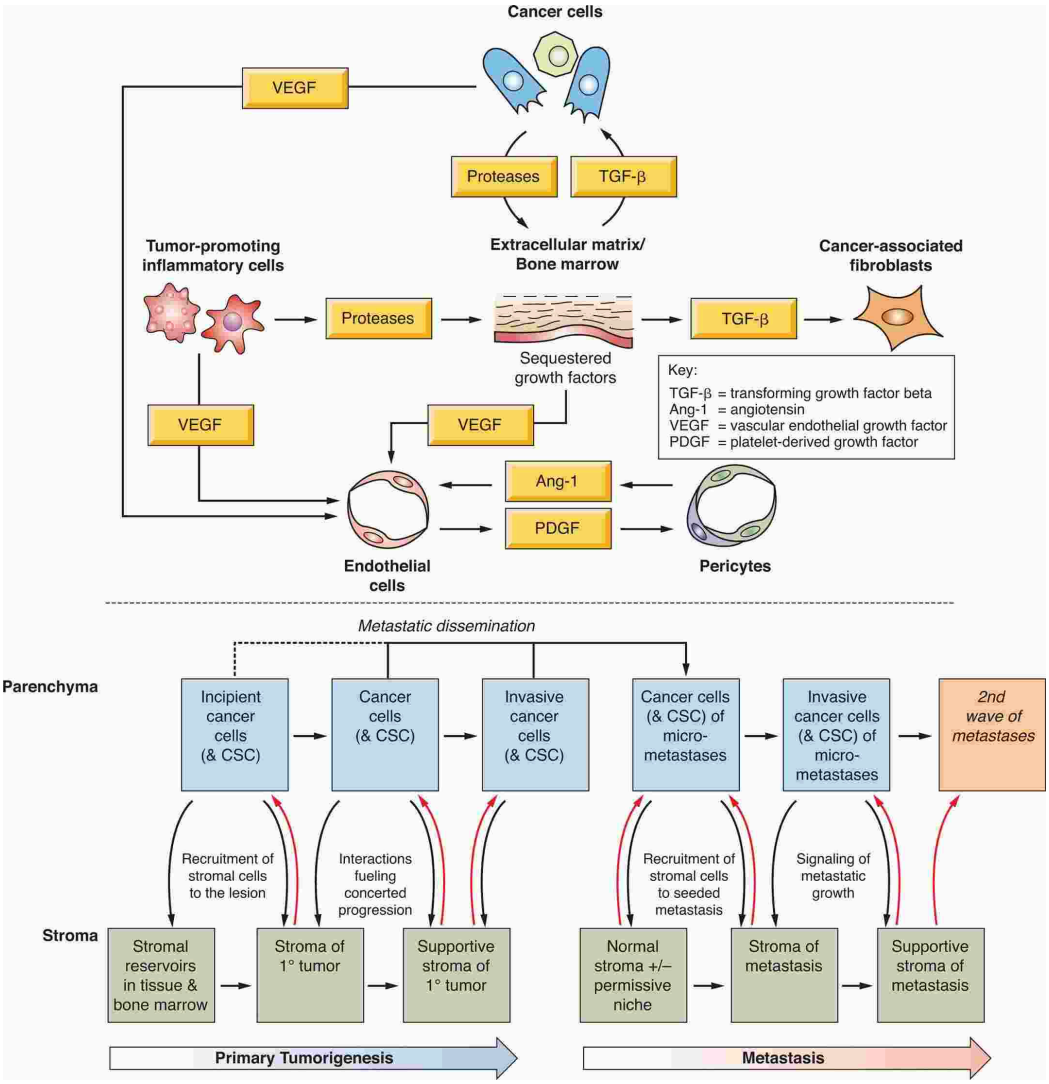

FIG. 25.29 Signaling Interactions in the Tumor Microenvironment During Malignant Progression.

Upper panel, Numerous cell types constitute the tumor microenvironment and are orchestrated and maintained by reciprocal interactions. *Lower panel*, The reciprocal interactions between the breast main tissue (parenchyma) and the surrounding stroma are important for cancer progression and growth. Certain organ sites of "fertile soil" or "metastasis niches" facilitate metastatic seeding and colonization. Cancer stem cells are involved in some or all stages of tumor

development and progression. (Adapted from Hanahan D, Weinberg R. Hallmarks of cancer: The next generation. *Cell*, 2011;144:646–674.)

The illustration in the upper panel depicts the growth factor involved in the interactions of the malignant tumor, which shows the cancer cells act on endothelial cells through vascular endothelial growth factor. Tumor-promoting inflammatory cells act on endothelial cells through vascular endothelial growth factor and proteases in the extracellular matrix or bone marrow which sequestered vascular endothelial growth factor lead to endothelial cell and transforming growth factor beta to cancer-associated fibroblasts. Endothelial cells and pericytes interact through angiotensin and platelet-derived growth factor. The illustration in the lower panel depicts the interaction between cancer cells of the parenchyma and stromal cells during primary tumorigenesis and metastasis. The metastatic dissemination in parenchyma interacts with the stroma causing primary tumorigenesis are given as follows. Incipient cancer cells and C S C interacts with stroma cell in the recruitment of stromal cells to the lesion causing stromal reservoirs in tissue and bone marrow leading to the stroma of the first tumor. Cancer cells and C S C interact with stroma cells in fueling concerted progression of the stroma of the first tumor to

supportive stroma of the first tumor. Invasive cancer cells and C S C interact with stroma cells in the first tumorâ€™s supporting stroma. Cancer cells and C S C of micrometastasis interact with stroma cells in the recruitment of stromal cells to seeded metastasis leading to normal stroma permissive niche to the stroma of metastasis. Invasive cancer cells and C S C of micrometastases interact with the signaling of metastatic growth, leading to the stroma of metastasis to the supportive stroma of metastasis which leads to the second wave of metastases.

Stromal fibroblasts adjacent to the breast tumor express aromatase, actively induce local estrogen production, and signal crosstalk between estrogen and growth factors, all of which affect the progression of breast carcinoma (Fig. 25.30).

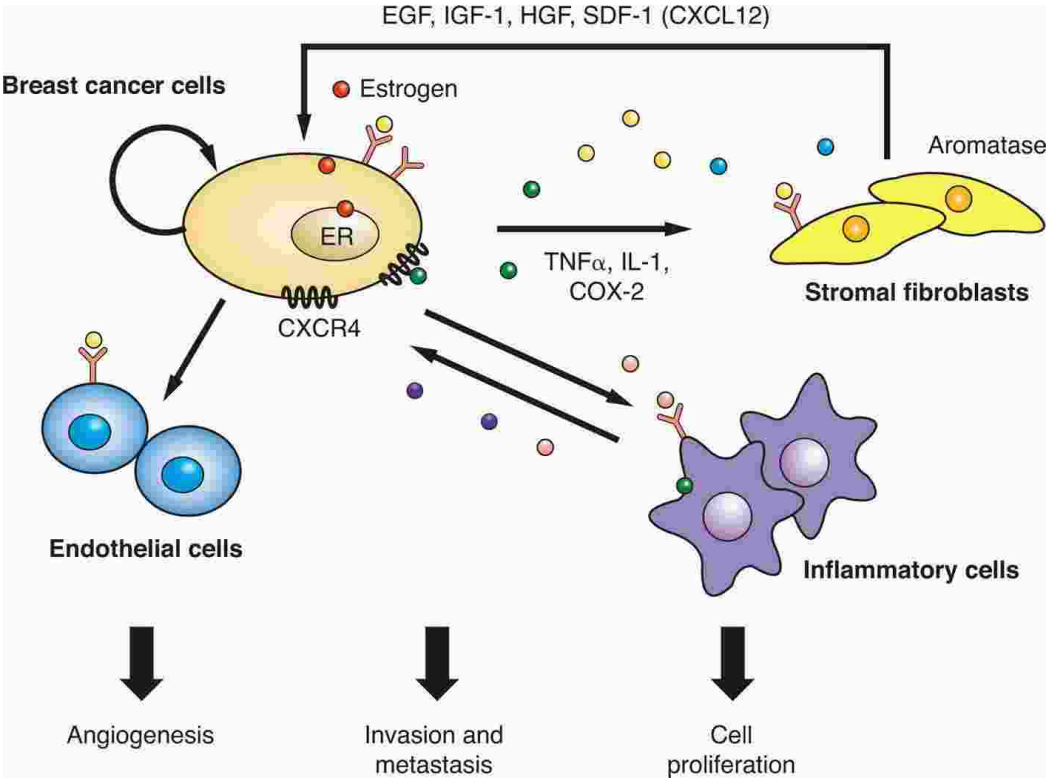

FIG. 25.30 Breast Cancer Cells and Stromal Fibroblasts Produce Estrogen.
In the microenvironment of breast carcinoma, breast cancer cells interact with different stromal cells through the secretion of growth factors and cytokines. Fibroblasts adjacent to cancer cells produce estrogen through the expression of the enzyme aromatase, which is induced by several factors including tumor necrosis factor-alpha *(TNF-α)*, interleukin-1 *(IL-1)*, and cyclooxygenase-2 *(COX-2)*. *EGF*, Epidermal growth factor; *ER*, estrogen receptor; *HGF*, hepatocyte growth factor; *IGF*, insulin-like growth factor; *SDF-1*, stromal-derived factor 1 also known as *CXCL12* or chemokine 12. These interactions lead to cancer cell proliferation, angiogenesis, and metastasis. (Adapted from Yamaguchi Y, Hayashi S. Estrogen-related cancer

microenvironment of breast carcinoma. *Endocrine Journal*, 2009;56(1):1–7.)

An illustration depicts the production of estrogen from breast cancer cell and stromal fibroblasts which shows breast cancer cells consisting E R and C X C R 4 interacts with aromatase of stromal fibroblasts including T N F alpha, I L-1, and C O X -2. Stromal fibroblasts produce estrogen including E G F, I G F-1, H G F, and S D F-1 (C X C L 12). Breast cancer cell interacts with endothelial cells and inflammatory cells causing angiogenesis, invasion and metastasis, and cell proliferation.

Remodeling or reprogramming of the breast during postpregnancy involution is important because it involves inflammatory and "wound healing–like" tissue reactions known as **reactive stroma** or **inflammatory stroma**. These tissue reactions increase the risk for tumor invasion and may facilitate the transition of CIS to invasive carcinoma. Overall, for breast cancer, the long-term protective effects of pregnancy affect remodeling of the stromal microenvironment by causing apoptosis and involution. In postlactational involution, the mammary gland regresses and remodels to its prepregnant state, whereby fibroblasts secrete proteases that degrade the ECM proteins. Consequently, the increased release of bioactive matrix fragments can promote tumor growth, motility, and invasion.[233]

Hormones, commonly estrogen, may act as accelerators, as well as initiators, delay involution, and influence the susceptibility of the breast epithelium to environmental carcinogens. Hormones control the differentiation of the mammary gland epithelium, thereby regulating the rate of stem cell division. A vast majority of breast

cancers are *initially* hormone dependent (estrogen positive [ER+] and/or progesterone positive [PR+]), with estrogens playing a crucial role in their development. Estrogens control processes critical for cellular functions by regulating activities and expression of key signaling molecules. These processes include regulation of receptor activity and receptor interaction with other intracellular proteins and DNA.

Endogenous estrogen may promote the progression of ER-negative breast cancer by stimulating cancer-associated fibroblasts to secrete factors from the microenvironment, which can recruit bone marrow–derived cells to the tumor microenvironment exerting tumor-promoting effects.[234] Estrogens can modulate immune function in the mammary gland. For example, estradiol can promote a proinflammatory phenotype in macrophages and estrogen can promote immunosuppression.

Progesterone also plays a complex role in breast physiology and carcinogenesis (Fig. 25.31).[216] In the breast, cell proliferation occurs during the luteal phase of the menstrual cycle and is accompanied by changes in the microenvironment.[235–237]

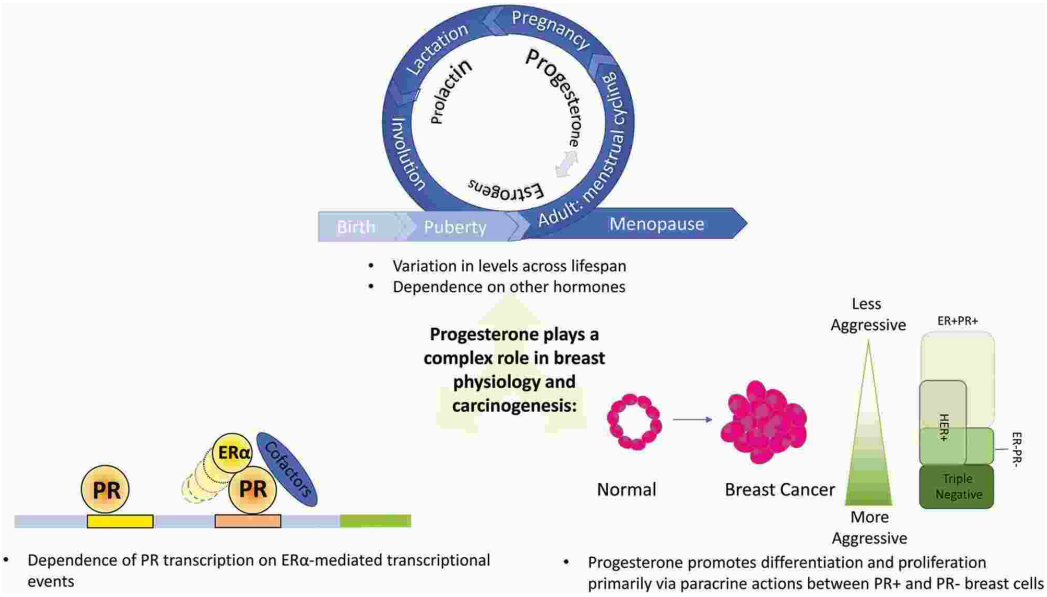

FIG. 25.31 A Graphical Presentation of Progesterone's Complex Role in Breast Physiology and Carcinogenesis. (From Trabert B, Sherman ME, Kannan N, Stanczyk FZ. Progesterone and breast cancer. *Endocrine Reviews*, 2020;41(2):320–344, https://doi.org/10.1210/endrev/bnz001.)

An abstract graphical shows three illustrations depicting progesterone plays a complex role in breast physiology and carcinogenesis. The illustration on the top represents the cyclic continuum which shows the variation of levels across lifespan and dependence on other hormones. Variations across the lifespan are labeled as birth, puberty, adult menstrual cycling, pregnancy, lactation involution, and menopause; dependence on other hormones includes estrogen, prolactin, and progesterone. The illustration on the left depicts the dependence of P R transcription on E R alpha-mediated transcriptional

events. The illustration on the left represents that progesterone promotes differentiation and proliferation primarily via paracrine actions between P R and P R breast cells.

Dormant cells appear to perpetuate carcinogenesis and form the precursors of eventual metastatic relapse and, sometimes, rapid recurrence. These dormant cells are called **minimal residual disease**. Cancer metastases require that primary tumor cells evolve the ability to intravasate into the lymphatic system or vasculature, and extravasate into and colonize secondary sites.

Clinical Manifestations

The majority of carcinomas of the breast occur in the upper outer quadrant, where most of the glandular tissue of the breast is located. The lymphatic spread of cancer to the opposite breast, to lymph nodes in the base of the neck, and to the abdominal cavity is caused by obstruction of the normal lymphatic pathways or destruction of lymphatic vessels by surgery or radiotherapy. The less common inner quadrant tumors may spread to mediastinal nodes or Rotter nodes, which are located between the pectoral muscles. Internal mammary chain nodes also are common sites of metastasis. Metastases from the vertebral veins can involve the vertebrae, pelvic bones, ribs, and skull. The lungs, kidneys, liver, adrenal glands, ovaries, and pituitary gland are also sites of metastasis.

The first sign of breast cancer is usually an irregularly shaped, firm, painless lump. Pain is rarely a sign of breast cancer. Other presenting signs include palpable nodes in the axilla, retraction of tissue (dimpling) (Fig. 25.32), or bone pain caused by metastasis to the vertebrae in rare cases. Table 25.10 summarizes the clinical manifestations of breast cancers. Manifestations vary according to the type of tumor and stage of disease.

FIG. 25.32 Retraction of Nipple Caused by Carcinoma. (From del Regato JA, Spjut HJ. *Ackerman and del Regato's cancer: Diagnosis, treatment, and prognosis*, 6th edition. St. Louis: Mosby; 1985.)

Table 25.10

Clinical Manifestations of Breast Cancer

Clinical Manifestation	Pathophysiology
Local pain	Local obstruction caused by tumor
Dimpling of skin	Can occur with invasion of dermal lymphatics because of retraction of Cooper ligament or involvement of pectoralis fascia
Nipple retraction	Shortening of mammary ducts
Skin retraction	Involvement of suspensory ligament
Edema	Local inflammation or lymphatic obstruction
Nipple/areolar eczema	Paget disease
Pitting of skin (similar to surface of an orange *[peau dorange]*)	Obstruction of subcutaneous lymphatics, resulting in accumulation of fluid
Reddened skin, local tenderness, and warmth	Inflammation
Dilated blood vessels	Obstruction of venous return by a fast-growing tumor; obstruction dilates superficial veins
Nipple discharge in a nonlactating woman	Spontaneous and intermittent discharge caused by tumor obstruction
Ulceration	Tumor necrosis
Hemorrhage	Erosion of blood vessels

Clinical Manifestation	Pathophysiology
Edema of arm	Obstruction of lymphatic drainage in axilla
Chest pain	Metastasis to lung

Evaluation and Treatment

Clinical breast examination, mammography, ultrasound, MRI, biopsy, hormone receptor assays, and gene expression profiling are used in evaluating breast alterations and cancer. Conventional x-ray mammography is one of the most valuable diagnostic tools for imaging of the breast and is the common preventive screening method for breast cancer. Currently, full-field digital mammography (FFDM) is frequently used. The USPSTF periodically reviews the evidence and issues guidelines to aid women about screening mammography (see Box 25.12).

Continuous technical development has led to several new imaging techniques, including digital breast tomosynthesis (DBT), phase contrast x-ray imaging, thermography,[238] and CT of the breast, as well as ultrasound and MRI. Despite technical innovations, except for ultrasound and MRI, these modalities require exposure of breast tissue to ionizing radiation.

Percutaneous breast biopsy is the preferred method of diagnosis because risks are minimal compared with surgical excisional biopsy. Most of the United States enacted laws mandating that mammography facilities report breast density, but inconsistent guidelines have caused confusion.[239] **Mammographic density (MD)** is the radiologic appearance of the breast, reflecting variations in breast composition (see Box 25.12). Mammographic breast density appears white or dense on a mammogram, is expressed as a percentage of the mammogram, and is a strong and consistent risk factor for breast cancer.[240–242]

A new hand-held breast-scanning device, called iBreastExam (iBE), can be used by community health workers to screen for breast

abnormalities. With the increasing incidence of breast cancer worldwide, especially for low-resource countries, such a device is critical. iBE technology is free of radiation and uses a piezoelectric sensor array, which can measure tissue compression and stiffness by top-down touching of the skin surface. The device can enhance clinical breast examination sensitivity by 19% while maintaining high specificity (94%) and a negative predictive value of 98%. This is a promising tool for early detection of relevant lesions, and it is useful in younger females with dense breasts.[243–245] iBE received FDA approval as an aid in documenting palpable breast lesions from a clinical breast exam; it is to be used by qualified health care professionals and is not intended for home use. It currently is being used in low-resource countries.

Treatment is based on the extent or stage of the cancer. The extent of the tumor at the primary site, the presence and extent of lymph node metastases, and the presence of distant metastases are all evaluated to determine the stage of disease. Treatment can include surgery with or without radiotherapy to achieve local control of cancer. The benefit of surgery for treatment is that it eliminates cancer bulk and the diversity of cancer cells, including therapy-resistant cells.[246] Systemic therapy in the form of chemotherapy, hormonal therapy, targeted therapy, or combination therapy is indicated when there is a risk for metastatic relapse. Minimal residual disease may remain after initial chemotherapy, radiotherapy, and surgery. Current treatments preferentially kill proliferating cells, but dormant cells are not proliferating, which renders them more resistant to almost all current treatments.[246] Evidence from the US Agency for Healthcare Research and Quality (AHRQ) shows that estrogen combined with progestogen has both beneficial effects (fewer osteoporotic fractures) and harmful effects (increased risk of breast cancer, gallbladder disease, venous thromboembolic events, and stroke). The AHRQ published a systematic review from 283 trials comparing the effectiveness of treatments for menopausal symptoms.[247]

Options for those who have a positive test for the *BRCA1* or *BRCA2* mutation include surveillance to detect cancers early, prophylactic surgery (i.e., bilateral mastectomy and bilateral salpingo-oophorectomy), risk factor avoidance, and promotion of breast-feeding. There is emerging science that suggests vitamin D may play a pivotal role in cancer prevention in addition to its role in bone metabolism (see Emerging Science Box: Vitamin D and Breast Cancer.)

Emerging Science Box

Vitamin D and Breast Cancer

Epidemiologic studies have identified that vitamin D may play a role in cancer prevention in addition to its role in bone metabolism. Vitamin D as a prohormone is metabolized in the liver and kidney, which produces calcitriol. Calcitriol then binds to the vitamin D receptor and regulates the expression of varied genes. Hormonally active calcitriol exerts antiproliferative, proapoptotic, and antiinflammatory effects. These properties have demonstrated anticancer effects in breast cancer cells. A study by Krishnan and colleagues found that dietary vitamin D_3 exhibits substantial tumor inhibitory effects in animal tissue of breast cancer equal to those of calcitriol. In a secondary analysis of the VITamin D and OmegA-3 TriaL (VITAL) randomized clinical trial, findings suggested dietary vitamin D_3 might reduce the risk of advanced cancer in individuals with normal body mass index. A study measuring the metabolite serum 25-hydroxyvitamin D also found that low levels were associated with poor prognosis in women with breast cancer. Studies continue to further evaluate appropriate vitamin D levels, recommended supplements, and further potential protective effects of vitamin D and cancers.

Data from Chandler PD, et al. Effect of vitamin D3 supplements on development of advanced cancer: A secondary analysis of the VITAL Randomized Clinical Trial. *JAMA Network Open*, 2020;3(11):e2025850, Erratum in *JAMA Network Open*, 2020;3(12):e2032460; Jeon SM, et al.

Exploring vitamin D metabolism and function in cancer. *Experimental and Molecular Medicine*, 2018;50(4):20; Krishnan AV, et al. Equivalent anticancer activities of dietary vitamin D and calcitriol in an animal model of breast cancer: Importance of mammary CYP27B1 for treatment and prevention. *Journal of Steroid Biochemistry and Molecular Biology*, 2013;136:289–295; and Yao S, et al. Association of serum level of vitamin D at diagnosis with breast cancer survival: A case-cohort analysis in the pathways study. *JAMA Oncology*, 2017;3(3):351–357.

DCIS should be considered a "risk factor" for invasive cancer and should prompt targeting for preventive strategies. Radiation therapy should not be routinely offered after lumpectomy for DCIS lesions that are not high-risk, because the absolute risk reduction in mortality was minimal (relative risk reduction in mortality of 23%).[248] Treatments for LCIS include close clinical follow-up and mammographic screening, tamoxifen, and bilateral prophylactic mastectomy.

The prognosis of stage 0 and stage I breast cancer has a 100% 5-year survival rate. Stage II and stage III has a 5-year survival rate of approximately 93% and 72%, respectively. However, as breast cancer spreads and metastasizes, the prognosis worsens. The 5-year survival rate is 22% for stage IV breast cancer.

Summary Review

Abnormalities of the Female Reproductive Tract

1. Abnormalities of the female reproductive tract have multifactorial causes, including genetics and environmental factors. Common abnormalities include uterine agenesis or structural malformations of the vagina, uterus, and fallopian tubes.

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, is marked by the development of secondary sex characteristics, rapid growth and ultimately, the ability to reproduce. The normal range for the onset of puberty is now 8 to 13 years of age and can vary geographically and ethnically.
2. Delayed puberty is the onset of sexual maturation after these ages.
3. Precocious puberty is the onset before these ages.
4. Treatment depends on the etiology of the alteration in sexual maturation.

Disorders of the Female Reproductive System

1. The female reproductive system can be altered by hormonal imbalances, infectious microorganisms, inflammation, structural abnormalities, and benign or malignant proliferative conditions.
2. Primary dysmenorrhea is painful menstruation not associated with pelvic disease. It results from excessive synthesis of $PGF_2\alpha$. It often results from excessive synthesis of prostaglandins, which cause the myometrium to contract and constrict blood vessels, resulting in ischemic pain.
3. Secondary dysmenorrhea results from endometriosis, pelvic adhesions, inflammatory disease, uterine fibroids, or adenomyosis.
4. Primary amenorrhea is the continued absence of menarche and menstrual function by 13 years of age without the development of secondary sex characteristics or by 15 years of age if these changes have occurred.
5. Secondary amenorrhea is the absence of menstruation for a time equivalent to three or more cycles in women who have previously menstruated. Secondary amenorrhea is associated with many disorders and physiologic conditions.
6. Abnormal uterine bleeding (AUB) is heavy or irregular bleeding in the absence of organic disease.

7. Polycystic ovary syndrome (PCOS) is a condition in which excessive androgen production is triggered by inappropriate secretion of gonadotropins. This hormonal imbalance prevents ovulation and causes enlargement and cyst formation in the ovaries, excessive endometrial proliferation, and often hirsutism. Insulin resistance and hyperinsulinemia play a key role in androgen excess.
8. Premenstrual syndrome (PMS) is the cyclic recurrence of physical, psychological, or behavioral changes distressing enough to disrupt normal activities or interpersonal relationships. Emotional symptoms, particularly depression, anger, irritability, and fatigue, are reported as the most distressing symptoms; physical symptoms tend to be less problematic.
9. Premenstrual dysmorphic disorder (PMDD) is a severe form of PMS.
10. Infection and inflammation of the female genitalia can result from microorganisms that are present in the environment and often are sexually transmitted or from overproliferation of microorganisms that normally populate the genital tract.
11. Pelvic inflammatory disease (PID) is an acute inflammatory process caused by infection. Many infections are sexually transmitted, and microorganisms that comprise the vaginal flora are implicated. PID is a substantial health risk to women, and untreated PID can lead to infertility.
12. Vaginitis is irritation or inflammation of the vagina, typically caused by infection. It is usually caused by sexually transmitted pathogens or *Candida albicans*, which causes candidiasis.
13. Bacterial vaginosis (BV) is the most common microbiologic syndrome reported among women of childbearing age. It is characterized by a shift in the vaginal flora from the dominant *Lactobacillus* to a polymicrobial flora. It is correlated with a wide array of health issues, including preterm births, PID, and increased susceptibility to HIV infection. No one microorganism can identify all cases of BV.

14. Cervicitis, which is infection of the cervix, can be acute (mucopurulent cervicitis) or chronic. Its most common cause is a sexually transmitted pathogen.
15. Vulvovestibulitis (VV) is an inflammation of the skin of the vulva. It can be caused by chemical and mechanical irritants, allergens, skin disorders, nerve problems, or vaginal infection, such as candidiasis.
16. Bartholinitis, also called *Bartholin cyst*, is an infection of the ducts that lead from the Bartholin glands to the surface of the vulva. Infection blocks the glands, preventing the outflow of glandular secretions.
17. Pelvic organ prolapse—uterine prolapse, cystocele, rectocele, and urethrocele—is caused by the relaxation of muscles and fascial supports, usually as a result of advancing age or after childbirth or other trauma. They are more likely to occur in women with a familial or genetic predisposition.
18. Benign growths and proliferative conditions of the female reproductive tract tend to affect the ovaries or uterine tissues (endometrial polyps, leiomyomas, and endometriosis).
19. Benign ovarian cysts develop from mature ovarian follicles that do not release their ova (follicular cysts) or from a corpus luteum that persists abnormally instead of degenerating (corpus luteum cyst). Cysts usually regress spontaneously.
20. Endometrial polyps consist of benign overgrowths of endometrial tissue and often cause abnormal bleeding.
21. Leiomyomas, also called *myomas* or *uterine fibroids*, are benign tumors arising from the smooth muscle layer of the uterus, the myometrium. Prevalence increases in women between ages 30 and 50; most myomas remain small and asymptomatic.
22. Adenomyosis is the presence of endometrial glands and stroma within the uterine myometrium.
23. Endometriosis is the presence of functional endometrial tissue (i.e., tissue that responds to hormonal stimulation) at sites outside the uterus. Endometriosis causes an

inflammatory reaction at the site of implantation and is a cause of infertility.

24. Most cancers of the female genitalia involve the uterus (particularly the cervix), cervix, and ovaries. Cancer of the vagina is rare.
25. Cervical cancer arises from the cervical epithelium and is triggered by HPV. The cellular transformational zone is called the *squamocolumnar junction*. The progressively serious neoplastic alterations are CIN (cervical intraepithelial neoplasia, also known as cervical dysplasia), cervical CIS (carcinoma in situ), and invasive cervical carcinoma. Cocarcinogens include immune responses, hormonal responses, and other environmental factors that determine regression or persistence of the HPV infection.
26. The HPV vaccination can substantially reduce the risk of cervical cancer as well as oropharyngeal and anal cancers. It is approved for girls and boys aged 11 through 26.
27. Primary cancer of the vagina is rare. Risk factors include age 60 or older, exposure to DES, infection with HPV-16, infection with HIV, and genital warts. The relationship of developing precancerous cell changes (called vaginal intraepithelial neoplasia) is controversial.
28. Risk factors for vulvar cancer include infection with HPV infection or squamous dysplasia of the vagina or cervix. Symptoms include chronic vulvar irritation, pruritus, bloody discharge, and a hard-ulcerated area of the vulva or cauliflower-like lesion. Peak incidence is in postmenopausal women, but younger women can be affected.
29. Endometrial cancer is the most common cancer of the pelvic region. Primary risk factors for endometrial cancer include exposure to unopposed estrogen (e.g., estrogen-only hormone replacement therapy, tamoxifen, early menarche, late menopause, nulliparity, failure to ovulate), chronic hyperinsulinemia, hyperglycemia, body fatness and adult weight gain, chronic inflammation, lack of physical exercise.

30. Risk factors for ovarian cancer include increased number of total lifetime ovulations (early menarche, late menopause), advancing age, genetic factors, family history, overweight and obesity, height, reproductive/hormonal factors, HRT, endometriosis, diabetes, previous cancer, smoking, asbestos, use of talc-based powder, and ionizing radiation.
31. BRCA1, BRCA2, and HNPCC gene abnormalities are linked with ovarian cancer. Ovarian cancer causes more deaths than any other genital cancer in women due to its presentation in advanced disease. New methods are being explored for routine screening.

Sexual Dysfunction

1. Sexual dysfunction is the lack of satisfaction with sexual function as a result of pain or a deficiency in sexual desire, arousal, or orgasm/climax.
2. Sexual function and dysfunction result from a complex set of personal and biologic factors that interact with the culture. Both organic and psychosocial disorders can be implicated in sexual dysfunction.

Impaired Fertility

1. Infertility, or the inability to conceive after 1 year of unprotected intercourse, affects approximately 15% of all couples. Fertility can be impaired by factors in the male, female, or both partners.
2. Female infertility decreases with age, and older women may opt for intervention sooner than younger women. It results from dysfunction of the normal reproductive process: menses and ovulation, fallopian tube function (transport of the egg to the uterus, and the tube as a site of fertilization), ovarian dysfunction, and implantation of the fertilized egg into a receptive endometrium.

3. Treatment depends on the cause of the infertility—ovulation disorders and tubal blockages are the most common pathologies.

Disorders of the Female Breast

1. Most disorders of the breast are disorders of the mammary gland (i.e., the female breast).
2. Galactorrhea, or inappropriate lactation, is the persistent secretion of a milky substance by the breasts of a woman who is not in the postpartum state or nursing an infant. Its most common cause is nonpuerperal hyperprolactinemia—a rise in serum prolactin levels.
3. Benign breast conditions are numerous and involve both ducts and lobules. Benign epithelial lesions can be broadly classified according to their future risk of developing breast cancer as (1) nonproliferative breast lesions, (2) proliferative breast disease, and (3) atypical (atypia) hyperplasia.
4. Nonproliferative lesions include simple breast cysts, papillary apocrine change, and mild hyperplasia of the usual type.
5. Proliferative breast lesions without atypia are diverse and include usual ductal hyperplasia, intraductal papillomas, sclerosing adenosis, radial scar, and simple fibroadenoma.
6. Proliferative breast lesions with atypia include ADH and ALH.
7. DCIS refers to a heterogeneous group of proliferations limited to breast ducts and lobules without invasion of the basement membrane. LCIS originates from the duct lobular unit.
8. Breast cancer is the most common form of cancer in women and second to lung cancer as the most common cause of cancer death. However, the inclusion of DCIS with invasive breast cancer statistics is controversial. Breast cancer is a heterogeneous disease with diverse molecular, phenotypic, and pathologic changes.
9. The major risk factors for breast cancer are reproductive factors, such as nulliparity; hormonal factors and growth

factors (e.g., excessive estradiol and insulin-like growth factor [IGF]-1), familial factors (e.g., a family history of breast cancer), and environmental factors (e.g., ionizing radiation). Two factors that have emerged as important are delayed involution of the mammary gland and breast density. Physical activity and avoiding postmenopausal weight gain may be risk-reducing factors.

10. A dominating belief in the field of cancer research is that epithelial function depends on the *entire* tissue, including the stroma or microenvironment. Breast cancer is now known as a tissue-based disease with a possible abnormal, aberrant wound healing and inflammatory stromal (reactive stroma) component.
11. Models of breast carcinogenesis include three interrelated themes: gene addiction, phenotype plasticity, and cancer stem cells. The exact molecular events leading to breast cancer invasion are complex and not completely understood. These events involve genetic and epigenetic alterations and cancer cell and stromal interactions. New concepts for breast cancer metastases include tumor dormancy and vascular mimicry.
12. Most breast cancers arise from the ductal epithelium and then may metastasize to the lymphatics, opposite breast, abdominal cavity, lungs, bones, kidneys, liver, adrenal glands, ovaries, and pituitary glands.
13. The first clinical manifestation of breast cancer is usually a small, painless lump in the breast. Other manifestations include palpable lymph nodes in the axilla, dimpling of the skin, nipple and skin retraction, nipple discharge, ulcerations, reddened skin, and bone pain associated with bony metastases.

Chapter Outline

OUTLINE

Alterations of Sexual Maturation 823
- Puberty: Premature, Delayed, and Contrasexual Development 823

Disorders of the Male Reproductive System 825
- Disorders of the Urethra 825
- Disorders of the Penis 826
- Disorders of the Scrotum, Testis, and Epididymis 834
- Disorders of the Prostate Gland 843
- Sexual Dysfunction: Erectile Dysfunction 853

Disorders of the Male Breast 855
- Gynecomastia 855
- Male Breast Cancer 855

Alterations of the male reproductive system span a wide range of concerns, from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common male reproductive disorders carry potentially serious physiologic and psychological consequences.

Alterations of Sexual Maturation

The process of sexual maturation, or puberty, is marked by the development of secondary sex characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty. Puberty that occurs too late (delayed puberty) or too early (precocious puberty) is

caused by the inappropriate onset of sex hormone production. While the average age of pubertal onset appears to be decreasing for girls, the age of pubertal onset (9 to 14 years) has remained essentially unchanged for boys.[1] Generally, boys tend to mature later than girls, around 14 years of age. In males, the first sign of maturity is enlargement of the testes and thinning of the scrotal skin.

Puberty: Premature, Delayed, and Contrasexual Development

Premature puberty or **precocious puberty** is early development of secondary sexual characteristics and is defined as pubertal development of secondary sexual characteristics before age 9 in males and before age 8 in females**. Delayed puberty** is based on the absence of breast development by age 13 or absence of menarche by age 16 for females and lack of testicular enlargement by age 14 for males.[2–4]**Contrasexual development** occurs when male or female children develop features of the opposite gender (e.g., feminization in boys mainly gynecomastia; virilization in girls).[5] Although contrasexual development is less common in boys, it is typically related to estrogen secreting tumors.[6] About 3% of children living in North America experience delayed development of secondary sex characteristics.[7]

Precocious puberty for either gender is caused by premature **adrenarche** (an increase in the production of androgens by the adrenal cortex that usually occurs during the eighth or ninth year of life), central nervous system and pituitary lesions, constitutional and idiopathic precocious puberty, McCune–Albright syndrome, or exogenous sex hormones (also see Chapter 25). Causes unique to males include gonadotropin secreting tumors, benign gynecomastia of adolescence, and familial gynecomastia. Table 26.1 presents the causes and pathophysiology of precocious puberty. Excess adiposity during childhood influences growth patterns and pubertal development. Obesity increases the risk of developing early puberty in children (see Chapter 23).[8–10]

Table 26.1

Causes and Pathophysiology of Precocious Puberty

Causes of Precocious Puberty Shared by both genders	Premature adrenarche	Premature presence of pubic or axillary hair, possible sebaceous gland activity (before 6 years old). Plasma DHEAS is usually elevated to pubertal levels. FSH, LH, estradiol, testosterone are typical in children before puberty. GnRH shows prepubertal levels and ACTH test may exclude congenital adrenal hyperplasia.
	CNS and pituitary lesions typically present with normal stages of puberty but occurs prematurely.	Children may have bone age greater than chronological age. Visual defects may present. MRI may be necessary.
	Constitutional/idiopathic precocious puberty more often in girls than boys. It is	Child responds to GnRH test with pubertal levels of sex hormones,

	considered idiopathic if no family links or no discovered causes.	including FSH and LH. Bone age higher than chronological age. Other causes must be ruled out such as CNS pathology and elevated levels of adrenal hormones.
	McCune-Albright syndrome	Associated with café-au-lait spots, polyostotic fibrous dysplasia and precocious puberty.
	Exogenous sex hormones (oral contraceptives, anabolic hormones.	Metabolites are found in the urine (urinalysis can rule out). Children will lack pubic hair. Boys will have small testicles, girls darkened areolae.
Causes of Precocious Puberty unique to males	Gonadotropin secreting tumors	Secrete hCG-Iike components similar function in signaling to LH, results in premature puberty in boys. Girls have the benefit of FSH in the ovaries so

		no premature development. Tumors that produce hCG include hepatomas, teratomas, and germinomas of the pineal gland. Benign gynecomastia of adolescence in mid to late puberty is common. The breast is tender and usually resolves on its own. Familial gynecomastia appears during puberty and has a genetic link, either x-Iinked recessive or sex-Iinked dominant.

From Breehl L, Caban O. *Physiology, puberty*. StatPearls Treasure Island, FL: StatPearls Publishing; 2021.

In about 95% of cases, a **constitutional delay of puberty and growth (CDPG)** is a normal physiologic event. Hormonal levels are normal, the hypothalamic-pituitary-gonadal axis is intact, and maturation is slowly occurring. Males with CDPG are generally healthy, but may appear short for age.[1] At birth, they are average

size; however, the rate of growth slows down around 3 to 6 months of age and at 3 or 4 years of age, they will be growing below but parallel to the third percentile line.[1] As their male peers experience puberty and a growth spurt, affected males will continue to have a lower growth velocity (2 to 4 cm/year) and pubertal delay (Table 26.2). Their growth spurt occurs at a later age, generally between 15 to 17 years of age.[11] Sometimes, it is often difficult to differentiate between CDPG and hypogonadotropic hypogonadism.[1] Treatment is seldom needed unless the delayed puberty is causing psychosocial problems (e g., low self-esteem or poor academic performance).[1,12] The other 5% of cases are caused by the disruption of the hypothalamic-pituitary-gonadal axis or by the outcomes of a systemic disease (Box 26.1). The reproductive system, hypothalamus, pituitary gland, adrenal glands, ovaries, and testes are all involved in the changes of puberty. Human gonadal function is partially controlled by luteinizing hormone (LH) and follicle-stimulating hormone (FSH), the release of which is regulated by the pulsatile secretion of hypothalamic gonadotropin-releasing hormone (GnRH).[13] The zona reticularis of the adrenal cortex produces the hormones responsible for adrenarche and function separately from the hypothalamic-pituitary-gonadal axis.[5] With the onset of puberty adrenal androgens can lead to the development of acne, axillary hair, body odor, and pubic hair.

Table 26.2

Tanner Staging for Puberty Assessment for Males

Tanner Stage	Genitalia	Pubic Hair	Growth	Other
1	Testes <2.5 cm	Villus hair only	2.0–2.4 inches per year	Adrenarche
2	Testes 2.5–3.2 cm Thinning and reddening of the saotum	Sparse hair at penis base	2.0–2.4 inches per year	Decreases in body fat
3	Testes 3.3–4.0 cmIncrease of penis length	Thicker curly hair spreads to the pubis	2.8–3.2 inches per year	Gynecomastia, voice break, increased muscle mass
4	Testes 4.1–4.5 cm, penis growth darkening: of scrotum	Adult hair does not spread to thighs	4.0 inches per year	Axillary hair, voice change, acne
5	Testes >4.5 cm, adult genitalia	Adult hair spreads to medial thigh	Deceleration, cessation	Facial hair, muscle mass increases

Tanner Stage	Genitalia	Pubic Hair	Growth	Other
1	Testes <2.5 cm	Villus hair only	2.0–2.4 inches per year	Adrenarche
2	Testes 2.5–3.2 cm Thinning and reddening of the saotum	Sparse hair at penis base	2.0–2.4 inches per year	Decreases in body fat
3	Testes 3.3–4.0 cmIncrease of penis length	Thicker curly hair spreads to the pubis	2.8–3.2 inches per year	Gynecomastia, voice break, increased muscle mass
4	Testes 4.1–4.5 cm, penis growth darkening: of scrotum	Adult hair does not spread to thighs	4.0 inches per year	Axillary hair, voice change, acne

Box 26.1

Causes of Delayed Puberty

Hypergonadotropic Hypogonadism: Low Testosterone, Increased Follicle-Stimulating Hormone and Luteinizing Hormone

1. Gonadal dysgenesis, most commonly Turner syndrome (45, X/46, XX; structural X or Y abnormalities, or mosaicism)
2. Klinefelter syndrome (47, XXY)
3. Bilateral gonadal failure
    a. Traumatic or infectious
    b. Postsurgical, postirradiation, or postchemotherapy
    c. Autoimmune
    d. Idiopathic empty scrotum or vanishing testes syndrome (congenital anorchia)

Hypogonadotropic Hypogonadism: Low Testosterone, Decreased Luteinizing Hormone, Depressed Follicle-Stimulating Hormone

1. Reversible
    a. Physiologic delay

b. Weight loss/anorexia
c. Strenuous exercise
d. Severe obesity
e. Illegal drug use; also use of marijuana in particular
f. Primary hypothyroidism
g. Congenital adrenal hyperplasia
h. Cushing syndrome
i. Prolactinomas

2. Irreversible
    a. Gonadotropin-releasing hormone (GnRH) deficiency (Kallmann syndrome) or idiopathic hypogonadotropic hypogonadism (IHH)
    b. Hypopituitarism
    c. Congenital central nervous system defects
    d. Other pituitary adenomas
    e. Craniopharyngioma
    f. Malignant pituitary tumors

Systemic Disease

1. Delayed puberty can occur in several illnesses
    a. Cystic fibrosis
    b. Sickle cell disease
    c. Celiac disease
    d. Diabetes mellitus
    e. Poor nutrition and long-term use of glucocorticoids

A thorough evaluation should be conducted that includes physical examination and medical and family history. The history should specifically target known contributors to delayed puberty.[13] Measurement of hormone levels may include testosterone, estradiol, FSH, and LH. A GnHR stimulation test is done to determine a central or peripheral cause. Treatment depends on the cause. The goal of treatment is the development of secondary sex characteristics and

fertility. Hormone replacement therapy can be used when there is insufficient sex hormone secretion, such as testosterone for males.[14,15]

Disorders of the Male Reproductive System

Disorders of the Urethra

Urethritis and urethral strictures are common disorders of the male urethra. Urethral carcinoma, an extremely rare form of cancer, can occur in men older than 60 years.

Urethritis

Urethritis is an inflammatory process that is usually, but not always, caused by a sexually transmitted microorganism (see Chapter 27). Infectious urethritis caused by *Neisseria gonorrhoea*e is often called *gonococcal urethritis (GU);* urethritis caused by other microorganisms is called *nongonococcal urethritis (NGU)*. Nonsexual origins of urethritis include inflammation or infection because of urologic procedures, insertion of foreign bodies into the urethra, anatomic abnormalities, or trauma. Noninfectious urethritis is rare and is associated with the ingestion of wood, ethyl alcohol, or turpentine. It is also seen with reactive arthritis.

Symptoms of urethritis include urethral tingling or itching or a burning sensation, and frequency and urgency with urination. The individual may note a purulent or clear mucus-like discharge from the urethra. Nucleic acid detection amplification tests allow early detection of *N. gonorrhoeae* and *Chlamydia trachomatis* in urine studies. Treatment consists of appropriate antibiotic therapy for infectious urethritis and avoidance of future exposure or mechanical irritation.

Urethral Strictures

A **urethral stricture** is a narrowing of the urethra, causing obstructive symptoms and affecting quality of life (Fig. 26.1).[16] Most urethral strictures result from injury to the urethral mucosa and surrounding tissues. Strictures can develop anywhere along the length of the male urethra and are due to several etiologies. The

strictures are sometimes classified into anterior and posterior, where anterior comprises 92.2% of cases.[16] The World Health Organization (WHO) recommends a different nomenclature for classification into seven segments: urethral meatus, fossa navicularis, penile, bulbar, membranous, prostatic urethra, and bladder neck.[17] The etiology of strictures is divided into four main categories: idiopathic, iatrogenic, inflammatory, and traumatic. Idiopathic causes are the result of unrecognized repetitive minor perineal traumas.[16] Nearly 45% of all strictures are iatrogenic and include those from trans-urethral resections (TUR) (41%), prolonged catheterization (36%), cystoscopy (12.7%), hypospadias repair (6.3%), radical prostatectomy (2% to 9%), and prostate cancer radiotherapy (3.4%) with the highest rate in high-dose-rate brachytherapy.[16,19,20] Children who have hypospadias repair have a 10% risk of developing urethral strictures later in life.[16] Inflammatory strictures are the result of post-infectious inflammation which leads to narrowing of the lumen and weakening of the epithelium. Post-infectious processes that cause inflammation include gonococcal urethritis, chlamydia, tuberculosis, and schistosomiasis.[16] Recurrent urinary tract infections (UTIs) and Lichen sclerosis (LS) are other causes of urethral strictures.[16,17]

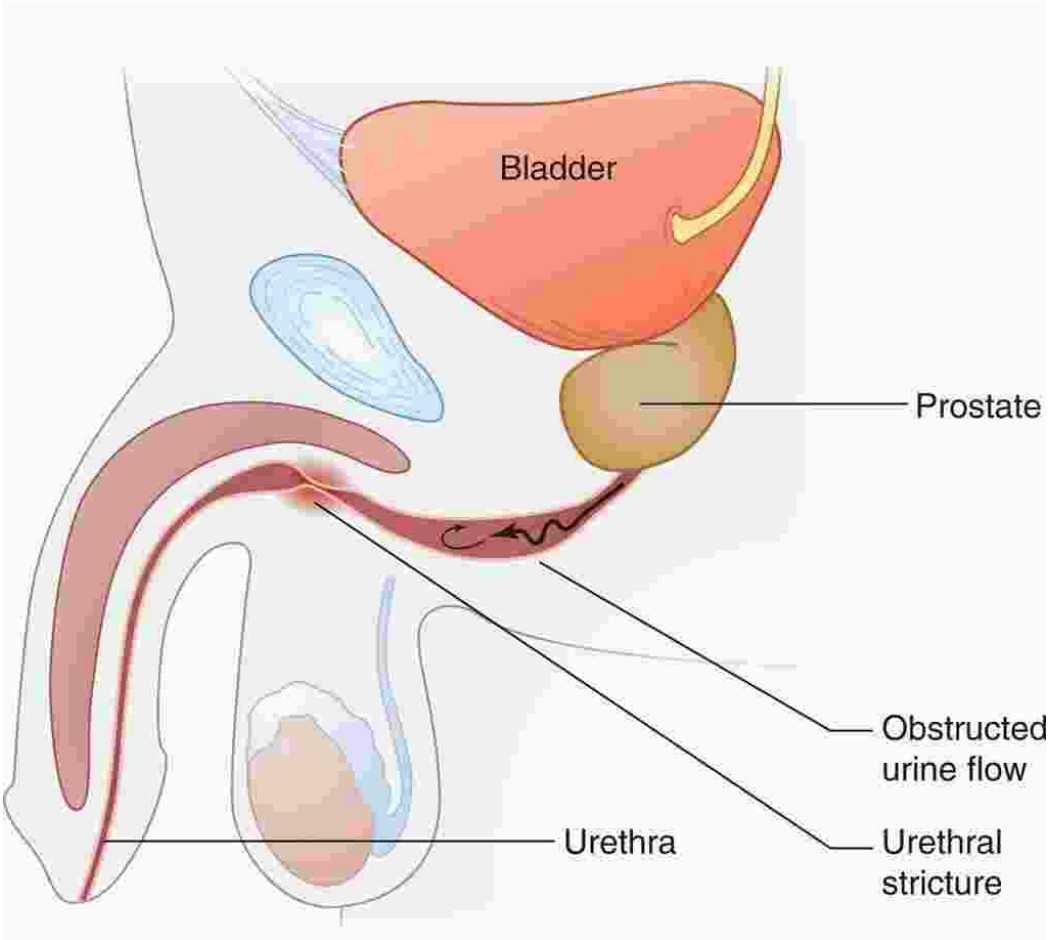

FIG. 26.1 Urethral Stricture.
From damage and fibrosis, the diameter of the urethra duct is less than normal and is called a urethral stricture.

Urethral strictures are common with a prevalence in the United States about 200 per 100,000 in younger men and more than 600 per 100,000 in men older than 65.[16,18] Estimated worldwide prevalence is 229 to 627 per 100,000.[21] Male urethral strictures account for 5000 hospital admissions yearly and 1.5 million clinic visits.[22]

Pathophysiology

An injury to the urethral epithelium or direct trauma to corpus spongiosum can cause urine to leak into the underlying area (corpus spongiosum).[16] The injury is then followed by inflammation and

fibrous changes. Fibrous tissue causes contraction, which compresses the urethral lumen.[22] The urethral epithelium undergoes metaplasia to stratified squamous epithelium. These changes make the area more vulnerable to pressure changes and stretch causing tears in the mucosa, which leads to increased urine leakage into the corpus spongiosum. Eventually, the alterations lead to fibrous changes and stricture.[23]

Clinical Manifestations

Most individuals present with progressive obstructive voiding symptoms, such as a weak stream.[16] Severity of symptoms varies widely especially in those with a slow progression or a discrete stricture where they may have absence of such symptoms.[16] These individuals may compensate with adaptive detrusor hypertrophy. Other obstructive symptoms include urinary hesitancy, intermittency, and dribbling.[24] The symptom most notably associated with strictures is the feeling of incomplete emptying. With acute obstruction, individuals can present with hematuria and commonly with UTIs.[16] Symptoms are troublesome and affect quality of life.

Evaluation and Treatment

A thorough history is required to determine the underlying etiology. Included is a history of interventions, previous infections, trauma, comorbidities, and an appropriate past medical history.[24] A physical exam is done with palpation of the urethra for any palpable fibrous tissue. Pale skin patches may indicate lichen sclerosus. These patches may be confined to the surrounding urethral meatus.[16] It is important to identify any scars from previous surgery.[16] Examination of the prostate is done to ascertain benign prostatic hyperplasia (BPH), prostate cancer, or prostatitis.[23,24]

Laboratory blood tests do not have a role in diagnosing urethral strictures; however, an elevated white blood cell count may reveal an infectious process. Lower urinary tract flow studies provide a

detailed assessment of the urethra; the preferred initial investigation is with uroflowmetry.[16] A triphasic uroflowmetry-based model can aid in distinguishing the voiding patterns of healthy individuals versus those with benign prostatic obstruction or those with urethral strictures. A maximum flow (Qmax) of less than 15 mL/s raises the suspicion of lower urinary tract stricture. The shape of the curve can help with the diagnosis as urethral strictures typically produce a plateau at the level of Qmax.[16] Reliable results from uroflowmetry studies are based on 150 mL in volume.[24–26]

Urethroscopy or cystoscopy can also be used to diagnose urethral stricture, and it can be done under local anesthesia (flexible cystoscopy).[16] Occasionally, the scope is unable to pass through the stricture in order to assess the length or the state of the urethra proximal to it, which causes the inability to provide information about the surrounding fibrosis. Hence, although it is of limited diagnostic value, it can provide a quick diagnosis in case of clinical doubt.[23,24,26] If clinical data are suggesting a stricture, urethrography is performed. If the individual is relaxed, a retrograde urethrography (RUG) can visualize the entire urethra up to the bladder.[16] However, RUG will not provide sufficient information if the stricture is significant and inadequate distention of the proximal urethra occurs.[16] With this situation, a voiding cystourethrography (VCUG) will provide useful additional information. This is done by either asking the individual to void after the bladder is filled with contrast from the RUG or by introducing the contrast through a suprapubic catheter.[16] The combination of RUG and VCUG can provide a sufficient image of the entire urethra providing information about the location, number, length, and severity of strictures. Thus, RUG and VCUG are definitive diagnostic tools.[16] These studies, however, have limitations when interpreting the images because of the position of the stricture and the state of the proximal urethra, as these techniques provide only a 2D image of a 3D structure.[23,24] The use of computed tomography (CT) voiding urethrography or sonoelastography also has utility and provides images of the

stricture and its characteristics.[27,28] If cancer is suspected to be the cause of the stricture, MRI can provide quality images and show the location of the tumor.[24] Assessment of the bladder and upper urinary tract is mainly done with ultrasonography.[23]

If symptoms are not troublesome, treatment should not be offered.[16] Without bladder thickness or incomplete emptying, there is no need for any intervention.[16] Acute complications caused by the stricture must be addressed first before offering treatment for the stricture.[16] Individuals presenting with acute urinary retention are given a suprapubic bladder fistula, and any existing UTI is treated with antibiotics. Afterward, definitive treatment for the stricture should be undertaken.[26]

Urethral stricture treatment can be divided into transurethral (dilation, internal urethrotomy) and open surgical (stricture resection and anastomosis, urethroplasty and perineal urethrostomy). Importantly, with any of the treatment options, recurrence tends to happen especially with long strictures and previously treated ones.[16,26]

Disorders of the Penis

Phimosis and Paraphimosis

Phimosis and paraphimosis are both disorders in which the foreskin (prepuce) is "too tight" to move easily over the glans penis. **Phimosis** is a condition in which the foreskin cannot be retracted back over the glans (Fig. 26.2A), whereas **paraphimosis** is the opposite: the foreskin is retracted and cannot be moved forward (reduced) to cover the glans (see Fig. 26.2C). Both conditions can cause penile pathologic conditions.

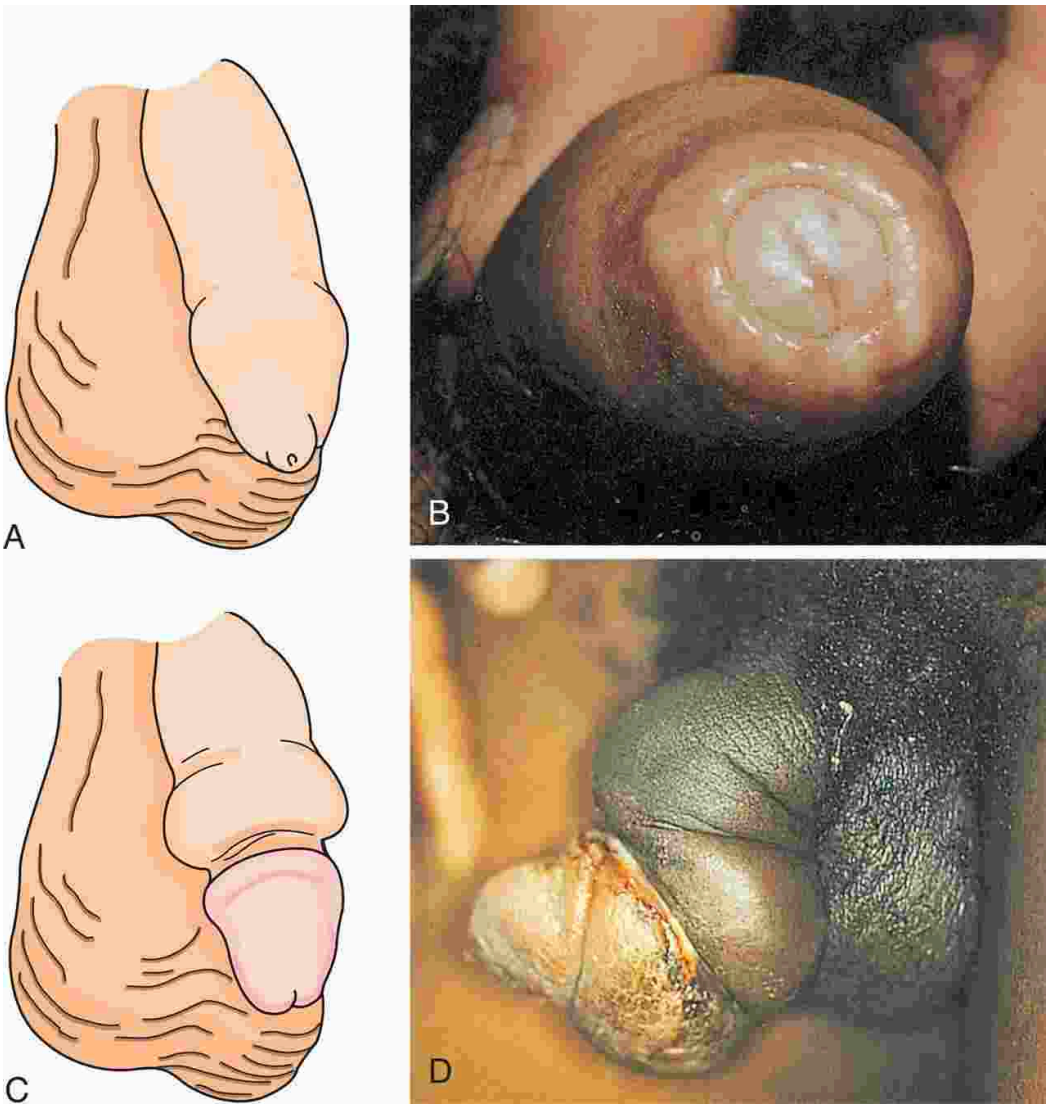

FIG. 26.2 Phimosis and Paraphimosis.
(A) Phimosis: the foreskin has a narrow opening that is not large enough to permit retraction over the glans. (B) Lesions on the prepuce secondary to infection cause swelling, and retraction of the foreskin may be impossible. Circumcision is usually required. (C) Paraphimosis: the foreskin is retracted over the glans but cannot be reduced to its normal position. Here it has formed a constricting band around the penis. (D) Ulcer on the retracted prepuce with edema. (A and C, From Monahan FD, et al. *Phipps' medical-surgical nursing: Health*

and illness perspectives, 8th edition. St. Louis: Mosby; 2007; B, From Taylor PK. *Diagnostic picture tests in sexually transmitted diseases*. St. Louis: Mosby; 1995; D, From Morse SA, et al. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2011.)

A. An illustration depicts the penis with the prepuce covering the glans. B. Close shot of penis with prepuce covering the glans. C. An illustration depicts the penis with the retracted prepuce. D. Close shot of penis with the retracted prepuce.

Phimosis is normal in babies and toddlers; the foreskin will not retract because it is still attached to the glans. In older children it may be the result of a skin condition that has caused scarring. Phimosis can occur at any age and is commonly caused by poor hygiene and chronic infection (see Fig. 26.2B and D). It rarely occurs with normal foreskin. In adults, phimosis can sometimes be caused by sexually transmitted infections (STIs). It is associated with different skin conditions such as eczema, psoriasis, lichen planus, and lichen sclerosus.

Reasons for seeking treatment include edema, erythema, tenderness of the prepuce (foreskin), purulent discharge, dysuria, *balanitis* (inflammation of the head of the penis), and *balanoposthitis* (thick discharge underneath the foreskin). Circumcision, if desired, is performed after infection has been eradicated. Complications of phimosis include balanitis, posthitis (inflammation of foreskin), and paraphimosis.

Paraphimosis occurs in uncircumcised males when the foreskin becomes trapped behind the corona of the glans penis.[29] It can lead to strangulation of the glans, painful vascular changes, distal venous engorgement, edema, and necrosis.[29] Paraphimosis mostly occurs iatrogenically, when the foreskin is retracted for cleaning,

preparation of a urinary catheter, penile examination, or procedures such as cystoscopy.[29,30] Caregivers who regularly change Foley catheters should replace the foreskin at the end of the procedure to prevent the development of paraphimosis.[29]

Evaluation of an individual with paraphimosis includes a history of any recent catheterizations, instrumentation, cleaning, or other procedures.[30] The person should be asked about cleaning techniques of the penis and if the foreskin is retracted for any reason.[29] The individual should also be asked if he is circumcised or uncircumcised.[29] In those with circumcision, it is still possible to develop paraphimosis.[29] If a Foley catheter is in place, it is recommended to review the reason why the catheter was needed and if any difficulties were present in placing the catheter.[29] Most of the time, it is not necessary to remove the catheter to reduce the paraphimosis.[30] Paraphimosis is a urologic emergency. If the foreskin cannot be reduced by manual reduction methods, surgery must be performed to prevent necrosis of the glans caused by constricted blood vessels. An elective circumcision or dorsal slit procedure is strongly recommended in all individuals who have had a significant paraphimosis because of a great risk of recurrence.[29]

Peyronie Disease

Peyronie disease (PD) is a progressive non-malignant disorder of the penis that results in an abnormal curvature when erect (Fig. 26.3). The abnormal curvature is the result of scar tissue in the erectile tissue; the exact mechanism, however, for the formation of the scar tissue remains unknown.[31] PD is a disorder of wound healing of the tunica albuginea, resulting in fibrosis or scarring. In the United States, PD is reported to affect more than 1 in 10 men.[32] The prevalence of PD ranges from 0.3% to 20.3% depending on the variability of several factors, such as country or self-report versus physician report.[33] PD is common in many sexual disorders, such as erectile dysfunction (ED) and impaired sexual performance, causing significant distress to those affected and their partners.[31,34]

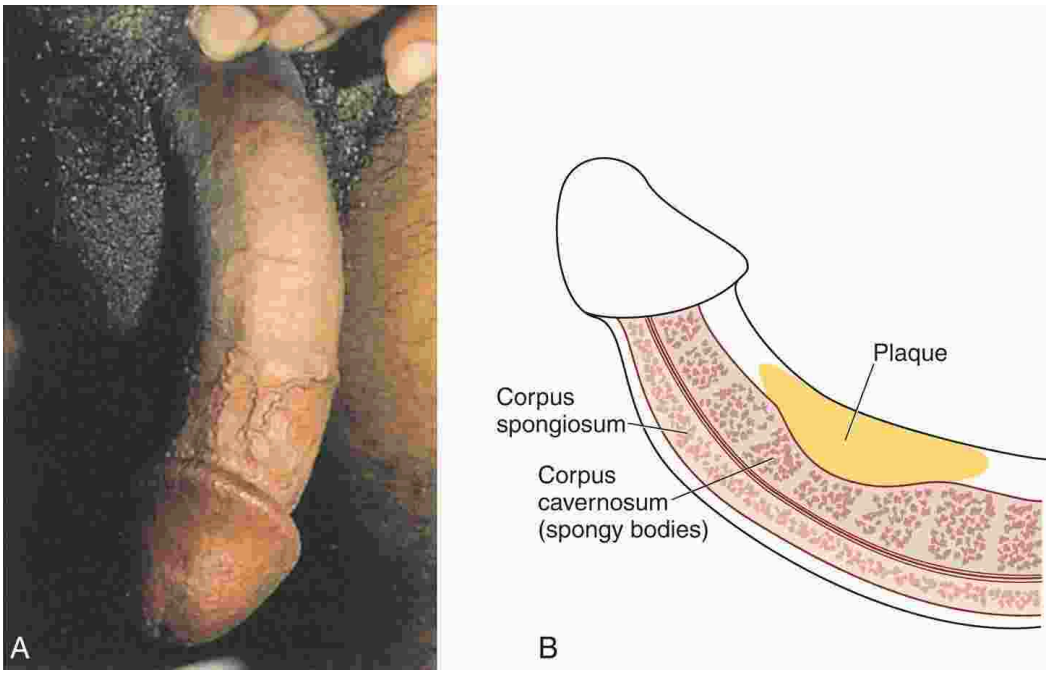

FIG. 26.3 Peyronie Disease (PD).
(A) This person complained of pain and deviation of his penis to one side on erection. (B) Schematic of the corpus spongiosum, tunica albuginea, and fibrous plaque showing point of curvature. PD is a wound disorder that affects the tunica albuginea of the penis. Its occurrence appears to be after injury or trauma. Abnormal scar tissue develops into plaque under the skin of the penis, causing er-ectile curvature. (A, From Taylor PK. *Diagnostic picture tests in sexually transmitted diseases*. St. Louis: Mosby; 1995; B, From Koesterman JL. *Buck's Step-by-Step Medical Coding*, 2022 Edition, St. Louis: Elsevier; 2022)

Each corpus cavernosum has a sheath of elastic fibers called the **tunica albuginea**, which has predominantly type 1 collagen fibers (see Fig. 26.3B).[31] The two corpora cavernosa are separated by a condensation of the tunica albuginea in the midline, which forms a septum that attaches to the top and bottom of the penis.[31] A fibrous plaque then forms in the tunica albuginea of the corpora cavernosa.

The fibrous plaque is inelastic and changes the smooth upward curvature of the erect penis to a more crimped appearance. Why the plaque forms is uncertain, but the most accepted theory is trauma to the penis.[31] Other theories include microvascular injury, chromosomal instability of fibroblasts as part of plaque formation, changes in the inducible nitric oxide pathways, and human leukocyte antigen (HLA) subtype.[35–37] Better understanding of the risk factors will help to identify who will develop PD. Susceptible men may include those who engage in vigorous sexual activities or nonsexual activities, such as sport events that may be associated with micro-injuries to the penis.[31]Box 26.2 shows modifiable and non-modifiable risk factors for PD from different levels of evidence.

Box 26.2

Modifiable and Non-Modifiable Risk Factors for Peyronie Disease

- *Penile injury*—Previous injury is a strong predictor of developing Peyronie disease (PD)[1]. Genital or perineal trauma, iatrogenic injury, including catheterization, cystoscopy, and transurethral resection of the prostate, all increase the risk of PD.[1–3]
- *Connective tissue disorders*—PD is associated with certain fibroproliferative diseases such as Dupuytren disease (DD) or contracture and plantar fasciitis.[4] Suggests a significant pathophysiologic and genetic interaction between these two superficial fibrosing disorders. The prevalence of DD in 415 men with PD was 22.1%.[5] The prevalence of DD is reported to be between 1% and 7.3% adding evidence that these conditions may have overlapping mechanisms and predisposing genetic factors.[6] Many studies have linked PD to other systemic fibrotic diseases including idiopathic

pulmonary fibrosis, Paget disease of the bone, retroperitoneal fibrosis, scleroderma, polyfibromatosis, and systemic sclerosis.[1]

- *Family history*—Genetic factors linked to PD are complex and reviewed by Gabrielsen.[7] Evidence of a genetic link exists and the interaction with penile trauma may increase the risk for genetically susceptible men.
- *Hypogonadism*—Both the risk of developing and the severity of PD is enhanced by hypogonadism. A prevalence of 74.4% of PD was reported in 121 individuals with hypogonadal testosterone levels less than 300.[8] Additionally, the degree of curvature was higher in the hypogonadal group compared with men with PD with normal testosterone levels. These data were corroborated by another study with 106 persons.[9] Serum testosterone levels influence wound healing and testosterone deficiency in those with PD increases the severity of PD by affecting penile deformity, plaque size, and erectile dysfunction.[9] Androgens have an essential role in wound healing by modulating matrix metalloproteinases[1] and in deficient states, the normal healing process is disrupted, thus increasing the risk of developing PD.[1]
- *Diabetes*-May enhance the fibrotic process involved in PD.[1] From a study of 206 diabetic patients 20.3% had PD, and penile curvature was present in 82.1%.[10] A higher prevalence of PD in those with diabetes has been reported in other studies.[11–14]
- *Smoking and alcohol*-There is limited data on the associations of smoking, as well as for alcohol.
- *Age*-Men in their 60 s are more commonly affected by PD[15] and the age at time of diagnosis varies from 52–57 years old.[16–19] PD can present at any age including as young as 21 years.[17]

Pathophysiology

The hallmark of PD is the tunical fibrosis of the corpora cavernosa resulting in plaques (see Fig. 26.3B).[31] The main characteristics include deposition of abnormal clumps of collagen with disordered, fragmented, and scant elastic fibers.[38–40] Other findings include the presence of fibrin in 95% of PD plaques.[41] Deposition of fibrin is consistent with the hypothesis that microvascular injury results in fibrin deposition in the tissue space.[41] Abnormal inflammation and wound healing may be responsible for the increased cellularity around the tunica, which results in perivascular lymphocyte infiltrate surrounding or within the tunica itself.[39,42–46] It seems clear that the avoidance of injury or trauma to the penis reduces the risk of development of PD.

Clinical Manifestations

There are two phases in PD, acute and chronic. The first 6 to 18 months of PD is considered the acute phase and progresses with penile deformity and associated pain in either the erect and/or flaccid

states.[31] Treatment is not recommended in this phase. The chronic phase is a plateau of symptoms for about 3 to 6 months; the deformity remains stable with some or complete improvement in pain.[31] It is with this phase that treatment is initiated.[31]

Evaluation and Treatment

A thorough history and examination is key for the diagnosis of PD. The history should include a detailed presenting complaint, as well as past medical and surgical history. For PD, a sexual history is important. Box 26.3 indicates how to determine if the person is in the acute phase or chronic phase.[31]

Box 26.3

To Help Determine Acute Versus Chronic Phase of Peyronie Disease

- *Deformity*: Have the person describe the deformity. Include the direction and degree of deformity
- *Pain*: If pain is present is it associated with both flaccid and erect states or only the erect state.
- *Erection*: the degree of rigidity, ability to sustain it, presence of nocturnal erections
- *Trauma*: History of penile trauma/fracture, urologic procedures, or surgeries
- *Family history*: Any history of Peyronie disease or Dupuytren disease
- *Medical/surgical history*: Diabetes, hypertension, and cardiovascular disease
- *Social history*: Sexual history, smoking, alcohol use, recreational use

- *Psychosocial history*: How has PD affected the person, mood, relationships, self-esteem, and depression

An accurate physical exam of penile deformity is necessary for planning care.[47,48] American Urology Association (AUA) guidelines include examination of the penis in the flaccid and erect state. Examination in the erect state can be performed after intracavernosal injection of vasoactive agents.[49] Ultrasound after intracavernosal injection is superior to photographs or vacuum erectile device-assisted erection to accurately determine the type and degree of PD deformity. Duplex doppler penile ultrasound is best for assessing plaque size, location, and calcification, as well as etiology.[31] Laboratory blood tests have a limited role for diagnostic testing except when hypogonadal cause is suspected.[31] The individual should, however, be screened for comorbidities such as diabetes, cardiovascular disease, and other fibroproliferative conditions.

A discussion of all available treatments is critical. The individual's distress over symptoms and the level of concern and willingness to undergo treatment is important to consider in the decision-making process.[31] Treatment consists of both nonsurgical and surgical interventions. Non-surgical approaches include a variety of oral and injectable therapies. Very few of these strategies, however, have well-designed, double-blind, placebo-controlled, randomized trials.[31] The lack of quality research for these approaches is an obstacle for determining the best patient-centered interventions. Surgical indications include: (1) a deformity that impairs sexual relations, (2) stable deformity without pain for at least three months, (3) substantial plaque calcification, and (4) failed nonsurgical management.[31] Main criteria for a surgical approach include: (1) nature and location of the deformity, (2) immensity of penile deformity, (3) baseline erection function, (4) penile dimensions, (5) surgeon's experience, and (6) individual's preference.[50] Complications of surgery may include postoperative ED, infection, penile hematoma, penile pain, and recurrence of curvature.[31] Penile

prosthesis placement is appropriate for men with ED, severe deformity refractory to medical treatment, or profound penile instability.[31] Prosthesis placement may be complicated because of the presence of plaque and corporal fibrosis, making the dilation of the corpora difficult and increasing the risk for corporal perforation.[31] There are associated psychosocial factors reported with PD, which include embarrassment, distress, self-image factors, mood, intimacy issues, and depression. Therefore, psychosocial support is an important aspect of treatment.

Priapism

Priapism is a disorder of prolonged, rigid penile erection in the absence of appropriate stimulation. Definitions of duration vary, but an erection lasting four hours or longer is considered priapism (Fig. 26.4).[51] Broad categories of priapism include ischemic, nonischemic, and recurrent ischemic. Ischemic causes are an emergency to prevent progression to complete and irreversible ED.[51] The etiology of priapism is determined by arterial flow with low flow (ischemic) and high flow (non-ischemic). The causes of ischemic priapism are numerous and include some hemoglobinopathies, such as sickle cell disease, thalassemia (see Chapter 30), and hypercoagulable state (see Chapter 29).[51] Other causes are vasoactive medications, including ED medications (phosphodiesterase 5 [PDE 5] inhibitors and intracavernous injections), antidepressants (e.g., Trazadone), and illicit drugs, such as cocaine.[51] Less common causes include neurologic disorders, infections, and neoplastic diseases. Recurrent ischemic causes of priapism have some of the same underlying etiologic factors as ischemic priapism except for dysregulated signaling of nitric oxide (NO) in intermittent ischemic episodes.[52] Nonischemic priapism is less common and results from trauma. Iatrogenic injury is a cause from surgical interventions, congenital malformations, or cancer.[51] In a small subset of individuals, no underlying cause or explanation is found.[53,54]

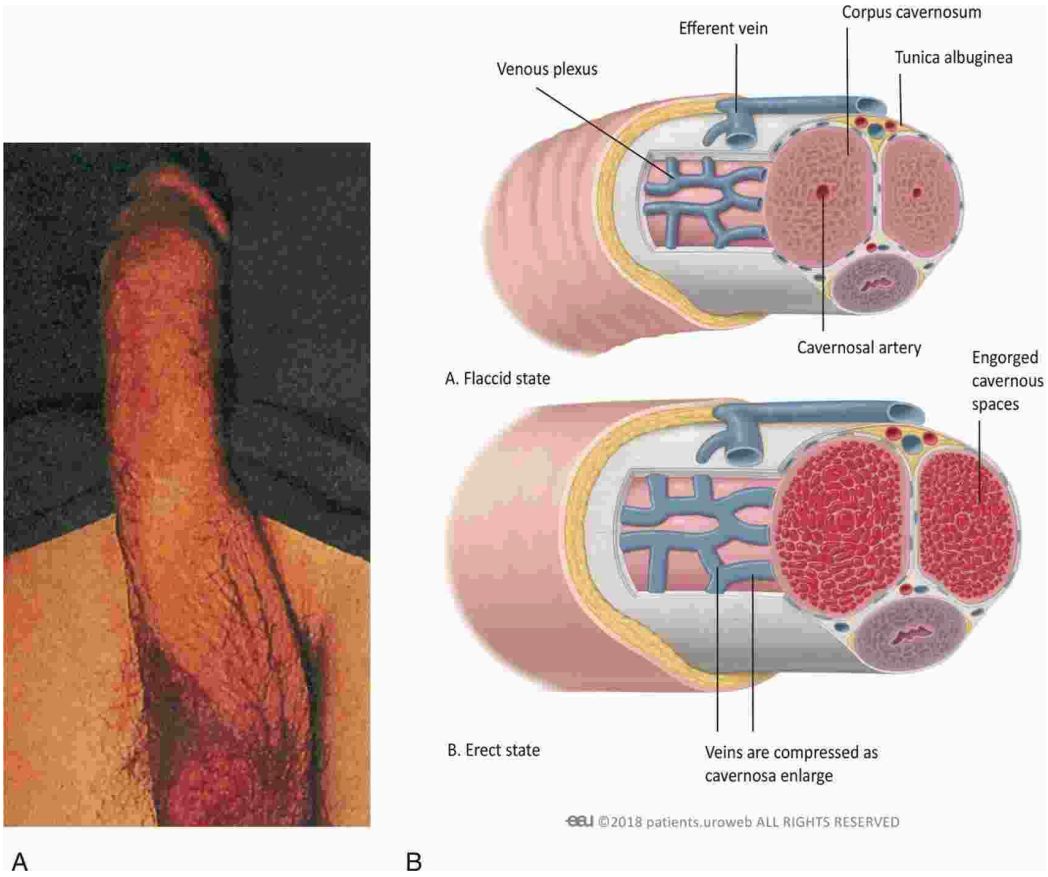

FIG. 26.4 Priapism.
(A) Erect penis. (B). With priapism the corpus cavernosum is engorged with compressed veins.
(A, From Lloyd-Davies RW. *Color atlas of urology*, 2nd edition. London: Wolfe Medical; 1994; B, From uroweb, 2017; B, From European Association of Urology © 2018 patients.uroweb. All rights reserved.)

A. Close shot of erected penis. B. The illustration on the top depicts the cutaway section of the flaccid penis with labels indicating the venous plexus, corpus carvernosum, cavernosal artery, efferent vein, and tunica albuginea. The illustration at the bottom depicts the cutaway section of an erect penis with

labels indicating veins are compressed as cavernosa enlarge and engorged cavernosal spaces.

Priapism has a bimodal presentation and peaks at ages 7 to 10 and 20 to 50 years.[51] In two–thirds of individuals the cause is use of intracavernosal drugs used to treat ED. Sickle cell disease accounts for a high number of cases (between 40% and 80%).[51] Sickle cell cases of priapism are mostly seen in African Americans.[55]

Pathophysiology and Clinical Manifestations

Ischemic priapism is a disease of low arterial blood inflow into the corpora cavernosa resulting in a rigid and prolonged erection (see Fig. 26.3A). Venous blood becomes trapped in the corpora cavernosa with increasing pressure which results in tissue ischemia and associated penile pain (see Fig. 26.3B).[51] Priapism typically does not cause engorgement of the glans penis and corpus spongiosum.[51] Nonischemic priapism is caused by unregulated arterial blood flow into the corpora cavernosa without venous trapping. These individuals usually do not develop tissue ischemia; thus, the presentation is mostly painless.[56]

Evaluation and Treatment

A complete history is essential to understand the etiology and document the type of priapism. The history reveals an erection of an abnormally long time in the absence of stimulation with associated penile pain.[51] Critical questions include the duration of symptoms, previous treatments received, injection therapy utilized, erectile function before the priapism episode, current medications, and history of underlying disorders known to provoke priapism. If the etiology is not determined from the history, then laboratory evaluation is performed to determine penile hemodynamics, metabolism, and any underlying diseases that may be contributory.[51]

If sickle cell disease is suspected, then hemoglobin S measurements are done.[51]

Ischemic priapism is an emergency. An erection lasting longer than 4 hours mandates early intervention to decrease the potential of irreversible damage and ED. Emergency department management is focused on achieving **detumescence** or diminution of erection. Several medications can be utilized while waiting for more advanced treatment; however, failure of oral therapies is common with about 75% failure rate.[51] In this situation, the need to perform corporal aspiration of blood is done with concurrent intracavernous injection of a sympathomimetic agent. Surgical intervention consists of shunt procedures with the underlying goal of reducing corporal pressures and, ultimately, penile pain.[53,57,58]

Non-ischemic priapism is typically managed conservatively because of the low probability of penile damage. The initial intervention should be an observation with treatment utilizing topical ice packs. Although aspiration can be completed for diagnostic purposes, it generally does not result in complete detumescence.[51] Many individuals elect to avoid surgery because of inherent risks of ED, and some are reported to maintain their capacity to obtain and maintain an erection despite years of non-ischemic priapism.[51] If a surgical procedure is desired, the general approach is selective embolization or direct ligation of the dysfunctional cavernous artery fistula.[51]

Balanitis

Balanitis is an inflammation of the glans penis (Fig. 26.5). Men present with penile pain and erythema. It affects about 3% to 11% of males during their lifetime. **Posthitis** is an inflammation of the foreskin or prepuce. **Balanoposthitis** involves both the glans and foreskin and occurs only in uncircumcised males.[59,60] Balanoposthitis occurs in approximately 6% of uncircumcised males.[61] Balanitis and balanoposthitis often occur together, and the terms are used interchangeably. Although balanitis is not a STI, infectious etiologies

of balanitis include certain fungi like yeast, and bacteria or viruses (including those that cause STIs such as gonorrhea).[61] While the actual disease is not transferable from one person to another, the transfer of the infecting organisms that cause balanitis is possible.[61] Recurrent balanoposthitis is a warning for occult diabetes, and these individuals should have blood glucose screening and evaluation by a urologist.

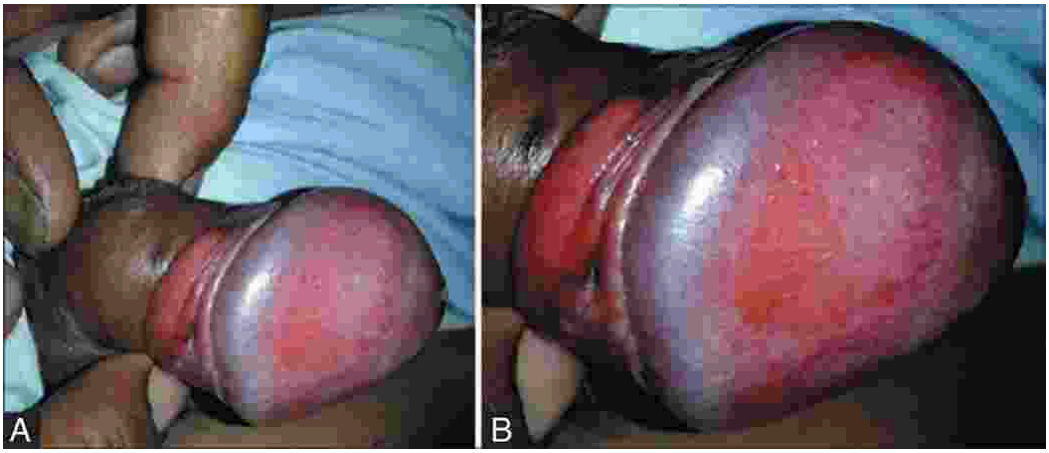

FIG. 26.5 Balanitis.
Orange-red shiny plaque on the glans penis and undersurface of the prepuce with multiple pin point sized red spots. (From Dayal S, Sahu P. Zoon balanitis: A comprehensive review. *Indian J Sex Transm Dis AIDS*. 2016;37(2):129–138.)

Balanitis is associated with inadequate hygiene and phimosis in uncircumcised males leading to infection. The moist and warm environment under the uncircumcised penile foreskin encourages the growth of organisms such as fungi.[61] Fungal infections are the most identifiable, with most infections from *Candida albicans*.[62]*C. albicans* is normally present on the skin of the glans and considered normal flora. The yeast can cause infection particularly with poor hygiene, overgrowth, or changes in pH. Other etiologies exist and are listed in Box 26.4.[61]

Box 26.4

Etiologies of Balanitis

Infectious Etiologies

- Candida species (most associated with diabetes)
- Group B and group A beta-hemolytic streptococci
- Neisseria gonorrhea
- Chlamydia species
- Anaerobic infection
- Human papillomavirus
- Gardnerella vaginalis
- Treponema pallidum (syphilis)
- Trichomonas species
- Borrelia vincentii and Borrelia burgdorferi

Noninfectious Etiologies

- Poor personal hygiene (most common)
- Chemical irritants (e.g., spermicides, detergents, perfumed soaps and shower gels, fabric conditioners)
- Edematous conditions, including congestive heart failure (right sided), cirrhosis, and nephrosis
- Drug allergies (e.g., tetracycline, sulfonamide)
- Morbid obesity
- Allergic reaction (condom latex, contraceptive jelly)
- Fixed-drug eruption (sulfa, tetracycline)
- Plasma cell infiltration (Zoon balanitis)
- Autodigestion by activated pancreatic transplant exocrine enzymes
- Trauma

- Neoplastic conditions

Balanitis can occur at any age and affects about 1 in every 25 boys and 1 in 30 uncircumcised males over the lifetime. The highest risk group is boys under 4 years of age and uncircumcised males.[61] The risk of balanitis decreases when boys reach the age of 5 years, and the foreskin is easier to retract. Circumcised males have a 68% lower prevalence of balanitis than uncircumcised males, and those with balanitis have a 3.8-fold increase in risk of penile cancer.[63]Box 26.5 presents risk factors for balanitis.

Box 26.5

Risk Factors for Balanitis

- Presence of foreskin
- Morbid obesity
- Poor hygiene
- Diabetes (particularly males with uncontrolled diabetes), probably due to glucose on the skin, encouraging bacterial and fungal growth
- Nursing home environment
- Condom catheters
- Sensitivity to chemical irritants (i.e., soaps and lubricants)
- Edematous conditions: Congestive heart failure, nephrosis
- Reactive arthritis
- Sexually transmitted infections

From Wray A, Velasquez J. *Balanitis*. StatPearls [Internet]. Treasure Island, FL: StatPearls; 2020.

Pathophysiology and Clinical Manifestations.

Balanitis occurs from the accumulation of smegma beneath the foreskin. **Smegma** is a whitish sebaceous secretion of dead skin (epithelial cells) and sebum or oily secretions produced by the sebaceous glands. In normal circumstances, smegma helps in the lubrication of the foreskin, decreasing friction and irritation. Tight foreskin, poor hygiene, and smegma are key for bacterial and fungal overgrowth leading to irritation and inflammation. White curd-like exudate is suspicious of candida infection. The yeast *C. albicans* is the most common fungal infection but other etiologies exist (psoriasis or lichen planus, allergic reactions, and less likely premalignant condition).[61] Without treatment, edema can occur promoting progression of balanitis. Inflammation and edema together can promote adherence of the foreskin to the glans.[61] Clinical manifestations include pain, tight shiny skin unable to retract on the glans, redness (see Fig. 26.5), soreness, itching, smegma, foul-smelling discharge from under the foreskin, painful urination, swollen glands near the penis, and sores on the glans. More severe symptoms may present in diabetic and immunosuppressed individuals.[63]

Evaluation and Treatment

The diagnosis of balanitis is visual, based on the clinical appearance and presence of lesions. Evaluation may include bacterial culture (in the presence of purulent exudate), herpes simplex virus (HSV) testing (with vesicular or ulcerative lesions), syphilis testing (presence of an ulcer), testing for scabies, trichomonas, and *Mycoplasma genitalium* (presence of urethritis). The mobility of the foreskin is assessed to exclude the complications of phimosis and paraphimosis. Hygienic care with frequent washing and drying of the prepuce is a preventive measure, but excessive genital washing with soap aggravates the disease. For balanoposthitis, topical antifungals usually for one to three weeks are the appropriate choice. First-line therapies are imidazoles such as clotrimazole 1% twice daily, and miconazole 1% twice daily.[61] In those with severe inflammation, the addition of fluconazole 150 mg stat orally or the

combination of a topical imidazole with a low-potency topical steroid (e.g., hydrocortisone 0.5%) twice daily, often is successful.[61] With a concern for concomitant cellulitis, treatment with a first-generation cephalosporin is appropriate. Circumcision is recommended for recurrent and intractable episodes in immunosuppressed and diabetic persons. Female sexual partners of men with balanitis should be offered testing for candida. Treatment to both partners will reduce the infection for the couple.[64]

Tumors of the Penis

Tumors of the penis are not common. The most frequent are the benign epithelial tumor condyloma acuminatum and penile carcinomas.

Condyloma acuminatum is a benign tumor caused by HPV, a microorganism that causes a STI (see Chapter 27). HPV type 6 and, less often, type 11, are the most frequent types and can cause a common wart and moist surface of the external genitalia. Giant condyloma (Buschke-Löwenstein) affect older men and may be 5 to 10 cm in size. Atypia may be evident in long-standing giant condyloma, and assessment of other HPV subtypes may be indicated to distinguish the lesion from a noninvasive warty carcinoma.

Penile Cancer

Penile squamous cell carcinoma (PSCC) is a rare cancer with orphan disease designation and a prevalence of 0.1 to 1 per 100,000 men in high-income countries.[65] Globally, penile cancer is rare with 26,000 cases estimated per year.[65] It can affect men 40 to 70 years of age; two–thirds of men are diagnosed at 65 years of age or older. Observed trends of early onset (≤64 years of age) are thought to be associated with changes in sexual practice that increases exposure to STIs and HPV infection.[66] Although the exact cause is unknown, risk factors include HPV infection, smoking, chronic inflammatory conditions (i.e., lichen sclerosus),[67] and psoriasis treatments (psoralens and ultraviolet A; PUVA).[68] Penile cancer is more common in men with phimosis and when circumcision is performed in

adulthood. However, circumcision at birth appears to decrease the risk.[69]

Pathophysiology

The standardized term for precursor lesions of penile cancer is **penile intraepithelial neoplasia** (**PeIN**).[65] PeIN is divided into two subtypes: a differentiated subtype, typically lichen sclerosus-associated, and an undifferentiated HPV-associated subtype.[70–72] PeIN are all squamous lesions confined to the epidermis by an intact basement membrane. Most PeIN lesions are HPV positive and have several HPV genotypes (HPV6, HPV11, or HPV 16).[65] HPV 16 is a concerning genotype because of its frequency and susceptibility to malignancy.[65] Estimated progression of HPV 16 infection to PeIN is up to 2% of cases within 2 years.[73]

Table 26.3 presents the WHO 2016 classification of PSCC of both HPV-related and non-HPV-related categories; each category has several different histologies. Best understood is the HPV-related biological pathway leading to penile carcinogenesis (Fig. 26.6) Persistent or recurrent exposure to HPV results in the integration of HPV deoxyribonucleic acid (DNA) into the host genome of penile tissue with eventual transformation into a malignant phenotype. Several chronic penile conditions, including balanoposthitis, phimosis, and lichen sclerosus, are risk factors for the development of penile cancer and share a common mechanism of inducing cyclooxygenase 2 (COX2) expression. COX2 has been associated with differentiated PeIN and primary and distant PSCC.[74] COX2 overexpression creates the overproduction of prostaglandins, notably prostaglandin E_2 and thromboxanes, leading to angiogenesis, proliferation, and invasion. Non-HPV-mediated penile carcinogenesis occurs through several gene alterations: amplifications, deletions, mutations, loss of heterozygosity, and/or epigenetic changes (see also Chapters 4, 6, and 12).[65]

Table 26.3

World Health Organization 2016 Pathologic Classification of Squamous Cell Carcinoma of the Penis

Non–HPV-Related Squamous Cell Carcinoma
Squamous cell carcinoma, usual type
Pseudohyperplastic carcinoma
Pseudoglandular carcinoma
Verrucous carcinoma
Carcinoma cuniculatum
Papillary squamous cell carcinoma
Adenosquamous carcinoma
Sarcomatoid (spindle cell) carcinoma
Mixed squamous cell carcinoma
HPV-Related Squamous Cell Carcinoma
Basaloid squamous cell carcinoma
Papillary-basaloid carcinoma
Warty carcinoma
Warty-basaloid carcinoma
Clear cell squamous carcinoma
Lymphoepithelioma-like carcinoma
Others

HPV, Human papillomavirus.

driven recommendations. *Histopathology*, 2018;72(6):893–904, In Kumar V, et al. *Robbins & Cotran Pathologic basis of disease*, 10th ed, 2021.

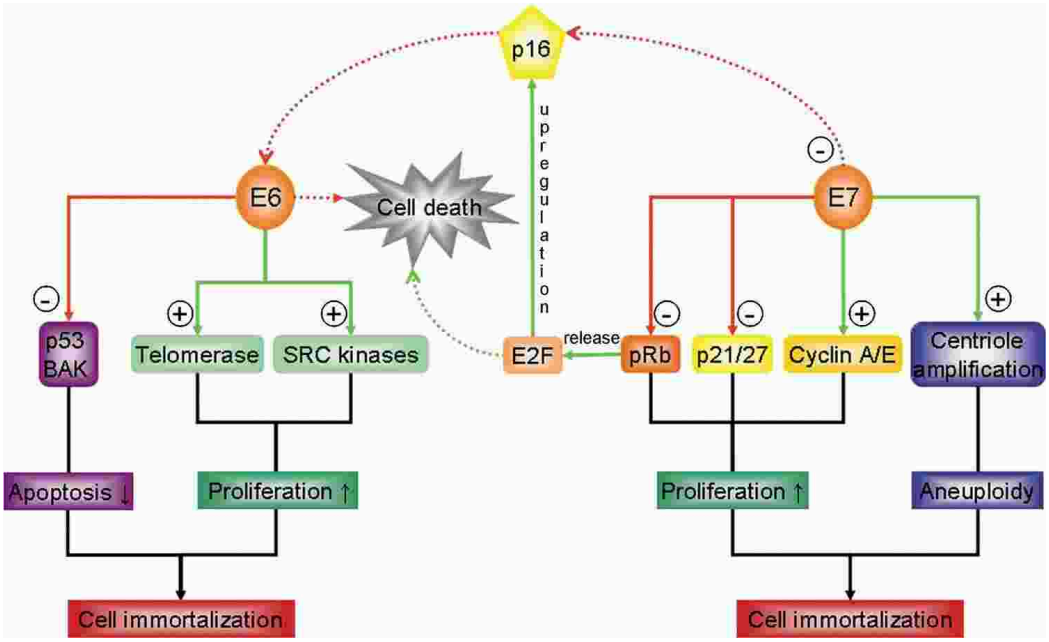

FIG. 26.6 Molecular Pathogenesis in HPV-Associated Penile Carcinogenesis.
HPV E6 and E7 oncoproteins interact with cellular pathways and induce cell immortalization. E6 activates telomerase and proto-oncogene tyrosine-protein kinase (SRC kinases) and inhibits p53 and BAK. E7 inhibits the tumor suppressor protein pRb, which causes the release of the E2F transcription factor, allowing E2F to interact with the cellular transcription machinery and stimulate upregulation of the tumor suppressor gene *(CDKN2A)*, which encodes the protein p16 ^{INK4a} (p16). pRb inactivation releases p16 from its negative feedback control, causing a paradoxical increase in the levels of this protein. This attempts to inhibit uncontrolled cellular replication. More simply, p16 is overexpressed in HPV-related tumors in an unsuccessful attempt to stop cell proliferation. E7 stimulates cyclin A and cyclin E; inactivates cyclin-dependent kinase inhibitors p21 and p27, which help to regulate cell cycle control (see Chapter 1); and induces centriole

amplification, leading to excessive cell proliferation and aneuploidy. BAK, BCL-2 homologous antagonist/killer; *CDKN2A*, cyclin-dependent kinase inhibitor 2A. (From Boulet G, Horvath C, Vanden Broeck D, et al. Human papillomavirus: E6 and E7 oncogenes. *Int J Biochem Cell Biol*. 2007;39(11):2006–2011.)

An illustration depicts the schematic representation of H P V-related biological pathway leading to penile carcinogenesis. The pathway is given as follows. â€¢ E 6 activates telomerase and S R C kinases and inhibits P 53 and B A K. â€¢ E 7 inhibits P R b which releases E 2 F transcription. E 2 F stimulates upregulation and encodes P 16. â€¢ E 7 activates cyclin A and E which induces centriole amplification and inhibits the P 21 and P 27. â€¢ Induced centriole amplification leads to Aneuploidy and proliferation causing cell immortalization. â€¢ Inactivated P 53 and B A K lead to apoptosis and the activated S R C kinases and telomerase lead to proliferation causing cell immortalization.

Clinical Manifestations

Clinical appearance of penile cancer is presented in Fig. 26.7. Because of decreased public awareness and embarrassment or shame, the majority of penile cancers have a delayed presentation but are clinically apparent.[75] The anatomical location on the penis and the exophytic appearance are distinct features. Tumor location typically arises on the mucosal surfaces of the penis, and in a review of 2000

cases, the tumor was mainly on the glans (35% to 48%) or inner prepuce (13% to 21%), with a small percentage on the penile shaft (2%).[76,77] The lesions are mainly painless and if under a phimotic foreskin, can be associated with a purulent discharge.[78] Ulcerative lesions have a wider differential diagnosis than exophytic lesions and are not diagnosed until histologically proven on either an incisional or punch biopsy for larger and glandular lesions or excisional biopsy for foreskin lesions.[65]

Evaluation and Treatment

Currently, there is no dedicated screening program for PSCC.[65] Clinical examination assesses the lesion size, location (glans, shaft, or foreskin), and morphology (papillary, nodular, ulcerating, fungating, or flat).[65] Clinically obvious are tumors of the penis with exophytic lesions. The majority of tumors are squamous cell carcinomas (SCCs 95%) which are predicted on appearance and location.[65] Diagnostic problems arise when the cancer is occluded under the foreskin or originates from the within the distal urethra. Even when it is very visible, small cancers or low-grade disease may be difficult to differentiate from benign genital dermatoses.[79]

Imaging is essential for cancer staging, surgical planning, and identification of skip lesions within the corpora cavernosa.[65]Penile ultrasound and MRI are the preferred types of imaging for the primary lesion.[65] Cross-sectional imaging such as CT allows disease staging at diagnosis and identification of abnormal inguinal or lymphadenopathy and distant metastatic disease.[65] The diagnostic pathway confirms the histological subtype, extent of invasion, and metastatic disease to regional or distant lymph nodes.[65] Palpation of the glans and penile shaft is associated with the extent of invasion into the corpus spongiosum or corpus cavernosum.[80] These data enable surgical planning, including the requirement for either a glansectomy or partial penectomy.[65] Generally, a diagnostic biopsy is mandatory in the management of solid tumors. With palpable inguinal lymph nodes, fine needle aspiration (FNA) confirming PSCC within the lymph nodes negates the need for a penile biopsy in

the presence of a clinically obvious PSCC. The results would not change the treatment decision-making for an individual with metastatic disease.[65] Most invasive lesions located on the prepuce or glans can be excised using penis-preserving procedures.

In the United States, the 5-year survival rate for penile cancer that has not spread after initial diagnosis is 80%.[81] In the United Kingdom, about 40% of men are diagnosed with localized penile cancer, which has a 5-year overall survival rate of approximately 90%; however, with metastases the prognosis worsens considerably.[65,82] Importantly, the overall prognosis has not improved in Europe and in the US since 1990. This may be due to late-stage initial diagnosis and limited improvements in care and management.[65,83]

Disorders of the Scrotum, Testis, and Epididymis

Disorders of the Scrotum

Men may seek treatment for painful or painless scrotal masses. Masses may be serious (cancer or torsion) or benign (hydrocele or cyst) and may require immediate surgical intervention or allow for careful observation. Varicocele, hydrocele, and spermatocele are common intrascrotal disorders. **Varicoceles** are dilated tortuous veins of the pampiniform plexus, the venous sinuses that drain the testicles (Fig. 26.8). Although usually painless, varicoceles are clinically significant because they are the most identified cause of abnormal semen analysis, low sperm count, decreased sperm motility, and altered sperm morphology.[84] The right internal spermatic vein terminates directly into the low-pressure inferior vena cava. On the left side, it joins with the somewhat high-pressure left renal vein, thus explaining why most clinically detectable varicoceles are on the left side.[85]Varicocele occurs in 15% to 20% of males and in about 40% of infertile males.[85] It is unclear how a varicocele disrupts the production, structure, and function of sperm, but there are several theories since the association of varicocele with infertility is well known.[85] Varicoceles are classified as small, medium, and large.

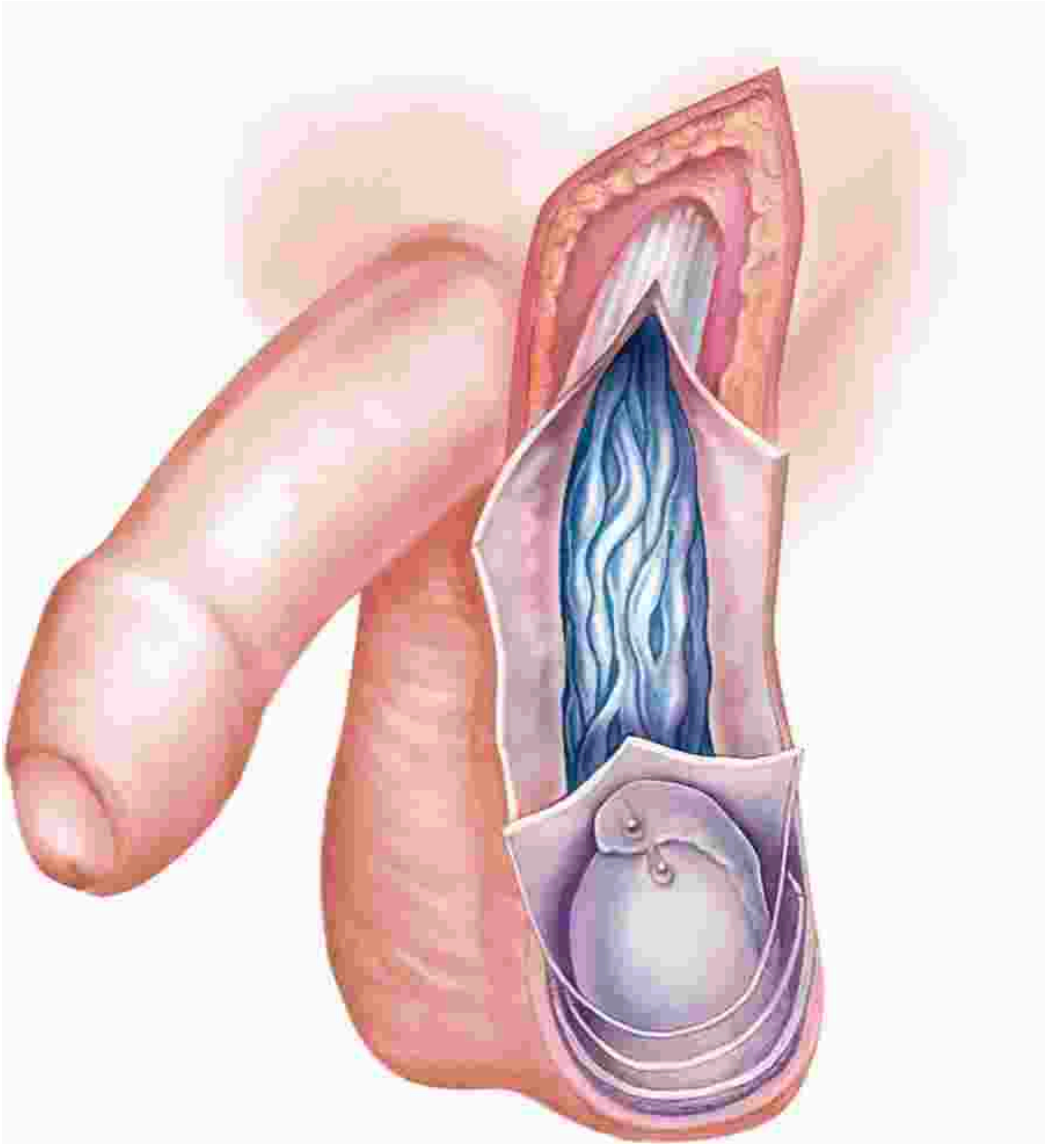

FIG. 26.8 Varicocele.
Dilation of veins within the spermatic cord. (From Ball JW, et al. *Seidel's guide to physical examination*, 8th edition. St. Louis: Mosby; 2015.)

The cause of varicocele is unknown. One hypothesis is that it develops from a backup of blood flow in the internal spermatic vein that causes venous engorgement and is detectable on scrotal examination.[86,87] Varicoceles are more common in the left testicle (80% to 90%), but if it is identified in the left testicle, there is a 30% to 40% probability that it is a bilateral condition.[85] Rare causes of

varicocele include deep vein thrombosis, renal arteriovenous malformations, and thrombosis of the pampiniform plexus.[85] Risk factors that increase the risk of male infertility include tobacco smoking and mutations in the gene glutathione S-transferase Mu1, which also may increase the risk for a varicocele.[85]

Pathophysiology and Clinical Manifestations

The main concern with a varicocele is infertility. Many men with varicoceles are fertile; however, others may have sperm that is compromised in structure and function, numbers, or motility.[85] The most accepted theory for sperm impairment is that increased blood flow leads to higher intratesticular temperatures.[88]

Progression from untreated varicoceles does not usually cause pain, although there are exceptions. **Orchialgia** or chronic testicular pain, when associated with varicoceles, is described as aching, dull, or throbbing and rarely can be acute, stabbing, or sharp.[89] Large varicoceles may cause testicular failure and result in lower hormonal production, oligospermia, and testicular atrophy.[83] Nuclear DNA integrity may be altered which links to sperm motility, viability, counts, and abnormal structure.[90] Varicoceles can cause a reduction in testosterone production in the testes by the Leydig cells.[85]

Evaluation and Treatment

After a complete history and physical examination, the varicocele is confirmed with high-resolution color-flow Doppler ultrasound.[85] Thermal imaging, another non-invasive and painless non-contact method, may also be used for evaluation.[91–93] A stress pattern is an abnormal semen analysis from a microscopic exam and includes a low sperm count, poor motility, and an increase in the percentage of abnormal sperm.[85] A possibility for a right-sided varicocele is renal cell carcinoma. A right-sided renal vein thrombus can expand into the vena cava forming venous obstruction causing spermatic vein obstruction and a right-sided varicocele. In this case, CT imaging is recommended.[94]

There are no effective medical treatments. Varicocelectomy improves the serum testosterone level in greater than 80% of individuals, with a mean increase between 100 and 140 ng/mL, and therefore may be a viable surgical option to permanently treat low testosterone levels in hypogonadal men with significant varicoceles.[85] Surgery is usually done as an outpatient procedure. Avoidance of the vas deferens and the testicular artery during surgery is mandatory.[95–98]

Percutaneous embolization from interventional radiology is usually reserved for open surgical failures or recurrences.[85] The process involves a catheter from the femoral vein, up the vena cava, laterally into the left renal vein and then inferiorly into the spermatic vein. An 89% success rate is reported with this approach.[85]

Identification of small anastomosing vessels is a strength of the microsurgical techniques.[85] This technique also permits better identification of the testicular artery, thus minimizing its unintentional injury.[85] Some pediatric urologists prefer a retroperitoneal, laparoscopic approach which allows for control of the spermatic vein near its insertion into a left renal vein; however, this technique has a fairly high recurrence rate of 15%.[85]

Complications include hematoma, hydrocele, infection, scrotal tissue injury, and arterial injury to the testis that may cause the loss of the testicle.[85] It is not clear which procedure improves male fertility more.[85] After surgery about 70% of individuals have improved semen factors and 40% to 60% have improved conception rates.[85] Surgery for infertility is not recommended for subclinical varicoceles by most experts because it typically does not affect fertility or sperm factors.[85,99] Recently, the use of intraoperative indocyanine green angiography has been used to help identify the testicular artery during dissection.[100]

A **hydrocele** is an abnormal collection of fluid between the layers of **tunica vaginalis** of testis (Fig. 26.9).[101] Accumulation of fluid can cause great enlargement of the scrotal sac. Hydroceles can be either congenital or acquired. **Acquired hydrocele (secondary)** occurs from

an underlying condition including infection **(**filariasis, tuberculosis of the epididymis, syphilis), injury (trauma, post-herniorrhaphy hydrocele), or malignancy.[102] In children the main cause of hydrocele is patency of **processus vaginalis** (embryonic pouch of peritoneum carried into the scrotum by the descent of the testicle; in the scrotum forms the tunica vaginalis). At birth, approximately, 80% to 90% of term male infants possess a patent processus vaginalis, and this figure declines to about 25% to 40% at two years of age.[102]

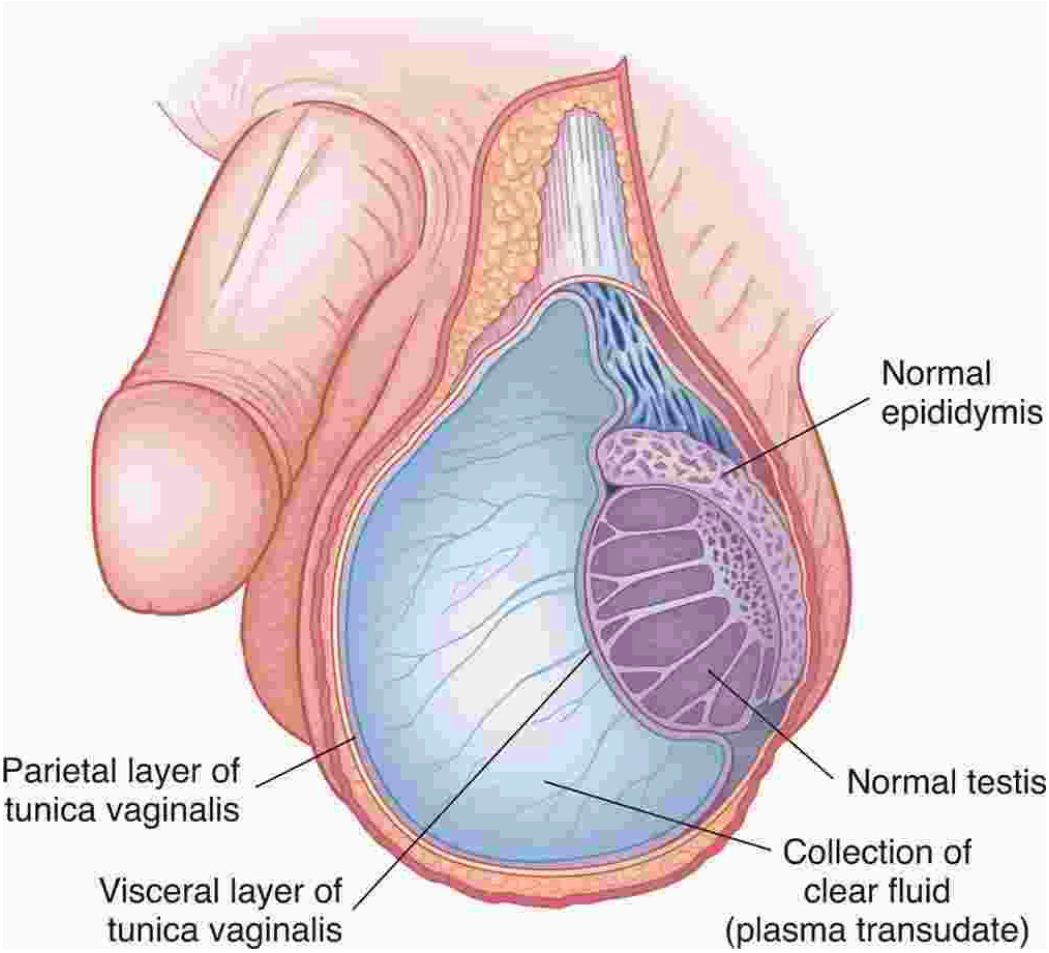

FIG. 26.9 Hydrocele.
Accumulation of clear fluid between the visceral (inner) and parietal (outer) layers of the tunica vaginalis.

An illustration depicts the cutaway section of the spermatic cord with a fluid-filled sac around a testicle and the labels indicating normal epididymis, normal testis, collection of clear fluid or plasma transudate, parietal layer of tunica vaginalis, visceral layer of tunica vaginalis.

Worldwide the cause in adults is filariasis (*Wuchereria* bancrofti), affecting 120 million people in more than 73 countries.[102,103] Iatrogenic causes are either trauma or post-herniorrhaphy complications.[102]

Hydroceles vary in size, and most are asymptomatic. The most important feature on physical examination is a tense, smooth scrotal mass that easily transilluminates. Transillumination, or holding a light behind the scrotum, can help distinguish a hydrocele from a hernia or a solid mass. Surgery is the treatment of choice and is warranted when the hydrocele becomes complicated or symptomatic.[102] A man presenting with a hydrocele in his third or fourth decade needs careful evaluation for testicular cancer.

Spermatoceles (epididymal cysts) are benign cystic collections of fluid of the epididymis located between the head of the epididymis and the testis. Spermatoceles are filled with a milky fluid containing sperm and are usually painless (Fig. 26.10). Spermatoceles that cause significant pain or discomfort are excised. Both spermatoceles and epididymal cysts present clinically as discrete, firm, freely mobile masses distinct from the testis that may be transilluminated.[104,105] Usually, however, spermatoceles are asymptomatic or produce mild discomfort that is relieved by scrotal support.

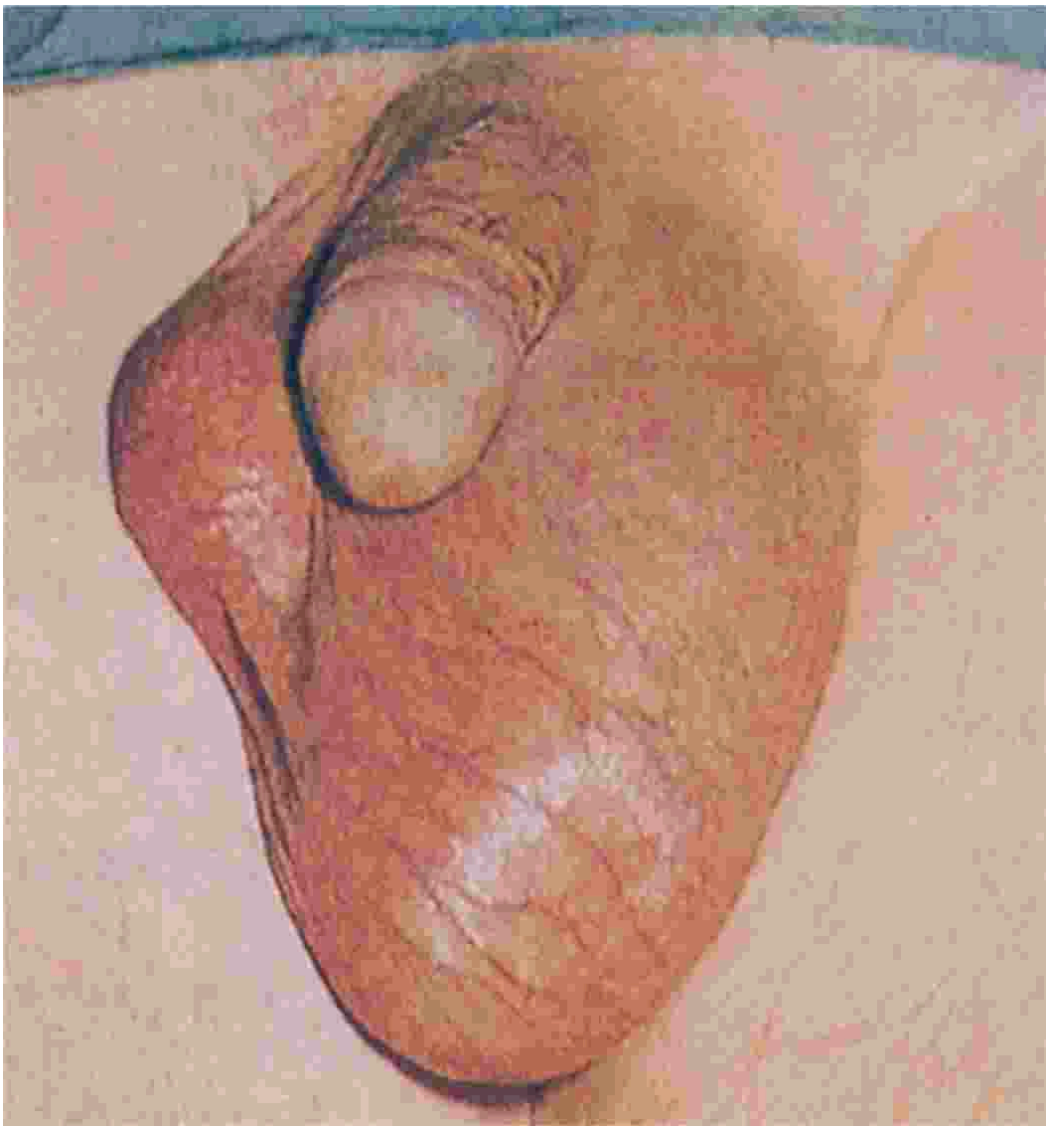

FIG. 26.10 Spermatocele.
Retention cyst of the head of the epididymis or of an aberrant tubule or tubules of the rete testis. The spermatocele lies outside the tunica vaginalis; therefore, on palpation it can be readily distinguished and separated from the testis. (From Lloyd-Davies RW et al. *Color atlas of urology*, 2nd edition. London: Wolfe Medical; 1994.)

Cryptorchidism

Cryptorchidism is the absence of at least one testicle from the scrotum. It is the most common birth defect of the male genitalia.[106] The testicle may be in several locations along the "path of descent," such as high in the retroperitoneal abdomen to the inguinal ring, in the inguinal canal, ectopic from the path of descent, hypoplastic, dysgenetic, absent, or unilateral (two-thirds). About 80% of cryptorchid testes descend by the third month making the incidence approximately 1%. About 3% of full-term and 30% of premature male infants are born with one or both testicles undescended.[107] Cryptorchidism may occur on both sides but is more common with the right testicle.[106] Undescended testicles are associated with decreased fertility in bilateral cases, and in up to 10% in unilateral cases, increased germ cell tumors (risk <1%), testicular torsion, inguinal hernias, and certain psychological problems.[106] Without surgical correction, an undescended testicle often descends during the first three months of life.[106]**Testicular dysgenesis syndrome (TDS)** includes cryptorchidism, hypospadias, testicular cancer, and poor semen quality. TDS is thought to be due to harmful environmental factors that interfere with embryonal programming and gonadal development during fetal life (Fig. 26.11).[108]

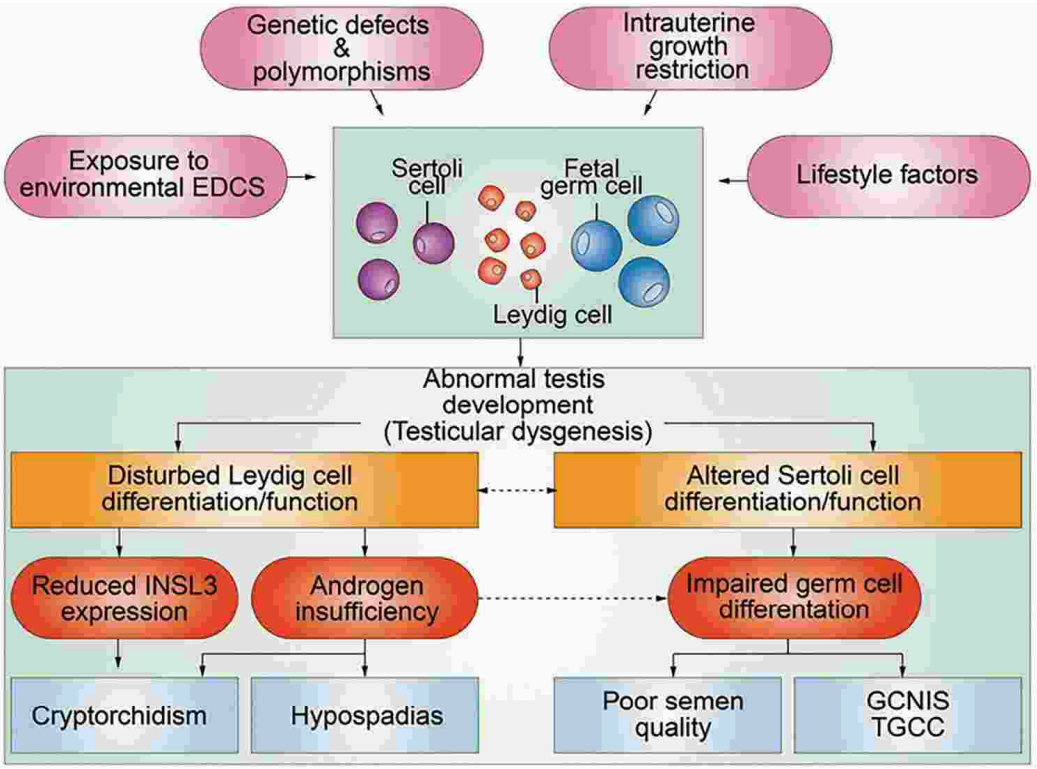

FIG. 26.11 Testicular Dysgenesis Syndrome. Working model of testicular dysgenesis syndrome (TDS) development may involve the following four key aspects: environmental exposure, genetic factors, intrauterine growth disorders, and lifestyle factors. These factors contribute to abnormal testis development which involve disturbed Leydig cell differentiation and altered Sertoli cell differentiation. Disturbed Leydig cell differentiation reduces insulin-like factor 3 (INSL3) and results in androgen insufficiency and altered Sertoli cell differentiation which leads to impaired germ cell function. *EDCS*, Endocrine-disrupting chemicals; *GCNIS*, germ cell neoplasia in situ; *TGCC*, testicular germ cell cancer. (From Xing J-S, Bai Z-M. Is testicular dysgenesis syndrome a genetic, endocrine, or environmental disease, or an unexplained reproductive disorder? *Life Sci*. 2018;194:120–129.)

A flowchart represents the working model of testicular dysgenesis syndrome. The chart begins as follows. â€¢ Four factors such as exposure to environmental E D C S, genetic defects and polymorphisms, intrauterine growth restriction, and lifestyle factors causes change in Sertoli cell, fetal germ cell, Leydig cell leading to abnormal testis development or testicular dysgenesis. â€¢ The abnormal testis development involves in disturbed Leydig cell differentiation or function and altered Sertoli cell differentiation or function. â€¢ Disturbed Leydig cell differentiation or function leads to reduced I N S L 3 expression and androgen insufficiency. Reduced I N S L 3 expression causes cryptorchidism and androgen insufficiency causes cryptorchidism and hypospadias. â€¢ Altered Sertoli cell differentiation or function leads to impaired germ cell differentiation causing poor semen quality and G C N I S T G C C.

Normal testicular descent depends on a normal hypothalamic-pituitary-gonadal axis. The main risk factor for undescended testes is birthweight followed by family history.[106] Typically, in full-term infants, the cause of cryptorchidism cannot be determined, making this a common, though sporadic, unknown birth defect.[106] Overall, genetics with maternal and environmental factors may disrupt hormones and physical changes that affect testicular development and descent. See Box 26.6 for other underlying risk factors.[106,107,109] Cryptorchidism occurs in about 1.5% to 4% of fathers and 6% of

brothers of those affected. Heritability in first-degree male relatives is estimated at 0.5% to 1%.[106] For unknown reasons there is an association between cryptorchidism and autism. Cryptorchidism and neurodevelopmental disorders may have shared genetic or in utero/early postnatal risk factors, which need much more investigation.[110]

Box 26.6

Risk Factors for Cryptorchidism

- Premature infants born before the descent of the testicles
- Small for gestational age infants
- Smaller placental weight
- Chemical endocrine disruptors may interfere with normal fetal hormone balance
- Maternal obesity
- Maternal diabetes
- Maternal exposure to Diethylstilbestrol (DES)
- Pesticides
- Alcohol consumption during pregnancy (5 or more drinks per week, 3x increase)
- Cigarette smoking
- Family history
- Cosmetics use
- Exposure to phthalate (DEHP)
- Ibuprofen
- Preeclampsia (The more severe the preeclampsia, the greater the risk of cryptorchidism)
- Congenital malformation syndromes—Down syndrome, Prader–Willi syndrome, and Noonan syndrome
- Persistent Mullerian Duct Syndrome

- In vitro fertilization

Data from Wray A, Velasquez J. *Balanitis*. StatPearls [Internet]. Treasure Island, FL: StatPearls; 2020.

Pathophysiology and Clinical Manifestations

One mechanism for the reduced function of cryptorchid testes is temperature. Additionally, it is probable that hormone deficiencies may result in lack of testicular descent and impair the development of spermatogenic tissue.[111] Men with undescended testes may have reduced fertility even after orchiopexy (surgery to move an undescended testicle).[112] Risk of testicular cancer if orchiopexy is done before puberty is about 3 times that of the general population.[106] The risk is 5 to 6 times higher when orchiopexy is done after puberty.[106]

Evaluation and Treatment

AUA guidelines indicate that experienced providers can palpate more than 70% of cryptorchid testes by physical examination and need no imaging.[106] The challenge in the other 30% of cases, with a nonpalpable testis, is to "confirm absence or presence of the testis and to identify the location of the viable nonpalpable testis."[106] Ultrasound can be used but has a sensitivity and specificity at 45% and 78%, respectively.[106] CT is not recommended because of the ionizing radiation exposure and expense.[106] MRI is more widely used and has greater sensitivity and specificity.[106] Presently, there is no radiological test that can conclude, with 100% accuracy and reliability, that a testis is absent.[113]

A genetic karyotype can confirm or rule out dysgenetic primary hypogonadism.[106] Certain hormone tests, such as gonadotropins and anti-mullerian (AMH) may confirm functional testicles, as well as stimulation with human chorionic gonadotropin (HCG) to provoke a rise in the testosterone level.[106] Further testing may be important in some cases with the likelihood of detecting intersex conditions.[112]

Hormonal therapy is not recommended by the AUA guidelines to induce testicular descent.[112] However, the American Pediatric Association Guidelines do recommend the use of hormones for those with undescended testis associated with Prader-Willi syndrome.[112] The rationale is that a therapeutic trial of HCG is indicated for treatment of undescended testes before surgery, because infants with low muscle tone who are at high risk for underlying respiratory compromise should avoid general anesthesia.[112]

According to AUA guidelines, surgery is recommended for congenital undescended testes between the ages of 6 and 18 months.[106] Many experts recommend surgery, around 6 months to optimize testicular growth and fertility. For premature babies, corrected age is used to determine surgery timing. Germ loss increases and fertility decreases the longer the cryptorchid testis remains untreated. Thus, early orchidopexy is the usual, standard remedy.[114]

Individuals with bilateral undescended testes who receive orchidopexies as adults are usually infertile and azoospermic (complete absence of sperm from the fluid ejaculated during orgasm).[115] For both acquired (testis documented normal before diagnosis) and entrapped (after hernia repair) undescended testes, surgery is recommended shortly after diagnosis. With retractile testes, a yearly physical examination is recommended because of the 2% to 50% reported risk of a retractile testis becoming an acquired undescended testis.[106] In those with a history of cryptorchidism and treatment, testicular cancer risk and infertility remains somewhat increased compared to the general population.[116]

Testicular Torsion and Testicular Appendages

Testicular torsion occurs when a testicle rotates twisting the spermatic cord and interrupting its blood supply (Fig. 26.12). In most individuals the testicle rotates between 90 and 180 degrees; complete torsion is rare and can quickly decrease viability of the testicle. Torsion of the testis is one of several conditions that cause an **acute**

scrotum, which is testicular pain and swelling. The testicle will become tender, swollen, and erythematous. It is a urologic emergency. Differentiation between testicular torsion and two other common causes of an acute scrotum is based on physical examination and history (Table 26.4).[117]

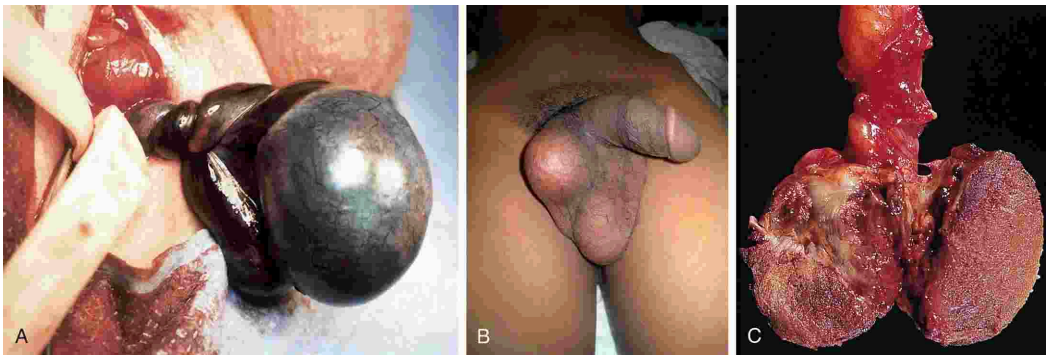

FIG. 26.12 Torsion of the Testis.
(A) Left testicular torsion in an adolescent with acute scrotum; the testis is necrotic. (B) Late phase torsion in an adolescent with severe testicular pain 1 month previously. Note the absence of inflammation and the high position of the testis in the scrotum. (C) The testes appear dark red and partially necrotic owing to hemorrhagic infarction. (A and B, From Kliegman RM et al. *Nelson's textbook of pediatrics*, 19th edition. Philadelphia: Saunders; 2011. C, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

A. A close shot of a black tarry testis B. Close shot of penis with left testes positioned higher than the right testes at an unusual angle. The left testes demonstrate a small, hard lump. C. Close shot of gross appearance of testes with hemorrhagic infarction.

Table 26.4

Diagnosis of Selected Conditions Responsible for the Acute Scrotum

Condition	Onset of Symptoms	Age	Tenderness	Urinalysis	Cremasteric Reflex	Treatment
Testicular torsion	Acute	Early puberty	Diffuse	Negative	Negative	Surgical exploration
Appendiceal torsion	Subacute	Prepubertal	Localized to upper pole	Negative	Positive	Bed rest and scrotal elevation
Epididymitis	Insidious	Adolescence	Epididymal	Positive or negative	Positive	Antibiotics

Condition	Onset of Symptoms	Age	Tenderness	Urinalysis	Cremasteric Reflex	Treatment
Testicular torsion	Acute	Early puberty	Diffuse	Negative	Negative	Surgical exploration
Appendiceal torsion	Subacute	Prepubertal	Localized to upper pole	Negative	Positive	Bed rest and scrotal elevation
Epididymitis	Insidious	Adolescence	Epididymal	Positive or negative	Positive	Antibiotics

Testicular torsion can occur at any age, including pre- or perinatal, but is most common in adolescents (during periods of growth).[118] It often presents as an abrupt onset of unilateral scrotal pain which may be constant, intermittent, but not positional.[118] The individual may have nausea or vomiting. There may be associated lower abdominal and inguinal pain, and these symptoms may be the presenting complaint rather than scrotal pain.[118] To help with diagnosis, the cremasteric reflex and the Prehn sign are not as reliable as once thought.[118] However, the TWIST scoring system is often used to help diagnose testicular torsion and includes hard testis (2 points), swelling (2 points), nausea/vomiting (1 point), absent cremasteric reflex (1 point), and high riding testis (1 Point). The higher the score, the higher probability of torsion. Ultrasound is recommended for those individuals with a low score.[118] Ultrasound is the primary diagnostic method, and color flow Doppler is used to evaluate both venous and arterial flow.[118] If urological intervention is not immediately available manual detorsion is done. Typically, the window for surgical intervention and testicular salvage is 6 hours from the onset of pain.[118]

Testicular appendages include the appendix testis (a remnant of the müllerian duct) and the appendix epididymis (a remnant of the wolffian duct). Torsion of the appendages is more common than testicular torsion and not as critical. During early-onset, severe tenderness is noted with palpation near the head of the epididymis or testis, palpation of an isolated tender nodule, and/or visualizing a blue dot appearance on the testis. All of these characteristics aid in differentiating torsion of the appendages from testicular torsion. The blue dot is due to the cyanotic torsed appendage.[118] The testicular appendage tends to calcify and degenerate over two weeks, and usually surgical treatment is not required.[118]

Orchitis

Orchitis is an acute inflammation of the testis and is usually unilateral (Fig. 26.13). On presentation, it can be acute and symptomatic, or asymptomatic and chronic.[119] Isolated orchitis is rare and usually accompanied by an infection of the epididymis.[120]Box 26.7 presents the various bacteria and viruses that cause orchitis. It develops in 14% to 35% of post-pubertal individuals with mumps.[120]Pathophysiology. There are two differences between orchitis and other infections of the male accessory sex organs: (1) the primary route of infection to the testis is blood-borne dissemination,[121] and (2) viruses are the significant infecting microorganisms.[120] Mumps virus is responsible for most of the cases of isolated orchitis. Common risk factors include a preexisting history of epididymitis, unprotected sexual contact, multiple sexual partners, long-term use of a urinary catheter, bladder outlet obstruction (BOO), and lack of immunization with measles, mumps, and rubella (MMR) vaccination (vaccination reduces the risk after mumps)[122]; however, cases of orchitis have been reported after receiving the MMR vaccine.[123]

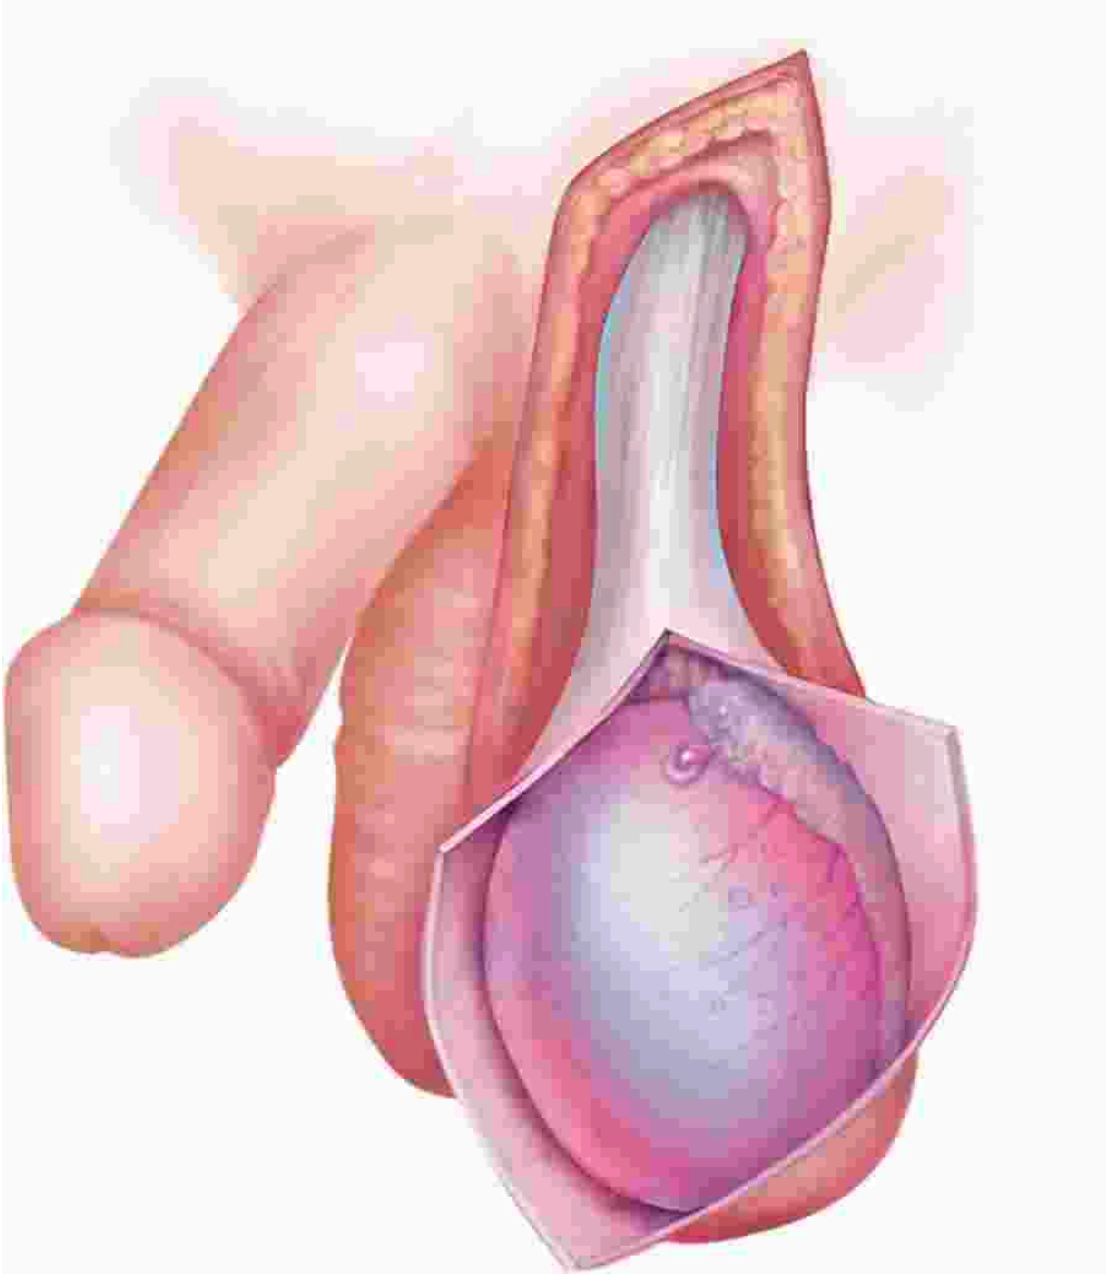

FIG. 26.13 **Orchitis.** (From Ball JW et al. *Seidel's guide to physical examination*, 8th edition. St. Louis: Mosby; 2015.)

Box 26.7

Bacteria and Viruses That Cause Orchitis

- In young individuals orchitis is usually viral; mumps and rubella are most common
- Other viruses include coxsackievirus, varicella, echovirus, and cytomegalovirus

- Bacterial origins include *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Staphylococcus* and *Streptococcus* species
- In sexually active males common bacteria are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Treponema pallidum*
- In immunocompromised males causes of orchitis are *Mycobacterium avium* complex, *Cryptococcus neoformans*, *Toxoplasma gondii*, *Haemophilus parainfluenzae*, and *Candida albican*.

Clinical Manifestations. The individual usually presents with acute onset of testicular pain, which initially involves one testis, and may spread to the entire scrotum. Other symptoms may include fever, malaise, fatigue, and chills.[120] Physical examination findings may include testicular enlargement, scrotal edema, tenderness, induration, and possibly erythema.[120] If orchitis is accompanied by epididymitis, the epididymis may be enlarged. Cremasteric reflex is normal in affected individuals. Mumps orchitis may also present with parotid enlargement, which is usually present 4 to 8 days after onset of parotitis.[120]

Evaluation and Treatment. Laboratory blood tests are generally not helpful but urethral swabs and urine samples are routinely obtained, as are cultures to rule out UTI and diagnose any STIs.[120] Healthcare providers must distinguish between torsion and inflammation of the testis when individuals present in the emergency department.[120] Antibiotics are not used for viral causes. Supportive therapies include bed rest, antipyretics, analgesics, scrotal support, and hot or cold packs for analgesics.[120] Bacterial infections are treated with antibiotics. STIs are treated according to CDC guidelines (see Chapter 27). Sexual partners of those with an STI should receive treatment.

Cancer of the Testis

Testicular cancer is the most common solid malignancy in young adult men, and its incidence in the last two decades has risen worldwide.[116,124,125] Testicular cancer accounts for approximately 1% of newly diagnosed cancer in men worldwide; it is the most common malignancy among men ages 14 and 44 years.[116]**Germ cell neoplasia in situ (GNIS**) is known as the precursor lesion to malignant **testicular germ cell tumors (TGCTs)**.[116,126] In western countries, the incidence of testicular cancer continues to increase with an estimated 9470 cases and 440 deaths in the United States in 2021.[124] Globally, the estimated incidence is 74,458 and 9334 estimated deaths.[127] In the United States, it is more common in white men (6.9 per 100,000 males) than in African Americans (1.2 per 100,000 males).[116] Despite the high incidences of testicular cancer in Europe, North America, Australia, and New Zealand, these areas account for only one-fifth of mortalities.[116] The highest mortality rates are reported in western Asia.[128] The most consistent risk factor for testicular cancer is cryptorchidism, which increases the risk almost fivefold.[116]

An important and causal pathway to cryptorchidism, hypospadias, low sperm count, and testicular cancer is disrupted signaling to endogenous hormones by prenatal xenobiotic exposure.[129,130] Emerging evidence suggests that postnatal environmental or lifestyle factors such as diet or environmental exposures to endocrine-disrupting chemicals influence testicular cancer development.[131] During the 20th century, populations of industrialized countries worldwide have experienced a decline in total fertility rates (TFR, average number of live births/woman). Simultaneously, a rise in testicular germ cell cancer (TGCC) has occurred globally.[132] Additionally, other male reproductive problems, several of which are linked to testicular cancer, including disorders of spermatogenesis, are widespread.[132] Therefore, investigators have proposed possible etiological roles of environmental, epigenetic, and genetic factors to account for these trends. The most common epidemiological risk factors, however, are summarized in Box 26.8.[133]

Box 26.8

Most Common Epidemiological Risk Factors Testicular Cancer

- Cryptorchidism
- Infections-HPV, EBV, CMV, Parvovirus B-19, and HIV
- Testicular trauma
- High maternal estrogen level
- Carcinoma in situ (intratubular germ cell neoplasia
- Prior history of testis cancer or extragonadal germ cell tumor
- Family history

HPV, Human papilloma virus; *EBV*, Epstein-Barr virus; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus.

Germ cell tumors were traditionally classified by histological composition. Another way for classification has also been the germ cell lineage and the age of onset of testicular cancer: pediatric, adolescent, or adult.[116] In 2016, the WHO published a classification system combining categories and defining the two major entities of TGCTs as GCNIS-related TGCTs and non-GNIS-related TGCTs (Box 26.9).[134,135]

Box 26.9

WHO Classification for Testicular Cancer

1. **Germ Cell Tumors**
    - Germ cell neoplasia in situ (GCNIS)
2. **Derived from Germ Cell Neoplasia in Situ (GCNIS)**
    - Seminoma
    - Embryonal carcinoma
    - Yolk sac tumor, post-pubertal type
    - Trophoblastic tumor
    - Teratoma, post-pubertal type
    - Teratoma with somatic-type malignancies
    - Mixed germ cell tumors
3. **Germ Cell Tumors Unrelated to GCNIS**
    - Spermatocytic tumor
    - Yolk sac tumor, pre-pubertal type
    - Mixed germ cell tumor, pre-pubertal type
4. **Sex Cord/Stromal Cell Tumors**
    - Leydig cell tumor
        Malignant Leydig cell tumor
    - Sertoli cell tumor
        Malignant Sertoli cell tumor
        Large cell calcifying Sertoli cell tumor
        Intratubular large cell hyalinizing Sertoli cell neoplasia
    - Granulosa cell tumor
        Adult type

Juvenile type
- Thecoma/fibroma group of tumors
- Other sex cord/gonadal stromal tumors
  Mixed
  Unclassified
- Tumors containing both germ cell and sex cord/gonadal stromal
  Gonadoblastoma

5. **Miscellaneous Non-specific Stromal Cell Tumors**
   - Ovarian epithelial tumors
   - Tumors of collecting ducts and rete testes
     Adenoma
     Carcinoma
   - Tumors of paratesticular structures
     Adenomatoid tumor
     Mesothelioma (epithelioid, biphasic)
     Epididymal tumors
   - Cystadenoma of the epididymis
   - Papillary cystadenoma
   - Adenocarcinoma of the epididymis
   - Mesenchymal tumors of the spermatic cord and the testicular adnexa

Data From Gaddam SJ, Chesnut GT. *Testicle cancer*. StatPearls[Internet]. Treasure Island, FL: StatPearls; 2021.

Pathophysiology

GCNIS is regarded as the precursor lesion to malignant testicular germ cell tumors (TGCTs).[116] Germ-cell tumors are observed secondary to a carcinogenic event in utero that results in an intratubular germ-cell neoplasia.[136] Intratubular germ-cell neoplasia is derived from gonocytes (cell that produces gametes) that have failed to differentiate into spermatogonia.[133,137] During puberty these cells attain invasive potential because of hormonal changes.[133] Seminomas are comprised of transformed germ cells that are blocked in their differentiation.[133] Embryonal carcinoma cells resemble undifferentiated stem cells, and their gene expression is like those of stem cells and intratubular germ-cell neoplasms.[138,139] Choriocarcinomas and yolk-sac tumors have extraembryonic (situated outside the embryo) differentiation, and teratomas have somatic differentiation.[133]

The origin of TGCT likely initiates in early embryogenesis and appears to be part of the TDS, where some early gonocytes are blocked in their differentiation. They are tightly regulated by epigenetic modifications (specific transcription factors discussed earlier) in terms of microRNA expression and DNA methylation retaining their early primordial germ cells (PGCs), or gonocyte changes progressing to testicular cancer.[140,141] Formation of different histologic subtypes may be associated with distinct gene expression through epigenetic regulation, including DNA methylation.[133,142]

Clinical Manifestations

Most men with testicular tumors present with a palpable lump that may or may not be painful (Fig. 26.14).[116] Rarely do they present with signs of metastatic disease such as cachexia, breathlessness, or hemoptysis.[116] Occurring gradually, it may be accompanied by a sensation of testicular heaviness or a dull ache in the lower abdomen. Sometimes, the testis is unable to be completely palpated because of the presence of a hydrocele. Uncommonly, individuals present with manifestations of metastatic disease (Box 26.10).[133]

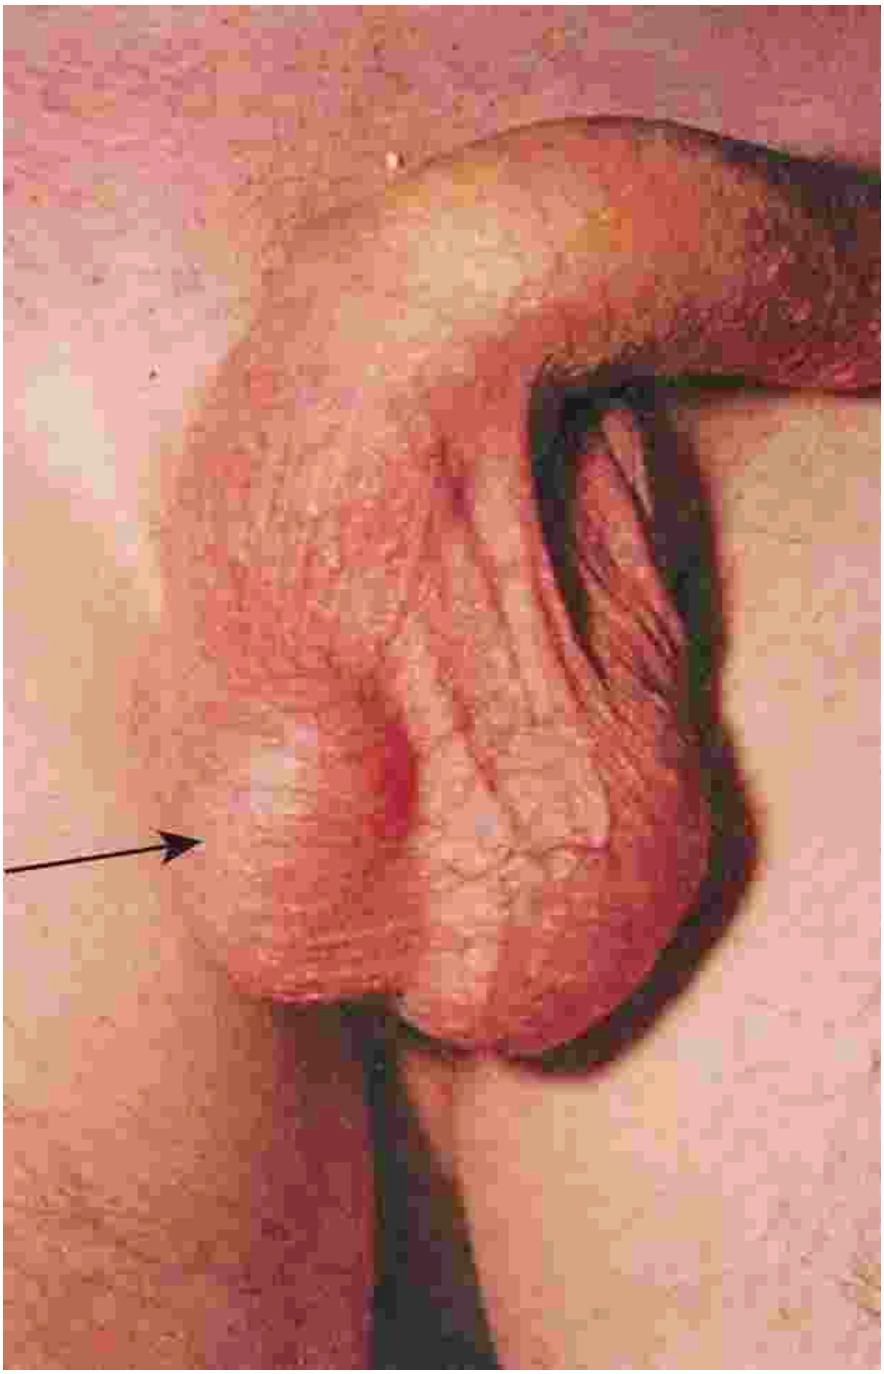

FIG. 26.14 **Testicular Tumor.** (From Wolfe J. 400 *Self-assessment picture tests in clinical medicine*. London: Wolfe Medical; 1984.)

Box 26.10

Manifestations of Metastatic Disease Testicular Cancer

- Systemic symptoms: weight loss, anorexia, malaise,

- Pulmonary metastasis: shortness of breath or cough
- Lymphatic metastasis: cervical or supraclavicular lymphadenopathy
- Retroperitoneal disease: bulky retroperitoneal disease can present as back pain or compression on the gonadal veins leading to findings of varicocele
- Vascular obstruction or thrombosis resulting in lower extremity edema
- Retroduodenal metastasis: nausea, vomiting, or gastrointestinal hemorrhage
- Central or peripheral nervous system metastasis: symptoms from the cerebral, spinal cord, or peripheral nerve root involvement.

Evaluation and Treatment

Evaluation begins with a thorough history, and careful physical examination, which generally will reveal a firm intratesticular lesion. Included are questions about the history of cryptorchidism, orchiopexy, or inguinal repair as an infant.[133] Questions include a family history of testicular cancer in father or brother. Unless proven otherwise, findings of any solid mass should be considered testicular cancer. The contralateral testis is examined because 0.6% of individuals have a synchronous contralateral testis tumor.[133] The primary imaging is with trans-scrotal ultrasound.[143–145] Ultrasound imaging, combined with physical examination for the diagnosis of testicular cancer, provides almost 100% sensitivity.[146] All individuals with TGCTs have further imaging with abdominopelvic CT scans. Additional scans are done in those with elevated serum tumor markers (AFP, α-fetoprotein; β-hCG, β-subunit of HCG; LDH, lactate dehydrogenase).[133] Further evaluation includes serum tumor markers (AFP, HCG, and LDH), which should be done before any intervention, including orchiectomy.[133] Many new immunohistochemical markers have been studied for diagnostic purposes. Counseling includes the possibility of infertility, testicular prosthesis if desired, and sperm banking with bilateral testicular pathology.[143,144] Persons should be referred to an oncology specialist for staging and treatment of cancer.

Epididymitis

Epididymitis is an inflammation of the epididymis testis, the tubular structure located on the posterior and superior part of the testis where sperm mature prior to ejaculation.[147] Testis proximity to the epididymis can cause the infection or inflammatory process to spread to the testis itself, which is known as **epididymo-orchitis**.[148] Epididymitis is the most common cause of acute scrotal pain in adults with more than 600,000 men in the Unites States affected yearly.[147] Most cases of epididymitis result from retrograde flow of urine, which commonly occurs in elderly males, and from STIs in males 20 to 40 years old (Fig. 26.15).[147] Approximately 50% of cases of sexually transmitted microorganisms in males less than 39 years old include *N. gonorrhoeae* or *C. trachomatis*. After 39 years of age, the most common etiologic agents are *Escherichia coli* and other coliform bacteria located in the gastrointestinal tract.[147]

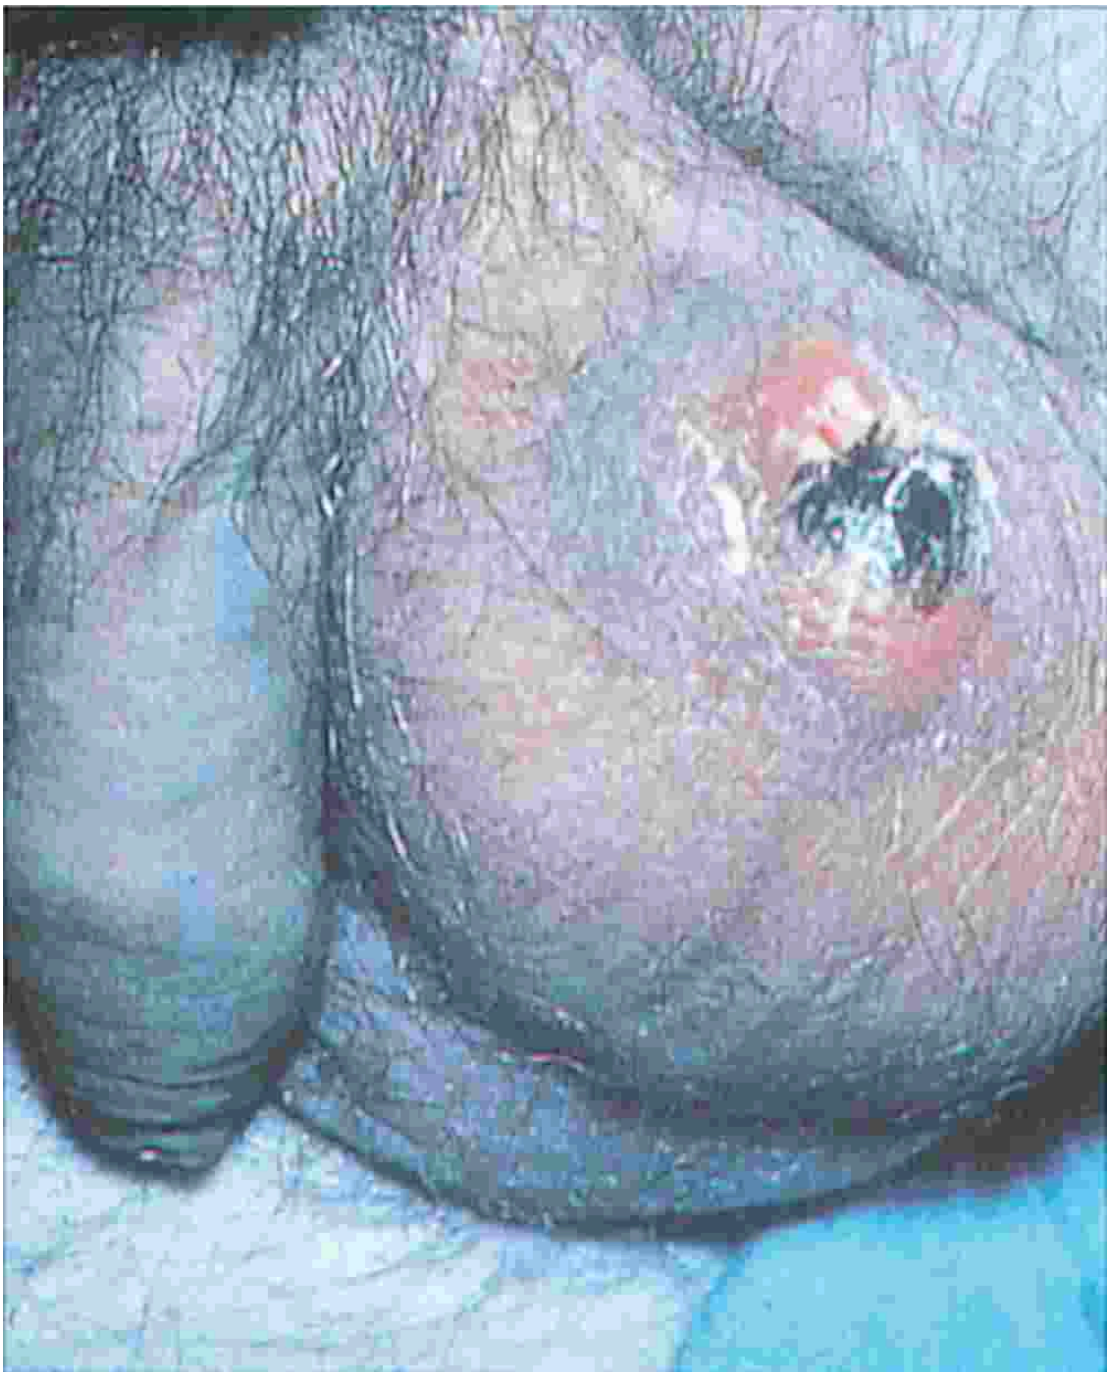

FIG. 26.15 Epididymitis Secondary to Gonorrhea or Nongonococcal Urethritis.
(This infection has spread to the testes, and rupture through the scrotal wall is threatened. (From Taylor PK. *Diagnostic picture tests in sexually transmitted disease*. London: Mosby; 1995.)

Pathophysiology

The main etiology of epididymitis is bacterial infection. Pathogens from STIs can be introduced during sexual intercourse and move through the genitourinary (GU) tract to the epididymis.[147]

Whereas, pathogens from UTIs cause epididymitis due to retrograde flow of urine or from stagnation of urine along the GU tract. Although rare, epididymitis may result from a chemical inflammation caused by the reflux of sterile urine into the ejaculatory ducts. Repetitive movement creating mobility of the scrotum can create inflammation of the testes or epididymis.[147] Young males prior to sexual maturity can develop epididymis as an inflammatory process from repetitive sports (e.g., jumping, running). Viral infection (e.g., mumps virus) can infect the testis resulting in epididymitis or epididymo-orchitis.[147] Chemical epididymitis can result from exercising or having sexual intercourse with a full bladder. Certain medications also can cause epididymitis, such as amiodarone used in the treatment of cardiac dysrhythmia.

Clinical Manifestations

The main symptom of epididymitis is scrotal or inguinal pain caused by inflammation of the epididymis and surrounding tissues. Onset of pain is gradual rather than acute.[147] Flank pain may occur if, as the urethra passes over the spermatic cord, edematous swelling of the cord then obstructs the urethra. The individual may have pyuria, bacteriuria, urinary frequency, urgency, or incontinence, and a history of urethral discharge. The scrotum on the involved side is erythematous and edematous. The tail of the epididymis, near the lower pole of the testis, usually swells first; swelling then ascends to the head of the epididymis. The spermatic cord also may be swollen and tender. Tender inguinal adenopathy may also be present.

Evaluation and Treatment

A careful history should focus on repetitive activities such as sports, complete sexual history including exposure to STIs, possibility of traumatic injury, and problems associated with GU tract, such as previous UTIs, prostatitis, or surgical procedures.[147] A physical exam will likely show swelling of the scrotum and palpation of the scrotum will reveal scrotal tenderness, usually unilaterally. The hallmark of epididymitis is tenderness upon palpation of the testis along the posterior and superior area.[147] Additionally, the tenderness may indicate epididymo-orchitis or orchitis. A urethral discharge may be demonstrated from physical exam of the penis.

Evaluation begins with a urinalysis; the presence of red blood cells and white blood cells, though nonspecific, may indicate an acute infectious or inflammatory condition. The definitive diagnosis is based on culture or Gram stain. A urethral swab is done where STI is considered after obtainment of the sexual history. Ultrasound can assess anatomy and vascular flow to the testis. It can demonstrate inflammation of the epididymis and testis in cases of epididymitis and epididymo-orchitis. It is critical to rule out the possibility of testicular torsion as a cause of scrotal pain. Pain from epididymitis is usually gradual; the pain of testicular torsion typically is very abrupt.[147]

Treatment includes antibiotic therapy for the infection itself. Improvement in pain and swelling occurs in many cases by using ice.[149–151] If the individual does not steadily improve, reevaluation is necessary within a few days for possible complications. The individual's sexual partner should be treated with antibiotics if the causative microorganism is a sexually transmitted pathogen.

Disorders of the Prostate Gland

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is nonmalignant growth or hyperplasia of prostate tissue (Fig. 26.16). It is not a premalignant lesion. BPH is a common cause of lower urinary tract symptoms (LUTS) and is the most common benign prostatic disease in men older than 50 years. Several definitions exist when describing BPH such as BOO, LUTS, and benign prostatic enlargement (BPE). BPH, the preferred term, is a histologic description (hyperplasia); BPE describes the increased size of the gland (typically secondary to BPH); and BOO describes the obstruction of flow.[152] Another term, benign prostatic obstruction, refers to those with BPE who present with

BOO.[153] With population aging, the incidence and prevalence of BPH and LUTS have increased rapidly.[154] Age is a significant predictor of both development of BPH and later LUTS, with 50% of men over the age of 50 having evidence of BPH and then development of LUTS, with a linear increase with age.[152] BPH prevalence in the United States is as high as 70% in those between 60 and 69 years of age and more than 80% in men over 70 years.[152]

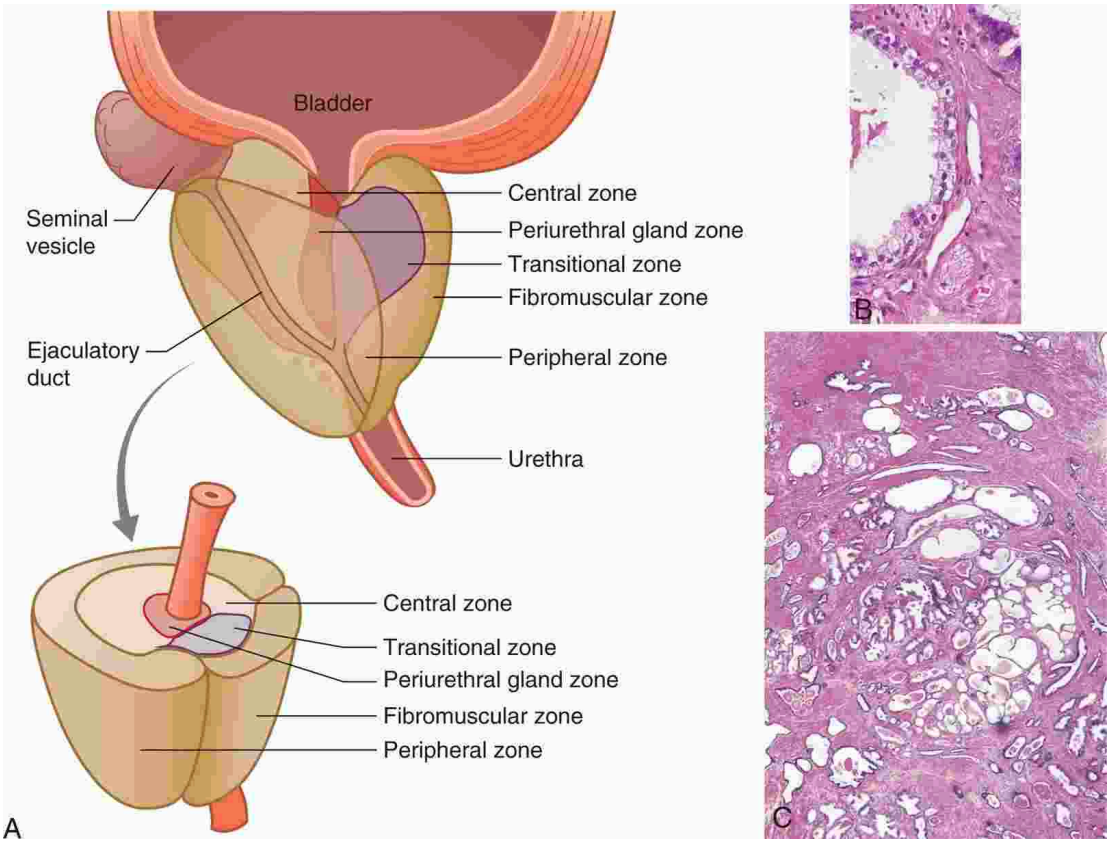

FIG. 26.16 Benign Prostatic Hypertrophy.
(A) The transitional zone is the principal site of benign prostatic hypertrophy (BPH). Size of the prostate gland remains stable until approximately 40 years of age, then hyperplasia of the gland develops. (B) Histological slides are presented of both a normal prostate and BPH tissue. (C) The BPH slide shows pleomorphism (stromal/epithelial ratio) and proliferation of the glandular epithelial cells. (From Chughtai B, Forde JC, Thomas DDM, et al. Benign prostatic hyperplasia. *Nat Rev Dis Primers*. 2016;2:16031. https://doi.org/10.1038/nrdp.2016.31)

A. An illustration depicts the structure of bladder and prostate with labels indicating the prostate zones clockwise from left. Seminal vesicle, central zone, periurethral gland zone, transitional zone, fibromuscular zone, peripheral zone, urethra and ejaculatory duct accompanied by the illustration of the cross-section of prostate with labels indicates the prostate zone from top to bottom. Central zone, transitional zone, periurethral gland zone, fibromuscular zone, and peripheral zone. B. Microscopic image represents the tissue of normal prostate which shows the infoldings of the columnar epithelium. C. Microscopic image represents the tissue of benign prostatic hypertrophy which shows the proliferated glandular epithelial cell.

Risk factors for BPH include increasing age, metabolic syndrome, diabetes, obesity, hypertension, diet, sex hormone levels, and genetic factors.[152,154] Metabolic syndrome includes

hypertension, glucose intolerance/insulin resistance, and dyslipidemia. Meta-analysis has shown those with metabolic syndrome and obesity have significantly higher prostate volume.[155] LUTS is associated with increased levels of glycated hemoglobin (HbA1c).[156] Observational studies have shown an associated risk of BPH with obesity.[157,158] Proposed mechanisms of these associations include increased levels of systemic inflammation and increased levels of estrogens.[159,160]

Pathophysiology

The cause of BPH is unknown.[161] Current causative theories for BPH focus on aging, the levels and ratios of endocrine factors (e.g., androgens and estrogens [androgen/estrogen ratio]), the role of chronic inflammation, and the effects of autocrine/paracrine growth-stimulating and growth-inhibiting factors (see Emerging Science Box: Benign Prostatic Hyperplasia). These factors may include insulin-like growth factors (IGFs), epidermal growth factor, nerve growth factor, fibroblast factors, IGF binding proteins, and transforming growth factor-beta (TGF-β).[162] Inflammation in men with BPH can be related to underlying metabolic syndrome and/or obesity (see Chapter 23).[152,154] Human prostate stromal cells can actively contribute to the inflammatory process from the induction of inflammatory cytokines and chemokines.

Emerging Science Box

Benign Prostatic Hyperplasia

Similar to prostate cancer, benign prostatic hyperplasia (BPH) occurs more often in Westernized countries (e.g., United States, United Kingdom, and Canada). BPH is the most common benign neoplasm of aging men and is present in approximately 8% of men in the fourth decade of life but up to 90% of men in the ninth decade. Overall, no clear patterns have emerged with risk of BPH and race. Being overweight or obese with central fat distribution (i.e., around the abdomen) increases the risk of developing BPH. Surgical procedures, including less invasive modalities, are generally indicated for failure of medical therapy, refractory urinary retention, recurrent urinary tract infection, persistent hematuria, bladder stones, or renal insufficiency.

Data from Langan RC. Benign prostatic hyperplasia. *Primary Care*, 2019;46:223–232.

Although androgens, such as dihydrotestosterone (DHT), are necessary for normal growth, their role in BPH remains unclear. With aging, circulating androgens are associated with BPH and prostate enlargement. Androgens are proposed as factors disrupting the *balance* of growth factor signaling pathways and stromal/epithelial interactions, creating a growth-promoting and tissue-remodeling microenvironment. However, BPH is a multifactorial disease, including lifestyle factors, and not all men respond well to currently available treatments, which suggests that factors other than androgens are involved.[163] For example, other effects related to estrogens include apoptosis, aromatase expression, and paracrine regulation that may be important for stimulating inflammation. The prostate is an estrogen target tissue, and estrogens directly and indirectly affect growth and differentiation of the prostate. Estrogens and selective estrogen receptor (ER) modulators have been shown to promote or inhibit prostate proliferation, signifying potential roles in BPH.[164] Testosterone, the primary circulating androgen in men, also can be metabolized through CYP19/aromatase into the potent estrogen, estradiol-17β. The precise role of endogenous and exogenous estrogens in directly affecting prostate growth and differentiation is an understudied area.

Increased levels of specific inflammatory mediators include IL-2, IL-4, IL-7, IL-17, IFN γ, and their appropriate receptors.[165–167] Chronic inflammation in BPH is associated with upregulation of COX2 in the glandular epithelium, generating pro-inflammatory prostaglandins which also cause

prostate cell proliferation.[168,169] The remodeled stroma promotes local inflammation with altered cytokine, reactive oxygen/nitrogen species, and chemoattractants. The resultant increased oxygen demands of proliferating cells cause a local hypoxia that induces angiogenesis and changes to fibroblasts.

BPH begins in the periurethral glands, which are the inner glands or layers of the prostate. The prostate enlarges as nodules form and grow (nodular hyperplasia), and glandular cells enlarge. The development of BPH occurs over a prolonged period, and changes within the urinary tract are slow and insidious.

Clinical Manifestations

As nodular hyperplasia and cellular enlargement progress, tissues that surround the prostatic urethra compress it, usually, but not always, causing **bladder outflow obstruction**. These symptoms are called the *lower urinary tract symptoms* (LUTS). LUTS can be divided into storage (frequency, nocturia, urgency) and voiding (stream, straining, hesitancy, prolonged micturition) symptoms.[152] These symptoms help to differentiate other causes of urinary symptoms such as UTI/overactive bladder, and identify the site affected (bladder versus prostate).[152] Men with BPH typically identify the most prominent symptoms of nocturia, poor stream, hesitancy, or prolonged micturition.[152] As the obstruction progresses, often over several years, the bladder cannot empty all the urine, and the increasing volume leads to long-term urine retention. The volume of urine retained may be great enough to produce uncontrolled "overflow incontinence" with any increase in intra-abdominal pressure. At this stage, the force of the urinary stream is significantly reduced, and more time is required to initiate and complete voiding. Hematuria, bladder or kidney infection, bladder calculi, acute urinary retention (hydroureter), hydronephrosis, and renal insufficiency are common complications.[170] The impact of LUTS on quality of life can be assessed using the American Urological Association Symptom Score (AUASS) as well as the International Prostate Symptom Score (IPSS).[171]

Evaluation and Treatment

The diagnosis is made from a medical history, physical examination, and laboratory tests, including urinalysis. Prostate-specific antigen (PSA) testing is used with caution and should not be done to investigate BPH routinely.[152] PSA levels may be increased in several conditions (large prostate, infection, catheterization, prostate cancer) and can cause unnecessary anxiety and trigger more investigations.[152] Careful review of symptoms is necessary. Ultrasound scans are used for evidence of hydronephrosis and indicated for men with high residual volumes or renal impairment.[152] Urine flow studies are done to assess volume of urine passed over time.[152] Flexible cystoscopy is only used to investigate "red flag" symptoms, such as hematuria/suspected bladder cancer and urethral strictures.[152]

In those men with LUTS, treatment options range from watchful waiting to medical and surgical intervention and depend on the degree of "discomfort or bother" or disease burden.[152] α_1-Adrenergic blockers (Tamsulosin and Alfuzosin) result in stromal smooth muscle relaxation and thus improve urinary flow. Alpha-reductase inhibitors (finasteride and dutasteride) block conversion of testosterone to DHT, causing shrinkage of the prostate. It takes several weeks to show noticeable improvement and six months to show maximal effectiveness.[154]

Antiandrogen agents lower the PSA level by 50% after 6 months of therapy with prostate volume decreasing up to 25%.[152] Worsening BOO can cause bladder detrusor instability, increasing urgency, or overactive bladder and frequency. These symptoms can be relieved with muscarinic receptor antagonists by blocking muscarinic receptors on detrusor muscle and

reducing smooth muscle tone.[152] The combination of an alpha-blocker and alpha-reductase inhibitor are used to achieve improvements in voiding symptoms.[172,173]

The guidelines for surgery in BPH are outlined by the European Association of Urology (EAU) and include[174]: (1) refractory urinary retention, (2) recurrent UTIs, (3) hematuria refractory to medical treatment (other causes excluded), (4) renal insufficiency, (5) bladder stones, (6) increased post-void residual, and (7) high-pressure chronic retention (absolute indication). Over the years, surgical innovations have increased with minimally invasive procedures. Recommended procedures include transurethral incision of the prostate, transurethral resection for the prostate, and newer techniques of laser vaporization and holmium laser enucleation, which have largely replaced open prostatectomy.[152] Bipolar diathermy has mostly replaced monopolar diathermy techniques for transurethral resection of the prostate (TURP).[152] Meta-analysis for HoLEP (Holmium laser enucleation of the prostate) has shown improved Qmax (flow rate), reduction in post-void residual, and lowered IPSS score as compared to TURP.[152]

Prostatitis

Prostatitis is an infection or inflammation of the prostate gland that presents as several syndromes with varying clinical features (Fig. 26.17). The term *prostatitis* is defined as microscopic inflammation of the tissue of the prostate gland. Prostatitis syndromes have been classified by the National Institutes of Health as (1) acute bacterial prostatitis (ABP), (2) chronic bacterial prostatitis (CBP), (3) chronic pelvic pain syndrome (CPPS), and (4) asymptomatic inflammatory prostatitis (Box 26.11). ABP and CBP are mostly caused by gram-negative Enterobacteriaceae and *Enterococci* species that originate in the gastrointestinal flora. Nonbacterial prostatitis (CP/CPPS) syndromes are caused by a cascade of inflammatory, immunologic, neuroendocrine, and neuropathic mechanisms, such that the initiating cause is unknown.

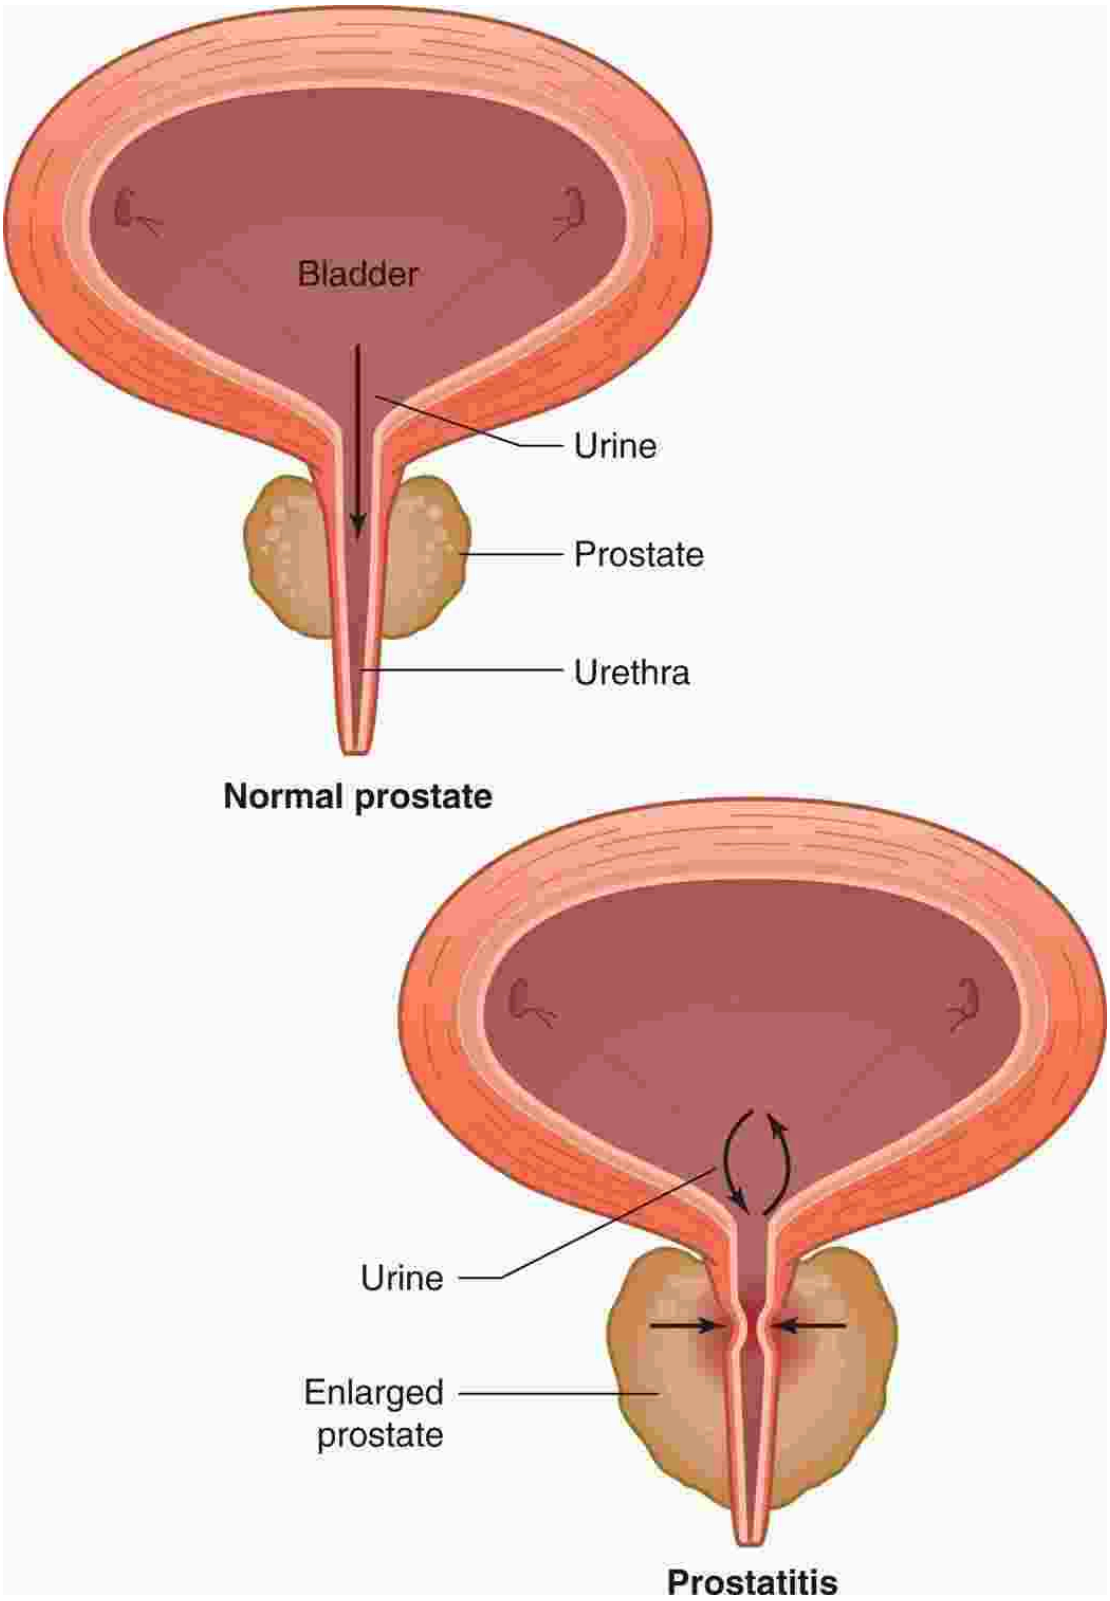

FIG. 26.17 Prostatitis.
Simple schematic of a normal prostate gland and an enlarged prostate gland secondary to prostatitis.

The illustration on the top depicts the cross-section of urinary bladder and normal prostate with labels indicating bladder, urine, prostate, and urethra. A downward arrow mark from bladder toward urethra indicates the flow of urine. The illustration in the bottom depicts prostatitis which shows the cross-section of urinary bladder with an enlarged prostate and compressed urethra indicated by arrow marks. The curved upward and downward arrow mark in the bladder indicates the flow of urine through compressed urethra.

Box 26.11

National Institutes of Health Classification of Prostatitis Syndrome

This system, developed for clinical research purposes, can be simplified for use in primary care practice (see text).

Category I, or acute bacterial prostatitis (ABP), is an acute infection of the prostate and is manifested by systemic signs of infection and a positive urine culture result.
Category II, or chronic bacterial prostatitis (CBP), is a chronic bacterial infection in which bacteria are received in significant numbers from a purulent prostatic fluid. These bacteria are thought to be the most common cause of recurrent urinary tract infection in men.
Category III, or chronic pelvic pain syndrome (CPPS), is diagnosed when no pathologic bacteria can be localized to the prostate (culture of expressed prostatic fluid or postprostatic massage urine specimen) and is further divided into IIIa and IIIb. Category IIIa is inflammatory CPPS, in which a significant number of white blood cells (WBCs) are localized to the prostate; category IIIb is noninflammatory.
Category IV is asymptomatic inflammatory prostatitis in which bacteria or WBCs are localized to the prostate, but individuals are asymptomatic.

Acute bacterial prostatitis (ABP, category I) is an ascending infection of the urinary tract that tends to occur in men between the ages of 30 and 50 years, but it is also associated with BPH in older men. In general, ABP is rare and often associated with BOO or an immunocompromised state. Infection stimulates an inflammatory response in which the prostate becomes enlarged, tender, firm, or boggy. The most common organism is *E. coli*, which is identified in approximately 50% to 90% of infections. *Klebsiella* species, *Proteus*, *Pseudomonas aeruginosa*, and *Serratia* species also are common gram-negative cultured microorganisms. Sometimes implicated are gram positive organisms such as *Enterococcus* species and *Staphylococcus* species as well as organisms from STIs, including *N. gonorrhoeae*, *C. trachomatis*, and *Ureaplasma urealyticum*.[175] Immunocompromised individuals are at an increased risk for BP from atypical organisms such as *Salmonella* species, *Mycobacterium* species, *Staphylococcus* species, and others.[175] Fungal and viral etiologies need consideration, especially with immunosuppressed states. Although Enterobacteriaceae are the most common causative microorganisms in both ABP and CBP, gram-positive and atypical microorganisms are more likely in CBP than in ABP. The role of gram-positive microorganisms in CBP is debated, but they sometimes are isolated in culture.[176,177]

The onset of prostatitis may be acute and unrelated to previous illnesses. It may follow prostate manipulation from procedures such as transrectal prostate biopsy, transurethral prostate biopsy, cystoscopy, and catheterization.[175,178,179]Box 26.12 provides a summary of risk factors.[173] In young men, common causes include an ascending infection following anal or vaginal intercourse. In older males, two common causes are prolonged catheterization and instrumentation.[175]

Box 26.12

Summary of Risk Factors for Bacterial Prostatitis

- Phimosis
- Intraprostatic ductal reflux
- Unprotected vaginal/anal intercourse
- Sexually transmitted infections
- Sexual abuse
- Development of a urinary tract infection
- Indwelling catheter
- Transurethral biopsy/surgery
- Prostate manipulation
- Urethral stricture
- Benign prostatic hyperplasia
- Diabetes
- Urethritis
- Congenital abnormality of the ureter

ABP usually presents with abrupt symptoms of infection. A sudden onset of malaise, low back, rectal, and perineal pain, fever, and chills. Other common symptoms include dysuria, inability to empty the bladder, nocturia, urinary retention, and painful ejaculation. The individual also may have symptoms of lower urinary tract obstruction, such as a slow, small, "narrowed" urinary stream, which may be a medical emergency. Acute inflammatory prostatic edema can compress the urethra, causing urinary obstruction. Systemic signs of infection include sudden onset of a high fever (up to 40° C [104° F]), fatigue, arthralgia, and myalgia. Prostatic pain may occur, especially when the individual is in an upright position, because the pelvic floor muscles tighten with standing, and compression of the prostate gland occurs. Palpation discloses an enlarged, extremely tender, and swollen prostate that is firm, indurated, and warm to the touch.

Once ABP is suspected, based on history and physical examination, a midstream urinalysis and urine culture is recommended. If a person meets sepsis criteria or has significant medical comorbidities, blood cultures, lactic acid, metabolic panel, and complete blood count are obtained. Although imaging is not required in all cases, a CT or transrectal ultrasound (TRUS) may be done to evaluate a prostatic abscess in individuals who are immunocompromised, at risk of bacteremia, or are not responding to treatment.[175] With ABP and individuals presenting with acute urinary retention, urology is consulted for possible suprapubic catherization.[175] Prostatic massage may express enough secretions from the urethra for direct bacterial examination. The four-glass test is a test of four different samples: voided urine, mid-stream urine, expressed prostatic secretions, and post-prostate massage urine. The 2-glass test is performed by obtaining pre-massage and post-

massage urine samples. The 4-glass is not performed often, as it is difficult for the individual and the supporting evidence is poor.[180,181]

To resolve the infection and control its spread, individuals may require antibiotics. In severe cases (individuals meet sepsis criteria, have urinary retention, treatment failure/resistant organisms), the individual is hospitalized and treated with intravenous antibiotics, followed by oral antibiotics. Complications include urinary retention, progression to chronic prostatitis, epididymitis, or pyelonephritis. At least 10% of individuals develop chronic pain.[175]

Chronic bacterial prostatitis (CBP (category II) is characterized by recurrent urinary tract symptoms. The pathophysiology of CBP is less well known and may involve the development of bacterial biofilms.[182]

CBP presents more subtly than ABP. The symptoms of CBP are chronic and recurring and less severe than ABP.[175] Although men with CBP do not usually appear acutely ill, their quality of life can be significantly impacted.[175] These men have chronic asymptomatic bacteriuria. The prostate may be tender but typically not inflamed, and men may present with sexual dysfunction (SD).[175]

CBP evaluation is appropriately performed by a urologist or in consultation with one. Diagnosis of CBP is best done by a urologist using either the Meares and Stamey four-glass test or the simpler two-glass pre-massage and post-massage test, and possibly semen sample with urodynamic studies.[175]

Treatment for CBP is guided by culture results, and initiating treatment emergently is not warranted because treatment can wait for culture results.[175] Typically, duration of treatment is two to six weeks.[175] Those who fail to respond to medical therapy may have a surgical procedure for an abscess.[175] Decreased fertility has been associated with massive bacterial infection of the prostate. A prostatic abscess is rare but may occur in those with indwelling catheters. Healthcare providers need to be aware that unnecessary urethral catheterization should be avoided. Education should be provided to individuals on barrier protection if participating in anal sex. Also, education is needed on adequate hydration and the use of antipyretics. Close communication between team members and the urologist is critical to lower morbidity and improve outcomes.[183,184]

Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS, category III) has no real consensus on its definition, etiology, and pathophysiology. The heterogeneity of the disorder has created major difficulties in defining CP/CPPS. One proposal is that CP/CPPS is logically defined as a set of associated symptoms rather than a single entity of disease.[185] Four elements are necessary to diagnose CP/CPPS and include: (1) symptoms occurring in perineal and/or low abdominal area, (2) infection and or inflammatory changes of the prostate with laboratory evidence of abnormal findings, (3) clinical presentations, mainly pain and discomfort derived from or associated with the prostate and lower urinary tract, and (4) symptoms appearing after an inducible cause with varied incubation times.[185] Shoskes divided CP/CPPS into six subtypes by clinical presentation, subjective presentation, and psychosocial background: urinary (U), psychosocial (P), organ specific (O), infection (I), neurologic/systemic (N), and tenderness (T), altogether UPOINT.[186]

A working group of the International Continence Society (ICS) published nine clinical domains: lower urinary tract, female genital, male genital, gastrointestinal, musculoskeletal, neurological, psychological, sexual, and comorbidities.[187] These publications provide further support for symptom-oriented diagnosis and treatment.

Recommendations for diagnosis include the phenotype-based diagnosis of CP/CPPS[186] and UPOINT.[188,189] Associated symptoms are linked to varicocele, irritable bowel syndrome, and melena.[190–193]

The terminology of CPPS by ICS is used for measuring scales and locations of pain.[187] The NIH-Chronic Prostatitis Symptom Index (NIH-CPSI) and the consensus guideline by the Prostatitis

Expert Reference Group are useful instruments for initial review of symptom severity and follow-up of treatment results.[185] Other taxonomies exist, including the International Association for the Study of Pain (IASP) and the EAU.

Definitive diagnosis and selection of an effective treatment are frustrations encountered by individuals and their urology care providers.[185] A multimodal approach to treatment for CP/CPP includes both pharmacologic and nonpharmacologic therapies. Pharmacologic treatment includes antimicrobials, α-blockers, anti-inflammatory and immunomodulatory agents, phytotherapy, phosphodiesterase inhibitors, antidepressants, neuromodulatory agents, and hormonal agents. The nonpharmacologic therapies include pelvic floor physical therapy, myofascial trigger point release, acupuncture, extracorporeal shock wave therapy (ESWT), and psychological support.[194]

Cancer of the Prostate

Prostate cancer affects millions of men worldwide.[195] It is the second most common cancer in men after lung cancer, accounting for 7% of newly diagnosed cancers in men globally and 15% of men in developed regions.[196] Globally, prostate cancer accounts for 1,148,515 estimated new cases and 375,304 estimated deaths (see Emerging Science Box: Prostate Cancer).[195] The regions of highest incidence are Australia, New Zealand, Oceania, North America, Europe, and Brazil. The lowest incidence of prostate cancer is found in low-income nations, including South Asia, Central Asia, and Sub-Saharan Africa, but these regions have the highest rates of annual increase in incidence.[197,198] In the United States estimated new cases of prostate cancer for 2021 is 248,530 and estimated deaths is 34,130.[199] Studies in Europe with long-term follow-up data have shown that repeated screening increases detection of all prostate cancers (including those that are indolent)[200,201] and reduces prostate cancer-specific mortality.[200,201] Overall, the majority of prostate cancers tend to grow slowly and are low-grade and low-risk with limited aggressiveness.[202]

Emerging Science Box

Prostate Cancer

Prostate cancer is the second most frequent cancer diagnosis made in males and the fifth leading cause of death worldwide. Prostate cancer incidence rates during the most recent 5 years have declined (five countries) or stabilized (35 countries), after increasing for many years. In contrast, rates continued to increase for four countries in Eastern Europe and Asia. During the most recent 5 data years, mortality rates among 76 countries examined increased (three countries), remained stable (59 countries), or decreased (14 countries). There is no evidence yet on how to prevent prostate cancer; however, it is possible to lower the risk by limiting high-fat foods, increasing intake of fruits and vegetables, and increasing activity with exercise.

Data from Culp MB, et al. Recent global patterns in prostate cancer incidence and mortality rates. *European Urology*, 2020;77:38–52; Rawla P. Epidemiology of prostate cancer. *World Journal of Oncology*, 2019;10(2):63–89. doi:10.14740/wjon1191.

The known major risk factors for prostate cancer are age, ethnicity, obesity, and family history.[202,203] Across age ranges, black men and men with a family history of prostate cancer have an increased risk of developing and dying of prostate cancer. Black men are approximately twice as likely to succumb to prostate cancer compared with men of other races in the United States, and the reason for this disparity is unknown. Other risk factors include increased height, hypertension, lack of exercise, Agent Orange exposure, and the typical Western diet.[202,204–206] Androgens and androgen receptor (AR) function have major roles in the development and progression of prostate

cancer.[207] Although the cause of prostate cancer is unknown, genetics play a role. Men with a first-degree relative (father or brother) with prostate cancer have twice the general population risk, and risk increases more with an affected brother than an affected father.[208] Prostate cancer-associated genetic changes are copy number alterations (CNAs) or gene structural rearrangements (see Pathophysiology discussion).[209,210] Acquired genetic and epigenetic alterations are involved in the development of prostate cancer.[161]

Diet, obesity, and microbiota

Although evidence exists for a dietary role in prostate cancer, the epidemiologic evidence is inconsistent. The nutrients in the epidemiology of prostate cancer that have received the most attention include carotenoids, fat, vitamin E, vitamin D/calcium, and selenium. Less studied are isoflavones, curcumin, lycopene, green tea, omega-3 polyunsaturated fats, and sulforaphane. Associations between obesity and prostate cancer are not clear because of inconsistencies, but obesity seems to be negatively associated with more indolent prostate cancer and positively associated with more aggressive disease and a worse outcome.[211–216] Several biological mechanisms have been proposed to understand how obesity may be related to prostate cancer. First, obesity may be associated with a low physical activity level, suspected to increase the risk of prostate cancer.[217] Second, obese men have higher levels of insulin and IGF[218,219] reported to promote carcinogenesis and inhibit apoptosis.[220–222] Last, experimental and epidemiological studies also suggested that chronic inflammation may be associated either with initiation or progression of several cancers, including prostate cancer.[223–228] Importantly, it has been suggested that obesity promotes a low-grade inflammation state that may contribute to cancer development (see Chapter 23).[211]

Hormones

Prostate cancer develops in an androgen-dependent epithelium and is usually androgen sensitive. The significance of androgens for maintaining the growth and survival of prostate cancer cells is noted from the therapeutic effect of castration or treatment with antiandrogens, which mostly induce disease regression.[161] Over time, most tumors become resistant to androgen blockage (see section Evaluation and Treatment). Androgens are synthesized not only in the testis, accounting for 50% to 60% of the total testosterone in the prostate, but also in the prostate gland itself. In a process called **intraprostatic conversion**, the hormone dehydroepiandrosterone (DHEA) produced by the adrenal glands is converted to testosterone and then into DHT in the prostate (Fig. 26.18). Additionally, prostate cancer cells have been reported to make androgens from cholesterol (i.e., de novo).

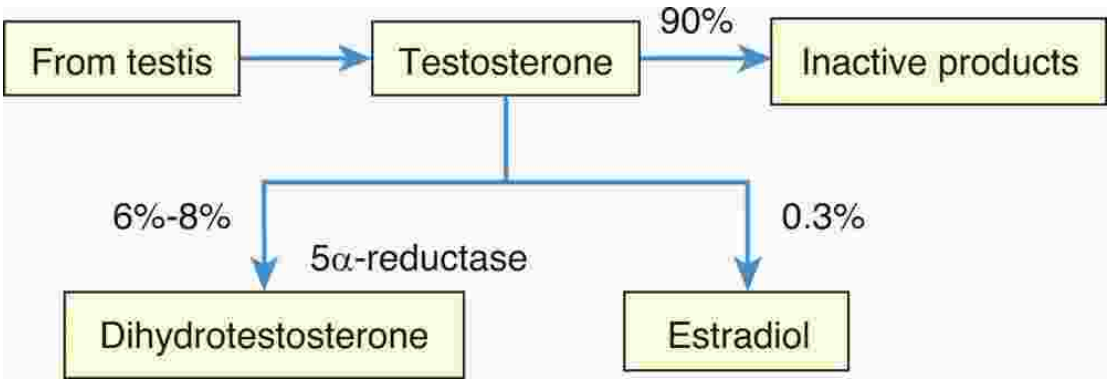

FIG. 26.18 **Testosterone and Conversion to Dihydrotesto-sterone.**

A chart represents the schematic representation of conversion of prostate testosterone to dihydrotestosterone which shows testosterone from testis produces 90 percent of inactive products; 6 to 8 percent of dihydrotestosterone by reduction through 5 alpha reductase and 0.3 percent of estradiol.

Estrogens also may have a role in prostate cancer development. Normal human prostate stem progenitor cells express ER-α and ER-β. Their roles in prostate cancer are discussed in the pathophysiology section.

Chronic inflammation

Chronic inflammation may be an important risk factor for prostatic adenocarcinoma. Possible causes of prostate inflammation are shown in Fig. 26.19. Chronic inflammation involves autocrine/paracrine growth-stimulating and growth-inhibiting factors. These factors include IGFs, epidermal growth factors, fibroblast factors, and TGF-β, as well as several others. Recent data show that human prostate stromal cells can actively contribute to the inflammatory process from the induction of inflammatory cytokines and chemokines. Importantly, continuous input from TGF-β and IGF in the tumor microenvironment or stroma results in cancer progression.

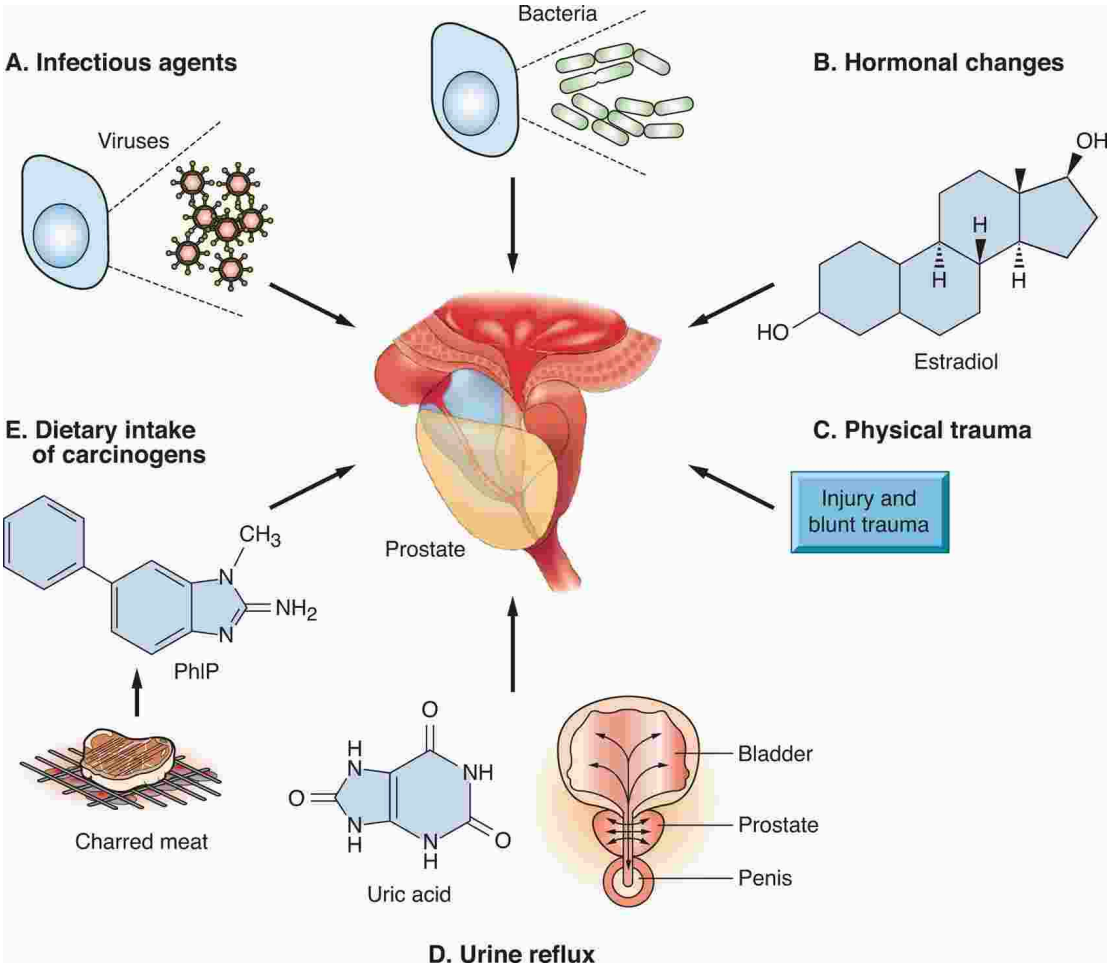

FIG. 26.19 Possible Causes of Prostate Inflammation.

An Illustration depicts the potential causes of prostatic inflammation. A. An illustration of viruses and bacteria depicts the infectious agents causing prostatic inflammation. B. The chemical structure of estradiol depicts the hormonal changes causing prostatic inflammation. C. An illustration depicts the physical trauma such as injury and blunt trauma causing prostatic inflammation. D. An illustration of urinary system with labels indicating bladder, prostate, and penis accompanied by the chemical structure of uric acid depicts the urine reflux causing prostatic inflammation. E. An illustration of charred meat accompanied by the chemical structure of P h I P depicts the dietary intake of carcinogens causing prostatic inflammation.

More than 95% of prostatic neoplasms are adenocarcinomas, and most occur in the periphery of the prostate (Figs. 26.20 and 26.21). Prostatic adenocarcinoma is a heterogeneous group of tumors with a diverse spectrum of molecular and pathologic characteristics and, therefore, diverse clinical behaviors and challenges. The cells of origin of a prostatic adenocarcinoma are thought to originate from the basal or luminal prostate epithelial cells, and genetic mutation is thought to be the primary driver of prostate carcinogenesis.[198] Interactions of environmental factors and genetic factors contribute to the notable differences in incidence of prostate cancer worldwide. Migration studies have shown the importance of environmental factors; for example, men of Asian descent living in Asia are at lower risk of prostate cancer than white men living in the United States, but the risk within Asian men reaches levels like white men when living in the United States.[229] Studies of twins and families show genetic predisposing factors. Many inherited germline variants have been identified and associated with prostate cancer risk, for example, variants that influence an important oncogene, *MYC*. Other rare variants have been identified and linked to high risk of early onset, aggressive disease including loss of function mutations in *BRCA2* and in DNA mismatch repair genes.[230] The rare mutations with the highest risk are those in *BRCA2* (sevenfold to eightfold) and *HOX13* mutations (threefold increased relative risk).[231] Acquired genetic and epigenetic alterations can alter the expression of tumor suppressor genes and oncogenes. The most common (~50%) genetic alteration in the prostate is a chromosomal rearrangement that juxtaposes (puts close together) the coding sequence of an ETS family transcription factor gene (e.g., *ERG* or *ETV1*) next to the androgen regulated *TMPRSS2* promotor. TMPRSS2 is an androgen-regulated cell surface serine protease[232] and plays an important role in prostate cancer invasion, extracellular matrix degradation, invasion, tumor growth, and metastasis (Fig. 26.22).[233]

FIG. 26.20 Prostate Zones, Benign Prostatic Hyperplasia, and Prostate Cancer Locations.

Two illustrations accompanied by a table depict the zones of prostate. The illustration on the left depicts the prostate with ejaculatory duct indicating the zones of prostate as follows. Central zone, fibromuscular zone, transitional zone, peripheral zone, and periurethral gland region denoted by a, b, c, d, and e respectively. The illustration on the right depicts the cross-section of prostate showing the central zone, fibromuscle zone, transitional zone, peripheral zone, and periurethral gland zone denoted by a, b, c, d, and e respectively. The table in the bottom represents the level of prevalence for the diagnosis in the prostate zones which shows three columns and six rows. The column headers are peripheral, transition, and central. The row headers are focal atrophy, acute inflammation, chronic inflammation, benign

prostatic hyperplasia, high-grade P I N, and carcinoma. The row-wise data are as follows. â€¢ Focal atrophy: High prevalence, medium-high prevalence, and low prevalence. â€¢ Acute inflammation: Low prevalence, none, and none. â€¢ Chronic inflammation: Medium-high prevalence, Medium-high prevalence, and low prevalence. â€¢ Benign prostatic hyperplasia: None, high prevalence, and none. â€¢ High-grade P I N: Medium-high prevalence, low prevalence, and low prevalence. â€¢ Carcinoma: Medium-high prevalence, low prevalence, and low prevalence.

Aggressive, castration-resistant cancers

FIG. 26.22 Interaction of Environmental and Genetic Risk Factors and Acquired Genetic and Epigenetic Alterations Leading to Prostate Cancer Development and Progression.
Prostate cancer is thought to be strongly associated with the accumulation of acquired somatic mutations over a man's lifetime. Risk factors include many environmental factors interacting with genes and epigenetic factors. Prostate cancer is highly heterogenous and individuals have a combination of one or more of these genetic changes. For example, *TMPRSS2-ETS* fusion, *PTEN* and *RB1* deletion, *TP53* mutation, and amplification of *MYC* are common genetic changes in all stages of prostate cancer. Although still debated, a putative precursor lesion, prostatic intraepithelial neoplasia (PIN), occurs in some cases of prostate cancer. (From Kumar V, Abbas AK, Aster JC. *Robbins & Cotran pathologic basis of disease*, 10th edition. Elsevier; 2021.)

An illustration depicts the role of environmental and genetic risk factors and genetic and epigenetic alterations involved in the development and progression of prostate cancer. â€¢ The dietary exposure, chronic inflammation, androgens, and germline M Y C variants acts on prostate epithelium leading to prostatic intraepithelial neoplasia which involves T M P R S S-E T S fusion gene, critical telomere shortening, and hypermethylation of G S T P I promotor. â€¢ Prostatic intraepithelial neoplasia with loss of P 27 leads to localized prostatic adenocarcinoma. â€¢ The localized prostatic adenocarcinoma with loss of P T E N and activation of telomerase causes metastatic prostatic adenocarcinoma which metastases to lymph, nodes, and bone. â€¢ The metastatic prostatic adenocarcinoma leads to aggressive, castration-resistant cancers by the androgen receptor mutations, T P 53, R B mutations, and M Y C amplifications.

Hormonal factors

Just as the testicles are the male equivalent of the female ovaries, the prostate is the male equivalent of the female uterus; in both situations they originate from the same embryonic cells. This may be important in understanding the role of the associated hormones testosterone (T), DHT, and estrogens in prostate cancer development (Fig. 26.23). The relationship between hormones and the pathophysiology of prostate carcinogenesis is incomplete and controversial. The main issues and controversies include (1) sources of androgen production outside of the testes, or extratesticular sources (e.g., from adrenal DHEA and from prostate tissue cholesterol [de novo] itself); (2) the role of prostatic AR; (3) the role of estrogens, aromatase enzyme, and the ERs ERα and ERβ; and (4) the role of the surrounding microenvironment or stroma.

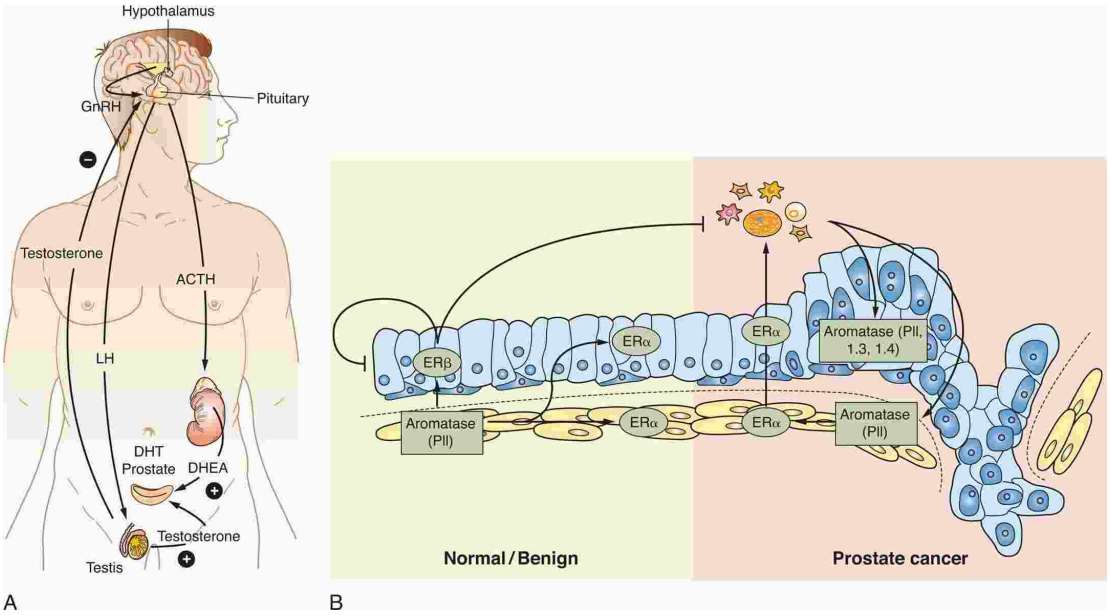

FIG. 26.23 Sources of Androgens and Aromatase and Estrogen Signaling in the Prostate.

(A) Body sources of androgens in the prostate gland. Hypothalamic gonadotropin-releasing hormone *(GnRH)* causes the release of luteinizing hormone *(LH)* from the anterior pituitary gland. LH stimulates the testes to produce testosterone, which accumulates in the blood. Pituitary adrenocorticotropic hormone *(ACTH)* release stimulates the adrenal glands, which secrete the androgen precursor dehydroepiandrosterone *(DHEA)* into the blood. DHEA is converted into testosterone and then into dihydrotestosterone *(DHT)* in the prostate. (B) Aromatase, and estrogen signaling in the prostate. In normal and benign tissue, aromatase is expressed within the stroma and regulated by promoter PII. Estrogen then exerts its effects in an autocrine fashion through the stromal ER-α receptor and in a paracrine fashion through both ER-α and ER-β receptors. With prostate cancer, aromatase is now expressed within the tumor cells and in stromal cells and is regulated by aromatase promoters 1.3, 1.4, and PII. Thus, estrogen exerts its effects in an autocrine way through stromal and epithelial ER-α and ER-β. Consequently, the increased levels of estrogen and abnormal ER-α signaling promote inflammation, which increases aromatase expression and the development of a positive feedback cycle. Inflammation drives aromatase expression, thus increasing estrogen, which in turn promotes further inflammation. *ER*, Estrogen receptor. (A, Adapted from Labrie F. Blockade of testicular and adrenal androgens in prostate cancer treatment. *Nat Rev Urol*. 20 1;8:73–80. B, From Ellem SJ, Risbridger GP. Aromatase and regulating the estrogen: Androgen ratio in the prostate gland. *J Steroid Biochem Mol Biol*. 2010;118(4–5):246–251.)

Illustration A depicts the pathway involved in the sources of androgens in the prostate gland which shows the G n R H from hypothalamus releases L H from pituitary which stimulates the testes to produce testosterone and the A C T H from pituitary stimulates the D H E A. The D H E A converted to testosterone and D H T in the prostate. Illustration B depicts the aromatase

and estrogen signaling in the prostate. The first panel depicts the aromatase in normal or benign tissue. The second panel depicts the aromatase in prostate cancer.

Testicular testosterone provides the main source of androgens in the prostate and is the major circulating androgen. The adrenal cortex contributes the far less potent DHEA that promotes synthesis of androgens in the prostate. In the target tissues, and to a lesser extent in the testes themselves, testosterone is converted to DHT by the enzyme 5α-reductase (see Fig. 26.18). Thus, DHT is the most potent intraprostatic androgen. About half of circulating testosterone is bound to sex hormone–binding globulin (SHBG), about half binds to albumin, and about 1% to 2% exists in a free state. Free testosterone, including testosterone disassociated from albumin and possibly SHBG, enters the prostate cell, where it is converted to DHT. DHT is a paracrine hormone because it affects the local environment or stroma. Several intraprostatic enzymes encoded by genes HSD3A and HDS3B are activated by DHT and are important components of intraprostatic androgen regulation. The growth, differentiation, and maintenance of the prostate gland depend mainly on androgens and are the basis of the antiandrogenic therapies for the treatment of primary prostate cancer. Development and physiology of the prostate is also directly regulated by somatotrophic hormones, such as insulin, prolactin, and growth hormone, retinoic acid, and estrogen.[234]

Prostate cancer growth and progression relies on the activation of the AR by testosterone (T), or its more potent metabolite, DHT. AR is associated with the origins of prostate tumors and with the recurrence of androgen independent cancer.[235] Estrogens are mediated by the ER. The two subtypes, ERα and ERβ, are the products of different genes and have different physiological roles (see below discussion).[234] Both ERα and ERβ are expressed in the prostate and in adults ERα and ERβ are preferentially found in the stroma and the epithelium, respectively.[234] ER expression, like the AR, might be suppressed by methylation of its promoters; this epigenetic alteration is suggested to be involved in both BPH and prostate cancer development.[236,237] It is well known that circulating androgens are converted into estrogens in various peripheral tissues by the enzyme aromatase.[238] Aromatase was also identified in the human prostate, suggesting that the human prostate is able to perform the aromatization reaction and is a logical local source of estrogen production (see Fig. 26.18).[239]

Estrogen effects are determined by the two receptors ER-α and ER-β. It is ER-α activation that is thought to contribute to prostate carcinogenesis and has been implicated with tumor progression.[240,241] In contrast, ER-β has been shown to be reduced in localized malignant lesions of the prostate as compared to benign lesions, thus supporting an anti-proliferative role in prostate tissue.[242] In addition to the ER-α and ER-β, the G protein—coupled estrogen receptor (GPER), a member of the G-protein family found in the endoplasmic reticulum, has been found to have differential expression between BTH and prostate cancer.[243] High estrogen and low T levels have been shown to lead to inflammation with aging and to the emergence of precancerous lesions.[244] The mechanism is not clearly understood and may involve estrogen-generated oxidative stress and DNA toxicity, and it requires androgen-mediated and ER–mediated processes, such as changes in sex steroid metabolism and receptor status.[245] In addition, there are changes in the balance between autocrine/paracrine growth-stimulatory and growth-inhibitory factors, such as the IGFs.

Prostate epithelial neoplasia

A precursor lesion, **prostatic epithelial neoplasia (PIN)** may be more concentrated in prostates containing cancer and is noted in proximity to cancer. However, the final fate of PIN is unknown, including the possibilities of latency, invasion, and even regression. The current working model of

prostate carcinogenesis suggests that repeated cycles of injury and cell death occur to the prostate epithelium because of damage (i.e., from oxidative stress) from inflammatory responses.[226,246] The direct injury is hypothesized as a response to infections; autoimmune disease; circulating carcinogens or toxins, or both, from the diet; or urine that has refluxed into the prostate (see Fig. 26.19). The resultant manifestation of this injury is focal atrophy or prostate intraepithelial atrophy (PIA). Biologic responses cause an increase in proliferation and a massive increase in epithelial cells that have a phenotype intermediate between basal cells and mature luminal cells.[226,246,247] Molecular genetic and epigenetic changes can increase genetic instability that might progress to high-grade PIN and early prostate cancer formation.[248].

Stromal environment

The prostate gland is composed of secretory luminal epithelium, basal epithelium, neuroendocrine cells, and various cell types comprising supportive tissue or stroma. **Stroma**, or tissue microenvironment, produces autocrine/paracrine factors as well as structural supporting molecules that help regulate normal cell behavior and organ homeostasis.[249] Stromal microenvironment in prostate cancer is altered compared to normal stroma and exhibits features of a wound repair stroma.[250] Stromal components in the tumor microenvironment are important contributions to tumor progression and metastasis. Reciprocal interactions between tumor cells and stromal components influence the metastatic, dormancy-related, and stem cell–like potential of tumor cells. The stromal compartment of the tumor is complex and includes inflammatory/immune cells, vascular endothelial cells, fibroblasts, myofibroblasts, adipocytes, and components of the extracellular matrix.[251]

Epithelial-mesenchymal transition (EMT) was first described in embryonic development and is observed in several solid tumors (see Chapter 12).[252] Cells that undergo EMT become more migratory and invasive and gain access to vascular vessels. Numerous studies have shown that these transition states (EMT and mesenchymal-epithelial transition [MET]) are a consequence of tumor-stromal interactions.[253]

Clinical Manifestations

Prostatic cancer often causes no symptoms until it is far advanced. The first manifestations of disease are those of BOO: slow urinary stream, hesitancy, incomplete emptying, frequency, nocturia, and dysuria. Unlike the symptoms of obstruction caused by BPH, the symptoms of obstruction caused by prostatic cancer are progressive and do not remit. Local extension is usually posterior, although late in the disease the tumor may invade the rectum or encroach on the prostatic urethra and cause BOO (obstructing the upper urinary tract ureters) (Fig. 26.24). Rectal obstruction also may occur, causing the individual to experience large bowel obstruction or difficulty in defecation. Prostatic cancer and its treatment also can affect sexual functioning. Symptoms of late disease include bone pain at sites of bone metastasis, edema of the lower extremities, enlargement of lymph nodes, liver enlargement, pathologic bone fractures, and mental confusion associated with brain metastases. The spread of cancer through blood vessels is illustrated in Fig. 26.25. The most common sites of distant metastasis are the lymph nodes, bones, lungs, liver, and adrenals. The pelvis, lumbar spine, femur, thoracic spine, and ribs are the most common sites of bone metastasis.

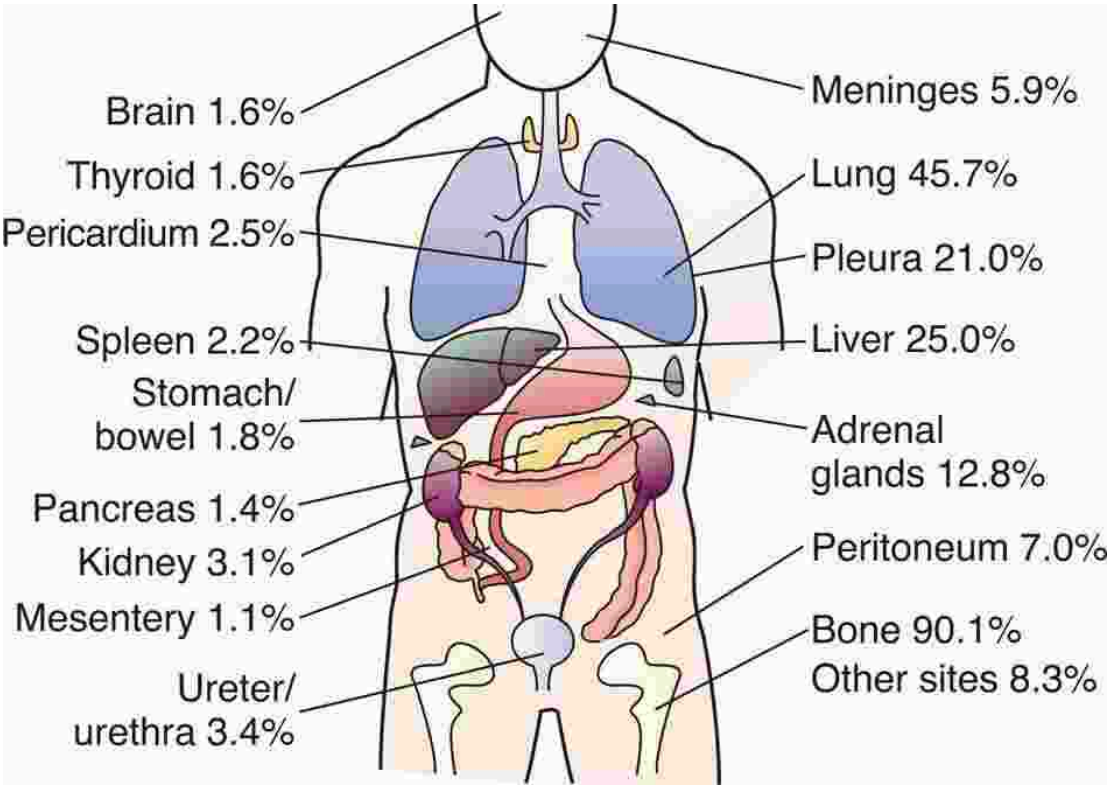

FIG. 26.25 Distribution of Hematogenous Metastases in Prostate Cancer.
The results are from a study of 556 men with metastatic prostate cancer. (Adapted from Budendorf L, Schöpfer A, Wagner U, et al. Metastatic patterns of prostate cancer: An autopsy study of 1,589 patients. *Hum Pathol*. 2000;31:578.)

An illustration of human anatomy depicts the distribution of hematogenous spread of prostate cancer. The percentage of metastases in organs are given as follows. Brain: 1.6; Thyroid: 1.6, pericardium: 2.5, spleen: 2.2, stomach or bowel: 1.8, pancreases: 1.4, kidney: 3.1, mesentery: 1.1, ureter or urethra: 3.4, meninges: 5.9, lung: 45.7, pleura: 21.0, liver: 25.0, adrenal glands: 12.8, peritoneum: 7.0, bone: 90.1, and other sites: 8.3.

Evaluation and Treatment

Screening for prostatic cancer includes PSA blood test and DRE. The issue of prostate cancer screening is controversial. Evidence is lacking on whether PSA screening or DRE reduces the mortality from prostate cancer or that the benefits outweigh the harms of screening.[254] Nonetheless, the PSA test is commonly used in the diagnosis and management of prostate cancer. For men aged 55 to 69 years, the decision to undergo periodic PSA-based screening for prostate cancer should be an individual one and should include discussion with their health care providers of the potential benefits and harms of screening. Screening for prostate cancer in any man 70 years or older is not recommended. Screening offers a small potential benefit to reduce the chance of death from prostate cancer in some men.[255] PSA screening may reduce the prostate cancer mortality risk but is associated with false positive results, biopsy complications, and overdiagnosis. DRE may detect early prostatic carcinomas, but it has low sensitivity and specificity. Cancer diagnosis is confirmed through tissue biopsy and microscopic examination of tissue. Lymphography, bone scans, MRI, and CT scans also may be used to determine metastasis to lymph, bone, or other adjacent tissue. Important for treatment is to accurately measure the size of the index (longest) tumor and its percentage Gleason grade of differentiation.[256]

Treatment of prostatic cancer depends on the stage of the neoplasm, the anticipated effects of treatment, and the age, general health, and life expectancy of the individual. Options include no treatment; surgical treatments, such as total prostatectomy, TURP, or cryotherapy; nonsurgical treatments, such as radiation therapy, hormone therapy, or chemotherapy; watchful waiting; and any combination of these treatment modalities. In addition, new approaches are using immunotherapy. Palliative treatment is aimed at relieving urinary, bladder outlet, or colon obstruction; spinal cord compression; and pain. Box 26.13 shows the stage groupings for prostate cancer. Prognosis and survival rates have improved steadily over the past 50 years. The 5-year relative survival rate for the vast majority (89%) of men diagnosed with local (74.3% of cancers) cancer approaches 100% but drops to 30% for those diagnosed with distant-stage disease.[257]

Box 26.13

AJCC Stage Groupings Prostate Cancer

Grade Group	Gleason Score	Gleason Pattern
1	≤6	≤3+3
2	7	3+4
3	7	4+3
4	8	4+4, 3+5, or 5+3
5	9 or 10	4+5, 5+4, or 5+5

Treatment for prostate cancer may lead to stress incontinence or loss of urinary control, which may or may not return to normal after several weeks or months, and SD. Sensation of orgasm is not usually affected, but smaller amounts of ejaculate will be produced, or men may experience a "dry" ejaculate because of retrograde ejaculation.

Sexual Dysfunction: Erectile Dysfunction

Male SD is not a single disease.[258] It involves the whole process of sexual activity including sexual arousal, penis erection, insertion, and ejaculation. **Sexual dysfunction** is the impairment of any or all these processes and can be caused by various physiologic, psychological, and emotional factors. Until the late 1970s, most cases of male SD were considered psychogenic. Now there is evidence that up to 90% of cases involve organic factors (Fig. 26.26). Most of these disorders cause **erectile dysfunction (ED)**.[259] ED is the most prevalent among diseases in SD and the most challenging to treat successfully.[258] Reportedly, 52% of 40- to 70-year-old men suffer from ED; it is closely associated to age and other comorbidities.[260,261] Epidemiological evidence suggests that impotence has affected 10 million American men.[262] Various implicated risk factors for SD are presented in Box 26.14.

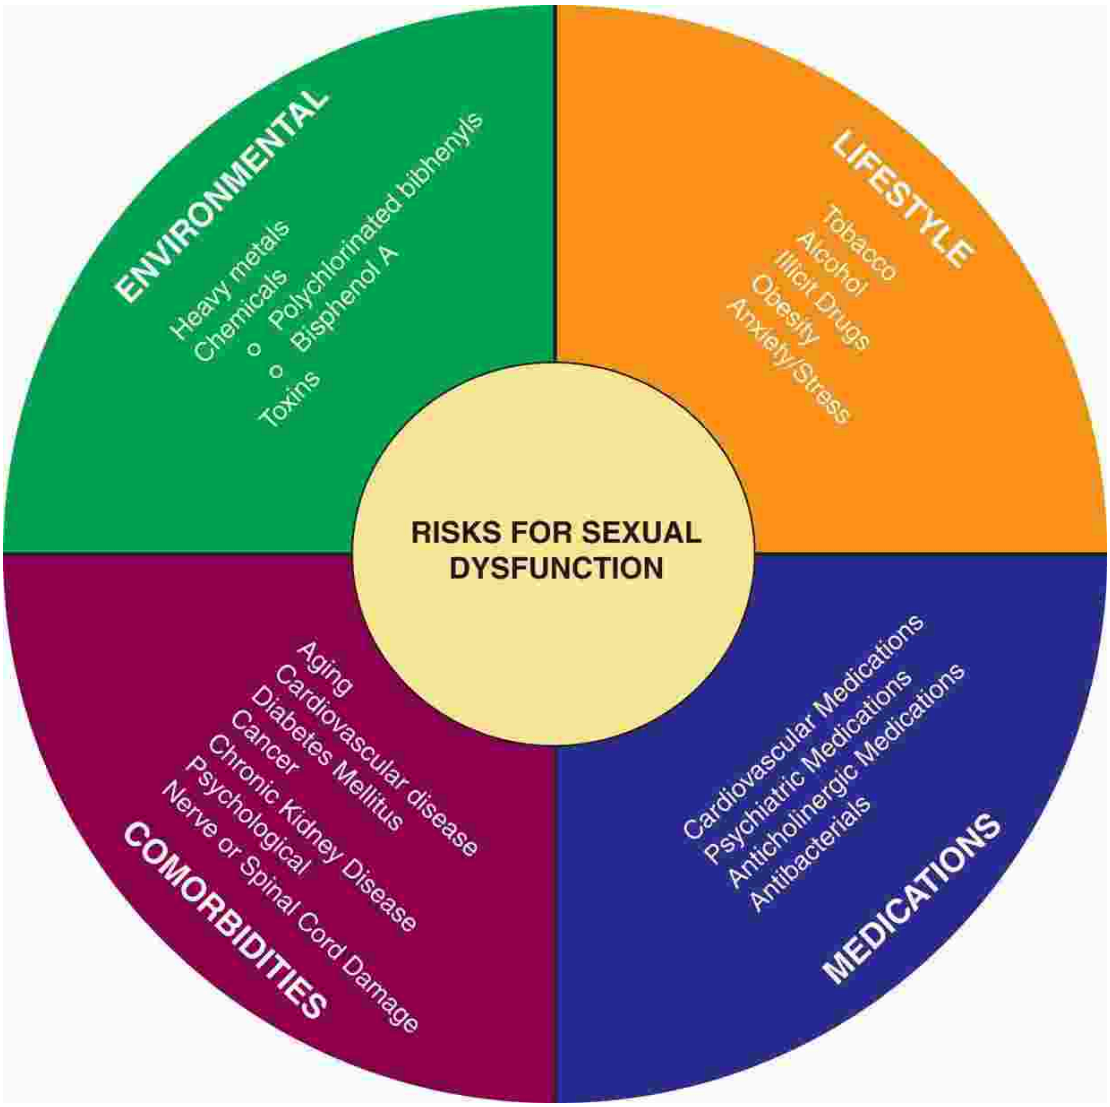

FIG. 26.26 **Risk Factors of Sexual Dysfunction.**

A circular wheel depicts the risk factors that determine sexual dysfunction. The factors are given as follows. Comorbidities factors include aging, cardiovascular disease, diabetes mellitus, cancer, chronic kidney disease, psychological, and nerve or spinal cord damage. Environment factors include heavy metals, chemicals including bisphenol A and polychlorinated biphenyl, and toxins. Lifestyle factor includes tobacco, alcohol, illicit drugs, obesity, and anxiety or stress. Medications factors include cardiovascular medications, psychiatric medications, antibacterial, and anticholinergic medications.

Box 26.14

Implicated Risk Factors for Sexual Dysfunction in Males

- Altered lifestyle
- Stressful living conditions
- Chronic diseases: cardiovascular, hypertension, hyperlipidemia, diabetes, chronic kidney disease, reproductive cancers, stroke, neurodegenerative, disorders, epilepsy, spinal cord injury, sleep apnea, chronic obstructive pulmonary disease (COPD), sequela of priapism, benign prostatic hyperplasia, lower urinary tract symptoms
- Diverse environmental pollutants: endocrine disruptors, heavy metals, radiation, estrogenic and destructive chemicals (bisphenol A, phthalates, organochlorine), lead exposure
- Drug side effects examples: anti-hypertensives, clofibrate, cimetidine, digoxin, anti-neoplastic, and various hormonal agents, recreational, others
- Psychological disturbances: depression, performance anxiety
- Dose-dependent alcohol intake
- Traumatic: pelvic fractures, spinal cord injuries
- Iatrogenic: post transurethral resection of the prostate
- Smoking
- Obesity
- Increased age
- Testosterone deficiency syndrome
- Hypogonadism

Pathophysiology

SD is complex and involves both risk and pathogenic factors. Pathogenic factors include endothelial dysfunction,[263] neurogenic factors,[264] hormonal pathways, and hemodynamic factors.[263] Men with ED have more endothelial damage than men without ED, and ED may be the first symptom of endothelial injury.[258] Penile erection requires a series of coordinated and complex events involving neuronal pathways, vascular response, and psychosomatic stimulation.[258] All of these actions are mediated by activation of the NO-cGMP dilator pathway.[265] NO released by the cavernous nerve terminals initiates erection, and NO from endothelial cells maintains the erection.[261]

Cyclic guanosine monophosphate (cyclic GMP) is stimulated by NO, and GMP enters the smooth muscle. Protein kinase G is activated by cyclic GMP which opens potassium channels while closing calcium channels.[261] Low intracellular calcium causes the intracavernosal smooth tissue to relax which allows arterial flow and veno-occlusive activity. The erection is then maintained with minimal blood flow moving into or out of the corpora. The process reverses when the corporal smooth muscle contracts again with the degraded GMP by the penile enzyme, phosphodiesterase. ED arises when any of these processes are disrupted by pathological changes.[261]

Endocrine regulation is critical for successful sexual development and for normal sexual function. Failure of the pituitary gland to maintain relative ratio of endogenous levels likely disrupts processes in sexual function.[258] Testosterone is the most important androgen for libido and spermatogenesis. Androgen deficiency can lead to SD, ED, loss of libido, and a decline in reproductive capacity.[258]

Emotional and psychologic response (e.g., anxiety, depression, and loss of self-esteem) to chronic illness can affect sexual functioning. In other chronic conditions, SD is associated with low energy

levels and loss of libido. The pathophysiologic mechanisms responsible for such changes are not known.

Evaluation and Treatment

A complete medical history, detailed sexual history, and physical examination are required. A complete list of all medications and supplements is necessary. Use of a scoring system is easier for individuals, with 100% being the best and hardest erection they ever had, 0% being completely flaccid, and 50% being firm enough for penetration.[261] A valid questionnaire called the International Index of Erectile Function (IIEF) is also available for individuals to complete in private.[266] Having the sexual partner present for the history greatly improves the outcome of the treatment process.[261] Obvious cases of psychogenic ED are referred to an appropriate mental health professional.

There are no specific tests required for the initial evaluation of ED. Routine blood testing includes a CBC, electrolytes, baseline renal and liver function tests, HgbA1c to screen for diabetes, and a lipid profile.[261] A morning testosterone level is recommended by the 2018 AUA Guidelines for Erectile Dysfunction, but it is not necessary unless there are symptoms of hypogonadism, such as loss of sexual desire or testicular atrophy.[261] Other tests may include LH prolactin (with hypogonadism), sickle cell in the African/Caribbean patient, and thyroid function. Because there is no effective cure for ED, identification of the underlying cause is useful only for detecting other potential health issues and comorbidities.[261] Thus, the focus changes from expensive diagnostic testing that will not significantly affect the outcome, to facilitating treatment selection after a candid and detailed discussion of reasonable therapeutic options.

Lifestyle modifications are the initial treatment recommendations. This approach improves erectile function and reduces cardiovascular risk. Lifestyle recommendations include increased physical activity, switching to a Mediterranean diet and/or nutritional counseling, drug, alcohol, and smoking cessation, and optimal control of diabetes, lipids, and cholesterol. If possible, these recommendations are given to both the patient and his partner. The drug history is carefully reviewed to remove or alter problem medications. Studies have shown some efficacy in treating mild to moderate ED with L-arginine supplementation.[267] Oral phosphodiesterase-5 inhibitors (PDE-5 inhibitors) are the first-line treatment of ED.[261] Importantly, PDE-5 inhibitors do not *initiate* the erectile response. Sexual stimulation is required to release NO from the vascular endothelium and penile nerve endings to begin the erectile process. PDE-5 inhibitors are effective and have an overall success rate of up to 76%.[268] The most common side effects (sildenafil) are headache, flushing, upset stomach, abnormal vision, nasal congestion, muscle pain, and dizziness. Known interactions of sildenafil and heart medications prompted the FDA to urge caution in those men who have experienced heart attack, stroke, or other serious cardiovascular events within six months of starting therapy. They should not be used at all with nitrates due to possible dangerous and significant hypotension.[261] Different PDE-5 inhibitors have varying half-lives which can influence the individual's final decision. Testosterone supplementation appears to be more effective for low libido than ED.[269,270] External vacuum device therapy is safe, effective, and the most inexpensive long-term therapy for ED.[261] Intracavernosal injection therapy has been reported as effective in up to 94% of individuals.[271] Prostaglandin E1 is relatively expensive and somewhat painful when injected into the corpora.[261] Combination therapy, such as Trimix or QuadMix, and is prepared by a compounding pharmacy. Side effects from intracavernosal injection include pain, priapism, bleeding, bruising, and scarring.[261] It is critical to warn individuals not to increase the injected dosage without the approval of their healthcare provider, not to mix it with other ED agents such as PDE-5 inhibitors, and to go to the nearest Emergency Department for reversal therapy if their erection lasts longer than 4 hours to prevent permanent damage to the corpora.[261]

Penile revascularization surgery is done in a very small subgroup of individuals (typically young men), about 5% of all persons with ED.[272]

Disorders of the Male Breast

Gynecomastia

Gynecomastia is the overdevelopment of breast tissue in a male. It appears more during certain ages of hormonal change such as birth, adolescence, and old age.[273] The incidence is greatest among adolescents and men older than 65 years. Gynecomastia results from hormonal alterations, which may be idiopathic or caused by systemic disorders, drugs including thiazides, digoxin, estrogens, phenothiazines, and theophylline, hypogonadism, or liver and kidney failure.[273] Marijuana is also associated with gynecomastia. Chemotherapeutic drugs known to cause gynecomastia include methotrexate, alkylating agents, imatinib, and vinca alkaloids. The most common drugs are those with estrogen-like actions, including cimetidine, spironolactone, ketoconazole, and finasteride. Contributing disorders associated with gynecomastia are breast cancer, adrenal disease, thyroid disease, cirrhosis, renal failure, hypogonadism, and malnutrition.[273] Most cases of gynecomastia are idiopathic; however, it is known to involve an imbalance of the estrogen/testosterone (estrogen/T) ratio.[274,275]

The normal estrogen/T ratio can be altered in one of two ways. First, estrogen levels may be excessively high, although T levels are normal. This is the case in drug-induced and tumor-induced hyperestrogenism. Second, T levels may be extremely low, although estrogen levels are normal, as is the case in hypergonadism. Gynecomastia also can be caused by alterations in breast tissue responsiveness to hormonal stimulation. Breast tissue may have increased responsiveness to estrogen or decreased responsiveness to androgen. Alterations of responsiveness may cause many cases of idiopathic gynecomastia.

Hormone-induced gynecomastia is usually bilateral. Pubertal gynecomastia is a self-limiting phenomenon that usually disappears within 4 to 6 months. Senescent gynecomastia usually regresses spontaneously within 6 to 12 months. Gynecomastia also is often seen in males receiving estrogen therapy such as in preparation for sex reasignment surgery or gender affirming surgery.

Pathophysiology

Gynecomastia is the result of enlargement of breast glandular tissue and adipose tissue. Estrogen is responsible for the growth of glandular tissue, as well as the suppression of testosterone. Estrogen suppresses LH, which is responsible for testicular secretion of testosterone. The hormonal imbalance leads to gynecomastia. Three types of gynecomastia related to the length of the condition are florid, fibrous, and intermediate. **Florid gynecomastia** is seen in early stages of the condition, four months or less, with an increase in ductal tissue and vascularity.[273]**Fibrous gynecomastia** is noted after a year duration with more stromal fibrosis and few ducts. **Intermediate gynecomastia**, seen after one year, is thought to be a progression from florid to fibrous.

Evaluation and Treatment

The diagnosis of gynecomastia is based on a complete history and physical examination. A careful review of all medications and recreational drug use is obtained. During the physical exam, the head and neck are examined for any abnormal masses or thyroid changes. The breasts and axilla regions are examined for masses, skin changes, nipple discharge, asymmetry, and tenderness. The testes are examined for asymmetry, enlargement, masses, or atrophy.[273] Males with feminizing characteristics have endocrine and genetic testing.[273] Identification and treatment of the cause are likely to be followed by resolution of the gynecomastia. The man should be taught to perform

breast self-examination and is examined at 6- and 12-month intervals if the gynecomastia persists. All unilateral breast enlargement in men warrants an evaluation for malignancy; workup includes fine-needle aspiration, cytology, mammography, ultrasound, and biopsy. If the underlying condition is treated, yet persists for longer than a year, surgical treatment is suggested.[276–278]

Male Breast Cancer

Male breast cancer (MBC) accounts for 0.26% of all male cancers and 1.1% of all breast cancers. In 2021, estimated new cases of MBC were 2650 and deaths 530.[199] Global incidence rates were generally less than 1 per 100,000 man-years, in contrast to much higher rates in females.[279] It is seen most after the age of 60 years, with the peak incidence between 60 and 69 years (men tend to be diagnosed at an older age than women). However, it has been reported in males as young as 6 years old and in adolescents. Klinefelter syndrome is the strongest risk factor for developing male breast carcinoma. Other risk factors include germline mutation in *BRCA1* or *BRCA2*, but familial cases usually have *BRCA2* rather than *BRCA1* mutations.[280]

Obesity increases the risk of MBC. Testicular disorders, including cryptorchidism, mumps, orchitis, and orchiectomy, are related to risk. The relationship between these factors and the risk of disease is not clearly defined.

Recent data on the most frequent molecular subtypes of MBC appears to be different from those for female breast cancers. Luminal A and luminal B are most common, and basal-like, unclassifiable triple-negative, and *HER2*-driven MBCs are rare.[280]

Male breast tumors often resemble carcinoma of the breast in women (see Breast Cancer in Chapter 25). The majority of MBCs express estrogen and progesterone receptors. The malignant male breast lesion is usually a unilateral solid mass located near the nipple. Because the nipple is commonly involved, crusting and nipple discharge are typical clinical manifestations. Other findings include skin retraction, ulceration of the skin over the tumor, and axillary node involvement. Patterns of metastasis are similar to those in females.

The diagnosis of cancer is confirmed by biopsy. Because of delays in seeking treatment, MBC tends to be advanced at the time of diagnosis and therefore is likely to have a poor prognosis. Treatment protocols are like those for female breast cancer, and endocrine therapy is used for MBC as male tumors are hormone dependent. The mainstay of treatment is modified mastectomy with axillary node dissection to assess the stage and prognosis. Because 90% of tumors are hormonal receptor positive, tamoxifen is standard adjuvant therapy. For metastatic disease, hormonal therapy is the main treatment, but chemotherapy also can provide palliation. An orchiectomy may need to be performed to treat metastatic disease to the testes.

Summary Review

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, is marked by the development of secondary sex characteristics, rapid growth, and ultimately, the ability to reproduce. Puberty begins later in boys than in girls; the onset of 9 to 14 years has remained unchanged in boys.
2. Precocious puberty is early development of secondary characteristics in boys before age 9. Contrasexual development occurs when male or female children develop features of the opposite gender. Delayed puberty in boys is when their growth spurt occurs later (15 to 17 years) and seldom requires treatment.

Disorders of the Male Reproductive System

1. Disorders of the urethra include urethritis (infection of the urethra) and urethral strictures (narrowing or obstruction of the urethral lumen caused by scarring).
2. Most cases of urethritis result from sexually transmitted pathogens. Urologic instrumentation, foreign body insertion, trauma, or an anatomic abnormality can cause urethral inflammation with or without infection.
3. Urethritis causes urinary symptoms, including a burning sensation during urination (dysuria), frequency, urgency, urethral tingling or itching, and a clear or purulent discharge.
4. Strictures mostly result from injury to the urethral mucosa and surrounding tissues. Etiologies include idiopathic, iatrogenic, inflammatory, and traumatic. Urethral strictures are common in the United States.
5. Pathophysiology of stricture is injury to the urethral epithelium from any of the specific etiologies causing a leak of urine to the corpus spongiosum or by direct trauma to the corpus spongiosum.
6. Manifestations of urethral stricture include those of bladder outlet obstruction: urinary frequency and hesitancy, mild dysuria, double urinary stream or spraying, and dribbling after voiding.
7. Phimosis and paraphimosis are penile disorders involving the foreskin (prepuce). In phimosis, the foreskin cannot be retracted over the glans. In paraphimosis, the foreskin is retracted and cannot be reduced (returned to its normal anatomic position over the glans). Phimosis is caused by poor hygiene and chronic infection. In adults it can be caused by sexually transmitted infections. Paraphimosis can constrict the penile blood vessels, preventing circulation to the glans.
8. The hallmark of Peyronie disease is the tunical fibrosis of the corpora cavernosa resulting in plaques. Fibrosis prevents engorgement on the affected side, causing a lateral curvature during erection. Peyronie disease can cause painful erection, painful intercourse for both partners, and poor erection distal to the involved area. It is a disorder of wound healing of the tunica albuginea.
9. Priapism is a disorder of prolonged, painful erection in the absence of appropriate stimulation. The causes of priapism are numerous and include hemoglobinopathies, sickle cell disease, thalassemia, vasoactive medications, intracavernous injections, antidepressants, and less commonly neurologic infections, and neoplastic diseases. Pathophysiology of priapism includes ischemic and nonischemic changes.
10. Balanitis is an inflammation of the glans penis. Posthitis is inflammation of the foreskin or prepuce. It is associated with phimosis, inadequate cleansing under the foreskin, skin disorders, and pathogens (e.g., *Candida albicans*). **Balanoposthitis** involves both the glans and foreskin and occurs only in uncircumcised males.
11. Balanitis is associated with inadequate hygiene and phimosis in uncircumcised males leading to infection. Other etiologies include chemical irritants, edematous conditions, drug allergies, morbid obesity, allergic reaction, trauma, neoplastic disorders, and others.
12. Condyloma acuminatum is a benign tumor caused by HPV.
13. Cancer of the penis is rare. It can affect men 40 to 70 years of age, Risk factors include HPV, smoking, chronic inflammatory conditions, certain treatments for psoriasis, obesity, and poor penile hygiene. The precursor lesion of penile cancer is penile intraepithelial neoplasia (PeIN).
14. Varicocele, hydrocele, and spermatocele are common disorders of the scrotum.
15. A varicocele is an abnormal dilation of the veins within the spermatic cord and is classically described as a “bag of worms.” Varicoceles are one of the most identified scrotal abnormalities and abnormal findings among infertile men.
16. A hydrocele is an abnormal collection of fluid between the layers of the tunica vaginalis of testis.

17. A spermatocele is a cyst located between the testis and epididymis that is filled with fluid and sperm.
18. Cryptorchidism is the absence of at least one testicle from the scrotum and is the most common birth defect of the male genitalia. About 80% of cryptorchid testes descend by the third month making the incidence about 1%. The main risk factor for undescended testes is birthweight followed by family history.
19. Testicular torsion occurs when a testicle rotates twisting the spermatic cord and interrupting its blood supply. Torsion of the testis is a surgical emergency and must be corrected within 6 hours from the onset of pain to preserve normal testicular function.
20. Orchitis is an acute inflammation of the testes and is usually unilateral. Common risk factors include a preexisting history of epididymitis, unprotected sexual contact, multiple sexual partners, long-term use of a urinary catheter, bladder outlet obstruction, and lack of immunization with MMR vaccination.
21. Testicular cancer is very uncommon and usually affects men between 14 and 44 years of age. It is, however, increasing worldwide and the etiology is not well documented. The most consistent risk factor is cryptorchidism, which increases risk of testicular cancer fivefold. Germ cell neoplasia (GNIS) is known as the precursor lesion to malignant testicular germ cell tumors (TGCTs). Germ-cell tumors are observed secondary to a carcinogenic event in utero. During puberty hormonal changes increase the invasive potential of these neoplasms.
22. Epididymitis, an inflammation of the epididymis testis, is commonly caused by a sexually transmitted pathogen (mostly bacteria) in younger men and from retrograde flow of urine in elderly males.
23. Benign prostatic hyperplasia is nonmalignant growth or hyperplasia of prostate tissue. This condition becomes symptomatic as the enlarging prostate compresses the urethra, causing symptoms of bladder outlet obstruction and urine retention.
24. Prostatitis is an infection or inflammation of the prostate gland. Prostatitis syndromes have been classified by the National Institutes of Health as (1) acute bacterial prostatitis (ABP), (2) chronic bacterial prostatitis (CBP), (3) chronic pelvic pain syndrome (CPPS), and (4) asymptomatic inflammatory prostatitis.
25. Prostate cancer is the most diagnosed, non–skin cancer in American males, and the incidence varies greatly worldwide. Risk factors include age, ethnicity, obesity, family history, height, hypertension, lack of exercise, Agent Orange exposure, and Western diet. Although the cause is unknown, genetics plays a role. Androgens and androgen receptor (AR) function have major roles in the development and progression of prostate cancer. Chronic inflammation may be an important risk factor for prostate adenocarcinoma.
26. Most cancers of the prostate are adenocarcinomas that develop at the periphery of the gland.
27. Sexual dysfunction in males can be caused by any physical or psychological factor that impairs erection, emission, or ejaculation. Erectile dysfunction is the most prevalent.
28. Spermatogenesis (sperm production by the testes) can be impaired by disruptions that reduce testosterone secretion and by testicular trauma, infection, atrophy from any cause, systemic illness involving high fever, ingestion of various drugs, exposure to environmental toxins, and cryptorchidism.

Disorders of the Male Breast

1. Gynecomastia is the overdevelopment of breast tissue in a male. The incidence is greatest among adolescents and men older than 65 years of age.

2. Gynecomastia can result from systemic disorders, drugs, neoplasms, or idiopathic causes. Most cases are idiopathic and involve an imbalance of the estrogen/testosterone ratio.
3. Breast cancer is relatively uncommon in males, but it has a poor prognosis because men tend to delay seeking treatment until the disease is advanced. The incidence is greatest in men in their sixties.

Chapter Outline

OUTLINE

Sexually Transmitted Urogenital Infections, 867
- Bacterial Infections, 867
- Viral Infections, 879
- Parasitic Infections, 884

Sexually Transmitted Infections of other body Systems, 886
- Hepatitis, 887
- Acquired Immunodeficiency Syndrome, 888

Newly acquired sexually contracted infections affect more than 26 million Americans per year, and half of those individuals are younger than 25 years of age (Box 27.1).[1–4] Sexually transmitted infections (STIs) are called the hidden epidemic by the Centers for Disease Control and Prevention (CDC).[1] They account for nearly $16 billion in healthcare costs in the United States.[5] STIs are so prevalent yet rarely discussed. Complications of STIs include short- and long-term morbidity, which can affect physical, emotional, and financial well-being, and even mortality.[5]

Box 27.1

Sexually Transmitted Infection Statistical Summary from 2019 Centers for Disease Control and Prevention Report

Each year in the United States:

- 20 million individuals contract a sexually transmitted infection.
- $16 billion is spent on sexually transmitted infection (STIs), not including long-term healthcare costs.
- Only half of people who need STI screening receive needed services.

Chlamydia cases:

- 1.8 million cases were reported a 19% increase since 2015.

Gonorrhea cases:

- 616,392 cases were reported in 2019, a 56% increase since 2015.
- Increasing antibiotic resistance means that gonorrhea may soon become resistant to all known treatments.

Syphilis cases:

- There was a 74% overall increase in cases reported since 2015.
- The syphilis rate is highest among men who have sex with men.

Viral STIs affect more than 70 million people in the United States:

- The use of the human papillomavirus (HPV) vaccine has demonstrated positive effects on the rates of HPV acquisition in the United States.
- 26 billion STIs in 2018 with almost half of new STIs among youth aged 15-24 in the United States.
- There are 18.6 million individuals living with herpes simplex-2.

Data from Centers for Disease Control and Prevention (CDC). *Sexually Transmitted Disease 2022*. Washington, DC: U.S. Department of Health and Human Services; 2022. https://www.cdc.gov/std/default.htm.

In the past, an infection transmitted through sexual intercourse was called a *venereal disease*. However, the term venereal disease has

been replaced with STI. STIs are contracted by genital contact or through contact with infected blood or body fluids. Infections can be transmitted directly through touch, or the infectious agent can be transmitted by an object, known as a fomite. STIs such as syphilis, gonorrhea, chlamydia, hepatitis, and human immunodeficiency virus (HIV) also can be transmitted from mother to child during pregnancy and birth, a process known as vertical transmission.

Many infected individuals are not screened for STIs because symptoms are absent, minor, or transient, or because health services are inaccessible, unaffordable, or culturally insensitive. When individuals do not know they have an STI, they often fail to prevent transmission to others. With adequate screening and early treatment and education, the prevalence and sequelae of STIs can be greatly reduced.

Behaviors are the greatest risk factor for STI acquisition. Individuals who have unprotected intercourse or genital/oral contact, especially with non-monogamous or multiple partners, are at the greatest risk. Certain populations as defined by age, behaviors, geographic location, traits, or race/ethnicity have a higher incidence of STIs. This increase is usually a result of increased risky behaviors by individuals in this group, but it can also be due to physical or cultural characteristics that contribute to transmission. For example, rates of gonorrhea, chlamydia, vaginitis, cervical condyloma, genital warts, and pelvic inflammatory disease (PID) are highest in adolescents and decline exponentially with increasing age (Fig. 27.1). Adolescents more often engage in risky behaviors and have a greater number of sexual partners than older adults. Individuals entering correctional facilities, such as jails, also have higher rates of STI prevalence related to their risky behaviors before incarceration.[1]

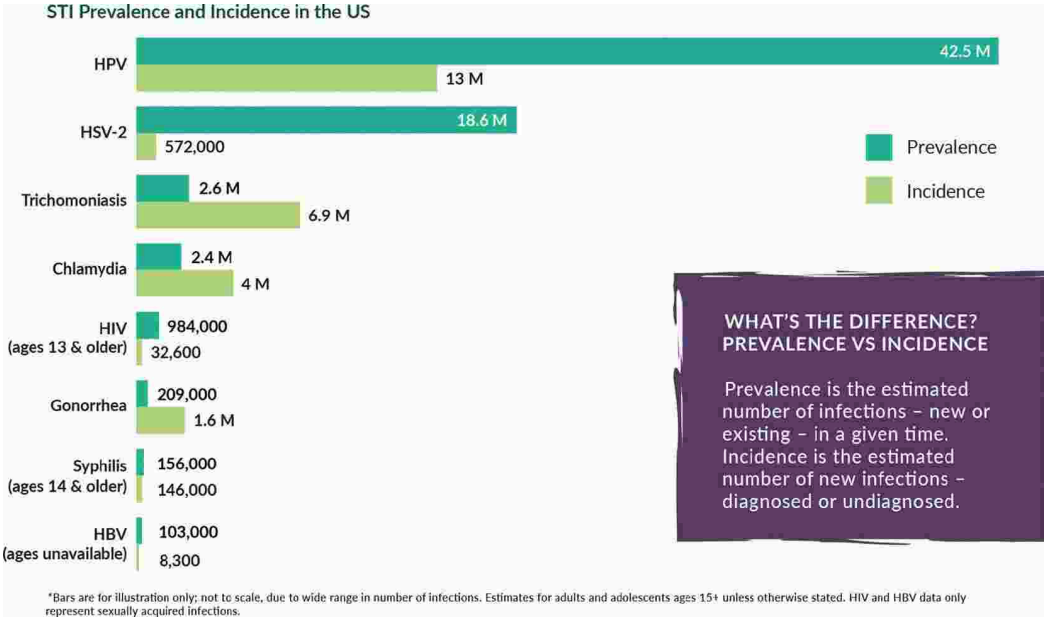

FIG. 27.1 Prevalence and Incidence of Sexually Transmitted Infections. (From Centers for Disease Control and Prevention [CDC]. *CDC Prevention Infographics; Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, page last reviewed;* 2022. http://www.cdc.gov/std/products/infographics.htm.)

A circular wheel depicts the risk factors that determine sexual dysfunction. The factors are given as follows. Comorbidities factors include aging, cardiovascular disease, diabetes mellitus, cancer, chronic kidney disease, psychological, and nerve or spinal cord damage. Environment factors include heavy metals, chemicals including bisphenol A and polychlorinated biphenyl, and toxins. Lifestyle factor includes tobacco, alcohol, illicit drugs, obesity, and anxiety or stress. Medications factors include

cardiovascular medications, psychiatric medications, antibacterial, and anticholinergic medications.

Some populations are at greater risk because of the pathophysiology of STI transmission. Transmission of many STIs is enhanced when the infectious agent contacts mucous membranes, such as the mouth, oropharynx, vagina, rectum, and the inner foreskin, which provide a more favorable environment for transmission than skin. Therefore women, uncircumcised men, and men who are the receptive partner in oral or anal sex are at increased risk.[1] In addition, prolonged contact with infectious body fluids also increases transmission, which occurs when semen is deposited in the vagina or rectum. Young women also are at greater risk for STI acquisition when compared with older women, which is related to the position of susceptible cells on the surface of their cervix.

STI transmission is enhanced when the infectious agent has contact with broken skin or blood vessels. Sexual contact that is damaging to the genitals increases STI acquisition. This is the case with penile-rectal penetration, as well as forced genital contact. Broken or friable skin caused by genital infections or trauma also can increase the risk of STI transmission. As a result, if an individual has one STI, susceptibility increases when exposed to other STIs.

Race and ethnicity are not direct factors in STI acquisition. STIs are prevalent in all socioeconomic and racial/ethnic groups. Publicly available data suggest a greater prevalence in minority groups or among people with low socioeconomic status, which may reflect greater STI reporting from public clinics that serve marginalized groups when compared with private providers who are not required to report all infections to authorities. Race and ethnicity alone do not alter STI risk but rather act as risk markers that correlate with other more fundamental determinants of health status, such as (1) poverty, (2) access to quality care, and (3) health-seeking behavior. In some geographic areas, racial, ethnic, or socioeconomic groups may be more or less likely to engage in at-risk behaviors such as intravenous

(IV) drug use and unprotected sex. Healthcare providers should provide risk-appropriate screening based on behaviors and physiologic risk factors without racial profiling. To assist clinicians, the CDC regularly publishes a comprehensive guideline detailing STI screening, evaluation, and treatment that specifies current at-risk groups. This guide and its corresponding smartphone app are the best sources of current information on STI screening and treatment because this area of clinical care changes rapidly.

An STI can be caused by bacteria, viruses, protozoa, parasites, or fungi (Table 27.1). Transmission rates and prevalence depend on the characteristics of the pathogen and complex factors associated with behavioral and societal factors. Bacterial, protozoan, parasitic, and fungal STIs can be successfully treated once diagnosed, but viral STIs cannot be cured by pharmacologic means alone and, depending on the virus, affected individuals have the potential to carry or transmit the virus throughout their life.

Table 27.1

Currently Recognized Sexually Transmitted Infections

Causal Microorganism	Infection
Bacteria	
Campylobacter	Campylobacter enteritis
Calymmatobacterium granulomatis	Granuloma inguinale
Chlamydia trachomatis	Urogenital infections; lymphogranuloma venereum
Polymicrobial	
Gardnerella vaginalis interaction with anaerobes (*Bacteroides* and *Mobiluncus* spp.) and genital mycoplasmas	Bacterial vaginosis
Haemophilus ducreyi	Chancroid
Mycoplasma	Mycoplasmosis
Neisseria gonorrhoeae	Gonorrhea
Shigella	Shigellosis
Treponema pallidum	Syphilis
Viruses	
Cytomegalovirus	Cytomegalic inclusion disease
Hepatitis B virus (HBV)	Hepatitis
Hepatitis C virus (HCV)	Hepatitis
Herpes simplex virus (HSV)	Genital herpes

Causal Microorganism	**Infection**
Human immunodeficiency virus (HIV)	Acquired immunodeficiency syndrome (AIDS)
Human papillomavirus (HPV)	Condylomata acuminata, cervical dysplasia, and cervical cancer
Molluscum contagiosum virus	Molluscum contagiosum
Zika virus	Zika virus disease
Protozoa	
Entamoeba histolytica	Amebiasis; amebic dysentery
Giardia lamblia	Giardiasis
Trichomonas vaginalis	Trichomoniasis
Ectoparasites	
Pthirus pubis	Pediculosis pubis
Sarcoptes scabiei	Scabies
Fungus	
Candida albicans	Candidiasis

Causal Microorganism	Infection
Bacteria	
Campylobacter	Campylobacter enteritis
Calymmatobacterium granulomatis	Granuloma inguinale
Chlamydia trachomatis	Urogenital infections; lymphogranuloma venereum
Polymicrobial	
Gardnerella vaginalis interaction with anaerobes (*Bacteroides* and *Mobiluncus* spp.) and genital mycoplasmas	Bacterial vaginosis
Haemophilus ducreyi	Chancroid
Mycoplasma	Mycoplasmosis
Neisseria gonorrhoeae	Gonorrhea
Shigella	Shigellosis
Treponema pallidum	Syphilis
Viruses	
Cytomegalovirus	Cytomegalic inclusion disease
Hepatitis B virus (HBV)	Hepatitis
Hepatitis C virus (HCV)	Hepatitis
Herpes simplex virus (HSV)	Genital herpes
Human immunodeficiency virus (HIV)	Acquired immunodeficiency syndrome (AIDS)
Human papillomavirus (HPV)	Condylomata acuminata, cervical dysplasia, and cervical cancer
Molluscum contagiosum virus	Molluscum contagiosum
Zika virus	Zika virus disease
Protozoa	
Entamoeba histolytica	Amebiasis; amebic dysentery
Giardia lamblia	Giardiasis
Trichomonas vaginalis	Trichomoniasis
Ectoparasites	
Pthirus pubis	Pediculosis pubis
Sarcoptes scabiei	Scabies
Fungus	
Candida albicans	Candidiasis

Treatment or symptom management of STIs depends on the causative pathogen. Treatments change frequently based on drug resistance and availability of medications. The treatment is personalized based on the individual's medical needs and personal preferences. Treatment of the individual and his or her sexual partner(s) is often complicated by inadequate access to medical care, drug cost, and privacy concerns.[1] Many states have enacted legislation to allow sexual partners to be treated without having to go to a clinic for an examination and prescription.[6,7] This practice is recommended and supported by many health organizations.[8,9]

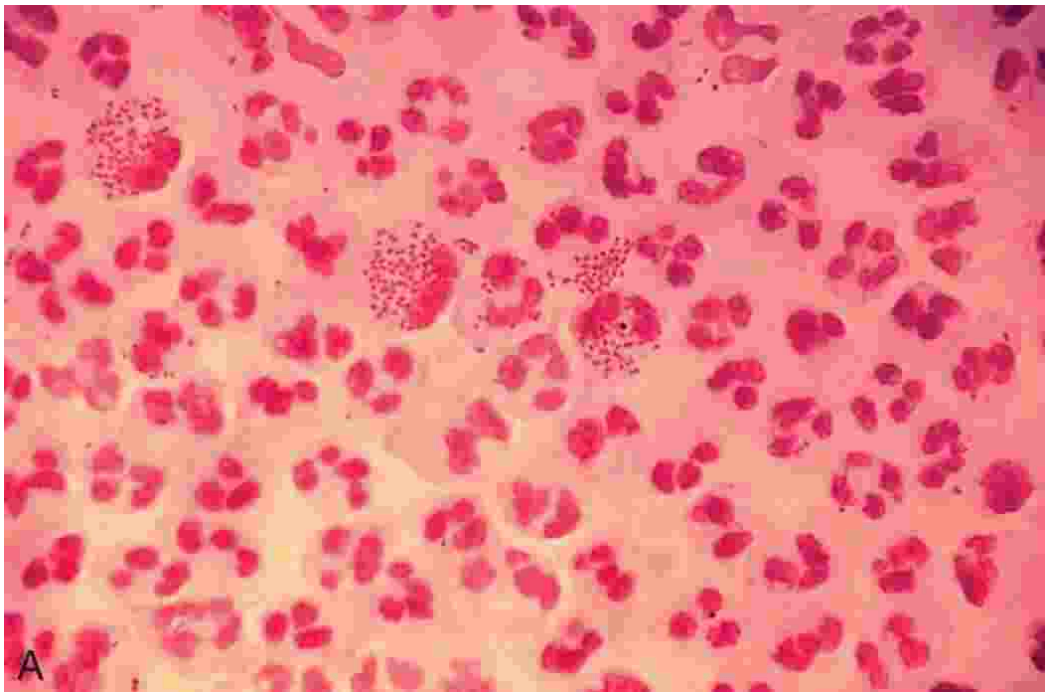
Prevention of STIs involves a multifaceted approach. This includes encouraging behavioral changes such as decreasing the number of sexual partners or using condoms to decrease transmission. Preexposure prophylaxis (PrEP), including vaccines for hepatitis and human papillomavirus (HPV), has been used to protect populations against viral STIs before exposure.[10] Medications also may be used to prevent acquisition of STIs as PrEP (e.g., emtricitabine/tenofovir) and postexposure prophylaxis (PEP), especially in the prevention of HIV.[10] Early treatment of STIs prevents transmission to new hosts and decreases the risk of additional STIs. Testing and treatment are especially helpful in preventing vertical transmission.

Sexually Transmitted Urogenital Infections

Bacterial Infections

Gonorrhea

Gonorrhea is caused by Neisseria gonorrhoeae, aerobic, non–spore-forming, oxidase-positive, gram-negative diplococci, organisms that usually appear in pairs with adjacent, slightly flattened sides (Fig. 27.2A). The rates for gonorrhea have increased in part because of widespread testing using more accurate nucleic acid amplification tests (NAATs).[11] In 2019, the CDC reported a total of 616,392 new cases, with as many as 1,000,000 cases undiagnosed.[5] This represents a 92% increase from the record low in 2009, including a 5.9% increase from 2018 to 2019. The rate of increase has occurred in all ethnic/racial groups and in all regions of the United States. The increase is consistently higher in men as compared with women.[10]



A

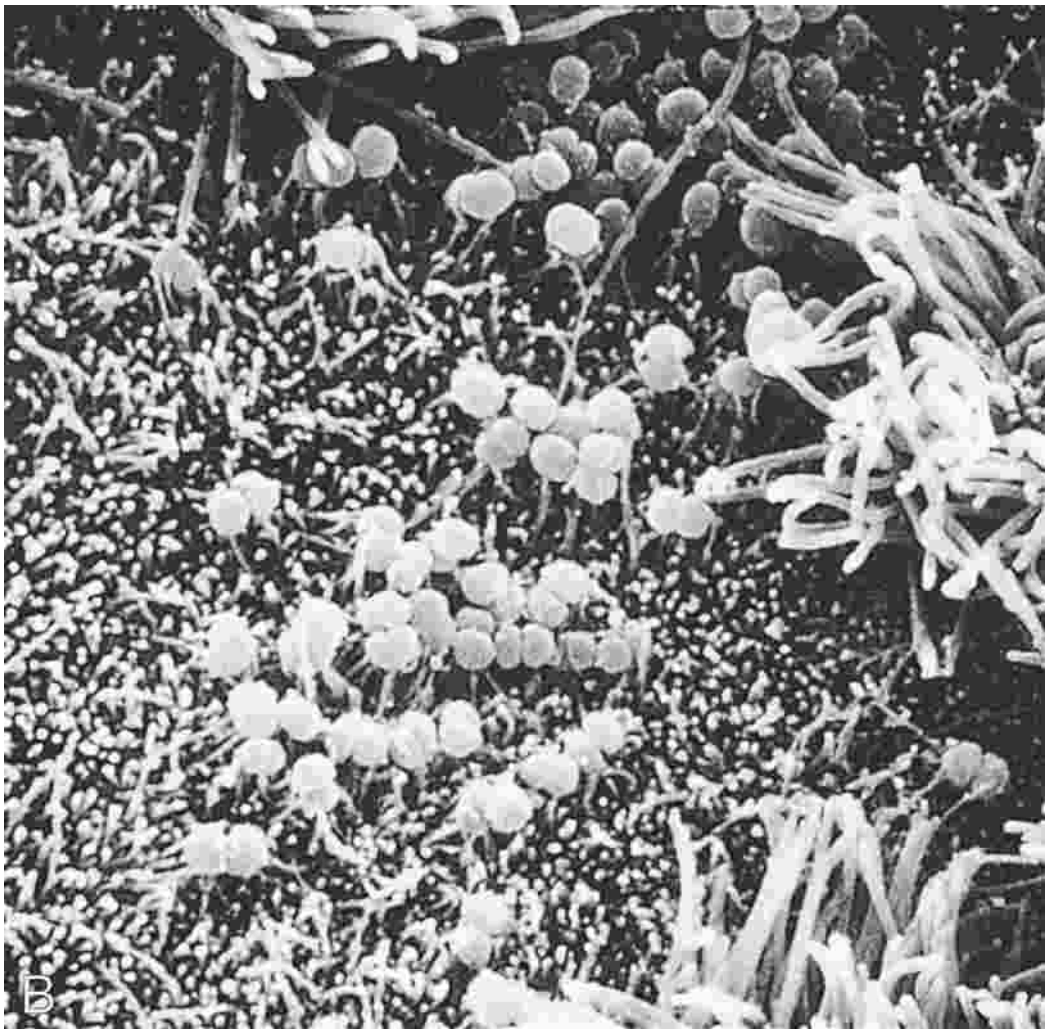


FIG. 27.2 (A) A Gram stain picture of *Neisseria gonorrhoeae*.(From Goldman L, Schafer AI. *Goldman-Cecil medicine*, 26th edition. Philadelphia: Elsevier; 2020.) (B) Gonococci. Scanning electron microscopy showing gonococci attaching to the nonciliated cells of human uterine/fallopian tube mucosa. (From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 3rd edition. London: Mosby; 2003.)

A circular wheel depicts the risk factors that determine sexual dysfunction. The factors are given as follows. Comorbidities factors include aging,

cardiovascular disease, diabetes mellitus, cancer, chronic kidney disease, psychological, and nerve or spinal cord damage. Environment factors include heavy metals, chemicals including bisphenol A and polychlorinated biphenyl, and toxins. Lifestyle factor includes tobacco, alcohol, illicit drugs, obesity, and anxiety or stress. Medications factors include cardiovascular medications, psychiatric medications, antibacterial, and anticholinergic medications.

The risk of developing gonorrhea from intercourse with an infected male partner is 50% to 80% for women, and with an infected female partner, it is 20% to 30% for men. The risk increases threefold to fourfold for men after four exposures to an infected partner. Men who have sex with infected men have a greater risk of contracting gonorrhea if they are the receptive partner.[12]

Transmission of gonococcal infection generally requires direct contact of epithelial (mucosal) surfaces, such as occurs during vaginal, oral, or anal intercourse. Infection in adults can be maintained in the vagina, rectum, oropharynx, or urethra.[13] A pregnant woman can transmit gonorrhea to her fetus through infected cervical and vaginal secretions that contact the baby's mucosal surfaces during birth. Following vertical transmission, the newborn eyes can be infected and can result in blindness if untreated.

Treatment for gonorrhea is becoming more difficult because of rapidly developing resistance to available antibiotics. In 2019, the CDC reported that more than half of infections were resistant to at least one antibiotic.[10]

Prior to 2021, both the CDC and the World Health Organization (WHO) advised dual drug treatment for gonorrhea to effectively treat infection and prevent increasing resistance.[10] In 2021, the CDC

STI Treatment Guidelines indicated that dual therapy may increase harm to the microbiome and currently recommend using only ceftriaxone for treating gonorrhea in the United States.[10,14] Antimicrobial resistance is increased in populations that frequently have oral or anal receptive intercourse, such men who have sex with men (MSM). The CDC states it is reasonable to expect that gonorrhea may become resistant to all known antibiotics soon.[10,14]

Pathophysiology

Humans are the only natural hosts for *N. gonorrhoeae*. Hair-like filaments on the gonococci, called *pili*, appear to help the microorganisms attach themselves to host cells: the epithelial cells of mucous membranes (Fig. 27.2B). Columnar, transitional, and stratified squamous epithelial cells are most often infected. First, the gonococci attach to the plasma membranes (cell walls) of these cells, and then they invade the cells and begin to damage the mucosa. In general, a quick leukocytic (inflammatory) response and exudate occurs at the site of infection.

In women, the endocervical canal (inner portion of the cervix) is a common site of initial gonococcal infection, although urethral colonization and infection of glands (paraurethral [Skene] glands and greater vestibular [Bartholin] glands) near the urethra and vagina also are common. Several factors facilitate ascent of gonococci into the uterus and the fallopian tubes, where they can cause PID. Among these factors are (1) disintegration of the cervical mucous plug and an increase in vaginal pH to greater than 4.5 during menstruation, (2) uterine contractions that may cause retrograde menstruation into the fallopian/uterine tubes, and (3) various microbes that possess virulent potentiating factors for chlamydia or gonococcal PID. Bacteria (*N. gonorrhoeae, Chlamydia trachomatis*) may adhere to sperm and be transported to the fallopian/uterine tubes. Once gonococci are in the fallopian/uterine tubes, progressive mucosal and submucosal invasion of the tissues causes sloughing of normal, ciliated tubal epithelium and a marked inflammatory

response causing the tubes to fill with exudate (see Chapter 25 for more discussion on PID).

In men, the gonococci typically infect the urethra or rectum. In men, untreated urethral infection can cause epididymitis and potentially lead to urethral stricture, fistula formation, and sterility. However, a few men maintain asymptomatic infections for long periods of time.[8]

Concurrent or isolated oropharyngeal and anorectal infection can be found in infected men and women and may be difficult to detect with common testing mechanisms.[12] These sites are associated with greater antibiotic resistance than urethral or vaginal infection and may need additional treatment and monitoring.[12] One hypothesis for the increase in resistant strains in populations with a high prevalence of oral and anal intercourse is that the oral and rectal mucosae normally contain many nonpathogenic forms of *Neisseria* bacteria. These bacteria are often exposed to antibiotics used for other non-STI conditions; however, instead of being eliminated, they develop antibiotic resistance. Gonococci frequently share plasmids and DNA across species, a process known as *conjugation*, facilitating the transfer of antibiotic resistance.[11] When the oropharynx and the rectum are infected by *N. gonorrhoeae*, the pathogens meet antibiotic-resistant bacteria that share plasmids and DNA. As the *N. gonorrhea* proliferate, they can acquire antibiotic resistance before being spread to new individuals through oral sexual contact.[11]

Clinical Manifestations

The clinical manifestations of gonorrhea can be categorized as local or systemic and uncomplicated or complicated. Uncomplicated local infections include urethral infections in men and urogenital infections in women. Although infection can initially be asymptomatic, most infected men will develop painful urination or purulent penile discharge, or both, within a week of infection.[10] These severe symptoms encourage most men in developed countries to seek treatment.[10] However, some men may have only a slight

discharge or urethral itching (pruritus). As many as 5% to 10% of infected men never have signs or symptoms of gonorrhea. Most cases of untreated gonococcal urethritis resolve spontaneously after several weeks. More than 95% of men are asymptomatic by 6 months after infection (although they may still be infectious).

In women, the incubation period varies, but those who develop symptoms usually manifest within 10 days of exposure or 1 to 2 days after the next menstrual period. More than half of gonorrhea infections in women are initially asymptomatic. Symptoms often do not appear until the infection has spread to the upper reproductive tract (uterus, fallopian/uterine tubes, and ovaries). Symptoms may include dysuria, increased vaginal discharge, abnormal menses (increased flow or dysmenorrhea), dyspareunia, lower abdominal/pelvic pain, and fever. Pelvic examination may identify cervical friability and erythema (redness) with mucopurulent discharge from the cervical os (Fig. 27.3). There may be discharge from the paraurethral (Skene) or greater vestibular (Bartholin) glands if these sites are involved.

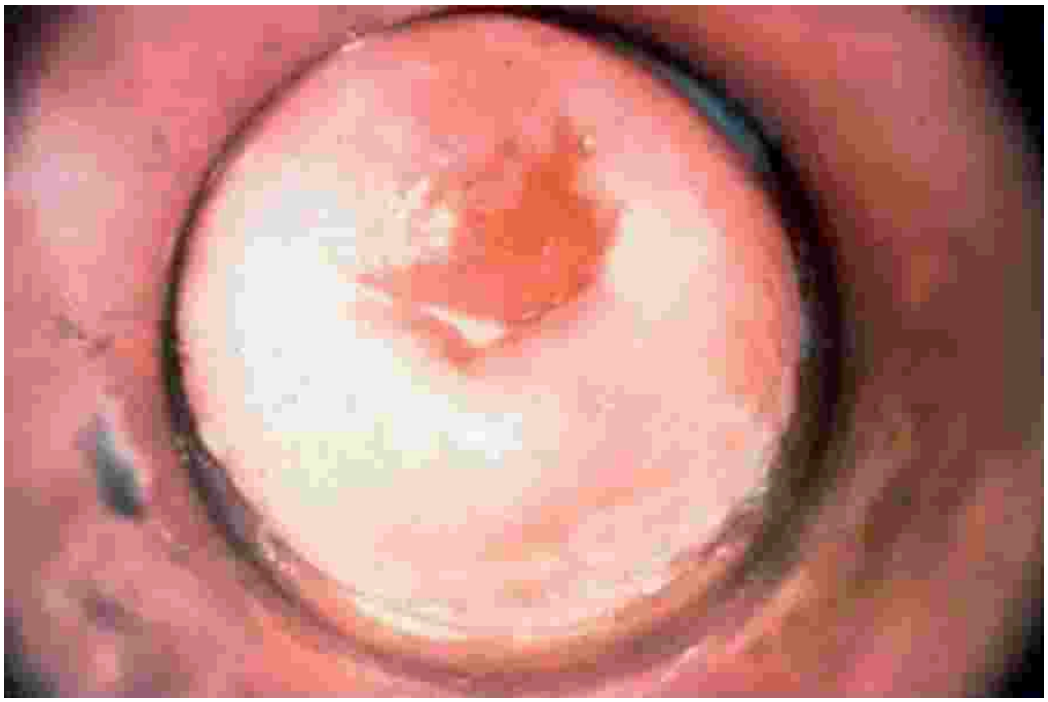

FIG. 27.3 Gonococcal Cervicitis.
The cervix is involved in 85% to 90% of cases in women, but discharge is profuse enough to be recognized in only 10%. (From Centers for Disease Control and Prevention [CDC]. *STD Clinical Slides [website]*. www.cdc.gov/std/training/clinicalslides/slides-dl.htm. Accessed December 6, 2020.)

Anorectal gonorrhea occurs more commonly in MSM but is also found in women both as an isolated finding and with coexisting urogenital gonorrhea.[1] Symptoms of anorectal gonorrhea range from mild anal pruritus (itching), mucopurulent rectal discharge, and slight rectal bleeding to severe rectal pain, tenesmus (painful and ineffectual straining at stool), and constipation. Findings on physical exam may include anal erythema and discharge and evidence of mucosal damage to the anus and rectum, such as friability, edema, and purulent exudate.

Gonococcal pharyngitis occurs after oral sexual contact with an infected partner. Symptomatic pharyngitis is indistinguishable from any other bacterial pharyngitis and can include fever, lymphadenopathy, and tonsillitis. However, 60% of people with

oropharyngeal infections are asymptomatic.[8] In addition, many clinicians neglect to test for oropharyngeal gonorrhea because they do not screen for unprotected oral sex. Cure rates for this type of gonorrhea are much lower because of inadequate antibiotic concentrations in oral tissue.[11] Other sites of uncomplicated local infections include the eyes, leading to conjunctivitis; this condition occurs almost exclusively in newborns born vaginally to infected mothers. Primary cutaneous infections have also been reported and usually manifest as a localized ulcer of the genitalia, perineum, proximal lower extremities, or fingers.

Complicated gonococcal infections in men include prostatitis, epididymitis, lymphangitis, and urethral stricture. Complicated gonococcal infections in women include bartholinitis and endometritis (infection of the uterine lining). Further spread into the fallopian tubes and peritoneum is known as *PID* and can result in severe inflammation and scarring. The onset of PID symptoms may be rapid and usually occurs during menses.[15] Women may experience chills, fever, nausea, vomiting, and lower abdominal/pelvic pain that worsens with movement, such as walking, coughing, sneezing, or intercourse. Abdominal palpation often discloses bilateral lower quadrant tenderness and rebound tenderness from peritoneal irritation.[8] Marked motion tenderness of the cervix and internal genitalia is often noted during pelvic examination (Chandelier sign).

PID resulting from any pathogen contributes to infertility through a variety of mechanisms. During infection, the delicate ciliated epithelium of the uterine tubes is permanently damaged. The lack of regular cilia movement can impair the transit of sperm and fertilized ova.[15] Scarring and adhesions of the tubes may further impair fertility. Up to 18% of women who have been diagnosed with PID experience later infertility. Because fertilization occurs in the midportion of the fallopian tube, ectopic pregnancy rates in this population are as high as 9% partially due to slowed motility of the cilia and scarring in the fallopian tubes.[15]

Disseminated gonococcal infection (DGI) is a rare systemic complication caused by the spread of infection through the bloodstream. Symptoms of this life-threatening condition include a generalized rash, severe joint pain, meningitis, and endocarditis.[8] Gonococcal strains that can cause DGI may cause genital inflammation before systemic dissemination.[8]

If during pregnancy a mother has gonorrhea at the time of delivery, she can transmit the infection to her child. Most states require that all infants receive prophylactic ophthalmic antibiotics to prevent gonococcal eye infection (ophthalmia neonatorum) (Fig. 27.4). Topical antibiotics may not be effective in eliminating neonatal infection, and systemic treatment is indicated for all newborns with known exposure.[8] Untreated infection causes bilateral corneal ulceration, with a profuse yellow or gray purulent exudate, and is followed by necrosis, scarring, and blindness. Newborns born to infected mothers also may develop gonorrheal rhinitis, anorectal infection, or an abscess at the site of electrode placement for fetal monitoring. Onset of symptoms generally occurs 1 to 12 days after birth.[8]

FIG. 27.4 Gonococcal Ophthalmia Neonatorum.
Examiner should be gloved. (From McMillan A, Scott GR. *Sexually transmitted infections*, 2nd edition. London: Churchill Livingstone; 2000.)

Evaluation and Treatment

Because of the large percentage of infected women without symptoms, routine genital tract screening for at-risk women (i.e., those younger than age 25, pregnant, or with a new sexual partner) is recommended.[16] Men should be screened according to risk factors and symptoms.[16,17] Clinical signs and symptoms are not sufficient for the differential diagnosis. The test that is used should be selected based on the suspected site of infection. Nucleic acid hybridization tests can be used on samples collected from the vagina and urethra (of adult males and females; female children but not male children), as well as urine (except in boys).[16,17] Culture should be used to diagnose infections of the rectum, oropharynx, and conjunctiva of both sexes and all ages, as well as any site on boys.[14,15] Microscopic evaluation of Gram-stained slides of specimens from symptomatic men also can be used for diagnosis and is deemed positive for *N. gonorrhoeae* if gram-negative diplococci with typical "kidney bean" morphology are seen inside polymorphonuclear leukocytes.

N. gonorrhoeae has developed resistance to many antibiotics and has the real potential to become resistant to all current treatments.[16,17] There is currently only one CDC-recommended drug (ceftriaxone) to treat gonorrhea, although less-effective alternatives are available.[16,17] To prevent further drug resistance, the CDC and WHO recommend a multidrug treatment for gonorrhea that also is effective against chlamydia.[16,17] The CDC is closely observing the drug resistance of gonorrhea through monitoring of samples obtained at clinics around the country. In 2019, the CDC reported increased resistance to azithromycin particularly in MSM (8.8%) compared with men having sex with women (3.3%).[16]Treatment guidelines are updated regularly, and the most recent edition, found on the CDC website or app, should be used. Current CDC treatment guidelines for uncomplicated gonorrheal infections are listed in Box 27.2.[16] Complicated infections require IV antibiotic therapy and possibly hospitalization.[16]Sexual partners also are assessed and

treated according to these protocols, and sexual contact is avoided until treatment is completed. Condoms for all genital contact, including oral sex, are strongly recommended to prevent future infection.

Box 27.2

Centers for Disease Control and Prevention Recommended Regimens for Uncomplicated Gonococcal Infections, 2020

Regimen for uncomplicated gonococcal infections of the cervix, urethra, or rectum:

Ceftriaxone 500 mg IM as a single dose for persons weighing <150 kg (300 lb)

- For persons weighing ≥150 kg (300 lb), 1 g of IM ceftriaxone should be administered.
- If chlamydial infection has not been excluded, providers should treat for chlamydia with doxycycline 100 mg orally twice daily for 7 days. During pregnancy, azithromycin 1 g as a single dose is recommended to treat chlamydia.

Alternative regimens for uncomplicated gonococcal infections of the cervix, urethra, or rectum if ceftriaxone is not available:

Gentamicin 240 mg IM as a single dose plus azithromycin 2 g orally as a single dose OR cefixime 800 mg orally as a single dose. If treating with cefixime, and chlamydial infection has not been excluded, providers should treat for chlamydia with doxycycline 100 mg orally twice daily for 7 days. During pregnancy, azithromycin 1 g as a single dose is recommended to treat chlamydia.

Recommended regimen for uncomplicated gonococcal infections of the pharynx:
Ceftriaxone 500 mg IM as a single dose for persons weighing <150 kg (300 lb)

- For persons weighing ≥150 kg (300 lb), 1 g of IM ceftriaxone should be administered.
- If chlamydia coinfection is identified when pharyngeal gonorrhea testing is performed, providers should treat for chlamydia with doxycycline 100 mg orally twice a day for 7 days. During pregnancy, azithromycin 1 g as a single dose is recommended to treat chlamydia.
- No reliable alternative treatments are available for pharyngeal gonorrhea. For persons with a history of a beta-lactam allergy, a thorough assessment of the reaction is recommended.[a]
- For persons with an anaphylactic or other severe reaction (e.g., Stevens Johnson syndrome) to ceftriaxone, consult an infectious disease specialist for an alternative treatment recommendation.

IM, Intramuscular.

Syphilis

Syphilis, caused by the spirochete *Treponema pallidum*, is a disease with local and systemic manifestations that stretch over years and has been well-known throughout history. With the advent of antibiotics and intensive public health efforts during and after World War II, the prevalence of syphilis declined sharply (Fig. 27.5).[18]

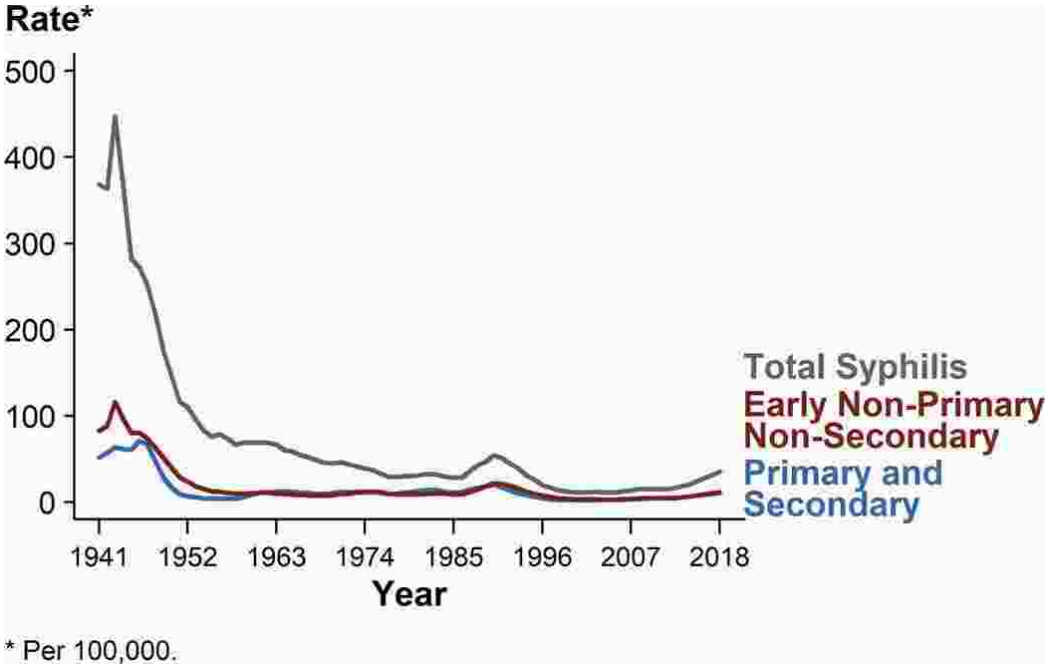

FIG. 27.5 Syphilis Cases Reported in 2018. In 2018, a total of 35,063 cases of P&S syphilis were reported in the United States, yielding a rate of 10.8 cases per 100,000 population. This rate represents a 14.9% increase compared with 2017 (9.4 cases per 100,000 population) and a 71.4% increase compared with 2014 (6.3 cases per 100,000 population). (From Centers for Disease Control and Prevention. https://www.cdc.gov/std/stats18/figures/35.htm.)

A graph represents the syphilis case reported in 2018. The horizontal axis represents the year ranging from 1941 to 2018. The vertical axis represents the rate per 100,000, ranging from 0 to 500. The graph labeled early non-primary, non-secondary is plotted from (1941, 100) through (2018, 10). The graph labeled primary and secondary is plotted from (1941, 50) through (2018, 55). The graph labeled total

syphilis is plotted from (194, 350) through (2018, 100). All data are approximate.

Rates of syphilis reached a record low of 2.1 cases per 100,000 in 2000.[19] However, since this all-time low, in 2019, 129,813 cases of syphilis in all stages were reported, an increase of 11.2% during 2018 to 2019.[16] Men account for nearly 82% to 91% of all new cases of syphilis, whereas rates between sexes were equivalent two decades ago.[18] While rates of syphilis have decreased among MSM, MSM accounts for more than 56.7% of all cases of primary and secondary syphilis.[2,19,20] Congenital syphilis (CS), caused by vertical transmission of the spirochete from mother to fetus, also has experienced resurgence in the United States. After years of decline, the rate of CS has increased each year since 2013. In 2019, CS was reported in 1870 cases, or 48.5 cases per 100,000 live births. This represents an increase of 41.4% from 2018 to 2019. Reported stillbirths also increased from 79 to 94 from 2018 to 2019.[21] This increase reflects the increase in primary and secondary syphilis.

Pathophysiology

T. pallidum, the cause of syphilis, is an anaerobic spirochete bacterium that can grow in any human organ or tissue but cannot be cultured in vitro. When viewed through dark-field microscopy, the *Treponema* (individual microorganism) resembles a corkscrew, with regular, tight spirals and a rotary motion.

Because the bacterium is present in exudate from moist mucosal or cutaneous lesions, the spirochete is usually transmitted to others during the first few years of infection.[8] Transmission generally occurs through minor abrasions during sexual intercourse but can occur extragenitally as well. Although condoms can decrease the likelihood of infection, if lesions are present on areas not covered during intercourse, transmission can occur even with safer sex practices.

The course of untreated syphilis consists of four stages based on clinical findings: primary, secondary, latent, and tertiary (Box 27.3); the division between stages is not always apparent, and the drug of choice is the same for all stages.[8]

Box 27.3

Progression of Untreated Syphilis

Stage I, primary syphilis—local invasion: *Treponema pallidum* multiplies in epithelium, producing granulomatous tissue reaction (chancre); lymph-containing microorganisms drain into adjacent lymph nodes and stimulate immune responses

Stage II, secondary syphilis—systemic disease: blood-borne bacteria spread to all major organ systems; immune system suppresses infection and symptoms regress spontaneously

Stage III, latent syphilis—silent infection: transmission of infection possible even though there are no clinical signs of infection

Stage IV, tertiary syphilis—noninfectious disease: significant morbidity and mortality occur; destructive skin, bone, and soft tissue lesions, or gummas, result from severe hypersensitivity; cardiovascular complications (aneurysms, heart valve insufficiency, heart failure) and neurosyphilis develop

Antibiotic resistance is rapidly increasing for this pathogen; please check current guidelines at the Centers for Disease Control and Prevention website at www.cdc.gov and search "gonorrhea."

Primary syphilis begins at the site of bacterial invasion (Fig. 27.6), where *T. pallidum* multiplies in the epithelium and produces a granulomatous tissue reaction called a chancre. Some

microorganisms drain with lymph into adjacent lymph nodes. Within the nodes and at the site of the chancre, the cell-mediated and humoral immune responses are stimulated.

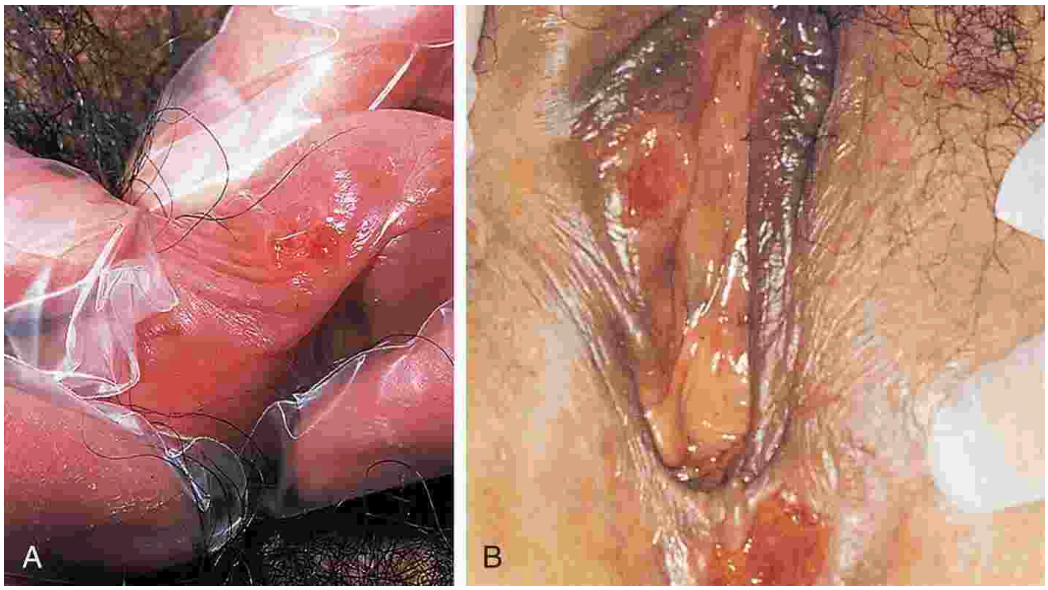

FIG. 27.6 Primary Syphilis.
(A) Penile chancre. (B) Vulval chancres; the labia and perineum show induration and edema of chancres. (A, From McMillan A, Scott GR. *Sexually transmitted infections*, 2nd edition. London: Churchill Livingstone; 2000; B, Courtesy Barbara Romanowski, MD, from Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2013.)

A graph represents the syphilis case reported in 2018. The horizontal axis represents the year ranging from 1941 to 2018. The vertical axis represents the rate per 100,000, ranging from 0 to 500. The graph labeled early non-primary, non-secondary is plotted from (1941, 100) through (2018, 10). The graph labeled primary and secondary is plotted from (1941, 50) through (2018, 55). The graph labeled total

syphilis is plotted from (194, 350) through (2018, 100). All data are approximate.

Secondary syphilis is systemic. During this stage, blood-borne bacteria spread to all major organ systems. The secondary stage is followed by a period during which the immune system can suppress the infection. Even without treatment, spontaneous resolution of the skin lesions occurs, and the individual enters the latent stage of infection.

Latent syphilis may be subdivided into early and late stages; however, no specific criteria delineate one from the other.[8] Medical history and serologic studies can show that syphilis is present, but the individual has no clinical manifestations. Transmission remains possible during this phase.

Tertiary syphilis is the most severe stage, involving significant morbidity and mortality. The pathogenesis of syphilitic manifestations at this stage remains unclear. The destructive skin, bone, and soft tissue lesions (called gummas) of tertiary syphilis probably are caused by a severe hypersensitivity reaction to the microorganism. Within the cardiovascular system, infection with *T. pallidum* may cause aneurysms, heart valve insufficiencies, and heart failure.

CS is caused by vertical transmission and is estimated to cause 500,000 fetal and neonatal deaths every year worldwide.[22] Syphilis becomes a systemic disease shortly after maternal infection and can be transmitted to the fetus as early as the ninth week of gestation because the spirochete can pass through the placental membrane to infect the fetus. Intrauterine infection causes fetal or perinatal death in 40% of affected infants and may lead to perinatal complications in more than 70% of cases. Many live-born infants have permanent, lifelong morbidity, including congenital abnormalities.[22] The risk of CS is estimated at up to 80% in primary syphilis and declines with advancing stages of the disease.[22] However, simple treatment with penicillin is 98% effective at preventing vertical transmission,

thereby decreasing morbidity and mortality if the disease can be diagnosed early in fetal development.[23]

Primary Stage

Clinical Manifestations

In adults, the incubation period of syphilis ranges from 12 days to 12 weeks after exposure and averages 3 weeks. A sore, or *hard chancre*, develops at the site of treponemal entry. Typically, the chancre is an eroded, painless, firm, and indurated (hard) ulcer up to 2 cm in diameter. Firm, enlarged, and nontender regional lymph nodes accompany chancres. Typical chancres of the penis and vulva are shown in Fig. 27.6. Syphilitic chancres are not always typical, and syphilis should be considered in the presence of any open lesion. With secondary infection, chancres can become necrotic and painful. Lesions on the fingers may be dry, scaly, and papular or moist and vegetative. If left untreated, the chancre of primary syphilis heals in 2 to 8 weeks and then spontaneously disappears, usually without leaving a scar.

Secondary Stage

Clinical manifestations of secondary syphilis usually develop 6 weeks after the first appearance of the chancre but may overlap with those of the primary stage. Systemic symptoms are variable and can include low-grade fever, malaise, sore throat, hoarseness, anorexia, generalized adenopathy, headache, joint pain, and skin or mucous membrane lesions or rashes. Cutaneous (skin) rashes are generally papulosquamous (raised and scaly), but any variation or combination of macular (flat), papular (raised), and pustular (pus-filled) lesions may be seen. Lesions are often widespread and bilateral, appearing on the palms and soles (Fig. 27.7). Some lesions become hypertrophied, flat, moist, and wart-like or vegetative (e.g., cauliflower-like). These lesions, called condylomata lata, are highly contagious and develop on the perineum, vulva, and groin of women (Fig. 27.8) and around the inner thigh and anal area in men

and women. Besides skin sores, oral mucous membrane lesions (known as *mucous patches*), lymphadenopathy, pruritus, and alopecia are common. Some individuals develop anemia, leukocytosis, increased erythrocyte sedimentation rate (ESR), hepatitis, transitory proteinuria, arthritis, electrocardiographic abnormalities, and central nervous system (CNS) symptoms. Regardless of treatment, cutaneous lesions generally heal in 2 to 10 weeks. Within the CNS, the presence of *T. pallidum* in cerebrospinal fluid may cause the manifestations of neurosyphilis, including altered mental status and meningitis, which can occur within any stage of syphilis infection but are more common in early stages of infection.[8]

Secondary syphilis to the palms and plantar surfaces. (From Morse S, et al., eds. *Atlas of Sexually Transmitted Diseases and AIDS*. 4th ed. London: Saunders; 2013.)

FIG. 27.8 Condylomata Lata.
Broad-based, moist, dark-field–positive condylomata lata of the perineum. (From McMillan A, Scott GR. *Sexually transmitted infections*, 2nd edition. London: Churchill Livingstone; 2000.)

Latent and Tertiary Stages

The asymptomatic, latent stage of syphilis may be as short as 1 year or as long as a lifetime. After the latent stage, tertiary syphilis may

present with gummas, cardiovascular lesions, and neurosyphilis manifestations, including *tabes dorsalis* and general paresis caused by demyelination of the spinal cord.[8] Tertiary syphilis is rare because of the widespread availability of antibiotics.

Congenital Syphilis

Although considered rare, CS was relatively stable from 2008 until 2013, when a significant increase in incidence occurred. Since 2013, the rate of CS has increased from 9.2 cases/100,000 births to 48.5 cases/100,000 births in 2019. When compared with the CS rates in 2015 with rates in 2019, the relative increase was 291.1%. Cases were reported in 43 states and the District of Columbia.[21]

CS can cause fetal death (79 in 2018 and 94 in 2019)[21] or growth abnormalities, including changes in the fetal bones, teeth, and neurologic system. Affected newborns can have a variety of manifestations of the disease, including growth abnormalities, rashes, hepatosplenomegaly, jaundice, and CNS involvement, including blindness and deafness. A classically reported late manifestation of CS is notched incisors (Hutchinson teeth) (Fig. 27.9).

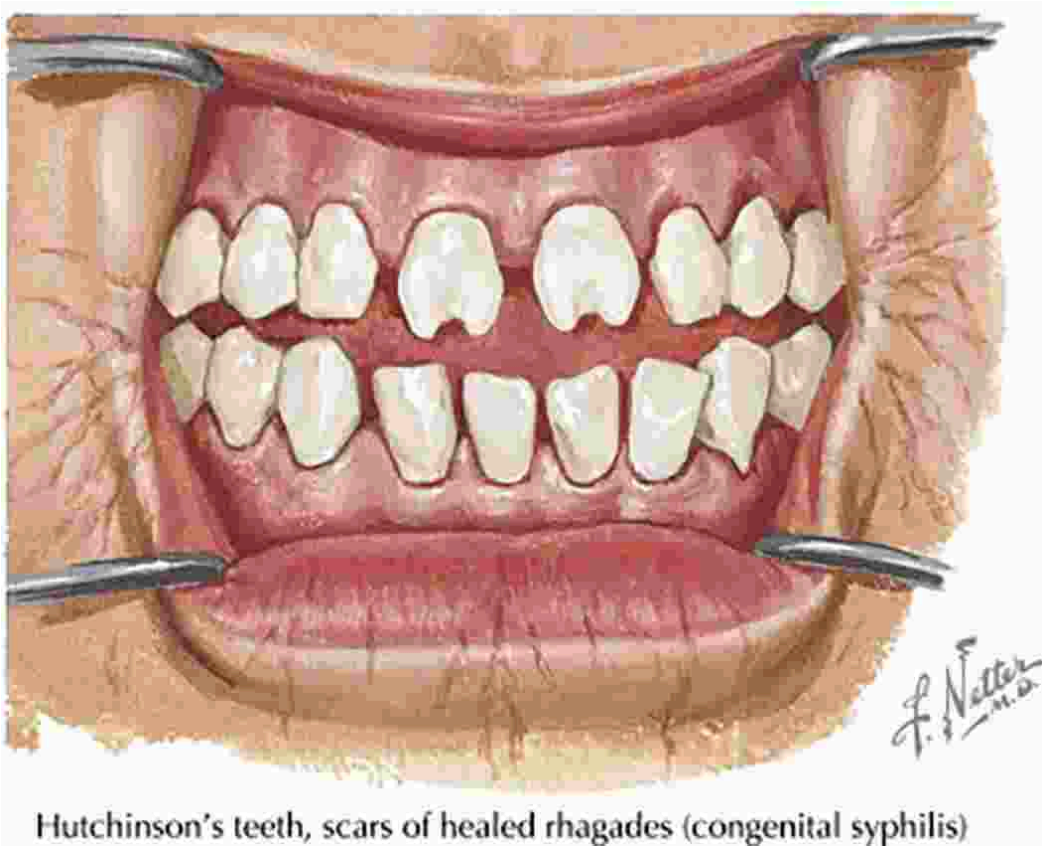

FIG. 27.9 Hutchinson Teeth. (From Jong EC, Stevens DL. *Netter's Infectious Diseases*. Philadelphia: Saunders; 2012.)

Evaluation and Treatment

Numerous dermatologic disorders can mimic the skin lesions of secondary syphilis, making differential diagnosis difficult. Laboratory confirmation is important. Two categories of serologic testing exist: nontreponemal antigen tests and treponemal antibody tests.[8] Nontreponemal antigen tests, such as the Venereal Disease Research Laboratory (VDRL) antigen and the rapid plasma reagin (RPR) tests, demonstrate the presence of *reagin* (a group of antibodies present in syphilis) in serum and provide indirect evidence of infection (Box 27.4). These tests yield a positive result (presence of reagin) in more than 50% of individuals with primary

syphilis and in 100% of individuals in the secondary phase of disease and can be useful in screening and assessing response to treatment.[8]

Box 27.4

False-Positive Serologic Tests for Syphilis

Reasons for False-Positive, Nontreponemal Reactions (VDRL, RPR)

Transient Reactions (<6 Months)

Technical error (low titer)
Mycoplasma pneumonia
Enterovirus infections
Infectious mononucleosis
Pregnancy
Narcotic abuse
Advanced tuberculosis
Scarlet fever
Viral and atypical pneumonia
Brucellosis
Rat-bite fever
Leptospirosis
Measles
Mumps
Lymphogranuloma venereum
Malaria
Trypanosomiasis
Varicella

Chronic Reactions (>6 Months)

Malaria
Leprosy
Systemic lupus erythematosus

Narcotic abuse
Other connective tissue diseases
Elderly population
Hashimoto thyroiditis
Rheumatoid arthritis
Reticuloendothelial malignancy
Familial false-positive reaction
Idiopathic

Reasons for False-Positive, Treponemal-Specific Reactions (FTA-ABS)

Technical error
Inefficient sorbents
Healthy individuals without syphilis
Genital herpes simplex
Pregnancy
Lupus erythematosus (skin only or systemic)
Alcoholic cirrhosis
Scleroderma
Mixed connective tissue disease

RPR, rapid plasma reagin; *VDRL*, Venereal Disease Research Laboratory.

Because the VDRL and RPR tests have high rates of false-positives, a treponemal test is performed if the screening test is positive. Treponemal tests are serologic-specific tests that are used to assess antibody response to *T. pallidum* and include enzyme immunoassays (EIAs), chemiluminescence immunoassays, the fluorescent treponemal antibody absorption (FTA-ABS) test, and the passive *T. pallidum* particle agglutination (TP-PA) assay.[8] Studies indicate that because of increased sensitivity and specificity (98% and 97.5%) of enzyme-linked immunosorbent assays (ELISAs) for *T. pallidum*, the

ELISA test has the potential to replace VDRL and RPR for screening.[24]

Preferred treatment for all stages of syphilis is parenteral injection of benzathine penicillin G. Other types of penicillin are not as effective. If the individual has manifested signs of the disease for less than 1 year, a single intramuscular dose is appropriate. If signs have been present for more than 1 year or they are asymptomatic and assumed to be in late latent syphilis, the treatment is three weekly injections. The CDC is the best source for current information on treatment regimens.[25]Penicillin therapy also is appropriate for pregnant women to prevent vertical transmission.[25] There is no evidence to date that *T. pallidum* has developed resistance to penicillin. In fact, it is highly sensitive; however, because of the slow replication time, serum levels must be maintained for 7 to 14 days. Men andnonpregnantwomen who are allergic to penicillin may receive oral doxycycline, 100 mg twice daily for 14 days, or tetracycline, 500 mg four times per day for 14 days. Pregnant women with a penicillin allergy should be desensitized and then treated with benzathine penicillin G as recommended by the CDC because the other available antibiotics cause lifelong discoloration of the forming teeth of the fetus.[26]

Repeated assessment of VDRL or RPR titers is used to determine effectiveness of treatment. Because the results of the VDRL and RPR testing are not interchangeable, the same test should be used for repeat testing. Titers should decrease fourfold if treatment was successful. Sexual partners also are tested and treated, and the use of condoms is recommended until effective treatment is verified.

Newborns of mothers with documented syphilis need careful evaluation after birth. Definitive diagnosis of CS is complicated by the presence of maternal antibodies in the newborn's blood. Treatment decisions are made based on maternal status, clinical symptoms of CS, and comparison of maternal and neonatal titers.[23] If the infant requires treatment, penicillin is the drug of choice with carefully titrated dosing depending on fetal weight and the day of treatment, and the CDC is the best source of current information.[23]

Chancroid

Chancroid, or soft chancre, is an acute infectious disease that is caused by *Haemophilus ducreyi*, a gram-negative bacillus. The incidence of chancroid is decreasing worldwide, and is infrequently seen in the United States.[1] Sporadic outbreaks occur throughout the world and tend to be associated with sex workers and illicit drug use, when individuals continue to engage in intercourse despite a painful genital lesion.[27] Chancroid is a risk factor for HIV acquisition, and existing HIV infection is a risk factor for chancroid infection with exposure.[8]

Pathophysiology

H. ducreyi is a gram-negative bacillus with rounded ends. It is commonly observed in small chains or clusters along mucous strands under a microscope. Transmission can occur through sexual contact and autoinoculation, but there is no evidence for vertical transmission.[8] Chancroid lesions are found throughout the genital area. Initially, the papule enlarges; then erodes into a soft, circumscribed ulcer containing a superficial exudate of varying size and presentation.[27] Beneath the ulcer is a lesion characterized by edema, endothelial proliferation, and a base of granulation tissue. Adjacent lymph nodes are acutely inflamed and full of polymorphonuclear leukocytes and necrotic cells.

Clinical Manifestations

Chancroid has an incubation period of 3 to 10 days.[27] Women are generally asymptomatic but, depending on the site of infection, can present with less obvious symptoms (dysuria, dyspareunia, vaginal discharge, pain on defecation, or rectal bleeding). Constitutional symptoms are unusual. An initial vesicopustular lesion forms at the site of inoculation and erodes to form a soft ulcer with a necrotic base, surrounding erythema, and a ragged, serpiginous (spreading) border (Fig. 27.10). Unilateral, painful, local lymphadenopathy

presents in approximately half of infected individuals. Inguinal buboes (unilocular abscess of the inguinal lymph nodes) develop 7 to 10 days after the initial chancre and fill with exudate. In 25% to 60% of cases, the buboes spontaneously rupture out onto the skin, spreading the infection through autoinoculation.

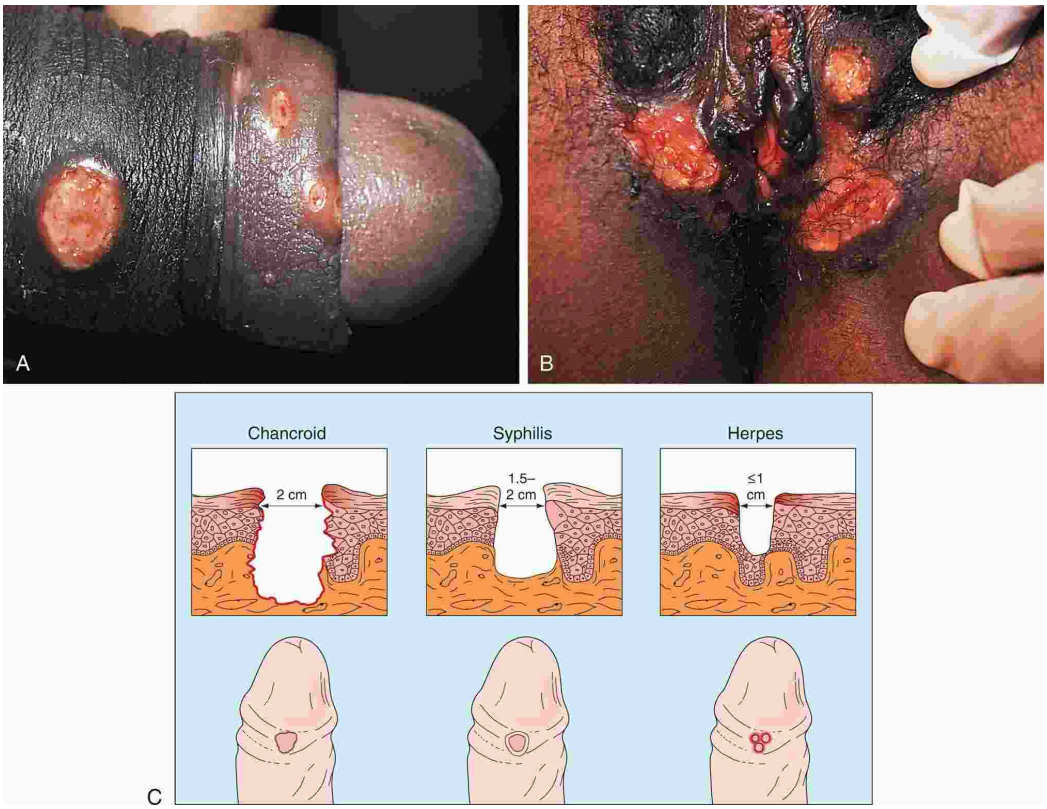

FIG. 27.10 Chancroid.
(A) Ulcers on the penile shaft. (B) Multiple vulvar lesions. (C) Differences in clinical appearance among chancroid, syphilis, and genital herpes.
(From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2013.)

A. Close shot of penis with few round open sores with raised edges in the prepuce. B. Close shot of vagina with severe reddish open sore with raised edges. C. The illustration on the left depicts the chancroid, which shows the penis with a small open sore accompanied by the illustration of a microscopic view of the prepuce with an open sore on the dermis region measuring 2 centimeters. The illustration in the middle depicts syphilis which shows the penis

with a small open sore and a raised edge accompanied by the illustration of a microscopic view of the prepuce with an open sore on the dermis region measuring 1.5 to 2 centimeters. The illustration in the last depicts herpes which shows the penis with a reddish open sore and a raised edge accompanied by the illustration of a microscopic view of the prepuce with an open sore on the dermis region measuring greater than or equal to 1 centimeter.

Ulcers on the foreskin may lead to phimosis or paraphimosis see Chapter 26. Other complications of chancroid include balanitis, secondary infections, necrosis, and fistula formation. Lesions may take months or years to heal and cause scarring.[8]

Evaluation and Treatment

Chancroid is easily confused with other types of genital ulcers, particularly those of syphilis, genital herpes, and granuloma inguinale (see Fig. 27.10). Unlike the syphilitic ulcer, the chancroid ulcer is painful, tender, and nonindurated and inguinal lymphadenopathy is pronounced. Microscopic analysis of a Gram-stained smear from the chancroid helps to identify the microorganism. Definitive diagnosis depends on recovery of *H. ducreyi* from cultured specimens; however, the culture medium is not commercially available.[28] Diagnosis depends on the clinical presentation of a painful genital ulcer with inguinal lymphadenopathy and with negative testing for syphilis and herpes simplex virus (HSV).[28] In addition, HIV testing is recommended because chancroid is a cofactor for transmission of HIV.

Resistance to recommended antibiotics has emerged in isolated instances worldwide. Treatment recommendations include a single intramuscular injection of ceftriaxone (250 mg) or a single dose of oral azithromycin (1 g). Effective oral multiple-dose regimens include ciprofloxacin, 500 mg orally twice daily for 3 days, or erythromycin, 500 mg three times daily for 7 days. Persons infected with HIV and uncircumcised men have higher rates of treatment failure and may require a longer treatment regimen. Treatment failure requires more intensive assessment for coinfection with other diseases.[28] Simultaneous treatment of sexual partners and use of condoms are recommended to prevent reinfection (see Emerging Science Box: New Therapeutics for Human Immunodeficiency Virus Prevention and Treatment).

Emerging Science Box *New Therapeutics for Human Immunodeficiency Virus Prevention and Treatment*

Although most sexually transmitted infections (STIs) can be cured with early diagnosis and therapeutic intervention, infection with the human immunodeficiency virus (HIV) still poses great risk to those persons who acquire the infection. Although there is still no cure for HIV, with proper treatment, those with HIV are now living longer and with less morbidity.

In recent years, significant work has been done to decrease the transmission and the acquisition of HIV through sexual contact. Preexposure prophylaxis (PrEP), first approved in 2012 using either the combination of emtricitabine with tenofovir disoproxil fumarate (Truvada) or emtricitabine with tenofovir alafenamide (Descovy) can reduce the risk of HIV acquired through sexual contact and by injected drug use by 99% and 74%, respectively, when taken appropriately and when used in conjunction with safe sexual practices using condoms.Early studies of women using a monthly vaginal ring containing dapivirine have shown that the risk of acquiring HIV is reduced by approximately 27%–34%.

Since January 2021, the World Health Organization recommends the use of the dapivirine vaginal ring for women at risk of HIV infection.

In 2019, a long-acting, monthly injectable combination of cabotegravir and rilpivirine was approved for use in Canada and in 2021 was approved in the United States in 2021 for individuals who are already virologically suppressed. Rates of suppression were as high as 93.6%.

Granuloma Inguinale

Granuloma inguinale (donovanosis) is a chronic, progressively destructive bacterial infection caused by *Klebsiella granulomatis*, a gram-negative intracellular bacterium. Although sexually transmitted, granuloma inguinale has a low transmission rate between sexual partners.[27] Infection through fecal contamination and autoinoculation also is possible.[27] As with all genital ulcerative diseases, granuloma inguinale plays a role in HIV transmission.[27] Granuloma inguinale very rarely occurs in the United States[27]; it is more prevalent in some tropical and subtropical parts of the world (India, New Guinea, Africa, central Australia, and to less extent the Caribbean and Brazil). With increased ease of travel, this may become more common in other parts of the world.

Pathophysiology

K. granulomatis is a gram-negative, nonsporing, nonmotile, encapsulated rod not easily cultured in the laboratory. After an individual is infected, bacteria survive and multiply within vacuoles of large histiocytic cells or polymorphonuclear leukocytes. The bacteria reproduce within these cells, and a vacuole may contain 20 to 30 microorganisms. These bacteria-filled vacuoles, identified by Charles Donovan in 1905, are termed Donovan bodies. Donovan bodies, when present, in tissue smears of material from the lesions are considered pathognomonic for diagnosis, but this test is difficult even in well-equipped laboratories.[29]

The incubation period of granuloma inguinale is 8 to 80 days. As lesions begin to form, single lesions often coalesce with nearby lesions or form new lesions by autoinoculation of nearby skin surfaces. Progression from the initial nodule to a large, granuloma-heaped ulcer occurs slowly. These lesions are vascularized and bleed easily.[29] Secondary infection may occur, increasing tissue damage and residual scarring. The disease may spread to the bones, joints, and liver.

Clinical Manifestations

The primary site for development of the lesions in men is the distal penis and in women the vaginal introitus. The initial lesion is an indurated, sharply defined, painless, subcutaneous nodule that is often preceded and accompanied by itching. Nodules bleed easily and contain abundant red, beefy-looking granulation tissue. These lesions spread as the disease progresses. Secondary infection may occur, increasing tissue damage and residual scarring. Although systemic symptoms are rare, the disease may spread to the bones, joints, and liver. In some cases, infection spreads to the inguinal area and produces pseudobuboes. In these instances, the affected lymph nodes are not directly affected, but the surrounding area may be infected and abscessed.

Evaluation and Treatment

Although the clinical manifestations of this disease are important for diagnosis, confirmation involves microscopic examination for Donovan bodies in a smear or biopsy specimen. Currently, there is not a US Food and Drug Administration (FDA)-approved laboratory test for detection of *K. granulomatis*.[29]

Many antibiotics successfully treat*K. granulomatis*. With effective antibiotic treatment, lesions begin to heal in 7 days, but treatment is continued for at least 3 weeks and until all lesions are healed. The recommended oral therapy is azithromycin, 1 g orally once weekly or 500 mg daily for 3 weeks or more or until lesions have completely healed. Alternative regimens include doxycycline, 100 mg twice a day for at least 3 weeks; erythromycin base, 500 mg four times a day for at least 3 weeks; or trimethoprim-sulfamethoxazole, 160 mg/800 mg, double-strength oral tablet twice a day for at least 3 weeks.[29] Despite effective initial therapy, relapses can occur 6 to 18 months later. Prolonged follow-up is necessary as is treatment of sexual partners. Because other STIs frequently coexist, individuals should be tested for chlamydia, gonorrhea, syphilis, hepatitis B, and HIV.

Bacterial Vaginosis

Bacterial vaginosis (BV) (previously called nonspecific vaginitis, nonspecific vaginosis, or *Haemophilus, Corynebacterium*, or *Gardnerella* vaginitis) is a sexually associated condition but is not necessarily considered an STI. The condition is associated with sexual contact, including genital touching and digital penetration, oral sex, and penile penetration. Although BV occurs mostly in sexually active women of reproductive age, it can affect women, especially menopausal women, who are not sexually active. Prevalence rates vary from 17% among women in family planning clinics to 37% among some groups of pregnant women. A majority of women clinically diagnosed with BV state they are asymptomatic.[30]

Pathophysiology

The exact etiology of BV is unknown but is thought to be a disruption of normal vaginal flora that is associated with sexual contact. *Gardnerella vaginalis* and various anaerobes, including *Mycoplasma hominis, Bacteroides*, and *Mobiluncus*, interact and proliferate when lactobacilli (the normal predominant vaginal flora) are decreased or absent. Bacteria adhere to vaginal epithelium and form a scaffolding-like biofilm to which other bacteria can adhere, facilitating their proliferation and causing a noninflammatory response in the surrounding tissues.[31] As the vaginal microbiome changes, catabolic enzymes degrade proteins into amines which elevate the vaginal pH and produce the characteristic fish-like odor associated with BV. BV has been implicated in PID, chorioamnionitis, preterm labor, and postpartum endometritis. In addition, BV increases a woman's risk of contracting other STIs, such as HIV.[30]

Clinical Manifestations

BV is characterized by a thin, gray, homogeneous, and malodorous discharge that adheres to the vaginal walls but is often copious enough to drain from the vagina. Occasionally, the discharge is bubbly or frothy. The normal vaginal pH is usually 5 to 5.5. Because odor is intensified by contact with alkaline secretions, including semen (pH 5.2 to 8.2) and menstrual discharge (pH 6.3 to 6.9), women often complain of a strong, foul, fish-like vaginal odor particularly after intercourse and during menses. Male and female partners of infected women may harbor the microorganisms responsible for BV but have no signs or symptoms.

Evaluation and Treatment

Diagnosis of BV can be made on the basis of the presence of three of four of the following criteria, known as *Amsel criteria:* (1) the presence of homogeneous, adherent gray or white vaginal discharge;

(2) a vaginal pH greater than 4.5; (3) a positive amine odor in the presence of an alkali, such as potassium hydroxide, known as the *whiff test;* and (4) the presence of clue cells on wet mount.[30] *Clue cells* are considered pathognomonic for BV. They are vaginal epithelial cells that are covered with bacteria, causing them to look as if they were sprinkled with pepper. The saline wet mount also may show the absence of lactobacilli and few or no leukocytes. There also is a commercially available test, Affirm VPIII, that uses DNA hybridization to detect *G. vaginalis*. Cultures for BV are not recommended; however, high-risk individuals should be screened for gonorrhea and chlamydia.[30]

The most commonly used treatment for BV is a course of oral metronidazole (Flagyl), 500 mg twice daily for 7 days; 0.75% metronidazole vaginal gel, once daily for 5 days; or clindamycin cream 2% applied vaginally for 7 days.[30] Alternative regimens include tinidazole, 2 g orally once daily for 2 days or 1 g orally for 5 days; oral clindamycin, 300 mg twice daily for 7 days; or clindamycin ovules, 100 mg intravaginally for 3 days.[30] Treatment for BV should be personalized based on the woman's needs and behaviors. For example, metronidazole and tinidazole strongly react with alcohol and should not be used by women who cannot or will not eliminate alcohol ingestion for the full duration of treatment plus an additional 24 hours. In addition, the ovules can weaken latex condoms and diaphragms. Women who are asymptomatic for BV do not need treatment.[30]

BV treatment in women infected with HIV is the same as that in individuals who are HIV negative. The CDC currently recommends treatment of symptomatic BV in pregnancy to reduce the risk of poor perinatal outcomes, including preterm birth.[30]

Chlamydia

Chlamydia is the common name for infections caused by *C. trachomatis*. *C. trachomatis* is responsible for a variety of syndromes, including acute urethral syndrome, nongonococcal urethritis (NGU), mucopurulent cervicitis, and PID. Chlamydia is a leading cause of

preventable infertility and ectopic pregnancy. In 2019, with more than 1.8 million new cases of infections reported, chlamydia was the most common reportable STI in the United States.[32] Because chlamydia is often asymptomatic, it is estimated that just over a million unreported infections occur annually. This represents a 19% increase since 2014.[1] Rates of chlamydia infections are increasing in all age groups, areas of the country, and racial/ethnic groups. This increase probably reflects the continued expansion of screening efforts and the increased use of more sensitive diagnostic tests, as well as an actual increase in incidence.[33] The majority of reported cases of chlamydia are in people younger than 26 years old, but the incidence in older adults is increasing.[1] Up to 90% of women with *C. trachomatis* infection are asymptomatic, which can delay diagnosis and increase the risk of long-term health sequelae.[33] Without timely treatment, 10% to 20% of women will have the infection spread to the uterus and uterine tubes.[33] Although the rate of chlamydia in men is lower than women, with increased use of urine screening testing, there was an increase of 32.1% in men from 2015 to 2019. This increased number of men include MSM, bisexual, and men who have sex with both men and women.[32]

Risk groups for chlamydia include age younger than 26, recent new sexual partner, and drug use or other risky behaviors.[1] Like gonorrhea, *Chlamydia* infection can be transmitted from mother to infant during birth and can cause eye infections and pneumonia in affected newborns.[33]

Pathophysiology

C. trachomatis is a gram-negative obligate intracellular bacterium that lacks the ability to reproduce without a host cell. It is differentiated from other bacteria by its unique two-part growth cycle. The first part consists of an elementary body that is small and resilient and is able to survive extracellularly.[34] Once this elementary body attaches itself to a receptor host cell, it is able to enter by endocytosis. Once

inside the cell, the second part of the cycle begins and the microorganism becomes a metabolically active parasite, reproducing within the cell until the cell is destroyed and ruptures, disseminating up to 1000 new elementary bodies. Infection with *C. trachomatis* produces an inflammatory reaction that results in permanent scarring of tissues.[34]

Because they are not part of the normal urogenital tract flora, *Chlamydia* microorganisms are always pathogens even though infection is often asymptomatic. Numerous serotypes, or strains, of *C. trachomatis* have been identified. Some cause urogenital infection; some, blindness; and others, lymphogranuloma venereum (LGV), which is discussed in the next section.[34] The strains of *C. trachomatis* that cause urogenital infection require squamous-columnar and columnar-epithelial cells as hosts. *C. trachomatis* infects and disrupts superficial tissues, causing damage and scarring, but does not seem to invade or destroy deeper tissues.[35]

In newborns, several sites may be inoculated with *Chlamydia* when passing through the infected maternal cervix. These include the eye, nasopharynx, rectum, and vagina. The infant may also aspirate infected secretions with its first breaths, resulting in chlamydial pneumonitis and substantial newborn morbidity.[32]

Clinical Manifestations

Chlamydial infections are asymptomatic in up to 90% of adults.[32] Urogenital infections caused by *Chlamydia* closely parallel those caused by gonorrhea. Both microorganisms infect superficial genital tract tissues, such as mucosa of the urethra and cervix, and both can invade the epididymis, the fallopian/uterine tubes, and (rarely) the hepatic capsule. Table 27.2 lists the pathophysiologic similarities of chlamydial and gonococcal infections. Men and women have different responses to the infection.

Table 27.2

Similarity of Clinical Syndromes Caused by *Neisseria gonorrhoeae* and *Chlamydia trachomatis*

Site of Infection	Clinical Syndrome	
	N. gonorrhoeae	*C. trachomatis*

Data from Stamm WE, Holmes KK. *Chlamydia trachomatis* infections in the adult. In: Holmes KK, et al., eds. *Sexually transmitted diseases*. 2nd edition. New York: McGraw-Hill; 1990.

The rate of chlamydial infection in men appears to be rising, with a 32.1% increase in diagnoses from 2015 to 2019. The rate of infection among adolescent males (15 to 19 years old) who have sex with women increased by 32.8% in the same time.[32] This increase may be an expression of increased testing as a result of easier screening methods.

Although most men do not have symptoms even while contagious, chlamydial infection can cause NGU. Clinically, urethritis caused by gonorrhea and chlamydia cannot be differentiated: both have a 7- to 21-day incubation period and cause dysuria. Although urethral discharge in men may be similar in the two infections, chlamydial discharge tends to be more clear and gonococcal discharge more purulent. Men might note a clear, mucous discharge or mild burning with urination.

Chlamydial epididymitis can accompany urethritis in men and is characterized by fever and a unilaterally painful, swollen scrotum. Chlamydial infection also causes proctitis (rectal inflammation) in men and women who have receptive anal intercourse. Chlamydial

proctitis is generally mild, although it may, like gonorrheal proctitis, cause rectal bleeding, mucous discharge, and diarrhea. Reiter syndrome (urethritis, conjunctivitis, arthritis, and characteristic mucocutaneous lesions) is also associated with untreated urogenital tract infections.

C. trachomatis can cause asymptomatic urethral infection or acute urethral syndrome (dysuria, urinary frequency, and presence of sterile pus in the urine) in infected women. Chlamydial infection of Bartholin/greater vestibular glands can cause purulent discharge leading to a Bartholin cyst. Women with chlamydial cervicitis may be asymptomatic or may have a yellow mucopurulent discharge from the cervical os and a hypertrophic, edematous, and friable area of cervical ectopy. The woman also may report intermenstrual or postcoital spotting. Although ectopy alone does not indicate a pathologic condition, an erythematous, raw, and friable cervix is suggestive of chlamydial cervicitis (Fig. 27.11).

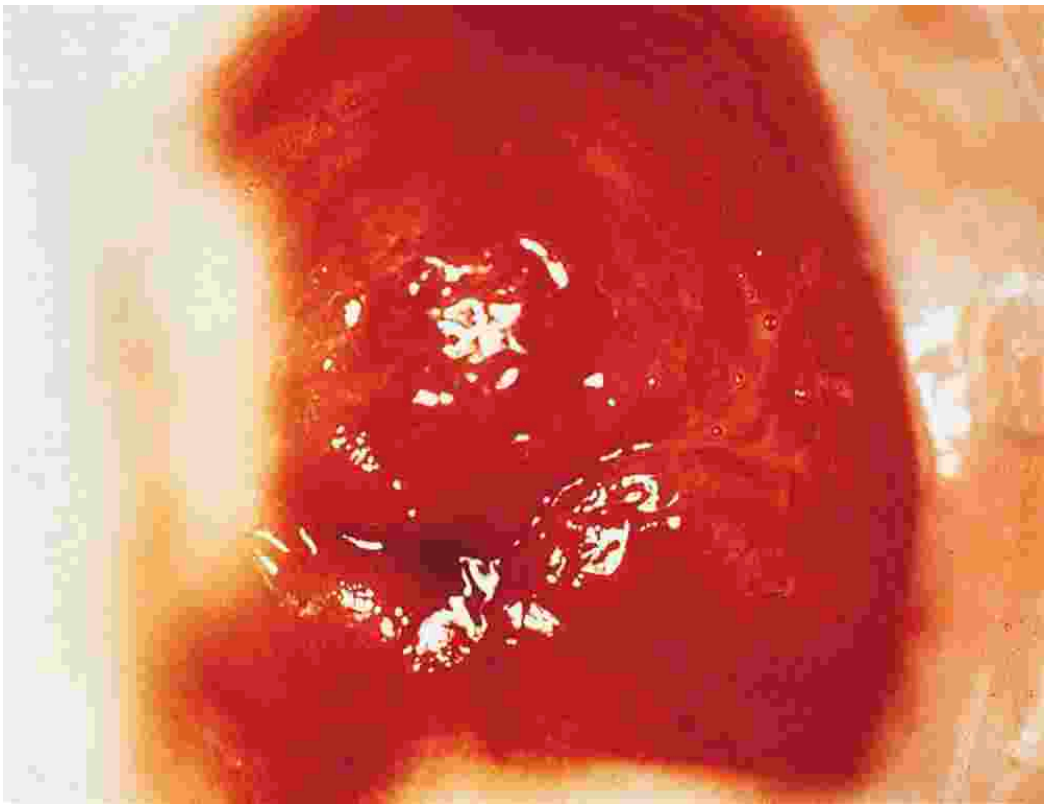

FIG. 27.11 Chlamydial Cervicitis.
Beefy red mucosa of columnar epithelium of cervix. (Courtesy Paul Weisner. From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2013.)

Chlamydia infection is the leading cause of tubal infertility in women because of infectious damage to the fallopian tubes like that which may occur with gonorrhea. Risk factors for infertility include the duration and severity of infection and the lifetime number of chlamydial infections. Even women with asymptomatic salpingitis have a risk of subsequent infertility.[32]

The most common manifestations of chlamydial infections in the newborn are conjunctivitis and pneumonia. Prophylactic treatment with antibiotic eye ointment at birth does not provide complete protection against neonatal conjunctivitis and does not protect against neonatal pneumonia. IV antibiotics are needed for any child at risk of acquisition. Chlamydial conjunctivitis begins between 5

and 14 days after delivery, when the infant's eyes begin to water. This discharge may become purulent, and both eyes may become red and swollen.

Scarring of the conjunctivae may result, but this infection does not cause blindness. Infants with chlamydial pneumonia develop staccato coughing spells, nasal congestion, and fever at 3 to 11 weeks of age.

Evaluation and Treatment

Since most infections are asymptomatic, the CDC recommends widespread screening of at-risk groups. A complete detailing of groups needing annual screening can be found in their treatment guideline, on their website, or through their smartphone app.[32] All sexually active women who are 25 years old or younger should be screened annually. In addition, the CDC recommends that all women, regardless of age, be screened if they have a new sexual partner or their partner is not monogamous. Pregnant women should be routinely screened for *Chlamydia* at least once during pregnancy.[32]

Methods for diagnosing chlamydial infections include tissue culture, direct chlamydial EIA, fluorescein-labeled monoclonal antibody tests, and NAAT. Currently, tests using chlamydia-specific NAAT are the most sensitive and cost-effective tests available. In addition, NAAT is easy to use with a variety of specimen types.[32] Concurrent testing for gonorrhea can be done using the same swab. NAAT can be performed on samples taken from the vagina, endocervix, or urethra, or urine specimens can be used. The person should be tested from all locations of genital contact. The ease of NAAT testing means that screening can be performed without a clinician, if needed, because the individual can collect the specimen following basic instructions.[32]

C. trachomatis is susceptible to inexpensive, readily accessible antibiotics, and treatment should begin as soon as possible to prevent complications. Treatment includes antibiotic therapy for

infected individuals and all sexual contacts. Abstinence or use of condoms during treatment and for 7 days after treatment is recommended. The CDC recommends observed, on-site treatment for both partners when feasible.[32]

Oral doxycycline, 100 mg twice daily for 7 days is the preferred treatment for chlamydial infection among adolescents and adults. Alternate regimens include azithromycin , 1 g given orally, as a single dose, or a 7-day course of oral levofloxacin 500 mg once daily for 7 days. Single-dose azithromycin is preferred if adherence to a multiple-dose, multiple-day regimen is not feasible for the individual. In pregnancy, oral azithromycin 1 g in a single dose is the drug of choice. A test of cure is needed only if there is concern that treatment of both partners was not successful. However, treatment failures are common, especially with multidose regimens and when the partner is not immediately provided with a prescription.[32]

Lymphogranuloma Venereum

C. trachomatis (invasive serovars of strains L1, L2, or L3) can cause a chronic STI known as lymphogranuloma venereum, which may be confused with syphilis, herpes, or chancroid. LGV was previously rare in the developed world but now is increasingly found in MSM and may spread to other populations.[36] The infection is acquired during sexual intercourse or through contact with contaminated exudate from active lesions. HIV infection increases the likelihood of acquisition and the severity of symptoms.[37] Because there is an increasing incidence of LGV in HIV-negative men, universal screening of MSM is recommended.[38]

Pathophysiology

The strain of *C. trachomatis* that causes LGV probably penetrates skin and mucous membranes through tiny abrasions. LGV spreads to genital and rectal lymphatic tissue, where it causes marked inflammation, necrosis, buboes, abscesses of inguinal lymph nodes,

and infection of surrounding tissues. Healing occurs by fibrosis after several weeks or months and results in scarring, damaging the lymph nodes and disrupting their function. LGV can cause permanent lymphatic disruption and genital disfigurement. Affected nodes become chronically swollen, hardened, and enlarged. *C. trachomatis* also spreads systemically through the bloodstream and can enter the CNS.[8]

Clinical Manifestations

The primary lesion of LGV appears after an incubation period of 5 to 21 days. The lesion is most commonly a herpetiform (multivesicular) ulcer, but it can assume various forms. The ulcer generally is asymptomatic and inconspicuous and heals rapidly, leaving no scar. However, when contracted through receptive anal intercourse (a common current mode of transmission), the ulcer is never visible. When rectal infection occurs, LGV can cause an inflammatory response that mimics inflammatory bowel disease or proctocolitis.[8] Other signs of primary LGV include a large, tender lymphatic nodule (especially unilateral) or bubo, urethritis, and cervicitis. Although historically this infection resulted in three clinical stages, anorectal infection has become the most common location of infection and results in symptoms that mimic other primary care conditions.[27]

Clinical symptoms of anorectal infection mimic other inflammatory bowel conditions and include irregular bowel movements, multiple ulcerations of the rectal mucosa, mucopurulent rectal discharge, and rectovaginal fistulae in women. Individuals may have fever, rectal pain, and tenesmus. Rectal strictures, perirectal abscesses, and anal fissures may develop with untreated infection.[8]

Evaluation and Treatment

Clinical manifestations, history ofsexual intercourse, and laboratory tests are used for LGV diagnosis. LGV is diagnosed with NAAT

testing at the suspected site of infection. If clinical symptoms match LGV presentation, pharmacologic treatment should begin while waiting definitive diagnosis with test results.[36] The recommended treatment for LGV is oral doxycycline, 100 mg twice daily for 21 days. An alternative 21-day course of erythromycin base 500 mg four times daily or azithromycin 1 g orally once a week for 3 weeks also is effective. Sexual partners within the past 60 days should be treated.[36] Pregnant/lactating women should be treated with erythromycin or azithromycin. Persons with HIV are treated using the same but possibly prolonged treatment protocols as if they were HIV negative.

Viral Infections

Genital Herpes

Genital herpes, which causes painful blisters (cold sores), is a chronic, lifelong viral infection and is the most common infectious cause of genital ulcerations in the United States. Although HSV is not a reportable disease, the CDC reports that approximately 572,000 new individuals are infected each year.[39]

Recurrent infections are mostly asymptomatic (50% to 70%) and affect an estimated 50 million Americans annually.[1] Eighty percent of infected individuals do not know they have herpes. Genital herpes can be caused by either of the two serotypes of HSV: HSV-1 or HSV-2. Historically, HSV-1 lesions were more common around the mouth, whereas HSV-2 lesions were more frequently found in the genital area. However, both HSV-1 and HSV-2 are increasingly found in both the oral and the anogenital area.[1] HSV-2 outbreaks are more frequent and more severe, so serologic testing to determine the HSV subtype is warranted at diagnosis to guide suppression efforts.[8]

HSV infection is transmitted through contact with HSV-infected fluids or skin as occurs with genital skin or mucosal contact with a person shedding the virus. There is even the possibility that saliva alone can transmit the virus when placed on mucous membranes or genitals for lubrication.[40] Persons without symptoms probably transmit most infections. Asymptomatic viral shedding occurs on

approximately 10% of days compared with 20% of days for those who are symptomatic. Transmission rates are not well identified. However, women and men who are the receptive partner for men are more susceptible to contracting herpes related to prolonged semen contact with the vaginal or rectal mucosa. Any type of rough intercourse that causes breaks in the skin surface increases transmission as well. It is estimated that a woman has an 80% to 90% risk of developing genital herpes after being exposed to an infected man.

Condoms reduce the risk of transmission, especially from males to females.[41] However, if lesions or shedding occur outside the area covered by the condom, transmission can still occur.[41] Female condoms offer a bit more protection from HSV because they cover and protect the vulva, but they do not eliminate risk. HSV infection greatly increases the risk of HIV acquisition. People with HSV are two to four times more likely to contract HIV if exposed, potentially because of skin splits that occur as a result of HSV infection.[39]

Neonatal infections can begin in utero or, more commonly, during the intrapartum or postpartum period. The risk of transmission of HSV to the neonate varies from less than 1% among women with recurrence of known herpes at term to up to 30% to 50% in women who acquire HSV near term.[39] Perinatal transmission can cause extensive morbidity and mortality. Intrauterine transmission is rare (only 5% of neonatal infections) but can occur through transplacental or ascending infection and can cause fetal malformations.[42]

Eighty-five percent of infections are transmitted during the intrapartum period.[42] Infants are at greatest risk if the mother has a primary infection acquired near the time of delivery rather than a recurrent infection or an infection acquired during the first half of pregnancy.[1] Ruptured membranes have a role in the development of HSV. Rupture of membranes for more than 4 hours increases the risk of the fetus contracting HSV. Internal fetal monitoring devices also increase the risk of vertical transmission because they break the fetal skin. Infants also may be exposed after birth through mouth-to-

mouth kissing by family members; there have been several cases of infants exposed during ritual circumcision involving direct orogenital suction.[43]

Pathophysiology

After initial exposure and entry of the virus at mucocutaneous sites or abraded skin, the virus undergoes replication locally in the dermis and epidermis. This leads to cell destruction, transudation, and vesicle formation. The virus spreads to contiguous cells and eventually into sensory nerves. This process often causes a systemic, inflammatory immune response, especially with HSV-2 infection, that includes fever and malaise. In rare cases, the herpes can cause CNS manifestations. Painful lesions can last from days to weeks. Eventually, the virus is transported through the axon to the dorsal root, where it remains in a latent stage until it becomes reactivated. After oral infection, the latent virus resides in the trigeminal ganglion; after genital infection, the virus resides in the dorsal sacral nerve roots. During the latent period, the viral genome is maintained in the host cell nucleus without causing cell death.

Reactivation of latent infections often occurs during times of physical or emotional stress causing a recurrent infection. Compared with HSV-1 infections, reactivation of the HSV-2 infection is twice as common, and the likelihood of HSV-2 recurrent infections is 8 to 10 times that of HSV-1. Reactivation of HSV is not well understood but may be attributable to physical, hormonal, and immunologic stimuli. During reactivation, the viral genomes are transported through the peripheral sensory nerves back to the dermal surface.

Shedding of the virus occurs during outbreaks and also may occur when the person is asymptomatic, increasing the likelihood of transmission. Antiviral medications decrease asymptomatic viral shedding and should be considered as an adjunct to safe sex practices.

Clinical Manifestations

Three distinct syndromes associated with HSV infection are first-episode primary genital infection, first-episode non–primary HSV, and recurrent infections. The manifestations of each one depend on the individual's immune state. First-episode primary genital infection occurs when an individual has no antibodies to HSV-1 or HSV-2. Many primary infections with HSV are asymptomatic or the symptoms are not severe enough to warrant medical attention. If symptoms occur, the individual may have small (1 to 2 mm), multiple, vesicular lesions at the site of infection, usually on the labia minora, fourchette, penis, or mouth (Fig. 27.12). They also may appear on the cervix, buttocks, and thighs and are often painful and pruritic. These lesions usually last about 10 to 20 days. The lesions of HSV-1 and HSV-2 can be very small and almost indistinguishable to the naked eye or large and clustered into raw areas. These wet lesions actively shed virus for approximately 10 to 14 days, after which they heal by reepithelialization. Small lesions may coalesce into larger ulcers and become secondarily infected.

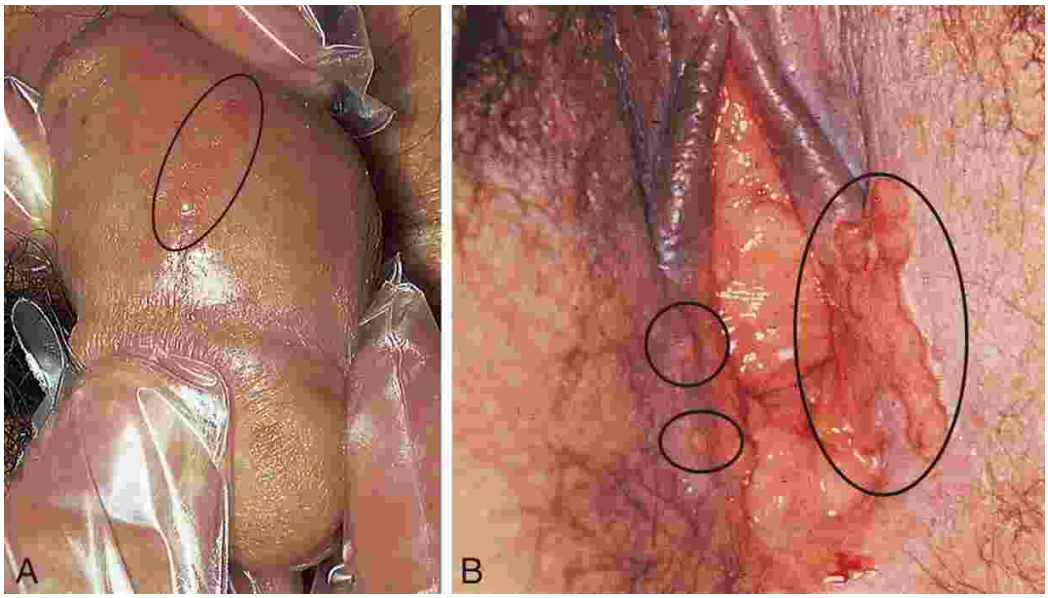

FIG. 27.12 Herpes Lesions.
(A) Herpetic vesicles on the penis. (B) Herpetic ulceration of the vulva. (A, From McMillan A, Scott GR. *Sexually transmitted infections*, 2nd edition. London: Churchill Livingstone; 2000. B, From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2013.)

Systemic manifestations such as fever, malaise, myalgia, lymphadenopathy, and urinary retention often accompany primary HSV infection. Pharyngitis, aseptic meningitis, and hepatitis also may accompany primary HSV infection. Fig. 27.13 illustrates the clinical course of primary genital HSV.

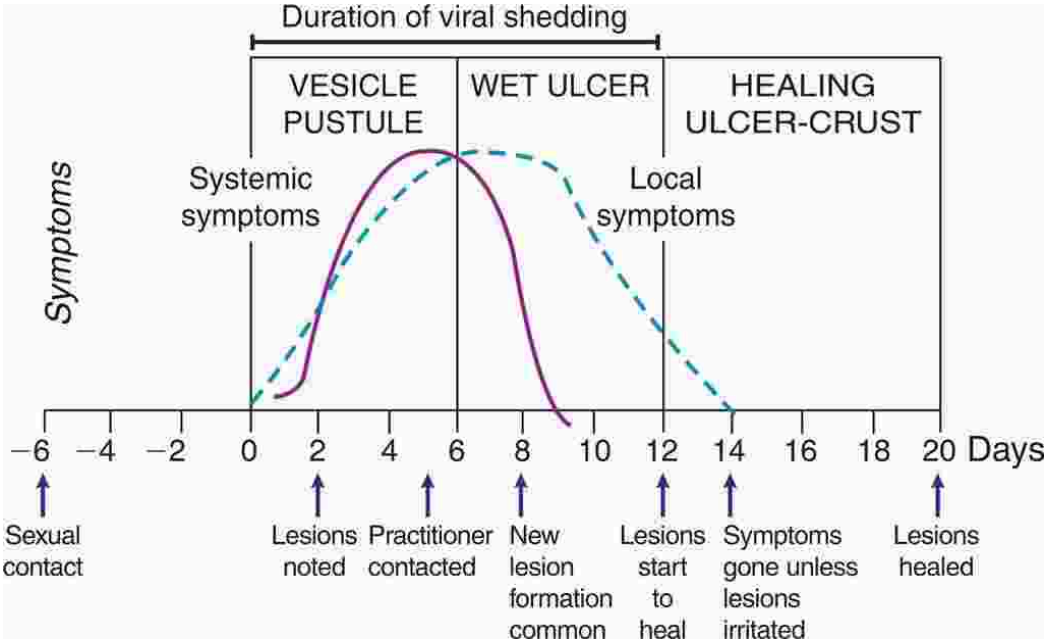

FIG. 27.13 Clinical Course of Primary Genital Herpes. (From Corey L. Genital herpes. In: Holmes KK, et al., eds. *Sexually transmitted diseases*, 2nd edition. New York: McGraw-Hill; 1990.)

A graph represents the clinical course of primary genital herpes simplex virus infection. The horizontal axis represents the days ranging from minus 6 through 20. The duration of viral shedding is given as follows. Vesicle pustule: 0 to 6 days where lesions were noted on day 2, practitioner contacted on day 5. Wet ulcer: 6 to 12 where new lesion formation on day 8, lesions start to heal on day 12. Healing ulcer-crust: 12 to 20 days where symptoms are gone unless lesions irritated on day 14 and lesions healed 20. The graph for systemic symptoms is plotted from day 0

to day 9, and the graph for local symptoms is plotted from day 0 to day 14. All data is approximate.

First-episode non–primary genital HSV occurs in individuals who have preexisting antibodies. In some individuals, the primary infection may not have had any clinical manifestations, but the HSV virus has become latent in the nerve root and can reactivate later in life. Compared with primary infection, the first episode of non–primary HSV is often milder with fewer lesions that are less painful and heal faster. Fewer systemic manifestations occur, and viral shedding is of shorter duration. However, the symptoms may be severe if the second infection occurs during a period of immunocompromised health status.

Recurrent infections usually produce mild local symptoms. The number of lesions is greatly reduced, and the lesions are less painful. Lesions are often unilateral, with crusting within 4 to 5 days. Recovery and healing are usually complete within 10 days. Asymptomatic viral shedding can occur with both HSV-1 and HSV-2 but is more common with HSV-2.[39]

Individuals infected with HSV-2 are more likely to experience recurrent infections. Recurrent infections occur on an average of five to eight times per year but may be more frequent in the first few years of infection. Individuals may experience prodromal symptoms (e.g., pruritus, tingling, dysesthesias) a few hours to 2 days before the eruption of lesions. Women may experience a vaginal discharge and dysuria, and 44% of men have dysuria.

Symptomatic HSV infection of the newborn may occur any time in the first month of life. Manifestations range from a local infection of the eyes, skin, or mucous membranes to a severe disseminated infection with CNS involvement. Approximately 70% of affected infants present with skin lesions. CNS involvement includes seizures and is associated with a mortality of more than 50% and extensive neurologic sequelae in survivors.[42]

Evaluation and Treatment

Genital HSV infection is suggested if typical genital lesions are present; painful genital lesions alone are enough to begin treatment. The CDC recommends serologic testing for diagnosis and to determine the virus subtype because the prognosis and the risk of transmission differ. Diagnosis of HSV-1 and HSV-2 with polymerase chain reaction (PCR) is much more rapid (6 to 14 hours) and more cost effective compared with previous viral cultures (7 to 14 days).

There is no cure for HSV, only symptom management and viral suppression treatments. All primary outbreaks should be treated with antiviral medications to prevent complications and speed healing.[44] Oral acyclovir, valacyclovir, penciclovir, and famciclovir are used for primary and periodic outbreaks and to prevent recurrences. Acyclovir has a better safety profile for pregnant and nursing women, but there is ongoing research supporting the safety of valacyclovir as well. IV acyclovir is reserved for very ill or severely immunocompromised individuals.[44]

Suppressive treatment is recommended for individuals with frequent or severe outbreaks and pregnant women at term with a history of herpes.[45] Suppressive treatment also may reduce asymptomatic viral shedding, decreasing transmission to sexual partners and infants born vaginally. Although there are few side effects with suppression drugs, the decision to take daily medication is complex for many individuals. Although male and female condoms offer some protection, individuals with HSV should refrain from all genital or oral contact when prodromal or symptomatic and understand that an undetermined risk of transmission exists even during asymptomatic periods.

Human Papillomavirus Infection

HPV infection is the most common symptomatic viral STI in the United States. Although more than 5.5 million cases are diagnosed yearly, the prevalence of 24 million cases is considered underestimated because HPV infection is often subclinical. More

sensitive measures of HPV indicate that 50% of all sexually active people are infected with the virus at some point in their lives, although these numbers are expected to decrease sharply in response to widespread vaccination. The virus is easily transmissible through direct contact with lesions or infected secretions. Vertical transmission in utero and during vaginal birth also is possible.[46,47]

Approximately 150 different types of HPV have been identified.[48] More than 40 serotypes are unique to the stratified squamous epithelia of the anogenital area, although research is finding these same subtypes also may infect the oropharynx.[49] These are divided into high-risk serotypes (high risk of causing cancer) and low-risk serotypes (associated with benign genital lesions or warts: condylomata acuminata of the vulva, vagina, penis, and perianal areas).

Serotypes 6 and 11 are associated with 90% of genital warts. These low-risk, or nononcogenic, subtypes can coexist with the high-risk types but do not cause cancer independently. Genital warts are very contagious, with transmission rates among individuals estimated to be between 38% and 95%. Such a wide range is attributable to the subclinical nature of some infections and various influencing factors that include number of exposures, HPV type, location of lesions, and cellular immunity response.

High-risk, or oncogenic, types 16 and 18 are the most common, causing up to 70% of anogenital cancers (cervical, penile, vulvar, vaginal, anal), and are highly associated with oropharyngeal cancers (see Chapters 12, 13, and 25).[1] HPV-related cancers of the anogenital and oropharynx areas are more common than ovarian cancer in women and more common than brain cancer in men. In future generations, most of these cancers can be prevented through vaccination before HPV exposure.[49]

HPV infection is closely associated with multiple sexual partners and early onset of sexual activity and is most common in teens and young adults 16 to 25 years of age. Fortunately, most cases of HPV are transient, and 70% of healthy individuals will spontaneously eliminate the virus.[50] The persistence of the virus and the immune

response play a role in the development of cancer following HPV exposure. Behaviors and conditions that affect overall health status affect the body's ability to clear HPV infection. Alcohol use, smoking, and HIV infection are strongly correlated with persistent HPV infection.[50]

Although three approved vaccines are available to protect against HPV (2-, 4-, and 9-valent), only the 9-valent vaccine is currently available in the United States.[48] Approved vaccines use noninfectious virus-like particles to induce an immune response. The CDC advises using the 9-valent vaccine because of greater prevention capability and cost-effectiveness.[48]

Routine HPV vaccination is recommended for all adolescents at age 11 or 12 but can start as early as age 11, with catch-up vaccination through age 26 if not previously vaccinated. If vaccination is begun before age 15, a two-dose schedule is recommended. For unvaccinated persons 27 to 45 years, the decision for vaccination is based on risk factors and shared decision making between provider and patent. For immunocompromised persons regardless of age, a three-dose vaccine schedule is recommended.[48] Prevention of HPV acquisition in young adults is important because they are more likely than older adults to contract STIs and because the cervix of younger women is more vulnerable to HPV. Public health officials are hopeful that vaccination of boys and girls before they become sexually active will decrease the burden of HPV infection in the future. Preliminary data suggest the effects of widespread vaccination that began in 2006 are already becoming apparent (Box 27.5).[51,52] There are even some reports that vaccination of pregnant women can decrease vertical transmission during vaginal birth because maternal antibodies to HPV cross the placenta.[53]

Box 27.5

Human Papillomavirus Vaccine

Every year in the United States:

- Nearly 1 in 4 adults have at least one strain of human papillomavirus (HPV).
- About 12,000 women are diagnosed with HPV-related cervical cancer.
- Almost 4000 women die from HPV-related cervical cancer.
- About 1900 men are diagnosed with HPV-related penile or anal cancer.

Vaccines are available in the United States to vaccinate 2, 4, or 9 strains of high-risk HPV:

- Vaccines are recommended for females and males beginning at age 11 years and up to age 26 depending on gender and risk factors.
- The Centers for Disease Control and Prevention (CDC) currently recommends children ages 11–12 years receive two doses of HPV vaccine rather than the previously recommended three doses; the second dose should be given 6–12 months after the first dose.
- Vaccines are highly effective in preventing high-risk HPV types associated with cervical cancer; they have been proven safe and effective by the CDC, with ongoing safety monitoring.
- Vaccines are not recommended for pregnant women because their safety is not yet established, but preliminary reports suggest that HPV vaccination in pregnancy may decrease vertical transmission during vaginal birth.
- Vaccinated women still need cervical cancer screening at regular intervals.
- The three-injection vaccine series is covered by most insurance plans, Medicaid, and the Vaccines for Children (VFC) program if individuals meet eligibility requirements, including age and financial need.

For more information, visit the Centers for Disease Control and Prevention (CDC). STD website at www.cdc.gov/std/default.htm. Data from Centers for Disease Control and Prevention (CDC). *Human Papillomavirus (HPV)*. The immune system is prepared to eliminate the virus through the immune response when previously vaccinated. When an individual has not been vaccinated, he or she may or may not be able to clear this viral infection. Although most HPV subtypes are not associated with abnormal cellular growth, high-risk HPV subtypes cause cellular changes that can lead to cell proliferation, causing warts or cancer.

Pathophysiology

HPV is a nonenveloped, circular, double-stranded DNA virus.[50] Transmission of the virus occurs through close physical contact with infected skin, mucosa, or fluids; however, the exact transmissibility of the virus into the cell is unknown. The initial infection follows trauma to the epithelium that allows the virus to reach and infect the basal cells of the epithelium, which appear to be supportive of viral propagation. Such minor trauma may occur during sexual intercourse. HPV may enter the nuclear DNA and change the expression of cell proteins, leading either to increased but noncancerous cell growth (e.g., warts) or to unchecked cell growth (e.g., cancer). It is not known exactly why some HPV serotypes are cleared from cells whereas other serotypes cause cellular

transformations, but immune response and other cofactors play a role.[50] HPV infection may occur months to years before symptoms appear, such as warts or precancerous lesions.

Clinical Manifestations

Genital warts, condylomata acuminata, are soft, skin-colored, white-pink to red-brown discrete growths. They may occur singly or in clusters, may be broad at the base or pedunculated, and may be feathery or smooth. Sometimes the warts enlarge to form cauliflower-like masses on the male frenulum, glans, foreskin, urinary meatus, shaft, scrotum, or anus and on the female labia, clitoris, perineum, vagina, or anus (Fig. 27.14). Although the lesions are usually not painful, they may cause dyspareunia (painful intercourse) and may be friable and bleed easily. Some individuals complain of pruritus. Common locations for condylomata are the on the vaginal introitus, the shaft of the penis, and under the foreskin. However, warts can be in any location infected by HPV along the reproductive tract, anus, and oropharynx.[8,31] Laryngeal papillomas can occur in infants and children whose mothers had genital warts at the time of delivery. Clinical manifestations of laryngeal warts include stridor, hoarseness, abnormal cry, cough, and respiratory distress.[53]

FIG. 27.14 Condylomata Acuminata—Vulva and Perineum.
The clinical diagnosis was giant condylomata. Such large and confluent lesions should be carefully examined and multiple biopsies obtained to rule out underlying malignancy. (From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2013.)

Precancerous changes related to HPV often do not have any visible manifestations. Because the lesions are not painful early detection is often hampered. In addition, cervical and anal cancers may not cause symptoms until late into the disease process. Routine screening for cervical cancer (see later) was begun to increase early detection since clinical symptoms are minimal.

Evaluation and Treatment

In general, the diagnosis of condylomata acuminata is made based on clinical manifestations. Verrucous, fleshy-pink lesions caused by HPV must be differentiated from condylomata lata (the whitish gray, flat lesions) of secondary syphilis. Because HPV infection often accompanies other STIs, testing for gonorrhea, chlamydia, and syphilis and wet prep for other vaginal organisms should be performed.

Treatments for external genital warts are considered cosmetic—not curative—and include individual-applied therapies (podofilox, imiquimod, and sinecatechins) and provider-administered therapies (cryotherapy, podophyllin resin, trichloroacetic acid [TCA], bichloroacetic acid [BCA], and surgery). Vaginal, urethral, or anal warts can be treated in the clinic using topical medications, cryotherapy, or surgical excision; the CDC provides specific guidance on therapies based on wart location and pregnancy status. Cervical and anal warts require additional screening to exclude more extensive lesions.[48] Success of treatment depends on response of the immune system. Surgical excision is the treatment for laryngeal warts in infants.

With currently available cytologic technology for cervical cell evaluation, the identification of both nononcogenic and oncogenic strains of HPV is readily available. In women who are unscreened, the identification of cervical cancer may be delayed because of poor innervation of the upper pelvis, allowing cancerous masses to grow large before causing symptoms. The development of the Papanicolaou, or "Pap," smear helped to reduce deaths related to cervical cancer by 80% since the 1950s.[54] Ideally, persistent HPV

infections can be identified to encourage greater screening for abnormal cellular changes. The appropriate screening for nongenital HPV infection is controversial because there are no guidelines delineating who should be screened for anal and oropharyngeal infection.

Following the development of the Pap smear, women were advised to have yearly Pap tests to detect cancer. However, over time, it became apparent that, although younger women often had abnormal Pap tests, they were often able to clear HPV infection and resolve cellular changes without treatment. Treatment of women younger than 20 years of age provides little to no benefit in reducing later rates of cervical cancer but results in pain, anxiety, and increased healthcare costs. Therefore the US Preventive Services Health Task Force, the American College of Obstetricians and Gynecologists, and many other national cancer agencies recommended that Pap smear testing begin only after 21 years of age.[55,56]

Women ages 21 to 29 should receive just Pap testing every 3 years, whereas women 30 to 65 years of age may receive Pap testing with HPV screening every 5 years (preferred) or Pap testing alone every 3 years. After 65 years of age, Pap testing and HPV screening are no longer recommended for women with previous normal testing results, because the risk of new malignancy is low. Women who have had a hysterectomy with removal of the uterine cervix for a noncancerous condition do not need Pap smears or HPV testing for the rest of their lives. Although the HPV vaccine does reduce the risk for cervical cancer, it does not change the frequency or need for Pap and HPV testing at this time.[56]

If the results of a Pap test are abnormal, the woman's cervix will be further evaluated using colposcopy, which involves applying 3% acetic acid (vinegar) and using magnification to examine the cervix for changes indicative of cancer or precancerous lesions. HPV-infected cells will appear white when exposed to acetic acid. In some developing countries with limited laboratory facilities, this test alone is used to screen for cervical cancer. Following visual investigation

of the cervix during colposcopy, the clinician biopsies suspicious areas for further evaluation. Treatment of precancerous and cancerous lesions varies and involves removal or destruction of the affected cells through excision or ablation.

Although infection with high-risk HPV strains is a risk factor for development of anogenital cancers, as well as cervical cancer, there is no consensus on screening for rectal and anal cancers.[49] Anyone who engages in receptive anal intercourse is at risk for rectal HPV and subsequent development of anal cancer. Women are approximately twice as likely as men to develop anal cancer, but MSM remain at risk.[49] It is hoped that the need for treatment of HPV-related genital conditions will decrease as more children and young adults are vaccinated for HPV before becoming sexually active.[46]

Molluscum Contagiosum

Molluscum contagiosum is a benign viral infection of the skin in children and adults. For detailed information, see Chapter 47. In adults, the disease is more commonly sexually transmitted and affects the lower abdomen, genitalia, and perianal area.[27] Molluscum contagiosum in adults is most common in men 20 to 29 years of age and in those with multiple sexual partners. Treatment for sexually transmitted molluscum contagiosum is the same as that for the nonsexually transmitted form of the disease; the CDC also includes information in their regularly updated guidelines.[8]

Parasitic Infections

Trichomoniasis

Trichomonas vaginalis, commonly known as "*trich,*" is estimated to be the most prevalent nonviral STI worldwide. Trichomonas affects more than 3.7 million people in the United States. Trichomoniasis affects greater than 11% of women older than 40 and is the most common nonviral STI in this age range.[1] The high rate of asymptomatic infection aids the spread of this pathogen. Male-

female vaginal intercourse is the most common route of transmission.[1] Although sexual transmission is clearly the most common means of disease spread, transmission through fomites is theoretically possible.

Pathophysiology

T. vaginalis is an anaerobic, unicellular, flagellated, parasitic protozoan that adheres to and damages squamous epithelial cells (Fig. 27.15). It is primarily spread through penile-vaginal sex, although anal sex and oral sex could be potential routes of infection.[38] Because this protozoan selectively affects squamous epithelia, the vaginal and urethral tissues in women are often infected, as are periurethral (Skene) and greater vestibular (Bartholin) glands. The endocervical canal is not affected because it is lined with columnar epithelium. In men, the urethra is the most common site of infection, although the protozoans, called trichomonads, can infect the epididymis and (rarely) the prostate. Uncircumcised men are more likely to become infected after exposure than circumcised men.[8] There are no conclusive data that the rectum or the oropharynx is a reservoir for infection.[8]

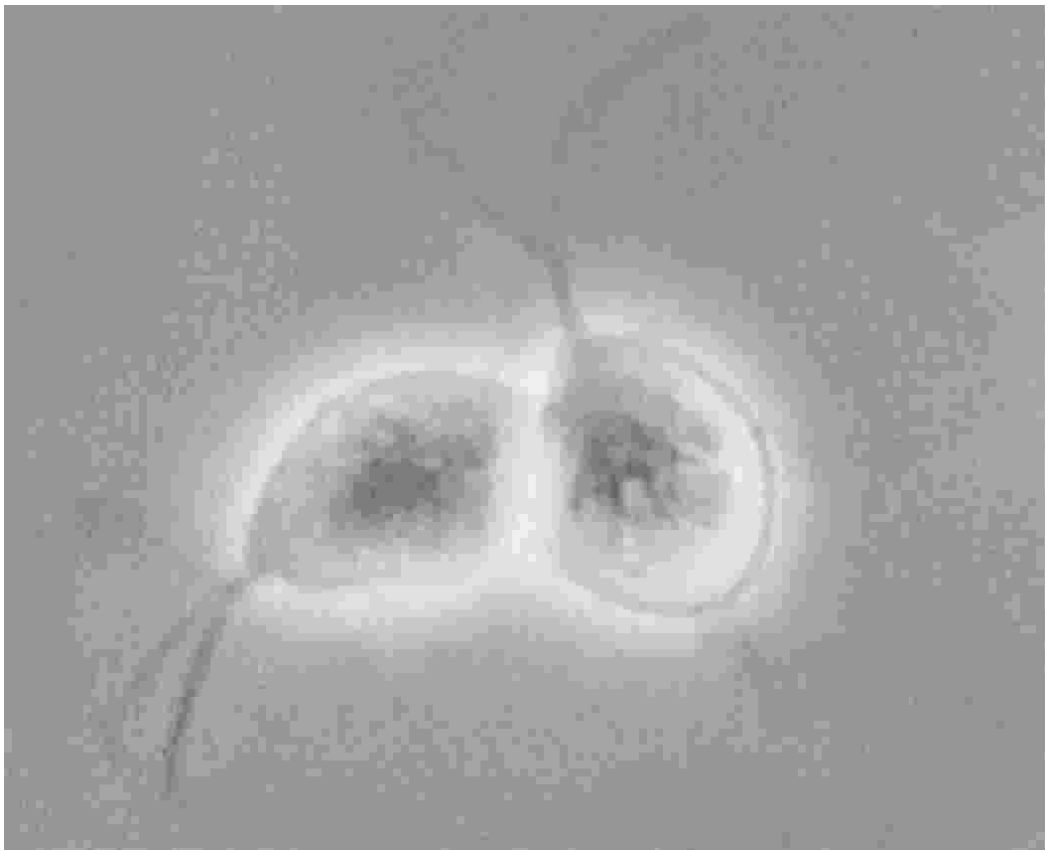

FIG. 27.15 Trichomonas vaginalis. (From CDC Public Health Information Library [PHIL].)

Clinical Manifestations

Manifestations of vaginal trichomoniasis range from none to severe. Up to 85% of those infected have minimal or no symptoms.[57] Vaginal discharge and internal pruritus are the most common manifestations of infection. Dyspareunia and dysuria also are fairly common. Some women report an increase in symptoms immediately after menses. Vaginal secretions can be copious, frothy, malodorous, and yellow-green to gray-green. On examination, the vaginal walls may appear erythematous and sore. Small, punctate red marks, sometimes called *strawberry spots*, are sometimes visible on the vaginal walls and cervix. Most men with trichomoniasis are asymptomatic but may have scant intermittent discharge, slight pruritus, and mild dysuria.[57]

Evaluation and Treatment

All women reporting abnormal vaginal discharge should be tested for trichomoniasis.[57] NAAT is the most sensitive and specific method for detection of *T. vaginalis* infection. Samples for testing can be obtained from the woman's endocervix, vagina, or urine. Samples for men ideally come from the penile meatus, but urine is acceptable as well. Self-collection of samples is acceptable; some tests have even been shown to be accurately used in self-testing,[57] which can aid diagnosis, especially in cases of recurrence. A microscopic examination of vaginal fluid mixed with saline (wet prep) was previously widely used to detect the presence of this protozoan, but, with a sensitivity of just greater than 50%, the wet prep is much less accurate than NAAT testing.[57] However, this method can be used when other tests are unavailable or cost prohibitive.

On microscopic examination, the ovoid microorganism is slightly larger than a polymorphonuclear leukocyte and has one rounded, flagellated end and one slightly pointed, flagellated end. The flagella give the trichomonads their characteristic twisting motility.

The recommended treatment of choice for trichomoniasis in women is metronidazole 500 mg orally two times daily for 7 days. For men, a single oral 2 g dose of metronidazole (Flagyl) is recommended. An alternative and more expensive regimen for women and men is tinidazole 2 g orally in a single dose. Metronidazole vaginal gel is not recommended.[57] These drugs have intense disulfiram-like reaction which causes severe nausea and vomiting when taken with alcohol; thus individuals must be able to abstain from all alcohol products for 3 days after treatment. Sexual partners, even if asymptomatic, also should be treated. There are high rates of reinfection and the CDC advises a 3-month follow-up after treatment for a test of cure.[8]

T. vaginalis infection in pregnant women is associated with an increased risk of preterm birth through unknown mechanisms that may be linked with inflammation.[58]The 2-g single dose of metronidazolecan be used to treat pregnant women. However, it is

not clear if treatment improves outcomes and metronidazole therapy may actually increase the rate of preterm delivery.[59,60] An alternative dosing regimen is available for lactating women, or the woman can abstain from breast-feeding for 12 to 24 hours after taking the drug.

Scabies

Scabies, a common parasitic infection caused by *Sarcoptes scabiei*, is spread by close skin-to-skin and sexual contact.[61] Although scabies is more common in children and the elderly than in adults,[61] sexual transmission is the most frequent cause of infection in adults.[8] (Detailed information on scabies is contained in Chapter 47.)

Pathophysiology

The discussion of scabies is presented in Chapter 47.

Clinical Manifestations

The classic symptom of scabies is intense pruritus, which increases at night. Pruritus is a result of a reaction to the presence of the *S. scabiei* mite. This reaction may take weeks with initial infection but only 24 hours if the person has been previously infected. The groin and buttocks are common locations for sexually transmitted scabies. Fig. 27.16 shows the typical sites of scabies burrows. The typical burrow of *S. scabiei* is a short, linear, curved, or S-shaped line (Fig. 27.17). There may be small, erythematous, excoriated larval papules near the burrows. Secondary infections are common and are caused by scratching. Even after successful treatment, some individuals will continue to experience pruritus for several weeks.[61]

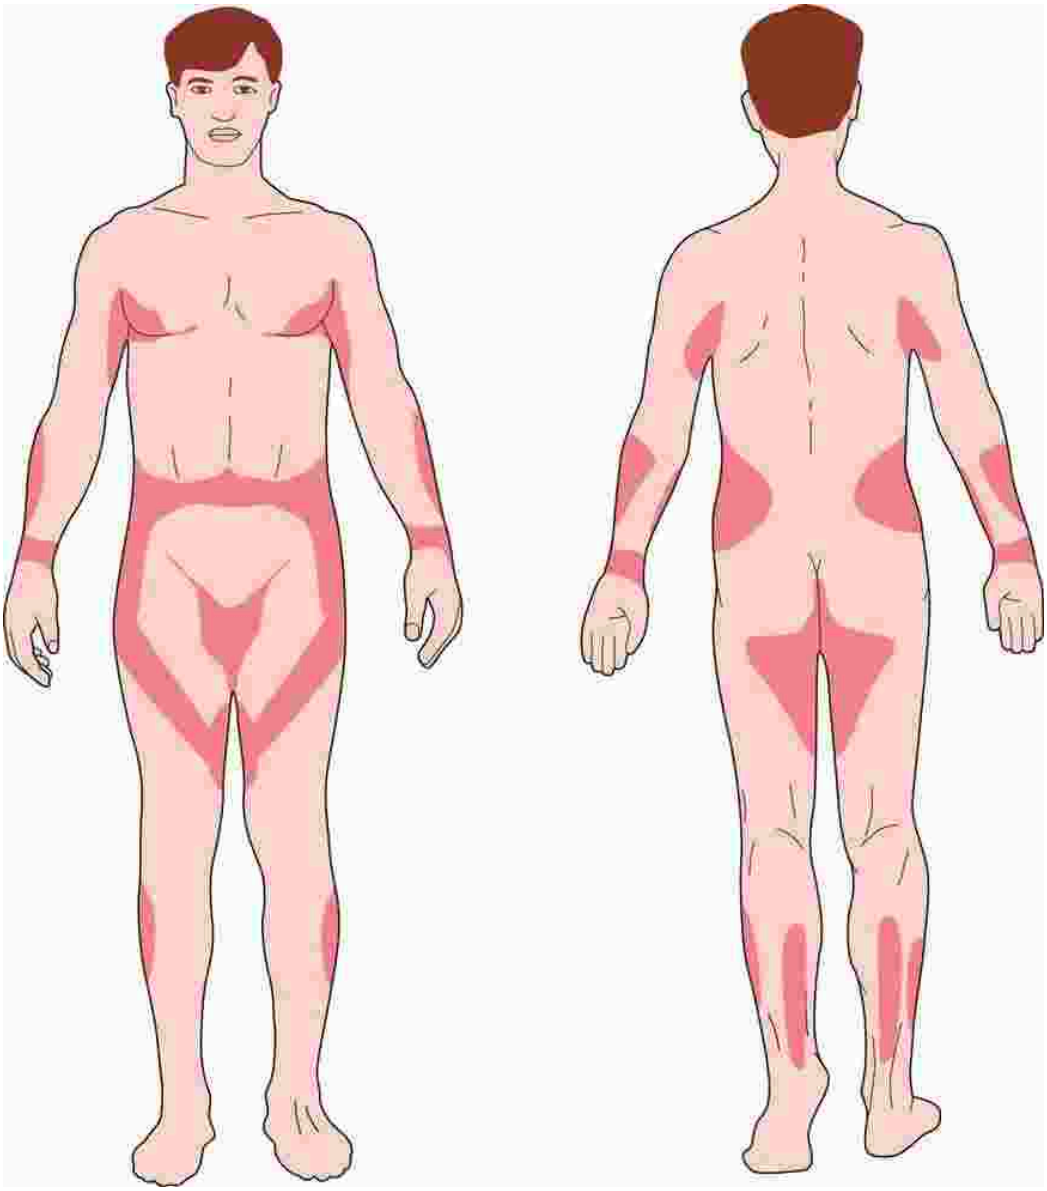

FIG. 27.16 Distribution of Skin Lesions of *Sarcoptes scabiei* Infestation.
Unshaded areas are rarely affected in healthy adults. (From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 3rd edition. London: Mosby; 2003.)

The illustration on the left depicts the anterior view of the male with shaded portions of the right and left

armpit, right and left wrist and hand, hip, genitalia, inner thigh, and legs, indicating the distribution of skin lesion of Sarcoptes scabiei Infestation. The illustration on the right depicts the posterior view of the male with shaded portions of the right and left armpit, right and left wrist and hand, hip, genitalia, inner thigh, and legs, indicating the distribution of skin lesions of Sarcoptes scabiei Infestation.

FIG. 27.17 Scabies Burrow.
An **S**-shaped burrow with a tiny vesicle at one end. (From Marks JG, Miller JJ. *Lookingbill and Marks' principles of dermatology*, 4th edition. St. Louis: Saunders; 2006.)

Evaluation and Treatment

The diagnosis of scabies is often made clinically when risk factors are present. Microscopic identification of the mite, eggs, larvae, or feces is ideal because the symptoms of scabies can imitate many dermatologic conditions. Superficial scrapings from an intact papule or burrow can be observed under the microscope. An application of 10% potassium hydroxide (KOH) to the skin scrapings facilitates mite visualization.

Preferred treatment is topical application of 5% permethrin massaged into the skin and left for 8 to 14 hours or ivermectin dosed at 200 µg/kg/dose orally and repeat the same dose again in 1 weeks. Ivermectin is an oral antiparasitic agent approved for the treatment of worm infestations. Evidence suggests that oral ivermectin may be a safe and effective treatment for scabies; however, ivermectin is not FDA-approved for this use.[61] Lindane (1%) lotion or cream also is effective if applied thinly to all areas of the body below the neck and washed thoroughly 8 hours after application. Because of its toxicity, lindane should be reserved for those who cannot tolerate any other therapy. Lindane should not be used during pregnancy or on children younger than 10 years old.[61] Pregnant women should be treated with permethrin.[61] Close household and sexual contacts should be examined and treated if infected.[61] To prevent reinfestation, clothing and bed linens should be washed and dried in a machine at high temperatures or kept away from body contact for 72 hours.[61]

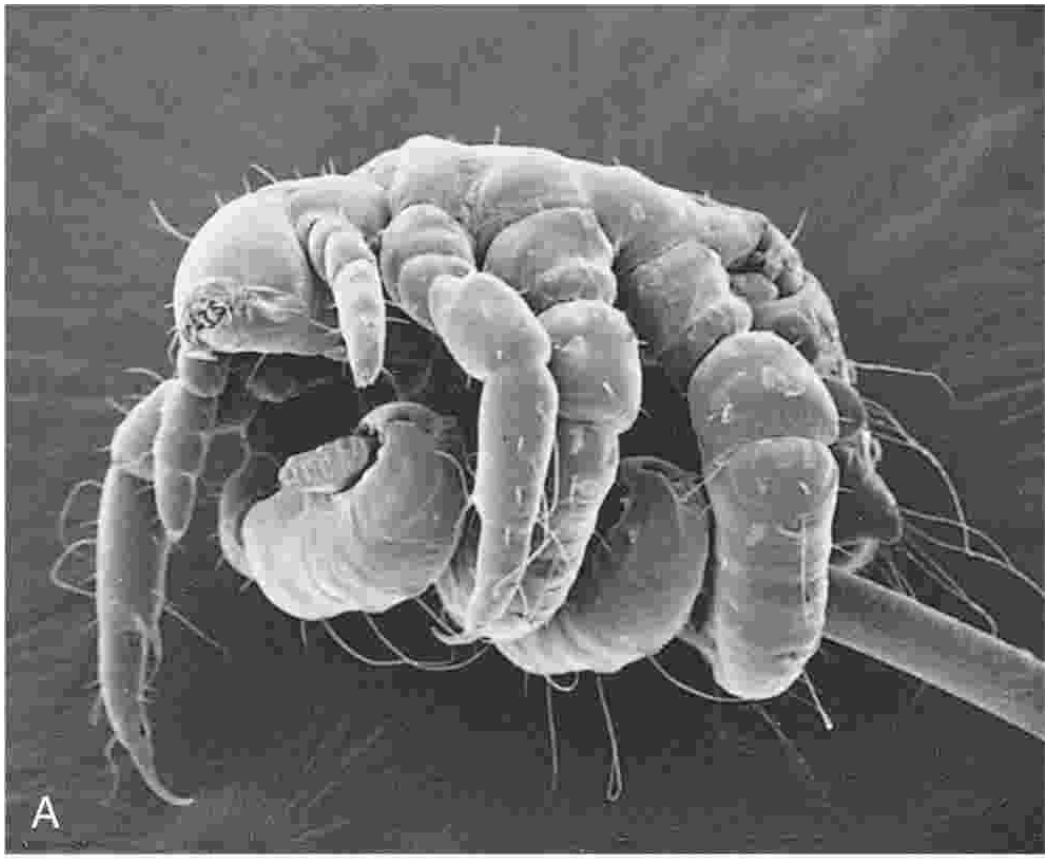
Pediculosis Pubis

Pthirus pubis, or crab louse, is one of three species of lice that infest humans. *P. pubis* is commonly transmitted by intimate sexual contact or by contact with infected linens and causes pediculosis pubis, or "crabs." It is highly contagious; there is a 95% chance of contracting lice during a single sexual encounter. Fomites are a common method of infection because crabs can live away from the body for several days. The transfer of lice from pubic hair is probably mechanical,

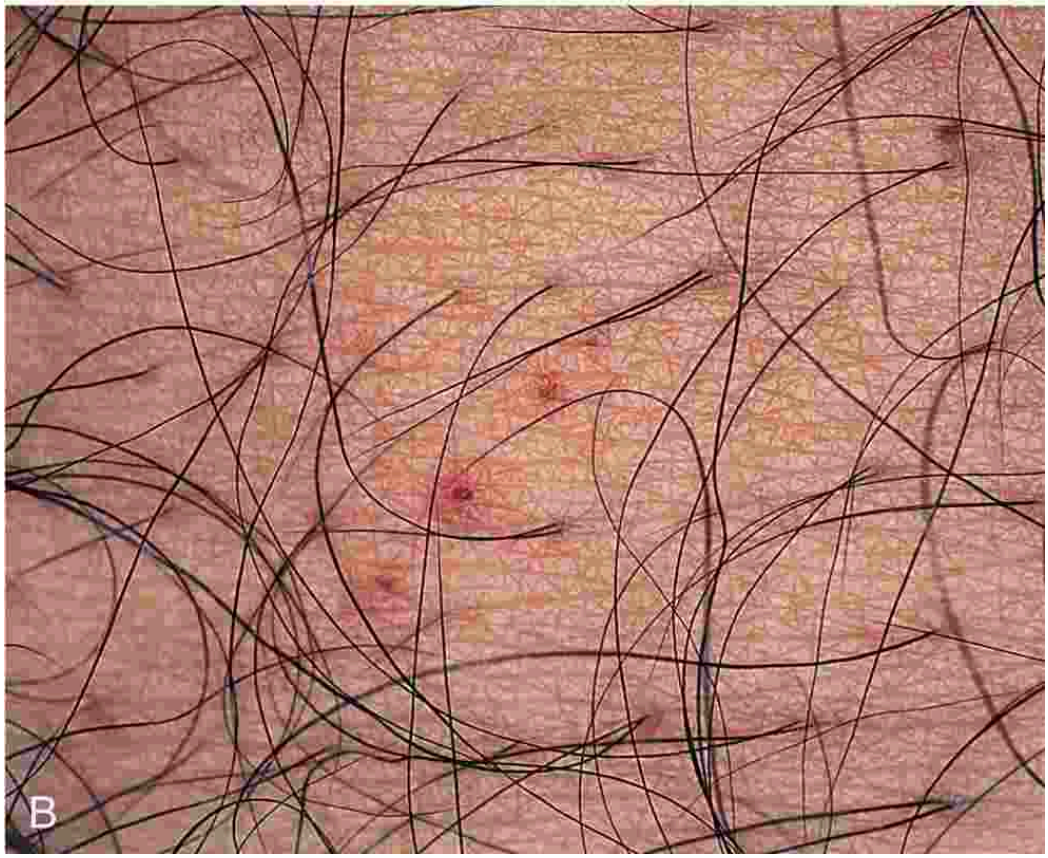
assisted by scratching, fingernails, and towels rather than by self-propulsion. Pubic lice usually infect the perineal and axillary hair and occasionally the hair of the trunk, beard, scalp, and eyelashes.

Pathophysiology

The crab louse has a 25- to 30-day life cycle that consists of five stages, all of which occur on the host: the egg (or nit) stage, three nymphal stages, and an adult stage. The white-gray nits of crab lice, found "glued" to hairs, are oval, 0.8 by 0.3 mm in length and hatch in 5 to 10 days (Fig. 27.18). In the adult stage, pubic lice are gray, are approximately 1 mm in length, and have a segmented body and claws to cling to hairs. They bite into the host's skin to feed on blood, causing itching and pain.



A



B

FIG. 27.18 Pubic Louse and Crab Louse.
(A) Pubic louse *(Pthirus pubis)* encircling a pubic hair; the claw-like legs produce a firm grip. (B) Crab louse bites *(P. pubis)*. (From Morse SA, et al., eds. *Atlas of sexually transmitted diseases and AIDS*, 4th edition. London: Saunders; 2013.)

Clinical Manifestations

The mites are visible, facilitating self-identification of infestation. Symptoms range from mild pruritus to severe, intolerable itching, depending on the individual's sensitivity to louse bites. Allergic sensitization occurs in approximately 5 days, when itching, erythema, and inflammation may worsen. Excessive scratching may lead to secondary infection.

Evaluation and Treatment

The individual usually presents with a history of itching in the infected area. Because the lice and nits are visible to the naked eye, a thorough clinical examination permits definitive diagnosis. Pediculosis pubis is treated with 1% permethrin cream rinse to the affected areas and washed off after 10 minutes or with piperonyl butoxide, an over-the-counter pyrethrin. For nonocular infections, the pediculicide is applied to infested and adjacent hairy areas and washed off after a specified time. Remaining nits can be removed with a fine-toothed comb. Permethrin is the first line treatment. However, drug resistance is widespread and increasing. Malathion and ivermectin are alternative regimens, although ivermectin does not adequately kill the eggs and requires redosing at 2 weeks. Malathion is undesirable because of its long duration of application and odor. Lindane is a higher-level treatment that should be reserved for when other treatments have failed. Because of the risk of toxicity, lindane cannot be used by pregnant women.[8] Sexual contacts from the past month should be treated regardless of

symptoms, and household contacts should be examined and treated if needed. Clothing and bed linens should be machine washed and dried at high temperatures or kept away from body contact for 72 hours.[8]

Sexually Transmitted Infections of other body Systems

The effects of some STIs extend beyond the urogenital tract. Many disorders have varied methods of transmission that may include nonsexual means. Although the major mode of transmission may be by oral ingestion or by direct contact with blood or body fluids (e.g., sharing of needles among drug users, blood transfusions, vertical transmission from mother to baby, health worker exposures), infection can be transmitted through intimate sexual contact as well. Anal contact and physically damaging sex can increase the transmission of many of these infections.

Among the most serious of these infections are acquired immunodeficiency syndrome (AIDS) caused by the HIV and hepatitis (all types). Worldwide, the main mode of transmission of HIV and hepatitis B is through sexual intercourse (primarily male female), but nonsexual exposure to infected blood and body fluids, especially through needle sharing, contributes to infection rates. The epidemiology, modes of transmission, pathophysiology, clinical manifestations, and evaluation and treatment of AIDS and hepatitis are discussed in detail in Chapters 10 and 42,respectively.

Sexual transmission of less serious but often debilitating infections, such as shigellosis and giardiasis, and systemic diseases, such as Epstein-Barr virus and cytomegalovirus infections, also can occur, although nonsexual transmission is more common. Table 27.3 provides a list of several gastrointestinal and systemic infections that are known to be transmitted by intimate sexual contact but in which the mode of transmission is primarily through other routes.

Table 27.3

Infections With Known Sexual Transmissibility: Main Mode of Transmission by Other Means

Infection/Disease	Main Route of Transmission
Gastrointestinal Infections	
Shigellosis caused by *Shigella* bacteria	Contact with infected feces Hand-to-mouth
Campylobacter enteritis caused by *Campylobacter jejuni* bacteria	Primarily an animal pathogen Hand-to-mouth
Giardiasis caused by *Giardia lamblia* protozoa	Contaminated drinking water Hand-to-mouth
Amebiasis caused by *Entamoeba histolytica* protozoa	Contaminated drinking water Hand-to-mouth

Infection/Disease	Main Route of Transmission
Hepatitides A and C (liver infection and inflammation)	Hepatitis A: contact with infected feces; hand-to-mouth Hepatitis C: blood-borne pathogen; direct exposure to contaminated blood; sexual transmission very uncommon
Systemic Diseases	
Epstein-Barr virus	Mucous membrane (oral) exposure
Cytomegalovirus	Body fluids; exposure via close interpersonal contact or direct transfer
Zika virus	Primary spread through bites from infected mosquitos but may be transmitted sexually and across the placental membrane

Infection/Disease	Main Route of Transmission
Gastrointestinal Infections	
Shigellosis caused by *Shigella* bacteria	Contact with infected feces Hand-to-mouth
Campylobacter enteritis caused by *Campylobacter jejuni* bacteria	Primarily an animal pathogen Hand-to-mouth
Giardiasis caused by *Giardia lamblia* protozoa	Contaminated drinking water Hand-to-mouth
Amebiasis caused by *Entamoeba histolytica* protozoa	Contaminated drinking water Hand-to-mouth
Hepatitides A and C (liver infection and inflammation)	Hepatitis A: contact with infected feces; hand-to-mouth Hepatitis C: blood-borne pathogen; direct exposure to contaminated blood; sexual transmission very uncommon
Systemic Diseases	
Epstein-Barr virus	Mucous membrane (oral) exposure
Cytomegalovirus	Body fluids; exposure via close interpersonal contact or direct transfer
Zika virus	Primary spread through bites from infected mosquitos but may be transmitted sexually and across the placental membrane

Hepatitis

Hepatitis is a liver infection that can be caused by six types of viruses: hepatitis A, B, C, D, E, and G. Each virus causes a syndrome of acute, icteric (jaundice-producing) liver inflammation. Additional information about hepatitis is found in Chapter 42. Of the three most common types, A, B, and C, the hepatitis B virus (HBV) is most sexually transmitted. Hepatitis A, like most other predominantly enteric infections, may be considered an STI because of anal-oral transmission, and vaccination is advised for MSM.[62]

Althoughhepatitis C virus (HCV) is not recognized as an STI, sexual exposure, particularly for individuals with multiple partners, MSM, and individuals with HIV, increases risk of transmission (Fig. 27.19) (see Emerging Science Box: Treatment Effectiveness for Hepatitis C).[63,64]

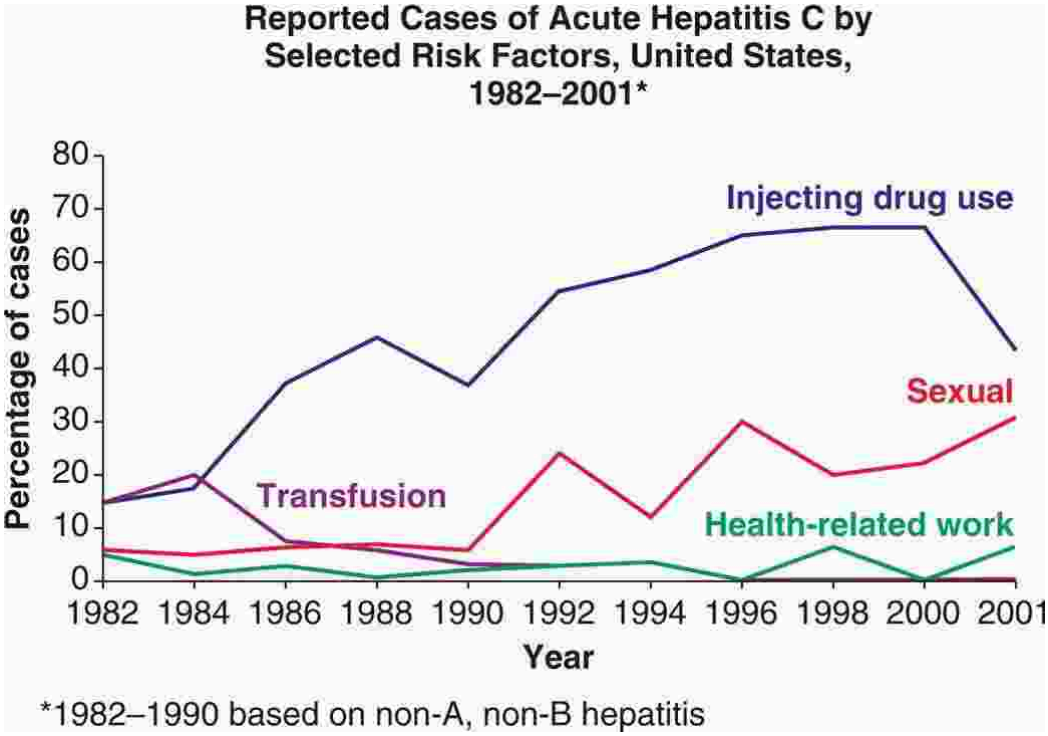


FIG 27.19 Risk for Hepatitis C Exposure. Comparison of injecting drug use *(blue)*, transfusions *(purple)*, health-related work *(green)*, and sexual exposure *(red)*. Note the rise in sexually transmitted incidences. (From Centers for Disease Control and Prevention [CDC]. *Hepatitis C: What Clinicians and Other Health Professionals Need to Know*; 2000. www.cdc.giv/ncid/diseases/hepatitis/c_training/edu/intro.)

A graph represents reported cases of acute hepatitis C by selected risk factors in the United States from 1982–to 2001. The horizontal axis represents the year, ranging from 1982 to 2001. The vertical axis represents the percentage of cases, ranging from 0 to 80. The graph labeled injecting drug use is plotted from (1982, 15) through (2001, 40). The graph labeled

sexual is plotted from (1982, 5) through (2001, 30). The graph labeled health-related work is plotted from (1982, 5) through (2001, 10). The graph labeled transfusion is plotted from (1982, 15) through (1992, 5). All data are approximate.

Emerging Science Box *Treatment Effectiveness for Hepatitis C*

In 2018, it was estimated there were 50,300 cases of acute hepatitis C virus (HCV) in the United States, with an estimated 2.4 million people living with chronic HCV. HCV is primarily transmitted through exposure to infected blood or blood containing body fluids. Although not truly classified as a sexually transmitted infection (STI), the transmission of HCV is spread through sex with an individual when blood is present. This is particularly seen in men who have sex with men, particularly with HIV-positive partners, or with an infected woman during her menstrual cycle. Transmission can also occur from an infected mother to her infant during pregnancy. In 2018, it was estimated there were 50,300 cases of acute HCV in the United States, with an estimated 2.4 million people living with chronic HCV. Of those infected, 5%–25% will develop cirrhosis within 10–20 years, with an additional 1%–4% acquiring hepatocellular carcinoma. Liver failure develops in approximately 5% HCV-infected individuals, of whom 15%–20% will die in the following year.

Currently, HCV is treatable with oral antiviral therapy resulting in cure for more than 90%. Recommended treatment regimens include direct-acting antiviral (DAA) combinations glecaprevir/pibrentasvir (Mavyret) for 8 weeks, sofosbuvir/velpatasvir (Epclusa) for 12 weeks, or ledipasvir/sofosbuvir (Harvoni). In addition, the oral treatment is better tolerated than previously used interferons.

Although these drugs are expensive, the cost savings of treatment is difficult to assess. However, early studies indicate that treatment with DAAs can improve quality of life at a reduced cost for longer periods of time when compared without treatment.

The effects of hepatitis C treatment eligibility criteria on all-cause mortality among people with human immunodeficiency virus. Clinical Infectious Diseases, 2019;69(9):1613–1620. https://doi.org/10.1093/cid/ciz008.

Hepatitis B prevalence varies dramatically worldwide, with some geographic areas having more than 10% of the population infected with the virus.[65] There are an estimated 21,600 new cases of HBV infection in the United States each year, and more than 2.2 million people are chronically infected.[66]

Those at risk for HBV infection in the United States are infants born to hepatitis-infected mothers, healthcare workers, individuals who have sex with HBV-infected persons, people with diabetes, and immigrants from areas of high HBV prevalence.[66] Widespread screening of pregnant women and vaccination of all infants since 1991 have decreased the rate of infection in the United States by more than 80% and are expected to have lasting effects into future decades.[67] Vaccination of healthcare workers also has decreased infection rates.[68]

Transmission of HBV can occur through needle puncture, blood transfusion, cuts or abrasions in the skin, and absorption by mucosal surfaces. Direct contact with infected body fluids, such as semen and vaginal fluid, may transmit the infection. HBV can survive dry and outside the body for up to 1 week, making it easily infectious on fomites.

In the United States, seropositivity generally increases with age.[66] This is a function of more time for exposure as well as the lack of

routine vaccination before the 1990s. However, the younger a person is when he or she contracts the virus, the greater likelihood of chronic infection.[62] Perinatal transmission of HBV is relatively common, especially in developed countries without routine screening of pregnant women. Neonates whose mothers are infectious have a 90% chance of becoming chronically infected with HBV during labor or delivery if they do not receive treatment but a 1% risk if they receive adequate treatment.[68] Infants of infected mothers should receive HBV vaccine and immunoglobulin against hepatitis within 12 hours of birth to reduce risk. The vaccine and immunoglobulin combination successfully prevents chronic carrier status in 99% of infants.[68] Although HBV is in many maternal body fluids, it is not found in breast milk, and breast-feeding is still encouraged for mothers with HBV.[69] More information about the pathology, diagnosis, and treatment of hepatitis is covered in Chapter 42.

Acquired Immunodeficiency Syndrome

Epidemiology, modes of transmission, pathophysiology, clinical manifestations, and evaluation and treatment of AIDS are discussed in detail in Chapter 10.

Summary Review

Sexually Transmitted Urogenital Infections

1. Sexually transmitted diseases many be more common in certain populations related to increased physiologic risk for acquisition (e.g., with younger women or with men who have sex with men) or insufficient access to quality healthcare (e.g., with lower socioeconomic groups, racial/ethnic minorities, and marginalized groups).
2. Gonorrhea is a sexually transmitted communicable disease that can be local or systemic. Complications include pelvic

inflammatory disease (PID), sterility, and disseminated infection.

3. Gonorrhea can be passed to the fetus from the mother and typically manifests as an eye infection 1 to 12 days after birth. Ophthalmic antibiotic prophylaxis alone is not sufficient to prevent vertical transmission.
4. Although gonorrhea may become resistant to available antibiotics, the CDC no longer recommends multiple drug therapy in the United States.
5. Syphilis is an sexually transmitted infections (STIs) that becomes systemic shortly after infection. The four stages of the disease are (a) primary syphilis with chancre formation at the site of infection; (b) secondary syphilis with systemic spread to all body systems; (c) latent syphilis with minimal symptoms or the development of skin lesions; and (d) tertiary syphilis, the most severe stage, with destruction of bone, skin, soft tissue, and neurologic tissues.
6. Congenital syphilis contributes to prematurity of the newborn with bone marrow depression, central nervous system involvement, renal failure, and intrauterine growth retardation.
7. Syphilis is diagnosed with serologic testing and is treated with injectable penicillin.
8. With chancroid infection *(Haemophilus ducreyi)*, women are generally asymptomatic. Men may develop inflamed, painful genital ulcers and inguinal buboes. The incubation period is 1 to 14 days. Single-dose therapy with injectable ceftriaxone or oral azithromycin for both partners is recommended. Persons with HIV may require a longer treatment regimen.
9. Granuloma inguinale (donovanosis) is rare in the United States. The bacteria are gram-negative and survive within macrophages. Localized nodules coalesce to form granulomas and ulcers on the penis in men and on the labia in women. Antibiotics provide effective treatment.
10. Although not a true STI, bacterial vaginosis (BV) is a sexually associated condition caused by an overgrowth of anaerobic

bacteria that produce aromatic amines and raise the pH of the vagina, promoting further bacterial growth (without an inflammatory response) and a fishy odor. "Clue cells" are found on the wet mount. Metronidazole (Flagyl) provides effective treatment. BV has been associated with PID, chorioamnionitis, preterm labor, and postpartum endometritis. Treatment of male sexual partners is not recommended.

11. Chlamydia *(Chlamydia trachomatiti),* the most common bacterial STI in the United States, is a leading preventable cause of infertility and ectopic pregnancy. *C. trachomatis* localizes to epithelial tissue and can spread throughout the urogenital tract or pass from the infected mother to the eyes and respiratory tract of newborn infants during birth. *C. trachomatis* is susceptible to inexpensive, readily accessible antibiotics. Single-dose azithromycin is the drug of choice for infected individuals and all sexual contacts. Because of the asymptomatic nature of chlamydia and the potential sequelae of infection, widespread screening is recommended by the CDC.
12. Lymphogranuloma venereum *(invasive strains of C. trachomatis)* is a chronic STI uncommon in the United States. The lesion begins as a skin infection and spreads to the lymph tissue, causing inflammation, necrosis, buboes, and abscesses of the inguinal lymph nodes. Primary lesions appear on the penis and scrotum in men and on the cervix, vaginal wall, and labia in women. Secondary lesions involve inflammation and swelling of the lymph nodes with formation of large buboes that rupture and drain. A 21-day or longer course of oral doxycycline or erythromycin is needed for treatment. Treatment of sexual partners is recommended.
13. Genital herpes simplex virus (HSV) is the most common genital ulceration in the United States and is caused by either HSV-1 or HSV-2. Lesions initially appear as groups of vesicles that progress to ulceration with pain,

lymphadenopathy, and fever. HSV can pass from mother to fetus. Women with active lesions should be delivered by cesarean section to avoid vertical transmission.

14. HSV infection is lifelong and can result in an initial outbreak and subsequent outbreaks. Individuals are contagious during outbreaks and episodes of asymptomatic viral shedding. Acyclovir reduces symptoms but does not cure the disease. Recurrent infections are most often attributable to HSV-2 and are generally milder and of shorter duration.
15. HPV is associated with the development of cervical dysplasia and cancer as well as condylomata acuminata. The high-risk strains of HPV (HR-HPV) that are precursors to the development of cervical cancer do not cause genital warts. Testing is available to detect HR-HPV and a vaccine is now available for the HPV types with highest risk for cervical cancer.
16. Condylomata acuminata (genital warts) are sexually transmitted and highly contagious. The velvety cauliflower-like lesions occur in the genital and anal areas, vagina, and cervix and are painless. Condylomata can be transmitted to the infant at birth.
17. Molluscum contagiosum is a benign viral infection of the skin. It is transmitted by skin-to-skin contact in children and adults. In adults, it tends to occur on the genitalia and is transmitted by sexual contact.
18. Trichomoniasis *(Trichomonas vaginalis)* causes vaginitis in women and urethritis in men. Both partners usually are infected. Women usually have a copious, malodorous, gray-green discharge with pruritus. Men usually are asymptomatic. Metronidazole is the treatment for both sexes.
19. Scabies *(Sarcoptes scabiei)* is a parasitic infection that spreads by skin-to-skin and sexual contact. The scabies mite burrows through the skin, depositing eggs, causing intense pruritus, especially at night. Treatment consists of topical application of a pediculicide.

20. Pediculosis pubis (crabs) *(Pthris pubis)* is commonly transmitted sexually. The lice bite into the skin for nutrition. Symptoms include mild and severe pruritus. Topical application of prescription or over the counter pediculicides is effective treatment.

Sexually Transmitted Infections of Other Body Systems

1. Systemic diseases known to be sexually transmitted include AIDS (see Chapter 10), cytomegalovirus infection, and Epstein-Barr virus.
2. Transmission of hepatitis B virus (HBV) can occur through needle puncture, blood transfusion, cuts in the skin, and contact with infected body fluids.
3. Hepatitis B infection poses significant health risks including chronic liver disease and hepatocellular cancer. Immunization against hepatitis B is the most effective means of preventing transmission. Universal vaccination of infants and children is recommended, as well as vaccination of high-risk adults.
4. The risk of perinatal transmission of HBV is high for infants of HBV-infected mothers unless they receive immunoglobulin and are vaccinated.
5. Hepatitis C is generally transmitted percutaneously but sexual transmission appears possible.

Aging and the Hematologic System 922

All the body's tissues and organs require oxygen and nutrients to survive. These essential needs are provided by the blood that circulates through miles of vessels found throughout the human body. The red blood cells provide the oxygen and the fluid portion of the blood carries the nutrients. The blood cleans discarded waste from the tissues; transports hormones; moves white blood cells (WBCs), platelets, and other components necessary to protect the body from injury and infection and initiate healing; and provides thermal regulation to maintain organs and tissues within an acceptable range of temperatures.

Components of the Hematologic System

Composition of Blood

Blood consists of various cells that circulate suspended in a solution of protein and inorganic materials (plasma), which is approximately 91% water and 9% dissolved

substances (solutes) (Fig. 28.1). The blood volume amounts to about 6 quarts (5.5 L) in adults. The continuous movement of blood guarantees that critical components are available to all parts of the body to carry out their chief functions: (1) delivery of substances needed for cellular metabolism in the tissues, (2) removal of the wastes of cellular metabolism, (3) defense against invading microorganisms and injury, and (4) maintenance of acid–base balance.

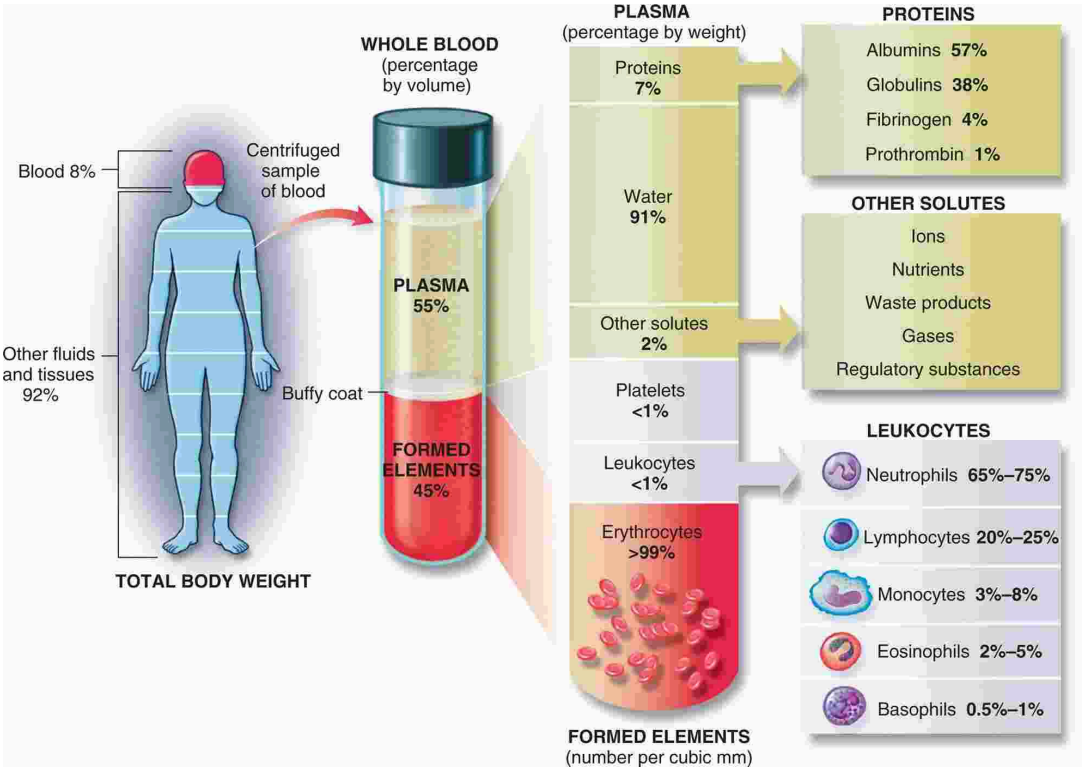

FIG. 28.1 Composition of Whole Blood.
Approximate values for the components of blood in a normal adult. (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

An illustration shows the composition of the whole blood. The total body weight has the following composition. • Blood, 8 percent. • Other fluids and tissues, 92 percent. The whole blood (percentage by volume) has the following composition. • Plasma, 55 percent. • Buffy coat. • Formed elements, 45 percent. The plasma (percentage by weight) has the following composition: • Proteins (plasma), 7 percent. • Water (plasma), 91 percent. • Other solutes (plasma), 2 percent. • Platelets (buffy coat), less than 1 percent. • Leukocytes, (buffy coat), less than 1 percent. • Erythrocytes (formed elements), greater than 99 percent, in number per cubic millimeters. The composition of proteins in plasma is as follows. • Albumins, 57 percent. • Globulins, 38 percent. • Fibrinogen, 4 percent. • Prothrombin, 1 percent. The composition of other solutes in plasma is as follows. • Ions. •

Nutrients. • Waste products. • Gases. • Regulatory substances. The composition of leukocytes in buffy coat is as follows. • Neutrophils, 65 to 75 percent. • Lymphocytes, 20 to 25 percent. • Monocytes, 3 to 8 percent. • Eosinophils, 2 to 5 percent. • Basophils, 0.5 to 1 percent.

Plasma and Plasma Proteins

In adults, plasma accounts for 50% to 55% of blood volume (see Fig. 28.1). Plasma is a complex aqueous liquid containing a variety of organic and inorganic elements (Table 28.1). The concentration of these elements varies, depending on diet, metabolic demand, hormones, and vitamins. Plasma differs from serum in that serum is free of clotting proteins (e.g., fibrinogen). The clotting proteins may interfere with some diagnostic tests.

Table 28.1

Organic and Inorganic Components of Arterial Plasma

Constituent	Major Functions
Water	**Medium for carrying all other constituents**
Electrolytes Na^+ K^+ Ca^{2+} Mg^{2+} Cl^- HCO3− Phosphate (mostly HPO4−)	Maintain H_2O in extracellular compartment; act as buffers; function in membrane excitability
Proteins Albumins Globulins Fibrinogen Transferrin Ferritin	Provide colloid osmotic pressure of plasma; act as buffers; bind other plasma constituents (e.g., lipids, hormones, vitamins, minerals); clotting factors; enzymes; enzyme precursors; antibodies (immunoglobulins); hormones; transporters
Gases	
CO_2 content	By-product of oxygenation, most CO_2 content is from HCO3− and acts as buffer
O_2	Oxygenation

Constituent	Major Functions
Water	**Medium for carrying all other constituents**
N_2	By-product of protein catabolism
Nutrients Glucose and other carbohydrates Total amino acids Total lipids Cholesterol Individual vitamins Individual trace elements Iron	Provide nutrition and substances for tissue repair
Waste products	
Urea	End product of protein catabolism
Creatinine (from creatine)	End product from energy metabolism
Uric acid (from nucleic acids)	End product from protein metabolism
Bilirubin (from heme)	End product of red blood cell destruction

Constituent	Major Functions
Water	**Medium for carrying all other constituents**
Individual hormones	Functions specific to target tissue

BUN, Blood urea nitrogen; Ca^{2+}, calcium; Cl^-, chloride; CO_2, carbon dioxide; H_2O, water;HCO3−, bicarbonate; HPO4−, phosphorus; K^+, potassium; Mg^{2+}, magnesium; N_2, nitrogen; Na^+, sodium.

Data from Vander AJ, et al. *Human physiology: The mechanisms of body function*. New York: McGraw-Hill; 2001.

Plasma contains a large number of proteins (plasma proteins) that make up about 7% of the total plasma weight. These vary in structure and function and can be classified primarily into two major groups, albumin and globulins, plus a small amount of clotting proteins. Most plasma proteins are produced by the liver. The major exception is antibody, which is produced by plasma cells (B cells) in the lymph nodes and other lymphoid tissues (see Chapter 8).

Albumin (about 57% of total plasma protein) serves as a carrier molecule for the normal components of blood and for drugs that have low solubility in water (e.g., free fatty acids, lipid-soluble hormones, thyroid hormones, bile salts). Its most essential role is regulation of the passage of water and solutes through the capillaries. Albumin molecules are large and do not diffuse freely through the vascular endothelium, and thus they maintain the critical colloidal osmotic pressure (or oncotic pressure) that regulates the passage of fluids and electrolytes into the surrounding tissues (see Chapters 1 and 3). Water and solute particles tend to diffuse out of the arterial portions of the capillaries because blood pressure (hydrostatic pressure) is greater in arterial than in venous blood vessels. Water and solutes move from tissues into the venous portions of the capillaries, where the pressures are reversed, oncotic pressure being greater than intravascular pressure or hydrostatic pressure (see Fig. 3.1). In the case of decreased production of albumin (e.g., cirrhosis, other diffuse liver diseases, protein malnutrition) or excessive loss of albumin (e.g., certain kidney diseases, extensive burns), the reduced plasma oncotic pressure leads to excessive movement of water and solutes into the tissue and decreased blood volume.

Most of the remaining plasma proteins are globulins (about 38% of total plasma protein), which are often classified by their properties in an electric field (serum electrophoresis). Under the normal conditions used to perform serum electrophoresis, albumin is the most rapidly moving protein. The globulins are classified into alpha, beta, and gamma groups by their movement relative to albumin. Alpha (α) globulins (those moving most closely to albumin) include high-density lipoproteins [HDLs], prothrombin, and proteins that transport hormones. Beta (β) globulins include low-density lipoproteins (LDLs). Gamma (γ) globulins (those with the least movement) consist primarily of immunoglobulin G (IgG) (see Chapter 8).

Plasma proteins also can be classified by function: clotting, defense, transport, or regulation. The clotting factors or **proteins** promote coagulation and stop bleeding from damaged blood vessels. Fibrinogen is the most plentiful of the clotting factors and is the precursor of the fibrin clot (see Fig. 28.19). Proteins involved in defense, or protection, against infection include antibodies (immunoglobulins) and complement proteins (see Chapters 8 and 9). Transport proteins specifically bind and carry a variety of inorganic and organic molecules, including iron (transferrin), copper

(ceruloplasmin), lipids and steroid hormones (lipoproteins) (see Chapter 1), and vitamins (e.g., retinol-binding protein for vitamin A transport). The plasma lipids, triglycerides, phospholipids, cholesterol, and fatty acids are transported through the blood as complexes with plasma proteins; they are known as *lipoproteins* (see Chapters 1 and 32). Regulatory proteins include a variety of enzymatic inhibitors (e.g., α_1-antitrypsin) that protect the tissues from damage; precursor molecules (e.g., kininogen) that are converted into active biologic molecules when needed; and protein hormones (e.g., cytokines) that communicate between cells.

Plasma also contains several charged inorganic ions that regulate cell function, osmotic pressure, and blood pH. These include the electrolytes sodium, potassium, calcium, chloride, and phosphate (Electrolytes are described in Chapters 1 and 3).

Cellular Components of the Blood

The cellular elements of the blood are broadly classified as red blood cells (erythrocytes), WBCs (leukocytes), and platelets (thrombocytes) (Fig. 28.2). The components of the blood are listed in Table 28.2.

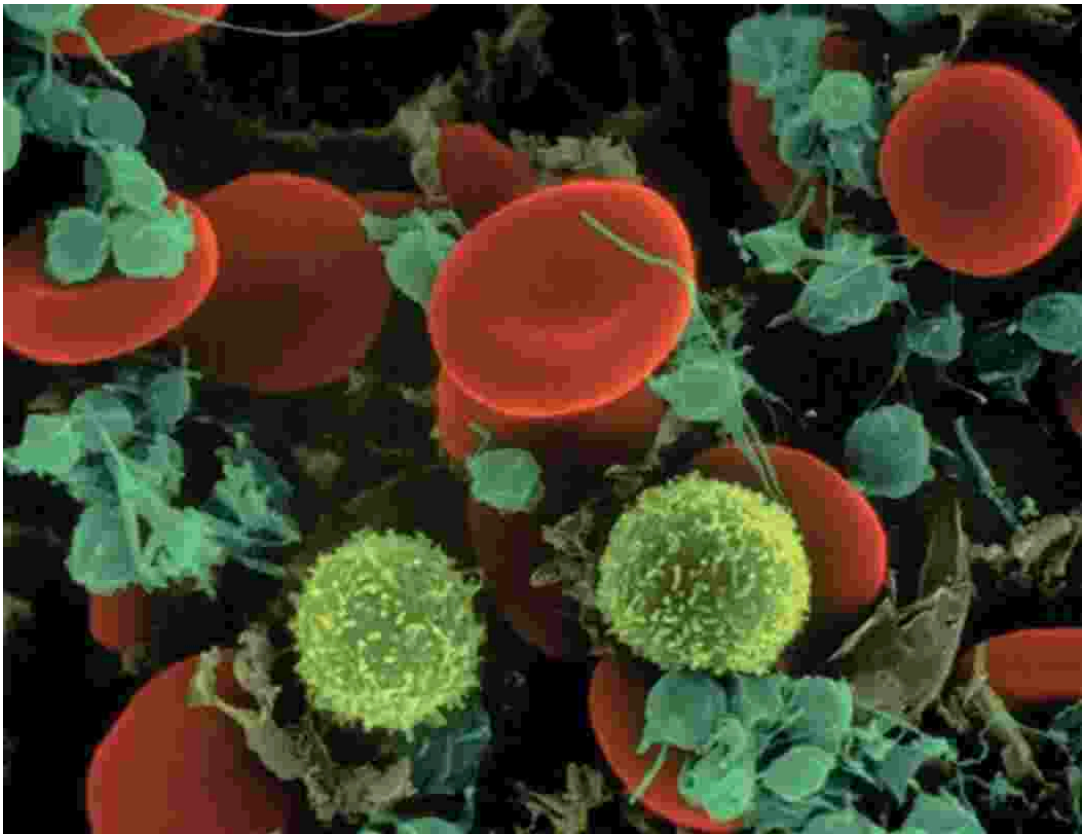

FIG. 28.2 Blood Cells and Platelets.
Leukocytes are spherical and have irregular surfaces with numerous extending pili. Leukocytes are the cotton candy–like cells *(yellow)*. Erythrocytes are flattened spheres with a depressed center *(red)*. Platelets are the smaller *(green)* cell fragments. (Copyright Dennis Kunkel Microscopy, Inc.)

Table 28.2

Cellular Components of the Blood

Cell	Structural Characteristics	Function	Life Span
Erythrocyte (red blood cell)	Nonnucleated cytoplasmic disk containing hemoglobin	Gas transport to and from tissue cells and lungs	80–120 days
Leukocyte (white blood cell)	Nucleated cell	Body defense mechanisms	See specific cells below
Neutrophil	Segmented polymorphonuclear granulocyte	Phagocytosis, particularly during early phase of inflammation	4 days
Eosinophil	Segmented polymorphonuclear granulocyte	Control of inflammation, phagocytosis, defense against parasites, allergic reactions	8–12 days
Basophil	Segmented polymorphonuclear granulocyte	Mast cell–like functions, associated with allergic reactions	Few hours to days
Monocyte and macrophage	Large mononuclear phagocyte	Phagocytosis; mononuclear phagocyte system	Months or years
Lymphocyte	Mononuclear immunocyte	Humoral and cell-mediated immunity	Days or years, depending on type
Natural killer cell	Large granular lymphocyte	Defense against some tumors and viruses	Unknown
Platelet	Irregularly shaped cytoplasmic fragment (not a cell)	Hemostasis after vascular injury; normal coagulation and clot formation/retraction;	8–11 days

Cell	Structural Characteristics	Function	Life Span
		release of growth factors	

Cell	Structural Characteristics	Function	Life Span
Erythrocyte (red blood cell)	Nonnucleated cytoplasmic disk containing hemoglobin	Gas transport to and from tissue cells and lungs	80–120 days
Leukocyte (white blood cell)	Nucleated cell	Body defense mechanisms	See specific cells below

Natural killer cell	Large granular lymphocyte	Defense against some tumors and viruses	Unknown
Platelet	Irregularly shaped cytoplasmic fragment (not a cell)	Hemostasis after vascular injury; normal coagulation and clot formation/retraction; release of growth factors	8–11 days

Erythrocytes

Erythrocytes (red blood cells [RBCs]) are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and about 42% in women. Erythrocytes are formed in the bone marrow, and there are 4.2 to 6.2 million erythrocytes/mm^3 circulating in normal blood. Erythrocytes are primarily responsible for tissue oxygenation. The erythrocyte contains hemoglobin (Hb), which carries the gases, and electrolytes, which regulate gas diffusion through the cell's plasma membrane. The mature erythrocyte lacks a nucleus and cytoplasmic organelles (e.g., mitochondria), so it cannot synthesize protein or carry out oxidative reactions. Because it cannot undergo mitotic division, the erythrocyte has a limited life span (approximately 100 to 120 days), ages, and is removed from the circulation, primarily in the spleen, to be replaced by new erythrocytes.

The erythrocyte's size and shape is ideally suited to its function as a gas carrier. It is a small disk with two unique properties: (1) a *biconcave* shape and (2) the capacity to be *reversibly deformed*. The flattened, biconcave shape (see Fig. 28.2) provides a surface area/volume ratio that is optimal for gas diffusion into and out of the cell and for deformity. During its life span, the erythrocyte, which is 6 to 8 μm in diameter, repeatedly circulates through splenic sinusoids and capillaries that are only 2 μm in diameter. Reversible deformity enables the erythrocyte to assume a

more compact torpedo-like shape, squeeze through the microcirculation (diapedesis), and return to normal (Fig. 28.3).

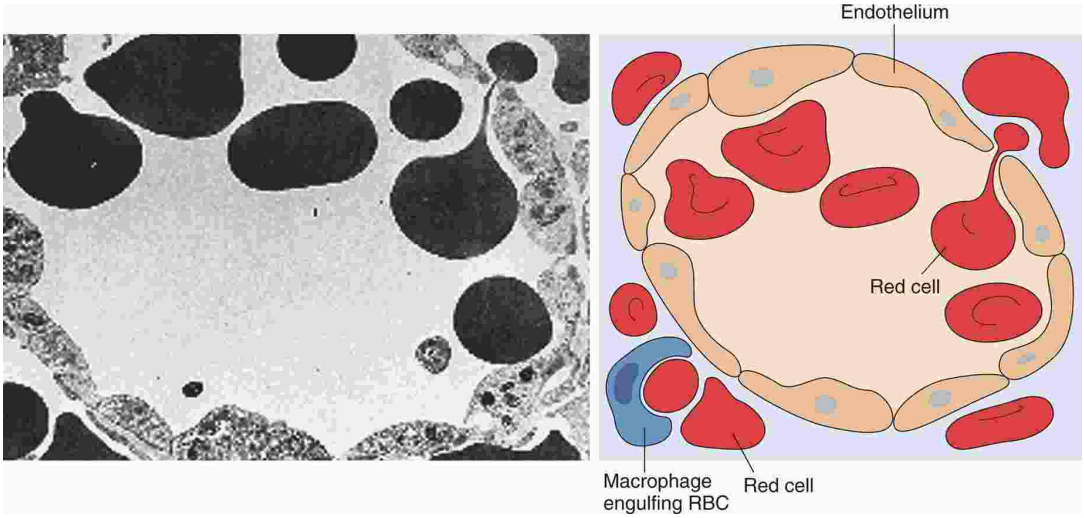

FIG. 28.3 Red Cells Moving in the Spleen.
Transmission electron micrograph and schematic drawing of erythrocytes in the process of moving by diapedesis from the red pulp cords into the sinus lumen. They resume their normal shape after squeezing through. Note the degree of deformability required for red cells to pass through the wall of the sinus. *RBC*, Red blood cell. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996. Schematic from Kumar V, Fausto N, Abbas A. *Robbins & Cotran pathologic basis of disease*, 7th edition. St. Louis: Saunders; 2005.)

A photomicrograph shows a ring of endothelium cells, surrounded by red cells. An accompanying illustration shows a similar ring of endothelium cells, surrounded by red cells. A macrophage engulfing R B C is also identified in the illustration.

Erythrocytes are also part of the innate immune system. Erythrocytes catch bacteria in the blood stream by electric charge attraction and kill them by oxycytosis, the release of oxygen from oxyhemoglobin (oxygen-dependent killing). The decomposed bacteria are then cleared in the liver and spleen. Oxycytosis is complimentary to leukocytosis (phagocytosis) as leukocytes cannot recognize and attach bacteria in the blood because of the velocity of blood flow.[1]

Leukocytes

Leukocytes (WBCs) (see Fig. 28.2) defend the body against organisms that cause infection and also remove debris, including dead or injured host cells of all kinds. The leukocytes act primarily in the tissues but are transported in the circulation. The average adult has approximately 5000 to 10,000 leukocytes/mm^3 of blood.

Leukocytes are classified according to structure as either granulocytes or agranulocytes and according to function as either phagocytes or immunocytes (cells that create immunity; see Chapter 8). The granulocytes, which include neutrophils, basophils, eosinophils, and mast cells, are all phagocytes. (Phagocytic action is described in Chapter 7.) Of the agranulocytes, the monocytes and macrophages are phagocytes, whereas the lymphocytes are immunocytes. Fig. 28.4 shows a microscopic image of the various types of leukocytes.

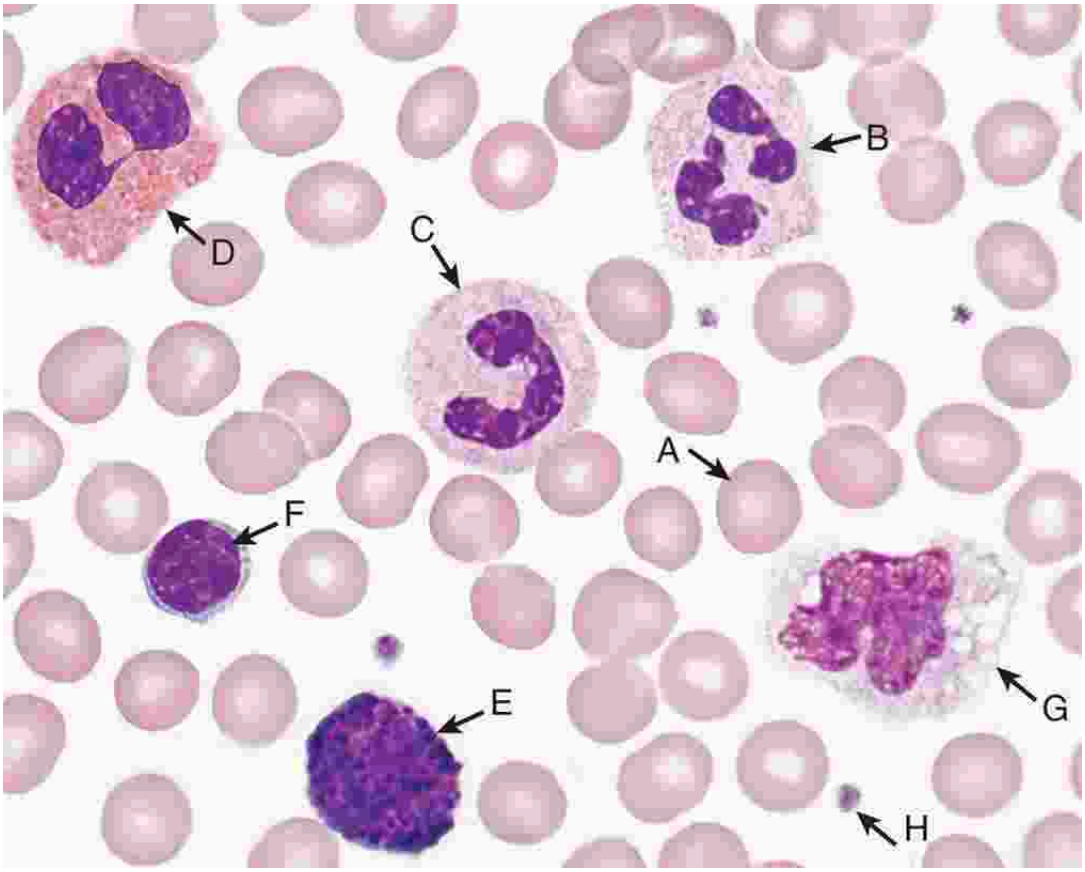

FIG. 28.4 Leukocytes.
Normal cells in peripheral blood. *A*, Erythrocyte (red blood cell); *B*, neutrophil (segmented); *C*, neutrophil (banded); *D*, eosinophil; *E*, basophil; *F*, lymphocyte; *G*, monocyte; *H*, platelet. (From Keohane E, Smith L, Walenga J. *Rodak's hemotology*, 5th edition. St. Louis: Saunders; 2016.)

Granulocytes

The granulocytes are formed in the red bone marrow and have a nucleus with several lobes (polymorphonuclear) and many membrane-bound granules in their cytoplasm. These granules contain enzymes capable of killing microorganisms and catabolizing debris ingested during phagocytosis. The granules also contain powerful biochemical mediators with inflammatory and immune functions. These mediators, along with the digestive enzymes, are released from granulocytes in response to specific stimuli and affect other cells in the circulation. The biochemical mediators have vascular and intercellular effects, and the enzymes participate in the breakdown of debris from sites of infection or injury. Granulocytes are capable of amoeboid movement, by which they migrate through vessel walls (diapedesis) and then to sites where their action is needed. They have a life span of only a few hours or days.

The neutrophil (polymorphonuclear neutrophil [PMN]) is the most numerous and best understood of the granulocytes. Neutrophils constitute about 65% to 75% of the total leukocyte count in adults. The results vary by laboratory and populations studied.

The cytoplasm of neutrophils contains small lysosomal granules and a central nucleus with two to five distinct lobes. Immature neutrophils are called *bands* or *stabs*. Mature neutrophils are called *segmented neutrophils* because of the characteristic appearance of their nucleus (see Fig. 28.4). Neutrophils reach a fully mature state in the bone marrow, where these mature neutrophils are called the *marrow neutrophil reserve*. Normally it takes about 14 days for neutrophils to develop from early precursors, but this process is accelerated by infection and treatment with colony-stimulating factors.

Neutrophils are the chief phagocytes of early inflammation. Soon after bacterial invasion or tissue injury, neutrophils migrate out of the capillaries and into the damaged tissue, where they phagocytize and destroy contaminating microorganisms and debris. Neutrophils also release nuclear DNA onto extracellular pathogens to control their growth and proliferation and aid the killing of bacteria. These extracellular DNA deposits are termed *neutrophil extracellular traps (NETs)*, and are a phagocytosis-independent anti-microbial pathway. In addition to their crucial role in fighting infection, neutrophils play a complex role in tumors. (see Emerging Science Box: Tumor Associated Neutrophils). Neutrophils are sensitive to the environment in damaged tissue (e.g., low pH, enzymes released from damaged cells) and die in 1 or 2 days. The breakdown of dead neutrophils releases digestive enzymes from their cytoplasmic granules. These enzymes dissolve cellular debris and prepare the site for healing. (This final function, called *débridement*, is described in Chapter 7.)

Eosinophils, which have large, coarse granules, constitute only about 2% to 5% of the normal leukocyte count in adults. Using a spectrum of pattern-recognition receptors, eosinophils are capable of amoeboid movement and phagocytosis. Unlike neutrophils, eosinophils ingest antigen-antibody complexes and are induced by

immunoglobulin E (IgE)–mediated hypersensitivity reactions to attack parasites by release of toxic molecules. Eosinophils also mediate immunity against bacterial, viral, and fungal infections by presenting bacterial, viral, and parasitic antigen to cytotoxic T cells. IL-5 promotes the maturation and migration of eosinophils during the inflammatory response. Eosinophilic inflammation mediated by IL-5, particularly from T helper cells, and other cytokines, contributes to the type 2 hypersensitivity response associated with asthma and other chronic eosinophilic inflammatory diseases (see Chapter 9). During inflammation, eosinophil death and cytolysis is known as *extracellular trap cell death (ETosis*), which differs from the processes of accidental necrosis or apoptosis. Eosinophil extracellular trap products consist of damage-associated molecular patterns (DAMPs) that are able to activate both the innate and adaptive immune systems (see Chapters 7 and 8).[2] Eosinophils also release IL-4 important for tissue repair and regeneration in muscle and liver.[3]

Eosinophil secondary granules contain toxic chemicals (e.g., major basic protein, eosinophil cationic protein, eosinophil peroxidase, eosinophil-derived neurotoxin) that are highly destructive to parasites and viruses. Eosinophil granules also contain a variety of enzymes (e.g., histaminase) that help control inflammatory processes. Eosinophils also release proinflammatory molecules, including leukotrienes, prostaglandins, platelet-activating factor (PAF), and a variety of cytokines (e.g., IL-1, IL-4, IL-6, tumor necrosis factor-alpha [TNF-α], and granulocyte-macrophage colony-stimulating factor [GM-CSF]). Type I and type II hypersensitivity allergic reactions and asthma are characterized by high circulating eosinophil counts (see Chapters 9 and 36). The eosinophils may be involved in a dual role: regulation of inflammation and contribution to the destructive inflammatory processes observed in allergic reactions (e.g., the lungs of persons with asthma and eosinophilic esophagitis).

Basophils, which make up less than 1% of leukocytes, are structurally similar to the mast cells (see Fig. 28.4). Basophils contain cytoplasmic granules that have an abundant mixture of biochemical mediators, including histamine, chemotactic factors, proteolytic enzymes (e.g., elastase, lysophospholipase), and an anticoagulant (heparin). Stimulation of basophils also induces synthesis of vasoactive lipid molecules (e.g., leukotrienes) and cytokines, including IL-6, which affects differentiation of type 1 T-helper cells (Th1 cells) (focus on intracellular parasites) and type 2 T-helper cell (Th2 cells) (focus on extracellular parasites). Basophils are a particularly rich source of the cytokine IL-4, which preferentially guides B-cell differentiation toward plasma cells that secrete IgE (see Chapter 8).

The number of basophils is often increased at sites of allergic inflammatory reactions and parasitic infection, particularly ectoparasites (e.g., ticks). IgE receptors on the basophil induce degranulation at sites of IgE-mediated hypersensitivity reactions and contribute to the local inflammatory response.

Mast cells are highly similar to basophils but are generated from a different set of precursor cells in the bone marrow, from which they migrate in an immature form into tissues. Mast cells reside in vascularized connective tissues just beneath body

epithelial surfaces, including the submucosal tissues of the respiratory and gastrointestinal tracts, as well as in the dermal layer that lies just below the surface of the skin. Mast cells play a central role in inflammation. Activation and degranulation of the mast cells affect a great number of other cells, including those involved in inflammation (e.g., vascular endothelial cells, smooth muscle cells, circulating platelets and leukocytes, nerves) and healing (e.g., fibroblasts), as well as glandular cells and cells of the immune system. Their activation contributes greatly to increased permeability of blood vessels and synthesis of mediators producing smooth muscle contraction (see Fig 7.4).

Agranulocytes

The agranulocytes—monocytes, macrophages, and lymphocytes—contain relatively fewer granules than granulocytes. Monocytes and macrophages make up the mononuclear phagocyte system (MPS) (see Chapter 7). Both monocytes and macrophages participate in the immune and inflammatory response, being powerful phagocytes. They also ingest dead or defective host cells, particularly blood cells.

The mononuclear phagocyte system (MPS), also known as the *reticuloendothelial system* or *macrophage system*, consists of specialized endothelial cells: promonocytes and their precursors in the bone marrow; monocytes in the peripheral blood; and a portion of macrophages that reside in the tissues, remaining there for months or perhaps years. Cells of the MPS ingest and destroy (by phagocytosis) unwanted materials, such as foreign protein particles, circulating immune complexes, microorganisms, debris from dead or injured cells, defective or injured erythrocytes, and dead neutrophils.

Monocytes are immature macrophages. They are the largest normal blood cell and have a horseshoe-shaped nucleus (see Fig. 28.4). Monocytes are formed and released by the bone marrow into the bloodstream. As they mature, monocytes migrate into a variety of tissues (e.g., liver [Kupffer cells], spleen, lymph nodes, peritoneum, gastrointestinal tract, brain [microglia], and bone) and differentiate into tissue macrophages with tissue-specific functions (Table 28.3). Monocytes also differentiate into myeloid linage dendritic cells and disseminate to lymphoid organs and body surfaces such as the skin and mucous membranes. Both macrophages and dendritic cells are part of the MPS. Other monocytes may migrate out of blood vessels and differentiate into macrophages in response to infection or inflammation. Macrophages are generally larger and are more active as phagocytes than monocytes. Dendritic cells frequently extend projections *(dendrites)* into the tissue and assume a "neuron-like" appearance. The origin and turnover of many of the tissue macrophages are not precisely known. It seems clear that once monocytes leave the circulation, they do not return. They can survive many months or even years.

Table 28.3

Mononuclear Phagocyte System

Name of Cell	Location
Committed Stem Cells	Bone marrow
Monoblasts	Bone marrow
Promonoblasts	Bone marrow
Monocytes	Bone marrow and peripheral blood
Macrophages	Tissue
Kupffer cells	Liver macrophages
Alveolar macrophages	Lung
Histiocytes	Connective tissue
Macrophages	Bone marrow
Fixed and free macrophages	Spleen and lymph nodes
Pleural and peritoneal macrophages Adipose macrophages	Serous cavities Adipose (fat) tissue
Microglial cells	Nervous system
Mesangial cells	Kidney
Osteoclasts	Bone
Langerhans cells	Skin
Dendritic cells	Lymphoid tissue, lining of respiratory and gastrointestinal tracts

Modified from Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.

The normal role of macrophages is to remove old and damaged cells and large molecular substances from the blood. Cellular targets of macrophage phagocytosis include circulating senescent or damaged erythrocytes and platelets (removed primarily in spleen), dead neutrophils (in the circulation and at sites of inflammation), and cells undergoing apoptosis. Noncellular targets include antigen-antibody complexes, cellular debris, products of coagulation, and macromolecules (such as lipids and carbohydrates synthesized by the body as the result of faulty metabolism, as in storage diseases). Macrophages remove and kill contaminating microorganisms in the blood (mostly in the liver and spleen) and at sites of infection. Macrophages and, particularly, dendritic cells are the major "antigen-processing" and "antigen-presenting" cells that initiate immune responses (see Chapter 8). Macrophages initiate wound healing and tissue remodeling and, if activated by cytokines from T cells, secrete a large array of biologically active chemicals that if uncontrolled result in chronic inflammation and tissue injury (see Chapter 7).

Lymphocytes constitute about 20% to 25% of the total leukocyte count and are the primary cells of the immune response (see Fig. 28.4 and Chapter 8). Lymphocytes arise from lymphoid stem cells in the bone marrow and subsequently develop and reproduce in the lymphatic tissues as mature T cells, B cells, or plasma cells. The lymphocytes do not contain any enzyme-filled digestive vacuoles. The life span of the lymphocyte can be days, months, or years, depending on its type and subtype.

Natural killer (NK) cells, which resemble large granular lymphocytes, recognize cells that do not express "self" proteins (self-antigens) on their plasma membrane or that contain foreign or abnormal antigens such as cancer cells or some virus-infected

cells without prior exposure to these antigens (see Chapters 7 and 8). Hence, they are named *natural killer cells* as they do not require exposure to antigen for activation to differentiate them from T-cytotoxic cells which are induced by antigen. NK cells also have the capacity to activate T cells and phagocytes and produce a variety of cytokines that can regulate immune responses. The predominant form of NK cells develops in the bone marrow and circulates in the blood, and is found mainly in the peripheral blood and spleen where it accounts for 5% to 10% of the circulating lymphoid pool. NK cells develop independent of the thymus, although some NK precursors are found in the thymus and may develop into NK T cells, which will then have markers of both NK cells and T cells.[4]

Platelets

Platelets (thrombocytes) are not true cells, but rather irregularly discoid-shaped cytoplasmic fragments that lack a nucleus and deoxyribonucleic acid (DNA) and are incapable of mitotic division. Platelets are essential for blood coagulation and control of bleeding. They are formed in the bone marrow by fragmentation of very large cells (40 to 100 μm in diameter) known as megakaryocytes. They contain cytoplasmic granules (e.g., dense granules, alpha granules, and lysosomes) and can release adhesive proteins and coagulation and growth factors when stimulated by injury to a blood vessel. Platelets can assume different shapes and form adhesive pseudopodia (long surface extensions) that increase their surface area and promote interconnectedness and adherence to collagen fibers in damaged vascular walls, plugging vascular openings to control bleeding (Fig. 28.5).

FIG. 28.5 Colored Micrograph of Platelets.
The platelet on the left is moderately activated, with a generally round shape and the beginning of formation of pseudopodia (foot-like extensions from the membrane). The platelet on the right is fully activated, with extensive pseudopodia. (Copyright Dennis Kunkel Microscopy, Inc.)

The normal platelet concentration is about 150,000 to 400,000 platelets/mm^3 of circulating blood, although the normal ranges may vary slightly from laboratory to laboratory. An additional one-third of the body's available platelets are in a reserve pool in the spleen. A platelet circulates for approximately 8 to 11 days, and is then removed by macrophages, mostly in the spleen.

Lymphoid Organs

The lymphoid system is closely integrated with the circulatory system. The lymphoid organs, some of which are merely aggregations of lymphoid tissue, are classified as primary or secondary. The primary lymphoid organs are the thymus and the bone marrow. The secondary lymphoid organs consist of the spleen, lymph nodes, tonsils, and Peyer patches in the ileum of the small intestine. All of the lymphoid organs link the hematologic and immune systems in that they are sites of residence, proliferation, differentiation, or function of lymphocytes and mononuclear phagocytes (monocytes and macrophages) (see Chapter 8). The liver, which is primarily a digestive organ and is described in Chapter 40, synthesizes both coagulant and anticoagulant proteins.

Spleen

The spleen is the largest of the lymphoid organs. It serves as a site of fetal hematopoiesis, filters blood-borne antigens, cleanses the blood through the action of mononuclear phagocytes, initiates an immune response to blood-borne microorganisms, destroys aged erythrocytes, and serves as a reservoir for blood.

The spleen is a concave, encapsulated organ that weighs about 150 g and is about the size of a fist. It is located in the left upper abdominal cavity, curved around a portion of the stomach. Strands of connective tissue (trabeculae) extend throughout the spleen from the splenic capsule, dividing it into compartments that contain masses of lymphoid tissue called *splenic pulp* (white and red) (Fig. 28.6). The spleen is interlaced with many blood vessels, some of which can distend to store blood. Blood that circulates through the spleen comes from the splenic artery, which branches from the descending aorta and reenters the circulatory system through the splenic vein and into the portal vein.

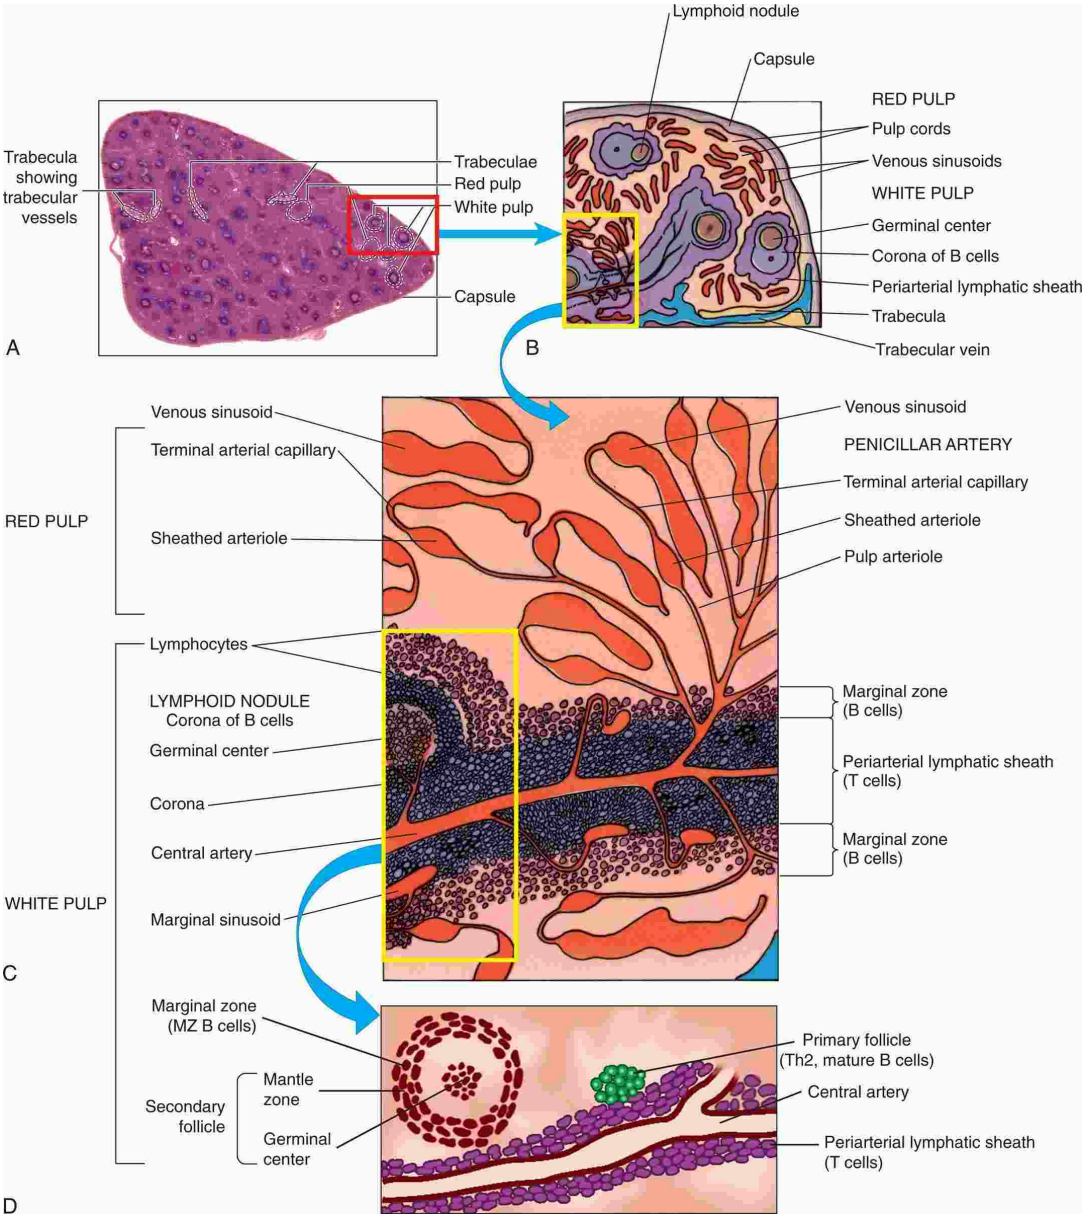

FIG. 28.6 Splenic Architecture.

(A) Cross-section of the spleen. The spleen is enclosed in a capsule with the interior pulp divided into compartments by strands of connective tissue. The splenic pulp contains regions that are rich in lymphocytes *(white pulp)* and those containing erythrocytes *(red pulp)*. (B) Subcapsular splenic structures. (C) Magnified view of red and white pulp structures. (D) The splenic artery branches into trabecular arteries and then to central arteries frequently surrounded by a periarterial lymphoid sheath, primarily containing T cells. The secondary lymphoid follicles contain B cells that are proliferating in response to antigen. *Th2*, T-helper 2 cells. (A, From Telser AG, Young JK, Baldwin KM. *Elsevier's*

integrated histology. St. Louis: Mosby; 2007; B and C, From Gartner LP, Hiatt JL. *Color textbook of histology*, 3rd edition. Philadelphia: Elsevier; 2007; D, From Hoffman R, et al. Hematology: *Basic principles and practice*, 6th edition. Philadelphia: Churchill Livingstone; 2013.)

Three illustrations, A, B, C, and D, shows the splenic architecture. Top-left panel, A. The illustration shows a cross-section of the spleen and highlights the following structures: trabecula showing trabecular vessels, trabeculae, red pulp, white pulp, and capsule. Top-right panel, B. The illustration shows and labels the following subcapsular splenic structures, clockwise from the top: lymphoid nodule, capsule, red pulp (pulp cords, venous sinusoids), and white pulp (germinal center, corona of B cells, periarterial lymphatic sheath, trabecula, and trabecular vein. Middle panel, C. The illustration shows magnified view of the red pulp and the white pulp. The red pulp comprises venous sinusoid, terminal arterial capillary, sheathed arteriole, venous sinusoid, penciller artery, terminal artery capillary, sheathed arteriole, and pulp arteriole. The white pulp comprises lymphocytes, lymphoid nodule corona of B cells, germinal center, corona, central artery, marginal sinusoid, marginal zone (B cells), periarterial lymphatic sheath (T cells), and marginal zone (B cells). Bottom panel, D. The illustration shows the splenic arteries and the trabecular arteries. The following structures on the illustration are labeled, marginal zone (M Z B cells), primary follicle (T h 2, mature B cells), secondary follicle (mantle zone and germinal center), and periarterial lymphatic sheath (T cells).

Arterial blood that enters the spleen first encounters the white splenic pulp, which consists of masses of lymphoid tissue containing macrophages and lymphocytes, primarily T lymphocytes in proximity to the arterioles (the periarterial lymphoid sheath) (see Fig. 28.6). Cellular clumps (lymphoid follicles) are formed in the white pulp around the splenic arterioles. The lymphoid follicles consist primarily of B lymphocytes and are the chief sites of immune function within the spleen. Here blood-borne antigens encounter lymphocytes, initiating the immune response and the conversion of lymphoid follicles into germinal centers in the middle of the

follicle where B cells proliferate and differentiate during the humoral immune response (see Chapter 8).

Some of the blood that enters the terminal capillaries continues through the microcirculation and enters highly distensible storage areas, called *venous sinuses*, in the red pulp of the spleen. The venous sinuses (and the red pulp) can store more than 300 mL of blood. Passive dilation of the venous sinuses enables the spleen to increase its storage capacity as needed by the body. Sudden reductions in blood pressure cause the sympathetic nervous system to stimulate constriction of the sinuses and expel as much as 200 mL of blood into the venous circulation, helping restore blood volume or pressure in the circulation and increasing the hematocrit by as much as 4%.

The endothelial lining of the venous sinuses is discontinuous (having gaps between endothelial cells) and therefore extremely permeable, allowing blood cells to exit the circulation. The red pulp contains a system of loosely interconnected resident macrophages that provide the principal site of splenic filtration. Because of the slow circulation in the sinuses, the macrophages easily phagocytose old, damaged, or dead blood cells of all kinds (but chiefly erythrocytes), microorganisms, macromolecules, and particles of debris. Hemoglobin from phagocytosed erythrocytes is catabolized, and heme (iron) is stored in the cytoplasm of the macrophages or released back into the blood (see Fig. 28.15). The macrophages also can remove particulate inclusions containing denatured hemoglobin (Heinz bodies) from erythrocytes without harming the cells themselves. Blood that filters through the red pulp then moves through the venous sinuses and into the portal circulation (blood flowing to the liver).

The spleen is not absolutely necessary for life or for adequate hematologic function. However, splenic absence as a result of any cause (atrophy, traumatic injury, or removal because of disease) has several secondary effects on the body. For example, leukocytosis (high levels of circulating leukocytes) often occurs after splenectomy, suggesting that the spleen exerts some control over the rate of proliferation of leukocyte stem cells in the bone marrow or their release into the bloodstream. Circulating levels of iron also may decrease, reflecting the spleen's role in the iron cycle (see the Iron Cycle section). The immune response to encapsulated bacteria (e.g., *Streptococcus pneumoniae* [pneumococcus], *Neisseria meningitidis* [meningococcus], and *Haemophilus influenzae*), which is primarily an IgM response, may be severely diminished, resulting in increased susceptibility to disseminated infections and sepsis. An increase in morphologically defective blood cells within the circulation after the loss of the spleen helps confirm the spleen's role in removing old or damaged cells. Thrombocytosis and thrombosis are complications of splenectomy and requires anticoagulation therapy.[5]

Lymph Nodes

Structurally lymph nodes are part of the lymphatic system. Lymphatic vessels collect interstitial fluid from the tissues and transport it, as lymph, through vessels of

increasing size to the thoracic duct, which drains into the superior vena cava and returns the lymph to the circulation. Lymph nodes are distributed throughout the body and provide filtration of the lymph during its journey through the lymphatics. Each lymph node is enclosed in a fibrous capsule, branches of which (trabeculae) extend inward to partition the node into several compartments. Reticular fibers of connective tissue divide the compartments into a meshwork throughout the lymph node. The node consists of outer (cortex) and inner (paracortex) cortical areas and an inner medulla. Lymph enters through multiple small afferent lymphatic vessels into the subcapsular sinus, just beneath the capsule, and drains into the cortical sinuses to the medullary sinuses, from which the lymph is collected and leaves the node by way of the efferent lymphatic vessel. Blood flows into the lymph nodes through the lymphatic artery, which ends in groups of postcapillary venules distributed throughout the outer cortex. The blood is drained through the lymphatic vein.

Functionally, lymph nodes are part of the hematologic and immune systems and are the primary site for the first encounter between antigen and lymphocytes. Lymphocytes enter the lymph node from the blood through specialized postcapillary venules called high endothelial venules (HEVs) by means of diapedesis across the endothelial lining (Fig. 28.7). Within the secondary lymph nodes, naïve T and B lymphocytes are segregated into different regions. B lymphocytes tend to migrate preferentially to nodes in the cortex and medulla, whereas T lymphocytes predominantly migrate to the paracortex. Macrophages reside in the lymph node; help filter the lymph of debris, foreign substances, and microorganisms; and provide antigen-processing functions. The dendritic cells encounter and process antigens (see Chapter 8) and microorganisms in other tissues, then enter the lymph node through the afferent lymph vessels, and migrate throughout the nodes. The reticular network provides adhesive surfaces for trapping large numbers of phagocytes and lymphocytes and facilitates their organization into follicles or primary nodules. The presence of antigen, either removed from the lymph by macrophages or presented on the surface of dendritic cells, results in the production of secondary nodules containing germinal centers. In the germinal centers lymphocytes, particularly B cells, respond to antigenic stimulation by undergoing proliferation and further differentiation into memory cells and plasma cells (see Chapter 8). Plasma cells migrate to the medullary cords. The B-lymphocyte proliferation in response to a great deal of antigen (e.g., during infection) may result in lymph node enlargement and tenderness (reactive lymph node), which can be palpable during a physical examination.

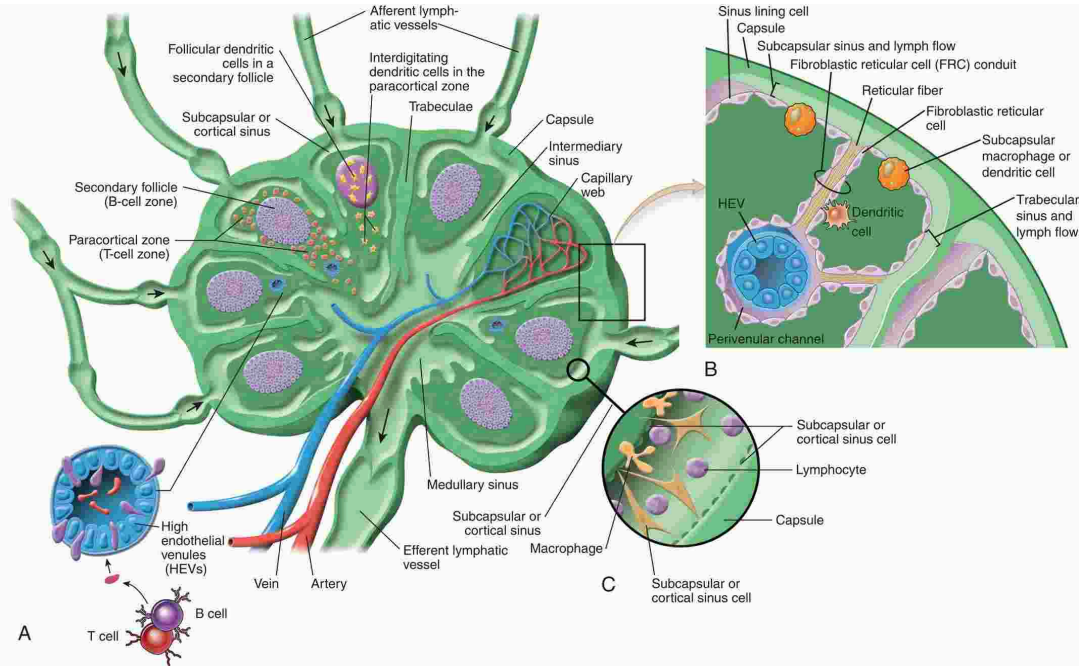

FIG. 28.7 Lymph Node Architecture.
(A) Cross section showing ingoing and outgoing lymph vessels (afferent and efferent), blood supply, compartmentalization of the B-cell region (secondary follicle), T-cell region (paracortical zone) with precapillary or high endothelium venules, follicular interdigitating dendritic cells, medullary sinus, intermediate sinus, and subcapsular or cortical sinus. Naive B and T lymphocytes enter through the high endothelial venule (HEV), shown in cross section, and are drawn to different areas of the node by chemokines that are produced in these areas and bind selectively to either cell type. **(B)** Cellular composition of the lymph node cortex depicting the route of lymph drainage from the subcapsular sinus, through fibroreticular cell conduits, to the perivenular channel around the high endothelial venule (HEV). Dendritic cells pick up antigen from peripheral sites of antigen entry and enter the lymph node through the afferent lymph vessels and migrate to the T-cell region of the node. **(C)** Cellular composition of subcapsular sinus. (A and C, From Paulsen F. *Sobottta atlas of human anatomy*. Vol. 1, 15th edition. Philadelphia: Elsevier; 2013; B, From Abbas AK, Pillai S. *Cellular and molecular immunology*, 9th edition. Philadelphia: Saunders; 2015.)

Three illustrations, A, B, and C, show the architecture of the lymph node. Left panel, A. The illustration shows a cross-section of the lymph vessel. The following structures on the illustration

are labeled, clockwise from the top: afferent lymphatic vessels, interdigitating dendritic cells in the paracortical zone, trabeculae, capsule, intermediary sinus, capillary web, medullary sinus, efferent lymphatic vessel, artery, vein, high endothelial venules (H E Vs), paracortical zone (T-cell zone), secondary follicle (B-cell zone), follicular dendritic cells in a secondary follicle, and subcapsular cortical sinus. Top-right panel, B. The illustration shows the cellular composition of the lymph node. The following structures on the illustration, clockwise from the top: sinus lining cell, capsule, subcapsular sinus and lymph flow, fibroblastic reticular cell (F R C) conduit, reticular fiber, fibroblastic reticular cell, subcapsular macrophage or dendritic cell, trabecular sinus and lymph flow, dendritic cell, H E V, and perivenular channel. Bottom-right panel, C. The illustration shows the subcapsular sinus and labels the following parts: subcapsular or cortical sinus cell, lymphocyte, capsule, subcapsular or cortical sinus cell, macrophage, and subcapsular or cortical sinus.

Development of Blood Cells

Bone Marrow

Bone marrow is confined to the cavities of bone and is the primary site of residence of hematopoietic stem cells (HSCs). The bone marrow environment provides HSC self-renewal, proliferation, differentiation, and apoptosis, and supports the developing progenitor cells.

Adults have two kinds of bone marrow: red marrow (active or hematopoietic marrow; also called myeloid tissue) and yellow marrow (inactive marrow). Bone cavities contain only red marrow at birth. The large quantity of fat in adult marrow is responsible for its yellow appearance. Not all bones contain active marrow. In adults, active marrow is found primarily in the flat bones of the pelvis (34%), vertebrae (28%), cranium and mandible (13%), sternum and ribs (10%), and in the extreme proximal portions of the humerus and femur (4% to 8%). Stem cells for transplant are commonly harvested from the flat bones of the pelvis. Inactive marrow predominates in cavities of other bones. (Bones are discussed further in Chapter 43.)

The hematologic compartment of the bone marrow consists of a variety of cellular and specialized molecular microenvironments, called bone marrow niches (Fig.

28.8). The niches provide essential autocrine, endocrine, and paracrine signals as well as direct cell-to-cell interactions necessary for the ability of HSCs to self-renew and to differentiate into all blood-cell lineages.

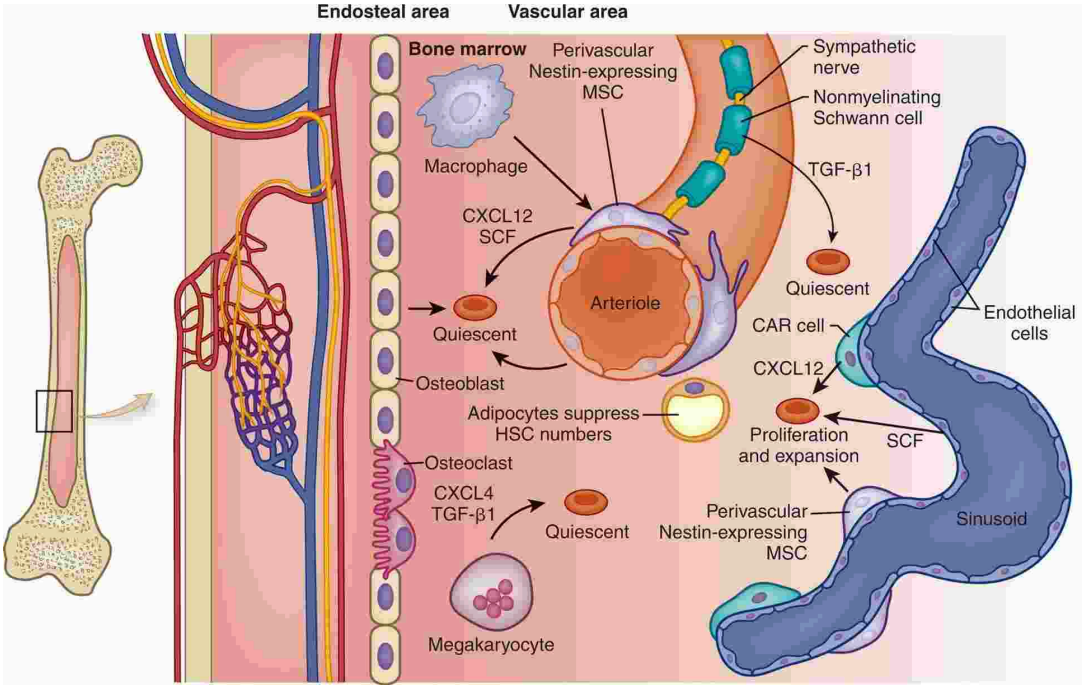

FIG. 28.8 Bone Marrow Stem Cell Niches.
Stem cell niches are microenvironments where stem cells undergo hematopoiesis into all forms of blood cells. Stem cell niches retain and maintain adult quiescent hematopoietic stem cells (HSCs) and are activated to promote cell self-renewal, proliferation, and differentiation to form new cells. The fate of individual HSCs is determined by interactions with specialized cells within the niches. *CAR*, CXCL12-abundant reticular cells; *CXCL4*, chemokine ligand 4 (also known as *platelet factor 4*); *CXLC12*, chemokine ligand 12; *MSC*, mesenchymal stem cells; *SCF*, stem cell factor; *TGF-β1*, transforming growth factor-beta 1. (Adapted from Boulais PE, Frenette PS. Making sense of hematopoietic stem cell niches. *Blood*, 2015;125(17):2621–2629; Schepers K, Campbell TB, Passegué E. Normal and leukemic stem cell niches: insights and therapeutic opportunities. *Cell Stem Cell*, 2015;16(3):254–267.)

An illustration shows a magnified view of a section of a bone. From the left to the right, the structure comprises an endosteal area and a vascular area. The endosteal area comprises a layer of osteoblast cells embedded with osteoclast cells. The vascular area comprises an arteriole. The following structures on the arteriole are identified: sympathetic nerve, nonmyelinating Schwann cell, T G F-beta 1 (quiescent), perivascular nestin-expressing M S C,

bone marrow, macrophage, and C X C L 12, S C F. The adipocytes suppress H S C numbers. The megakaryocyte release C X C L 4 and T G F-beta 1 to the quiescent. The following structures on the sinusoid are identified: endothelial cells, C A R cell, C A C L 12, S C F, and perivascular nestin-expressing M S C, which contribute to proliferation and expansion of the quiescent.

At least two populations of stem cells are found in bone marrow niches. Hematopoietic stem cells (HSCs) are progenitors of all the cell types of myeloid and lymphoid lineages (see Fig. 28.10). Mesenchymal stem cells (MSCs) are stromal cells (connective tissue cells) that can differentiate into a variety of cells, including osteoblasts (produce bone), adipocytes (store fat), chondrocytes (produce cartilage), sinusoidal endothelial cells, fibroblasts, and other stromal cells (connective tissue cells). The stromal cells secrete substances that form an extracellular matrix critical for cell growth and for anchoring developing blood cell progenitors in the bone marrow. Both populations of stem cells undergo continuous proliferation and self-renewal in the niches of the microenvironment of the bone marrow so that additional HSCs and MSCs are produced to replace those undergoing differentiation.

Hematopoietic niches are specialized microenvironments within the bone marrow that promote the maintenance of stem cells and regulate their function. The two main niches are the endosteal niche located close to endosteal bone, and the perivascular niche located more centrally near blood vessels and venous sinusoids. Different cell types reside in each niche. The primary cells of the *endosteal niche* are osteocytes, osteoblasts, osteoclasts, megakaryocytes, and macrophages. Osteoblasts are derived from MSCs and are responsible for construction of bone and support myelopoiesis through the release of soluble factors. Osteocytes are terminally differentiated osteoblasts and are the mature cell of the bone matrix. They are indirectly involved in the maintenance of the HSC pool through their interaction with osteoblasts. Osteoclasts are cells which originate from mononuclear cells of the HSC lineage and remodel bone by resorption. Additionally, osteoblasts can promote differentiation of B cells and osteoclasts can present antigen to T cells and are phagocytic, providing a link to immune function.[6]

Megakaryocytes and macrophages promote HSC migration and proliferation in the perivascular niches of the bone marrow. Megakaryocytes lie close to vascular sinuses where they produce platelets releasing them into the blood stream. Macrophages are also important for erythroid proliferation, differentiation, and maturation and supplying iron. Bone marrow adipocytes are a subpopulation of stromal adipocytes located throughout the bone marrow and support HSC maintenance.

Perivascular niches contain two specialized MSCs: chemokine ligand 12 (CXCL12)-abundant sinusoidal reticular (CAR) cells and periarteriolar and sinusoidal nestin-expressing cells. These cells closely interact with HSCs and provide intercellular signaling and cross-talk through several HSC regulatory molecules important for retention, expansion, maintenance, and quiescence or dormancy (prevents cell exhaustion and maintain their numbers throughout life) of HSCs. These regulatory molecules include CXCL12 (promotes retention and expansion of HSCs), stem cell factor (SCF, stimulates hematopoiesis), vascular cell adhesion molecule 1 (VCAM-1, promotes HSC retention), secreted protein angiopoietin 1 (ANG1, promotes quiescence or HSC stemness or ability to self-replicate), and transforming growth factor-beta (TGF-β, regulates quiescence and self-renewal).[7] The sympathetic nervous system acts with SCF to promote HSC maintenance and retention and regulates HSC mobilization.[8] The perivascular niche is also essential for gas exchange and delivery of nutrients and waste removal in the bone marrow.[9]

Hematopoietic marrow is vascularized by the primary arteries of the bones. Arterial vessels enter the bone, branch near the endosteum into smaller arterioles and capillaries, and drain into venous sinusoids. These sinuses coalesce into a large central sinus in the central cavity. Hematopoietic marrow and yellow marrow fill the spaces surrounding the network of venous sinuses. Newly produced blood cells traverse narrow openings between endothelial cells (diapedesis) in the venous sinus walls and thus enter the circulation. The low blood flow of the arteriole/sinusoid network limits gas exchange, creates a relatively hypoxic microenvironment, and maintains HSC dormancy.

Cellular Differentiation

All humans originate from a single cell (the fertilized egg) that has the capacity to proliferate and eventually differentiate into the huge diversity of cells of the human body. After fertilization, the egg divides over a 5-day period to form a hollow ball (blastocyst) that implants on the uterus. Until about 3 days after fertilization, each cell (blastomere) is undifferentiated and retains the capacity to differentiate into any cell type. During this period, the outer layer of cells of the blastocyte has undergone differentiation and commitment to become the placenta. Cells of the inner cell mass, however, continue to have unlimited differentiation potential (currently referred to as being *embryonic pluripotent stem cells*) and can grow into different kinds of tissue—blood, nerves, heart, bone, and so forth. After implantation, cells of the inner cell mass begin differentiation into other cell types. *Differentiation* is a multistep process and results in intermediate groups of stem cells with more limited, but still impressive, abilities to differentiate into many different types of cells. These are known as *multipotent stem cells* and include the HSCs (Fig. 28.9).

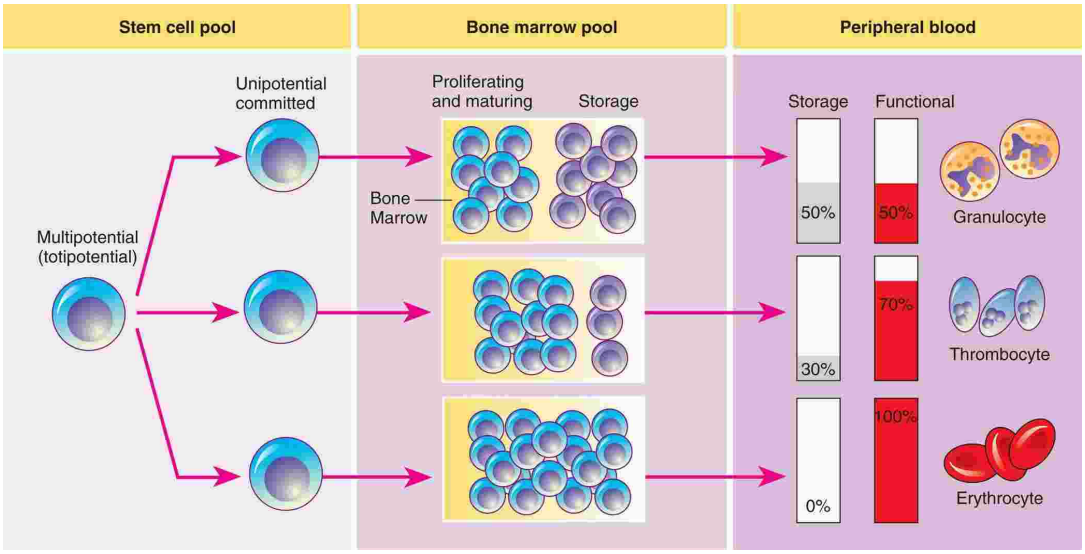

FIG. 28.9 Hematopoiesis.
Hematopoiesis from the stem cell pool; activity mainly in the bone marrow and in the peripheral blood.

A three-panel illustration shows the process of hematopoiesis. Left panel, stem cell pool. A multipotential (totipotential) cell differentiates to unipotential committed cells. Middle panel, bone marrow pool. Half the pool proliferates and matures, while the other half is stored; most of the pool proliferates and matures, while the rest is stored; or the entire pool proliferates and matures. Right panel, peripheral blood. There are three types of cells. • Granulocyte: 50 percent stored and 50 percent functional. • Thrombocyte: 30 percent stored and 70 percent functional. • Erythrocyte: 0 percent stored and 100 percent functional.

Within the bone marrow niches, each type of blood cell originates from HSCs that proliferate and differentiate under control of a variety of cytokines and growth factors (Table 28.4). As with all stem cells, the HSCs are self-renewing (they have the ability to proliferate without further differentiation) so that a relatively constant population of stem cells is available. Some HSCs will continue differentiation into hematopoietic progenitor cells. Progenitor cells retain proliferative capacity but are *committed* to possible further differentiation into particular (unipotent) lineages of hematologic cells. The cell lineages include lymphoid lineages (T and B lymphocytes, NK cells) and myeloid lineages (monocytes, macrophages, neutrophils, basophils, eosinophils, megakaryocyte/platelets, and erythrocytes) (Fig. 28.10).

Table 28.4

Human Hematopoietic Growth Factors (Cytokines, Colony-Stimulating Factors)

Factor	Cell Origin	Primary Cell Stimulated
M-CSF	Macrophage, lymphocyte, fibroblast, endothelial cell, osteoblast	Monocyte progenitor to monocyte
GM-CSF	Macrophage, T cell, endothelial cell, fibroblast, mast cell	Common myeloid progenitor to granulocyte progenitor and monocyte progenitor
G-CSF	Macrophage, fibroblast, endothelial cell	Granulocyte progenitor to neutrophil
IL-2	Th cell	T-cell progenitor to T cell
IL-3	T cell, monocyte/macrophage, stromal cell	Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series
IL-4	Th cell	B-cell progenitor to B cell
IL-5	Th cell, mast cell	Common myeloid progenitor to eosinophil
IL-7	Stromal cell, intestinal epithelium	Hematopoietic stem cell to common lymphoid progenitor Common lymphoid progenitor to progenitor B cell, pro NK cell, and progenitor T cell Progenitor T cell to T cell and progenitor B cell to B cell
IL-11	Stromal cell	Megakaryocyte progenitor to megakaryocyte
IL-15	Monocyte/macrophage	NK progenitor to NK cell

Factor	Cell Origin	Primary Cell Stimulated
Erythropoietin	Peritubular kidney cell and Kupffer cell	Common myeloid progenitor to erythrocyte progenitor Erythrocyte progenitor to erythrocyte
Thrombopoietin	Liver, kidney, skeletal muscle	All cells in megakaryocyte lineage from common myeloid progenitor to platelet
Stem cell factor	Stromal cell in bone marrow and many other cells	Hematopoietic progenitor to common myeloid progenitor Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series

Factor	Cell Origin	Primary Cell Stimulated
M-CSF	Macrophage, lymphocyte, fibroblast, endothelial cell, osteoblast	Monocyte progenitor to monocyte
GM-CSF	Macrophage, T cell, endothelial cell, fibroblast, mast cell	Common myeloid progenitor to granulocyte progenitor and monocyte progenitor
G-CSF	Macrophage, fibroblast, endothelial cell	Granulocyte progenitor to neutrophil
IL-2	Th cell	T-cell progenitor to T cell
IL-3	T cell, monocyte/macrophage, stromal cell	Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series
IL-4	Th cell	B-cell progenitor to B cell
IL-5	Th cell, mast cell	Common myeloid progenitor to eosinophil
IL-7	Stromal cell, intestinal epithelium	Hematopoietic stem cell to common lymphoid progenitor Common lymphoid progenitor to progenitor B cell, pro NK cell, and progenitor T cell Progenitor T cell to T cell and progenitor B cell to B cell
IL-11	Stromal cell	Megakaryocyte progenitor to megakaryocyte
IL-15	Monocyte/macrophage	NK progenitor to NK cell
Erythropoietin	Peritubular kidney cell and Kupffer cell	Common myeloid progenitor to erythrocyte progenitor Erythrocyte progenitor to erythrocyte
Thrombopoietin	Liver, kidney, skeletal muscle	All cells in megakaryocyte lineage from common myeloid progenitor to platelet
Stem cell factor	Stromal cell in bone marrow and many other cells	Hematopoietic progenitor to common myeloid progenitor Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony–stimulating factor; *IL*, interleukin; *M-CSF*, macrophage colony-stimulating factor; *NK*, natural killer; *pro*, progenitor; *Th*, T helper.

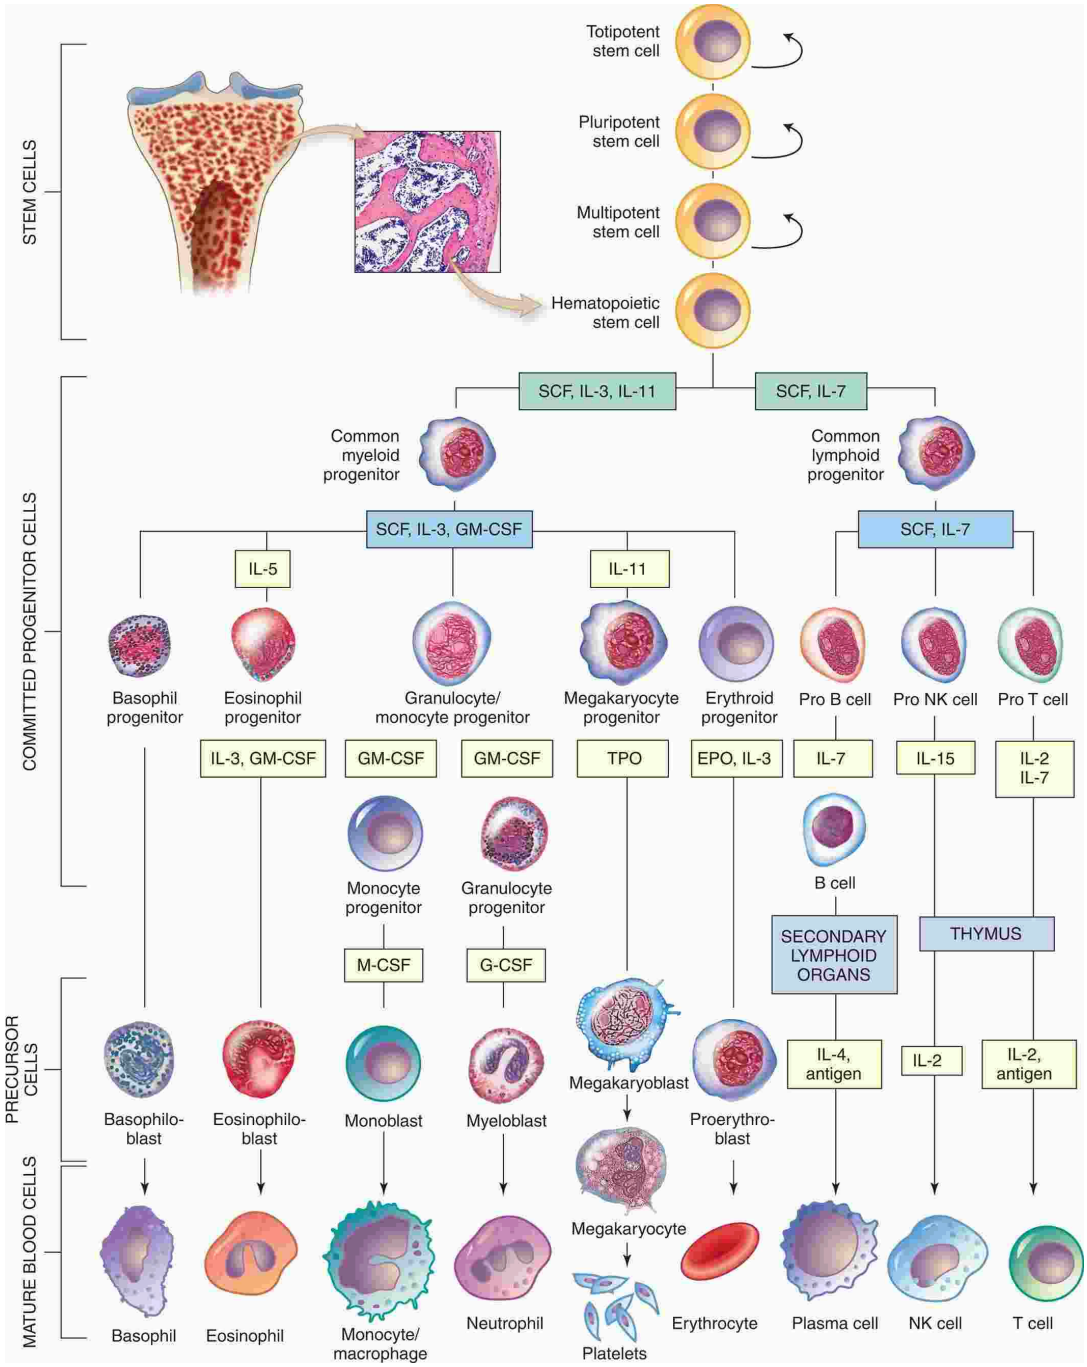

FIG. 28.10 Differentiation of Hematopoietic Cells.
Curved arrows indicate proliferation and expansion of prehematopoietic stem cell populations. Yellow boxes are the hematopoietic growth factors needed for proliferation and differentiation (see Table 28.4) *EPO*, Erythropoietin; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony–stimulating factor; *IL*, interleukin; *M-CSF*, macrophage colony-stimulating factor; *NK*, natural killer; *SCF*,

stem cell factor; *TPO*, thrombopoietin. (Modified from Patton K. *Anatomy and Physiology*. 10th ed. Elsevier; 2019.)

An illustrated flowchart tracks the differentiation of hematopoietic cells from stem cells through committed progenitor cells and precursor cells to mature blood cells. Stem cells: The cells can be totipotent, pluripotent, multipotent, or hematopoietic. The differentiation of the committed progenitor cells is as follows. 1. Hematopoietic cells. Leads to 2 and 3. 2. S C F, I L-3, I L-11. Leads to 4. 3. S C F, I L-7. Leads to 5. 4. Common myeloid progenitor. Leads to 6, 7, 8, 9, and 10. 5. Common lymphoid progenitor. Leads to 11, 12, and 13. 6. Basophil progenitor. 7. I L-5: Eosinophil progenitor (I L-3, G M-C S F). 8. Granulocyte or monocyte progenitor (G M-C S F). 9. I L-11: Megakaryocyte progenitor (T P O). 10. Erythroid progenitor (E P O, I L-3). 11. Pro B cell (I L-7). 12. Pro N K cell (I L-15). 13. Pro T cell (I L-2, I L-7). The differentiation of the precursor cells and mature blood cells is as follows. • Basophiloblast from basophil progenitor; to basophil. • Eosinophiloblast from I L-3 and G M-C S F; to eosinophil. • Monoblast from M-C S F of monocyte progenitor (G M-C S F); to monocyte or macrophage. • Myeloblast from G-C S F of granulocyte progenitor (G M-C S F); to neutrophil. • Megakaryoblast from T P O; to megakaryocyte and subsequently to platelets. • Proerythroblast from E P O and I L-3; to erythrocyte. • I L-4 and antigen from secondary lymphoid of B cell (I L-7); to plasma cell. • I L 2 from thymus (I L -15); to N K cell. • I L-2 and antigen from thymus (I L-2 and I L-7); to T cell.

Several cytokines participate in hematopoiesis, particularly colony-stimulating factors (CSFs or hematopoietic growth factors), which stimulate the proliferation of progenitor cells and their progeny and initiate the maturation events necessary to produce fully mature cells (see Table 28.4 and Fig. 28.10). Multiple cell types in hematopoietic organs, including endothelial cells, fibroblasts, granulocytes, monocytes, and lymphocytes, produce the necessary CSFs

Hematopoiesis in the bone marrow occurs in two separate pools: the stem cell pool and the bone marrow pool (see Fig. 28.9). The stem cell pool is the product of

self-renewal that maintains the number of pluripotent stem cells and partially committed progenitor cells. The bone marrow pool, the largest pool, contains cells that are proliferating and maturing in preparation for release into the circulation and mature cells that are stored for later release into the peripheral blood. The peripheral blood also contains two pools of cells: those in the circulation and those stored around the walls of the blood vessels (often called the marginating storage pool). The marginating storage pool primarily consists of neutrophils that adhere to the endothelium in vessels where the blood flow is relatively slow. These cells can rapidly move into tissues and mucous membranes when needed (e.g., during an inflammatory response).

Under certain conditions, the levels of circulating hematologic cells need to be rapidly replenished. Medullary hematopoiesis can be accelerated by any or all of three mechanisms: (1) conversion of yellow bone marrow, which does not produce blood cells, to red marrow, by the actions of erythropoietin (a hormone produced primarily by the kidney that stimulates erythrocyte production); (2) faster proliferation of stem cells into progenitor cells; and (3) faster differentiation of progenitor cells.

Hematopoiesis

The typical human requires about 100 billion new blood cells per day. Hematopoiesis is the production of blood cells. Blood cell production is constantly ongoing, occurring in the liver and spleen of the fetus, but only within the bone marrow (medullary hematopoiesis) after birth. This process involves the biochemical stimulation of populations of relatively undifferentiated cells to undergo mitotic division (i.e., proliferation) and maturation (i.e., differentiation) into mature hematologic cells (Fig. 28.10). Although proliferation and differentiation are usually sequential, certain blood cells proliferate and differentiate simultaneously. Erythrocytes and neutrophils generally differentiate fully before entering the blood, but monocytes and lymphocytes continue to mature in the blood and in secondary lymphatic organs.

Hematopoiesis continues throughout life, increasing in response to a need to replenish aged or destroyed circulating cells or in response to infection. In general, long-term stimuli, such as chronic diseases, cause a greater increase in hematopoiesis than do acute conditions, such as hemorrhage. Various abnormalities in medullary hematopoiesis have been identified and are discussed in Chapter 29.

Extramedullary hematopoiesis is blood cell production in tissues other than bone marrow, primarily the liver and spleen, but less frequently in the lymph nodes, adrenal glands, cartilage, adipose tissue, intrathoracic areas, and kidneys. Extramedullary hematopoiesis is usually a sign of disease and can occur in pernicious anemia, sickle cell anemia, thalassemia, hemolytic disease of the newborn (erythroblastosis fetalis), hereditary spherocytosis (abnormal sphere-shaped RBCs), and certain leukemias.

Development of Erythrocytes

Erythropoiesis is the development of RBCs. In the confines of the bone marrow, progenitor cells proliferate and differentiate into large, nucleated proerythroblasts, which are committed to producing erythroid cells (Fig. 28.11). The proerythroblast, which has ribosomes and can produce protein, differentiates through several intermediate forms of erythroblast (sometimes called **normoblast**) while progressively eliminating most intracellular structures (including the nucleus), synthesizing hemoglobin, and becoming more compact, eventually assuming the shape and characteristics of an erythrocyte.

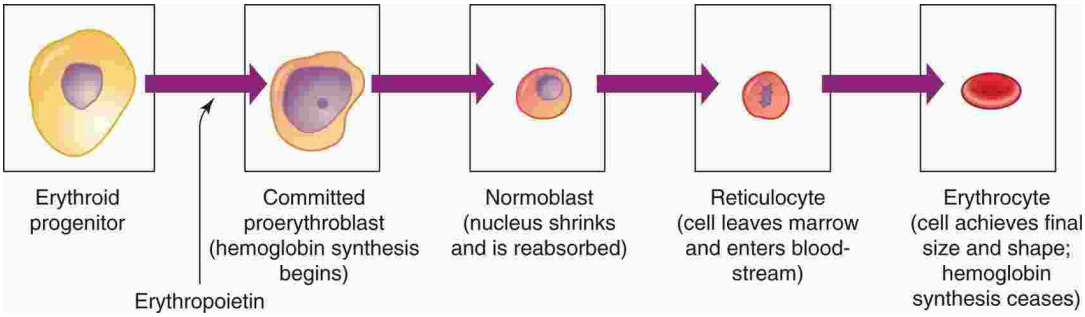

FIG. 28.11 Erythrocyte Differentiation.
Erythrocyte differentiation from large, nucleated progenitor cells to small nonnucleated erythrocytes.

A series of illustration shows the differentiation of erythrocyte. The sequence of differentiation is as follows. • Erythroid progenitor. • Erythroid progenitor in the presence of erythropoietin develops into committed proerythroblast. • Committed proerythroblast (hemoglobin synthesis begins). • Normoblast (nucleus shrinks and is reabsorbed). • Reticulocyte (cell leaves marrow and enters blood-stream). • Erythrocyte (cell achieves final size and shape; hemoglobin synthesis ceases).

The last immature form is the reticulocyte, which is anucleate and contains a mesh-like (reticular) network of ribosomal ribonucleic acid (rRNA). The reticulocyte contains polyribosomes (for globin synthesis) and mitochondria (for oxidative metabolism and heme synthesis). The reticulocyte matures into an erythrocyte within 24 to 48 hours. During this period, mitochondria and ribosomes disappear and the cell becomes smaller and more disc-like. With these final changes, the erythrocyte loses its capacity for hemoglobin synthesis and oxidative metabolism. Reticulocytes remain in the marrow approximately 1 day and are released into the

venous sinuses. They continue to mature in the bloodstream and may travel to the spleen for several days of additional maturation. The normal reticulocyte count is 1% of the total RBC count. Approximately 1% of the body's circulating erythrocyte mass normally is generated every 24 hours. Therefore, the reticulocyte count is a useful clinical index of erythropoietic activity and indicates whether new red cells are being produced.

Regulation of erythropoiesis

In healthy humans, the total volume of circulating erythrocytes remains surprisingly constant. Most steps of erythropoiesis are primarily under the control of a feedback loop involving erythropoietin (EPO) and other cytokines (see Table 28.4). In conditions of tissue hypoxia, EPO is secreted primarily by the peritubular cells of the kidney (Fig. 28.12). Rising circulating levels of EPO cause a compensatory increase in erythrocyte production. The normal steady-state rate of production of 2.5 million erythrocytes per second can increase to 17 million per second under anemic or low-oxygen states, such as high-altitude environments or pulmonary disease. Thus the body responds to reduced oxygenation of blood in two ways: (1) by increasing the intake of oxygen through increased respiration and (2) by increasing the oxygen-carrying capacity of the blood through increased erythropoiesis.

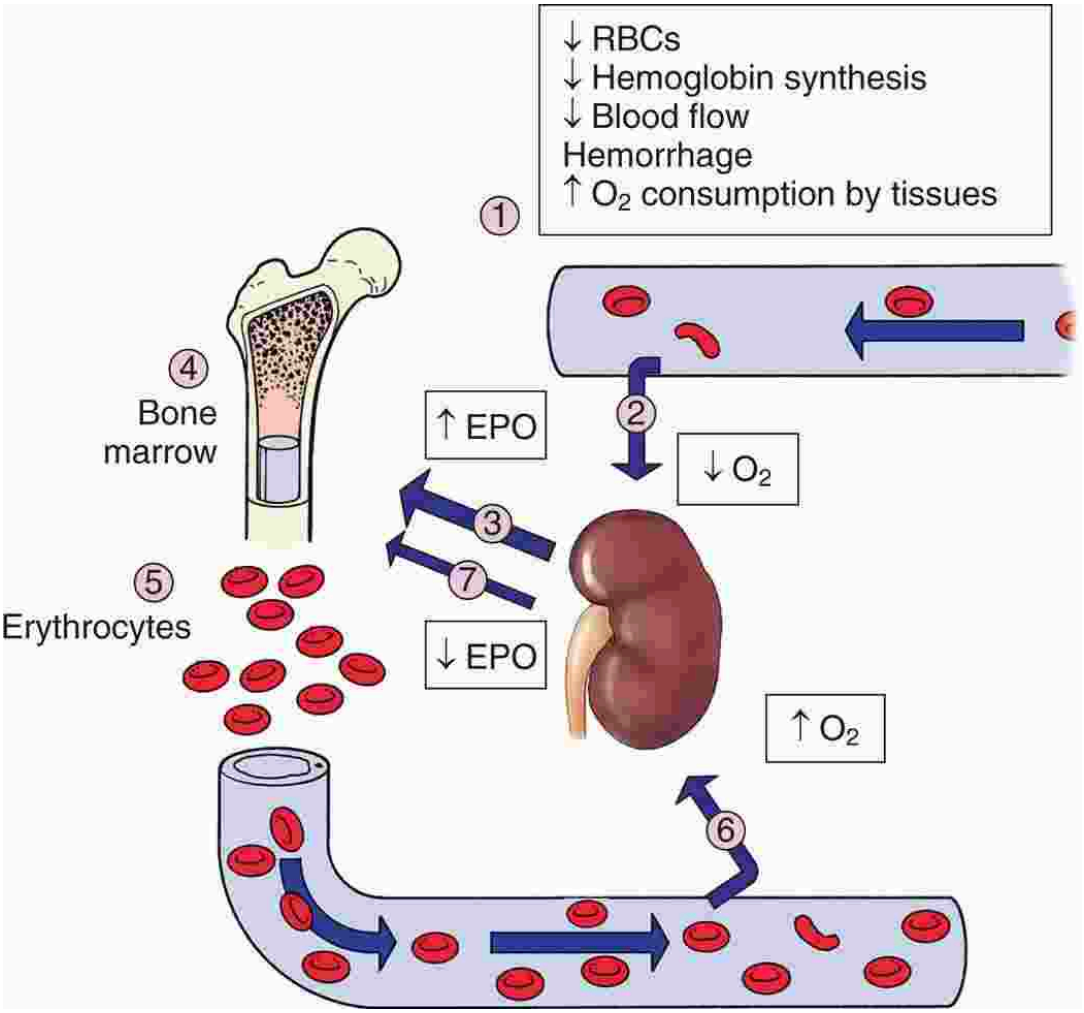

FIG. 28.12 Role of Erythropoietin in Regulation of Erythropoiesis.
(1) Decreased arterial oxygen levels result in decreased tissue oxygen (hypoxia) that *(2)* stimulates the kidney to increase production *(3)* of erythropoietin. Erythropoietin is carried to the bone marrow *(4)* and binds to erythropoietin receptors on proerythroblasts, resulting in increased red cell production *(5)*. The increased release of red cells into the circulation frequently corrects the hypoxia in the tissues. Perception of normal oxygen levels by the kidney *(6)* causes diminished production *(7)* of erythropoietin (negative feedback) and a return to normal levels of erythrocyte production. *EPO*, Erythropoietin; O_2, oxygen in the blood and tissue; *RBCs*, red blood cells.

An illustration shows the role of erythropoietin in regulation of erythropoiesis. 1. Decreased R B Cs, decreased hemoglobin

synthesis, decreased blood flow, hemorrhage, and increased oxygen consumption by tissues stimulate the kidney. 2. Oxygen level decreases. 3. E P O increases. 4. Triggers the bone marrow. 5. Erythrocytes increase. 6. Oxygen level increases. 7. E P O decreases.

Recombinant human erythropoietin (r-HuEPO) is used in individuals with anemia secondary to decreased EPO from chronic renal failure. An immediate effect of EPO administration is an increase in the blood reticulocyte count, followed by increasing levels of erythrocytes. The most significant side effect is increased blood pressure.

Hemoglobin synthesis

Erythrocytes form hemoglobin in the bone marrow. Hemoglobin (Hb), the oxygen-carrying protein of the erythrocyte, constitutes approximately 90% of the cell's dry weight. Hb-packed blood cells take up oxygen in the lungs and exchange it for carbon dioxide in the tissues. A single erythrocyte can contain as many as 300 hemoglobin molecules. Hb increases the oxygen-carrying capacity of blood by 100-fold. Each Hb molecule is composed of two pairs of polypeptide chains (the globins) and four colorful complexes of iron plus protoporphyrin (the hemes), which are responsible for the blood's ruby-red color and oxygen-carrying capacity (Fig. 28.13).

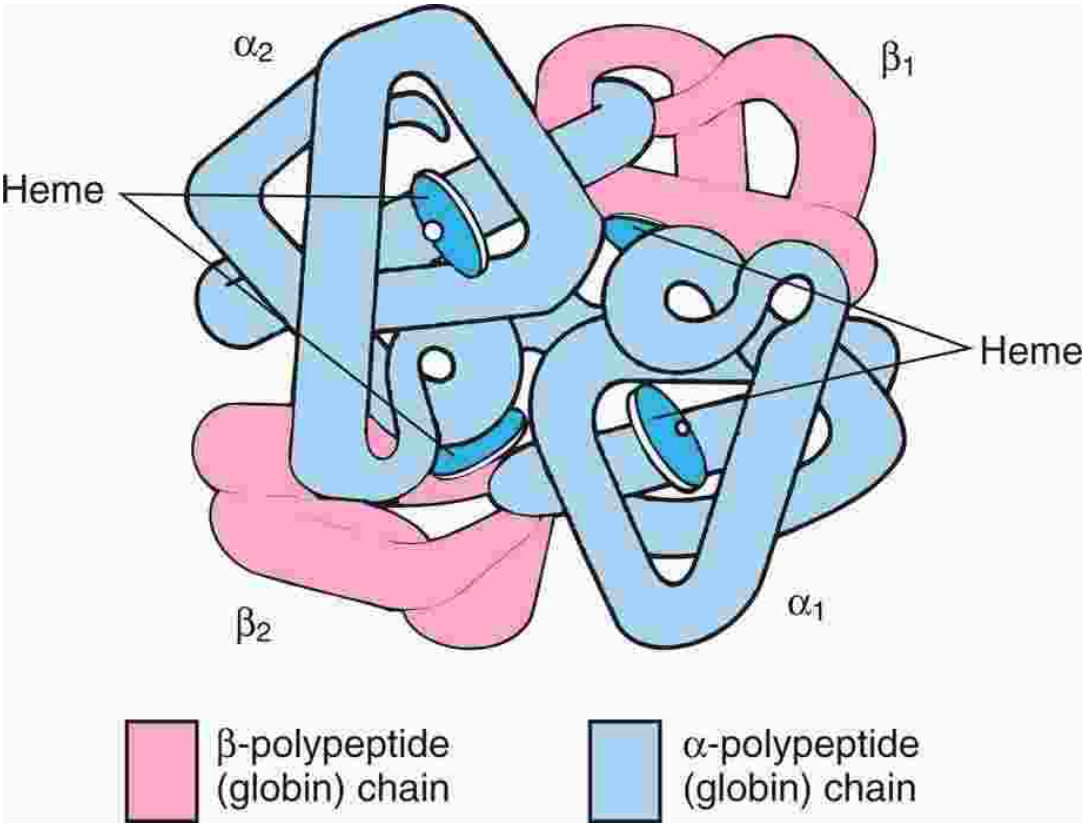

FIG. 28.13 Molecular Structure of Hemoglobin.
Molecule is spherical and contains a pair of α-polypeptide chains, a pair of β-polypeptide chains, and four heme groups.

Each polypeptide chain contains approximately 150 amino acids and is arranged in a knotted-sausage configuration. The chains assemble to form a tetrahedron containing two pairs of identical chains. Several variants of Hb exist (Table 28.5), and they differ only slightly in primary structure based on the use of different polypeptide chains: alpha, beta, gamma, delta, epsilon, or zeta (α, β, γ, δ, ε, or ζ, respectively). Hb A, the most common type in adults, is composed of two α- and two β-polypeptide chains ($\alpha_2\beta_2$) (see Fig. 28.13). A normal variant, fetal Hb (Hb F), is a complex of two α- and two γ-polypeptide chains ($\alpha_2\gamma_2$) that binds oxygen with a much greater affinity than adult Hb. Other variants are genetic mutations associated with various diseases (see Chapter 29).[10]

Table 28.5

Structure of Normal Hemoglobin Molecules

Type of Hemoglobin (Hb)	Identity of Polypeptide Chain	Significance
HbA	$\alpha_2\beta_2$	92% of adult Hb
HbA_{1c}	α_2 (β-*NH*-glucose)	5% of adult Hb; increased in diabetes (see Chapter 22)
HbA_2	$\alpha_2\delta_2$	2% of adult Hb; increased in β-thalassemia (see Chapter 29)
HbF	$\alpha_2\gamma_2$	Major fetal Hb from the third through ninth month of gestation; promotes oxygen transfer across platelets; increased in β-thalassemia
Hb Gower I	ε_4 or $\zeta_2\beta_2$	Present in early embryo; function unknown
Hb Gower II	$\alpha_2\varepsilon_2$	Present in early embryo; function unknown
Hb Portland	$\zeta_2\gamma_2$	Present in early embryo; function unknown

NH, Amine.

Heme is a large, flat, iron-protoporphyrin disc that is synthesized in the mitochondria and can carry one molecule of oxygen (O_2). Thus, an individual Hb molecule with its four hemes can carry four oxygen molecules. If all four oxygen-binding sites are occupied by oxygen, the molecule is said to be saturated. Through a series of biochemical reactions, protoporphyrin, a complex four-ringed molecule, is produced and bound with ferrous iron. It is crucial that the iron be correctly charged; reduced ferrous iron (Fe^{2+}) can bind oxygen in the lungs and release it in the tissues, whereas ferric iron (Fe^{3+}) cannot. Binding of O_2 to ferrous iron temporarily oxidizes Fe^{2+} to Fe^{3+} (oxyhemoglobin), but after the release of O_2 the body reduces the iron to Fe^{2+} and reactivates the Hb (deoxyhemoglobin [reduced hemoglobin]). Without reactivation, the Fe^{3+}-containing Hb (methemoglobin) cannot bind O_2. An excess of ferric iron occurs with certain drugs and chemicals, such as nitrates and sulfonamides, and reduces oxygen-carrying capacity.

Hb undergoes a conformational change when binding O_2. When one of the iron molecules binds O_2, the porphyrin ring changes shape, increasing the exposure of the three remaining iron atoms to O_2. This greatly increases the affinity for the oxygen-carrying capacity of Hb, as occurs in the lungs. When oxygen is unloaded

from Hb, the oxygen-carrying capacity of hemoglobin is low, facilitating the transport of carbon dioxide back to the lungs.

Several other molecules can competitively bind to deoxyhemoglobin. Carbon monoxide (CO) directly competes with O_2 for binding to Fe^{2+} with an affinity that is about 200-fold greater than that of O_2. Thus even a small amount of CO can dramatically decrease the ability of Hb to bind and transport O_2. Hb also binds carbon dioxide (CO_2), but at a binding site separate from where O_2 binds. In the lungs, CO_2 is released, allowing hemoglobin to bind O_2.

Erythrocytes may also play a role in the maintenance of vascular relaxation and blood flow. Nitric oxide (NO) produced by blood vessels is a major mediator of relaxation and dilation of the vessel walls. In the lungs, Hb can concurrently bind O_2 to the Fe^{2+} and NO to cysteine residues in the globins. As Hb transfers its O_2 to tissue, it may also shed small amounts of NO, contributing to dilation of the blood vessels and helping transfer of the O_2 into tissues.

Nutritional requirements for erythropoiesis

Normal development of erythrocytes and synthesis of hemoglobin depend on an optimal biochemical state and adequate supplies of the necessary building blocks, including protein, vitamins, and minerals (Table 28.6). If these components are lacking for a prolonged time, erythrocyte production slows and anemia (insufficient numbers of functional erythrocytes) may result (see Chapter 29).

Table 28.6

Nutritional Requirements for Erythropoiesis

Nutrient	Role in Erythropoiesis	Consequence of Deficiency[a]
Protein (amino acids)	Structural component of plasma membrane	Decreased strength, elasticity, and flexibility of membrane; hemolytic anemia
Synthesis of hemoglobin		Decreased erythropoiesis and life span of erythrocytes
Cobalamin (vitamin B_{12})	Synthesis of DNA, maturation of erythrocytes, facilitator of folate metabolism	Macrocytic (megaloblastic) anemia
Folate (folic acid)	Synthesis of DNA and RNA, maturation of erythrocytes	Macrocytic (megaloblastic) anemia
Vitamin B_6 (pyridoxine)	Heme synthesis	Microcytic-hypochromic anemia
Vitamin B_2 (riboflavin)	Oxidative reactions	Normocytic-normochromic anemia
Vitamin C (ascorbic acid)	Iron metabolism, acts as reducing agent to maintain iron in its ferrous (Fe^{2+}) form	Normocytic-normochromic anemia
Pantothenic acid	Heme synthesis	Unknown in humans[b]
Niacin	None, but needed for respiration in mature erythrocytes	Unknown in humans
Vitamin E	Heme synthesis (?); protection against oxidative damage in mature erythrocytes	Hemolytic anemia with increased cell membrane fragility; shortens life span of erythrocytes in individual with cystic fibrosis
Iron	Hemoglobin synthesis	Iron deficiency anemia

Nutrient	Role in Erythropoiesis	Consequence of Deficiency[a]
Copper	Optimal mobilization of iron from tissues to plasma	Microcytic-hypochromic anemia

DNA, Deoxyribonucleic acid; *RNA*, ribonucleic acid.

[a]See Chapter 29.

[b]Although pantothenic acid is important for optimal synthesis of heme, experimentally induced deficiency failed to produce anemia or other hematopoietic disturbances.

Data from Lee GR, et al. *Wintrobe's Clinical Hematology*, 9th edition. Philadelphia: Lea & Febiger; 1993; Harmening DM. *Clinical hematology and fundamentals of hemostasis*, 3rd edition. Philadelphia: FA Davis; 1997.

Erythropoiesis cannot proceed in the absence of vitamins, especially B_{12}, folate (folic acid), B_6, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin E. Dietary vitamin B_{12} is a large molecule that requires a protein secreted by parietal cells into the stomach (intrinsic factor [IF]) for transport across the ileum. Once absorbed, vitamin B_{12} is stored in the liver and used as needed in erythropoiesis. Defects in IF production lead to decreased B_{12} absorption, which may lead to pernicious (megaloblastic) anemia.

Folate is the second most important vitamin for erythrocyte production and maturation. Folate is necessary for DNA and ribonucleic acid (RNA) synthesis in precursor RBCs. Lack of folate results in an increase in abnormally large, nucleated precursor RBCs (megaloblasts) with a reduced capacity to carry O_2. Folate is absorbed principally in the upper small intestine and is stored in the liver. Folate deficiency is more common than vitamin B_{12} deficiency and occurs more rapidly. Folate stores can be depleted within a few months, whereas vitamin B_{12} depletion can take years. Folate supplements are prescribed for pregnant women because pregnancy increases the demand for folate. Supplements may prevent anemia and can protect against neural tube defects because folate is also required for embryonic neural tube closure (see Chapter 20).

Normal destruction of senescent erythrocytes

After about 120 days in the circulation, old erythrocytes are removed by tissue macrophages, primarily in the spleen.[11] Although mature erythrocytes lack nuclei, mitochondria, and the endoplasmic reticulum, they do have cytoplasmic enzymes capable of glycolysis (anaerobic glucose metabolism) and production of small quantities of adenosine triphosphate (ATP). ATP provides the energy needed to maintain cell function and keep its plasma membrane pliable. Metabolic processes diminish as the erythrocyte ages, so less ATP is available to maintain plasma membrane function. The aged or senescent red cell becomes increasingly fragile and

loses its reversible deformability due to disruption of the anchorage between the cytoskeleton and the plasma membrane, thus becoming susceptible to rupture while passing through narrowed regions of the microcirculation.

Additionally, the plasma membrane of senescent red cells undergoes phospholipid rearrangement, signaling macrophages (primarily in the spleen) to selectively remove and sequester the senescent red cells. If the spleen is dysfunctional or absent, macrophages in the liver (Kupffer cells) assume control of this process. The erythrocytes are digested by proteolytic and lipolytic enzymes in the phagolysosomes (digestive vacuoles) of the macrophage. The heme and globin dissociate easily, and the globin is broken down into its component amino acids. The iron in hemoglobin is oxidized, forming Fe^{3+} (methemoglobin), and recycled.

During digestion of Hb in the macrophage, porphyrin reduces to unconjugated bilirubin, which is conjugated (made water soluble) and excreted from the liver into the intestine or into bile (Fig. 28.14). Bacteria in the intestinal lumen transform conjugated bilirubin into urobilinogen. Although a small portion is reabsorbed and excreted by the kidneys, most urobilinogen is excreted in feces. Conditions causing accelerated erythrocyte destruction increase the load of serum unconjugated bilirubin, increased liver conjugation of bilirubin, and increased urinary excretion of urobilinogen. Gallstones (cholelithiasis) can result from a chronically elevated rate of bilirubin excretion.

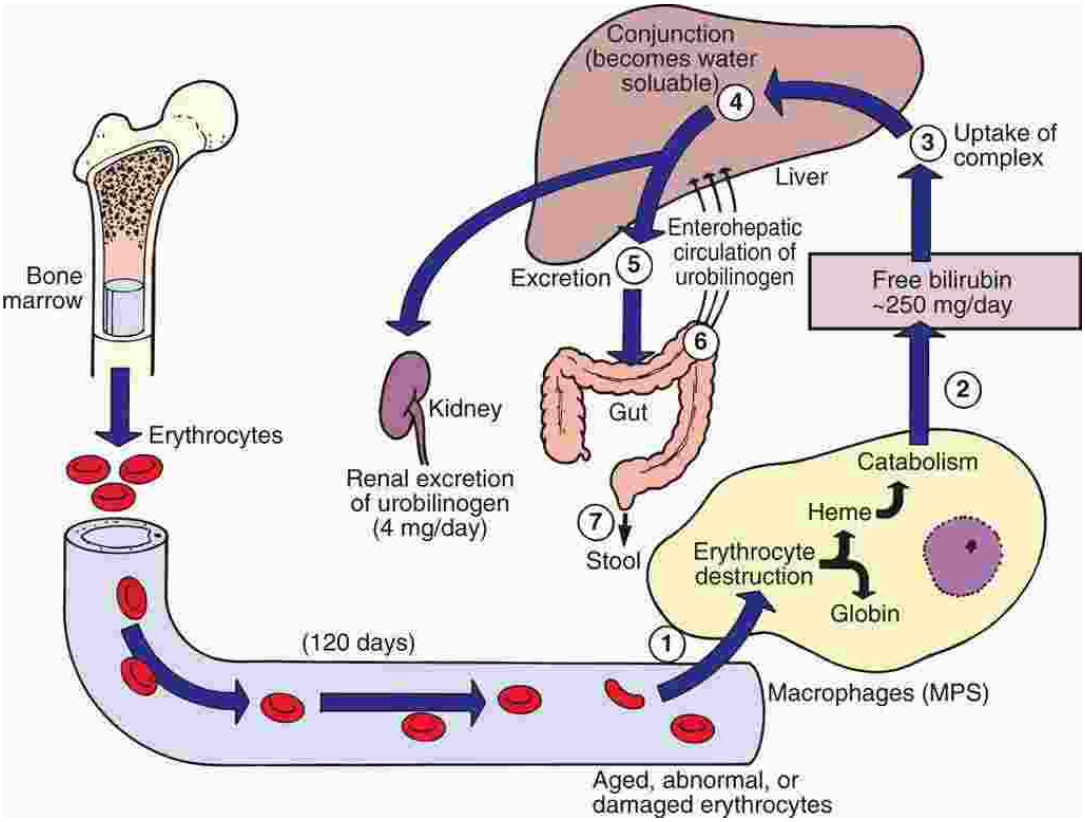

FIG. 28.14 Metabolism of Bilirubin Released by Heme Breakdown.
(1) Senescent red blood cells (RBCs) are consumed by macrophages. During digestion, *(2)* the porphyrin in the RBC reduces to bilirubin. *(3)* Bilirubin is taken up by the liver, where it is *(4)* conjugated by glucuronyl transferase and then is *(5)* excreted as bile. *(6)* Bacteria in the intestine transform conjugated bilirubin into urobilinogen, *(7)* most of which is excreted in feces. *MPS*, Mononuclear phagocyte system.

An illustration shows the metabolism of bilirubin released by heme. Erythrocytes from the bone marrow, at 120 days, become aged, abnormal, or damaged. 1. Erythrocytes are attracted to the macrophages (M P S), where they are destructed as heme or globin. 2. Heme undergoes catabolism releasing free bilirubin by 250 milligrams per day. 3. Uptake of complex. 4. Conjunction (becomes water soluble). 5. Excretion. 6. Enterohepatic circulation of urobilinogen. 7. Urobilinogen is excreted as stool. Conjunction

also triggers the kidney, supporting the renal excretion of urobilinogen of 4 milligrams per day.

Iron cycle

Approximately 67% of total body iron is bound to heme in erythrocytes (Hb), and about 5% to 10% is bound to heme-containing myoglobin in muscle cells. Approximately 30% is stored in mononuclear phagocytes (i.e., macrophages) and hepatic parenchymal cells as either ferritin (iron bound to protein) or hemosiderin (intracellular bound iron). The remaining 3% (less than 1 mg) is lost daily in urine, sweat, bile, sloughing of epithelial cells from the skin and intestinal mucosa, and minor bleeding, as occurs with menstruation in women. There is no excretory mechanism for iron. Unbound, or free, iron is toxic to human cells. Approximately 25 mg of iron is required daily for erythropoiesis; only 1 to 2 mg of iron is dietary, and the remainder is obtained from continual recycling of iron from erythrocytes through a process known as the iron cycle.[12] Pregnant women require more iron to meet the needs of the placenta and growing fetus.

The methemoglobin released from the breakdown of senescent or damaged erythrocytes is dissociated by the enzyme heme oxygenase, and the iron is released into the bloodstream, where it binds again to transferrin or is stored in the macrophage's cytoplasm as ferritin or hemosiderin (Fig. 28.15). A minute amount of iron is stored in muscle cells by the heme-containing protein myoglobin. Unavailable stores of iron are present in cytochromes, catalases, and peroxidase enzymes.

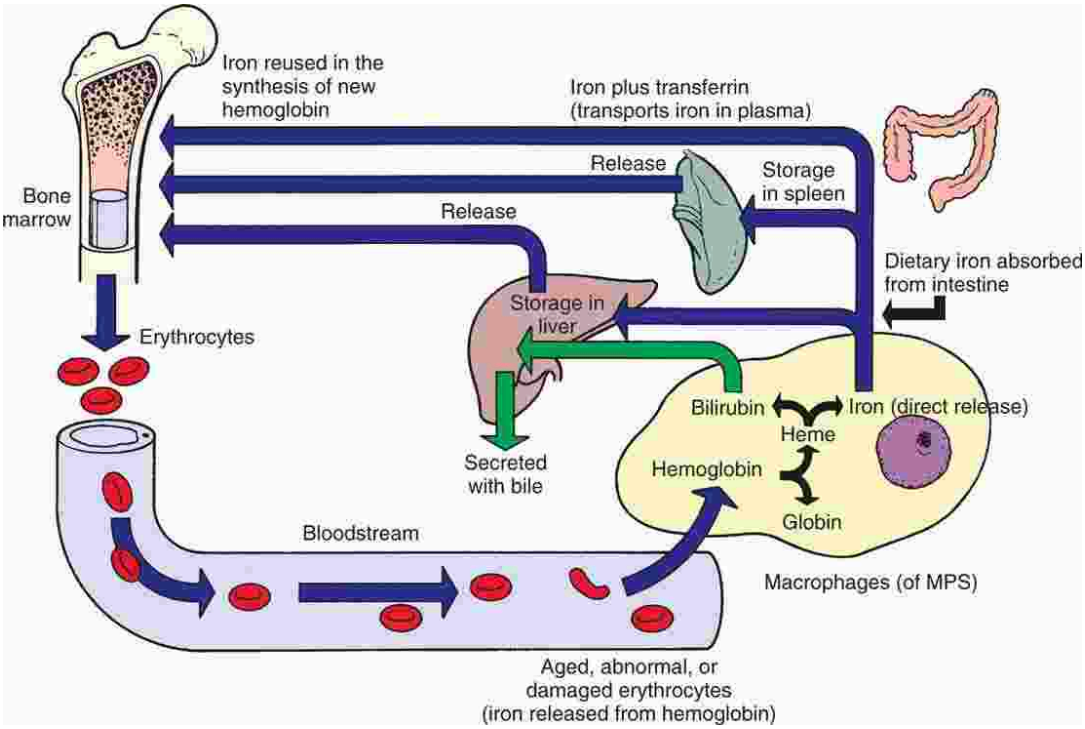

FIG. 28.15 **Iron Cycle.**
Iron released from gastrointestinal epithelial cells circulates in the bloodstream associated with its plasma carrier, transferrin. It is delivered to erythroblasts in bone marrow, where most of it is incorporated into hemoglobin. Mature erythrocytes circulate for approximately 120 days, after which they become senescent and are removed by the mononuclear phagocyte system *(MPS)*. Macrophages of the MPS (mostly in the spleen) break down ingested erythrocytes and return iron to the bloodstream directly or after storing it as ferritin or hemosiderin.

An illustration shows the iron cycle. Erythrocytes from the bone marrow enter the blood stream and tend to become aged, abnormal, or damaged (iron released from hemoglobin). These erythrocytes are consumed by macrophages (M P S), where the hemoglobin is destructed as heme or globin. The heme destructs as bilirubin, which is stored in the liver or secreted with bile, or as iron, which is released directly. Dietary iron absorbed from the intestine is: • Stored in the liver or released into the bone marrow. • Stored in the spleen or released into the bone marrow.

• Iron plus transferrin (transports iron in plasma). • Iron reused in the synthesis of new hemoglobin in the bone marrow.

Ferritin is the major intracellular iron storage protein. Apoferritin is ferritin without attached iron and can store thousands of atoms of iron. Apoferritin binds to free Fe^{2+} and stores it as Fe^{3+}, becoming ferritin. Excess accumulations of iron produce large intracellular iron storage complexes, known as hemosiderin. Hemosiderin is visible as an iron-based pigment under a light microscope as cell inclusions. The iron within deposits of hemosiderin is poorly available because it is not water-soluble, but it is available when iron requirements increase. The most common cause of hemosiderin deposition is simple bruising. Hemosiderin in small amounts within iron-rich tissues (i.e., spleen, liver, bone marrow) is considered normal. Large aggregates or its presence in tissue, such as the lungs or subcutaneous tissue, suggests a pathologic condition known as hemosiderosis.

Iron from either dietary sources, release of iron stores, or erythrocyte catabolism is transported in the blood bound to apotransferrin, thus becoming transferrin. Under normal conditions, only one-third of the iron-binding sites on transferrin molecules are occupied. Apotransferrin is a glycoprotein synthesized primarily by hepatocytes in the liver but also produced in small quantities by tissue macrophages, submaxillary and mammary glands, and ovaries or testes. Iron for hemoglobin production is carried by transferrin to the bone marrow, where it binds to transferrin receptors on erythroblasts. Transferrin receptors are on the plasma membrane of all nucleated cells, but at particularly high levels on erythroid precursors and rapidly proliferating cells (e.g., lymphocytes), and are thought to be the only route of cellular entry for transferrin-attached iron. Transferrin is recycled (transferrin cycle) by intracellular dissociation of iron from transferrin and secretion of the resultant apotransferrin to the bloodstream. The iron is transported to the erythroblast's mitochondria (the site of Hb production), where the enzyme heme synthetase inserts Fe^{2+} into protoporphyrin to form heme. Heme then is bound to globin to form Hb. Iron not used in erythropoiesis is stored temporarily as ferritin or hemosiderin and later excreted or recycled.

Splenic red pulp macrophages are specialized for iron recycling with increased expression of proteins for the uptake of hemoglobin, the breakdown of heme, and the export of iron.[13] The body's iron homeostasis is primarily controlled by the hormone hepcidin. Hepcidin is the regulator of the systemic transportation of iron.[14] It is a protein synthesized in the liver and released into the plasma, where it is bound with high affinity to α_2-macroglobulin and with less affinity to albumin. Hepatocellular hepcidin production is regulated physiologically by the levels of iron in the body, rate of erythropoiesis, and percentage of oxygen saturation. Hepatocytes (liver cells) sense levels of circulating iron by means of receptors for transferrin. Excess iron is stored in hepatocytes and macrophages, and hepatocytes sense these levels by means of receptors for bone morphogenetic protein (BMP),

most likely BMP-6, which is a growth factor produced to a large extent by bone marrow sinusoid endothelial cells. Hepcidin production also can be induced by inflammation through IL-6 and other inflammatory cytokines, produced in response to infection or chronic conditions such as cancer.

Hepcidin regulates iron levels through its binding capacity to ferroportin, which is a transmembrane iron exporter found in the plasma membrane of cells that transport or store iron, including macrophages, hepatocytes, enterocytes (intestinal cells), and erythrocytes. The body's total iron balance is maintained through controlled absorption rather than excretion. Dietary iron (primarily as Fe^{2+}) is transported directly across the membranes of enterocytes in the duodenum and proximal jejunum and is carried in the plasma by transferrin. (Transport mechanisms are described in Chapter 1.) Hepcidin induces internalization and degradation of ferroportin, thus leading to increased intracellular iron stores, decreased dietary iron absorption, and decreased levels of circulating iron. Decreased production of hepcidin leads to release of stored iron and increased dietary absorption. Thus, if the body's iron stores are low or the demand for erythropoiesis increases, dietary iron is transported rapidly through the epithelial cell and into the plasma. If body stores are high and erythropoiesis is not increased, iron transport is stopped. Hepcidin production also can be induced by inflammation. During inflammation, increased levels of hepcidin lead to sequestering of iron as a result of down-regulation of ferroportin expression on macrophages and enterocytes and thus can cause anemia.

Development of Leukocytes

Leukocytes consist of lymphocytes, granulocytes, and monocytes (their pathways of differentiation are shown in Fig. 28.10). Most of the leukocytes arise from stem cells in the bone marrow. HSCs differentiate into two populations of progenitor cells: common lymphoid progenitors and common myeloid progenitors. Lymphopoiesis (lymphocytopoiesis) is the generation of lymphocytes from lymphoid progenitor cells released into the bloodstream to undergo further maturation in the primary and secondary lymphoid organs (see Chapter 8).

Myelopoiesis is the development of granulocytes (neutrophils, eosinophils, and basophils) and monocytes from the differentiation of myeloid progenitor cells in the bone marrow. The common myeloid progenitors differentiate into progenitors for basophils, mast cells, eosinophils, and megakaryocytes, and into granulocyte/monocyte progenitors. The granulocyte/monocyte progenitors further differentiate into monocyte progenitors and granulocyte progenitors, which develop into monocytes/macrophages and neutrophils, respectively. Development from HSCs to common granulocyte-monocyte progenitors primarily is under the control of SCF, IL-3, and GM-CSF, whereas further differentiation into granulocytic and monocytic progenitors is controlled by granulocyte colony stimulating factor (G-CSF) and macrophage stimulating factor (M-CSF), respectively (see Table 28.4 and Fig. 28.10).

Monocytic progenitors undergo development into monocytes within 24 hours and are released into the circulation. Monocytes mature into various forms of macrophages, a process that is usually completed within 1 or 2 days after their release.

Progenitor cells for granulocytes normally fully mature in the bone marrow into neutrophils, eosinophils, and basophils. The ultimate phenotype is determined by relative local bone marrow concentrations of early- and late-acting cytokines, including GM-CSF, G-CSF, IL-3, IL-5, SCF, and others (see Table 28.4). Granulocytes are released into the blood within 10 to 14 days of development. The bone marrow selectively retains immature granulocytes as a reserve pool that can be rapidly mobilized in response to the body's needs.

Most leukocytes exist in the body from days to years, depending on type (e.g., mature neutrophils live for hours and some macrophages live for years). Maintenance of optimal levels of granulocytes and monocytes in the blood depends on the availability of pluripotent stem cells in the marrow, induction of these into committed stem cells, timely release of new cells from the marrow, and mobilization of the granulocyte reserve pool. Leukocyte production increases in response to infection, to the presence of steroids, and to reduction or depletion of reserves in the marrow. It is also associated with strenuous exercise, convulsive seizures, heat, intense radiation, paroxysmal tachycardias, pain, nausea and vomiting, and anxiety.

Development of Platelets

Thrombopoiesis is the development of platelets. Platelets (thrombocytes) are derived from stem cells and progenitor cells that differentiate into megakaryocytes (see Fig. 28.10). During thrombopoiesis, the megakaryocyte nucleus enlarges and becomes extremely polyploidy (up to 100-fold or more of the normal amount of DNA) without cellular division. Concurrently, the numbers of cytoplasmic organelles (e.g., internal membranes, granules) increase and the cell develops cellular surface elongations and branches that progressively fragment into platelets. A single large (up to 100 μm) megakaryocyte may produce thousands of smaller platelets (2 to 3 μm). Like erythrocytes, platelets released from the bone marrow lack nuclei but contain granules that promote their stickiness. About two-thirds of platelets enter the circulation, and the remainder resides in the splenic pool.

Thrombopoietin (TPO), a hormone growth factor, stimulates the production and differentiation of megakaryocytes and is the main regulator of the circulating platelet numbers.[15] TPO is primarily produced by the liver and induces platelet production in the bone marrow. Platelets express receptors for TPO and, when circulating platelet levels are normal, TPO is adsorbed onto the platelet surface and prevented from accessing the bone marrow and initiating further platelet production. When platelet levels are low, however, the amount of TPO exceeds the number of available platelet TPO receptors, and free TPO can enter the bone marrow. During inflammation IL-6 induces increased production of TPO, which increases production of newly formed platelets, which are more thrombogenic.

Platelets circulate in the bloodstream for about 8 to 10 days before beginning to lose their ability to perform thrombogenic activity and biochemical reactions. Senescent platelets are sequestered and destroyed in the spleen by macrophage phagocytosis.

Mechanisms of Hemostasis

Hemostasis is the arrest of bleeding by formation of blood clots at sites of vascular injury (Fig. 28.16). As a result of hemostasis, damaged blood vessels may maintain a relatively steady state of blood volume, pressure, and flow. Three equally important interactive components of hemostasis are the vasculature (endothelial cells and subendothelial matrix), platelets, and clotting factors. The general sequence of events in hemostasis is as follows:

1. Vascular injury leads to a transient arteriolar vasoconstriction to limit blood flow to the affected site.
2. Damage to the endothelial cell lining of the vessel exposes prothrombogenic subendothelial connective tissue matrix, leading to platelet adherence and activation and formation of a *hemostatic plug* to prevent further bleeding (primary hemostasis).
3. Tissue factor, produced by the endothelium, collaborates with secreted platelet factors and activated platelets to activate the clotting (coagulation) system to form fibrin clots and further prevent bleeding (secondary hemostasis).
4. The fibrin/platelet clot contracts to form a more permanent plug, and regulatory pathways are activated (fibrinolysis) to limit the size of the plug and begin the healing process.

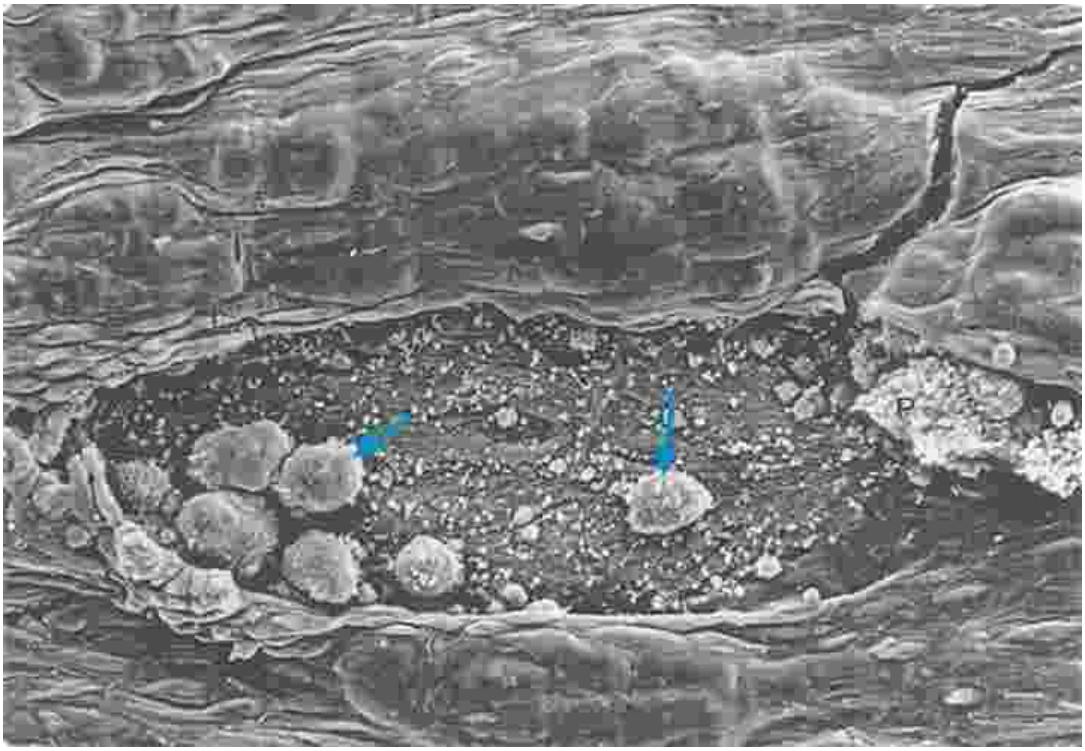

FIG. 28.16 Platelet Adhesion.
After endothelial denudation, platelets and leukocytes *(blue arrows)* adhere to the subendothelium in a monolayer fashion.
(From Zipes DP, et al. *Braunwald's heart disease: A textbook of cardiovascular medicine*, 8th edition. Philadelphia: Saunders; 2019, as reproduced from Faggiotto A, Ross R. Studies of hypercholesterolemia in the nonhuman primate. II. Fatty streak conversion to fibrous plaque. *Arteriosclerosis*. 1984;4:341–356.)

The relative importance of the hemostatic mechanisms clearly varies with vessel size. Damage to large vessels cannot easily be controlled by hemostasis but requires vascular contraction and dramatically decreased blood flow into the damaged vessels (Table 28.7).

Table 28.7

Types of Bleeding: Sources, Vessel Size, and Sealing Requirements

Types and Sources of Bleeding	Involved Vessel	Size	Sealing Requirements
Pinpoint petechial hemorrhage (blood leakage from small vessels)	Capillary Venule Arteriole	Smallest	Generally direct sealing Mostly fused platelets Mostly fused platelets
Ecchymosis (large, soft tissue bleeding)	Vein		Vascular contraction, fused platelets, perivascular and intravascular hemostatic factor activation
Rapidly expanding "blowout" hemorrhage	Artery	Largest	Greater vascular contraction, more fused platelets, greater perivascular and intravascular hemostatic factor activation

Types and Sources of Bleeding	Involved Vessel	Size	Sealing Requirements
Pinpoint petechial hemorrhage (blood leakage from small vessels)	Capillary	Smallest	Generally direct sealing
	Venule		Mostly fused platelets
	Arteriole		Mostly fused platelets
Ecchymosis (large, soft tissue bleeding)	Vein		Vascular contraction, fused platelets, perivascular and intravascular hemostatic factor activation
Rapidly expanding "blowout" hemorrhage	Artery	Largest	Greater vascular contraction, more fused platelets, greater perivascular and intravascular hemostatic factor activation

Modified from Harmening DM, ed. *Clinical hematology and fundamentals of hemostasis*, 3rd edition. Philadelphia: FA Davis; 1997.

Function of Blood Vessel Endothelium

The vessel walls consist of a layer of endothelial cells that adhere to an underlying subendothelial matrix of connective tissue. The matrix contains a variety of proteins, including collagen, fibronectin, and laminins. Endothelial cells adhere to the matrix and to each other through receptors that are expressed only on the intercellular and basal surfaces.

Under normal conditions the endothelium actively regulates blood flow and prevents spontaneous activation of platelets and the clotting system. Endothelial cells produce nitric oxide (NO), also known as endothelium-derived vasorelaxant factor (EDRF),[16] and synthesize prostacyclin (prostaglandin I2 [PGI2]), both of which are vasodilators that modulate blood flow and pressure and maintain platelets in an inactive state. Synergism between PGI_2 and NO is significant. PGI_2 production varies a great deal in response to stimuli, whereas NO is released continually to regulate vascular tone. Endothelium also produces adenosine diphosphatase, which degrades adenosine diphosphate (ADP), a potent activator of platelets.

The endothelial cell surface contains antithrombotic molecules, such as glycosaminoglycans (e.g., heparan sulfate), thrombomodulin, and plasminogen activators. These limit platelet activation and fibrin deposition. Although thrombomodulin and plasminogen activators help control hemostasis in normal vessels, their effects are magnified during vascular damage and clot formation.

As a result of damage to the vessels, the endothelial cell barrier is frequently compromised, the remaining endothelial cells are activated by products of tissue

damage, and the underlying subendothelial matrix is exposed. Endothelial cells contain intracellular structures that contain von Willebrand factor (vWF, clotting factor VIII), which is released during vascular injury and activates platelets for hemostasis.

Function of Platelets

Platelets normally circulate freely, suspended in plasma, in an unactivated state. The roles of platelets are to (1) contribute to regulation of blood flow into a damaged site by induction of vasoconstriction (vasospasm); (2) initiate platelet–platelet interactions (adhesion and aggregation) and attachment to injured endothelium, resulting in formation of a platelet plug to stop further bleeding; (3) release granules that activate the coagulation (or clotting) cascade to stabilize the platelet plug; and (4) initiate repair processes, including clot retraction and clot dissolution (fibrinolysis) and release of growth factors.[17]

The normal platelet count ranges from 150,000 to 400,000/mm^3. Thrombocytopenia (abnormally low numbers of platelets) develops if the platelet count drops below 100,000/mm^3, and an individual may experience longer than normal clotting times. Spontaneous major bleeding episodes do not generally occur unless the platelet count falls below 20,000/mm^3. If platelet numbers are elevated (thrombocytosis), the risk for spontaneous blood clots (thrombosis), stroke, or heart attack is increased.

Damage to the vessel initiates a process of platelet activation: (1) increased platelet *adhesion* to the damaged vascular wall; (2) *activation* leading to platelet degranulation, which stimulates changes in platelet shape and biochemistry; (3) *aggregation* as platelet–vascular wall and platelet-platelet adherence increases; and (4) activation of the clotting system and development of an immobilizing meshwork of platelets and fibrin.

Adhesion

Normally platelets are generally observed "rolling" along the margins of vessels. At sites of vessel injury, however, platelets become adherent to the site of endothelial damage, where the subendothelial matrix is exposed and endothelial cells have released vWF and decreased their antithrombotic activities (Fig. 28.17). Platelet adhesion is mostly mediated by the binding of platelet surface receptor glycoprotein Ib (GPIb) to vWF. The vWF protein is found in the subendothelial matrix and is released by endothelial cells and platelets. Platelet adhesion narrows the diameter of the blood vessel, resulting in increasing shear forces that could strip platelets off the vessel surface. However, those same forces induce conformational changes in the vWF molecule that result in increased affinity with the adhesive GPIb, thus stabilizing the adherent platelet.

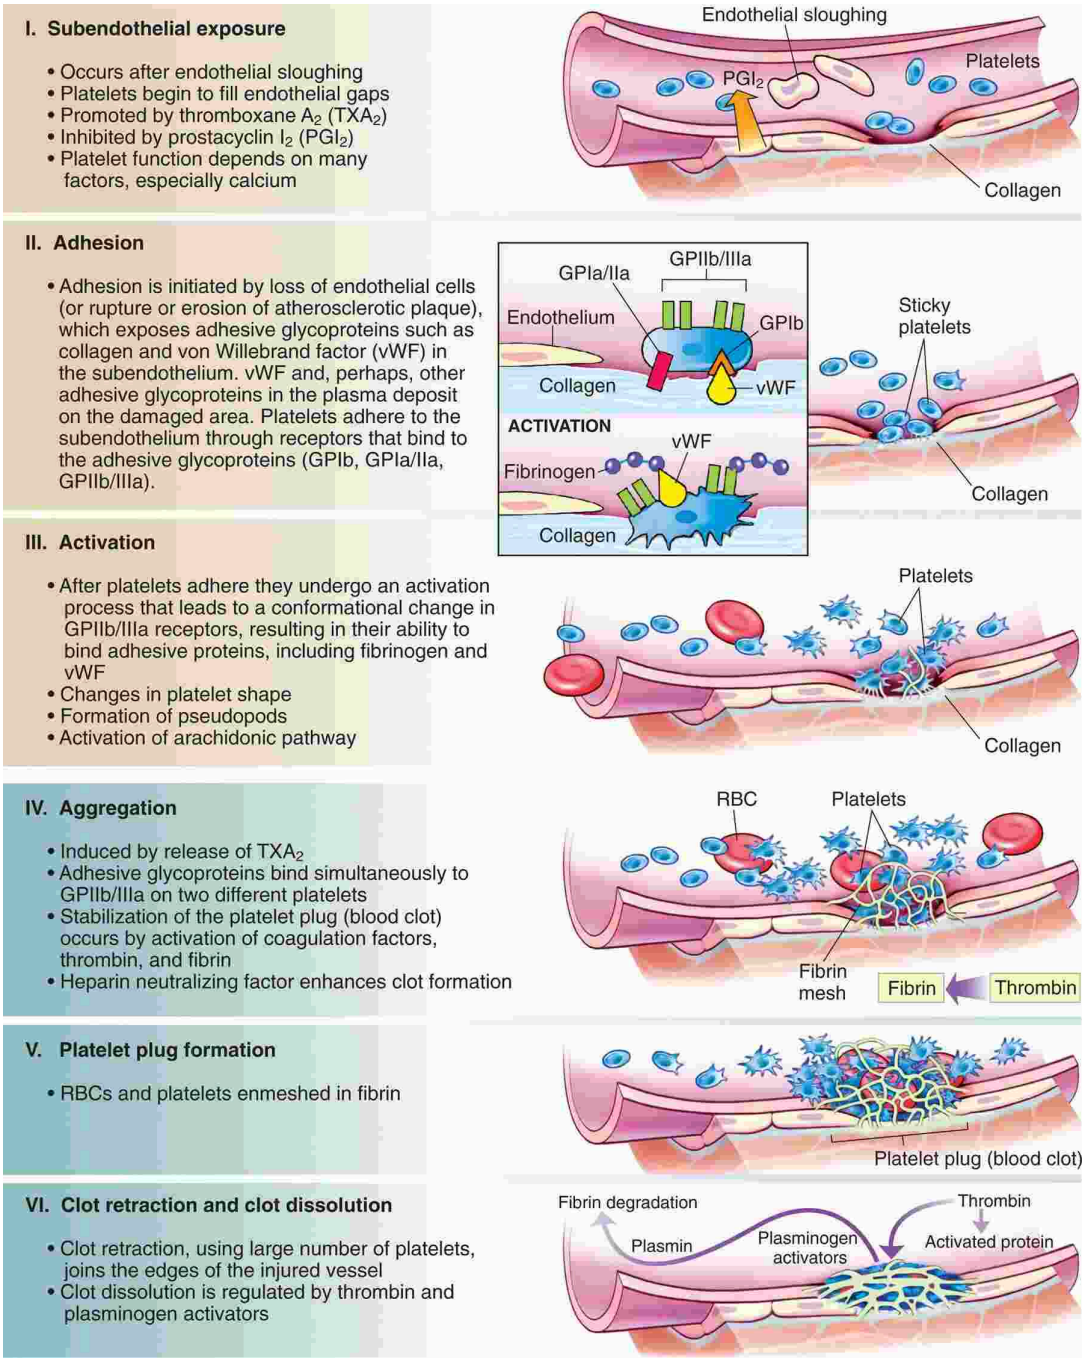

FIG. 28.17 Blood Vessel Damage, Platelet Activation, Blood Clot, and Clot Dissolution.

A series of illustrations show blood vessel damage, platelet activation, blood clot, and clot dissolution. Subendothelial exposure. The illustration shows collagen, P G I sub 2, platelets, and endothelial sloughing. • Occurs after endothelial sloughing.

• Platelets begin to fill endothelial gaps. • Promoted by thromboxane A sub 2 (T X A sub 2). • Inhibited by prostacyclin I sub 2 (P G I sub 2). • Platelet function depends on many factors, especially calcium. Adhesion. The illustration shows collagen and sticky platelets. An accompanying magnified view identifies a G P 1 b with G P 1 a or 2 a and G P 2 b or 3 a on the endothelium and collagen with v W F attached to fibrinogen. Adhesion is initiated by loss of endothelial cells (or rupture or erosion of atherosclerotic plaque), which exposes adhesive glycoproteins such as collagen and von Willebrand factor (v W F) in the subendothelium. v W F and, perhaps, other adhesive glycoproteins in the plasma deposit on the damaged area. Platelets adhere to the subendothelium through receptors that bind to the adhesive glycoproteins (G P 1 b, G P 1 a or 2 a, G P 2 b or 3 a). Activation. The illustration shows platelets concentrated at the collagen. • After platelets adhere they undergo an activation process that leads to a conformational change in G P 2 b or 3 a receptors, resulting in their ability to bind adhesive proteins, including fibrinogen and v W F. • Changes in platelet shape. • Formation of pseudopods. • Activation of arachidonic pathway. Aggregation. The illustration shows platelets attached to the R B C. Thrombin converted to fibrin, which forms a mesh on the platelets. • Induced by release of T X A sub 2. • Adhesive glycoproteins bind simultaneously to G P 2 b or 3 a on two different platelets. • Stabilization of the platelet plug (blood clot) occurs by activation of coagulation factors, thrombin, and fibrin. • Heparin neutralizing factor enhances clot formation. Platelet plug formation. The illustration shows a fibrin mesh covering a cluster of platelets attached to R B Cs. RBCs and platelets enmeshed in fibrin. Clot retraction and clot dissolution. The illustration shows a thick fibrin mesh. Thrombin activates protein and triggers the mesh generating plasminogen activators that produce plasmin for fibrin degradation. • Clot retraction, using large number of platelets, joins the edges of the injured vessel. •

Clot dissolution is regulated by thrombin and plasminogen activators.

Platelet adhesion is also facilitated by other interactions between platelet receptors and exposed molecules of the subendothelial matrix. For instance, adhesion is increased through binding of the platelet collagen receptors GPVI and integrin $\alpha_2\beta_1$ to exposed collagen in the matrix.

Activation

As a result of interactions with the endothelium or the subendothelial matrix, as well as exposure to inflammatory mediators produced by the endothelium and other cells, the platelets are activated. Activation results in reorganization of the platelet cytoskeleton, leading to dynamic changes in platelet shape from smooth spheres to those with spiny projections (increases surface area) (see Fig. 28.5) and degranulation (also called the platelet-release reaction) and resulting in the release of various potent biochemicals.

Platelets contain three types of granules: dense bodies, alpha granules, and lysosomes. The contents of the dense bodies and alpha granules are particularly important in hemostasis. The dense bodies contain ADP, serotonin, and calcium. ADP recruits and activates other platelets through specific receptors. During activation the platelet plasma membrane experiences several important changes, including becoming ruffled and sticky; undergoing cellular spreading to make tight contacts between neighboring platelets, causing the platelet plug to seal the injured endothelium; and externalizing the phospholipid phosphatidylserine, which provides a matrix for activation of clotting factors. Serotonin is a vasoactive amine that functions like histamine and increases vasodilation and vascular permeability. Calcium is necessary for many of the adhesive interactions as well as for intracellular signaling mechanisms that control platelet activation.

Alpha granules contain a mixture of clotting factors (e.g., fibrinogen), growth and angiogenic factors (e.g., platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF], basic fibroblast growth factor), and angiogenesis inhibitors (e.g., platelet factor 4, thrombospondin, inhibitors of metalloproteinases). Platelet factor 4 also is a heparin-binding protein and enhances clot formation at the site of injury. Depending on the particular stimulus, platelets may selectively release promoters or inhibitors of angiogenesis. Many of these mediators either promote or inhibit platelet activity and the eventual process of clot formation. PDGF stimulates smooth muscle cells and promotes tissue repair.

Platelet lysosomes have a role in the digestion of phagocytic and cytosolic components, similar to that in nucleated cells. Lysosomal contents also may have important extracellular functions, such as supporting receptor cleavage, fibrinolysis and degradation of extracellular matrix components, and remodeling of the vasculature.[18]

Platelets also initiate production of the prostaglandin derivative thromboxane A2 (TXA2), which counters the effects of PGI_2 produced by endothelial cells. TXA_2 causes vasoconstriction and promotes the degranulation of platelets, increases expression of platelet fibrinogen receptors, and stimulates platelet aggregation, whereas PGI_2 promotes vasodilation and inhibits platelet degranulation. Arachidonic acid metabolism by cyclooxygenase (COX) is a major pathway for blood platelet activation. An isoform of cyclooxygenase (COX-1) converts arachidonic acid to TXA_2 in platelets. Aspirin at low doses specifically and irreversibly inactivates COX-1, decreasing production of TXA_2 and decreasing platelet activation and aggregation.[19] Daily intake of low doses of aspirin leads to more than 95% inhibition of TXA_2 in just a few days.

Other stimuli of platelet activation include epinephrine, thrombin, and collagen. Thrombin and collagen are particularly strong stimuli. Thrombin cleaves the extracellular domain of G-protein–coupled protease-activated receptors (PARs), thereby initiating transmembrane signaling.

Aggregation

Platelet aggregation is stimulated primarily by TXA_2 and ADP, which induce functional fibrinogen receptors on the platelet. The glycoprotein IIb/IIIa (GPIIb/IIIa) complex (also called *integrin* $\alpha IIb\beta_3$) undergoes a conformational change during activation to become a calcium-dependent receptor for fibrinogen, allowing it to bind other matrix proteins (e.g., fibronectin, fibrinogen, thrombospondin). Although the GPIIb/IIIa complex is the most abundant fibrinogen receptor on the platelet, receptors for vWF and collagen also contribute to the process. Interplatelet aggregation and clot retraction, which forms the *primary hemostatic plug*, are facilitated by fibrinogen bridges between receptors on the platelets. The GPIIb/IIIa–fibrinogen pathway is essential for the formation of a thrombus and as such is an important therapeutic target for blockage by antiplatelet drugs. In addition, fibrin strands within the clot shorten and become denser and stronger, helping the clot to approximate the edges of the injured vessel wall and sealing the site of injury. Contraction of myosin and actin filaments in the platelet cytoskeleton mediates *platelet contraction* and fusion of the platelet mass into a *secondary hemostatic plug*. Contraction expels serum from the fibrin meshwork, resulting in greater packing and increased strength.

If blood vessel injury is minor, hemostasis is achieved temporarily by formation of the platelet plug within 3 to 5 minutes of injury. Platelet plugs adhere to damaged vessel walls and seal the many minute ruptures that occur daily in the microcirculation, particularly in capillaries. With too few platelets, numerous small hemorrhagic areas called *purpuras* develop under the skin and throughout the tissues (see Chapter 29). If primary hemostasis is inadequate to prevent further bleeding, the process proceeds through secondary hemostasis to create a larger

complex of more tightly interactive platelets within a matrix created by activation of the clotting system.

Function of Clotting Factors

A blood clot is a meshwork of protein strands that stabilizes the platelet plug and traps other cells, such as erythrocytes, phagocytes, and microorganisms (see Fig. 28.16). The strands are made of fibrin, which is produced by the clotting (coagulation) system. The clotting system was described in Chapter 7 and consists of a family of proteins that circulate in the blood in inactive forms (proenzymes). The proteins of the clotting system are all produced in liver hepatocytes. Initiation of the system results in sequential activation (cascade) of proteolytic enzymes which activate downstream enzymes in the system until a fibrin clot is created (Table 28.8).

Table 28.8

Coagulation Factors and Synonyms

Factor	Synonym	Primary Function
I	Fibrinogen	Source of fibrin to form clot
II	Prothrombin	Source of thrombin that activates fibrinogen, V, VII, VIII, XI, XIII, protein C, platelets
Tissue factor (thromboplastin)	Previously called *factor III*	Cofactor for factor VIIa
Calcium	Previously called *factor IV*	Cofactor for clotting factor binding to phosphatidylserine
V	Labile factor	Va is cofactor in prothrombinase complex
VII	Stable factor, proconvertin	VIIa forms complex with tissue factor and activates factors IX and X
VIII	Antihemophilic factor	VIIIa is component of tenase complex
IX	Christmas factor	IXa is component of tenase complex, activates factor X
X	Stuart-Prower factor	Xa is component of prothrombinase complex, activates prothrombin
XI	Plasma thromboplastin antecedent	XIa activates factor IX
XII	Hageman (contact) factor	XIIa activates factor XI
XIII	Fibrin-stabilizing factor	XIIIa cross-links fibrin

The clotting system is commonly presented as two pathways of initiation: the extrinsic pathway (also known as the *tissue factor pathway*) and the intrinsic pathway (also known as the *contact activation pathway*). These two pathways join to form a common pathway, with activation of factor X, which proceeds to thrombin, fibrin, and clot formation. These pathways are controlled by anticoagulant proteins. The

extrinsic pathway is activated when there is vascular injury and blood escapes into the tissue, with activation of tissue factor. The process is a normal mechanism of hemostasis. Tissue factor (TF) (also called tissue thromboplastin) is abundant in vascular subendothelium, in the surrounding larger blood vessels, and body organs, particularly the skin, brain, lungs, kidney, and placenta. There also are receptors for TF on activated monocytes. With vessel trauma and bleeding, TF binds with high affinity to circulating activated factor VII (TF/VIIa), initiating the clotting pathway. TF mediates a number of changes in disease-related activities, including inflammation, tumor angiogenesis metastasis, cell migration, and clotting associated with atherosclerosis (Fig. 28.18). The extrinsic pathway is evaluated in vitro by adding TF to a sample of plasma and measuring the prothrombin time (time to form a fibrin clot).

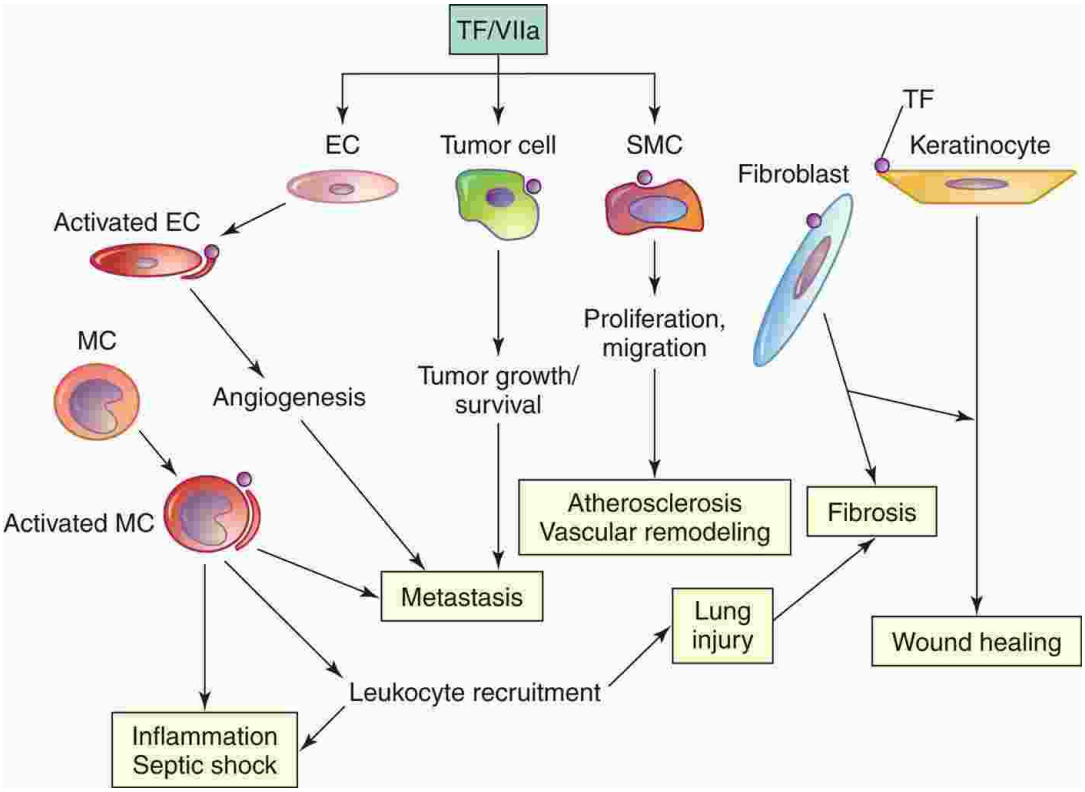

FIG. 28.18 Tissue Factor (TF) and Disease.
Factor VIIa signaling through TF expressed on the surface of cells mediates changes in disease-related cellular activities. EC, Endothelial cell; MC, monocyte/macrophage; SMC, smooth muscle cell. (Modified from Rao LV, Pendurthi UR. Tissue factor-factor VIIa signaling. *Arteriosclerosis, Thrombosis, and Vascular Biologyl*, 2005;25(1):47–56.)

A flowchart illustrates tissue factor (T F) and disease. 1. T F or factor 7 a. Leads to 2, 3, and 4. 2. E C. Leads to 5. 3. Tumor cell. Leads to 8. 4. S M C. Leads to 9. 5. Activated E C. Leads to 6. 6. Angiogenesis. Leads to 7. 7. Metastasis. 8. Tumor growth or survival. Leads to 7. 9. Proliferation and migration. Leads to 10. 10. Atherosclerosis and vascular remodeling. 11. M C. Leads to 12. 12. Activated M C. Leads to 7, 13, and 14. 13. Leukocyte recruitment. Leads to 15. 14. Inflammation and septic shock. 15. Lung injury. Leads to 16. 16. Fibrosis. 17. Fibroblast. Leads to 16 and 19. 18. T F on keratinocyte. Leads to 19. 19. Wound healing.

Factor XIIa (Hageman factor), prekallikrein (PK), and high-molecular-weight kininogen (HK; activates factor XII) initiate the intrinsic coagulation pathway through activation of the downstream substrate factor XI. The terms *intrinsic* or *contact* mean that the pathway is activated within the blood vessel by contact with anionic (negatively charged) surfaces (e.g., exposure of subendothelial collagen from vessel damage) or other substances without the action of TF. The intrinsic pathway is not a significant pathway for normal hemostasis but is a pathophysiologic surface defense mechanism against foreign proteins, microbial pathogens, and artificial materials. Individuals with deficiencies in intrinsic pathway components (e.g., factor XI, factor XII) do not have disruption of hemostasis or prolonged bleeding with the exception of hemophilia C (deficiency of factor XI that usually causes mild bleeding).

In the activation of the intrinsic pathway, factor XIIa recruits HK that is complexed with PK. Factor XIIa activates PK to kallikrein, which in turn generates more factor XIIa and amplifies the pathway. Factor XIIa also activates HK to release bradykinin (a proinflammatory mediator). Other exogenous artificial surfaces also can activate factor XII (e.g., use of tubing for blood flow during hemodialysis, cardiopulmonary bypass, or extracorporeal membrane oxygenation) and require anticoagulation therapy. More recently it has been discovered that naturally occurring polyphosphates (e.g., RNA and DNA from injury in arterioles), activated platelets, neutrophil extracellular traps, and cell membranes from bacteria can activate the intrinsic pathway and promote thrombin formation and thrombosis. The intrinsic pathway also may be essential for stabilization of thrombi and prevention of embolism.[20]

It is important to recognize that factor XIa and factor IXa can be generated by routes independent of factor XIIa (e.g., thrombin also can activate factor XI, as well as factors V and VIII). Thrombin activation of XI and IX is a feedback mechanism that amplifies the coagulation pathway and maintains the clot over time.

Activated platelets are important participants in clotting as previously described. The phosphatidylserine-rich surface produced during platelet activation provides a matrix on which several important complexes of clotting factors are formed. These include the intrinsic pathway's *tenase complex* (factor X and activated factors VIII and IX) that activates factor X and the *prothrombinase complex* (prothrombin and activated factors X and V) that activates prothrombin into thrombin. Thrombin then converts fibrinogen into fibrin, which polymerizes into a fibrin clot (see Fig. 28.16). Thrombin has broad activity in the inflammatory response. In addition to producing fibrin, thrombin is an activator of other coagulation proteins (e.g., factors V, VIII, XI, XIII), platelets (e.g., aggregation, degranulation), endothelial cells (e.g., up-regulation of adhesion molecules for leukocytes, increased NO, PGI_2, PDGF), and monocytes (e.g., cytokine secretion and increased receptors for endothelial cells). In addition to these pathways, RBCs can also promote clotting, particularly when there are diseases that affect the vasculature or there is an increase in the concentration of RBCs (see Emerging Science Box: Red Bloods Cells and Hemostasis).

Control of Hemostatic Mechanisms

Blood normally remains fluid despite the continual presence of clotting factors and platelets in the circulation. This is because under normal conditions, spontaneous activation of hemostasis is prevented by factors residing on the endothelial cell surface. These include thrombin inhibitors (e.g., antithrombin III), tissue factor inhibitors (e.g., tissue factor pathway inhibitor), and mechanisms for degrading activated clotting factors (e.g., protein C). When the endothelium is damaged, it transitions to the hemostatic action (vasoconstriction, platelet and clotting factor activation) described previously.

Antithrombin III (AT-III) is a circulating inhibitor of plasma serine proteases. AT-III is produced by the liver and binds to heparin sulfate found naturally on the surface of endothelial cells, or with heparin administered clinically to prevent thrombosis. Heparin induces a change in AT-III that greatly enhances its capacity to inhibit thrombin and other activated clotting factors. Under normal conditions the presence of endothelial cell heparan sulfate and the available AT-III in the circulation cooperate to protect the vessels from the effects of spontaneously activated thrombin. Acquired AT-III deficiencies can result from infection with bacteria that produce AT-III inhibitors, sepsis, liver disease, and nephrotic syndrome and lead to venous thrombosis and pulmonary embolism (PE).

Tissue factor pathway inhibitor (TFPI) is produced by endothelial cells and platelets and is the primary inhibitor of the initiation of blood clotting. TFPI forms complexes with and reversibly inhibits factor Xa. The resultant TFPI/Xa complex inhibits the extrinsic coagulation initiation complex TF/VIIa and prothrombinase (converts prothrombin to thrombin) and thus inhibits clotting.[21]

Thrombomodulin is a transmembrane thrombin-binding protein on the surface of endothelial cells and a receptor for thrombin. When thrombin binds to thrombomodulin, it no longer serves as a procoagulant and cannot activate platelets, convert fibrinogen to fibrin, or amplify fibrin generation. Protein C in the circulation binds to thrombomodulin-thrombin complex and is rapidly converted to activated protein C. Activated protein C, in association with a cofactor (protein S), degrades factors Va and VIIIa, inhibits fibrin formation, and inhibits coagulation. Deficiencies of AT-III, protein C, or protein S are important inherited causes of hypercoagulation (increased clotting). Expression of thrombomodulin and the endothelial cell protein C receptor is down-regulated by cytokines and other products of inflammation (e.g., IL-1α, TNF-α, endotoxin), thereby enhancing clot formation. Activated protein C inhibits the adhesion of neutrophils to the endothelium, but during inflammation neutrophil elastase enzymatically removes thrombomodulin from the endothelial cell surface and regulates clot formation.[22]

Retraction and Lysis of Blood Clots

After a clot is formed, it retracts, or "solidifies." Fibrin strands shorten, becoming denser and stronger, which approximates the edges of the injured vessel wall and

seals the site of injury. Retraction is facilitated by the large numbers of platelets trapped within the fibrin meshwork. The platelets contract and "pull" the fibrin threads closer together while releasing a factor that stabilizes the fibrin. Contraction expels serum from the fibrin meshwork. This process usually begins within a few minutes after a clot has formed, and most of the serum is expelled within 20 to 60 minutes.[23]

Lysis (breakdown) of blood clots is carried out by the fibrinolytic system (Fig. 28.19). Another plasma protein, plasminogen, is converted to plasmin by several products of coagulation and inflammation, especially by the enzymatic action of tissue plasminogen activator (t-PA). Endothelial cells express t-PA, which is activated maximally after binding to fibrin. Another activator of plasminogen is urokinase-like plasminogen activator (u-PA). The u-PA binds to a specific cellular u-PA receptor (u-PAR), causing activation of plasminogen. This urokinase is the major activator of fibrinolysis in the *extravascular*, or tissue, compartment, whereas t-PA is largely involved in *intravascular* fibrinolysis. Several cancers appear to use membrane-bound u-PA to digest intercellular matrix and greatly facilitate tumor invasion and metastasis. Both t-PA and u-PA have been used clinically to treat diseases associated with a blood clot (e.g., PE, myocardial infarction, stroke).

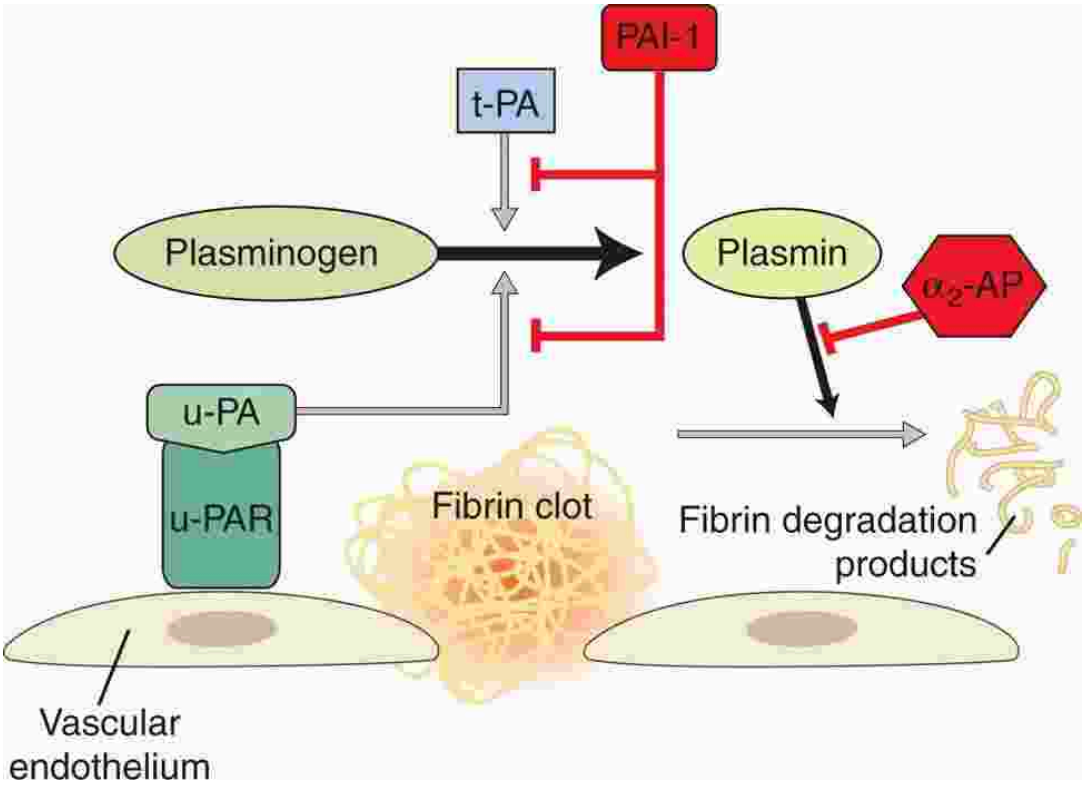

FIG. 28.19 The Fibrinolytic System.
Fibrinolysis is initiated by the binding of plasminogen to fibrin. Although tissue plasminogen activator *(t-PA)* initiates intravascular fibrinolysis, urokinase plasminogen activator *(u-PA)* is the major activator of fibrinolysis in tissue (extravascular). Plasmin digests the fibrin into smaller soluble pieces (fibrin degradation products). *u-PAR*, Urokinase-like plasminogen activator receptor.

An illustration, representing the fibrinolytic system, shows a layer of vascular endothelium with a fibrin clot between two cells. u-P A R attracts u-P A. P A I-1 and alpha 2-A P are inhibitors, former inhibits plasminogen and later inhibits plasmin.

As with most components of inflammation, plasmin interacts greatly with other factors. In addition to activation by t-PA and u-PA, plasminogen is activated to plasmin by thrombin, fibrin, factor XIIa, factor XIa, and kallikrein. Plasmin is proteolytic to several substrates, and cleaves fibronectin, fibrin, thrombospondin, laminin, and vWF. Cross-linked fibrin is deposited in tissues around wounds, inflammatory sites, and tumors. Fibrin removal is an important biologic process, for

intravascular and extravascular spaces, with various controlling mechanisms that can lead to abnormalities of fibrin accumulation and thrombotic events and can be a structural barrier to tumor invasion.

Plasmin is an enzyme that dissolves clots (fibrinolysis) by degrading fibrin and fibrinogen into fibrin degradation products (FDPs). A major FDP is D-dimer. Measurement of levels of circulating d-dimer (a small protein fragment of fibrin degradation) has been used for diagnosis because D-dimer can be elevated in cases of deep venous thrombosis (DVT) or PE.

Clinical Evaluation of the Hematologic System

Tests of Bone Marrow Function

Several abnormal conditions in the numbers or morphology of circulating blood cells or suspected infection of the marrow may justify further investigation of the bone marrow. Usually bone marrow is aspirated from the sternum or pelvis using a needle. In children a bone marrow aspirate can be obtained from the vertebrae or the femur. The aspirate is examined microscopically and may be cultured if infection (e.g., fungi, mycobacteria, brucellosis, typhoid fever) is suspected. Microscopic evaluation may also include flow cytometry, chromosome analysis, or polymerase chain reaction (PCR) related to the presence of atypical cells, the presence of atypical numbers of normal cells, and the absence of particular cell types. A normal bone marrow aspirate contains stromal cells (fibroblasts, macrophages, osteoblasts, adipocytes), stem cells (hematopoietic, mesenchymal, and endothelial), and immature and mature forms of blood cells (erythrocytes, leukocytes, platelets) (Fig. 28.20A). The differential cell count of a bone marrow aspirate involves examining approximately 400 nucleated cells under oil-immersion magnification and counting populations of cells differentiated on the basis of morphology. The relative number of each type of stem cell is expressed as a fraction of 400 (Table 28.9).

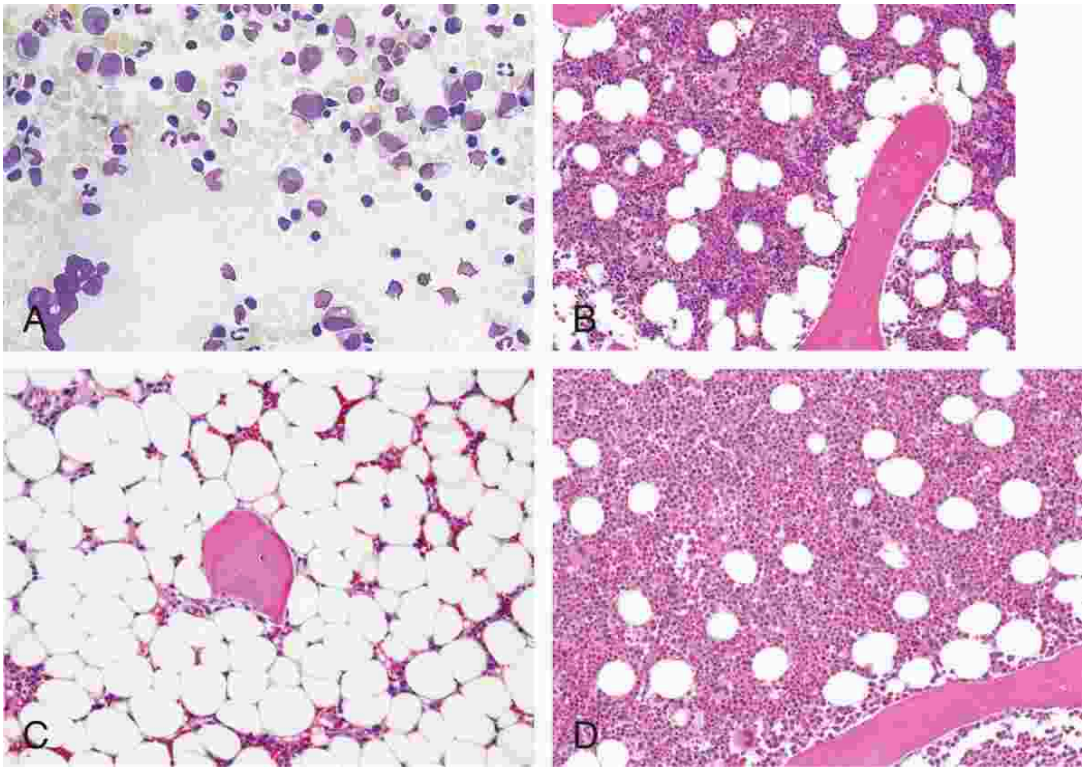

FIG. 28.20 Bone Marrow Samples.
(A) Normal bone marrow aspirate stained by the May-Grünwald/Giemsa technique. **(B–D)** Bone marrow biopsies representing conditions of normal cellularity **(B)**, hypocellularity **(C)** as would be seen in conditions of bone marrow depletion such as aplastic anemia, and hypercellularity **(D)** as seen in malignant conditions. (A and C, From Hoffbrand V, et al. *Color atlas of clinical hematology*, 4th edition. Philadelphia: Mosby; 2013; B–D, From Jaffe E. *Hematology*. Philadelphia: Saunders; 2010.)

Four photomicrographs, A, B, C, and D, show bone marrow samples. A. Normal bone marrow. There is a normal amount of hematopoietic cells. B. Hypocellularity. There is a decreased amount of hematopoietic cells. C. Aplastic Anemia or hypercellularity. There is an increased amount of large hematopoietic cells. D. Malignant. There are very less hematopoietic cells.

Table 28.9

Differential Cell Counts in Bone Marrow with Age

Developing Cells in Marrow	Birth	1 Month–1 Year	1–4 Years	4–12 Years	Adult
Erythrocytic series	14	8	19	21	20
Lymphocytic series	14	47	22	18	17
Eosinophilic series	3	3	6	3	3
Neutrophilic series	60	33	50	52	57
Myeloid/erythroid ratio	4:3	4:0	1:3	2:5	1:3

Developing Cells in Marrow	Birth	1 Month–1 Year	1–4 Years	4–12 Years	Adult
Erythrocytic series	14	8	19	21	20
Lymphocytic series	14	47	22	18	17
Eosinophilic series	3	3	6	3	3
Neutrophilic series	60	33	50	52	57
Myeloid/erythroid ratio	4:3	4:0	1:3	2:5	1:3

NOTE: Values are percentages of cell types counted during examination of a marrow specimen containing approximately 400 nucleated cells.

Bone marrow iron stores, primarily in macrophages, can be examined using special stains (e.g., Prussian blue) for iron-containing granules. A direct measure of iron stores also can be obtained only from liver biopsy specimens, although bone marrow is preferred because it is a safer procedure and because bone marrow is the immediate source of iron destined for erythrocyte production.

Bone marrow aspiration is an important diagnostic test for severe central defects in hematopoiesis (e.g., aplastic anemia, metabolic anemias arising from insufficient iron or inadequate EPO, thrombocytopenia, and neutropenia). Examination of the bone marrow is also useful to diagnose B-lymphocyte immune deficiencies, nonmalignant myeloproliferative disorders (e.g., polycythemia vera), and lymphoid/monocytic malignancies (e.g., leukemias, myelomas, lymphomas). This test can also be used to monitor the effects of chemotherapy on malignancies that have invaded the bone marrow. A marrow aspirate that is richly cellular implies normal or increased hematopoiesis but does not indicate whether marrow activity is effective.

Results from bone marrow aspiration are sometimes limited because this technique disturbs the architecture of the marrow and only provides an analysis of the general cellularity (numbers of constituent cells) of the marrow. On occasion, analysis of an aspirate may only suggest the presence of a malignancy or a central defect in hematopoiesis without being clearly confirmatory, or the sample may be inadequate for diagnosis of bone marrow fibrosis. In these cases the need for a bone marrow biopsy may be indicated.

During a biopsy, a special needle is used to obtain a "core" or cylindrical sample of bone and marrow in which the three-dimensional structure of the marrow is preserved. The biopsy specimens provide the most reliable and complete information about marrow cellularity (see Fig. 28.20B–D). Obtaining a bone marrow biopsy is, however, usually more painful and expensive than aspiration. Therefore biopsy is not performed unless insufficient information is obtained from aspiration.

Blood Tests

Blood tests provide information about the absolute and relative numbers of blood cells in a specimen of blood, as well as various structural and functional characteristics of the cells, and usually provide the initial justification for performing a bone marrow aspiration. Deviations from the normal differential distribution and the presence of abnormal or immature cells can reflect disease, physiologic states (e.g., pregnancy, infancy, old age), injury, or dysfunction in almost any part of the body. Blood tests that reflect chiefly hematologic disorders are listed in Table 28.10.

Table 28.10

Blood Tests for Hematologic Disorders

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
Erythrocytes		
Red cell count	Number (in millions) of erythrocytes/μL of blood	Altered erythropoiesis, anemias, hemorrhage, Hodgkin disease, leukemia
Mean corpuscular volume	Size of erythrocytes	Anemias, thalassemias
Mean corpuscular hemoglobin (MCH)	Amount of hemoglobin in each erythrocyte (by weight)	Anemias, hemoglobinopathy
Mean corpuscular hemoglobin concentration (MCHC)	Concentration of hemoglobin in each erythrocyte (percentage of erythrocyte occupied by hemoglobin)	Anemias, hereditary spherocytosis
Hemoglobin determination	Amount of hemoglobin (by weight)/dL of blood	Anemias
Hematocrit determination	Percentage of a given volume of blood that is occupied by erythrocytes	Hemorrhage, polycythemia, erythrocytosis, anemias, leukemia
Reticulocyte count	Number of reticulocytes/μL of blood (also expressed as percentage of reticulocytes in total red cell count)	Hyperactive or hypoactive bone marrow function

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
Erythrocyte osmotic fragility test	Cellular shape (biconcavity), structure of plasma membrane	Anemias, hemolytic disease caused by ABO or Rh blood group incompatibility, Hodgkin disease, polycythemia vera, thalassemia major
Hemoglobin electrophoresis	Relative percentage of different types of hemoglobin in erythrocytes	Sickle cell disease, sickle cell trait, hemoglobin C disease, hemoglobin C trait, thalassemias
Sickle cell test	Presence of hemoglobin S in erythrocytes	Sickle cell trait, sickle cell anemia
Glucose-6-phosphate dehydrogenase (G6PD) deficiency test	Deficiency of G6PD in erythrocytes	Hemolytic anemia
Hemoglobin Metabolism		
Serum ferritin determination	Depletion of body iron (potential deficiency of heme synthesis)	Iron deficiency anemias
Total iron-binding capacity (TIBC)	Amount of iron in serum plus amount of transferrin available in serum (mcg/dL)	Hemorrhage, iron deficiency anemia, hemochromatosis, hemosiderosis, iron overload, anemias, thalassemias
Transferrin saturation	Percentage of transferrin that is saturated with iron	Acute hemorrhage, hemochromatosis, hemosiderosis, sideroblastic anemia, iron deficiency anemia, iron overload, thalassemias
Porphyrin analysis (protoporphyrin analysis)	Concentration of protoporphyrin in erythrocytes (mcg/dL); an	Megaloblastic anemia, congenital erythropoietic porphyria

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
	indicator of iron-deficient erythropoiesis	
Direct antiglobulin test (DAT)	Antibody binding to erythrocytes	Hemolytic disease of the newborn, autoimmune hemolytic anemia, drug-induced hemolytic anemia, transfusion reaction
Antibody screen (indirect Coombs test)	Detection of antibodies to erythrocyte antigens (other than the ABO antigens)	Same as for DAT
Leukocytes		
Differential white cell count (absolute number of a type of leukocyte/μL of blood)	See below	See below
Neutrophil count	Neutrophils/μL	Myeloproliferative disorders, hematopoietic disorders, hemolysis, infection, immune deficiency
Lymphocyte count	Lymphocytes/μL	Infectious lymphocytosis, infectious mononucleosis, hematopoietic disorders, anemias, leukemia, lymphosarcoma, Hodgkin disease, primary immune deficiency
Plasma cell count	Plasma cells/μL	Infectious mononucleosis, lymphocytosis, plasma cell leukemia, primary immune deficiency
Monocyte count	Monocytes/μL	Hodgkin disease, infectious mononucleosis, monocytic leukemia, non-Hodgkin

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
		lymphoma, polycythemia vera, primary immune deficiency
Eosinophil count	Eosinophils/μL	Hematopoietic disorders
Basophil count	Basophils/μL	Chronic myelogenous leukemia, hemolytic anemias, Hodgkin disease, polycythemia vera
Platelets and Clotting Factors		
Platelet count	Number of circulating platelets (in thousands)/μL of blood	Anemias, multiple myeloma, myelofibrosis, polycythemia vera, leukemia, disseminated intravascular coagulation (DIC), hemolytic disease of the newborn, idiopathic thrombocytopenic purpura, transfusion reaction, lymphoproliferative disorders
Bleeding time	Duration of bleeding following a standardized superficial puncture wound of the skin, integrity of the platelet plug; measured in minutes following puncture	Leukemia, anemias, DIC, fibrinolytic activity, purpuras, hemorrhagic disease of the newborn, infectious mononucleosis, multiple myeloma, clotting factor deficiencies, thrombasthenia, thrombocytopenia, von Willebrand disease
Clot retraction test	Platelet number and function, fibrinogen quantity and use; measured in hours, which is required for expression of serum from a clot incubated in a test tube	Acute leukemia, aplastic anemia, factor XIII deficiency, increased fibrinolytic activity, Hodgkin disease, hyperfibrinogenemia or hypofibrinogenemia, idiopathic thrombocytopenic purpura, multiple myeloma, polycythemia vera, secondary

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
		thrombocytopenia, thrombasthenia
Platelet adhesion studies	Ability of platelets to adhere to foreign surfaces	Anemia, macroglobulinemia, Bernard-Soulier syndrome, multiple myeloma, myeloid metaplasia, plasma cell dyscrasias, thrombasthenia, thrombocytopathy, von Willebrand disease
Platelet aggregation tests	Ability of platelets to adhere to one another	Afibrinogenemia, Bernard-Soulier syndrome, thrombasthenia, hemorrhagic thrombocythemia, myeloid metaplasia, plasma cell dyscrasias, platelet-release defects, polycythemia vera, preleukemia, sideroblastic anemia, von Willebrand disease, Waldenström macroglobulinemia, hypercoagulability
Whole blood clotting time (Lee-White coagulation time)	Overall ability of blood to clot; measured in minutes in a test tube	Afibrinogenemia, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia, hypoprothrombinemia, leukemia
Circulating anticoagulants (immunoglobulin G [IgG] or M [IgM] antibodies that inhibit coagulation)	Presence of antibodies that neutralize clotting factors and inhibit coagulation, as indicated by prolonged clotting time, prothrombin time, or partial thromboplastin time	Afibrinogenemia, presence of fibrin-fibrinogen degradation products, macroglobulinemia, multiple myeloma, DIC, plasma cell dyscrasias

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
Partial thromboplastin time (PTT)	Effectiveness of clotting factors (except factors VII and VIII), effectiveness of intrinsic pathway of coagulation cascade; measured in seconds in a test tube	Presence of circulating anticoagulants, DIC, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia and afibrinogenemia, prothrombin deficiency, von Willebrand disease, acute hemorrhage
Prothrombin time (PT)	Effectiveness of activity of prothrombin, fibrinogen, and factors V, VII, and X; effectiveness of vitamin K–dependent coagulation factors of the extrinsic and common pathways of the coagulation cascade; measured in seconds in a test tube	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; DIC; deficiency of factors V, VII, or X; presence of fibrin degradation products, increased fibrinolytic activity, hemolytic jaundice, hemorrhagic disease of the newborn; acute leukemia, polycythemia vera, prothrombin deficiency, multiple myeloma
Thrombin time	Quantity and activity of fibrinogen; measured in seconds in a test tube	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; hemorrhagic disease of the newborn, polycythemia vera; increase in fibrin-fibrinogen degradation products; increased fibrinolytic activity
Fibrinogen assay	Amount of fibrinogen available for fibrin formation	Acute leukemia, congenital hypofibrinogenemia or afibrinogenemia, DIC, increased fibrinolytic activity, severe hemorrhage

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
Fibrin-fibrinogen degradation products (fibrin-fibrinogen split products)	Fibrinogenic activity as measured by levels of fibrin-fibrinogen degradation products (in mcg/mL of blood)	Transfusion reactions, DIC, internal hemorrhage in the newborn, deep vein thrombosis, pulmonary embolism

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
Erythrocytes		
Red cell count	Number (in millions) of erythrocytes/μL of blood	Altered erythropoiesis, anemias, hemorrhage, Hodgkin disease, leukemia
Mean corpuscular volume	Size of erythrocytes	Anemias, thalassemias
Mean corpuscular hemoglobin (MCH)	Amount of hemoglobin in each erythrocyte (by weight)	Anemias, hemoglobinopathy
Mean corpuscular hemoglobin concentration (MCHC)	Concentration of hemoglobin in each erythrocyte (percentage of erythrocyte occupied by hemoglobin)	Anemias, hereditary spherocytosis
Hemoglobin determination	Amount of hemoglobin (by weight)/dL of blood	Anemias
Hematocrit determination	Percentage of a given volume of blood that is occupied by erythrocytes	Hemorrhage, polycythemia, erythrocytosis, anemias, leukemia
Reticulocyte count	Number of reticulocytes/μL of blood (also expressed as percentage of reticulocytes in total red cell count)	Hyperactive or hypoactive bone marrow function
Erythrocyte osmotic fragility test	Cellular shape (biconcavity), structure of plasma membrane	Anemias, hemolytic disease caused by ABO or Rh blood group incompatibility, Hodgkin disease, polycythemia vera, thalassemia major
Hemoglobin electrophoresis	Relative percentage of different types of hemoglobin in erythrocytes	Sickle cell disease, sickle cell trait, hemoglobin C disease, hemoglobin C trait, thalassemias
Sickle cell test	Presence of hemoglobin S in erythrocytes	Sickle cell trait, sickle cell anemia
Glucose-6-phosphate dehydrogenase (G6PD) deficiency test	Deficiency of G6PD in erythrocytes	Hemolytic anemia
Hemoglobin Metabolism		
Serum ferritin determination	Depletion of body iron (potential deficiency of heme synthesis)	Iron deficiency anemias
Total iron-binding capacity (TIBC)	Amount of iron in serum plus amount of transferrin available in serum (mcg/dL)	Hemorrhage, iron deficiency anemia, hemochromatosis, hemosiderosis, iron overload, anemias, thalassemias
Transferrin saturation	Percentage of transferrin that is saturated with iron	Acute hemorrhage, hemochromatosis, hemosiderosis, sideroblastic anemia, iron deficiency anemia, iron overload, thalassemias
Porphyrin analysis (protoporphyrin analysis)	Concentration of protoporphyrin in erythrocytes (mcg/dL); an indicator of iron-deficient erythropoiesis	Megaloblastic anemia, congenital erythropoietic porphyria
Direct antiglobulin test (DAT)	Antibody binding to erythrocytes	Hemolytic disease of the newborn, autoimmune hemolytic anemia, drug-induced hemolytic anemia, transfusion reaction
Antibody screen (indirect Coombs test)	Detection of antibodies to erythrocyte antigens (other than the ABO antigens)	Same as for DAT
Leukocytes		
Differential white cell count (absolute number of a type of leukocyte/μL of blood)	See below	See below
Neutrophil count	Neutrophils/μL	Myeloproliferative disorders, hematopoietic disorders, hemolysis, infection, immune deficiency
Lymphocyte count	Lymphocytes/μL	Infectious lymphocytosis, infectious mononucleosis, hematopoietic disorders, anemias, leukemia, lymphosarcoma, Hodgkin disease, primary immune deficiency
Plasma cell count	Plasma cells/μL	Infectious mononucleosis, lymphocytosis, plasma cell leukemia, primary immune deficiency
Monocyte count	Monocytes/μL	Hodgkin disease, infectious mononucleosis, monocytic leukemia, non-Hodgkin lymphoma, polycythemia vera, primary immune deficiency
Eosinophil count	Eosinophils/μL	Hematopoietic disorders

(Continued...)

Cell Type and Test	Property Evaluated by Test	Possible Hematologic Cause of Abnormal Findings
Basophil count	Basophils/μL	Chronic myelogenous leukemia, hemolytic anemias, Hodgkin disease, polycythemia vera
Platelets and Clotting Factors		
Platelet count	Number of circulating platelets (in thousands)/μL of blood	Anemias, multiple myeloma, myelofibrosis, polycythemia vera, leukemia, disseminated intravascular coagulation (DIC), hemolytic disease of the newborn, idiopathic thrombocytopenic purpura, transfusion reaction, lymphoproliferative disorders
Bleeding time	Duration of bleeding following a standardized superficial puncture wound of the skin, integrity of the platelet plug; measured in minutes following puncture	Leukemia, anemias, DIC, fibrinolytic activity, purpuras, hemorrhagic disease of the newborn, infectious mononucleosis, multiple myeloma, clotting factor deficiencies, thrombasthenia, thrombocytopenia, von Willebrand disease
Clot retraction test	Platelet number and function, fibrinogen quantity and use; measured in hours, which is required for expression of serum from a clot incubated in a test tube	Acute leukemia, aplastic anemia, factor XIII deficiency, increased fibrinolytic activity, Hodgkin disease, hyperfibrinogenemia or hypofibrinogenemia, idiopathic thrombocytopenic purpura, multiple myeloma, polycythemia vera, secondary thrombocytopenia, thrombasthenia
Platelet adhesion studies	Ability of platelets to adhere to foreign surfaces	Anemia, macroglobulinemia, Bernard-Soulier syndrome, multiple myeloma, myeloid metaplasia, plasma cell dyscrasias, thrombasthenia, thrombocytopathy, von Willebrand disease
Platelet aggregation tests	Ability of platelets to adhere to one another	Afibrinogenemia, Bernard-Soulier syndrome, thrombasthenia, hemorrhagic thrombocythemia, myeloid metaplasia, plasma cell dyscrasias, platelet-release defects, polycythemia vera, preleukemia, sideroblastic anemia, von Willebrand disease, Waldenström macroglobulinemia, hypercoagulability
Whole blood clotting time (Lee-White coagulation time)	Overall ability of blood to clot; measured in minutes in a test tube	Afibrinogenemia, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia, hypoprothrombinemia, leukemia
Circulating anticoagulants (immunoglobulin G [IgG] or M [IgM] antibodies that inhibit coagulation)	Presence of antibodies that neutralize clotting factors and inhibit coagulation, as indicated by prolonged clotting time, prothrombin time, or partial thromboplastin time	Afibrinogenemia, presence of fibrin-fibrinogen degradation products, macroglobulinemia, multiple myeloma, DIC, plasma cell dyscrasias
Partial thromboplastin time (PTT)	Effectiveness of clotting factors (except factors VII and VIII), effectiveness of intrinsic pathway of coagulation cascade; measured in seconds in a test tube	Presence of circulating anticoagulants, DIC, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia and afibrinogenemia, prothrombin deficiency, von Willebrand disease, acute hemorrhage
Prothrombin time (PT)	Effectiveness of activity of prothrombin, fibrinogen, and factors V, VII, and X; effectiveness of vitamin K–dependent coagulation factors of the extrinsic and common pathways of the coagulation cascade; measured in seconds in a test tube	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; DIC; deficiency of factors V, VII, or X; presence of fibrin degradation products, increased fibrinolytic activity, hemolytic jaundice, hemorrhagic disease of the newborn; acute leukemia, polycythemia vera, prothrombin deficiency, multiple myeloma
Thrombin time	Quantity and activity of fibrinogen; measured in seconds in a test tube	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; hemorrhagic disease of the newborn, polycythemia vera; increase in fibrin-fibrinogen degradation products; increased fibrinolytic activity
Fibrinogen assay	Amount of fibrinogen available for fibrin formation	Acute leukemia, congenital hypofibrinogenemia or afibrinogenemia, DIC, increased fibrinolytic activity, severe hemorrhage
Fibrin-fibrinogen degradation products (fibrin-fibrinogen split products)	Fibrinogenic activity as measured by levels of fibrin-fibrinogen degradation products (in mcg/mL of blood)	Transfusion reactions, DIC, internal hemorrhage in the newborn, deep vein thrombosis, pulmonary embolism

DAT, Direct antiglobulin test; *DIC*, disseminated intravascular coagulation.

Pediatrics and the Hematologic System

Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood. Table 28.11 lists normal ranges during infancy and childhood. The immediate rise in values is the result of accelerated hematopoiesis during fetal life and the increased numbers of cells that result from the trauma of birth and cutting of the umbilical cord.

Table 28.11

Mean Hematologic Differential Counts from Birth to Adulthood

Hematologic Differential	Newborn (Cord Blood)	2 Weeks of Age	3 Months of Age	6 Months to 6 Years of Age	7–12 Years of Age	Adult
Hemoglobin (g/dl)	16.8	16.5	12	12	13	13
Hematocrit (%)	55	50	36	37	38	40
Reticulocytes (%)	5	1	1	1	1	1
Leukocytes (WBCs/mm^3)	18,000	12,000	12,000	10,000	8000	8000
Neutrophils (%)	61	40	30	45	55	55
Lymphocytes (%)	31	48	63	48	38	35
Eosinophils (%)	2	3	2	2	2	2
Monocytes (%)	6	9	5	5	5	5
Platelets ($10^3/mm^3$)	290	252	150–400	150–400	150–400	150–400

Hematologic Differential	Newborn (Cord Blood)	2 Weeks of Age	3 Months of Age	6 Months to 6 Years of Age	7–12 Years of Age	Adult
Hemoglobin (g/dl)	16.8	16.5	12	12	13	13
Hematocrit (%)	55	50	36	37	38	40
Reticulocytes (%)	5	1	1	1	1	1
Leukocytes (WBCs/mm^3)	18,000	12,000	12,000	10,000	8000	8000
Neutrophils (%)	61	40	30	45	55	55
Lymphocytes (%)	31	48	63	48	38	35
Eosinophils (%)	2	3	2	2	2	2
Monocytes (%)	6	9	5	5	5	5
Platelets ($10^3/mm^3$)	290	252	150–400	150–400	150–400	150–400

WBCs, White blood cells.

Average blood volume in the full-term neonate is about 85 mL/kg of body weight. The premature infant has a slightly larger blood volume of 90 mL/kg of body weight. In both full-term and premature infants, blood volume decreases during the first few months. Thereafter the average blood volume is about 75 to 80 mL/kg, which is similar to that of older children and adults.

The hypoxic intrauterine environment stimulates EPO production in the fetus and accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) in the newborn. After birth, the oxygen from the lungs

saturates arterial blood, and more oxygen is delivered to the tissues. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of EPO and the rate of blood cell formation decrease. The active rate of fetal erythropoiesis is reflected by the large numbers of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. After birth, the number of reticulocytes decreases by 50% every 12 hours, so it is rare to find an elevated reticulocyte count after the first week of life. During this period of rapid growth, the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, the normal erythrocyte life span is 60 to 80 days; in premature infants, it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—100 to 120 days.

The postnatal fall in hemoglobin and hematocrit values is more marked in premature infants than it is in full-term infants. Fetal hemoglobin has higher affinity for oxygen compared to adult globins, which presumably allows for efficient maternal–embryonic gas exchange in the placental environment. In preschool and school-aged children, hemoglobin, hematocrit, and RBC counts gradually rise. Metabolic processes within the erythrocytes of neonates differ significantly from those found in erythrocytes of normal adults. The relatively young population of erythrocytes in newborns consumes greater quantities of glucose than do erythrocytes in adults. Platelet counts in full-term neonates are comparable with those in adults and remain so throughout infancy and childhood.

Most coagulation factors (both procoagulants and anticoagulants) in children reach adult levels by 6 months of age, and some not until adolescence. Children have quantitative and qualitative differences in clotting factors that result in decreased risk for thrombosis without increased risk for bleeding (developmental hemostasis) because the reduction of procoagulant and anticoagulant proteins is balanced. Laboratory values for hemostasis (e.g., prothrombin time and activated partial thromboplastin time) are referenced by age.[24]

WBCs develop and mature during fetal life, including neutrophils, monocyte-macrophages, eosinophils, and lymphocytes, but the function of the cells at birth is weak because the cells are immature. At birth the lymphocyte count is high, and it continues to rise during the first year of life. Then it steadily declines until the lower value seen in adults is reached. The lymphocytes of children also tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. A possible explanation is that children tend to have more frequent viral infections, some of which are subclinical, and are receiving vaccinations, both of which are associated with atypical lymphocytes.

The neutrophil count, like the lymphocyte count, is high at birth and rises during the first days of life. After 2 weeks, the neutrophil count falls to within or below the normal adult range. Although the exact age can vary, by approximately 7 years of age, the neutrophil count is the same as that of an adult. The eosinophil count is higher in the first year of life and higher in children than in teenagers or adults.

Monocyte counts also are high in the first year of life but then decrease to adult levels.

Newborn infants are at risk for impaired phagocytosis, bacterial infections, and delayed wound healing. Immature lymphocytes also increase the risk for viral infection, and there is a weak response to the production of antibodies and a poor response to foreign antigens. Protection against infectious disease is provided by passive IgG antibody transfer from the mother transplacentally and in breast milk. By 2 months of age the WBCs have matured enough for the infant to begin receiving protection from infectious disease by vaccination. As the child ages, immunity is further enhanced by intercurrent infection and vaccinations, with the formation of antibodies and memory T cells that provide lifelong protection.

Aging and the Hematologic System

Blood composition changes little with age, although some components may be altered by iron deficiency. Values of total serum iron level, total iron-binding capacity, and intestinal iron absorption are all decreased somewhat in elderly persons. The erythrocyte life span is normal, although the erythrocytes are replenished more slowly after bleeding and their deformability decreases with advanced age.[25] Hemoglobin levels may be low, and the plasma membranes of erythrocytes become increasingly fragile, with portions being lost, presumably because of physical trauma inflicted during circulation. Chronic inflammation and the presence of chronic disease, including diabetes mellitus, chronic heart disease, chronic renal insufficiency, and Parkinson disease, are associated with suppressed erythropoiesis and anemia occurring in older adults.[26] Lymphocyte function decreases with age, causing changes in cellular immunity and some decline in T-cell function. The humoral immune system is less able to respond to antigenic challenge and to vaccination.

Platelet count remains relatively stable during middle age (25 to 60 years old) but falls in older people (greater than 60 years),[27] yet platelet adhesiveness increases, which may be related to oxidative stress. Fibrinogen levels and levels of factors V, VII, and IX and also vWF tend to be increased. In addition, thrombin generation and platelet activation are enhanced in older adults. Consequently, there is an increased incidence of venous thromboembolism.[28]

Summary Review

Components of the Hematologic System

1. Blood consists of a variety of components—about 91% water and 9% solutes. In adults, the total blood volume is approximately 5.5 L.
2. Plasma, a complex aqueous liquid, contains two major groups of plasma proteins: albumins and globulins.

3. The cellular elements of blood are the red blood cells (erythrocytes), white blood cells (leukocytes), and platelets.
4. Erythrocytes are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and approximately 42% in women. Erythrocytes are responsible for tissue oxygenation.
5. Leukocytes are fewer in number than erythrocytes and constitute approximately 5000 to 10,000 cells/mm^3 of blood. Leukocytes defend the body against infection and remove dead or injured host cells.
6. Leukocytes are classified as either granulocytes (neutrophils, eosinophils, basophils) or agranulocytes (monocytes/macrophages, lymphocytes, natural killer cells).
7. The mononuclear phagocyte system (MPS) is composed of monocytes in bone marrow and peripheral blood and macrophages in tissue. Cells of the MPS ingest and destroy unwanted materials, such as foreign protein particles, circulating immune complexes, microorganisms, debris from dead or injured cells, defective or injured erythrocytes, and dead neutrophils.
8. Platelets are irregularly shaped anuclear cytoplasmic fragments. Platelets are essential for blood coagulation and control of bleeding.
9. The lymphoid organs are sites of residence, proliferation, differentiation, or function of lymphocytes and mononuclear phagocytes.
10. 10 The spleen is the largest lymphoid organ and functions as the site of fetal hematopoiesis, filters and cleanses the blood, and acts as a reservoir for lymphocytes and other blood cells.
11. The lymph nodes are the site of development or activity of large numbers of lymphocytes, monocytes, and macrophages.

Development of Blood Cells

1. Bone marrow consists of red (active or hematopoietic) marrow and yellow (inactive) marrow.
2. The hematopoietic marrow consists of a variety of cellular and molecular microenvironments called niches. Niches support the hematopoietic stem cells by direct cell-to-cell signaling and production of growth factors and cytokines important for retention, expansion, maintenance, and quiescence.
3. The bone marrow contains multiple populations of stem cells. Hematopoietic stem cells develop into blood cells. Mesenchymal stem cells develop into osteoblasts, adipocytes, chondrocytes, sinusoidal endothelial cells, fibroblasts, and other stromal cells.
4. Osteoblasts (responsible for construction of bone) and osteoclasts (remodel bone by resorption) produce cytokines that affect proliferation and maintenance of hematopoietic cells.
5. Specific hematopoietic growth factors (e.g., colony-stimulating factors) are necessary for the adequate production of myeloid, erythroid, lymphoid, and

megakaryocytic lineages.

6. Hematopoiesis, or blood cell production, occurs in the liver and spleen of the fetus and in the bone marrow after birth.
7. Hematopoiesis involves two stages: mitotic division (i.e., proliferation) and maturation (i.e., differentiation). Each type of blood cell has parent cells called stem cells.
8. Hematopoiesis continues throughout life to replace blood cells that grow old and die, are killed by disease, or are lost through bleeding.
9. Regulation of erythropoiesis (development of red blood cells) is mediated by erythropoietin, which is secreted by the kidneys in response to tissue hypoxia. Erythropoietin causes a compensatory increase in erythrocyte production if the oxygen content of the blood decreases because of anemia, high altitude, or pulmonary disease.
10. Hemoglobin, the oxygen-carrying protein of the erythrocyte, enables the blood to transport 100 times more oxygen than could be transported dissolved in plasma alone.
11. Erythropoiesis depends on the presence of vitamins (especially vitamin B_{12}, folate, vitamin B_6, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin E).
12. The iron cycle reutilizes iron released from old or damaged erythrocytes. Iron binds to transferrin in the blood, is transported to macrophages, and is stored in the cytoplasm as ferritin.
13. Iron homeostasis is controlled by hepcidin, a small hormone produced by hepatocytes, which regulates ferroportin, the principal transporter of iron from stores in hepatocytes and macrophages and from intestinal cells that absorb dietary iron.
14. Myelopoiesis is the development of granulocytes (neutrophils, eosinophils, and basophils) and monocytes from the differentiation of myeloid progenitor cells in the bone marrow. Granulocytes are released into the blood and are either functioning cells that circulate in the blood or stored cells that are stored around the walls of blood vessels (marginating storage pool). Monocytes are released into the blood and travel to various tissues to become tissue macrophages and dendritic cells.
15. Lymphocytes, which are generated from lymphoid progenitor cells in a process called lymphopoiesis, are released into the bloodstream to undergo further maturation in the primary and secondary lymphoid organs.
16. Platelets develop from megakaryocytes by a process called thrombopoiesis, which is controlled by thrombopoietin. During thrombopoiesis, megakaryocytes undergo mitosis but not cell division and the cytoplasm and plasma membrane fragment into platelets.

Mechanisms of Hemostasis

1. Hemostasis, or arrest of bleeding, involves (1) vasoconstriction (vasospasm), (2) formation of a platelet plug, (3) activation of the clotting cascade, (4) formation of a blood clot, and (5) clot retraction and clot dissolution.
2. The normal vascular endothelium prevents spontaneous clotting by producing factors such as nitric oxide (NO) and prostacyclin I_2 (PGI_2) that relax the vessels and prevent platelet activation.
3. Platelet activation involves three linked processes: (1) adhesion, (2) activation, and (3) aggregation.
4. A blood clot is a meshwork of protein strands that stabilizes the platelet plug. The strands are made of fibrin. Fibrin is the end product of the coagulation cascade.
5. Lysis of blood clots is the function of the fibrinolytic system. Plasmin, a proteolytic enzyme, splits fibrin and fibrinogen into fibrin degradation products that dissolve the clot.

Clinical Evaluation of the Hematologic System

1. Tests of bone marrow function include bone marrow aspiration and bone marrow biopsy.
2. Cells contained in the marrow specimen are assessed with respect to (a) relative numbers of stem cells and their developing daughter cells, and (b) morphologic structure.

Pediatrics and the Hematologic System

1. Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood. Platelet counts in full-term neonates are comparable with those in adults and remain so throughout infancy and childhood.
2. White blood cells develop during fetal life but the function of the cells at birth is weak as the cells are immature.
3. Newborn infants are at risk for impaired phagocytosis, bacterial infections, and delayed wound healing. Immature lymphocytes also increase risk for viral infection and there is a weak response to the production of antibodies and a poor response to foreign antigens.

Aging and the Hematologic System

1. Blood composition changes little with age. Erythrocyte replenishment may be delayed after bleeding, presumably because of iron deficiency.
2. Lymphocyte function appears to decrease with age. Particularly affected is a decrease in cellular immunity.

3. Platelet numbers decrease with age, but adhesiveness increases.

Emerging Science BoxTumor Associated Neutrophils

The role of tumor-associated neutrophils (TANs) in cancer is complex and can include both the killing of cancer cells (N1 neutrophils) or the promotion of tumor growth and metastasis (N2 neutrophils). The variance in function is related to significant genetic variation among populations of neutrophils. Tumors can induce myelopoiesis and recruit immature neutrophils to the tumor microenvironment (TME) where these cells undergo reprogramming and transitioning to myeloid-derived suppressor cells with a pro-tumorigenic phenotype (N2 neutrophils). These N2 neutrophils produce a broad range of mediators and growth factors to promote DNA instability resulting in tumor growth, angiogenesis, and metastasis. Tumor cells are also captured by neutrophil extracellular traps which facilitate their migration to distant sites. N2 neutrophils also suppress the anti-tumor activity of tumor-infiltrating cytotoxic T lymphocytes and exclude these cells from the TME. An elevated neutrophil-to-lymphocyte ratio (NLR) has been correlated with poor responses to cancer therapy. Realization of the pro-tumorigenic activities of N2 TANs has resulted in the evaluation of a range of adjunctive strategies targeting the recruitment of these cells and/or the harmful activities of their mediators of immunosuppression.Data from Rapoport BL, et al. Emerging Science BoxRed Bloods Cells and Hemostasis

Red blood cells (RBCs) contribute to clotting and hemostasis by the expression of adhesive proteins, aggregation, hemolysis, and release of extracellular microvesicles and interaction with platelets and fibrin. Exposure of phosphatidylserine from the RBC wall promotes clotting via thrombin formation through a factor XII-dependent pathway without tissue factor activity. RBC interaction with the endothelial wall of vessels is normally minimal, but with pathological conditions such as retinal venous occlusion, hypertension, diabetic mellitus, and stroke there is increased adhesion of RBCs and increased thrombosis. Erythrocyte volume (hematocrit) affects blood viscosity and flow velocity, particularly in veins. High hematocrit slows blood flow velocity and is associated with thrombus formation. There is an increase in platelet margination, adhesion, and activation and prothrombotic activity. Slower flow velocity also

promotes rouleaux formation (linear arrays of stacked red blood cells) and promotes thrombus formation particularly in veins. On the other hand, low hematocrit is associated with bleeding. RBCs are incorporated into blood clots and can play a role in the contraction of clots by platelets, adherence to fibrin, and the lysis of clots by fibrinolysis. RBC modulation of clot structure affects clot stability, embolization, and the efficacy of anticoagulation and therapeutic thrombolysis. Changes in RBC membrane deformability with increased stiffness or rigidity of RBC walls makes movement through the microvasculature difficult, increases thrombotic potential, and enhances platelet aggregation. These changes are associated with diseases such as autoimmune hemolytic anemia, sickle cell disease, thalassemia, hereditary spherocytosis, and xerocytosis. The multifactorial mechanisms of the role of RBCs is complex and not fully understood, emphasizing the need for further investigation.Data from Alamin AA. Alterations of erythrocyte function involve either insufficient or excessive numbers of erythrocytes in the circulation or normal numbers of cells with abnormal components. Anemias are conditions in which there are too few erythrocytes or an insufficient volume of erythrocytes in the blood. Polycythemias are conditions in which erythrocyte number or volume is excessive. Each of these conditions has many causes and shares pathophysiologic manifestations with other disease states.

Disorders involving white blood cells (leukocytes) can range from increased numbers of leukocytes (leukocytosis) in response to infections, or proliferative disorders (e.g., leukemia), to decreased numbers of leukocytes (e.g., leukopenia). Many hematologic and nonhematologic malignancies metastasize to the bone marrow and affect leukocyte production. Thus, a large portion of this chapter is devoted to malignant disease.

The primary role of clotting (hemostasis) is to stop bleeding through an interaction of endothelium lining the vessels, platelets, and clotting factors. Several disease states increase or decrease clotting in at least one of the three main components of the clotting process.

Anemia

Classification and General Characteristics

Anemia is a reduction in the total number of erythrocytes in the circulating blood or a decrease in the quality or quantity of hemoglobin. The term anemia refers to a true decrease in erythrocyte number, rather than a relative decrease due to increases in plasma volume (hemodilution). The overall prevalence of anemia is approximately 10% to 15% of individuals in the United States affecting approximately 40% of men and 22% of women over the age of 85.[1]

Anemias commonly result from (1) blood loss (acute or chronic), (2) impaired erythrocyte production, (3) increased erythrocyte destruction, or (4) a combination of these three factors (Fig. 29.1). Anemias are classified based on etiology (e.g., acute blood loss or anemia of inflammation [AI]) or by the changes that affect the size, shape, or substance of the erythrocyte. The most common classification of anemias is based on the changes that affect the cell's size and hemoglobin content (Table 29.1). Terms used to identify anemias reflect these characteristics. Terms that end with *-cytic* refer to cell size, and those that end with *-chromic* refer to hemoglobin content. Additional terms describing erythrocytes found in some anemias are **anisocytosis** (assuming various sizes) and **poikilocytosis** (assuming various shapes).

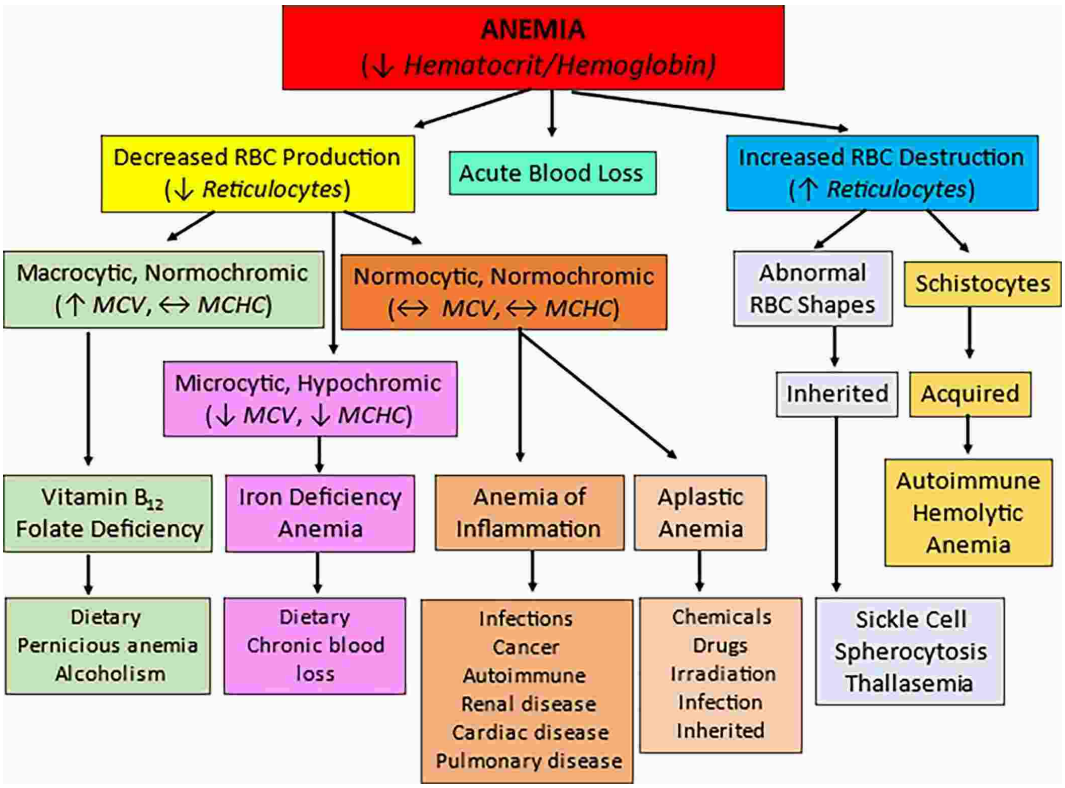

FIG. 29.1 Classification of Anemia.
Anemias can be classified into three major categories: acute blood loss, decreased RBC production in which reticulocytes are decreased, and increased RBC destruction in which reticulocyte counts are increased. Further classification relies on the size (*-cytic*), color (*-chromic*), and shape of the cells. Based on these factors, the most common types and causes of anemia can be identified. *MCHC*, Mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume.

A hierarchy chart represents the classification of anemia. 1. Anemia (decreased hematocrit or hemoglobin). Two classifications: 2 and 3. 2. Decreased R B C production (reduced reticulocytes). Three classifications: 5, 6, and 9. 3. Acute blood loss (equilibrium M C V, equilibrium M C H C). 4. Increased R B C destruction (reduced reticulocytes). Two classifications: 7 and 8. 5. Macrocytic; normochromic

(increased M C V, equilibrium M C H C). One classification: 12. 6. Normocytic; normochromic (decreased M C V, decreased M C H C). Two classifications: 14 and 15. 7. Abnormal R B C shapes. One classification: 10. 8. Schistocytes. One classification: 11. 9. Macrocytic, hypochromic (equilibrium M C V, equilibrium M C H C). One classification: 13. 10. Inherited. One classification: 20. 11. Acquired. One classification: 21. 12. Vitamin B 12; folate deficiency. One classification: 16. 13. Iron deficiency; anemia. One classification: 17. 14. Anemia of inflammation. One classification: 18. 15. Aplastic anemia. One classification: 19. 16. Dietary; pernicious anemia; alcoholism. 17. Dietary; chronic blood loss. 18. Infections; cancer; autoimmune; renal disease; cardiac disease; pulmonary disease. 19. Chemicals; drugs; irradiation; infection; inherited. 20. Sickle cell; spherocytosis; thalassemia. 21. Autoimmune; hemolytic; anemia.

Table 29.1

Morphologic Classification of Anemias

Structure of Erythrocytes	Name and Mechanism of Anemia	Primary Cause
Macrocytic-normochromic anemia: large, abnormally shaped erythrocytes, normal hemoglobin concentrations	Pernicious anemia: lack of vitamin B_{12}; abnormal DNA and RNA synthesis in erythroblast; premature cell death	Congenital or acquired deficiency of intrinsic factor (IF); genetic disorder of DNA synthesis
	Folate deficiency anemia: lack of folate; premature cell death	Dietary folate deficiency
Microcytic-hypochromic anemia: small, abnormally shaped erythrocytes and reduced hemoglobin concentration	Iron deficiency anemia: lack of iron for hemoglobin; insufficient hemoglobin	Chronic blood loss, dietary iron deficiency, disruption of iron metabolism or iron cycle
	Sideroblastic anemia: dysfunctional iron uptake by erythroblasts and defective porphyrin and heme synthesis	Congenital dysfunction of iron metabolism in erythroblasts, acquired dysfunction of iron metabolism as result of myelodysplastic syndromes, dietary deficiencies, drugs or toxins

Structure of Erythrocytes	Name and Mechanism of Anemia	Primary Cause
Normocytic-normochromic anemia: normal size, normal hemoglobin concentration	Posthemorrhagic anemia: blood loss	Increased erythropoiesis; iron depletion
	Aplastic anemia: insufficient erythropoiesis	Depressed stem cell proliferation
	Anemia of Inflammation; diminished erythropoiesis	Defects in iron metabolism
Anemia with abnormal cell shapes or the presence of schistocytes	Hemolytic anemia: premature destruction (lysis) of mature erythrocytes in circulation	Autoimmune targeting of erythrocyte antigens
	Sickle cell anemia: abnormal hemoglobin synthesis, abnormal cell shape with susceptibility to damage, lysis, and phagocytosis	Congenital dysfunction of hemoglobin synthesis
	Hereditary spherocytosis: destruction of mature erythrocytes that have abnormal cell membranes and spherical shapes	Genetic mutations leading to changes in erythrocyte membrane structure

Structure of Erythrocytes	Name and Mechanism of Anemia	Primary Cause
	Thalassemia: impaired synthesis of α- or β-chain of hemoglobin A; phagocytosis	Genetic defect of globin synthesis

Structure of Erythrocytes	Name and Mechanism of Anemia	Primary Cause
Macrocytic-normochromic anemia: large, abnormally shaped erythrocytes, normal hemoglobin concentrations	Pernicious anemia: lack of vitamin B_{12}; abnormal DNA and RNA synthesis in erythroblast; premature cell death	Congenital or acquired deficiency of intrinsic factor (IF); genetic disorder of DNA synthesis
	Folate deficiency anemia: lack of folate; premature cell death	Dietary folate deficiency
Microcytic-hypochromic anemia: small, abnormally shaped erythrocytes and reduced hemoglobin concentration	Iron deficiency anemia: lack of iron for hemoglobin; insufficient hemoglobin	Chronic blood loss, dietary iron deficiency, disruption of iron metabolism or iron cycle
	Sideroblastic anemia: dysfunctional iron uptake by erythroblasts and defective porphyrin and heme synthesis	Congenital dysfunction of iron metabolism in erythroblasts, acquired dysfunction of iron metabolism as result of myelodysplastic syndromes, dietary deficiencies, drugs or toxins
Normocytic-normochromic anemia: normal size, normal hemoglobin concentration	Posthemorrhagic anemia: blood loss	Increased erythropoiesis; iron depletion
	Aplastic anemia: insufficient erythropoiesis	Depressed stem cell proliferation
	Anemia of Inflammation; diminished erythropoiesis	Defects in iron metabolism
Anemia with abnormal cell shapes or the presence of schistocytes	Hemolytic anemia: premature destruction (lysis) of mature erythrocytes in circulation	Autoimmune targeting of erythrocyte antigens
	Sickle cell anemia: abnormal hemoglobin synthesis, abnormal cell shape with susceptibility to damage, lysis, and phagocytosis	Congenital dysfunction of hemoglobin synthesis
	Hereditary spherocytosis: destruction of mature erythrocytes that have abnormal cell membranes and spherical shapes	Genetic mutations leading to changes in erythrocyte membrane structure
	Thalassemia: impaired synthesis of α- or β-chain of hemoglobin A; phagocytosis	Genetic defect of globin synthesis

DNA, Deoxyribonucleic acid; *RNA*, ribonucleic acid.

Clinical Manifestations

The main clinical effect of anemia is a **reduced oxygen-carrying capacity** of the blood resulting in tissue hypoxia. Symptoms of anemia vary, depending on the body's ability to compensate for the reduced oxygen-carrying capacity. Anemia that is mild and starts gradually is usually easier to compensate and may cause problems for the individual only during

physical exertion. As red cell reduction continues, symptoms become more pronounced and alterations in specific organs and compensation effects are more apparent. Compensation generally involves the cardiovascular, respiratory, and hematologic systems (Fig. 29.2).

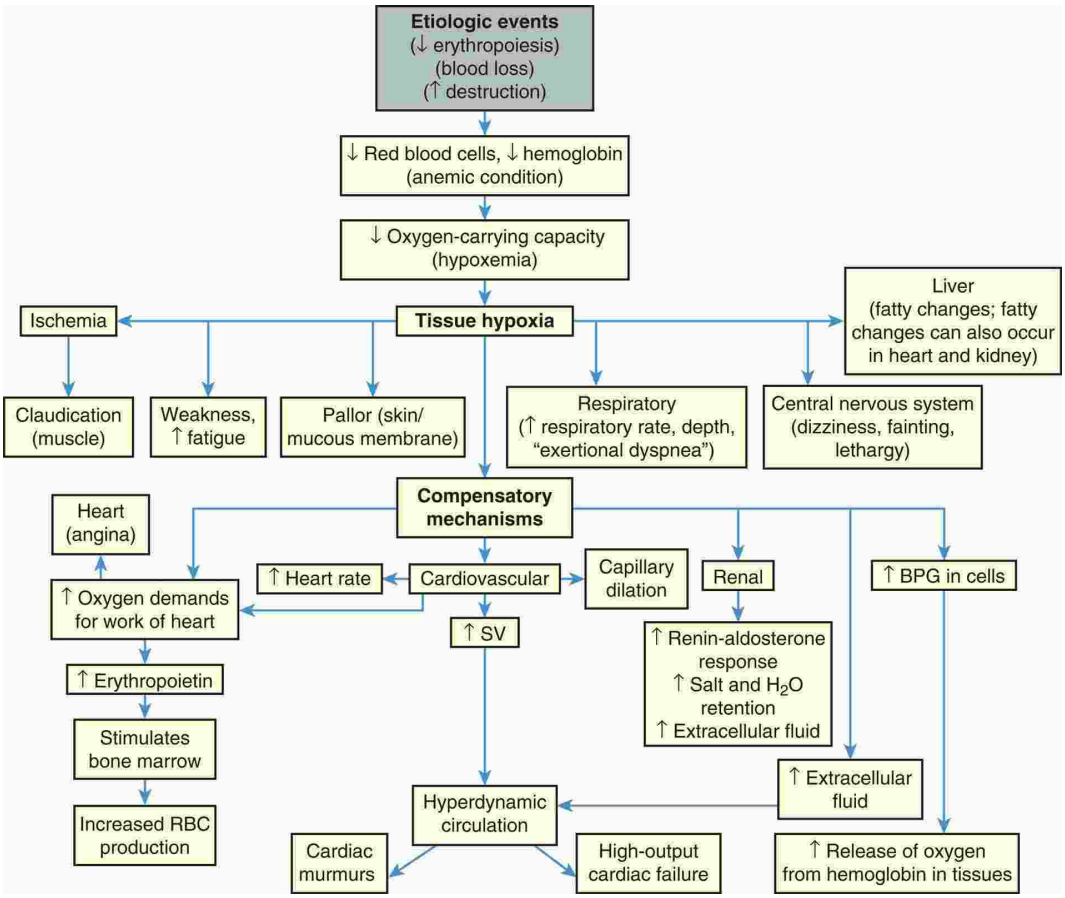

FIG. 29.2 Progression and Manifestations of Anemia.
BPG, Bisphosphoglycerate; *SV*, stroke volume.

A flowchart shows the progression and manifestations of anemia. 1. Etiologic events (decreased erythropoiesis, blood loss, increased destruction). Progresses to 2. 2. Decreased red blood cells, decreased hemoglobin (anemic condition). Progresses to 3. 3. Decreased oxygen-carrying capacity (hypoxemia). Progresses to 4. 4. Tissue hypoxia. Progresses to 5, 6, 8, 9, 10, and 11. 5. Ischemia. Progresses to 7. 6. Liver (fatty changes; fatty changes can also occur in heart and kidney). 7. Claudication (muscle). 8. Weakness (increased fatigue). 9. Pallor (skin or mucous membrane). 10. Respiratory (increased respiratory rate, depth, exertional dyspnea). 11. Central nervous system

(dizziness, fainting, lethargy). 12. Compensatory mechanisms. Progresses to 14, 16, 18, 19, and 28. 13. Heart (angina). 14. Increased oxygen demands for work of heart. Progresses to 21. 15. Increased heart rate. 16. Cardiovascular. Progresses to 20. 17. Capillary dilation. 18. Renal. Progresses to 22. 19. Increased B P G in cells. Progresses to 29. 20. Increased S V. Progresses to 25. 21. Increased erythropoietin. Progresses to 22. 22. Increased renin-aldosterone response, increased salt and water extracellular fluid. 23. Stimulates bone marrow. Progresses to 24. 24. Increased R B C production. 25. Hyperdynamic circulation. Progresses to 26 and 27. 26. Cardiac murmurs. 27. High-output cardiac failure. 28. Increased extracellular fluid. Progresses to 25. 29. Increased release of oxygen from hemoglobin in tissues.

A reduction in the number of blood cells causes a reduction in the consistency and volume of blood. Initial compensation for cellular loss is movement of interstitial fluid into the blood, causing an increase in plasma volume. This movement maintains an adequate blood volume, but the viscosity (thickness) of the blood decreases. The "thinner" blood flows faster and more turbulently than normal blood, causing a hyperdynamic circulatory state. This hyperdynamic state creates cardiovascular changes—increased stroke volume and heart rate. These changes may lead to cardiac dilation and heart valve insufficiency if the underlying anemic condition is not corrected.

Hypoxemia, reduced oxygen level in the blood, further contributes to cardiovascular dysfunction by causing dilation of arterioles, capillaries, and venules in the systemic circulation, thus increasing flow through them. Increased peripheral blood flow and venous return further contributes to an increase in heart rate and stroke volume in a continuing effort to meet normal oxygen demand and prevent cardiopulmonary congestion. These compensatory mechanisms may lead to heart failure.

Tissue hypoxia creates additional demands and effects on the pulmonary and hematologic systems. The rate and depth of breathing increase, in an effort to increase oxygen availability, accompanied by an increase in the release of oxygen from hemoglobin (see Chapter 34). All these compensatory mechanisms may cause individuals to experience shortness of breath (dyspnea), a rapid and pounding heartbeat, dizziness, and fatigue. In mild chronic cases, these symptoms may be present only when there is an increased demand for oxygen (e.g., during physical exertion), but in severe cases, symptoms may be experienced even at rest.

Manifestations of anemia may be seen in other parts of the body. The skin, mucous membranes, lips, nail beds, and conjunctivae become either pale because of reduced hemoglobin concentration or yellowish (jaundiced) because of accumulation of end products of red cell destruction **(hemolysis)** if that is the cause of the anemia. Tissue hypoxia of the skin results in impaired healing and loss of elasticity, as well as thinning and early graying of the hair. Nervous system manifestations may occur in which the cause of anemia is a deficiency of vitamin B_{12}. Myelin degeneration may occur, causing a loss of nerve fibers in the spinal cord, resulting in paresthesia (numbness), gait disturbances, extreme weakness, spasticity, and reflex abnormalities. Decreased oxygen supply to the gastrointestinal (GI) tract often produces abdominal pain, nausea, vomiting, and anorexia. Low-grade fever (<101°F [38.3°C]) occurs in some anemic individuals and may result from the release of inflammatory pyrogens from ischemic tissues.

When the onset of anemia is severe or acute (e.g., hemorrhage), the initial compensatory mechanism is peripheral blood vessel constriction, which diverts blood flow to essential vital organs. Decreased blood flow detected by the kidneys activates the renin-angiotensin response, causing salt and water retention in an attempt to increase blood volume (see Chapters 31 and 37). These situations are emergencies and require immediate intervention to correct the underlying problem that caused the acute blood loss; therefore, long-term compensatory mechanisms do not develop.

Therapeutic interventions for slowly developing anemic conditions should focus on treatment of the underlying condition with improvement of associated symptoms. Therapies include dietary correction, administration of supplemental vitamins or iron, removal of toxic agents (e.g., drugs), and interventions that are directed at treating hemolytic conditions (e.g., sickle cell disease). Transfusion therapy is used when anemia is severe and cannot be reversed quickly.

Anemias of Blood Loss

Acute Blood Loss

Posthemorrhagic anemia is a **normocytic-normochromic anemia** (see Table 29.1) caused by acute blood loss. Acute blood loss is mainly a loss of intravascular volume, and its effects depend on the rate of hemorrhage. If the blood loss is rapid, it can lead to cardiovascular collapse, shock, and death. A major cause of acute blood loss is **trauma**. Severe trauma is a rising global problem, resulting in an annual worldwide death rate of more than 5 million or 9% of mortalities.[2,3] Uncontrolled posttraumatic bleeding is the leading cause of potentially preventable death among injured individuals. Table 29.2 presents classification of estimated blood loss for a 70 kg male based on initial presentation. The pathophysiologic mechanism of traumatic injury is an evolving field of study. Emerging is the understanding that persons with bleeding trauma are already developing complications of coagulopathy upon hospital admission. The presence of coagulopathy is related to an increased risk of multiple organ failure and death (see Emerging Science Box: Traumatic Coagulopathy).

Table 29.2

Classification of Estimated Blood Lossa

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	>2000
Blood loss (% blood volume)	Up to 15	15–30	30–40	>40
Pulse rate (beats/min)	<100	100–120	120–140	>140
Systolic blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14–20	20–30	30–40	>35
Urine output (mL/h)	>30	20–30	5–15	Negligible
Central nervous system/mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Initial fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	>2000
Blood loss (% blood volume)	Up to 15	15–30	30–40	>40
Pulse rate (beats/min)	<100	100–120	120–140	>140
Systolic blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14–20	20–30	30–40	>35
Urine output (mL/h)	>30	20–30	5–15	Negligible
Central nervous system/mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Initial fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

[a]For a 70-kg man.

Data from Rossaint R, Bouillon B, Cerny V, et al. The European guideline on management of major bleeding and coagulopathy following trauma: Fourth edition. *Critical Care*, 2016;20:100.

Within 24 hours of acute blood loss, lost plasma is replaced from the movement of water and electrolytes from tissues and interstitial spaces into the intravascular system. The hematocrit becomes lowered because of resulting hemodilution. Red blood cells are normocytic and normochromic (i.e., mean corpuscular volume [MCV] and mean corpuscular hemoglobin concentration [MCHC] are within normal range). A rapid elevation of circulating neutrophils occurs within a few hours due to a release of leukocytes from the bone marrow into the circulation. The platelet count can rise significantly during the early recovery from acute blood loss. Erythropoietin is stimulated from the reduction in tissue oxygenation and increases bone marrow production of erythrocytes. However, iron stores may be depleted due to loss of red blood cells from the body, and erythropoiesis may be impeded. To restore blood volume, saline, dextran, albumin, or plasma is typically used, and with large blood losses it may be necessary to transfuse fresh whole blood.

Red blood cell transfusion is an option for both acute and chronic blood loss. However, transfusion of critically ill individuals may worsen the outcome and increase morbidity and mortality. Stored red blood cells undergo structural and metabolic impairments including formation of toxic products, phosphatidylserine exposure, and shedding of microparticles. These changes promote thrombotic complications such as deep venous thrombosis (DVT) after infusion.[4] In an effort to improve patient outcomes, patient blood management is a patient-centered and multidisciplinary approach to effectively manage anemia, reduce iatrogenic blood loss, and improve outcomes for those with anemia.[5]

Chronic Blood Loss

Anemia from chronic blood loss occurs if the loss is greater than the replacement capacity of the bone marrow. Hemorrhage that is slow and chronic produces less prominent adaptations, but an **iron deficiency anemia (IDA)** may develop. In adults, an otherwise unexplained IDA should be evaluated for an occult source of blood loss such as a bleeding ulcer or a malignancy.

Anemias of Diminished Erythropoiesis

There are many varied anemias of diminished red cell production that can be classified according to the underlying mechanism (Table 29.3). IDA is the most common type of anemia in the world. Other common anemias of diminished red cell production are the result of ineffective erythrocyte DNA synthesis caused by nutritional deficiencies of vitamin B_{12} (cobalamin) or folate (folic acid). IDA causes a microcytic anemia, whereas deficiencies of vitamin B_{12} and folate cause macrocytic (megaloblastic) anemias (Fig. 29.3).

Table 29.3

Classification of Anemia According to Underlying Mechanism

Mechanism	Specific Examples
Blood Loss	
Acute blood loss	Trauma
Chronic blood loss	Gastrointestinal tract lesions, gynecologic disturbances[a]
Anemias of Diminished Erythropoiesis	
Inherited Defects	
Defects leading to stem cell depletion	Fanconi anemia, telomerase defects
Defects affecting erythroblast maturation	Thalassemia syndromes
Acquired Defects	
Deficiencies affecting DNA synthesis	B_{12} and folate deficiencies
Deficiencies affecting hemoglobin synthesis	Iron deficiency anemia
Erythropoietin deficiency	Renal failure, anemia of chronic disease
Immune-mediated injury of progenitors	Aplastic anemia, pure red cell aplasia
Inflammation-mediated iron sequestration	Anemia of inflammation
Primary hematopoietic neoplasms	Acute leukemia, myelodysplasia, myeloproliferative disorders
Space-occupying marrow lesions	Metastatic neoplasms, granulomatous disease

Mechanism	Specific Examples
Infections of red cell progenitors	Parvovirus B19 infection
Unknown mechanisms	Endocrine disorders, hepatocellular liver disease
Anemias of Increased Destruction (Hemolysis)	
Inherited Defects	
Red cell membrane disorders	Hereditary spherocytosis, hereditary elliptocytosis
Enzyme deficiencies	
• Hexose monophosphate shunt enzyme deficiencies	G6PD deficiency, glutathione synthetase deficiency
• Glycolytic enzyme deficiencies	Pyruvate kinase deficiency, hexokinase deficiency
Hemoglobin abnormalities	
• Deficient globin synthesis	Thalassemia syndromes
• Structurally abnormal globins (hemoglobinopathies)	Sickle cell disease, unstable hemoglobins
Acquired Defects	
Deficiency of phosphatidylinositol-linked glycoproteins	Paroxysmal nocturnal hemoglobinuria
Antibody-mediated destruction	Hemolytic disease of the newborn (Rh disease), transfusion reactions, drug-

Mechanism	Specific Examples
	induced, autoimmune disorders
Mechanical trauma	
• Microangiopathic hemolytic anemias	Hemolytic uremic syndrome, disseminated intravascular coagulation, thrombotic thrombocytopenia purpura
• Cardiac traumatic hemolysis	Defective cardiac valves
• Repetitive physical trauma	Bongo drumming, marathon running, karate chopping
Infections of red cells	Malaria, babesiosis
Toxic or chemical injury	Clostridial sepsis, snake venom, lead poisoning
Membrane lipid abnormalities	Abetalipoproteinemia, severe hepatocellular liver disease
Sequestration	Hypersplenism

Mechanism	Specific Examples
Blood Loss	
Acute blood loss	Trauma
Chronic blood loss	Gastrointestinal tract lesions, gynecologic disturbances[a]
Anemias of Diminished Erythropoiesis	
Inherited Defects	
Defects leading to stem cell depletion	Fanconi anemia, telomerase defects
Defects affecting erythroblast maturation	Thalassemia syndromes
Acquired Defects	
Deficiencies affecting DNA synthesis	B_{12} and folate deficiencies
Deficiencies affecting hemoglobin synthesis	Iron deficiency anemia
Erythropoietin deficiency	Renal failure, anemia of chronic disease
Immune-mediated injury of progenitors	Aplastic anemia, pure red cell aplasia
Inflammation-mediated iron sequestration	Anemia of inflammation
Primary hematopoietic neoplasms	Acute leukemia, myelodysplasia, myeloproliferative disorders
Space-occupying marrow lesions	Metastatic neoplasms, granulomatous disease
Infections of red cell progenitors	Parvovirus B19 infection
Unknown mechanisms	Endocrine disorders, hepatocellular liver disease
Anemias of Increased Destruction (Hemolysis)	
Inherited Defects	
Red cell membrane disorders	Hereditary spherocytosis, hereditary elliptocytosis
Enzyme deficiencies	
• Hexose monophosphate shunt enzyme deficiencies	G6PD deficiency, glutathione synthetase deficiency
• Glycolytic enzyme deficiencies	Pyruvate kinase deficiency, hexokinase deficiency
Hemoglobin abnormalities	
• Deficient globin synthesis	Thalassemia syndromes
• Structurally abnormal globins (hemoglobinopathies)	Sickle cell disease, unstable hemoglobins
Acquired Defects	
Deficiency of phosphatidylinositol-linked glycoproteins	Paroxysmal nocturnal hemoglobinuria
Antibody-mediated destruction	Hemolytic disease of the newborn (Rh disease), transfusion reactions, drug-induced, autoimmune disorders
Mechanical trauma	
• Microangiopathic hemolytic anemias	Hemolytic uremic syndrome, disseminated intravascular coagulation, thrombotic thrombocytopenia purpura
• Cardiac traumatic hemolysis	Defective cardiac valves
• Repetitive physical trauma	Bongo drumming, marathon running, karate chopping
Infections of red cells	Malaria, babesiosis
Toxic or chemical injury	Clostridial sepsis, snake venom, lead poisoning
Membrane lipid abnormalities	Abetalipoproteinemia, severe hepatocellular liver disease
Sequestration	Hypersplenism

G6PD, Glucose-6-phosphate dehydrogenase.

[a]Most often cause of anemia is iron deficiency, not bleeding.

Data from Kumar V, Abbas A, Aster JC. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.

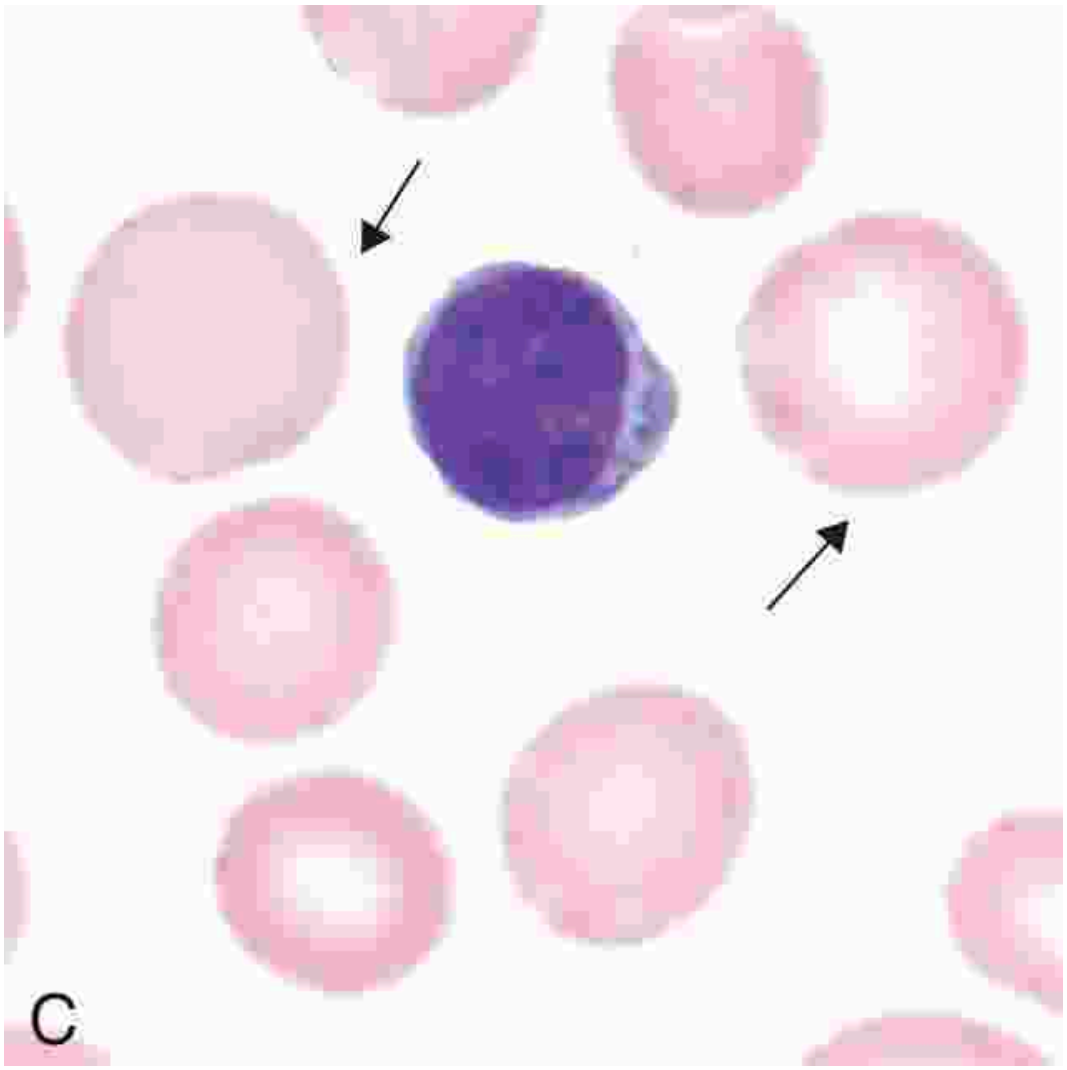

FIG. 29.3 Variations in Size of Erythrocytes
(A) Microcytes (mean cell volume [MCV] <80 fL) associated with iron deficiency anemia, thalassemia minor, chronic inflammation (some cases), lead poisoning, hemoglobinopathies (some), and sideroblastic anemia. (B) Normocytes (mean cell volume [MCV] 80–100 fL). Normal erythrocytes are approximately the same size as the nucleus of a small lymphocyte. (C) Macrocytes (mean cell volume [MCV] >100 fL). Associated with vitamin B12 deficiency, folate deficiency, liver disease, neonates, and reticulocytosis. (From Rodak BF, Carr JH. *Clinical hematology atlas*. 5th edition. St. Louis: Elsevier; 2017)

Three photomicrographs show variations in erythrocyte sizes. Top panel, A. The cell comprises hemoglobin and a layer of membrane. Middle panel, B. The cell comprises hemoglobin and a hardly visible layer of membrane. Bottom panel, C. The cell comprises hemoglobin with no membrane.

Macrocytic (Megaloblastic)—Normochromic Anemias

The **macrocytic (megaloblastic) anemias** are characterized by large stem cells (megaloblasts) in the marrow (Fig. 29.4) that mature into erythrocytes that are unusually large in size (macrocytic; elevated MCV) thickness, and volume (see Fig. 29.3C). The most common etiology for macrocytic anemias is vitamin B12 or folate deficiencies. Vitamin B12 is dependent on dietary B12 intake. Plants and vegetables contain little cobalamin and strictly vegetarian and macrobiotic diets do not provide adequate amounts. Folate is found in green leafy vegetables, fruits, nuts, eggs, and meats. Both vitamin B12 and folate levels can be affected by disorders that decrease absorption of these vitamins from the gut, and by increased demand for these nutrients in conditions such as pregnancy, hyperthyroidism, chronic infection, and disseminated cancer. Another important cause of megaloblastic anemia is medications that interfere with DNA synthesis such as chemotherapeutic drugs.

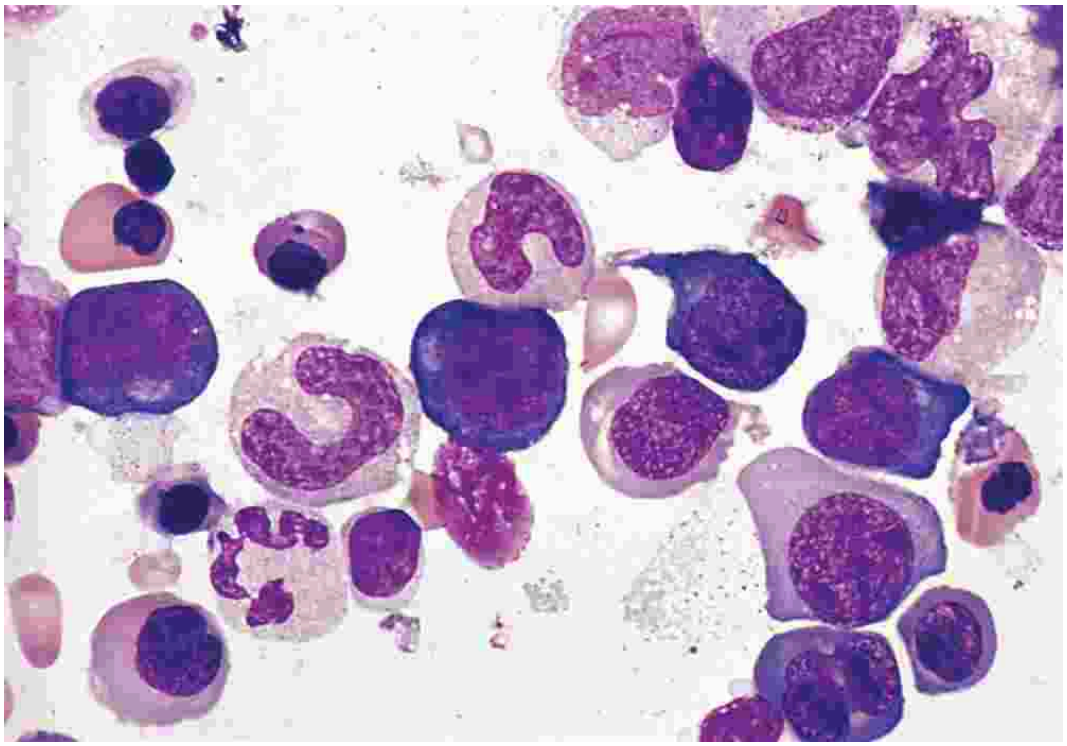

FIG. 29.4 Bone Marrow Aspirate from Individual With Pernicious Anemia.
Bone marrow aspirate smear from an individual with megaloblastic red blood cell precursors and giant metamyelocytes. The chromatin in the red blood cell nuclei is more dispersed than that in normal red blood cell precursors at comparable stages of maturation; the giant metamyelocytes have dispersed nuclear chromatin in contrast to a normal metamyelocyte, which has condensed chromatin (Wright-Giemsa stain). (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

The defective erythrocytes in megaloblastic anemias die prematurely, which decreases their numbers in the circulation, causing anemia. Premature death of damaged erythrocytes, **eryptosis**, is a common mechanism of cellular loss in individuals with anemia secondary to nutritional deficiencies, infections (e.g., malaria, mycoplasma), chronic diseases (e.g., diabetes, renal disease), genetic diseases (e.g., beta-thalassemia, glucose-6-phosphate dehydrogenase [G6PD] deficiency, sickle cell anemia), and myelodysplastic syndrome.[6]

Deoxyribonucleic acid (DNA) synthesis and cell division are blocked or delayed in megaloblastic anemias. Defective DNA synthesis causes red cell growth and development to proceed at unequal rates. However, ribonucleic acid (RNA) replication and protein (hemoglobin) synthesis proceed normally. Asynchronous development leads to an overproduction of hemoglobin during prolonged cellular division, creating a larger than normal erythrocyte with a disproportionately small nucleus. With each cell division, the disproportion between increased RNA and cell size and decreased DNA becomes more apparent.

Pernicious anemia

Pernicious anemia (PA) is a type of megaloblastic anemia and is caused by vitamin B_{12} (cobalamin) deficiency due to intestinal malabsorption. The main disorder in PA is the absence of **intrinsic factor (IF)** which is essential for the absorption of vitamin B12 in the ileum (see Chapter 28). *Pernicious* means highly injurious or destructive and reflects the fact that this condition was once fatal. It most commonly affects individuals older than age 30 who are of Northern European descent; however, it is now recognized in all populations and ethnic groups.

Deficiency of IF may be congenital. It is more often acquired as the result of an autoimmune process or conditions that damage the gastric mucosa. Congenital IF deficiency is a genetic disorder with an autosomal recessive inheritance pattern. Approximately 20% of individuals with PA have a family member with PA, although the pattern of transmission has not been identified.[7] PA most commonly is caused by autoimmune processes directed against gastric parietal cells or IF itself. It may be a component of a cluster of autoimmune diseases affecting endocrine organs such as autoimmune thyroiditis and type 1 diabetes mellitus.[8] Chronic infection with *Helicobacter pylori* is also implicated. Other causes include surgical removal of the stomach, resection of the ileum, and tapeworms. Environmental conditions that may contribute to the development of PA include excessive alcohol intake and smoking.

Pathophysiology

Individuals with autoimmune PA commonly have two types of antibodies: one to parietal cells and the other to IF or its binding site in the small bowel.[7] IF deficiency in PA is most often associated with type A chronic atrophic (autoimmune) gastritis, whereby autoantibodies destroy parietal

and zymogenic (relating to an enzyme) cells leading to gastric atrophy (see Chapter 41). *H. pylori* infection may cause an increase in antibody production. These autoantibodies often target gastric H+-K+ adenosine triphosphate (ATP)ase, which is the major protein constituent of parietal cell membranes. Early in progression of disease, the gastric submucosa becomes infiltrated with inflammatory cells. These cells include autoreactive T cells, which initiate gastric mucosal injury and trigger the formation of autoantibodies. Gastric mucosal injury and atrophy result in a deficiency of all secretions of the stomach—hydrochloric acid (achlorhydria), pepsin, and IF. Without adequate IF, vitamin B12 malabsorption develops. Vitamin B_{12} is essential for nuclear maturation and DNA synthesis in red blood cells. Deficiencies lead to an anemia characterized by abnormal RBC precursor cells in the bone marrow (megaloblasts) and enlarged mature RBCs in the circulation (macrocytes). In addition, there is an increased risk for gastric cancer in individuals with chronic gastritis and PA.

Approximately 40% to 60% of individuals with PA have autoantibodies to intrinsic factor antibodies (IFA) directly leading to vitamin B_{12} malabsorption in the ileum. Many of these individuals have a history of IDA and gastric achlorhydria. Individuals with unexplained IDA should be screened for autoimmune gastritis and PA.[7]

Clinical Manifestations

PA develops slowly (over 20 to 30 years), so by the time an individual seeks treatment, it is usually severe. Early symptoms are often ignored because they are nonspecific and vague and include infections, mood swings, and GI, cardiac, or kidney ailments.[9] When the hemoglobin level has decreased to 7 to 8 g/dL, the individual experiences classic symptoms of PA: weakness, fatigue, paresthesia of feet and fingers, difficulty walking, loss of appetite, abdominal pain, weight loss, and a sore tongue that is smooth and beefy red (glossitis). The skin may become "lemon yellow" (sallow), caused by a combination of pallor and jaundice. Hepatomegaly and splenomegaly, indicating right-sided heart failure, may be present in the elderly.

Neurologic manifestations result from nerve demyelination that may produce neuronal death. The most frequently recognized deficit is a sensory neuropathy resulting in a loss of position and vibration sense that is especially prominent in the feet leading to ataxia.[10] The spinal cord is affected, causing weakness and spasticity. Vision may also be impaired.

Early diagnosis and treatment improve chances of recovery, and while only a small percentage experience a complete neurological recovery, most individuals experience some improvement in symptoms after treatment.[11] The cerebrum also may be involved with manifestations of affective disorders, most commonly depression. Low levels of vitamin B_{12} have been associated with neurocognitive disorders and Alzheimer disease.

Evaluation and Treatment

Diagnosis of PA is based on clinical manifestations and test results demonstrating a macrocytic (high MCV) normochromic (normal MCHC) anemia (see Table 29.1) and low serum levels of vitamin B_{12}. Reticulocyte counts are decreased. Confirmatory studies include bone marrow aspiration, detection of circulating antibodies against parietal cells and IF, and gastric biopsy.[9]

Replacement of vitamin B_{12} (cobalamin) is the treatment of choice. Initial injections of vitamin B_{12} are administered weekly until the deficiency is corrected, followed by monthly injections for the remainder of the individual's life. Conventional practice assumed that oral preparations were ineffective because the lack of IF meant there would be continued malabsorption of vitamin B_{12}. However, high doses of orally administered vitamin B_{12} can be absorbed across the small bowel in many individuals and can be considered as an alternative treatment for PA.[7] The effectiveness of B_{12} replacement therapy is determined by a rising reticulocyte count. Blood counts return to normal within 5 to 6 weeks. PA cannot be cured, so maintenance therapy is lifelong. Treated individuals should be monitored for the development of gastric cancer and IDA.

Folate deficiency anemia

A deficiency of folic acid results in a megaloblastic anemia having the same pathologic consequences as those caused by vitamin B_{12} deficiency**. Folate (folic acid)** is an essential vitamin required for RNA and DNA synthesis within the maturing erythrocyte. Humans are totally dependent on dietary intake of folate to meet the daily requirement of 50 to 200 mg/day. It is estimated that at least 10% of North Americans are folate deficient, but the incidence has been decreasing in the United States since the fortification of foods with folate and the increased use of folate supplements. Increased amounts are required for lactating and pregnant females, and deficiencies

of folate can cause neural tube defects in the developing fetus. Folate deficiency occurs more often than B_{12} deficiency, particularly in alcoholics and individuals with chronic malnourishment. Inflammatory bowel disease (ulcerative colitis) may be the underlying cause of folate malabsorption in some individuals, and treatment with sulfasalazine decreases folate absorption from the gut.

Folate is absorbed from the upper small intestine and does not require any other element (e.g., IF) to facilitate absorption. After absorption, folate circulates through the liver, where it is stored. Folates are coenzymes required for the synthesis of thymine and purines (adenine and guanine) and the conversion of homocysteine to methionine.[12] Deficient production of thymine affects cells undergoing rapid division (e.g., bone marrow cells undergoing erythropoiesis) resulting in megaloblastic precursor cells and a macrocytic anemia.

Clinical manifestations are similar to those apparent in individuals with PA. Specific manifestations include cheilosis (scales and fissures of the mouth), stomatitis (inflammation of the mouth), and painful ulcerations of the buccal mucosa and tongue characteristic of burning mouth syndrome. *Burning mouth syndrome* also may be secondary to other disorders (e.g., extremely dry mouth, infection, autoimmune disease, nutritional deficiencies, and other conditions) and is not diagnostic for folate deficiency. Dysphagia, flatulence, and watery diarrhea may be present, as well as histologic changes in the GI tract similar to those seen in celiac disease (see Chapter 42). Neurologic manifestations, if present, may be caused by thiamine deficiency, which often accompanies folate deficiency in malnourished individuals.

Evaluation of folate deficiency is based on clinical manifestations, the appearance of macrocytic RBCs (high MCV) in the blood, and the measurement of serum folate levels. Treatment requires administration of oral folate preparations until adequate blood levels are obtained and manifestations are reduced or eliminated. Long-term therapy is not necessary if the appropriate dietary adjustments are made to maintain adequate intake. Manifestations of anemia disappear within 1 to 2 weeks after administration of folate.

Megaloblastic anemia caused by medications

Many drugs can directly affect DNA synthesis and thereby interfere with RBC maturation leading to megaloblastic anemia.[12] These drugs include

immunomodulatory drugs (e.g., azathioprine and leflunomide), chemotherapeutics (e.g., fluorouracil and methotrexate), allopurinol, and trimethoprim (sulfa drug).[12] Other medications reduce vitamin B_{12} or folate absorption. Management includes discontinuation of the drug if possible, or if not, vitamin supplementation is indicated.

Microcytic-Hypochromic Anemias

The microcytic-hypochromic anemias are characterized by abnormally small erythrocytes (low MCV) (see Figs. 29.1 and 29.3A) that contain reduced amounts of hemoglobin (low MCHC). Sideroblastic anemia can cause erythrocytes to be microcytic and hypochromic, (see Table 29.1), but IDA is far more common.

Iron deficiency anemia

IDA is the most common nutritional disorder worldwide, affecting 10% to 20% of the world's population, occurring in both developed and developing countries.[13] The causes of IDA include (1) dietary deficiency, (2) impaired absorption (e.g., celiac disease, disorders of fat absorption), (3) increased requirement, (4) chronic blood loss, and (5) chronic diarrhea.

IDA is common in the United States, particularly in toddlers, adolescent girls, and women of childbearing age. Other populations at risk for IDA include those living in poverty, infants consuming cow's milk (decreased bioavailability of iron), older individuals ingesting restricted diets, and teenagers with poor diets (junk food). An increased prevalence of iron deficiency has been observed in those with eating disorders, as well as in overweight children, adolescents, and women.[13] Premenopausal women have an increased iron requirement, especially during pregnancy and with excessive menstrual bleeding. Increased requirement also is a major cause of iron deficiency in growing infants, children, and adolescents. Other causes of IDA include bariatric surgery and surgical procedures that decrease stomach acidity.

Both sexes may have IDA secondary to bleeding as a result of gastric or duodenal ulcers, hiatal hernia, esophageal varices, cirrhosis, hemorrhoids, inflammatory bowel disease, or cancer. In fact, unexplained IDA in a male or a postmenopausal woman may be the first indication of GI disease.

Children in developing countries often are affected by chronic parasite infestations that result in blood and iron loss that is greater than dietary intake, thus causing IDA. Treatment of helminth infections improves the

anemia as well as appetite and growth. *H. pylori* infection impairs iron uptake and is a cause of iron-refractory or iron-dependent anemia of previously unknown origin in adults. Children in resource-poor conditions often are exposed to unsafe levels of toxins such as lead (see Chapter 2). Chronic lead poisoning can produce a mild microcytic anemia, and the absorption of lead can prevent the normal addition of iron to heme molecules resulting in IDA.[14] Furthermore, IDA is associated with pica, which can lead to ingestion of lead-containing paint and soil. IDA and lead poisoning can act synergistically to cause anemia more severe than would either condition alone. Treatment for iron deficiency is associated with a decrease in lead levels.

Pathophysiology

IDA is a hypochromic-microcytic anemia (see Fig. 29.3A) and occurs when iron stores are depleted. Inadequate dietary intake and excessive blood loss deplete iron stores and reduce hemoglobin synthesis. When total body stores of iron are low, iron deprivation for erythroblasts and other tissues occurs. In some cases, iron stores may be sufficient, but delivery is inadequate to maintain heme synthesis, thus producing a functional or relative iron deficiency. For example, inflammation can cause withholding of iron from the plasma, particularly through the action of the peptide **hepcidin**, the main regulator of systemic iron balance (see Chapter 28).[15] Hepcidin inhibits iron transfer to the plasma by binding to ferroportin, causing it to be endocytosed and degraded.[16]

Iron in the form of hemoglobin is in constant demand by the body. Iron is recyclable; therefore, the body maintains a balance between iron that is contained in hemoglobin and iron that is in storage and available for future hemoglobin synthesis (see Chapter 28). Blood loss disrupts this balance by creating a need for more iron, thus depleting the iron stores more rapidly to replace the iron that is lost from the body due to bleeding.

Iron contributes to immune function by regulating several immune mechanisms. Acquired *hypoferremia* (deficiency of iron in the blood) due to a decrease in hepcidin may be part of the body's response to infection.[17] Many pathogens require iron for survival; thus, hypoferremia would hamper their growth. In contrast, neutrophils and macrophages require adequate iron to function appropriately in the innate immune response to infection. The precise benefits or detriments of iron deficiency and immunity remain under investigation.

IDA occurs when the demand for iron exceeds the supply and develops slowly through three overlapping stages. Stage I is characterized by decreased bone marrow iron stores; hemoglobin and serum iron remain normal. In stage II, iron transportation to bone marrow is diminished, resulting in iron-deficient erythropoiesis. Stage III begins when the small hemoglobin-deficient cells enter the circulation to replace the normal aged erythrocytes that have been removed from the circulation. The manifestations of IDA appear in stage III, when there is depletion of iron stores and diminished hemoglobin production.

Clinical Manifestations

Symptoms of IDA begin gradually, and individuals may not seek medical attention until hemoglobin levels have decreased to about 7 to 8 g/dL. Nonspecific early symptoms include fatigue, weakness, shortness of breath, and pale earlobes, palms, and conjunctivae (Fig. 29.5A). As the condition progresses and becomes more severe, structural and functional changes occur in epithelial tissue. **Koilonychia** or *spoon-shaped* fingernails become brittle, thin, and coarsely ridged as a result of impaired capillary circulation (see Fig. 29.5B). Other manifestations include cheilosis (scales and fissures of the mouth), stomatitis (inflammation of the mouth), and painful ulcerations of the buccal mucosa and tongue characteristic of burning (glossitis) (see Fig. 29.5C). Difficulty in swallowing (dysphagia) is associated with an esophageal *web*, a thin, concentric extension of normal esophageal tissue consisting of mucosa and submucosa at the juncture between the hypopharynx and esophagus. Dysphagia is worsened by hyposalivation. Individuals with IDA also exhibit gastritis, neuromuscular changes, headache, irritability, tingling, numbness, and vasomotor disturbances. Alterations in gait are rare. Iron deficiency in children is associated with numerous adverse manifestations, especially cognitive impairment. Cognitive impairment may be long-lasting and irreversible (see Chapter 30).

FIG. 29.5 Manifestations of Iron Deficiency Anemia. (A) Pallor and iron deficiency. Pallor of the skin, mucous membranes, and palmar creases in an individual with a hemoglobin level of 9 g/dL. Palmar creases become as pale as the surrounding skin when the hemoglobin level approaches 7 g/dL. (B) Koilonychia. The nails are concave, ridged, and brittle. (C) Glossitis. Tongue of individual with iron deficiency anemia has bald, fissured appearance caused by loss of papillae and flattening. (From Hoffbrand AV, Pettit JE, Vyas P. *Color atlas of clinical*

hematology, 4th edition. London: Mosby; 2009; B, Courtesy Dr. S.M. Knowles.)

Four closeups show manifestations of iron deficiency anemia. Top panel, A. The closeup on the left shows creased eyes. The closeup on the right shows creased palms. Middle panel, B. The closeup shows the nails with concave dents at the center and elevated edges. Bottom panel, C. The closeup shows fissures on a personâ€™s tongue.

Evaluation and Treatment

Initial evaluation is based on symptoms and decreased levels of hemoglobin and hematocrit and the finding of microcytic (low MCV) and hypochromic (low MCHC) erythrocytes in the blood. Decreased serum iron, ferritin, and transferrin saturation levels are also found. A sensitive indicator of heme synthesis is the amount of free erythrocyte protoporphyrin (FEP) within erythrocytes.

An initial step in treatment of IDA is to identify and eliminate sources of blood loss. Oral iron replacement therapy is indicated, and hematocrit levels should improve within 1 to 2 months of therapy. Parenteral iron replacement is used in instances of uncontrolled chronic blood loss, intolerance to oral iron replacement, intestinal malabsorption, or poor adherence to oral therapy. Serum ferritin level is a more precise measurement of improvement. A rapid decrease in fatigue, lethargy, and other associated symptoms is generally seen within the first month of therapy. Replacement therapy may continue for many months. Menstruating females may need daily oral iron replacement therapy until menopause.

Normocytic-Normochromic Anemia

Some causes of anemia do not change the size, color, or shape of erythrocytes (see Figs. 29.1 and 29.3B). Two important causes of normocytic-normochromic anemia are AI and aplastic anemia (AA).

Anemia of inflammation

Anemia of inflammation (AI) (also called anemia of chronic inflammation and anemia of chronic disease [**ACD**]), is a mild to moderate anemia resulting from decreased erythropoiesis and impaired iron utilization in individuals with chronic diseases that produce systemic inflammation (e.g., infections, cancer, and chronic inflammatory or autoimmune diseases). It is one of the most common conditions encountered in medicine. Table 29.4 lists some of these causes of AI. AI is a common type of anemia in hospitalized individuals where it is observed in individuals with chronic obstructive pulmonary disease (COPD) and congestive heart failure (CHF); in persons with critical illnesses after acute events such as major surgery, severe trauma, myocardial infarction, and sepsis; and in the elderly. The elderly may be predisposed to AI related to age-associated hematopoietic changes with increased concentrations of inflammatory cytokines. More than 50% of elderly individuals who reside in nursing homes have anemia, with two-thirds of cases being AI or unexplained. The elderly with characteristics of AI without an underlying malignancy or inflammatory condition are described as having primary defective iron utilization syndrome.

Table 29.4

Underlying Causes of Anemia of Inflammation

Associated Diseases	Estimated Prevalence (%)
Infections: Acute and chronic; viral infections including HIV infection, bacterial, parasitic, fungal	18–95
Cancer: Hematologic, solid tumor	30–63
Systemic Inflammatory Disorders: Rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, vasculitis, or systemic sclerosis, sepsis	33–60
Aging: Due to the presence of inflammatory conditions or chronic kidney disease in older aging individuals Chronic Disorders: Chronic obstructive pulmonary disease, congestive heart failure, chronic kidney disease, immune-mediated diseases Other:	33 Unknown Unknown

Associated Diseases	Estimated Prevalence (%)
Critical illnesses after acute events, major surgery, severe trauma, myocardial infarction, obesity, anemia of the elderly

Blood. 2019 Jan 3;133(1):40-50. doi: 10.1182/blood-2018-06-856500. Epub 2018 Nov 6. PMID: 30401705; PMCID: PMC6536698.

Pathophysiology

AI usually develops after 1 to 2 months of disease activity. The initial severity is related to the underlying disorder, but, although persistent, it usually does not progress. AI results from a combination of (1) decreased erythrocyte life span, (2) suppressed production of erythropoietin, (3)

ineffective bone marrow response to erythropoietin, and (4) altered iron metabolism and iron dynamics in macrophages. During chronic inflammation, a large variety of cytokines are released by lymphocytes, macrophages, and the affected tissue. Inflammatory cytokines increase hepcidin levels, which reduces iron absorption, sequesters iron in macrophages, and suppresses erythropoietin production (Fig. 29.6).[16] Impaired iron metabolism is partially the result of iron sequestration (Emerging Science Box: Regulation of Iron Metabolism). Normal iron transport by transferrin also may be decreased as a result of inflammation-related increases in the levels of circulating lactoferrin and apoferritin.

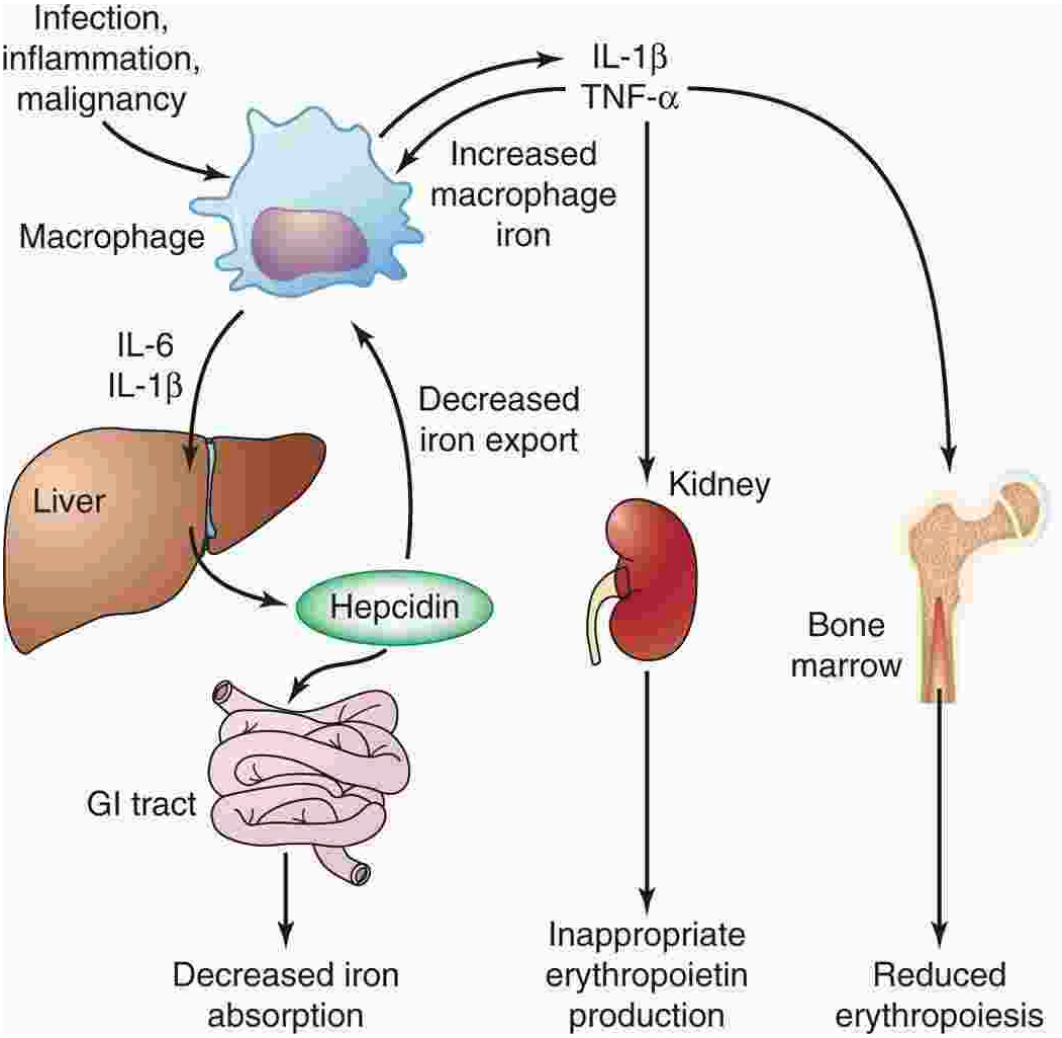

FIG. 29.6 Mechanism for the Anemia of Inflammation.
GI, Gastrointestinal; *IL-6*, interleukin-6; *IL-1β*, interleukin-1β; *TNF-α*, tumor necrosis factor-α.

An illustrated flowchart shows the mechanism for the anemia of inflammation. â€¢ T N F-alpha triggers the bone marrow in producing reduced erythropoiesis. â€¢ T N F-alpha triggers the kidney in producing inappropriate erythropoietin. â€¢ T N F-alpha produces increased macrophage iron. â€¢ Infection, inflammation, and malignancy macrophage produces I L-1 beta. â€¢ I L-6 and I L-1 beta from macrophage triggers the liver in producing

hepcidin. â€¢ Hepcidin decreases iron export to the macrophage. â€¢ Hepcidin triggers the G I tract in decreasing iron absorption.

The erythropoietic defect in AI is failure to increase erythropoiesis in response to decreased numbers of erythrocytes. In part, decreased erythropoiesis results from diminished production of erythropoietin by the kidneys. In addition, the failure in erythropoiesis may reflect decreased responsiveness of erythroid progenitors to erythropoietin. Decreased availability of iron would diminish the rate of erythropoiesis. Proliferation of erythroid cells also is inhibited by proinflammatory cytokines. Loss of integrins may prevent adequate interaction with stromal cells and matrix proteins and inhibit erythropoiesis.

Erythrocyte destruction is the result of eryptosis (described earlier in this chapter). Most of the diseases responsible for AI cause damage to erythrocytes resulting in macrophage activity. Platelet function also may be defective in these individuals, which results in chronic bleeding and loss of erythrocytes.

Clinical Manifestations

AI is usually in the mild to moderate range. Individuals may be asymptomatic, or the anemia may be a chance clinical finding. If there is a significant drop in hemoglobin levels, clinical manifestations of anemia appear.

Evaluation and Treatment

Initially, AI is normocytic-normochromic, but with persistence it becomes hypochromic and microcytic (see Table 29.1). AI is characterized by low levels of circulating iron and reduced levels of transferrin. The most significant finding of AI is very high total body iron storage, although inadequate iron is released from the bone marrow for erythropoiesis. A first indication of AI is often a failure to respond to conventional iron replacement therapy. Levels of erythropoietin are generally lower than expected for the degree of anemia. Individuals frequently present with low or normal total iron-binding capacity (TIBC), normal or high serum ferritin levels, and low concentrations of soluble transferrin receptor. It occasionally may be difficult to differentiate AI from IDA.

Use of erythropoietin in treatment of AI associated with arthritis, malignancies, and acquired immunodeficiency syndrome (AIDS) has met with limited success. Individuals with severe anemia secondary to chronic kidney disease (CKD) can be treated successfully with erythropoietin and treatments to increase iron stores. However, the optimal degree of restoration of hemoglobin levels has not been determined; a return to normal levels increases the risk of hypertension, stroke, and death.[18] The principal treatment is easement of the underlying disorder. Individuals with AI, but without evidence of inflammatory or infectious conditions, should be screened for malignancies.

Aplastic anemia

Aplastic anemia (AA) is a hematopoietic failure of the bone marrow leading to a reduction in the effective production of mature blood cells and resulting in peripheral **pancytopenia** (anemia, neutropenia, and thrombocytopenia), which is a reduction or absence of all three blood cell types. (Fig. 29.7) The incidence of AA in the United States is low; however, the incidence in developing countries is higher related to greater exposure to certain chemicals known to cause AA. The incidence is bimodal, with one peak occurring between 15 and 25 years of age and a second peak occurring in individuals older than age 60. AA is equally distributed between genders.

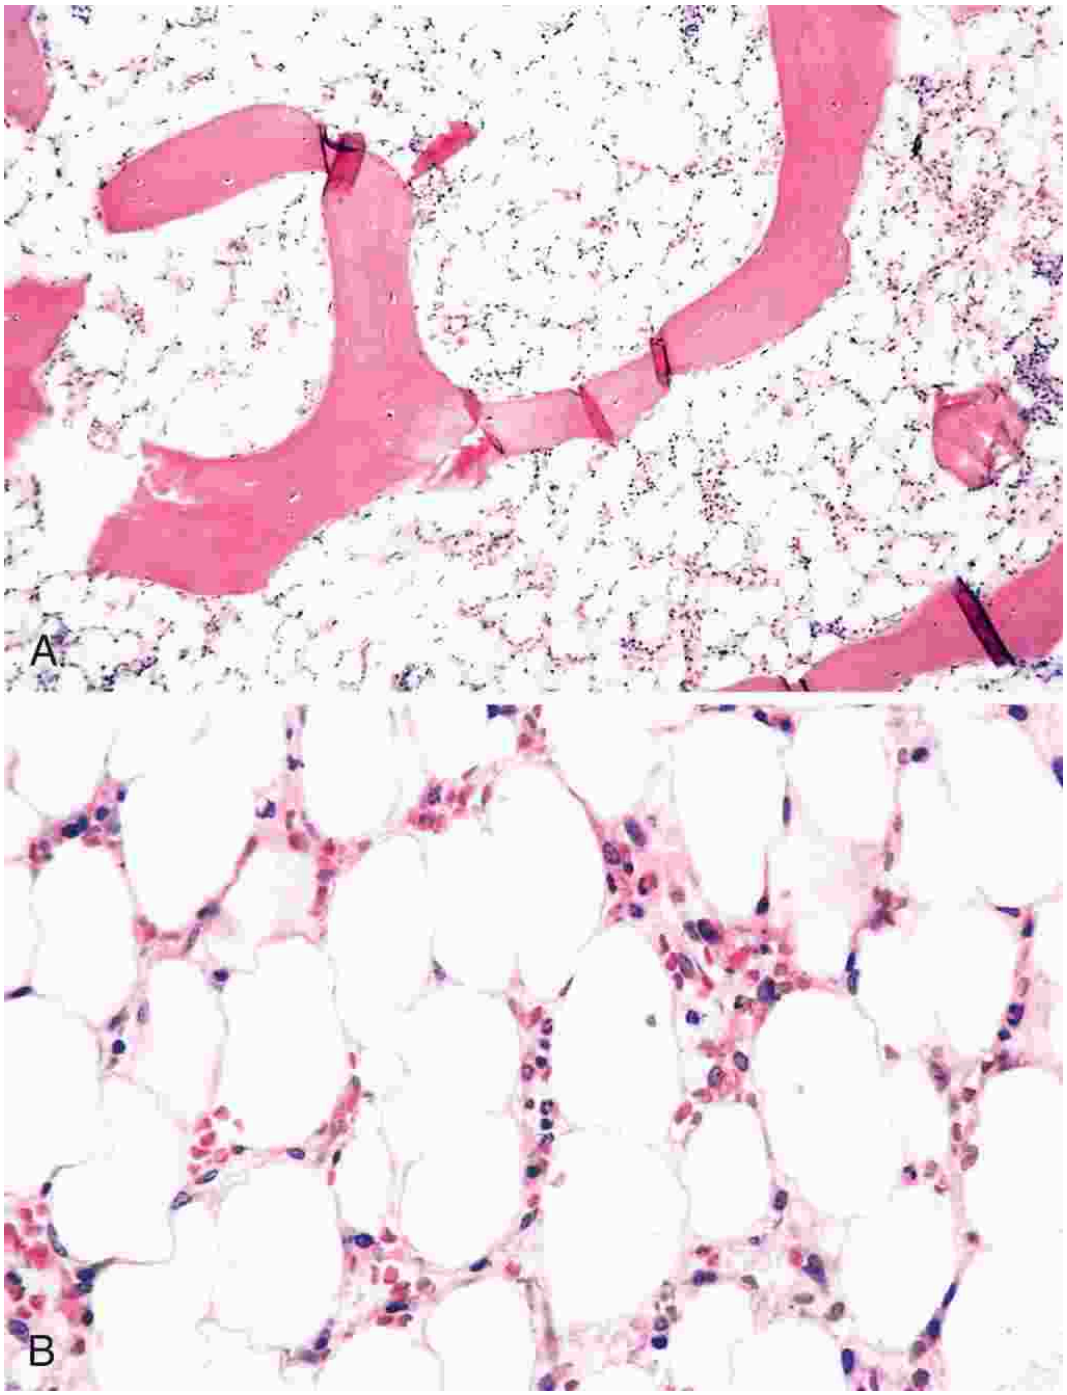

FIG. 29.7 Aplastic Anemia.
The common pathology of the bone marrow replaced by fat can result from chemical or physical damage (iatrogenic; benzene); immune destruction (mainly T cells); and as a constitutional defect in genes important in maintenance of cell integrity and immune regulation. (A) Low power. (B) High power. (From Kumar V, Abbas A,

Aster J. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.)

Idiopathic AA (primary acquired; autoimmune) accounts for approximately 75% of all confirmed cases. *Secondary* AA, which accounts for approximately 15% of cases, is caused by a variety of known chemical agents and ionizing radiation (Box 29.1). Total body irradiation is a well-described cause of AA and in certain instances may be used therapeutically for this effect in the treatment of certain cancers or for organ and bone marrow transplantation (BMT). Infections also are known to cause AA, with viruses being the most common agent, including the human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), and hepatitis (non-A, non-B, non-C, and non-G forms of the virus). Persistent parvovirus B19 infection also has been identified as producing bone marrow failure resulting in AA.

Box 29.1

Major Causes of Aplastic Anemia

Acquired

- Idiopathic
- Acquired stem cell defects
- Immune mediated

Chemical Agents

- Dose related
  - Alkylating agents
  - Antimetabolites
  - Benzene
  - Chloramphenicol
  - Inorganic arsenicals
- Idiosyncratic
  - Chloramphenicol
  - Phenylbutazone
  - Organic arsenicals

- Methylphenylethylhydantoin
- Carbamazepine
- Penicillamine
- Gold salts

Physical Agents

- Whole-body irradiation
- Viral infections
- Hepatitis (unknown virus)
- Cytomegalovirus infections
- Epstein-Barr virus infections
- Herpes zoster (varicella zoster)

Inherited

- Fanconi anemia
- Telomerase defects

From Kumar V, Abbas A, Aster J. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.

Another condition associated with AA is **pure red cell aplasia (PRCA)**, in which only the erythrocytes are affected. PRCA is a rare disorder and has been associated with autoimmune, viral, and neoplastic (leukemias) disorders; infiltrative disorders of the bone marrow (myelofibrosis); renal failure; hepatitis; mononucleosis; and systemic lupus erythematosus (SLE). It also is a well-recognized but infrequent complication of allogeneic BMT, particularly when there is donor-recipient ABO mismatch. A thymoma often is found in association with PRCA and is also present in Diamond-Blackfan syndrome, a congenital disorder.

AA is associated with one or more somatic mutations. A subset of these is found to have defective telomerase RNA, resulting in shortened telomere.[19] A very small percentage of AA cases are linked to inherited genetic alterations. **Fanconi anemia** is a rare genetic anemia characterized by pancytopenia resulting from defects in DNA repair. This anemia develops early in life and is accompanied by multiple congenital anomalies.

Pathophysiology

The characteristic lesion of AA is a hypocellular bone marrow that has been replaced with fat. Although the pathogenesis is not fully defined, AA results from loss of hematopoietic stem cells (HSCs) or their progenitors at various stages of differentiation. Two etiologies and mechanisms are observed: an immune-mediated destruction of bone marrow progenitor cells (idiopathic AA) and an intrinsic abnormality of stem cells (secondary AA).

Several immune abnormalities are found in individuals with idiopathic AA including dysregulated CD4 +, CD8 +, natural killer, and Th-17 T-cell responses and reduced numbers of regulatory T cells.[20] Elevations of circulating levels of inflammatory or myelosuppressive cytokines, such as interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and transforming growth factor-beta (TGF-β) are seen. The initial immune response may be triggered by pathogens, drugs, or chemicals, or by neoantigens through epigenetic mechanisms. It also is interesting that transient and persistent bone marrow hypoplasia has been linked to many microorganisms, and the interaction between the gut microbiota and immune system is hypothesized as an initial insult in the development of bone marrow failure syndromes such as AA.[21]

In secondary AA, stem cells and the bone marrow microenvironment may be altered from exposure to drugs, infectious agents, or other environmental factors.[20] Somatic changes in stem cell chromosomes may trigger these autoimmune processes and may contribute to the development of myelodysplastic syndrome and leukemia in individuals with AA.[19,20]

Clinical Manifestations

The onset of symptoms in AA is related to the rapidity with which the bone marrow is destroyed and replaced. Approximately 50% of AA cases progress rapidly, with a high risk of death from overwhelming infection or bleeding. In some cases, the rate of decline is slow, and the individual may adapt progressively to a new level of hematologic function. This condition is referred to as hypoplastic anemia rather than AA.

Initial symptoms depend on which cell line is affected. Rapidly progressing disease is usually associated with hypoxemia, pallor, and weakness. Other symptoms include fever and dyspnea and rapidly developing signs of hemorrhaging if platelets are affected (e.g., unexplained bruising, nosebleeds, bleeding gums, bleeding in the GI tract,

prolonged bleeding at sites of minor injury). A more insidious onset over weeks or months is characterized by progressive weakness and fatigue with gradually developing signs of hemorrhaging. Major hemorrhage may occur from any organ at any time; however, it is generally observed in the late stages and is often secondary to other events. In both rapid onset and slow onset AA, diminished leukocyte production may result in a progressive frequency and prolongation of infections. Ulcerations of the mouth and pharynx or a low-grade cellulitis in the neck may be seen. Neurologic changes may become evident when hemorrhages have occurred within the system.

Evaluation and Treatment

AA is suspected if levels of circulating erythrocytes, leukocytes, and platelets are diminished. The diagnosis is confirmed by bone marrow biopsy. The bone marrow usually has reduced cellularity (e.g., less than 25% normal cellularity). The morphology of the few remaining hematopoietic cells is usually normal. Occasionally the erythrocytes are macrocytic, with anisocytosis and poikilocytosis, and may appear immature.

Bone marrow and, most recently, peripheral blood stem cell transplantation (SCT) from a histocompatible sibling often cures the underlying bone marrow failure. Before transplantation, the recipient usually receives radiation or chemotherapy to deplete the bone marrow of disease-causing precursor cells. Infection and graft-versus-host (GVH) disease are major contributors to premature death after transplantation.[22]

For those individuals unable to undergo BMT or who lack a suitable sibling donor, immunosuppression remains the treatment of choice. Drugs like antithymocyte globulin (ATG) and cyclosporine suppress the activity of autoimmune cells. Corticosteroids are often used concurrently with ATG and cyclosporine. The addition of recombinant hematopoietic growth factors (e.g., granulocyte-macrophage colony–stimulating factor [GM-CSF], IL-6, and epoetin) to immunosuppressive therapy can produce significant additional benefit in both children and adults. A promising new treatment for AA is the oral thrombopoietin (TPO) receptor agonist eltrombopag which improves HSC maintenance and expansion.[23]

Anemias of Increased Destruction

Hemolytic anemia is premature accelerated destruction of erythrocytes, either episodically or continuously. They can be inherited or acquired (see Fig. 29.1). Hemolytic anemias may develop due to destruction outside of blood vessels or intravascularly. *Extravascular hemolysis* is the destruction of erythrocytes by macrophages which are abundant in the spleen, bone marrow, and liver. Macrophages will phagocytose erythrocytes that have been opsonized by antibodies, erythrocytes with structural alterations of the membrane surface, or erythrocytes that have become more rigid due to intracellular defects. *Intravascular hemolysis* most often is caused by antibody-mediated complement fixation. It can also be caused by mechanical injury, intracellular parasites, or exogenous toxic factors (e.g., clostridial sepsis, snake venom, lead poisoning). Although compensatory erythropoiesis provides new erythrocytes to replace those that are lost, if destruction outpaces production, then anemia develops. Hemolytic anemias may be either congenital or acquired.

Congenital hemolytic anemias result from intrinsic defects in erythrocytes, including the red cell membrane (e.g., hereditary spherocytosis, paroxysmal nocturnal hemoglobinuria), enzymatic pathways (e.g., glucose6-phosphate dehydrogenase deficiency), and hemoglobin synthesis (e.g., the thalassemia syndromes, sickle cell anemia) (see Chapter 30).

Acquired hemolytic anemias are usually immunologic, such as erythrocyte destruction caused by autoantibodies against erythrocyte antigens (e.g., autoimmune hemolytic anemia), isohemagglutinins (e.g., mismatched erythrocyte transfusions), or allergic reactions against drug antigens adsorbed onto the erythrocyte surface (drug-induced hemolytic anemia). Isohemagglutinins, erythrocyte antigens, autoantibodies, and allergic reactions are discussed in Chapter 9.

Pathophysiology

Autoimmune hemolytic anemias (AIHAs) are acquired disorders caused by autoantibodies, complement, or both, directed against antigens on the surface of erythrocytes. Aging, genetic background, autoimmune disorders, infections, medications, cancers (especially lymphomas), and organ transplants are risk factors for AIHA development. Recent studies implicate T- and B-cell dysregulation, reduced T regulatory cell function, and impaired lymphocyte apoptosis.[24] Five types of AIHAs have been described: (1) warm reactive antibody type, (2) cold agglutinin type, (3) cold hemolysin type (paroxysmal cold hemoglobinuria), (4) alloimmune

hemolytic anemia, and (5) drug-induced hemolytic anemia. This classification is based on the optimal temperature at which the antibody binds to erythrocytes and the mechanism of erythrocyte destruction.

Warm autoimmune hemolytic anemia is the most common form of AIHA accounting for about 1/3 of cases.[24] Approximately half of the cases are associated with other diseases, especially lymphomas but also chronic lymphocytic leukemia, other neoplastic disorders, or SLE. The anemia is caused by immunoglobulin G (IgG) antibodies that bind to erythrocytes at normal body temperature. The most common targets of these antibodies are Rh antigens on the erythrocyte surface.[25] The IgG-coated erythrocytes bind to the Fc receptors on monocytes and splenic macrophages and are removed by phagocytosis (see Chapter 9).

Cold agglutinin autoimmune hemolytic anemia is mediated by immunoglobulin M (IgM) antibodies and occurs less often than warm antibody hemolysis. These antibodies optimally bind to erythrocytes at colder temperatures (lower than 31°C [87.8°F]). Cold agglutinin autoantibodies may appear acutely during recovery from certain infectious disorders, particularly infectious mononucleosis (IM), *Mycoplasma pneumoniae*, and disseminated tuberculosis (TB). Chronic cold agglutinin AIHAs also can occur in association with lymphoid neoplasm and other unknown or idiopathic conditions. IgM autoantibodies are directed against erythrocyte carbohydrate antigens on the surface of erythrocytes.[25] In the colder areas of the body (e.g., fingers, toes, nose, ears, exposed skin), particularly during cold weather, the IgM autoantibodies bind to circulating erythrocytes where they activate complement leading to phagocytosis by mononuclear phagocytes in the liver and spleen (see Chapter 9). The IgM is rapidly released when the blood recirculates and warms. The severity of hemolysis is variable and may result in a progressive chronic anemia. Prolonged exposure to the cold may lead to gangrene.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) is a disorder in which exposure to cold initiates acute intravascular hemolysis that, unlike cold agglutinin anemia, is severe enough to cause hemoglobinuria. The acute form occurs primarily in children younger than the age of 10 years and is usually preceded by an upper respiratory tract infection or flulike symptoms. Viral infections with measles, mumps, or varicella, as well as *M. pneumoniae* infections, have also been linked to an onset of paroxysmal cold hemoglobinuria. The anemia

may be rapidly progressing and associated with fever, reddish brown urine, hemoglobinuria, jaundice, abdominal pains, and pallor, with about 25% of individuals presenting with hepatomegaly and splenomegaly.

A transfusion reaction is an example of **alloimmune hemolytic anemia** (see Chapter 9). Transfused blood that is mismatched for ABO antigens is destroyed by preexisting isohemagglutinins in the recipient. Isohemagglutinins, which are generally IgM antibodies, activate complement, resulting in a rapid intravascular hemolysis. The individual may immediately experience fever, chills, dyspnea, and hypotension and may progress to shock.

Drug-induced hemolytic anemia is a form of immune hemolytic anemia usually resulting from an allergic reaction against foreign antigens (e.g., antibiotics) (see Chapter 9). A low molecular weight drug may function as a hapten and bind to proteins on the surface of erythrocytes. IgG antibody is directed against the drug or against the unique antigen formed by the binding of the drug and erythrocyte protein (Fig. 29.8A). This leads to opsonization of the erythrocyte and phagocytosis by macrophages in the liver. Autoimmunity also can occur due to the formation of immune complexes which attach to erythrocytes and activate complement (see Fig. 29.8B). This mechanism also may explain some of the anemia observed in other immune complex conditions, such as SLE. Rarely, a drug (e.g., methyldopa) initiates the formation of cross-reactive antibodies that bind with erythrocyte antigens leading to phagocytosis by macrophages (see Fig. 29.8C).

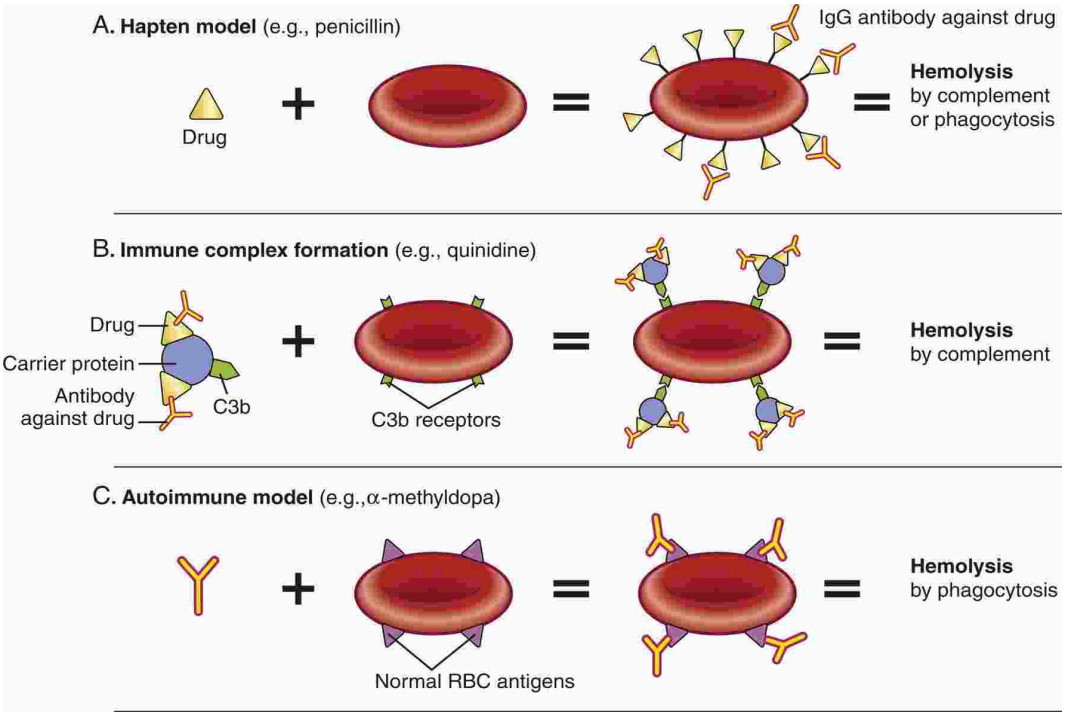

FIG. 29.8 Models of Drug-Induced Hemolytic Anemia.

Three illustrations show models of drug induced hemolytic anemia. Top panel, A. Hapten model (example, penicillin). The illustration shows: drug plus red blood cell bound with I g G antibody against drug equals hemolysis by complement or phagocytosis. Middle panel, B. Immune complex formation (example, quinidine). The illustration shows: carrier protein (has C 3 b component) with drug and antibody against drug plus blood cell with C 3 b receptors equals blood cell with C 3 b receptors attracting carrier proteins equals hemolysis by complement. Bottom panel, C. Autoimmune model (example, alpha-methyldopa). I g G antibody plus blood cell with normal R B C antigens equals blood cell with

normal R B C antigens attracting I g G antibody equals hemolysis by phagocytosis.

Clinical Manifestations

The presence and severity of signs and symptoms of hemolytic anemia depend on the degree of anemia and hemolysis and the success of compensatory erythropoiesis.[24] Bone marrow is capable of increasing red cell production up to eight times its normal rate. When accelerated erythrocyte production is incapable of keeping up with destruction, anemia develops. The severity of anemia varies widely among individuals, even in those who have the same underlying illness. Severe disease may be diagnosed shortly after birth or within the first year of life. Mild to moderate anemia is more common because the shortened erythrocyte survival time is offset by increased erythropoiesis. Some individuals have no symptoms of anemia, and the underlying hemolytic process remains undetected unless some other complications develop during the course of the disease. Acute conditions that disrupt the delicate equilibrium of accelerated erythropoiesis and erythrocyte destruction may precipitate a crisis. The most common type of crisis is aplastic and results from failure of bone marrow erythrocyte production.

Jaundice (icterus) is present when heme release from destroyed erythrocytes exceeds the liver's ability to conjugate and excrete bilirubin (see Chapter 41). Adults with mild or moderate hemolytic anemia may not have icterus, or it may be visible only in the sclera, and thus remains unnoticed. Cardiovascular and respiratory manifestations vary with the degree of anemia. Thromboembolism may occur, and pulmonary embolism is a common finding during autopsies of individuals with immune hemolytic anemia.[25] Individuals with congenital hemolytic disorders demonstrate splenomegaly, and in some cases, the spleen may become quite enlarged. Children who have hemolytic anemia may develop skeletal abnormalities caused by expansion of erythroid bone marrow during the active phase of growth and development.

Evaluation and Treatment

Diagnosis of AIHA is based on clinical manifestations and blood tests. A normocytic- normochromic anemia, in which the erythrocytes are damaged

or have abnormal shapes (schistocytes), combined with increased numbers of reticulocytes are indicative of hemolysis. Studies to detect the presence of autoantibodies (Direct Antiglobulin Test [DAT]) are performed and have 90% to 95% sensitivity in diagnosing AIHA.[25] Bone marrow biopsy may be indicated in certain individuals. Evaluation for the underlying cause of the hemolysis is conducted.

Acquired hemolytic anemias are treated by removing the cause or treating the underlying disorder when possible. Folate is given to prevent megaloblastic anemia because long-term erythrocyte turnover increases folate requirements. Corticosteroids are used for initial treatment in most cases, with a response rate of over 80%.[25] However some individuals relapse unless the underlying cause can be removed. The most commonly used second-line treatment is administration of rituximab (monoclonal antibody that reduces the number of B lymphocytes and thus antibody production), although it may be used as initial therapy for cold agglutinin AIHA. Third-line treatments may include splenectomy and the use of more potent immune-suppressive medications.[25] Most treatments for AIHA confer an increased risk for infection, and individuals should be monitored carefully. Acute fulminating hemolytic anemia (hemolytic crisis) is treated with fluid and electrolyte replacement to prevent shock and renal damage, which may be caused by erythrocyte debris clogging the kidney tubules. Transfusions of blood products is reserved for severe life-threatening acute anemia. If repeated transfusion is required, an erythropoiesis-stimulating agent may be used.[24]

Myeloproliferative Red Cell Disorders

Hematologic dysfunction results from an overproduction of cells, as well as a deficiency. One or more hematopoietic lines may be overproduced in the marrow in response to exogenous (e.g., exposure to radiation, drugs) or endogenous (e.g., physiologic compensatory response, immune disorder) signals. Excessive red cell production is classified as **polycythemia**. Polycythemia exists in two forms: relative and absolute. **Relative polycythemia** results from hemoconcentration of the blood associated with dehydration that may be caused by decreased water intake, diarrhea, excessive vomiting, or increased use of diuretics. Its development is usually of minor consequence and resolves with fluid administration or treatment of underlying conditions.

Absolute polycythemia consists of two types: primary and secondary (Table 29.5). *Primary polycythemia* comes in two forms. The more common form (but still rare) is polycythemia vera which occurs in older adults and is a type of malignancy of erythrocyte precursor cells in the bone marrow. Familial (congenital) polycythemia is most often caused by an autosomal dominant mutation of the erythropoietin receptor of erythroid progenitors causing hypersensitivity to erythropoietin and leading to increased rate of erythropoiesis.[26] Familial polycythemia also can be caused by inherited defects in hemoglobin (e.g., Chesapeake Hb, San Diego Hb) which have a greater affinity for oxygen, causing isolated erythrocytosis in asymptomatic individuals. *Secondary polycythemia* is the most common type of polycythemia and is most often a physiologic response to hypoxia leading to increases in erythropoietin secretion. Chronic hypoxia is found in individuals living at higher altitudes (>10,000 ft), smokers with increased blood levels of carbon dioxide (CO), and individuals with COPD or heart failure, or both. Secondary polycythemia caused by nonphysiologic responses results from the production of erythropoietin by certain tumors (see Table 29.5).

Table 29.5

Disorders Classified as Polycythemia

Type of Polycythemia	Mechanism of Increased Erythropoiesis	Cause of Associated Disorder
Primary polycythemia 1. Polycythemia vera 2. Familial (congenital) polycythemia	Excessive proliferation of erythroid precursors in marrow Increased sensitivity of stem cell to erythropoietin; or production of abnormal hemoglobin (Chesapeake Hb, San Diego Hb)	Mutation in the Janus kinase 2 gene (JAK2 gene) resulting in increased intracellular stimulation of cell division Inherited mutation of the erythropoietin receptor of erythroid progenitors causing hypersensitivity to erythropoietin; or the production of abnormal hemoglobin which has a greater affinity for oxygen
Secondary polycythemia	Physiologic increase in erythropoietin secretion by kidneys in response to underlying systemic disorder	Tissue hypoxia caused by cardiopulmonary disorders (chronic obstructive pulmonary disease, congestive heart failure), decreased barometric pressure, cardiovascular malformations causing mixing of arterial and venous blood, methemoglobinemia, carboxyhemoglobinemia, smoking, obesity

Type of Polycythemia	Mechanism of Increased Erythropoiesis	Cause of Associated Disorder
	"Nonphysiologic"[a] increase in erythropoietin secretion	Renal disorders, cerebellar hemangioblastomas, hepatoma (liver tumor), ovarian carcinoma, uterine leiomyoma, pheochromocytoma, adrenocortical hypersecretion

Type of Polycythemia	Mechanism of Increased Erythropoiesis	Cause of Associated Disorder
Primary polycythemia 1. Polycythemia vera 2. Familial (congenital) polycythemia	Excessive proliferation of erythroid precursors in marrow Increased sensitivity of stem cell to erythropoietin; or production of abnormal hemoglobin (Chesapeake Hb, San Diego Hb)	Mutation in the Janus kinase 2 gene (JAK2 gene) resulting in increased intracellular stimulation of cell division Inherited mutation of the erythropoietin receptor of erythroid progenitors causing hypersensitivity to erythropoietin; or the production of abnormal hemoglobin which has a greater affinity for oxygen
Secondary polycythemia	Physiologic increase in erythropoietin secretion by kidneys in response to underlying systemic disorder	Tissue hypoxia caused by cardiopulmonary disorders (chronic obstructive pulmonary disease, congestive heart failure), decreased barometric pressure, cardiovascular malformations causing mixing of arterial and venous blood, methemoglobinemia, carboxyhemoglobinemia, smoking, obesity
	"Nonphysiologic"[a] increase in erythropoietin secretion	Renal disorders, cerebellar hemangioblastomas, hepatoma (liver tumor), ovarian carcinoma, uterine leiomyoma, pheochromocytoma, adrenocortical hypersecretion

[a]*Nonphysiologic* means that there is no obvious physiologic explanation for hypersecretion of erythropoietin.

Polycythemia Vera

Polycythemia vera (PV) is a slowly growing blood cancer in which the bone marrow makes too many red blood cells. PV is quite rare, with a peak incidence between the ages of 60 and 80 years. However, PV has been observed in individuals younger than the age of 40. Males are twice as likely as females to develop PV. It is more common in whites of Eastern European Jewish ancestry. PV is rarely seen in children or in multiple members of a single family; however, an autosomal dominant form exists that causes increased secretion of erythropoietin. Median survival for PV is 15 years; however, the survival rate for individuals 40 and younger is 37 years.[27]

PV is one of several disorders collectively known as *myeloid malignancies* (Box 29.2). These disorders all result from abnormal regulation of the HSCs. Specifically, the common pathogenic feature is the presence of a mutation in the **Janus kinase 2 gene (*JAK2*gene)**. Normally, the *JAK2* gene makes a protein that helps the body produce blood cells. When JAK2 is mutated, there is an increased intracellular stimulation of cell division and an overproduction of blood cells.[27] Because of numerous characteristics (e.g., overproduction of different blood cells, marrow hypercellularity, or fibrosis) shared by these disorders and a lack of specific molecular markers, the diagnosis can be quite challenging. The major characteristics shared by these disorders include (1) involvement of a hematopoietic progenitor cell, (2) overproduction of one or more of the formed elements in blood in the absence of a defined stimulus, (3) dominance by a transformed progenitor cell, (4) hypercellular bone marrow or fibrosis, (5) chromosomal (cytogenetic) abnormalities, (6) predisposition to thrombus formation and hemorrhage, and (7) spontaneous transformation to leukemia.

Box 29.2

2016 World Health Organization Classification of Myeloid Malignancies

Acute Myeloid Leukemia (AML) and Related Neoplasms	**Chronic Myeloid Neoplasms**
AML with recurrent genetic abnormalities AML with myelodysplasia-related changes Therapy-related myeloid neoplasms AML, not otherwise specified Myeloid sarcoma Down associated myeloid proliferations	Myeloproliferative neoplasms (MPN) 1. Chronic myeloid leukemia, BCR-ABL1+ 2. Chronic neutrophilic leukemia, often CSF3R mutated 3. Chronic eosinophilic leukemia, not otherwise specified 4. MPN, unclassifiable (MPN-U) 5. Polycythemia vera (PV) 6. Essential thrombocythemia (ET) 7. Primary myelofibrosis (PMF) Mastocytosis Myeloid/lymphoid neoplasms with eosinophilia and PDGFRA, PDGFRB, FGFR1, or PCM1-JAK2 mutations Myelodysplastic/myeloproliferative neoplasms (MDS/MPN) Myelodysplastic syndromes (MDS) Myeloid neoplasms with germ line predisposition
Definition of Smoldering Multiple Myeloma	
Both criteria must be met:	

Acute Myeloid Leukemia (AML) and Related Neoplasms	Chronic Myeloid Neoplasms
Serum monoclonal protein (IgG or IgA) ≥ 30 g/L or urinary monoclonal protein ≥ 500/24 h and/or clonal bone marrow plasma cells 10%–60% Absence of myeloma-defining events or amyloidosis	

Acute Myeloid Leukemia (AML) and Related Neoplasms	Chronic Myeloid Neoplasms
AML with recurrent genetic abnormalities	Myeloproliferative neoplasms (MPN)
AML with myelodysplasia-related changes	1. Chronic myeloid leukemia, BCR-ABL1+
Therapy-related myeloid neoplasms	2. Chronic neutrophilic leukemia, often CSF3R mutated
AML, not otherwise specified	3. Chronic eosinophilic leukemia, not otherwise specified
Myeloid sarcoma	4. MPN, unclassifiable (MPN-U)
Down associated myeloid proliferations	5. Polycythemia vera (PV)
	6. Essential thrombocythemia (ET)
	7. Primary myelofibrosis (PMF)
	Mastocytosis
	Myeloid/lymphoid neoplasms with eosinophilia and PDGFRA, PDGFRB, FGFR1, or PCM1-JAK2 mutations
	Myelodysplastic/myeloproliferative neoplasms (MDS/MPN)
	Myelodysplastic syndromes (MDS)
	Myeloid neoplasms with germ line predisposition
Definition of Smoldering Multiple Myeloma	
Both criteria must be met: Serum monoclonal protein (IgG or IgA) ≥ 30 g/L or urinary monoclonal protein ≥ 500/24 h and/or clonal bone marrow plasma cells 10%–60% Absence of myeloma-defining events or amyloidosis

International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. *Lancet Oncology*, 2014;15(12):e538–e548.

Pathophysiology

PV is a stem cell disorder with hyperplastic and neoplastic bone marrow alterations. It is characterized by an abnormal uncontrolled proliferation of red blood cells (frequently with increased levels of white blood cells [leukocytosis] and platelets [thrombocytosis]). The polycythemia is responsible for most of the clinical symptoms, including an increase in

blood volume and viscosity. Proliferation of erythroid progenitors occurs in the bone marrow independent of the hormone erythropoietin. More than 95% of individuals with PV have an acquired mutation in the tyrosine kinase *JAK2* gene.[27] Normal JAK2 protein increases the activity of the erythropoietin receptor and is self-regulatory so that JAK2 activity diminishes over time. The mutation associated with PV negates the self-regulatory activity of JAK2 so that the erythropoietin receptor is constantly active regardless of the level of erythropoietin. Overall, the mutated tyrosine kinases bypass normal controls, causing growth factor–independent proliferation and survival of marrow progenitors or precursor cells. The cause of the mutation is unknown.

Increased numbers of erythrocytes and other blood cells increase the blood viscosity. This alters blood flow and creates a hypercoagulable state that results in thrombotic occlusion of blood vessels. Tissue injury (ischemia) and death (infarction) are the outcomes of blood vessel blockage. These outcomes are directly correlated with hematocrit levels. Increases in numbers of thrombocytes, as well as production of dysfunctional platelets, also contribute to this hypercoagulable condition. Leukemia develops in approximately 3% of individuals with PA, and fibrotic transformation of the bone marrow limits survival in 15%.[28]

Clinical Manifestations

Clinical manifestations of PV are a result of the increased red cell mass and hematocrit leading to increased blood volume and viscosity. This combined with thrombosis leads to symptoms of ischemia in vital organs (pain, hypoxia, decreased peripheral circulation). Circulatory alterations caused by the thick, sticky blood give rise to other manifestations, such as plethora (ruddy, red color of the face, hands, feet, ears, and mucous membranes) and engorgement of retinal and cerebral veins. Other symptoms may include headache, drowsiness, delirium, mania, psychotic depression, chorea, and visual disturbances. Individuals frequently have an enlarged spleen with abdominal pain and discomfort. Death from cerebral thrombosis is approximately five times greater in individuals with PV.

Cardiovascular function, despite the vascular alterations, remains relatively normal. Cardiac workload and output remain constant; however, increased blood volume does increase blood pressure. Coronary blood flow may be affected, precipitating angina, although cardiovascular infarctions are uncommon. Other cardiovascular manifestations include Raynaud phenomenon and thromboangiitis obliterans.

A unique feature of PV, and helpful in diagnosis, is the development of intense, painful itching that appears to be intensified by heat or exposure to water *(aquagenic pruritus)* so that individuals avoid exposure to water, particularly warm water when bathing or showering. The intensity of itching is related to the concentration of mast cells in the skin and is generally not responsive to antihistamines or topical lotions.

Evaluation and Treatment

PV may be suspected because of clinical features, such as a thrombotic event, splenomegaly, or aquagenic pruritus. Blood and laboratory findings confirm the diagnosis. Diagnostic criteria include a hemoglobin greater than 16.5 g/dL or a hematocrit greater than 49% in men and greater than 48% in women.[27] Erythrocytes appear normal, but anisocytosis may be present. There also may be moderate increases in white blood cells and platelets. A bone marrow examination demonstrates proliferation of precursor cells and the presence of a *JAK2* mutation which confirms the diagnosis. Serum erythropoietin levels are decreased.

Treatment of PV consists of reducing red cell proliferation and blood volume, controlling symptoms, and preventing clogging and clotting of the blood vessels. In low-risk individuals (e.g., those younger than age 60 or with no history of thrombosis and without risk factors for cardiovascular disease), the recommended therapy is phlebotomy (300 to 500 mL at a time to reduce erythrocytosis and blood volume) and low-dose aspirin. Frequent phlebotomies also reduce iron levels, a condition that impedes erythropoiesis.[28]

In high-risk PV, systemic anticoagulation is indicated. Hydroxyurea, a nonalkylating myelosuppressive, is the drug of choice for myelosuppression because of a reduced incidence to cause leukemia and thrombosis. IFN-α or busulfan are used when other forms of treatment have failed. Ruxolitinib inhibits the JAK2 pathway and is showing positive results in multiple studies.[28]

Iron Overload

Iron overload can be primary, as in hereditary hemochromatosis (HH), or secondary. The secondary causes of iron overload include anemias with inefficient erythropoiesis (e.g., AA), dietary iron overload, or conditions that require repeated blood transfusions or iron dextran injections.

Hereditary Hemochromatosis

Hemochromatosis is caused by excessive iron absorption. **Hereditary hemochromatosis (HH)** is a common inherited iron overload disorder characterized by excessive absorption of iron. It is due to a deficiency of hepcidin or to decreased binding of hepcidin to ferroportin, the transmembrane protein that exports iron outside the cell (Fig. 29.9).[29] HH is characterized by increased iron absorption from the GI tract, with subsequent tissue iron deposition. Excess iron is deposited first in the liver and pancreas, followed by the heart, joints, and endocrine glands. Excess iron causes tissue damage that can lead to diseases such as cirrhosis, diabetes, heart failure, arthropathies, and impotence.

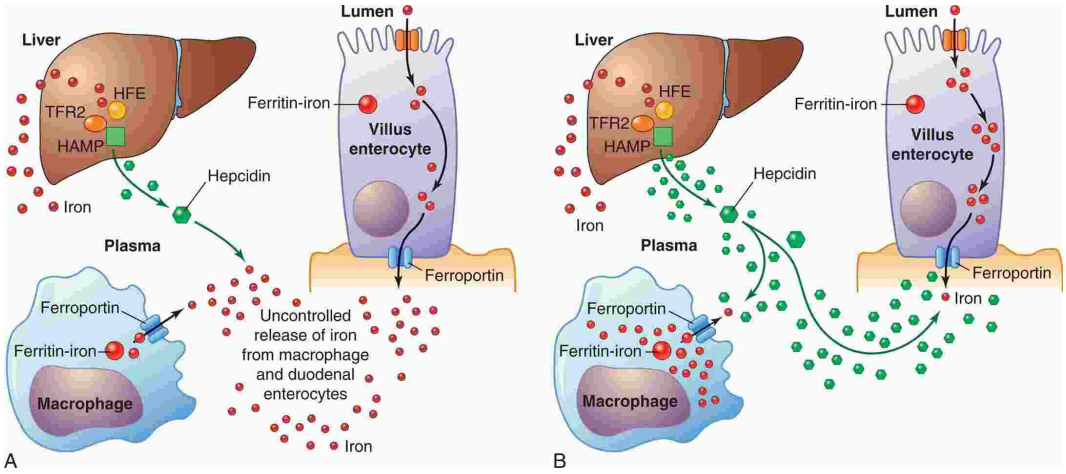

FIG. 29.9 Hemochromatosis.
(A) Mutations in genes affecting HFE, TFR2, or HAMP lead to decreased levels of hepcidin causing excessive absorption of iron. (B) Mutations to ferroportin cause decreased binding of hepcidin and iron accumulation within cells. *HAMP*, Hepatic antimicrobial protein; *HFE*, human homeostatic iron regulator protein; *TFR2*, transferrin receptor 2. (Adapted from Pietrangelo A. Hereditary hemochromatosis. Biochimica et Biophysica Acta (BBA). *Molecular Cell Research*, 2006;1763(7):700–710.)

Left panel, A. The illustration shows a macrophage, the liver, and a lumen. The lumen and macrophage release iron not through the ferroportin. Mutations affecting T F R 2, H F E, and H A M P in the liver decrease hepcidin levels. Liver also releases iron. All factors lead to uncontrolled release of iron from macrophage and duodenal enterocytes. Right panel, B. The illustration shows macrophage, the liver, and a lumen. Mutations in the ferroportin of the macrophage and lumen result in the storage of iron within the cells. Normal hepcidin levels regulate the absorption of iron by the liver.

Pathophysiology

Different forms of HH result from mutations in various genes that play important roles in regulating absorption, transport, and storage of iron. HH is classified by type (1, 2, 3, and 4) based on which proteins involved in iron homeostasis are affected. Type 1 HH is the most frequent form and is characterized by one of two mutations of the human homeostatic iron regulator (HFE) gene. These mutations result in decreased synthesis of **hepcidin**. Hepcidin is a hormone secreted by the liver in response to increased serum iron, and it inhibits iron absorption from the intestine by degrading ferroportin-1. (see Chapter 28). Most affected individuals have a homozygous C282Y mutations in the HFE gene (type 1a).[30] Less common is H63D mutation, which by itself does not cause significant iron overload, but may become clinically significant when associated with excessive alcohol intake or hepatitis C infection or may act as a cofactor in combination with C282Y. This combined C282Y/H63D genotype is classified as HH type 1b.[29] The other HH genotypes have a much lower prevalence. Type 2 HH, also called juvenile hemochromatosis, is associated with mutations in either the HJV gene or the hepatic antimicrobial protein (HAMP) gene leading to hepcidin deficiency. Type 2 is the most severe form of primary iron overload and develops in younger individuals. Type 3 HH is associated with mutations in the transferrin receptor 2 (TFR2) gene, also leading to hepcidin deficiency. Type 4 A HH results from autosomal dominant mutations in the ferroportin gene (SLC40A1) These mutations disrupt the export function of ferroportin despite normal levels of hepcidin. Intracellular iron rises in association with low levels of plasma iron and normal levels of transferrin saturation but elevated levels of serum transferrin. Type 4B HH results from resistance of ferroportin to hepcidin.[29]

In all types of HH, iron accumulates in tissues and organs disrupting their normal function.[30] In the liver, this accumulation of iron may lead to the development of cirrhosis and hepatocellular carcinoma.[31] Cardiac complications are the second-leading cause of death in HH and include cardiomyopathy, arrhythmias, and heart failure. HH injures the pancreatic β-islet cells and contributes to the development of hepatic insulin resistance leading to diabetes in 13% to 23% of affected individuals.[29] Iron deposits in the skin lead to increased melanin deposition, causing bronzing. Arthropathy most commonly involves the second and third metacarpophalangeal joints.

Clinical Manifestations

Clinical HH, more common in men than women, is characterized by excessive storage of iron in the liver, skin, pancreas, heart, joints, and testes. Fatigue and arthralgias are the most common symptoms encountered early in the disease. Other early symptoms may include weakness and weight loss. The risk of cirrhosis is significantly increased when the serum ferritin level is higher than 1000 ng/mL.[29] Upper right quadrant abdominal pain, ascites, and edema indicate liver dysfunction and cirrhosis. Symptoms of heart failure (dyspnea, orthopnea, edema) may develop. Other findings include progressive increase in skin pigmentation, diabetes mellitus, arthritis, and hypogonadism. Most individuals are diagnosed as a result of elevated liver function tests found during routine health screening.

Evaluation and Treatment

The American College of Gastroenterology (ACG) published guidelines for diagnosis and management of hemochromatosis in 2019.[29] Serum transferrin saturation and serum ferritin are the first-line diagnostic tests for HH. Individuals with abnormal results should undergo genetic testing. Magnetic resonance imaging is used to estimate hepatic iron concentration. However, if another source of liver disease is suspected, liver biopsy is indicated. First-degree relatives of individuals diagnosed with HH should be screened for mutations.

Phlebotomy is first-line treatment, with a goal of reducing serum ferritin to 50 to 100 ng/mL.[29] Therapeutic phlebotomy to remove excess iron is indicated in the presence of iron overload or evidence of end-organ damage (e.g., advanced cirrhosis, cardiac failure, skin pigment changes, or diabetes). Initially, phlebotomy may be needed weekly, but once therapeutic ferritin levels are reached, phlebotomy may be needed only every 2 to 3 months. Iron chelation therapy can be used in selected individuals who cannot tolerate phlebotomy and may decrease the risk for development of cirrhosis and hepatocellular cancer but is associated with numerous side effects. Individuals should be instructed to refrain from drinking alcohol, taking iron supplements, and consuming raw fish or shellfish. Vaccination against hepatitis A and B is advised. Regular screening for the development of hepatocellular carcinoma should be performed every 6 months.[31]

Alterations of Leukocyte Function

Leukocyte function (infection fighting) is affected if too many or too few white cells are present in the blood or if the cells that are present are structurally or functionally defective. **Quantitative leukocyte disorders** result from decreased production in the bone marrow or accelerated destruction of cells in the circulation. In addition, quantitative alterations occur in response to infections.

Qualitative leukocyte disorders consist of disruptions of leukocyte function. Phagocytic cells (granulocytes, monocytes, macrophages) may lose their ability to act as effective phagocytes, and the lymphocytes may lose their ability to respond to antigens. (Disruptions of inflammatory and immune processes caused by leukocyte disorders are described in Chapter 7.) Other leukocyte alterations include IM and cancers of the blood—leukemia and multiple myeloma (MM).

Quantitative Alterations of Leukocytes

Leukocytosis is present when the count is higher than normal; **leukopenia** is present when the count is lower than normal. Leukocytosis and leukopenia may affect a specific type of white blood cell and may result from a variety of physiologic conditions and alterations.

Leukocytosis occurs as a normal protective response to physiologic stressors, such as invading microorganisms, strenuous exercise, emotional changes, temperature changes, anesthesia, surgery, pregnancy, and some drugs, hormones, and toxins. It also is caused by pathologic conditions, such as malignancies and hematologic disorders. Unlike leukocytosis, leukopenia is never normal and is defined as an absolute blood cell count less than 4000 cells/μL. Leukopenia is associated with a decrease in neutrophils, which increases risk for infection. The absolute neutrophil count (ANC) is calculated by multiplying the white blood cell count by the percent of band and segmented neutrophils. The ANC is classified as mild (1000 to 1500 cells/μL), moderate (500 to 1000 cells/μL), or severe (<500 cells/μL). When the ANC is less than 500/μL, the possibility for life-threatening infections is high. Leukopenia may be caused by radiation, anaphylactic shock, autoimmune disease (e.g., SLE), immune deficiencies (see Chapter 9), and certain drugs, such as glucocorticoids and chemotherapeutic agents.

Granulocytes and Monocytes

Increased numbers of circulating granulocytes (neutrophils, eosinophils, basophils) and monocytes are chiefly a physiologic response to infection. Increased numbers also occur as a result of myeloproliferative disorders that increase stem cell proliferation in the bone marrow.

Decreased numbers occur when infectious processes deplete the supply of circulating granulocytes and monocytes, drawing them out of the circulation and into infected tissues faster than they can be replaced. Decreases also can be caused by disorders that suppress marrow function, such as severe congenital neutropenia or immune-related neutropenia.

Granulocytosis—an increase in granulocytes (neutrophils, eosinophils, or basophils)—begins when stored blood cells are released. **Neutrophilia** is another term that may be used to describe *granulocytosis* because neutrophils are the most numerous of the granulocytes (Table 29.6). Neutrophilia occurs in the early stages of infection or inflammation and is established when the absolute count exceeds 7500/μL. Release and depletion of stored neutrophils stimulates granulopoiesis to replenish neutrophil reserves.

Table 29.6

Other Conditions Associated With Neutrophils, Eosinophils, Basophils, Monocytes, and Lymphocytes

Condition	Cause	Example
Neutrophil		
Neutrophilia (granulocytosis)	Inflammation or tissue necrosis	Surgery, burns, MI, pneumonitis, rheumatic fever, rheumatoid arthritis
	Infection	Bacterial: gram-positive (staphylococci, streptococci, pneumococci), gram-negative (*Escherichia coli, Pseudomonas* species)
	Physiologic	Exercise, extreme heat or cold, third-trimester pregnancy, emotional distress
	Hematologic	Acute hemorrhage, hemolysis, myeloproliferative disorder, chronic granulocytic leukemia
	Drugs or chemicals	Epinephrine, steroids, heparin, histamine, endotoxin
	Metabolic	Diabetes (acidosis), eclampsia, gout, thyroid storm
	Neoplasm	Liver, GI tract, bone marrow
Neutropenia		

Condition	Cause	Example
	Primary neutropenia Congenital Acquired Decreased marrow production, ineffective granulopoiesis	Cyclic neutropenia, neutropenia with congenital immunodeficiencies, and multiple syndromes Megaloblastic anemias (vitamin B_{12} and folate deficiency), leukemia, aplastic anemia starvation, anorexia nervosa, radiation, chemotherapy,
	Secondary neutropenia Increased destruction, reduced survival, abnormal distribution	Splenomegaly, hemodialysis, autoimmune disease (rheumatoid arthritis, systemic lupus erythematous, Felty syndrome, Sjögren syndrome)
	Prolonged infection	Gram-negative (typhoid), viral (influenza, hepatitis B, measles, mumps, rubella), severe infections, protozoal infections (malaria)
Eosinophil		
Eosinophilia	Allergy	Asthma, hay fever, drug sensitivity
	Infection	Parasites (trichinosis, hookworm), chronic (fungal, leprosy, TB)

Condition	Cause	Example
	Malignancy	CML, lung, stomach, ovary, Hodgkin disease
	Dermatosis	Pemphigus, exfoliative dermatitis (drug-induced)
	Drugs	Digitalis, heparin, streptomycin, tryptophan (eosinophilia-myalgia syndrome), penicillins, propranolol
Eosinopenia	Stress response	Trauma, shock, burns, surgery, mental distress
	Drugs	Steroids (Cushing syndrome)
Basophil		
Basophilia	Inflammation	Infection (measles, chickenpox), hypersensitivity reaction (immediate)
	Hematologic	Myeloproliferative disorders (CML, polycythemia vera, Hodgkin lymphoma, hemolytic anemia)
	Endocrine	Myxedema, antithyroid therapy
Basopenia	Physiologic	Pregnancy, ovulation, stress
	Endocrine	Graves disease
Monocyte		

Condition	Cause	Example
Monocytosis	Infection	Bacterial (subacute bacterial endocarditis, TB), recovery phase of infection
	Hematologic	Myeloproliferative disorders, Hodgkin disease, agranulocytosis
	Physiologic	Normal newborn
Monocytopenia	Rare	
Lymphocyte		
Lymphocytosis	Physiologic	4 months to 4 years
	Acute infection	Infectious mononucleosis, CMV infection, pertussis, hepatitis, mycoplasma pneumonia, typhoid
	Chronic infection	Congenital syphilis, tertiary syphilis
	Endocrine	Thyrotoxicosis, adrenal insufficiency
	Malignancy	ALL, CLL, lymphosarcoma cell leukemia
Lymphocytopenia	Immunodeficiency syndrome	AIDS, agammaglobulinemia
	Lymphocyte destruction	Steroids (Cushing syndrome), radiation, chemotherapy
		Hodgkin lymphoma
		CHF, renal failure, TB, SLE, aplastic anemia

Condition	Cause	Example
Neutrophil		
Neutrophilia (granulocytosis)	Inflammation or tissue necrosis	Surgery, burns, MI, pneumonitis, rheumatic fever, rheumatoid arthritis
	Infection	Bacterial: gram-positive (staphylococci, streptococci, pneumococci), gram-negative (*Escherichia coli, Pseudomonas* species)
	Physiologic	Exercise, extreme heat or cold, third-trimester pregnancy, emotional distress
	Hematologic	Acute hemorrhage, hemolysis, myeloproliferative disorder, chronic granulocytic leukemia
	Drugs or chemicals	Epinephrine, steroids, heparin, histamine, endotoxin
	Metabolic	Diabetes (acidosis), eclampsia, gout, thyroid storm
	Neoplasm	Liver, GI tract, bone marrow
Neutropenia	Primary neutropenia Congenital Acquired Decreased marrow production, ineffective granulopoiesis	Cyclic neutropenia, neutropenia with congenital immunodeficiencies, and multiple syndromes Megaloblastic anemias (vitamin B_{12} and folate deficiency), leukemia, aplastic anemia starvation, anorexia nervosa, radiation, chemotherapy,
	Secondary neutropenia Increased destruction, reduced survival, abnormal distribution	Splenomegaly, hemodialysis, autoimmune disease (rheumatoid arthritis, systemic lupus erythematous, Felty syndrome, Sjögren syndrome)
	Prolonged infection	Gram-negative (typhoid), viral (influenza, hepatitis B, measles, mumps, rubella), severe infections, protozoal infections (malaria)
Eosinophil		
Eosinophilia	Allergy	Asthma, hay fever, drug sensitivity
	Infection	Parasites (trichinosis, hookworm), chronic (fungal, leprosy, TB)
	Malignancy	CML, lung, stomach, ovary, Hodgkin disease
	Dermatosis	Pemphigus, exfoliative dermatitis (drug-induced)
	Drugs	Digitalis, heparin, streptomycin, tryptophan (eosinophilia-myalgia syndrome), penicillins, propranolol
Eosinopenia	Stress response	Trauma, shock, burns, surgery, mental distress
	Drugs	Steroids (Cushing syndrome)
Basophil		
Basophilia	Inflammation	Infection (measles, chickenpox), hypersensitivity reaction (immediate)
	Hematologic	Myeloproliferative disorders (CML, polycythemia vera, Hodgkin lymphoma, hemolytic anemia)
	Endocrine	Myxedema, antithyroid therapy
Basopenia	Physiologic	Pregnancy, ovulation, stress
	Endocrine	Graves disease
Monocyte		
Monocytosis	Infection	Bacterial (subacute bacterial endocarditis, TB), recovery phase of infection
	Hematologic	Myeloproliferative disorders, Hodgkin disease, agranulocytosis
	Physiologic	Normal newborn
Monocytopenia	Rare	
Lymphocyte		
Lymphocytosis	Physiologic	4 months to 4 years
	Acute infection	Infectious mononucleosis, CMV infection, pertussis, hepatitis, mycoplasma pneumonia, typhoid
	Chronic infection	Congenital syphilis, tertiary syphilis
	Endocrine	Thyrotoxicosis, adrenal insufficiency
	Malignancy	ALL, CLL, lymphosarcoma cell leukemia
Lymphocytopenia	Immunodeficiency syndrome	AIDS, agammaglobulinemia
	Lymphocyte destruction	Steroids (Cushing syndrome), radiation, chemotherapy
		Hodgkin lymphoma
		CHF, renal failure, TB, SLE, aplastic anemia

AIDS, Acquired immunodeficiency syndrome; *ALL*, acute lymphocytic leukemia; *CHF*, congestive (left) heart failure; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myelogenous leukemia; *CMV*, cytomegalovirus; *GI*, gastrointestinal; *MI*, myocardial infarction; *SLE*, systemic lupus erythematosus; *TB*, tuberculosis.

When the demand for circulating mature neutrophils exceeds the supply, immature neutrophils (and other leukocytes) are released from the bone marrow. Premature release of the immature cells is responsible for the phenomenon known as a **shift-to-the-left, or leukemoid reaction**. This refers to the microscopic detection of disproportionate numbers of immature leukocytes in peripheral blood smears. Many diagrams present cellular differentiation and maturation progressing from left to right within the drawing, instead of vertically as shown in Fig. 28.10. The early release of immature white cells prevents the completion of the sequence and shifts the distribution of leukocytes in the blood toward those on the left side of the diagram. This phenomenon is also seen in the blood smear of individuals with leukemia, hence the term *leukemoid reaction*. As infection or inflammation diminishes, and granulopoiesis replenishes circulating granulocytes, a **shift-to-the-right**, or return to normal, occurs.

Neutropenia is a condition associated with a reduction in circulating neutrophils and exists clinically when the neutrophil count is less than 2000/μL. Reduction in neutrophils occurs in severe prolonged infections when production of granulocytes cannot keep up with demand. Severe neutropenia, **granulocytopenia** (less than 500/μL), or **agranulocytosis** (complete absence of granulocytes in blood) is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation. Chemotherapeutic agents used to treat hematologic and other malignancies cause bone marrow suppression. Several other drugs cause agranulocytosis, which occurs rarely but carries a high mortality of 10% to 50%. Clinical manifestations of agranulocytosis include severe infection (particularly of the respiratory system) leading to septicemia, general malaise, fever, tachycardia, and ulcers in the mouth and colon. If this condition remains untreated, sepsis caused by agranulocytosis results in death within 3 to 6 days.

Other causes of neutropenia, in the absence of infection, may be (1) decreased neutrophil production or ineffective granulopoiesis, (2) reduced neutrophil survival, and (3) abnormal neutrophil distribution and sequestration. Neutropenia also is classified as primary or secondary, and primary disorders are further identified as congenital or acquired. Primary acquired neutropenia is associated with multiple conditions. The

megaloblastic anemias (vitamin B_{12} and folate deficiency), as well as starvation and anorexia nervosa, cause neutropenia because of an inadequate supply of vitamins and nutrients for protein production.

Congenital defects in neutrophil production include cyclic neutropenia, neutropenia with congenital immunodeficiencies, and multiple syndromes. Reduced neutrophil survival and abnormal distribution and sequestration are usually secondary to other disorders. Neutropenia occurs in a variety of immunologic disorders, particularly SLE, rheumatoid arthritis, Felty and Sjögren syndromes, splenomegaly, and drug-related causes.

Eosinophilia is an absolute increase (>450/μL) in the total number of circulating eosinophils. Allergic disorders (type 1) associated with asthma, hay fever, parasitic infections, and drug reactions often cause eosinophilia. Hypersensitivity reactions trigger the release of eosinophilic chemotaxic factor of anaphylaxis (ECF-A), and histamine from mast cells attracts eosinophils to the area. Mast cells release interleukin-5 (IL-5), which stimulates the bone marrow to produce more eosinophils into the blood. Areas with abundant mast cells, such as the respiratory and GI tracts, are commonly affected. Eosinophilia also may occur in dermatologic disorders, eosinophilia-myalgia syndrome, and parasitic invasion.

Eosinopenia, a decrease in the number of circulating eosinophils, generally is caused by migration of eosinophils into inflammatory sites. It also may be seen in Cushing syndrome and as a result of stress caused by surgery, shock, trauma, burns, or mental distress.

Basophilia, an increase in the number of circulating basophils, is rare and generally is a response to inflammation and immediate hypersensitivity reactions. Basophils contain histamine that is released during an allergic reaction. Increased numbers of basophils are seen in myeloproliferative disorders, such as chronic myeloid leukemia and myeloid metaplasia.

Basopenia (also known as *basophilic leukopenia*) is a decrease in circulating numbers of basophils. It is seen in hyperthyroidism, acute infection, ovulation and pregnancy, and long-term therapy with steroids.

Monocytosis is an increase in numbers of circulating monocytes (generally >800/μL). It is often transient and not related to a dysfunction of monocyte production. If present, it is usually associated with neutropenia during bacterial infections, particularly in the late stages or recovery stage, when monocytes are needed to phagocytize surviving microorganisms and debris. Increased monocytes also may indicate marrow recovery from agranulocytosis. Monocytosis is often seen in

chronic infections such as TB, brucellosis, listeriosis, and subacute bacterial endocarditis (SBE). Monocytosis has been found to correlate with the extent of myocardial damage after myocardial infarctions. **Monocytopenia**, a decrease in the number of circulating monocytes, is rare but has been identified with hairy cell leukemia and prednisone therapy.

Lymphocytes

Quantitative alterations of lymphocytes occur when lymphocytes are activated by antigenic stimuli, usually microorganisms (see Chapters 7 and 8). **Lymphocytosis (absolute lymphocytosis)** is an increase in the number or proportion of lymphocytes in the blood. It is rare in acute bacterial infections and is seen most in acute viral infections, particularly those caused by the EBV, a causative agent in IM.

Lymphocytopenia is a decrease in the number of circulating lymphocytes in the blood. It may be attributed to (1) abnormalities of lymphocyte production associated with neoplasias and immune deficiencies and (2) destruction by drugs, viruses, or radiation. It is also known to occur without any detectable cause. The lymphocytopenia associated with heart failure and other acute illnesses may be caused by elevated cortisol levels. Lymphocytopenia is a major problem in AIDS. AIDS-related lymphocytopenia is caused by HIV, which destroys T-helper lymphocytes. (For a detailed discussion of AIDS, see Chapter 9.) Other conditions associated with increases or decreases in these specific types of white blood cells are listed in Table 29.6.

Infectious Mononucleosis

Infectious mononucleosis (IM) is a benign, acute, self-limiting, lymphoproliferative clinical syndrome characterized by acute viral infection of B lymphocytes (B cells). It is associated with several human tumors, such as B-cell and T-cell lymphomas, Hodgkin lymphoma (HL), and nasopharyngeal carcinoma.[32] The virus has been linked to posttransplant lymphoproliferative diseases (PTLDs), and gastric carcinoma.[33] The most common cause is EBV. EBV is a ubiquitous herpesvirus and accounts for most IM cases. Other viruses that cause symptoms resembling IM include cytomegalovirus (CMV), adenovirus, HIV, hepatitis A, influenza A and B, and rubella, as well as the bacteria *Toxoplasma gondii, Corynebacterium diphtheriae*, and *Coxiella burnetii*. The classic symptoms of IM are pharyngitis, lymphadenopathy, and fever. In individuals with immunodeficiency, the proliferation of infected B cells

may be uncontrolled and can lead to the development of B-cell lymphomas.[34] Individuals who are coinfected with malaria or HIV are at increased risk of developing EBV-associated lymphomas, including Burkitt lymphoma (BL). EBV also is etiologically linked to subgroups of HL.

EBV has not been documented from environmental sources, thus humans are considered the major reservoir. More than 90% of individuals worldwide have antibodies to EBV.[33,35] Approximately 50% to 85% of children are infected with EBV by age 4. These early infections are usually asymptomatic and provide immunity to EBV; thus, early EBV infections rarely develop into IM. IM may arise when the initial infection occurs during adolescence or later, but still only results in IM in 35% to 50% of these individuals. Symptomatic IM usually affects young adults between ages 15 and 35 years, with the peak incidences occurring between ages 15 and 24 years; males have a later peak (18 to 24 years) than females. The overall incidence rate for this age group is 6 to 8 cases per 1000 persons per year. Children from low socioeconomic environments are particularly susceptible to infections with EBV. IM is uncommon in individuals older than age 40; however, if it does occur, IM is more commonly caused by CMV.

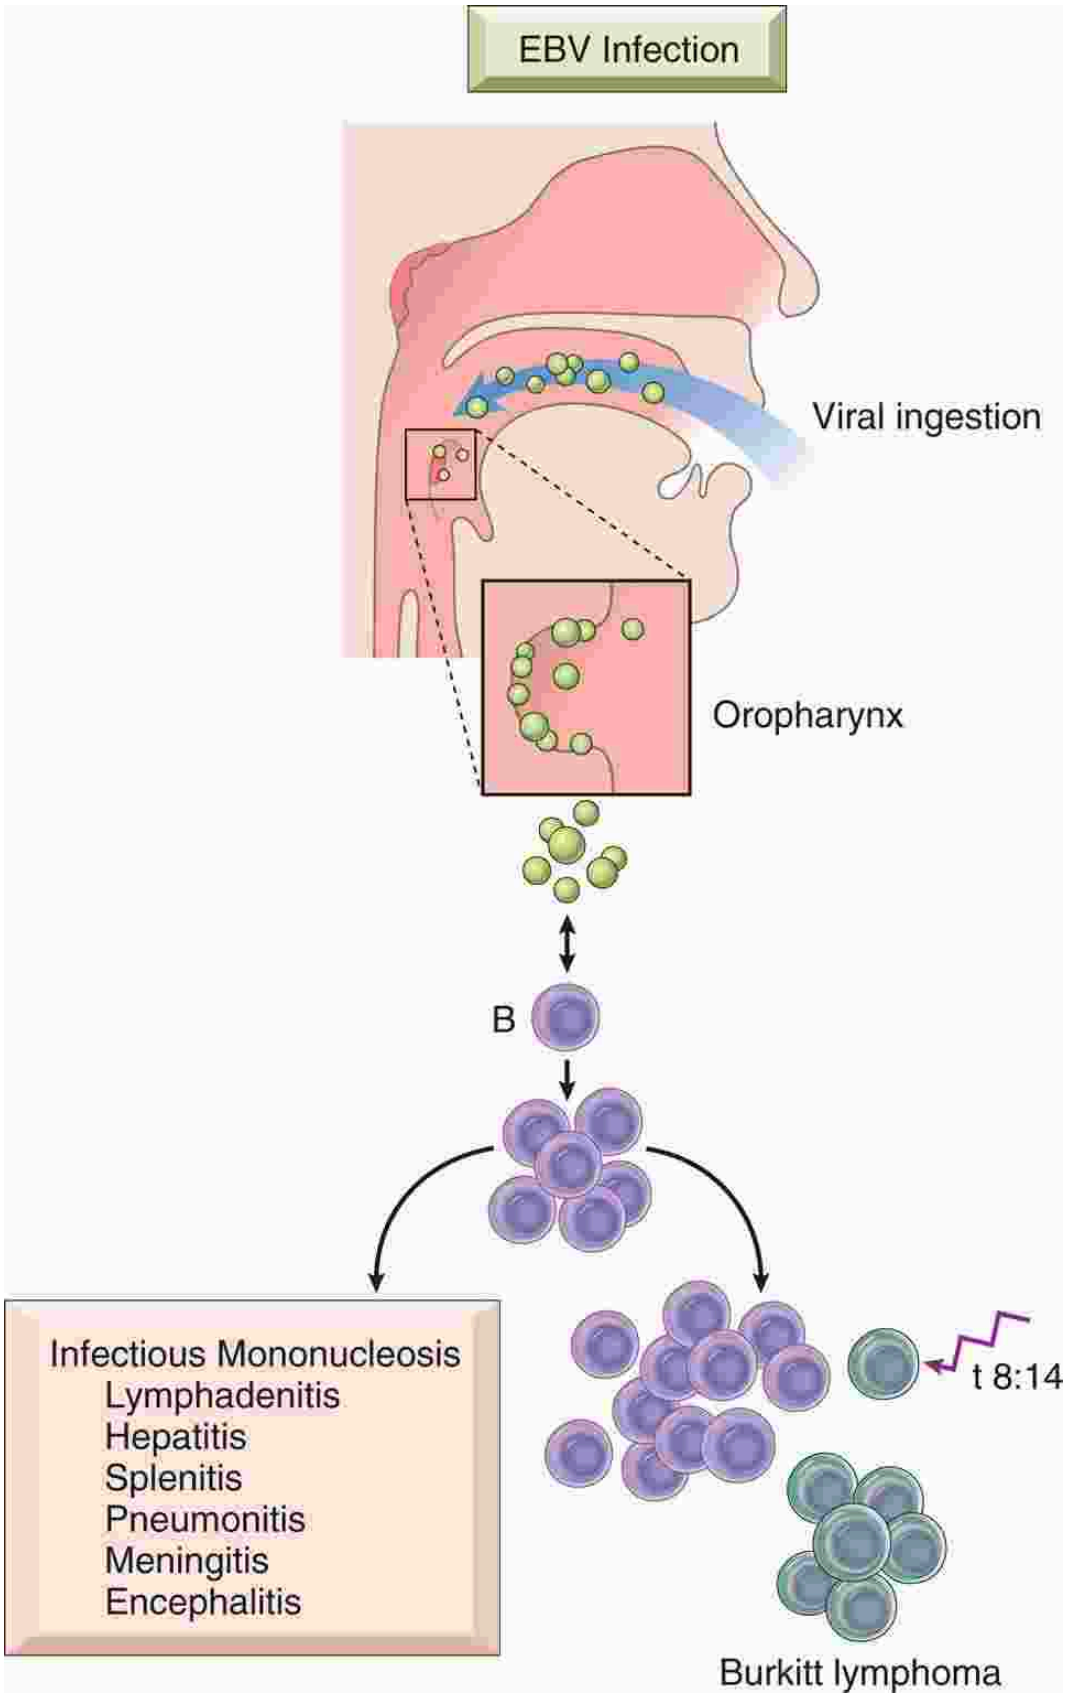
Transmission of EBV involves (1) person-to-person, (2) breastfeeding, and (3) sexual transmission.[35] From *person-to-person transmission* the virus is shed in salivary secretions at high levels for a prolonged time.[35] After the onset of illness, viral oral shedding persists for a median duration of about six months.[36] Once a person is infected with EBV, the virus may be intermittently shed in the oropharynx for decades.[36,37]

EBV has been isolated from healthy *breastfeeding* mothers, however, it is still not considered an important route of transmission.[35] Transmission may occur *sexually* because it has been isolated in cervical and male seminal fluid. In a study of university students in Scotland, sexual activity before college admission was significantly associated with EBV seropositivity and the seropositive status increased with the number of sexual partners.[38] A longitudinal study also found that EBV was associated with sexual activity in young women.[39] The virus also may be secreted in other mucosal secretions of the genital, rectal, and respiratory tracts, as well as blood. The infection begins with widespread invasion of the B lymphocytes, which have receptors for EBV. The virus initially infects the oropharynx, nasopharynx, and salivary epithelial cells with later spread into lymphoid

tissues and B cells. Once the virus enters the bloodstream, the infection spreads systemically.

Pathophysiology

In the immunocompetent individual, unaffected B cells produce antibodies (IgG, IgA, IgM) against the virus. At the same time, there is a massive activation and proliferation of cytotoxic T cells (CD8) that are directed against EBV-infected cells (see Chapter 8). The immune response against EBV-infected cells is largely responsible for the cellular proliferation in the lymphoid tissue (lymph nodes, spleen, tonsils, and, occasionally, liver). Sore throat and fever are caused by inflammation at the site of initial viral entry and initial infection (the mouth and throat). Outcomes of EBV are presented in Fig. 29.10.



EBV Infection
Viral ingestion
Oropharynx
B
Infectious Mononucleosis
Lymphadenitis
Hepatitis
Splenitis
Pneumonitis
Meningitis
Encephalitis
t 8:14
Burkitt lymphoma

FIG. 29.10 Outcomes of Epstein-Barr Virus (EBV). In individuals with normal immune function, infection is typically asymptomatic or leads to mononucleosis. With immunodeficiency, proliferation of B cells may be uncontrolled and progress to the development of B-cell neoplasms. Individuals without evidence of immunodeficiency can also develop EBV-positive neoplasms. In Burkitt lymphoma, the individual's susceptibility to EBV causes B cells to undergo genetic alterations (usually an 8;14 chromosomal translocation). EBV also is implicated in Hodgkin lymphoma, nasopharyngeal carcinoma, and other rare non-Hodgkin lymphomas. (From Kumar V, Abbas A, Aster JC. *Robbins & Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.)

An illustration shows the viral ingestion of E B V (through the mouth) and its passage through the oropharynx, resulting in the formation of B-cell and subsequent proliferation to Burkitt lymphoma. Outcomes of infectious mononucleosis include lymphadenitis, hepatitis, splenitis, pneumonitis, meningitis, and encephalitis.

Clinical Manifestations

The incubation period for IM is approximately 30 to 50 days. Early flulike symptoms, such as headache, malaise, joint pain, and fatigue, may appear during the first 3 to 5 days, although some individuals are without symptoms. At the time of diagnosis, the individual commonly presents with the *classic group of symptoms*: fever, sore throat (pharyngitis), cervical lymph node enlargement, and fatigue. The pharyngitis is usually diffuse with a whitish or grayish green thick exudate. It can be painful, causing the individual to seek treatment. Characteristics with progression may include a generalized lymphadenopathy, enlarged spleen, and atypical activated T lymphocytes (mononucleosis cells) in the blood (Fig. 29.11). IM is usually self-limiting, and recovery occurs in a few weeks. Fatigue, however, may last for 1 to 2 months after resolution of the infection.

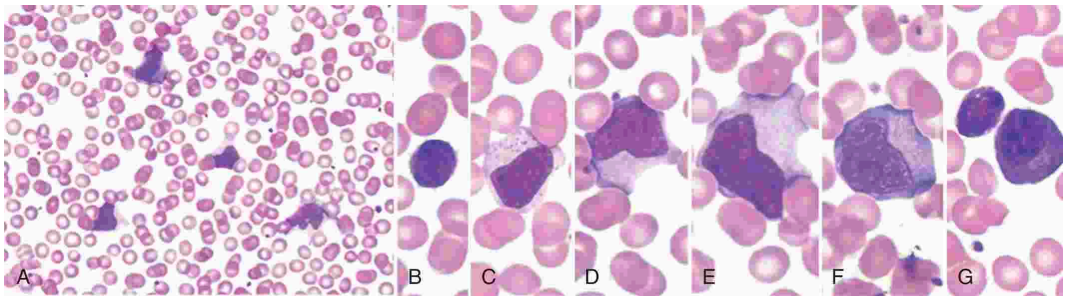


FIG. 29.11 Peripheral Blood Smear in Infectious Mononucleosis.

Low power (A) shows moderately high white blood cell count and a high number of reactive, or "atypical," lymphocytes. Higher power (B–G) illustrates the spectrum of lymphoid morphology, including small resting lymphocytes (B) for comparison, large granular lymphocytes (C), atypical forms (D–F) (also referred to as reactive lymphs), and circulating plasma cells (G). (From Hoffman R, et al. *Hematology*, 6th edition. Philadelphia: Churchill Livingstone; 2013.)

Severe clinical complications are rare. With progression of IM, general lymph node enlargement may develop with enlargement of the spleen and liver. Splenomegaly is clinically evident 50% of the time and is demonstrated radiologically 100% of the time. Difficulty in detecting splenomegaly with physical examination contributes to the underestimation of actual enlargement. Splenic rupture is rare (only 0.1% to 0.5% of all cases) and can occur spontaneously as a result of mild trauma, arising primarily in men younger than 25 years of age and between days 4 and 21 after the onset of symptoms. It is the most common cause of death related to IM. Other causes of fatalities are hepatic failure, extensive bacterial infection, and viral myocarditis. Other organ systems are rarely involved, but such involvement may be present with characteristic manifestations, such as fulminant hepatitis with jaundice and anemia, encephalitis, meningitis, Guillain-Barré syndrome, and Bell palsy. Eye manifestations may include eyelid and periorbital edema, dry eyes, keratitis, uveitis, and conjunctivitis. Reye syndrome has been known to develop in children with EBV infection. Pulmonary and respiratory failure has been documented but is more likely to occur in immunocompromised individuals. A generalized maculopapular, urticarial, or petechial rash may emerge; however, the mechanisms for the rash are not clear.[35] Approximately 3% to 10% of adults older than 40 years of age have never

been infected with EBV and are susceptible to IM later in life. In these individuals, the classic symptoms are not generally present, making diagnosis more difficult.

Evaluation and Treatment

Children commonly present with fever, pharyngitis, lymphadenitis, and manifestations discussed earlier. Young adults present with malaise, fatigue, and lymphadenopathy and often a fever of unknown origin. Palatal petechiae, splenomegaly, and posterior cervical adenopathy are very suggestive of IM, and the absence of cervical lymphadenopathy and fatigue make the diagnosis less likely.[35] The blood of affected individuals contains an increased number of white blood cells or lymphocytosis (absolute count >4500/μL, or on peripheral count >50% with many atypical lymphocytes (≥10%).[35] The diagnosis of IM depends on the following specific findings: (1) an increase in the number of lymphocytes, commonly based on Hoagland criteria of at least 50% lymphocytes and at least 10% atypical lymphocytes in the blood, and (2) a positive heterophile antibody (heterogeneous group of IgM antibodies that are agglutinins against nonhuman red blood cells [e.g., sheep, horse]) reaction (Monospot test). Although a rising titer of specific antibodies for EBV antigens can be used to make the diagnosis, the results of the heterophile test type return more quickly; and it may not be necessary for individuals with a reactive heterophile antibody.[35] Use of the Monospot test is, however, limited because other infections (e.g., CMV, adenovirus) and toxoplasmosis also produce heterophilic antibodies. Thus, 5% to 15% of Monospot tests yield false-positive results. False-negative rates are highest during the beginning of clinical symptoms.[35] Heterophilic antibodies in the blood increase as the condition progresses, although some individuals and children younger than 4 years of age do not produce them. Diagnosis of EBV infection specifically may be increased with newer viral-specific tests that identify EBV-specific antibodies. Not all individuals with fever, pharyngitis, and lymphadenopathy have infection due to EBV. Other potential causative organisms include group A streptococcus, *Arcanobacterium haemolyticum*, CMV, acute HIV, or rarely *Toxoplasma gondi*.[35]

IM is usually self-limiting and medical intervention is rarely required. Treatment is supportive and consists of rest and alleviation of symptoms with analgesics and antipyretics. Aspirin is avoided with children because of its association with Reye syndrome. Streptococcal pharyngitis, which

occurs in 20% to 30% of cases, is treated with penicillin or erythromycin, not ampicillin—ampicillin is known to cause a rash. Bed rest with avoidance of strenuous activity and contact sports is indicated. Steroids are not recommended for routine cases of IM; however, they may be used in cases with *severe* complications such as impending airway obstruction or other organ involvement (central nervous system [CNS] manifestations, thrombocytopenic purpura, myocarditis, pericarditis).[40] Severe complications require emergent consultation with an otolaryngologist. Acyclovir has been used in immunocompromised individuals, but significant clinical benefit has not been shown and is not considered standard therapy. In the rare event of splenic rupture, the treatment has been removal of the spleen and continues to be the choice in hemodynamically unstable individuals.

Lymphoid Neoplasm: Leukemias

Leukemia is a clonal malignant disorder of the bone marrow and usually, but not always, of the blood. The common pathologic feature of all forms of leukemia is an uncontrolled proliferation of malignant leukocytes, causing an overcrowding of bone marrow and decreased production and function of normal hematopoietic cells. Chromosomal abnormalities and translocations are common in the majority of leukemias. When genes become mutated, they create genomic aberrations that block cell maturation and activate pro–growth signaling pathways that prevent apoptotic cell death.

With time, the overall classification of leukemia has become increasingly complex with notable changes. These changes have created a blurring between the once discrete categories *lymphoma* and *leukemia*. Some cancers known as *lymphoma* have *leukemic* presentations, and evolution to leukemia is not unusual during the progression of incurable lymphoma. The World Health Organization (WHO) currently groups the lymphoid neoplasms into five broad categories, which are defined by the cell of origin:

1. Precursor B-cell neoplasms (immature B cells)
2. Peripheral B-cell neoplasms (mature B cells)
3. Precursor T-cell neoplasms (immature T cells)
4. Peripheral T-cell and NK (natural killer)-cell neoplasms (mature T cells and NK cells)
5. Hodgkin lymphoma (Reed-Sternberg [RS] cell and variants)

The 2016 revision of the WHO classification of lymphoid neoplasms clarifies the diagnosis and management of lymphoid neoplasms, details expanding genetic/molecular criteria for some neoplasms and their clinical correlates, and refers to investigations for targeted treatment strategies.[41] Most lymphoid neoplasm classifications relate to stages of cell differentiation of B-cell or T-cell differentiation (Fig. 29.12A). Fig. 29.12B provides a simple schematic overview of the main types of leukemia.

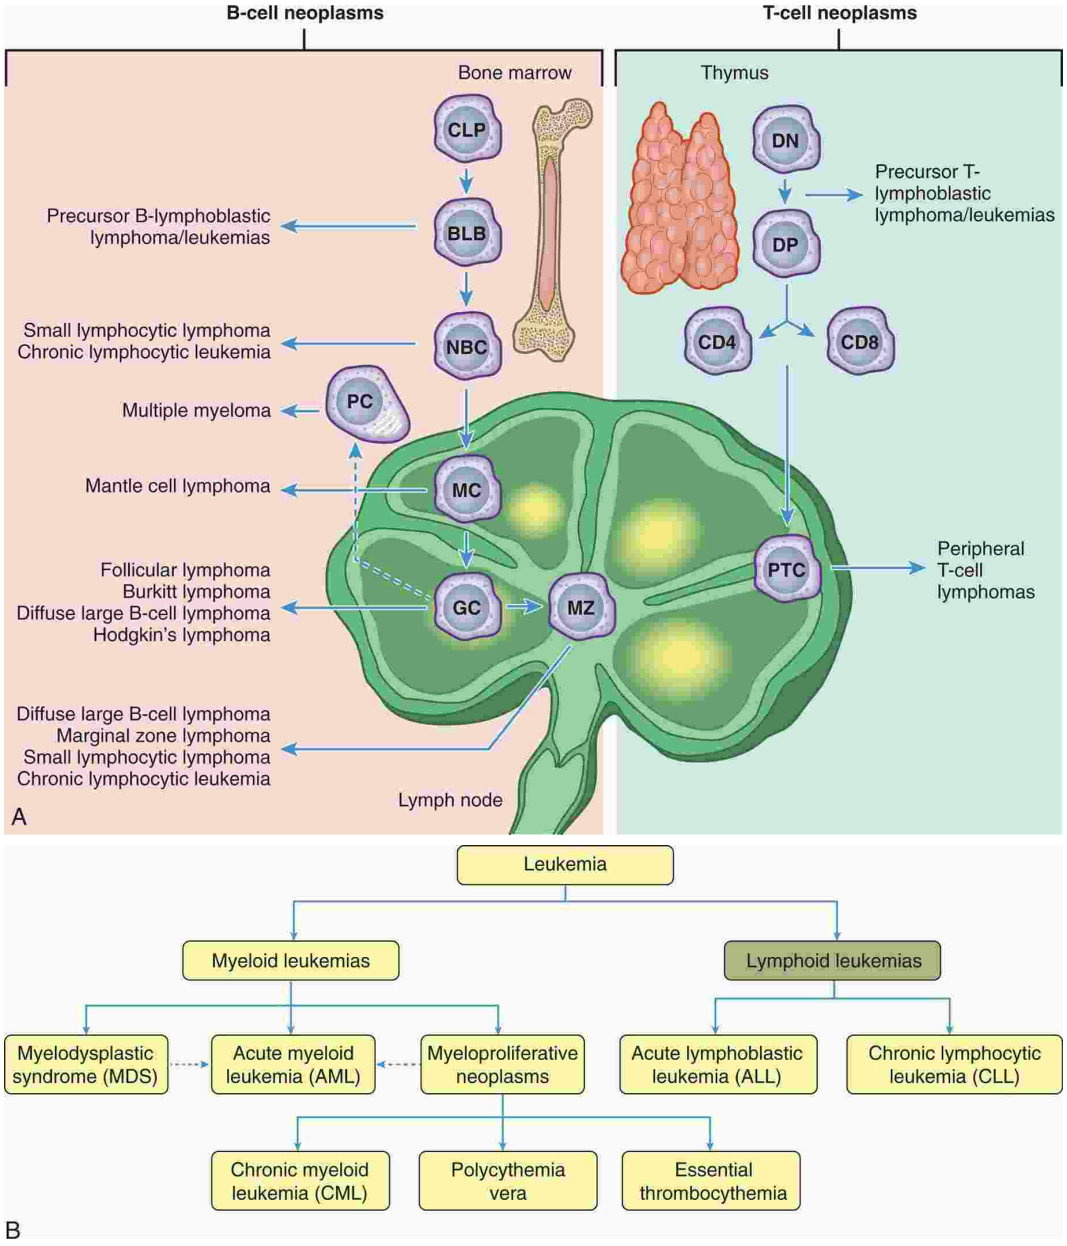

FIG. 29.12 Origin of Lymphoid Neoplasms.
(A) Specific lymphoid tumors emerge from stages of B- and T-cell differentiation. (B) Overview of main types of leukemia. Acute myeloid leukemia *(AML)* may arise de novo or be preceded by myelodysplastic phase. Not all cases of myelodysplastic syndrome (MDS) evolve to AML *(dashed line)*. Some myelodysplastic neoplasms can transform into AML, although very rarely *(dotted line)*. *BLB*, Pre-B lymphoblast; *CLP*, common lymphoid precursor; *DN*, CD4/CD8 double-negative pro-T cell;

DP, CD4/CD8 double-positive pre-T cell; *GC*, germinal-center B cell; *MC*, mantle B cell; *MZ*, marginal zone B cell; *NBC*, naïve B cell; *PTC*, peripheral T cell. (A, From Kumar V, Abbas A, Aster JC. *Robbins & Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015. B, From Khwaja A, et al. Acute myeloid leukaemia. *Nature Reviews Disease Primers*, 2016;2:16010.)

Top panel, A. An illustrated flowchart shows the tumors associated with B-cell and T-cell differentiation. The left half of the illustration of a lymph node represents B-cell neoplasms. The tumors are as follows. â€¢ C L P from bone marrow differentiates to B L B, causing precursor B-lymphoblastic lymphoma or leukemias. â€¢ B L B differentiates to N B C, causing small lymphocytic lymphoma or chronic lymphocytic leukemia. â€¢ N B C differentiates to M C, causing mantle cell lymphoma. â€¢ M C differentiates to G C, causing follicular lymphoma, Burkitt lymphoma, diffuse large B-cell lymphoma, or Hodgkin's lymphoma. â€¢ G C can differentiate to P C, causing mantle cell lymphoma. â€¢ G C differentiates to M Z, causing diffuse large B-cell lymphoma, marginal zone lymphoma, small lymphocytic lymphoma, or chronic lymphocytic leukemia. The right half of the illustration of a lymph node represents T-cell neoplasms. The tumors are as follows. â€¢ D N from the thymus causes precursor T-lymphoblastic lymphoma or leukemias. â€¢ D N differentiates to D P. â€¢ D P produces C D 4 or C D 8. â€¢ D P differentiates to P T C, causing peripheral T-cell lymphomas. Bottom panel, B. A hierarchy diagram shows an overview of the main types of leukemia. â€¢ Leukemia can be one of two classifications: myeloid leukemias or

lymphoid leukemias. â€¢ Myeloid leukemias can be one of three classifications: myelodysplastic syndrome (M D S), acute myeloid leukemia (A M L), or myeloproliferative neoplasms. M D S and myeloproliferative neoplasms can also lead to A M L. â€¢ Lymphoid leukemias can be one of two classifications: acute lymphoblastic leukemia (A L L) or chronic lymphocytic leukemia (C L L). â€¢ Myeloproliferative neoplasms can be one of three classifications: chronic myeloid leukemia (C M L), polycythemia vera, or essential thrombocythemia.

Acute leukemia is characterized by undifferentiated or immature cells, usually a **blast cell**. The onset of disease is abrupt and rapid. Without treatment, disease progression results in a short survival time. In **chronic leukemia**, the predominant cell is more differentiated but does not function normally, with a relatively slow progression. There are four general types of leukemia: acute lymphocytic (ALL), acute myelogenous (AML), chronic lymphocytic (CLL), and chronic myelogenous (CML).

Leukemia occurs with varying frequencies at different ages and is more common in adults than in children. More than 61,090 cases of leukemia were estimated for 2021, with males having a higher incidence than females (Table 29.7). Estimated deaths for 2021 was 23,660 individuals.[42] CLL and AML are the most common types in adults, but CML is also a common leukemia in adults (see Chapter 30 for leukemia in children).

Table 29.7

Estimated New Cases and Deaths from Leukemia in the United States —2021

Types of Leukemia	TOTAL NEW CASES (Proportion of New Cases) (%)	NEW CASES BY SEX		DEATHS BY SEX	
		Male	Female	Male	Female
All types	61,090 (100)	35,530	25,560	13,900	9,760
Acute lymphocytic leukemia	5,690 (12)	3,000	2,690	900	680
Chronic lymphocytic leukemia	21,250 (30)	13,040	8,210,	2,620	1,700
Acute myelogenous leukemia	20,240 (36)	11,230	9,010	6,620	4,780
Chronic myelogenous leukemia	9,110 (11)	5,150	3,960	680	540
Other	4,800 (11)	3,110	1,690	3,080	2,060

Types of Leukemia	TOTAL NEW CASES (Proportion of New Cases) (%)	NEW CASES BY SEX Male	Female	DEATHS BY SEX Male	Female
All types	61,090 (100)	35,530	25,560	13,900	9,760

Data from American Cancer Society. *Cancer Facts and* Figures—2021. Atlanta: The Society; 2021.

Over the past 2 decades, the rates of induced remission and survival in most forms of leukemia have increased. Current 5-year relative survival rates range from 29% for AML to 86% for CLL, and as high as 91% for

children and adolescents younger than 15 years of age with ALL.[43] Risk factors for the onset of leukemia include environmental factors, genetic factors, and other diseases (see Acute Leukemias and Chronic Leukemias sections for further discussion on risk factors).

Pathophysiology

All leukemias have certain pathophysiologic features in common. Most lymphoid neoplasms arise from B-cell and T-cell differentiation pathways (see Fig. 29.12A). The hypothesis of origin for leukemias is "clonal disorders driven by genetically abnormal progenitor cells or stem-like cancer cells (SLCCs)." The majority (85% to 90%) of lymphoid neoplasms are of B-cell origin, followed by T-cell tumors and, rarely, NK-cell tumors. Abnormal immature white blood cells, called **leukemic blasts**, fill the bone marrow and can spill into the blood. Leukemic blasts literally "crowd out" the bone marrow, compete for growth factors, and cause cellular proliferation of the other cell lines to decrease or cease. For example, AML is an age -related disease that is very dependent on the bone marrow microenvironment (see section on acute myeloid leukemia).[44] Tissues accumulate senescent cells with increasing age, characterized by an irreversible arrest of cell proliferation and the secretion of proinflammatory cytokines, chemokines, and growth factors, broadly called the **senescence-associated secretory phenotype (SASP)** (Fig. 29.13). Leukemic blasts induce a *senescent phenotype* in the stromal cells within the bone marrow microenvironment driven by the protein (cell cycle regulator) p16INK4a expression. Deletion of these senescent p16INK4a-expressing bone marrow stromal cells (BMSCs) slows tumor progression and extends survival.[44] The senescent response may have evolved to *suppress* the development of cancer, but also to assist tissue repair and regeneration. Because senescent cells gradually increase with age as does cancer, the senescent response may become *maladaptive* with age, and emerging evidence reveals that they contribute to several age-related phenotypes and pathologies.[45–47] Additionally, blast cell longevity is promoted by adipocytes. Emerging studies are revealing that bone marrow adipocytes support the survival and proliferation of AML blasts (see AML section for further discussion).[48]

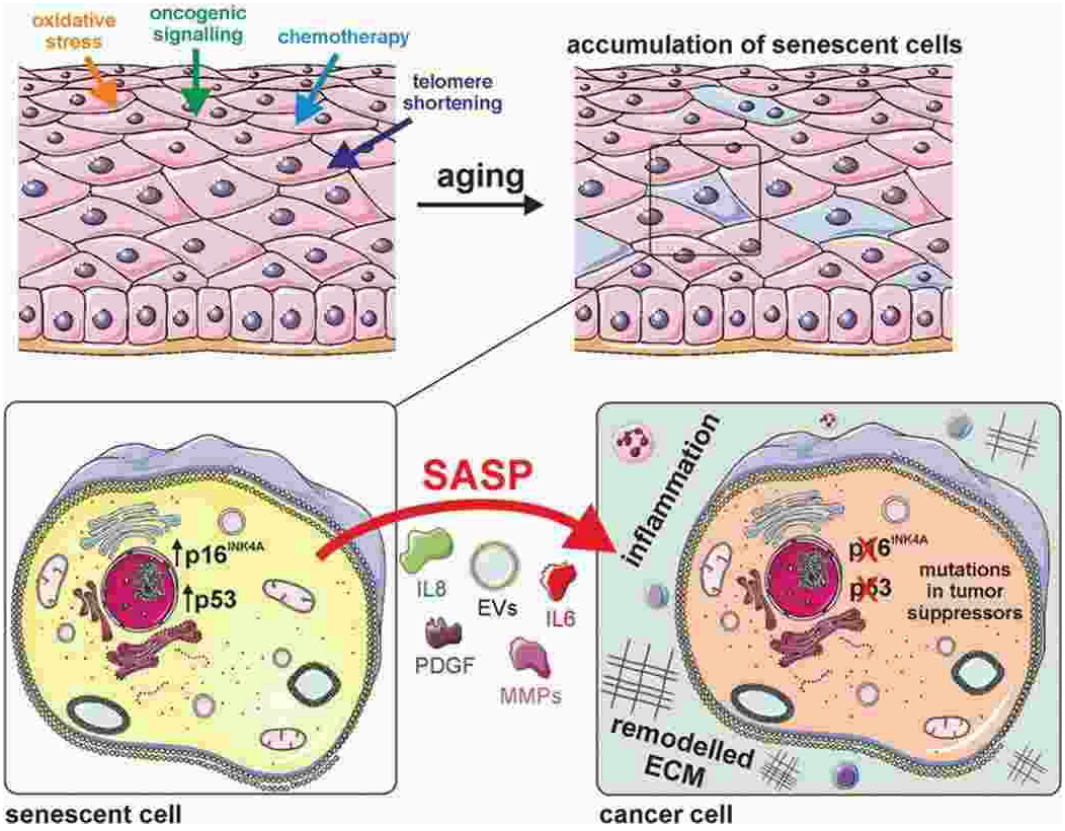

FIG. 29.13 Cellular Senescence Produces a Pro-tumorigenic Microenvironment.
Various stimuli lead to cellular senescence and their accumulation in aged tissues. The senescent state is characterized by activation of the potent tumor suppressors p16INK4a and /or p53, as well as by secretion of cytokines *(IL-6, IL-8)*, growth factors *(PDGF)*, matrix metalloproteinases *(MMPs)*, and extracellular vesicles *(EVs)*. This senescence-associated secretory phenotype *(SASP)* produces a pro-tumorigenic microenvironment by causing extracellular matrix remodeling and inflammation. (From Schosserer M, Grillari J, Brietenbach M. The dual role of cellular senescence in developing tumors and their response to cancer therapy front. *Oncology*, 2017;23. https://doi.org/10.3389/fonc.2017.00278.)

A series of four illustrations shows cellular senescence. Top-left panel. The illustration shows a normal tissue

layer. Oxidative stress, oncogenic signaling, chemotherapy, and telomere shortening with aging leads to accumulation of senescent cells. Top-right panel. The illustration shows accumulation of senescent cells amid normal cells in the tissue layer. Bottom-left panel. The illustration shows the structure of a senescent cell identifying increased p 16 and p 53. S A S P (including I L 8, E Vs, I L 6, P D G F, and M M Ps) produce cancer cells. Bottom-right panel. The illustration shows a cancer cell with loss of p 16 and p 53, mutations in tumor suppressors, inflammation, and remodeled E C M.

Normal granulocytic-monocytic, lymphocytic, erythrocytic, and megakaryocytic progenitor cells can cease to function, leading to **pancytopenia** (a reduction in all cellular components of the blood). Genetic translocations (mitotic errors) are observed in leukemic cells. The most common genetic abnormality is the reciprocal translocation between chromosomes 9 and 22—t(9;22) (q34;q11), the **Philadelphia chromosome**. The Philadelphia chromosome was first observed in persons with CML and is present in 95% of those with CML, up to 3% of individuals with AML, about 25% of adults with ALL, and 10% of children with ALL.[49,50] This translocation results in the novel fusion of the *BCR1* gene region from chromosome 22 and the proto-oncogene *ABL1* from chromosome 9 (Fig. 29.14). The BCR-ABL1 joining results in the expression of a unique fused oncoprotein, BCR-ABL1. The ABL1 protein excessively activates intracellular pathways that promote cell proliferation, decrease sensitivity to apoptosis, and cause premature release of immature cells into the circulation. The BCR-ABL1 variant proves to be essential for transformation into leukemic cells. In most leukemias and lymphomas a single major genetic abnormality, such as the t(9;22) translocation, does not lead to an aggressive malignancy. The initial event is usually followed by a series of secondary genetic changes. Therefore, the original tumor becomes genetically unstable and diverse. In most cases leukemic cells are ejected into the blood where they accumulate. These cells also may infiltrate and accumulate in the liver, spleen, lymph nodes, and other organs throughout

the body. The presentation of large numbers of leukemic cells in the blood may be one of the most dramatic indicators of leukemia; however, leukemia is still a primary disruption of the bone marrow.

FIG. 29.14 Philadelphia Chromosome.
The Philadelphia chromosome is an example of a reciprocal chromosomal translocation that results in an abnormal gene product responsible for a clinical disorder. (A) An exchange occurs between the long arm of chromosome 9 (black chromosome) and the long arm of chromosome 22 (blue chromosome); t(9;22)(q34;q11). (B) Mechanism of action of imatinib. By occupying the ATP-binding pocket of the ABL kinase domain, imatinib prevents substrate phosphorylation and downstream activation of signals, thus inhibiting the leukemogenic effects of BCR-ABL1 on cells in chronic myelogenous leukemia. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *BCR-ABL*, Breakpoint cluster region-Abelson; *P*, phosphate group. (A, Top portion from Rakel R, Bope E. *Conn's current therapy*. Philadelphia: Saunders; 2008; lower portion from Yanoff M, Duker J. *Ophthalmology*, 3rd edition. Edinburgh: Mosby; 2009; B From Goldman L, Schafer AI. *Goldman's Cecil medicine*, 24th edition. Philadelphia: Saunders; 2012.)

Top panel, A. An illustration shows the translocation in chromosome 9 and chromosome 22. Chromosome break occurs at a b l in chromosome 9 and at b c r in changed chromosome 22. The broken segments translocate, resulting in the Philadelphia chromosome. Bottom panel, B. The illustration shows the mechanism of imatinib. B C R-A B L is a fused form with A D P on the B C R and substrate on the A B L. A T P activates the A D P. Effectors from the substrate results in signaling. This leads to B C R-A B L with imatinib mesylate. A T P does not activate imatinib mesylate. Substrate does not activate the effector. There is no signaling.

Acute leukemias

Acute leukemias include two types: **acute lymphocytic leukemia (ALL)** and **acute myelogenous leukemia (AML)**. ALL is a disease of the bone marrow, an aggressive, fast-growing leukemia with too many *lymphoblasts* (immature lymphocyte with altered morphology) or lymphocytes in the bone marrow and peripheral blood. It also is called *acute lymphoblastic leukemia*.

AML is a disease of the bone marrow, an aggressive fast-growing leukemia, and highly heterogenous disease. AML is a malignancy of the stem cell precursors of the myeloid lineage [red blood cells, platelets, and white blood cells (except B and T cells)].[51] It is characterized by overproduction of neoplastic clonal myeloid stem cells or *myeloblasts* (i.e., immature white blood cells that are not lymphoblasts).[51,52] It is also called *acute myeloblastic leukemia*, *acute myeloid leukemia*, or *acute nonlymphocytic leukemia* (*ANLL*). The WHO updated guidelines distinguish six groups of AML: (1) AML with recurrent genetic abnormalities, (2) AML with myelodysplasia-related changes, (3) Therapy-related myeloid neoplasms, (4) AML not Otherwise Specified, (5) Myeloid sarcoma, and (6) Myeloid proliferations related to Down syndrome.[53]

Acute leukemias are seen in both sexes and in all ages. AML is the more common acute leukemia in adults, with the median age at diagnosis around 70 years. There is a rise in the age-related incidence around 40 to 50 years of age, and a steep increase from 60 to 64 years of age. Mortality for all acute leukemias in the United States is about 7 per 100,000. In children younger than 15 years, leukemia accounts for one-third of all deaths from cancer (see chapter 30). North America and Scandinavian countries have the highest mortality; Eastern European countries, Asia (except Japan), and Central America have the lowest mortality. The higher mortality in Japan is the result of the atomic bombs dropped in World War II.[54] Black and Hispanic people have increased mortality compared with whites.[55]

More than 5690 new cases of ALL and 20,240 cases of AML were estimated for 2021, with more than 2480 deaths from ALL and 18,020 deaths from AML.[42]

Increased risk for ALL has been linked to exposure to x-rays before birth, being exposed to ionizing radiation (postnatally), past treatment with chemotherapy, certain chemical exposures (e.g., benzene, glues, detergents, art supplies, paint strippers), certain viral infections (see below), age (children and adults over age 50), race/ethnicity (more common in whites),

gender (more common in males), and certain genetic conditions.[56] Leukemia has a statistically significant tendency to reappear in families. Controversial and unproven, increased risk in adults also has been linked to exposure to cigarette smoke. Large doses of ionizing radiation in particular result in an increased incidence of myelogenous leukemia. There is growing concern about the effect of low-dose radiation on subsequent risk of leukemia.[57] Infections with HIV or hepatitis C virus increase the risk for lymphoid neoplasms. It is now widely accepted that some types of leukemia are caused by infection with the human T-cell leukemia/lymphoma virus-1 (HTLV-1).

Acute leukemia also may develop secondary to certain acquired disorders, such as CML, CLL, HL, and others. Unlike other forms of leukemia, ALL develops at different rates in different geographic locations and the reason is unclear. People from developed countries and those of higher socioeconomic categories have an increased incidence of ALL. AML can arise in people *de novo*, those with an underlying hematological disorder, or as a consequence of prior treatment.[52] It is the most frequently reported secondary cancer after high doses of chemotherapy for HL, non-Hodgkin lymphoma (NHL), MM, ovarian cancer, and breast cancer.

Pathophysiology

ALL presumably progresses from malignant transformation of immature B- or T-cell progenitor cells (like a stem cell) (Fig. 29.15).[16] Most cases of ALL occur in children and often in the first decade (see Chapter 30). Although adults account for about 20% of all cases, their mortality rate is significantly higher. The significant difference between the incidence of ALL in adults and children may be because of differences in the biology of the disease (see Chapter 30).

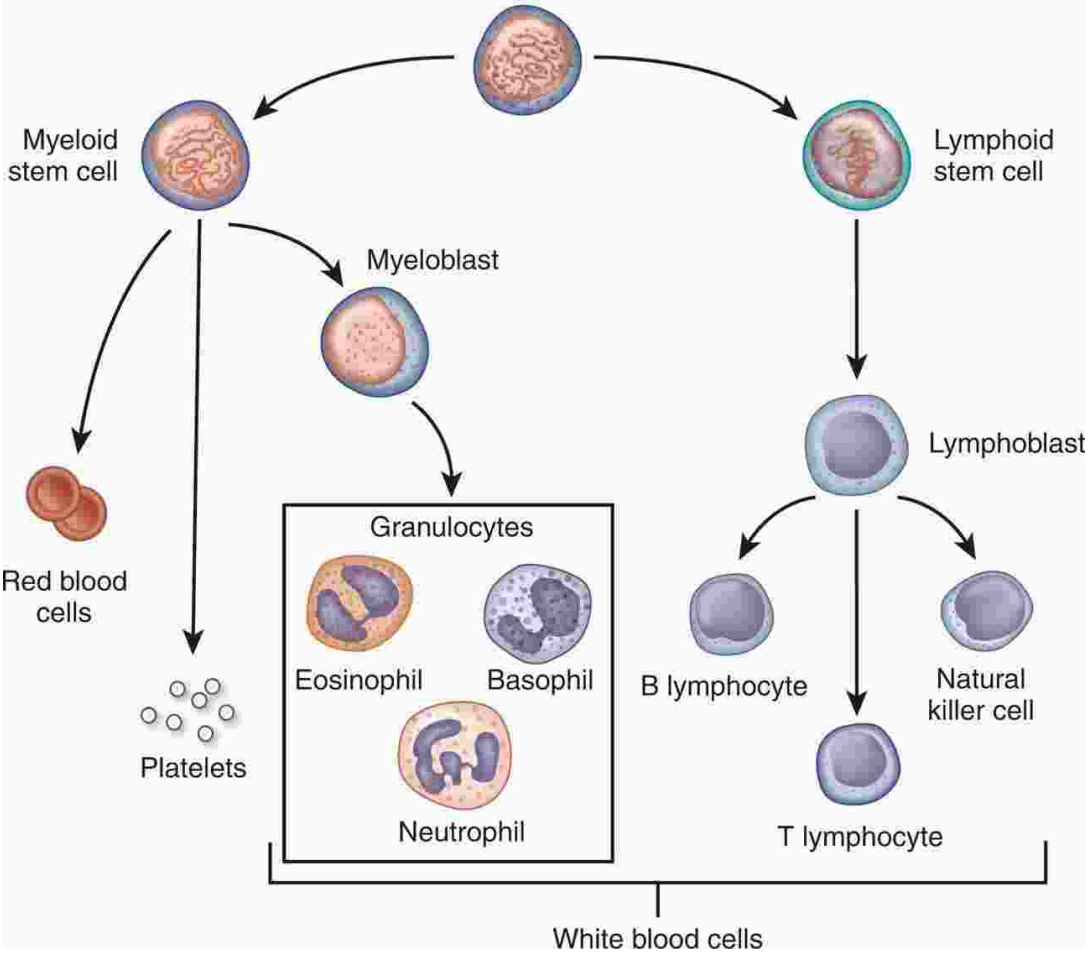

FIG. 29.15 Leukemia Arises From Stem-Like Cells.
A blood stem cell undergoes multiple steps to finally become a red blood cell, platelet, or white blood cell. (© 2007 Terese Winslow LLC, U.S. Govt. has certain rights.)

An illustrated flowchart shows the formation of white blood cells from stem cells. â€¢ Stem cells can be one of two classifications: myeloid stem cell or lymphoid stem cell. â€¢ Myeloid stem cells can be one of three classifications: red blood cells, platelets, or myeloblast. â€¢ Myeloblast can be one of three classifications of white blood cells: eosinophil, basophil, or neutrophil. â€¢ Lymphoid stem cell transforms to lymphoblast. â€¢ Lymphoblast

can be one of three classifications of white blood cells: B lymphocyte, T lymphocyte, or natural killer cell.

Chromosomal aberrations in ALL disrupt normal B- and T-cell development by causing the dysregulation of expression and function of transcription factors. Most T-ALLs have mutations in *NOTCH1*, a gene necessary for normal T-cell development. Many B-ALLs have mutations affecting genes required for differentiation of early precursor cells, such as *PAX5*, *TCF3*, *ETV6*, and *RUNX1*.[16] By altering these "prime" regulatory factors, the mutations promote maturation arrest and increased self-renewal, creating a stem-cell like phenotype.[16] The identification of mutations found in ALL is ongoing and includes mutations that drive cell growth and mutations that increase tyrosine kinase activity and RAS signaling.

AML is the most common adult leukemia. Driver mutations in AML include four categories:

1. *Transcription factor mutations that disrupt normal myeloid differentiation*. For example, the two most common chromosomal rearrangements, t(8;21) and inv(16), alter the genes RUNX1 and CBFB, respectively.[16]
2. *Mutation of signaling proteins that promote pro-growth/survival pathways*. An example for AMLs is the t(15;17) which often have activating mutations in FLT3, a receptor tyrosine kinase that mimics normal growth factor signaling and promotes cellular proliferation and survival.
3. *Mutations of genes that regulate or maintain the epigenome*. Some of these mutations may lead to abnormal DNA methylation (see Chapter 6).
4. *Mutation of TP53 or genes that regulate p53*. AMLs with these alterations have complex karyotypes, significant dysplasia, and a poor prognosis due to resistance to standard therapies.[16]

More simply, genetic alterations in AML alter genes that encode transcription factors needed for normal myeloid differentiation; consequently, differentiation becomes arrested. These mutations affect the epigenome, suggesting that epigenetic alterations are key in AML. Mutations may lead to proliferation by activating growth factor signaling, as well as a decreased rate of apoptosis. Thus, the bone marrow and peripheral blood are characterized by leukocytosis and a predominance of blast cells. With an increase in immature blasts, they displace normal myelocytic blood cells, megakaryocytes, and erythrocytes. This displacement can lead to complications of bleeding, anemia, and infection. Several hereditary conditions are known to increase the risk for AML (e.g., Down syndrome, Fanconi aplastic anemia, Bloom syndrome, and others).

Numerous interactions between the bone marrow microenvironment and HSCs determine the balance between the proliferation, differentiation, and homeostasis of the stem cell compartment. Changes in this tightly regulated network promote

malignant transformation.[58] Leukemic blast cells interact with the perivascular niche (Fig. 29.16). Secreted factors and cell-cell interactions regulate the survival, proliferation, and resistance of AML cells in the perivascular niche. Understanding these interactions will help to define targeted therapies.

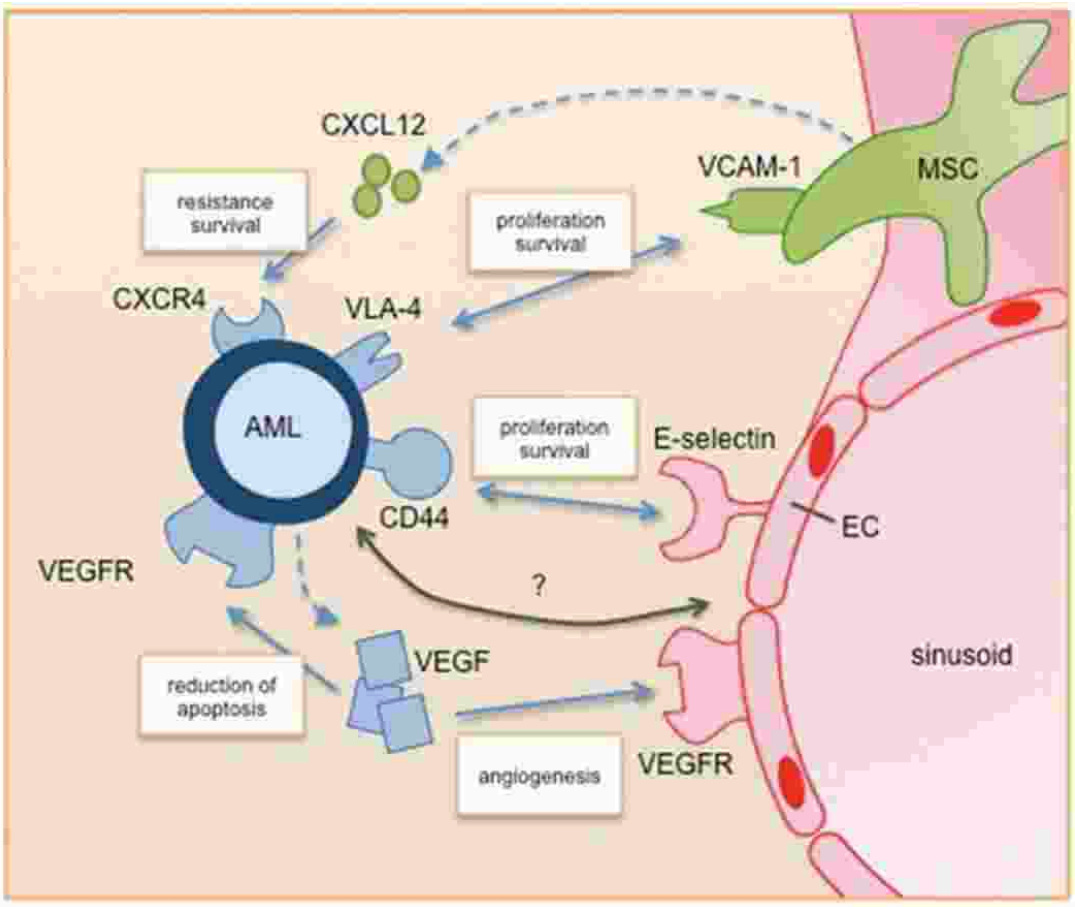

FIG. 29.16 Leukemic Blast Cells Interact With the Perivascular Niche.
A tight relationship between leukemic cells and endothelial cells supports AML development and progression. Understanding these pathways (autocrine and paracrine) is critical for targeted therapy development. *AML*, Acute myeloid leukemia; *CXCL12*, C-X-C motif chemokine12; *CXCR4*, C-X-C chemokine receptor 4; *EC*, endothelial cell; *MSC*, mesenchymal stromal cell; *VEGF*, vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptor; *VCAM-1*, vascular cell adhesion molecule1; *VLA-4*, very late antigen 4. (From Behrmann L, Wellbrock J, Fiedler W. Acute myeloid leukemia and the bone marrow niche—Take a closer look. *Frontiers in Oncology*, 2018;8. https://doi.org/10.3389/fonc.2018.00444.)

An illustration shows how leukemic blast cells interact with perivascular niche. The illustration shows and labels the following structures: M S C, sinusoid, E C, V C A M-1, E-selectin, V E G F R, C X C L 12, V L A-4, C D 44, V E G F, V E G F R, and C X C R 4. The mechanisms identified are as follows. â€¢ Proliferation

survival: V C A M-1 (on M S C) and V L A-4 (on A M L). â€¢ Proliferation survival: E-selectin (on E C) and C D 44 (on A M L). â€¢ Angiogenesis: V E G F and V E G F R (on sinusoid). â€¢ Reduction of apoptosis: V E G F and V E G F R (on A M L). â€¢ Resistance survival: C X C R 4 (on A M L) and C X C L 12 (from M S C).

Clinical Manifestations

Within days to a few weeks of the first symptoms is an abrupt stormy onset, which is more prevalent in ALL. The clinical manifestations of all varieties of acute leukemia are generally similar. Mechanisms associated with common manifestations are summarized in Table 29.8. Signs and symptoms related to bone marrow depression include fatigue caused by anemia, bleeding resulting from thrombocytopenia, and fever caused by infection. Bleeding may occur in the skin, gums, mucous membranes, and GI tract. Visible signs include petechiae and ecchymosis, as well as discoloration of the skin, gingival bleeding, hematuria, and midcycle or heavy menstrual bleeding.

Table 29.8

Clinical Manifestations and Related Pathophysiology in Leukemia

Clinical Manifestations	Laboratory Abnormalities	Cause	Comments
Anemia	Relative *proportion* of erythroblasts to total count (decreased in anemia) is key	Decreased stem cell input or ineffective erythropoiesis, or both	In acute leukemia, anemia is usually present from beginning, often first symptom noticed, and severe; mild form without symptoms is common in CML and CLL; hemorrhage common in acute forms, occasional in CML, but rare in CLL
Bleeding (purpura, petechiae, ecchymosis, hemorrhage)	Decreased and possibly abnormal platelets	Reduction in megakaryocytes leading to thrombocytopenia	Bleeding more common in acute than in chronic leukemia
Infection	Increased multisegmented neutrophils	Opportunistic organisms; decreased protection resulting from granulocytopenia or immune deficiency secondary to chemotherapy, corticosteroids, and disease process	Major sites of infection: oral cavity, throat, lower colon, urinary tract, lungs, and skin; prevention of infection focuses on restoring host defenses, decreasing invasive procedures,

Clinical Manifestations	Laboratory Abnormalities	Cause	Comments
			and reducing colonization of microorganisms
Weight loss	Decreased 24-h urinary creatinine excretion; hypoalbuminemia	Condition can be attributed to pain, depression, chemotherapy, radiation therapy, loss of appetite, and alterations in taste	Severe weight loss may be related to excess production of TNF-α
Bone pain	Often no radiographic evidence of bone problems	Result of bone infiltration by leukemic cells or intramedullary infection	If combination drug regimens are ineffective, radiation therapy is used
Liver, spleen, and lymph node enlargement	Biopsy abnormal for liver and spleen	Leukemic cell infiltration	Lymph nodes also undergo leukemia proliferation in CLL
Elevated uric acid level	Normal excretion of uric acid is 300–500 mg/day; leukemic individual can excrete 50 times more	Increased catabolism of protein and nucleic acid; urate precipitation increased from dehydration caused by anorexia or fever and drug therapy	Hyperuricemia is present in both acute leukemia and CML; treatment focuses on increasing urine pH or decreasing acid production with drug allopurinol

CLL, Chronic lymphocytic leukemia; *CMA*, chronic myelocytic leukemia; *RBC*, red blood cell; *TNF-α*, tumor necrosis factor-α.

Infection sites include the mouth, throat, respiratory tract, lower colon, urinary tract, and skin and may be caused by gram-negative bacilli *(Escherichia coli)*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*. Fever is an early sign and is often accompanied by chills.

Anorexia is accompanied by weight loss, diminished sensitivity to sour and sweet tastes, wasting of muscle, and difficulty swallowing. Liver, spleen, and lymph node enlargement occurs more commonly in ALL than in AML. Liver and spleen enlargement commonly occur together. The leukemic individual often experiences abdominal pain and tenderness. Pain in the bones and joints is thought to result from leukemia infiltration with secondary stretching of the periosteum.

Neurologic manifestations are common and may be caused by either leukemic infiltration or cerebral bleeding. Headache, vomiting, papilledema, facial palsy, blurred vision, auditory disturbances, and meningeal irritation can occur if leukemic cells infiltrate the cerebral or spinal meninges.

Evaluation and Treatment

Diagnosis is made through examination of blood cells and bone marrow. For ALL, diagnostic confusion with AML, hairy cell leukemia, and malignant lymphoma is not uncommon. It is critical to obtain an accurate diagnosis because of the differences in treatment and prognosis of ALL and AML. Also critical is that bone marrow aspirates should be done by an experienced oncologist, hematologist, hematopathologist, or general pathologist experienced in interpreting conventional and specially stained specimens. The morphologic aspects of leukemia cells are seen in Fig. 29.17.

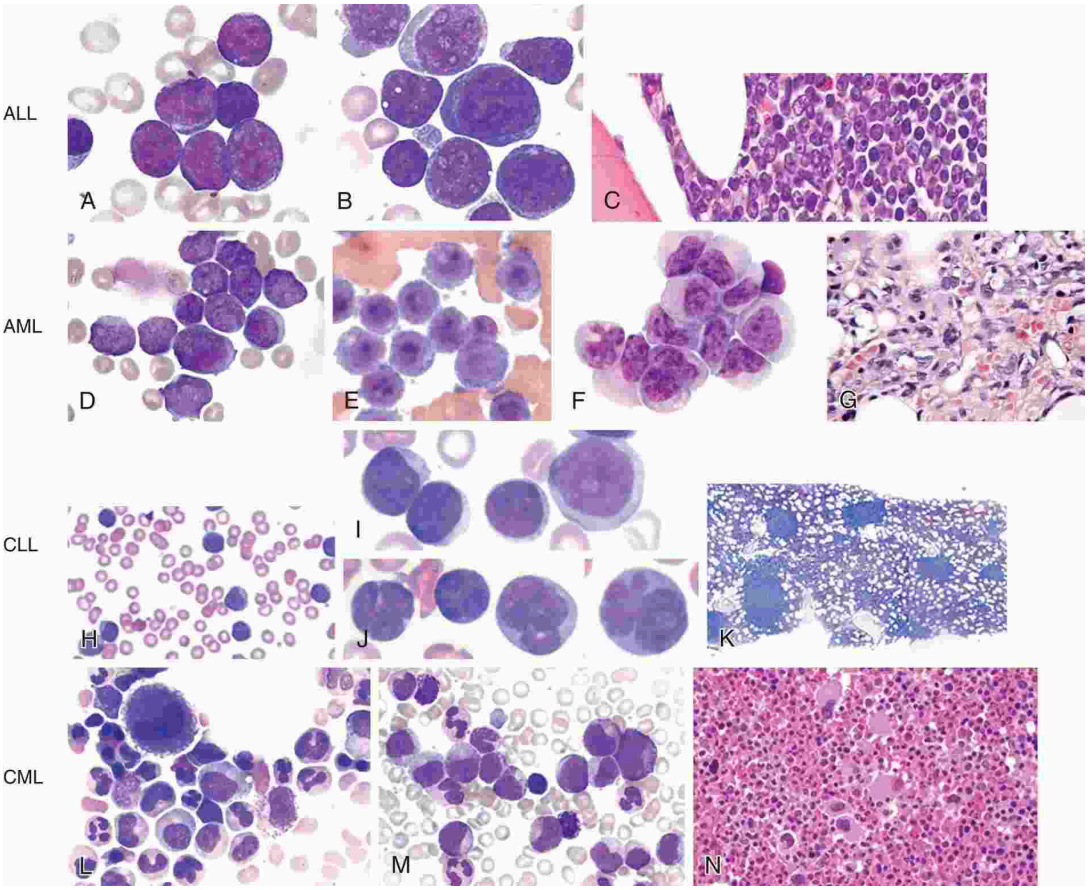

FIG. 29.17 Morphologic Aspects of Leukemia Cells.
Acute lymphoblastic leukemia *(ALL)* (A–C). (A) Typical uniform lymphoblasts with intermediate-sized nuclei, fine but "smudgy" chromatin, absence of nucleoli, and scant cytoplasm. (B) Lymphoblasts with more cytologic variation, including variability in size, number of nucleoli, and amount of cytoplasm. (C) Histologic features of ALL in bone core biopsy. Acute myeloid leukemia *(AML)* (D–G). (D) Acute myeloblastic leukemia with minimal or no maturation. The cells are myeloblasts with dispersed chromatin and variable amounts of agranular cytoplasm. Some display medium-sized, poorly defined nucleoli. (E) Acute monoblastic leukemia; characteristic monoblasts with round nuclei and delicate chromatin and prominent nucleoli. Cytoplasm is abundant. (F) Acute monocytic leukemia with most of the cells in this field being promonocytes. Monoblasts and an abnormal monocyte also are present. (G) Marrow biopsy of acute megakaryoblastic leukemia containing large and small blasts and atypical megakaryocytes. Chronic lymphocytic leukemia *(CLL)* (H–K). (H) Peripheral blood smear typically shows lymphocytosis. Cytologic features of CLL cells differ. (I) Classic cells have a small nucleus with a "soccer ball" chromatin pattern. (J) Some cases have increased large cells,

or prolymphocytes, with more open chromatin and prominent "punched-out" nucleoli (prolymphocyte, right side). (K) The bone marrow can show nodular infiltrates of CLL cells. Chronic myelogenous leukemia *(CML)* (L–N). (L) Peripheral smear shows marked leukocytosis attributable to a granulocytic proliferation of all stages with particularly increased myelocytes and absolute basophilia. (M) Bone core biopsy illustrates markedly hypercellular marrow attributable to granulocytic proliferation and increased small hypolobated megakaryocytes. (N) Bone marrow aspirate shows granulocytic proliferation and small, "dwarf" megakaryocyte. (A–C and H–N, From Hoffman R, et al. *Hematology: Basic principles and practice*, 6th edition. Philadelphia: Churchill Livingstone; 2013. D–G, From Abeloff M, et al. *Abeloff's clinical oncology*, 4th ed. Philadelphia: Churchill Livingstone; 2008.)

Fourteen photomicrographs of blood smears A through N show morphology of leukemias. Photomicrographs A through C show the morphology of acute lymphoblastic leukemia; D through G show the morphology of acute myeloid leukemia; H through K show the morphology of chronic lymphocytic leukemia; L through N show the morphology of chronic myelogenous leukemia.

Chemotherapy, used in various combinations, is the treatment of choice for leukemia.[59] Successful treatment of ALL is control of bone marrow and systemic disease and the treatment (or prevention) of sanctuary-site disease, especially the CNS.[59] Treatment is divided into three phases: remission induction, CNS prophylaxis, and post remission.[59] CNS prophylaxis is achieved with chemotherapy (intrathecal and /or high-dose systemic therapy) and, in some cases, cranial radiation therapy.[60] Other types of treatment include chemotherapy with stem cell transplant and other drug therapy. Supportive measures include antibiotics, antifungals, antivirals, and blood transfusions.[60] It is critical that stem cell transplants be done in hospitals with very experienced staff for both the procedure and the recovery phase.

There are an increasing number of targeted treatment strategies to treat AML, yet patient outcomes remain poor. Relapses after chemotherapy continues to be a major obstacle, driving demand for new treatment approaches.[61] Attainment of complete remission requires aggressive treatment. However, particularly problematic in persons greater than 60 years is a diminished tolerance for intensive chemotherapy and increased treatment-related toxicity, leading to an estimated treatment-related mortality from 10% to 30%.[62] Determining who is fit or unfit for standard treatments among older adults remains a challenge.[63]

Historically, maintenance therapy for AML was administered for several years but it has not been shown to benefit persons with AML in several studies. However, two strategies have shown a benefit: (1) midostaurin in individuals with *FLT3*-mutated AML and (2) oral azacytidine.[64]

Post remission therapy appears to be more effective when given immediately after remission is achieved. Factors influencing increased survival rate include the use of combined and multimodality treatment methods; improved supportive services, such as nutritional support; and antimicrobial treatment. The presence of the Philadelphia chromosome (observed in about 5% of children with ALL, in 30% of adults with ALL, and occasionally in AML) is a poor prognostic indicator. Dramatic responses, however, have been achieved in B-ALL with chimeric antigen receptor T cells against the B-cell antigen CD19, but with associated toxicities that are sometimes fatal and with high economic costs.[16]

Myelosuppression is both a consequence of leukemia and a treatment for the disease. Hematologic support with blood products and granulocyte colony-stimulating factor (G-CSF) or GM-CSF has effectively shortened the time of neutropenia and improved survival by reducing the risk for infection.

Chronic leukemias

The two main types of chronic leukemia are (1) **chronic lymphocytic leukemia (CLL)** and (2) **chronic myelogenous leukemia (CML)**. CLL is a disorder of structurally mature but immunologically immature lymphocytes. It is manifested by progressive accumulation of these cells in the blood, bone marrow, and lymphatic tissues.[65] In adults, CLL is the most common leukemia in the Western world. It is a slow-growing cancer. CLL and **small lymphocytic lymphoma (SLL**) differ only in the amount of proliferation of peripheral blood lymphocytes.

CML is also called *chronic granulocytic leukemia* and *chronic myeloid leukemia*. It is classified as a myeloproliferative neoplasm (MPN). CML is a slowly progressing disease with increased numbers of maturing granulocytic precursors in the bone marrow, which usually includes elevated proportions of eosinophils and basophils.[16] The peripheral blood reveals a leukocytosis, often exceeding 100,000 cells/mm^3.[16] CML is mostly a disease of adults but can occur in children or adolescents (see Chapter 30). The peak incidence is the fifth to sixth decades. Individuals with chronic leukemia have a longer life expectancy, usually extending several years from the time of diagnosis.

It is estimated 21,250 new cases of CLL and 4320 deaths, and 9110 new cases of CML and 1220 deaths in 2021.[42] CML is one of a group of diseases called myeloproliferative disorders—acquired abnormalities in signaling pathways that lead to growth factor–independent proliferation. The only known cause of CML is exposure to ionizing radiation.

Exposure to pesticides, deltamethrin,[66] and herbicides[67] has been associated with the development of CLL.[68] The most convincing association is Agent Orange used during the Vietnam War.[69,70] Radon has shown a similar relationship.[71] The link with

ionizing radiation is controversial. An underlying immune defect may be involved because respiratory tract infections, cellulitis, and herpes zoster can portend the diagnosis of CLL.[72–74] Additionally, hypogammaglobulinemia is common in CLL and can precede the diagnosis.[68,75,76]

Among leukemias, CLL has the highest incidence of familial association, with first-degree relatives having more than an eightfold higher likelihood of developing the disease.[68,77] Contrarily, the low CLL incidence among Asians/Pacific Islanders, particularly Japanese, does not increase when living in the United States.[68,78] These observations strongly imply involvement of inheritable susceptibility alleles that promote or prevent disease.[68,79] Consistent with these findings is recent work with persons with CLL and myeloma revealing the shared risk loci affecting genes involved in B-cell development.[80] Susceptible genes can influence many points along the B-cell differentiation pathways.[68]

Pathophysiology

CML is defined by the fusion oncoprotein *BCR-ABL1*.[81] The Philadelphia chromosome with a shortened chromosome 22 and reciprocal translocation t(9;220 (q34;q11.2) occurs in 90% to 95% of patients (see Fig. 29.14).[81] The presence of the BCR-ABL1 protein is responsible for initiation of CML (Fig. 29.18).

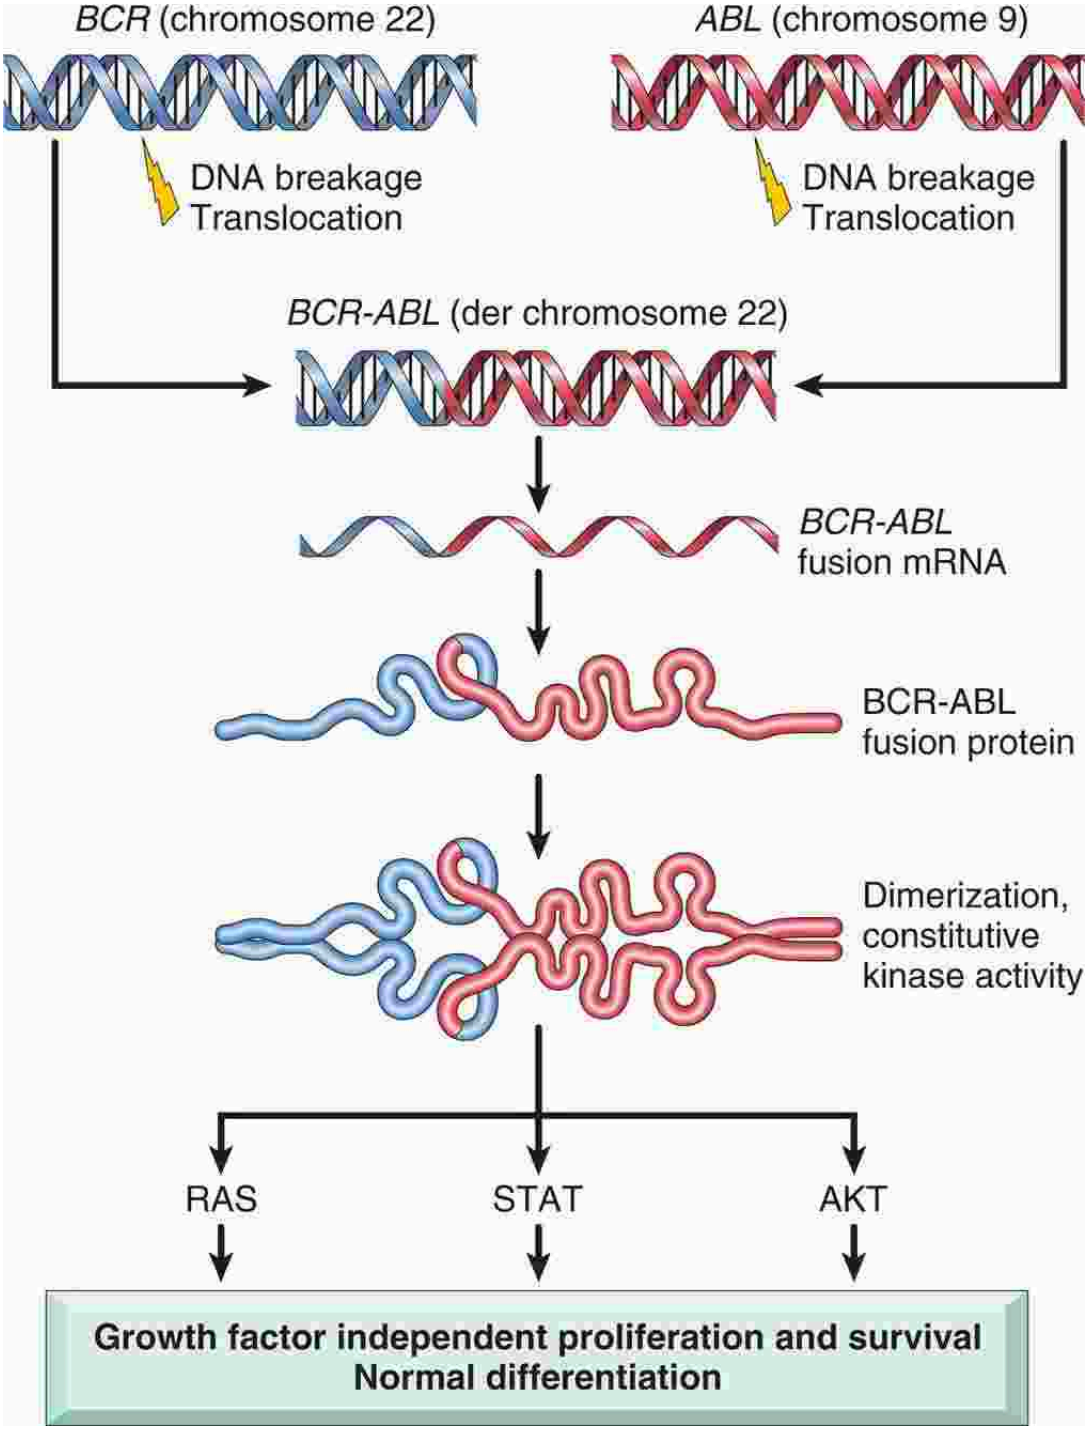

FIG. 29.18 Pathogenesis of Chronic Myeloid Leukemia.
The breakage and joining of *BCR* and *ABL* creates the chimeric fusion gene *BCR-ABL*. *BCR-ABL* genetically encodes an active BCR-ABL intracellular tyrosine kinase (an enzyme that controls intracellular "on-off" switches). The ABL kinase in turn induces signaling through the same pro-growth and pro-survival pathways that are activated by normal hematologic growth factors. Altogether

the activation of many downstream pathways drives growth factor–independent proliferation and survival of bone marrow progenitors. *der chromosome* is a structurally rearranged chromosome. *AKT*, Serine/threonine kinases; *BCR-ABL*, breakpoint cluster region-Abelson; *RAS*, rat sarcoma; *STAT*, signal transducer and activator of transcription. (From Kumar V, et al. *Robbins & Cotran pathologic basis of disease*, 9th edition. St. Louis: Elsevier; 2015.)

An illustrated flowchart represents the pathogenesis of chronic myeloid leukemia. â€¢ B C R (chromosome 22) and A B L (chromosome 9) each undergo D N A breakage and translocation. â€¢ B C R-A B L (der chromosome 22) differentiates to form B C R-A B L fusion m R N A. â€¢ The m R N A differentiates to form B C R-A B L fusion protein. â€¢ The protein undergoes dimerization, constitutive kinase activity, resulting in R A S, S T A T, or A K T. â€¢ R A S, S T A T, and A K T undergo growth factor independent proliferation and survival or normal differentiation.

CLL involves malignant transformation and accumulation of B lymphocytes co-expressing low levels of surface immunoglobulin (IG) of a single IG light (L) chain type. Unlike most other lymphoid malignancies, CLL rarely involves chromosomal translocations. The most common genetic disturbances are deletions of 13q14.3, 11q, and 17p and trisomy 12q.[16] Studies of chromosome 13 reveal two incriminating microRNAs miR-15a and miR-16-1 tumor suppressor genes.[16] Loss of these miRs is thought to result in overexpression of the anti-apoptotic protein BCL2.[16,68] Overexpression of BCL2 is observed in CLL and *small lymphocytic lymphoma* (SLL; therefore, both neoplasms are often discussed together (*CLL/SLL*). B lymphocytes with a CLL phenotype can be found in the blood of normal individuals, sometimes years before the diagnosis, and is called *monoclonal B-cell lymphocytosis (MBL)*.[68] Annually, only 1% of subjects with MBL progress to CLL requiring treatment.[68] MBL and CLL have similar mutation burdens with less found in MBL, consistent with the stepwise unfolding from one to the other.[68] Individuals with MBL, as in CLL, may have a more global immune defect. Such individuals have a higher incidence of severe infections and non-hematologic cancers and may have an increased incidence of hypogammaglobulinemia.[68]

Clinical Manifestations

Chronic leukemia advances slowly and insidiously. Approximately 70% of individuals with CLL are asymptomatic at the time of diagnosis. When symptoms do appear, the most common finding is lymphadenopathy. The most significant effect of CLL is

suppression of humoral immunity and increased infection with encapsulated bacteria. Frequently, the level of neutrophils is depressed, which adds to the risk of infection. Invasion of most organ cells is uncommon, but infiltration does occur in lymph nodes, liver, spleen, and salivary glands. CNS involvement is rare. Approximately 10% of individuals develop a more aggressive malignancy, usually a diffuse large B-cell lymphoma. In these individuals, extreme fatigue, weight loss, night sweats, low-grade fever, elevated levels of the enzyme lactic dehydrogenase, hypercalcemia, anemia, and thrombocytopenia are common.

Individuals with CML may progress through three phases of the disease: a chronic phase, during which symptoms may not be apparent, often never requiring treatment; an accelerated phase, during which the primary symptoms develop and require treatment; and a terminal blast phase ("blast crisis") necessitating treatment. The accelerated phase is characterized by excessive proliferation and accumulation of malignant cells. Splenomegaly is prominent and becomes painful, but lymphadenopathy generally is not present. Liver enlargement also occurs, but liver function is rarely altered. Hyperuricemia is common and produces gouty arthritis. Infections, fever, and weight loss also are seen often. The terminal blast phase is characterized by rapid and progressive leukocytosis with an increase in basophils. In the later stages of the terminal phase, which then resembles AML, blast cells or promyelocytes predominate and the individual experiences a "blast crisis."

The acute effects of CML resemble those of acute leukemia but with more prominent and painful splenomegaly. Lymphadenopathy generally is found only in the acute phase of the disease. Hyperuricemia is usually present and produces gouty arthritis. Infections, fever, and weight loss are common findings with CML.

Evaluation and Treatment

Diagnosis of chronic leukemia depends on laboratory analyses of peripheral blood and bone marrow. Diagnosis of CLL is based on detection of a monoclonal B-cell lymphocytosis in the blood. The cells must have the characteristic immunophenotype (CD5+, CD19+, CD20 [weak], CD23+) at levels more than 5000 cells/μL over a sustained period (usually 4 weeks). Confusion with other diseases may be avoided by determination of cell surface markers.

Treatment of CLL ranges from periodic observation with treatment of infection, hemorrhage, or immunologic complications. Because the disease mostly occurs in the elderly and the rate of progression is slow, it is often simply observed until the disease progresses. Randomized trials show no survival advantage for immediate versus delayed treatment of those individuals with early-stage disease. For individuals with progressing CLL, treatment with conventional doses of chemotherapy is not curative; selected individuals treated with allogeneic SCT have achieved prolonged disease-free survival. Antileukemic therapy is frequently unnecessary in uncomplicated early disease. From older clinical trials (1970s through the 1990s), the median survival for all individuals ranges from 8 to 12 years. However, a large variation in survival exists, ranging from several months to a normal life expectancy. Treatment must be individualized based on the clinical behavior of the disease. The complexity and

variability in clinical course and in leukemia biology warrants the use of algorithms that have been devised to better predict outcomes and response to therapy.[68] For example, individual's age, disease stage (Rai or Binet systems), TP53 disruption, immunoglobulin heavy chain variable region gene (IgHV) mutation status, and serum β2-microglobulin levels are included in the Chronic Lymphocytic Leukemia International Prognostic Index (CLL-IPI).[82]

Complications of pancytopenia, including hemorrhage and infection, are a major cause of death. Typically, individuals with CLL survive 10 years or more. Those with certain risk factors, however, have a more aggressive disease, shortening survival to less than 3 years.

Diagnosis of CML involves fluorescent *in situ* studies of the *BCR/ABL* translocation on the bone marrow aspirate or on the peripheral blood of individuals. A small subset of patients has *BCR/ABL* detectable only by reverse transcriptase-polymerase chain reaction (RT-PCR).[83] Treatment of individuals with CML is usually initiated when the diagnosis is established. Establishment is done by the presence of an elevated white blood cell count, splenomegaly, thrombocytosis, and identification of the *BCR/ABL* translocation.[83]

Current treatment modalities for CML do not cure the disease or prevent blastic transformation. Standard treatment consists of combined chemotherapy, biologic response modifiers, and allogenic BMT or SCT. BMT or SCT use is limited by donor availability and high toxicity in older adults (older than 65 years). Imatinib mesylate (Gleevec), a tyrosine kinase inhibitor, led to changes in the management of CML. Other tyrosine kinase inhibitors have been developed; however, concerns about disease persistence and resistance still exist.[84] Gleevec produces a complete cytogenic response in more than 80% of newly diagnosed persons; however, it does not cure CML because it does not kill leukemia stem cells both in the laboratory and in vivo.

Alterations of Lymphoid Function

Lymphadenopathy

Lymphadenopathy is characterized by enlarged lymph nodes (Fig. 29.19). Lymph node enlargement occurs because of an increase in the size and number of its germinal centers caused by proliferation of lymphocytes and monocytes (immature phagocytes) or invasion by malignant cells. Normally, lymph nodes are not palpable or are barely palpable. Enlarged lymph nodes are palpable and often also may be tender or painful to touch, although not in all situations.

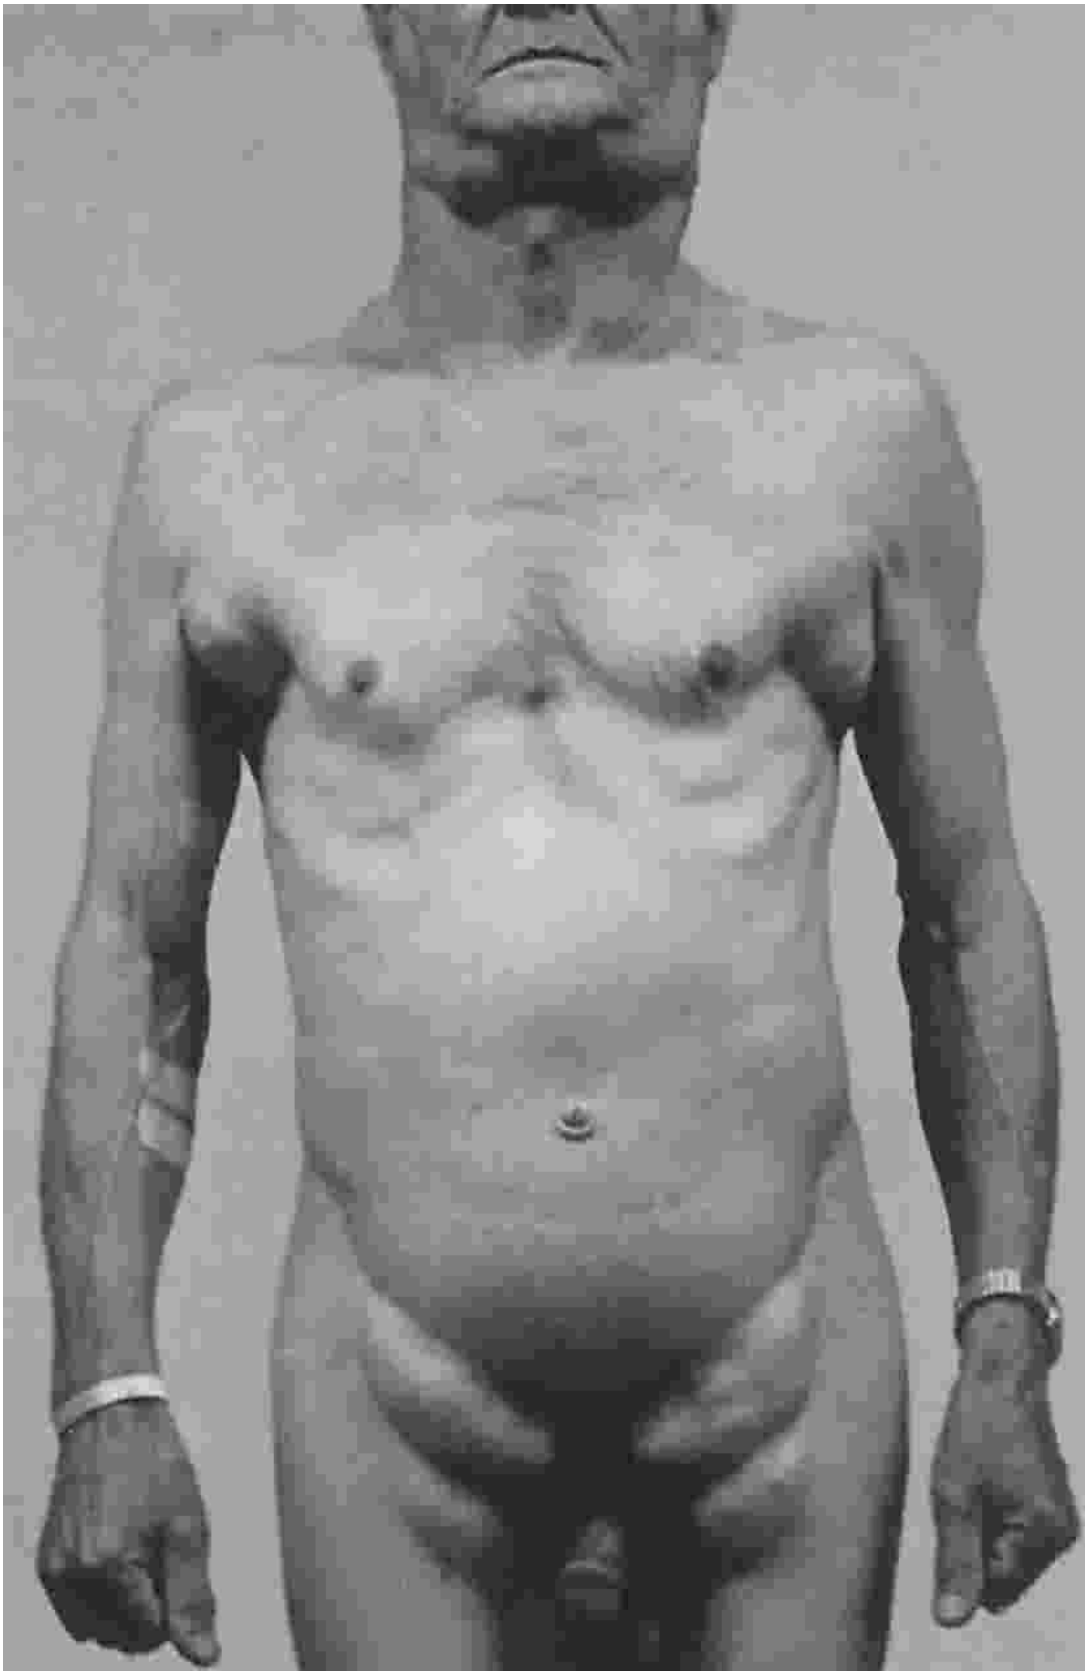

FIG. 29.19 Lymphadenopathy.
Individual with lymphocyte leukemia with extreme but symmetric lymphadenopathy. (Courtesy Dr. A.R. Kagan, Los Angeles. From del Regato JA, et al. *Cancer: Diagnosis, treatment, and prognosis*, 6th edition. St. Louis: Mosby; 1985.)

Localized lymphadenopathy usually indicates drainage of an area associated with an inflammatory process or infection (reactive lymph node). *Generalized lymphadenopathy* occurs less often and is usually seen in the presence of infections, autoimmune diseases, or disseminated malignancy. Palpable nodes, however, do not always indicate serious disease and may indicate a minor trauma or infection. The location and size of the enlarged nodes are important factors in diagnosing the cause of the lymphadenopathy, as are the individual's age, sex, and geographic location. Generalized lymphadenopathy occurs with NHLs, CLL, histiocytosis, and disorders that produce lymphocytosis. In general, lymphadenopathy results from four types of conditions: (1) neoplastic disease, (2) immunologic or inflammatory conditions, (3) endocrine disorders, or (4) lipid storage diseases. Diseases of unknown cause, including autoimmune diseases and reactions to drugs, also may lead to generalized lymphadenopathy.

Malignant Lymphomas

Lymphomas consist of a diverse group of neoplasms that develop from the proliferation of malignant lymphocytes in the lymphoid system. The WHO publishes the Revised European American Lymphoma (REAL) classification based on the cell type from which the lymphoma probably originated. The basic groups include *HL* and *NHL*. Three major groups of lymphoid malignancies based on morphology and cell lineage include (1) B-cell neoplasms, (2) T-cell neoplasms, and (3) NK-cell neoplasms. MM, which was previously classified independently, is included as a B-cell lymphoma. NHL can be further divided into cancers that have an *indolent*, slow-growing course, and those with an *aggressive*, fast-growing, course. Both HL and NHL occur in children and adults, and the overall treatment and prognosis depend on the stage and type of lymphoma.

Lymphoma is the most common blood cancer in the United States. Incidence rates of lymphoma differ with respect to age, sex, geographic location, and socioeconomic class. The estimated new cases of lymphoma include 8830 cases of HL and 81,560 cases of NHL.[42] It was estimated in 2021 that 20,720 will die from NHL and 960 from HL. Since the early 1970s, the incidence of NHL has nearly doubled. The exact reason for this increase remains a mystery; however, a modest portion of the increase had been attributed to lymphomas developing in association with immune deficiencies, including AIDS and organ transplants. Conversely, the incidence of HL has declined over the same time period, especially among older adults.

In general, lymphomas are the result of genetic mutations or viral infection. Globally, however, the incidence of lymphoma is increased in more developed countries (except for BL); therefore, investigators are studying the following potential

risk factors: diet, obesity, metabolic syndrome, sedentary lifestyle, stress, advances in medical care and access, increases in longevity, and exposure to compounds from industrialization. Malignant transformation produces a cell with uncontrolled and excessive growth that accumulates in the lymph nodes and other sites, producing tumor masses. Lymphomas usually start in the lymph nodes or lymphoid tissues of the stomach or intestines (Fig. 29.20).

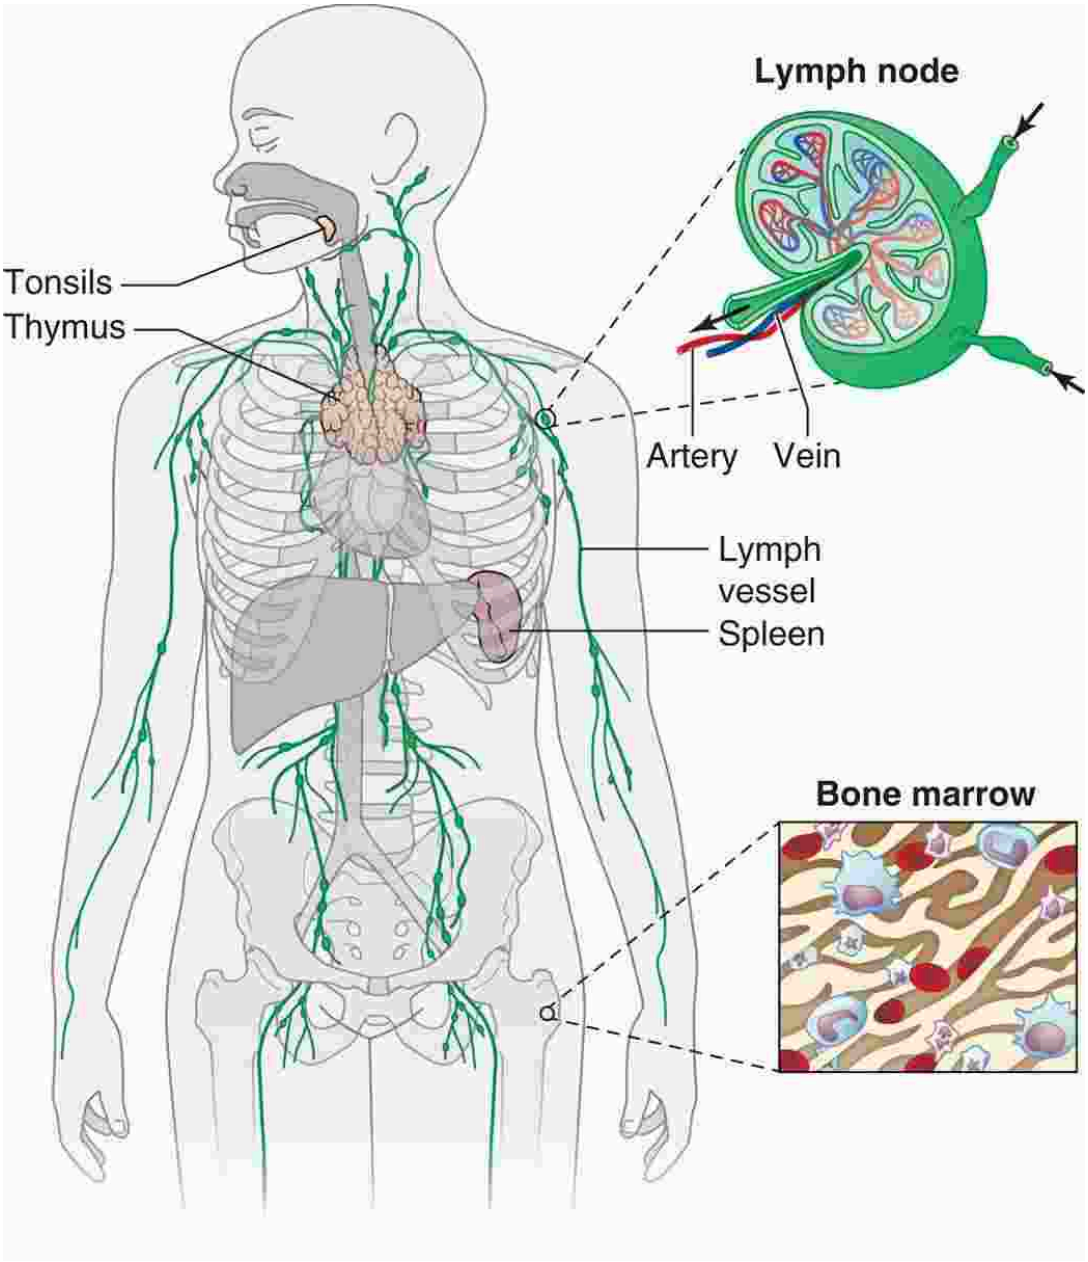

FIG. 29.20 Lymphomas Start in Lymph Nodes or Lymphoid Tissue.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is a malignant lymphoma that progresses from one group of lymph nodes to another and includes the development of systemic symptoms and the presence of multinucleated cells derived from B lymphocytes called **Hodgkin and Reed-Sternberg (HRS) cells** (see the Pathophysiology section). Estimates of new cases of HL include 8480 cases in 2020 and 970 deaths.[42] The incidence of HL is slightly higher in females and occurs mostly in young adults and less frequently in elderly individuals.[85] The overall incidence of HL is low, about 2 to 3/100,000 individuals of European ancestry[86]; however, HL is one of the most common cancers diagnosed in young adults (see Chapter 30). HL peaks at two different ages: early in life in the second and third decades and later in life during the sixth and seventh decades. Incidence is greater in whites than blacks and lower in Hispanic Americans, Asians/Pacific Islanders, American Indians, and Alaskan natives.[87]

HL has unique characteristics among human cancers, including young age of onset; rarity of malignant cells or HRS cells and are usually present within a microenvironment with lots of immune effector cells; a high cure rate, even when the individual presents with metastatic spread; and a particular sensitivity to radiation therapy.[85]

EBV has been linked to the pathogenesis of HL, but the virus is detected in only a small subset of cases, and absolute risk for HL after EBV infections is very small.[88] Individuals with HIV infection or AIDS are at increased risk of HL *since* the introduction of highly active retroviral therapy (HAART).[89]

Pathophysiology

The HRS cell represents the malignant transformed lymphocyte (Fig. 29.21). HRS cells are often large and binucleate with occasional mononuclear variants. HRS cells are necessary for the diagnosis of HL. In rare instances, cells resembling HRS cells can be found in benign illnesses, as well as in other forms of cancer, including NHLs and solid tissue cancers and in IM.

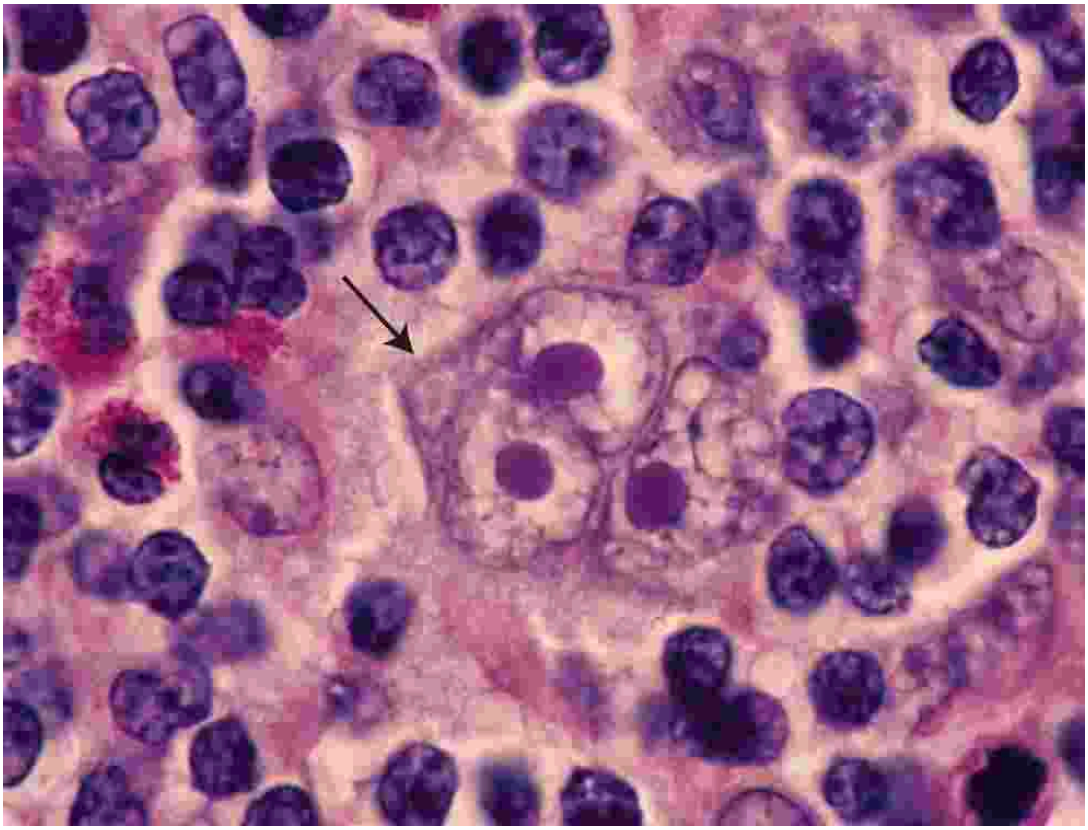

FIG. 29.21 Lymph Nodes.
Diagnostic Reed-Sternberg cell *(arrow)*. A large multinucleated or multilobed cell with inclusion body–like nucleoli surrounded by a halo of clear nucleoplasm. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

The neoplastic HRS cells originate from a germinal center or post-germinal center B cell.[16] The triggering mechanism for the malignant transformation of cells remains unknown. Classic HL appears to be derived from a B cell in the germinal center that has not undergone successful immunoglobulin gene rearrangement (see Chapter 8) and would normally be induced to undergo apoptosis. Survival of this cell may be linked to infection with EBV. Laboratory and epidemiologic studies have linked HL with EBV infections. The HRS cells secrete and release cytokines (e.g., IL-10, TGF-β) that result in the accumulation of inflammatory cells in the tumor microenvironment, which produces the local and systemic effects (Fig. 29.22). The inflammatory cell infiltrate produces molecules that bind to proteins expressed on the cell membrane of the HRS cell.[85] These cellular interactions lead to activation of pathways that support the growth and survival of the HRS cells. Tumor-associated macrophages have been reported to be the prominent cells that support HRS cell growth and participate in forming an immune-prosperous niche.[85]

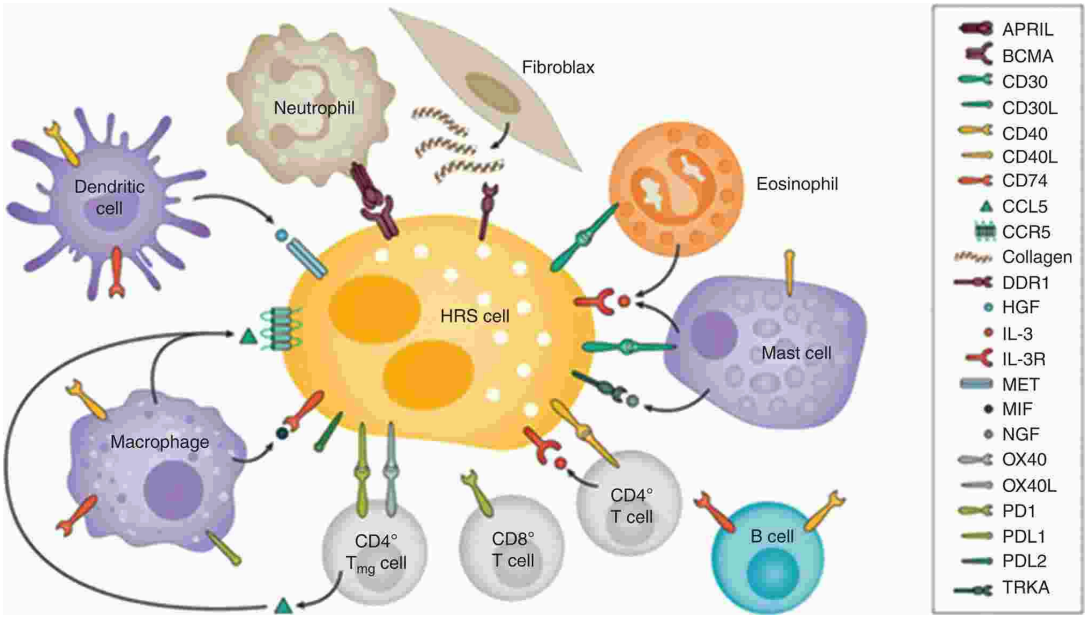

FIG. 29.22 Hodgkin Disease and the Tumor Microenvironment. A diagnostic Hodgkin and Reed-Sternberg (HRS) cell surrounded by the inflammatory tumor microenvironment. The range of microenvironment changes are associated with all four types of classic Hodgkin lymphoma (cHL). The inflammatory cell infiltrate produces molecules that bind to the cell membrane of the HRS cell. These interactions lead to pathways that support the growth and survival of the HRS cells. APRIL, A proliferation-inducing ligand; BCMA, B cell maturation antigen; CD30L, CD30 ligand; CD40, CD40 ligand; CCR5, CC-chemokine receptor 5; DDR1, discoidin domain receptor 1: HGF, hepatocyte growth factor; IL3R, IL-3 receptor; Met, protooncogene Met; MIF, migration inhibitory factor: NGF, nerve growth factor; OX40, OXO40L receptor; OX40L, OX40 ligand; TRKA, tyrosine kinase receptor. An illustration of the H R S cell identifies the tumor microenvironment. â€¢ Fibroblast releases collagen, which is attracted to D D R 1 on the H R S cell. â€¢ Eosinophil comprises C D 30 L, which is attracted to C D 30 on the H R S cell. â€¢ Eosinophil and mast cell release I L-3, which is attracted to the I L-3 R on the H R S cell. â€¢ Mast cell comprises C D 30 L, which is attracted to C D 30 on the H R S cell. â€¢ Mast cell releases N G F, which is attracted to T R K A on the H R S cell. â€¢ C D 4 T cell

comprises C D 40 L, which is attracted to C D 40 on the H R S cell. â€¢ C D 4 T cell releases I L-3, which is attracted to I L-3 R on the H R S cell. â€¢ B cell comprises C D 40 and C D 74. â€¢ C D 8 T cell comprises P D 1. â€¢ C D 4 T reg cell comprises O X 40, which is attracted to O X 40 L on the H R S cell. â€¢ C D 4 T reg cell comprises P D 1, which is attracted to P D L 1 on the H R S cell. â€¢ C D 4 T reg cell releases C C L 5, which is attracted to C C R 5 on the H R S cell. â€¢ Macrophage comprises C D 40, C D 74, and P D L 1. â€¢ Macrophage releases C C L 5, which is attracted to C C R 5 on the H R S cell. â€¢ Macrophage releases M I F, which is attracted to C D 74 on the H R S cell. â€¢ Dendritic cell comprises C D 40 and C D 74. â€¢ Dendritic cell releases H G F, which is attracted to M E T on the H R S cell. â€¢ H R S cell comprises P D L 2.

Clinical Manifestations

Many clinical features of HL can be explained by the complex action of cytokines and other growth factors that are secreted and released by the malignant cells. These substances induce infiltration and proliferation of inflammatory cells, resulting in an enlarged, painless lymph node in the neck (often the first sign of HL) (Fig. 29.23A and B). The discovery of an asymptomatic mediastinal mass on routine chest x-ray is not uncommon. The cervical, axillary, inguinal, and retroperitoneal lymph nodes are commonly affected in HL (Fig. 29.24). Local symptoms caused by pressure and obstruction of lymph nodes are the result of the lymphadenopathy.

A

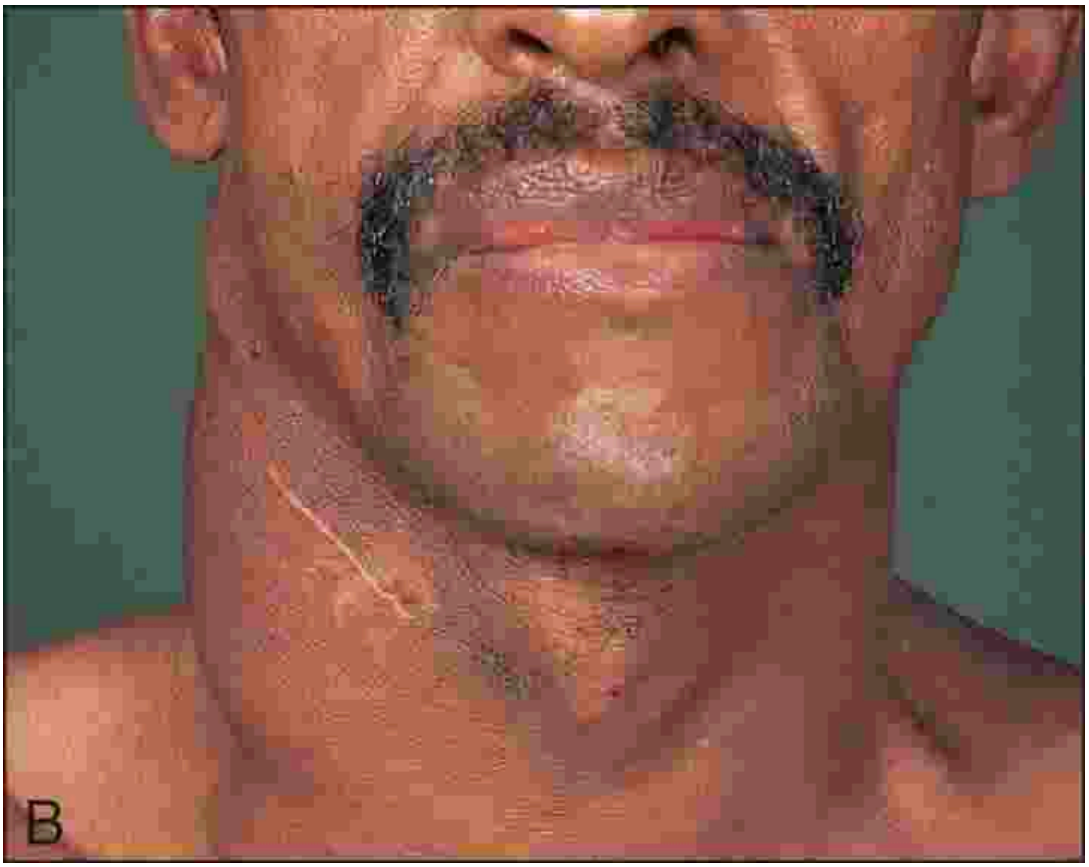

FIG. 29.23 Hodgkin Lymphoma and Enlarged Cervical Lymph Node.

Typical enlarged cervical lymph node in the neck (A) *(arrow)* of a 35-year-old woman with Hodgkin lymphoma and (B) *(arrow)* of a man with Hodgkin lymphoma. The scar of a previous biopsy incision is well healed. (A, From del Regato JA, et al. *Cancer: Diagnosis, treatment, and prognosis*, 6th edition. St. Louis: Mosby; 1985. B, From Hoffbrand AV, Petit JE, Vyas P. *Color atlas of clinical hematology*, 4th edition. Philadelphia: Mosby, Elsevier; 2009.)

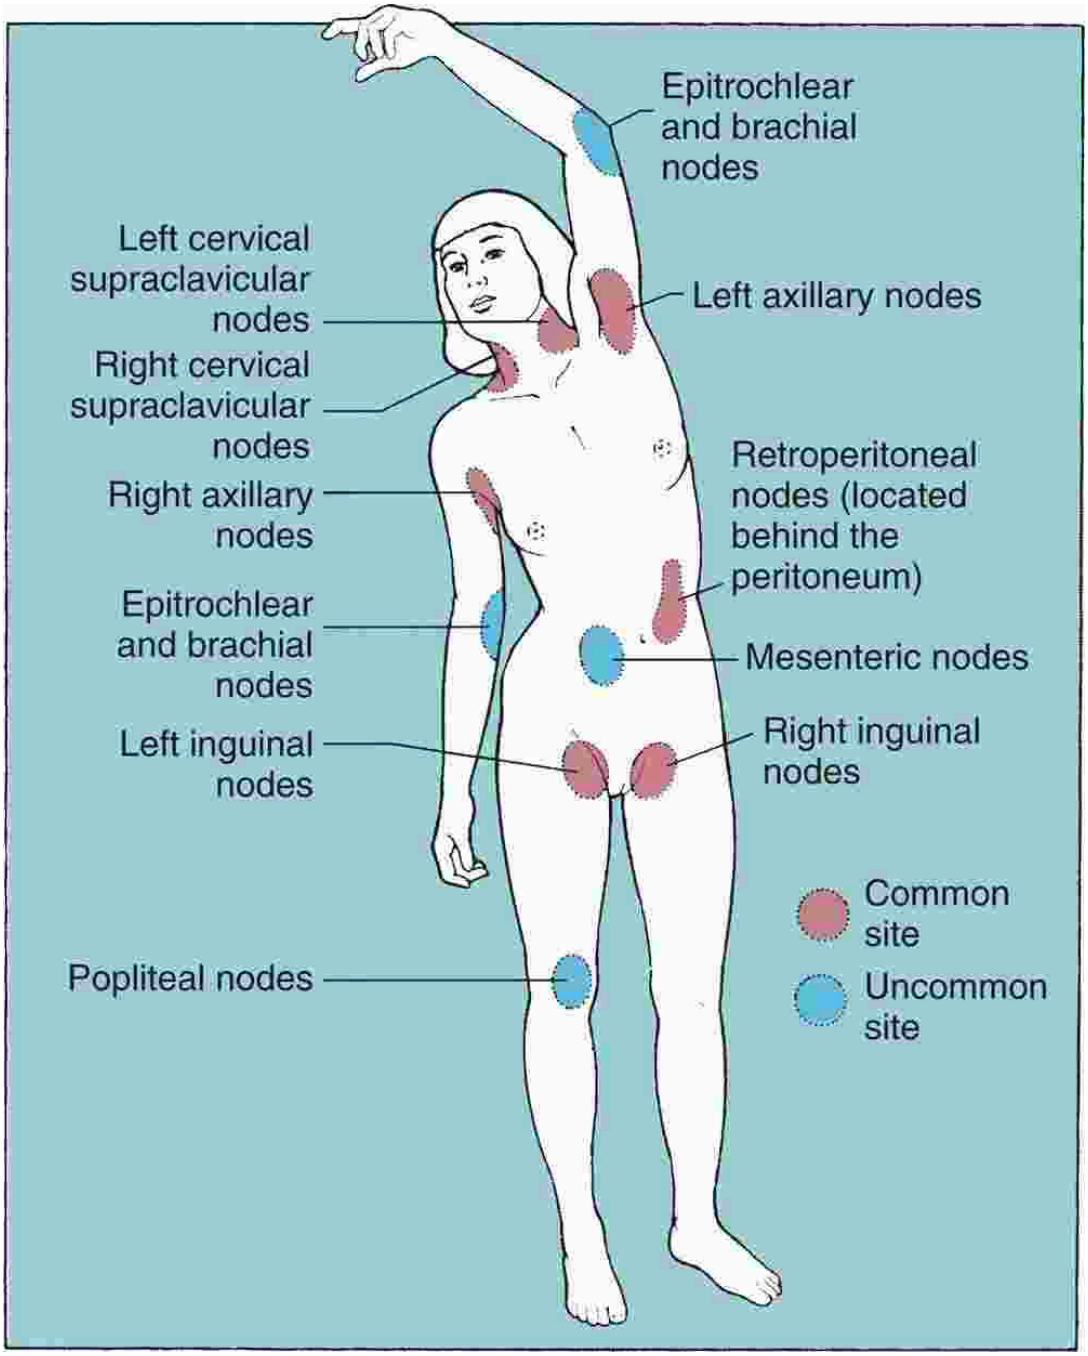

FIG. 29.24 Common and Uncommon Involved Lymph Node Sites for Hodgkin Lymphoma.

An illustration of the anterior view of the human body highlights the common and uncommon sites for Hodgkin lymphoma. â€¢ Common sites: left axillary nodes, right axillary nodes, left cervical supraclavicular nodes, right cervical supraclavicular nodes,

retroperitoneal nodes (located behind the peritoneum), left inguinal nodes, and right inguinal nodes. â€¢ Uncommon sites: epitrochlear and brachial nodes, mesenteric nodes, and popliteal nodes.

About one-third of individuals will have some common systemic symptoms, such as intermittent fever, without other symptoms of infection, drenching night sweats, itchy skin (pruritus), and fatigue. These constitutional symptoms accompanied by weight loss are associated with a poor prognosis.

Although HL rarely arises in the lung, mediastinal and hilar node adenopathy can cause secondary involvement of the trachea, bronchi, pleura, or lungs. Retroperitoneal nodes can involve vertebral bodies and nerves and can cause displacement of ureters. Spinal cord involvement is more common in the thoracic and lumbar regions than in the cervical region. Skin lesions, although uncommon, include psoriasis and eczematoid lesions, causing itching and scratching.

As a result of direct invasion from mediastinal lymph nodes, pericardial involvement can cause pericardial friction rub, pericardial effusion, and engorgement of neck veins. The GI tract and urinary tract are rarely involved. Anemia is often found in individuals with HL accompanied by a low serum iron level and reduced iron-binding capacity. Other laboratory findings include elevated sedimentation rate, leukocytosis, and eosinophilia. Leukopenia occurs in advanced stages of HL.

Splenic involvement in HL depends on histologic type. In mixed cellularity and lymphocytic deletion types of HL, the spleen is involved in 60% of cases. With lymphocyte and nodular sclerosis types, 34% of cases involve the spleen.

Evaluation and Treatment

Treatment depends on the stage of HL. Because of the variability in symptoms, early definitive detection may be challenging. Asymptomatic lymphadenopathy can progress undetected for several years. Diagnosis is made from physical examination and history; complete blood count (CBC); and blood chemistry studies, including sedimentation rate, and imaging. Radiologic examination may include CT scans of the neck, chest, abdomen, and pelvis; or metabolic imaging with positron emission tomography–computed tomography (PET-CT).[90] Occasionally, biopsy of suspicious nodes is needed if imaging studies are indeterminate and treatment decisions are affected by confirmation of involvement.[88] The current staging system for HL is the Lugano classification derived from Ann Arbor staging with Cotswolds modifications (Table 29.9).[88]

Table 29.9

Lugano Classification for Staging Lymphomas (Derived from Ann Arbor Staging With Cotswolds Modifications)

Stage I—Involvement of a single lymph node region (e.g., cervical, axillary, inguinal, mediastinal) or lymphoid structure such as the spleen, thymus, or Waldeyer ring.
Stage II—Involvement of 2 or more lymph node regions or lymph node structures on the same side of the diaphragm. Hilar nodes should be considered to be "lateralized" and when involved on both sides, constitute stage II disease. For the purpose of defining the number of anatomic regions, all nodal disease within the mediastinum is considered to be a single lymph node region, and hilar involvement constitutes an additional site of involvement. The number of anatomic regions should be indicated by a subscript (e.g., II-3).
Stage III—Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm. This may be subdivided to stage III.1 or 111.2: stage III.1 is used for persons with involvement of the spleen or splenic hilar, celiac, or portal nodes; and stage III.2 is used for those with involvement of the paraaortic, iliac, inguinal, or mesenteric nodes.
Stage IV—Diffuse or disseminated involvement of 1 or more extranodal organs or tissue beyond that designated "E," with or without associated lymph node involvement.
All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant unexplained fever, night sweats, or unexplained weight loss exceeding 10% of body weight during the 6 months prior to diagnosis.
The designation "E" refers to extranodal contiguous extension (i.e., proximal or contiguous extranodal disease) that can be encompassed within an irradiation field appropriate for nodal disease of the same anatomic extent. More extensive extranodal disease is designated stage IV.

Bulky disease: A single nodal mass, in contrast to multiple smaller nodes, of 10 cm or ≥ {1/3} of the transthoracic diameter at any level of thoracic vertebrae as determined by CT; record the longest measurement by CT scan. The term T (used in the Ann Arbor staging system) is no longer necessary.
The subscript "RS" is used to designate the stage at the time of relapse.

Stage I—Involvement of a single lymph node region (e.g., cervical, axillary, inguinal, mediastinal) or lymphoid structure such as the spleen, thymus, or Waldeyer ring.
Stage II—Involvement of 2 or more lymph node regions or lymph node structures on the same side of the diaphragm. Hilar nodes should be considered to be "lateralized" and when involved on both sides, constitute stage II disease. For the purpose of defining the number of anatomic regions, all nodal disease within the mediastinum is considered to be a single lymph node region, and hilar involvement constitutes an additional site of involvement. The number of anatomic regions should be indicated by a subscript (e.g., II-3).
Stage III—Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm. This may be subdivided to stage III.1 or 111.2: stage III.1 is used for persons with involvement of the spleen or splenic hilar, celiac, or portal nodes; and stage III.2 is used for those with involvement of the paraaortic, iliac, inguinal, or mesenteric nodes.
Stage IV—Diffuse or disseminated involvement of 1 or more extranodal organs or tissue beyond that designated "E," with or without associated lymph node involvement.
All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant unexplained fever, night sweats, or unexplained weight loss exceeding 10% of body weight during the 6 months prior to diagnosis.
The designation "E" refers to extranodal contiguous extension (i.e., proximal or contiguous extranodal disease) that can be encompassed within an irradiation field appropriate for nodal disease of the same anatomic extent. More extensive extranodal disease is designated stage IV.
Bulky disease: A single nodal mass, in contrast to multiple smaller nodes, of 10 cm or ≥ {1/3} of the transthoracic diameter at any level of thoracic vertebrae as determined by CT; record the longest measurement by CT scan. The term T (used in the Ann Arbor staging system) is no longer necessary.
The subscript "RS" is used to designate the stage at the time of relapse.

CT, Computed tomography.

Pretreatment evaluation includes history and physical exam, laboratory studies, imaging (PET/CT), and specialized studies to determine the individual's fitness for treatment and to determine the disease stage.[88] MRI can be used for anatomical imaging of PET-positive lesions to characterize involvement of certain organs (e.g., brain, liver). CNS involvement with HL is rare; if involved, it should be evaluated by MRI. Persons with neurologic findings should also undergo lumbar puncture with cytology.[88] Exploratory laparotomy, with or without splenectomy, was used frequently in the past, but is not used now because of associated morbidity and improved imaging.[88] Prognostic indicators include clinical stage, histologic type, tumor cell concentration and tumor burden, constitutional symptoms, and age of the individual.

The effectiveness of treatment is related to the age, sex, and general health of the individual; signs and symptoms; stage of the disease; blood test results; type of HL; and classification of the disease as recurrent or progressive. HL in adults usually can

be cured with early diagnosis and treatment. Treatment approaches include chemotherapy and radiation options. Radiation therapy alone is almost never used to treat individuals newly diagnosed with early favorable disease.[90] When mediastinal radiation will encompass the left side of the heart or will increase breast cancer risk in young female patients, proton therapy may be considered to reduce the radiation dose to organs at risk. When used as a single modality, radiation therapy is delivered to the neck, chest, and axilla (mantle field) and then to an abdominal field to treat para-aortic nodes and the spleen (splenic pedicle). In some individuals, pelvic nodes are treated with a third field. The three fields constitute *total nodal radiation therapy*.[90] Treatment for pregnant women includes watchful waiting and steroid therapy. Treatment with chemotherapy or radiation therapy, or both, may increase the risk of second cancers, cardiovascular disease, and other health problems for many months or years after treatment. The National Cancer Institute has developed tables to assist with understanding the treatment options. Persons with HL who are older than 60 years may have more treatment-related morbidity and mortality.

Non-Hodgkin Lymphomas

Non-Hodgkin lymphomas (NHLs) are a heterogeneous group of lymphoid tissue neoplasms with differing biologic and clinical patterns of activity and responses to treatment. For unknown reasons, NHL incidence rates increased worldwide from 1950 to 2000, tripling in adults older than 65 years of age.[91,92] The previously used generic classification of NHL has been reclassified in the WHO/REAL scheme into (1) **B-cell neoplasms**, which include a variety of lymphomas and myelomas that originate from B cells at various stages of differentiation; and (2) **T-cell** and **NK-cell neoplasms**, which include lymphomas that originate from either T or NK cells. These cancers are differentiated from HL by lack of HRS cells and other cellular changes not characteristic of HL.

More than 81,560 new cases of NHL and 20,720 deaths are estimated for 2021.[42] The median age of diagnosis is 67 years, with a higher occurrence in men than women. Gene changes related to NHL are usually acquired during life and not inherited. However, having a family history of lymphoma (HL, NHL, CLL) does seem to increase the risk of lymphoma.[42] The highest incidences are in North America, Europe, Oceania, and several African countries. Part of the increased incidence has been attributed to diagnostic improvements as well as AIDS-related cancers after the HIV epidemic. Conversely, the mortality has risen at a slower rate. It is thought that newer treatment modalities are improving survival rates.

Risk factors for adult NHL include being older, male, or white and having one of the following: immunosuppression (e.g., HIV/AIDS, organ transplantation), viruses and other pathogens (EBV, HTLV, HHV8, Hepatitis C, SV40, and *H. pylori*), autoimmune and chronic inflammatory disorders (rheumatoid arthritis, Sjogren syndrome, celiac, and SLE), occupational exposure (pesticides like phenoxy acids, organophosphates, and organochlorines).[93]

Pathophysiology

NHL is a progressive clonal expansion of B cells, T cells, or NK cells. B cells account for 85% to 90% of NHLs, with most of the remainder being T cells and rarely NK cells. A very small percentage originates from macrophages. The key pathogenic mechanisms include immunosuppression, especially in relation to T-cell function and loss of control of latent EBV infection, and chronic antigen stimulation[93] as above. Chronic antigenic stimulation increases B-cell proliferation, which can lead to random genetic mistakes, particularly immunoglobulin gene rearrangements. Immunosuppression in a variety of medical conditions increases the risk of NHL. For example, dysregulation or suppression of T-cell function occurs with HIV/AIDS and organ transplantation, which promotes EBV driven B-cell proliferation and transformation.[93] Oncogenes may be activated by chromosomal translocations or the tumor-suppressor loci may be inactivated by deletion or mutation of chromosomes. Certain subtypes may have altered genomes by oncogenic viruses. Infections are characterized by their pathogenic effects and include those that directly transform lymphocytes (e.g., HTLV1, HIV, EBV [particularly in parts of Africa for BL], HHV8), infections that weaken the immune system (e.g., HIV), and infections that cause chronic immune stimulation (e.g., *H. pylori*, *Chlamydophilia psittac*i, *Campylobacter jejuni*, hepatitis C).[94] Various subtypes of NHL are identified by specific diagnostic markers related to various cytogenetic lesions. The most common type of chromosomal alteration in NHL is translocation, which disrupts the genes encoded at the breakpoints. Unlike HL, NHL spreads in a less predictable way and spreads widely early.

Clinical Manifestations

Clinical manifestations of NHL usually begin as localized or generalized lymphadenopathy, similar to HL. Differences in clinical features are noted in Table 29.10. The cervical, axillary, inguinal, and femoral lymph node chains are the most affected sites. Generally, the swelling is painless, and the nodes have enlarged and transformed over a period of months or years. Other sites of involvement are the nasopharynx, GI tract, bone, thyroid, testes, and soft tissue. Some individuals have retroperitoneal and abdominal masses with symptoms of abdominal fullness, back pain, ascites (fluid in the peritoneal cavity), skin rash or itchy skin, fatigue, fever of unknown origin, drenching night sweats, and leg swelling.

Table 29.10

Clinical Differences Between Non-Hodgkin Lymphoma and Hodgkin Lymphoma

Characteristics	Non-Hodgkin Lymphoma	Hodgkin Lymphoma
Nodal involvement	Multiple peripheral nodes	Localized to single axial group of nodes (i.e., cervical, mediastinal, paraaortic)
	Mesenteric nodes and Waldeyer ring commonly involved	Mesenteric nodes and Waldeyer ring rarely involved
Spread	Noncontiguous	Orderly spread by contiguity
B symptoms[a]	Uncommon	Common
Extranodal involvement	Common	Rare
Extent of disease	Rarely localized	Often localized

Characteristics	Non-Hodgkin Lymphoma	Hodgkin Lymphoma
Nodal involvement	Multiple peripheral nodes	Localized to single axial group of nodes (i.e., cervical, mediastinal, paraaortic)
	Mesenteric nodes and Waldeyer ring commonly involved	Mesenteric nodes and Waldeyer ring rarely involved
Spread	Noncontiguous	Orderly spread by contiguity
B symptoms[a]	Uncommon	Common
Extranodal involvement	Common	Rare
Extent of disease	Rarely localized	Often localized

[a]Fever, weight loss, night sweats.

Lymphomas are classified as low, intermediate, or high grade. A low-grade lymphoma, which also may be termed *indolent*, has a slow progression. Individuals with low-grade lymphoma commonly present with a painless, peripheral adenopathy. Spontaneous regression of these nodes may occur, mimicking the presence of an infection. Night sweats with an elevated temperature (more than 38°C [100.4°F]) and weight loss, as well as extra nodular involvement, are not commonly present in the early stages but are common in advanced or end-stage disease. *Cytopenia*, or reduction in the number of blood cells, reflective of bone marrow involvement is often observed. Hepatomegaly is common; splenomegaly is present in approximately 40% of individuals. Fatigue and weakness are more prevalent with advanced stages.

Intermediate and high-grade lymphomas, which are more aggressive, have a more varied clinical presentation. A high-grade lymphoma also may be termed *aggressive*.

Evaluation and Treatment

The primary means for diagnosis of NHL is biopsy. A common finding in NHL is noncontiguous lymph node involvement, which is not common in HL. Staging is determined from physical exam, blood tests, radiologic studies (PET and CT), biopsy, and examination of bone marrow aspirate (often, but not always done).

Treatment for NHL is quite diverse and depends on type (B cell or T cell), tumor stage, histologic status (low, intermediate, or high grade), symptoms, age, and presence of comorbidities. Depending on the type (B cell or T cell) of the tumor, stage of disease, and aggressiveness of the tumor, treatment is usually initiated at the time of diagnosis. However, because treatment is not curative for some low-grade indolent lymphomas that are widely disseminated, observation without treatment may be the most appropriate choice. These indolent tumors are often not symptomatic for the individual, and this approach improves quality of life. In some individuals the disease may be so slow growing that treatment is not needed for an extended period.

Treatment with chemotherapy alone may be adequate for many individuals, although radiation therapy is often included. Low-dose chemotherapy has been followed by autologous SCT in some NHLs or for recurrent disease. Immunotherapies are emerging (see Emerging Science Box: Immunotherapy). Treatment using monoclonal antibody alone or in combination with radiation therapy (radioimmunotherapy) also is being used. Rituximab-based chemoimmunotherapy has improved the response and survival of people with follicular lymphoma.[95]

Individuals with NHL can survive for extended periods. A partial remission may be achieved in some cases in which evidence of the disease remains, but the disease does not progress. Survival with nodular lymphoma ranges up to 15 years, but those with diffuse disease generally do not survive as long. Overall, the survival rates of NHL are less than those for HL. Survival rates for NHL with modern treatment are over 60% at 5 years.

Burkitt leukemia/lymphoma adult

Burkitt lymphoma is a B-cell NHL with unique clinical and epidemiologic features. It is highly aggressive and is the fastest growing human tumor. It is derived from germinal or post-germinal center B cells.[96] There are three main types of BL: endemic, nonendemic, and immunodeficiency related. *Endemic* BL commonly occurs in Africa and is linked to the EBV, and *nonendemic* BL occurs worldwide. *Immunodeficiency-related* BL is most often seen in individuals with AIDS. BL occurs most often in children and young adults (see Chapter 30). Endemic cases, usually from Africa, involve a rapidly growing tumor of the jaw and facial bones (Fig. 29.25). In the United States, BL is rare, usually involves the abdomen, and is characterized by extensive bone marrow invasion and replacement. BL and Burkitt leukemia are classified as different manifestations of the same disease.[97] With advances in diagnostic criteria, many older studies included a heterogenous patient population that contained those who today would not be diagnosed with BL by current criteria.[96,97]

FIG. 29.25 Burkitt Lymphoma. Burkitt lymphoma involving the jaw in a young African boy. (Courtesy I. Magrath MD, Bethesda MD. From Zitelli BJ, et al. *Zitelli and Davis' atlas of pediatric physical diagnosis*, 6th edition. Philadelphia: Saunders; 2012.)

Pathophysiology

The different clinical subtypes of BL (e.g., endemic, nonendemic, and immunodeficiency related) probably arise from B cells at different stages of development.[96,97] Virtually all cases of BL are associated with chronic EBV infection.

Perhaps suppression of the immune system by other illnesses (e.g., HIV infection, chronic malaria) increases the individual's susceptibility to EBV. B cells are particularly sensitive because of specific surface receptors for EBV. As a result, the B cell undergoes chromosomal translocations that result in overexpression of the myelocytomatosis (*c-MYC* proto-oncogene and loss of control of cell growth (Fig. 29.26). The most common translocation (75% of individuals) is between chromosomes 8 (containing the *c-MYC* gene) and 14 (containing the immunoglobulin heavy chain genes). Other translocations have been reported between chromosome 8 and chromosomes 2 or 22, which contain genes for immunoglobulin light chains.

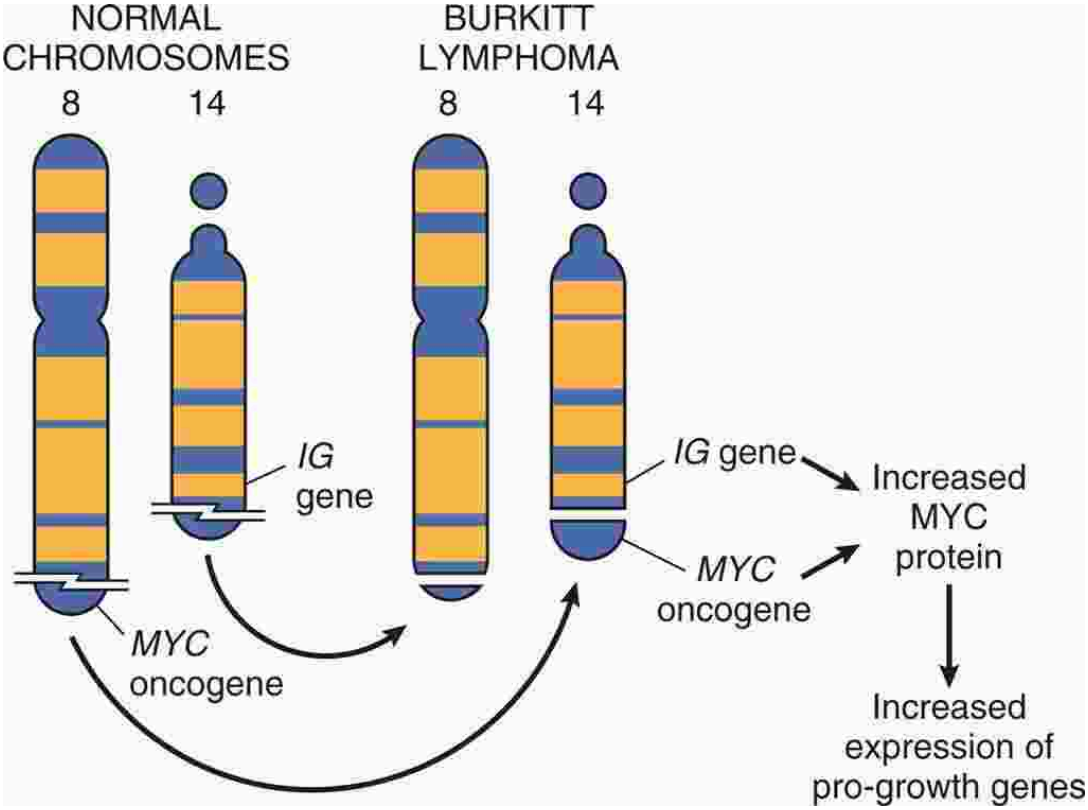

FIG. 29.26 Burkitt Lymphoma Cells.
The 8,14 chromosomal translocation and associated oncogenes in Burkitt lymphoma.

An illustration shows the translocation of M Y C oncogene in chromosome 8 and I G gene in chromosome 14, resulting in Burkitt lymphoma. This leads to increased M Y C protein and subsequently to increased expression of pro-growth genes.

Clinical Manifestations

In non-African BL the most common presentation is abdominal swelling. Manifestations of most tumors occur at extra nodal sites. More advanced disease may involve the eye, ovaries, kidneys, or glandular tissue (breast, thyroid, tonsils) and presents with type B symptoms (night sweats, fever, weight loss). Common manifestations may include nausea and vomiting; loss of appetite or change in bowel habits, or both; GI bleeding; symptoms of an acute abdominal condition; intestinal perforation; and renal failure.

Evaluation and Treatment

Usually indicative of BL is the presence of tumors in the jaw and facial bones, enlarged lymph nodes, and bone marrow containing malignant B cells. Laboratory studies include CBC, electrolytes, liver and renal function tests, lactate dehydrogenase (LDH), hepatitis B, HIV, and uric acid.[96,97] Treatment is aggressive multidrug regimens, such as combination chemotherapy. There is no role for radiation therapy in treatment of people with BL.[96,97]

Plasma Cell Malignancy

Multiple Myeloma

Multiple myeloma (MM) is a clonal plasma cell cancer characterized by the neoplastic proliferation of plasma cells producing a monoclonal immunoglobulin.[98] The plasma cells proliferate in the bone marrow (Fig. 29.27). These masses are associated with *lytic bone lesions* (round, punched-out regions of bone) (Fig. 29.28A and B). Uncommon variants include *solitary myeloma (plasmacytoma)* with a single mass in bone or soft tissue and *smoldering myeloma*, which is defined by a lack of symptoms and a high plasma abnormal antibody called the **M protein**.

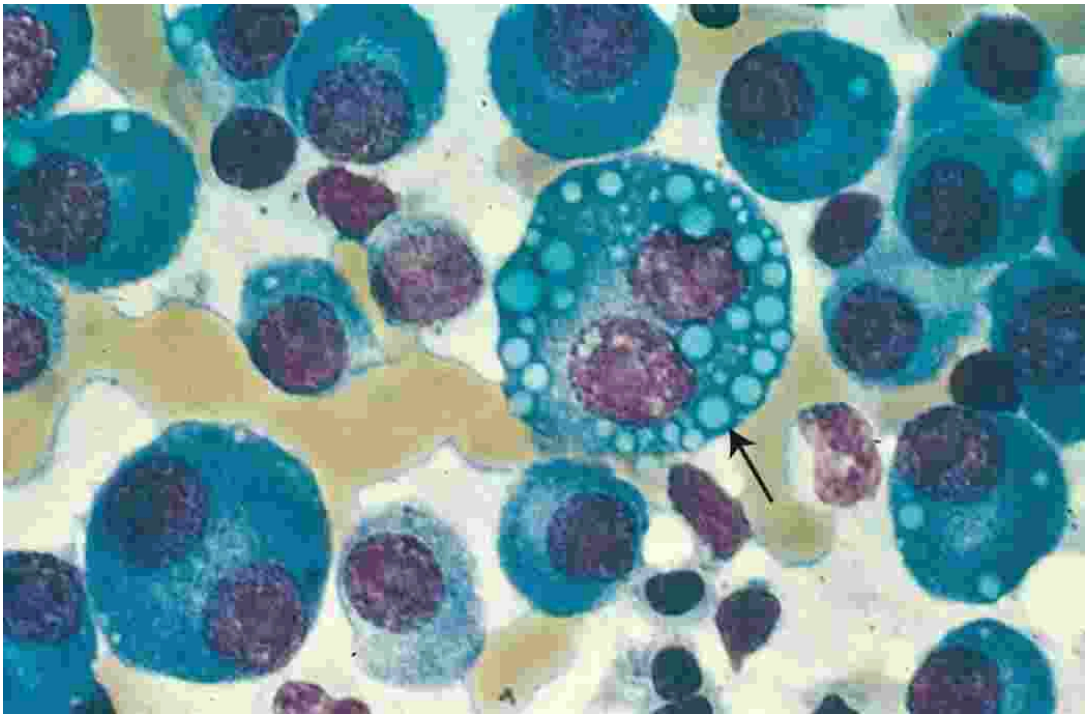

FIG. 29.27 Multiple Myeloma, Bone Marrow Aspirate.
Normal marrow cells are largely replaced by plasma cells, including atypical forms with multiple nuclei *(arrow)*, and cytoplasmic droplets *containing* immunoglobulin. (From Kumar V, et al. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Saunders; 2015.)

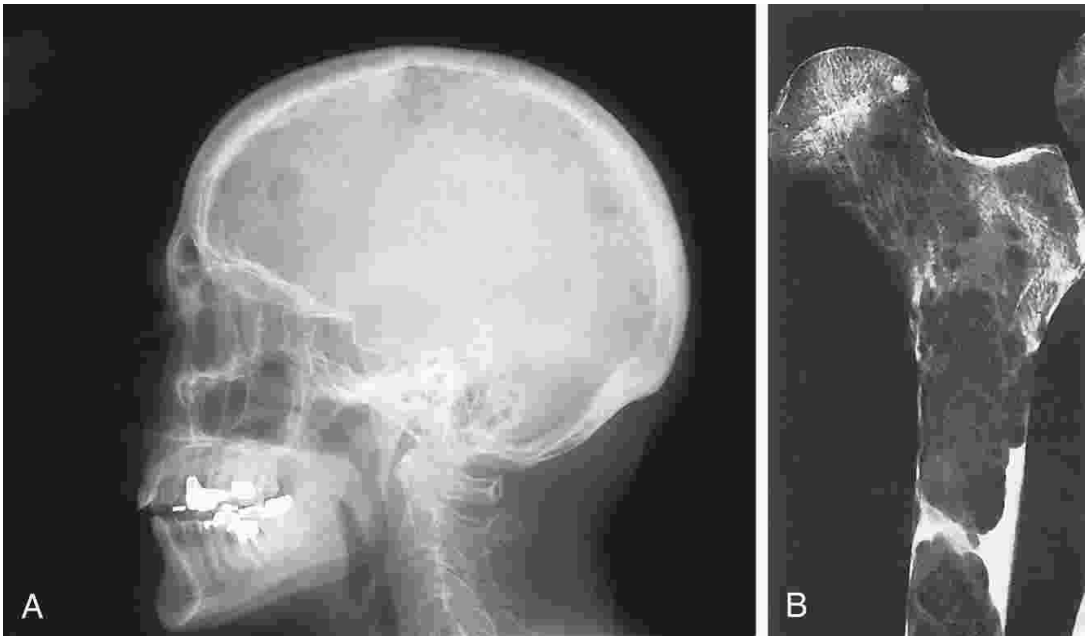

FIG. 29.28 Osteolytic Lesions in Individuals With Multiple Myeloma.
(A) Radiograph showing skull lesions in a client with myeloma. (B) Radiograph of femur showing extensive bone destruction caused by tumor. Note absence of reactive bone formation. (A, From *Abeloff M, et al. Abeloff's clinical oncology*, 4th edition. Philadelphia: Churchill Livingstone; 2008. B, From Kissane JM, ed. *Anderson's pathology*, 9th edition. St. Louis: Mosby; 1990.)

Left panel, A. A radiograph of the left lateral view of a skull with multiple lytic lesions of various sizes scattered throughout the skull. Right panel, B. A radiograph of a degenerative femur with multiple areas of tumor cells.

Myeloma cells reside in the bone marrow and are usually not found in the peripheral blood. As the number of myeloma cells increases, fewer red blood cells, white blood cells, and platelets are produced. It may occasionally spread to other tissues, especially in very advanced stages of the disease. For unknown reasons, the reported incidence of MM has doubled in the past 2 decades. About 34,920 new cases and 12,410 deaths are estimated for 2021.[42] MM occurs in all races, but the incidence in blacks is about twice that of whites. It rarely occurs before the age of 40 years—the median age of diagnosis is between 65 and 74 years. It is slightly more common in men (7.7 estimated new cases per 100,000 persons) than in women (4.9 new cases per 100,000 persons). Other risk factors include overweight or obesity, Agent Orange, and a history of monoclonal gammopathy of undetermined significance (MGUS; see Clinical Manifestations) or plasmacytoma.[98] MM has been observed in some

irradiated populations including Hiroshima and Nagasaki, where the relative risk increased with dose in males and females aged 20 to 59 at the time of bombing and was not apparent until 20 years later. No excess risk of MM was evident in 150,000 women who were followed for more than 15 years after radiation therapy for carcinoma of the uterine cervix.[99]

Pathophysiology

MM is a plasma cell neoplasia that causes lytic bone lesions (bony disease; radiologically appears as punched-out defects), hypercalcemia, renal failure, anemia, and immune abnormalities. It is a biologically complex disease with significant heterogeneity (wide range of genetic abnormalities, differences in clinical response, and survival in those with the same treatment). Multiple mutations in different pathways alter the intrinsic biology of the plasma cell, generating the features of myeloma. Although some steps in these pathways are identified, many are unknown.[98] Defining the main, or driver, mutations and heterogeneity is essential for treatment decisions. Many myelomas are aneuploid and, in most individuals with myeloma, chromosomal translocations are the most common. Development of further secondary genetic alterations increases progression to an aggressive MM. Investigators are studying various epigenetic alterations and interactions with extracellular matrix proteins. For example, myeloma cells interact and secrete peptides that adhere to stromal cells, inducing cytokines that promote inflammation. Myeloma cells are prone to the accumulation of misfolded protein, such as unpaired immunoglobulin chains. Misfolded proteins activate apoptosis.

Malignant plasma cells arise from one clone of B cells that produce abnormally large amounts of one class of immunoglobulin (usually IgG, occasionally IgA, and rarely IgM, IgD, or IgE). The malignant transformation may begin early in B-cell development, possibly before encountering antigen in the secondary lymphoid organs. The myeloma cells return either to the bone marrow or to other soft tissue sites. Cytokines, particularly IL-6, have been identified as essential factors that promote the growth and survival of MM cells (lymphocytes and cytokines are described in Chapters 7 and 8). IL-6 in particular acts as an osteoclast-activating factor and stimulates osteoclasts to reabsorb bone. This process results in bone lesions and hypercalcemia (high calcium levels in the blood) attributable to the release of calcium from the breakdown of bone.

The antibody produced by the transformed plasma cell is frequently defective, containing truncations, deletions, and other abnormalities, and is often referred to as a *paraprotein* (abnormal protein in the blood). Because of the large number of malignant plasma cells, the abnormal antibody, or M protein, becomes the most prominent protein in the blood (Fig. 29.29). Suppression of normal plasma cells by the myeloma results in diminished or absent normal antibodies. The excessive amount of M protein also may contribute to many of the clinical manifestations of the disease. Frequently, the myeloma produces free immunoglobulin light chain **(Bence Jones protein)** that is present in the blood and urine and contributes to damage of renal tubular cells.

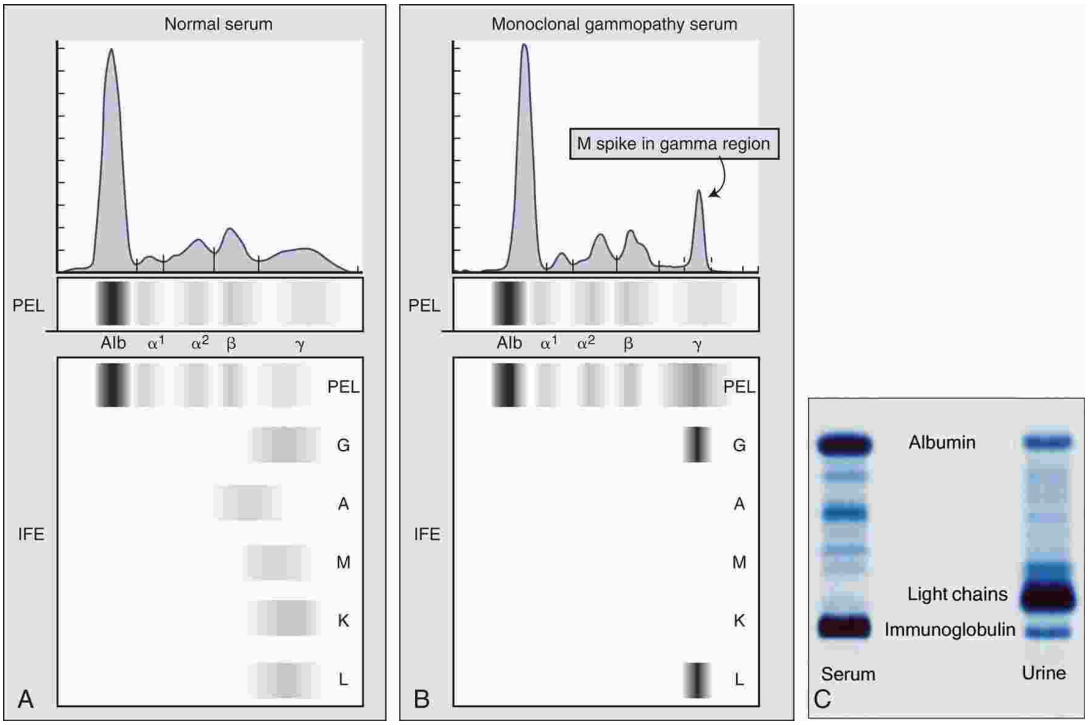

FIG. 29.29 M Protein.
Serum protein electrophoresis *(PEL)* is used to screen for M proteins in multiple myeloma (MM). (A) In normal serum the proteins separate into several regions between albumin *(Alb)* and a broad band in the gamma *(γ)* region, where most antibodies (gamma globulins) are found. Immunofixation *(IFE)* can identify the location of IgG *(G)*, IgA *(A)*, IgM *(M)*, and kappa *(κ)*, and lambda *(λ)* light chains. (B) Serum from an individual with MM contains a sharp M protein *(M spike)*. The M protein is monoclonal and contains only one heavy chain and one light chain. In this instance the IFE identifies the M protein as an IgG containing a lambda light chain. (C) Serum and urine protein electrophoretic patterns in an individual with MM. Serum demonstrates an M protein *(Immunoglobulin)* in the gamma region, and the urine has a large amount of the smaller sized light chains with only a small amount of the intact immunoglobulin. (A and B, From Abeloff M, et al. *Abeloff's clinical oncology*, 4th edition. Philadelphia: Churchill Livingstone; 2008. C, From McPherson R, Pincus M. *Henry's clinical diagnosis and management by laboratory methods*, 22nd edition. Edinburgh: Saunders; 2012.)

Three illustrations depict the densitometric tracing accompanied by a gel picture showing serum protein electrophoresis in normal serum and monoclonal gammopathy serum. Illustration A depicts the densitometric tracing of normal serum showing one M-spike

accompanied by a gel picture showing one M-band. Illustration B depicts the densitometric tracing of monoclonal gammopathy serum showing two M-spikes accompanied by a gel picture showing two M-bands in the gamma region. Illustration C Gel picture demonstrating serum and urine electrophoretic patterns, showing one light band in urine and two light bands in serum.

Clinical Manifestations

MM is characterized by elevated levels of calcium in the blood (hypercalcemia), renal failure, anemia, and bone lesions. The hypercalcemia and bone lesions result from infiltration of the bone by malignant plasma cells and stimulation of osteoclasts to reabsorb bone. This process results in the release of calcium (hypercalcemia) and the development of lytic lesions of bone (see Fig. 29.28A and B). Destruction of bone tissue causes pain, the most common presenting symptom, and pathologic fractures. The bones most involved, in decreasing order of frequency, are the vertebrae, ribs, skull, pelvis, femur, clavicle, and scapula. Spinal cord compression, because of the weakened vertebrae, occurs in about 10% of individuals.

A condition called **amyloidosis** may occur, in which antibody proteins increase and stick together in peripheral nerves and organs, such as the kidney and heart. Signs and symptoms of amyloidosis include fatigue, purple spots on the skin, enlarged tongue, diarrhea, edema, and numbness or tingling in the legs and feet.

Proteinuria is observed in 90% of individuals. Renal failure may be either acute or chronic and is usually secondary to the hypercalcemia. Bence Jones protein may lead to damage of the proximal tubules. Anemia is usually normocytic and normochromic and results from inhibited erythropoiesis caused by tumor cell infiltration of the bone marrow.

The high concentration of paraprotein in the blood may lead to hyperviscosity syndrome. The increased viscosity interferes with blood circulation to various sites (brain, kidneys, extremities). Hyperviscosity syndrome is observed in up to 20% of persons. Additional neurologic symptoms (e.g., confusion, headaches, blurred vision) may occur secondary to hypercalcemia or hyperviscosity.

Suppression of the humoral (antibody-mediated) immune response results in repeated infections, primarily pneumonias, and pyelonephritis. The most involved microorganisms are encapsulated bacteria that are particularly sensitive to the effects of antibody; pneumonia caused by *Streptococcus pneumoniae, Staphylococcus aureus*, or *K. pneumoniae;* or pyelonephritis caused by *E. coli* or other gram-negative organisms. Cell-mediated (T-cell) function is relatively normal. Overwhelming infection is the leading cause of death from MM.

MM is a progressive disorder and is often preceded by a condition known as **monoclonal gammopathy of undetermined significance (MGUS)**. MGUS is diagnosed by the presence of an M protein in the blood or urine without additional

evidence of MM.[100] MGUS is present in approximately 1% of the general population and in 3% of individuals older than 70 years. Although MGUS is considered a benign condition and requires no treatment, *about 1% of individuals with MGUS progress to malignant plasma cell disorders*.[16] Progression of MM after MGUS advances to asymptomatic MM and finally symptomatic MM. Asymptomatic MM also may be referred to as **smoldering myeloma**. Smoldering myeloma is usually characterized by the presence of an M protein and clonal bone marrow plasma cells, but with no indication of end-organ damage.

Evaluation and Treatment

Diagnosis of MM is made by symptoms and radiographic and laboratory studies; a definitive diagnosis requires a bone marrow biopsy. The International Myeloma Working Group's new criteria for the diagnosis of MM and smoldering MM are presented in Box 29.2. Several types of radiologic studies document the presence of bone lesions and areas of destruction. Optimal use of imaging methods is provided by the International Myeloma Working Group for imaging at different stages.[101] Quantitative measurements of immunoglobulins (IgG, IgM, IgA) are usually done, and serum electrophoretic analysis reveals increased levels of M protein. Bence Jones protein may be observed in the urine or serum by immunoelectrophoresis, or in the serum using available enzyme-linked immunosorbent assays (ELISAs). However, variants of MM include individuals in which only free light chain is produced and a rare variant that produces only free heavy chain; about 1% of cases are non-secretory so that neither M protein nor Bence Jones protein is produced. Measurement of another protein, free **β2-microglobulin**, is used as an indicator of prognosis or effectiveness of therapy.

Treatment options include combinations of chemotherapy; other drug therapy; targeted therapy; high-dose chemotherapy with stem cell transplant; biologic therapy; radiation therapy (bone lesions of the spine); and, sometimes, surgery. New therapies, called *proteasome inhibitors*, are emerging. Dose intensification improves outcomes in younger persons; however, long-term remissions occur in a minority of people. Gene expression profiling (GEP) helps improve the treatment of MM because it identifies prognostic subgroups and defines the molecular pathways associated with these subgroups. Newer agents (e.g., bortezomib, lenalidomide) have expanded therapeutic regimens for end-stage myeloma. Preliminary results show lenalidomide may delay the development of MM in those with smoldering myeloma.[102,103] The 5-year survival rate for all stages of MM is 54%.[43] Approval of new drugs has changed the management of MM, and research for survival improvement is ongoing.

Alterations of Splenic Function

The complexities of splenic function are not totally understood, and its mysteries are still being studied. The normal functions of the spleen that may affect disease states include (1) phagocytosis of blood cells and particulate matter (e.g., bacteria), (2) antibody production, (3) hematopoiesis, and (4) sequestration of formed blood

elements. The spleen is known as a *secondary lymphoid organ* and is the site for maturation and storage of T and B lymphocytes playing a role in the synthesis of IgG.[104] The spleen is part of the mononuclear phagocyte system and is involved in all systemic inflammations, hematopoietic disorders, and many metabolic disorders.

In the past, **splenomegaly** (enlargement of the spleen) has been associated with various disease states. It is now recognized that splenomegaly is not necessarily pathologic; an enlarged spleen may be present in certain individuals without any evidence of disease. Splenomegaly may be, however, one of the first physical signs of underlying conditions, and its presence should not be ignored. In conditions in which splenomegaly is present, the normal functions of the spleen may become overactive, producing a syndrome known as **hypersplenism**.

Current criteria indicating the presence of hypersplenism include (1) cytopenias (anemia, leukopenia, thrombocytopenia, or combinations of these), (2) cellular bone marrow, (3) splenomegaly, and (4) improvement after splenectomy. Some individuals may seek treatment for problems even though they have not met all these clinical criteria; thus, the relevance and significance of hypersplenism are still uncertain. Primary hypersplenism is recognized when no etiologic factor has been identified; secondary hypersplenism occurs in the presence of another condition.

Pathophysiology

Specific conditions causing splenomegaly and resulting hypersplenism are many (Box 29.3). Different pathologic processes that produce splenomegaly are described briefly.

Box 29.3

Disorders Associated With Splenomegaly Infections

Nonspecific splenitis of various blood-borne infections (particularly infectious endocarditis)
- Infectious mononucleosis
- Tuberculosis
- Typhoid fever
- Brucellosis
- Cytomegalovirus
- Syphilis
- Malaria
- Histoplasmosis
- Toxoplasmosis
- Kala-azar
- Trypanosomiasis
- Schistosomiasis
- Leishmaniasis
- Echinococcosis

Congestive states related to portal hypertension
Cirrhosis of the liver
Portal or splenic vein thrombosis
Cardiac failure

From Kumar V, Abbas A, Aster J. *Robbins & Cotran pathologic basis of disease*, 10th edition. Philadelphia: Elsevier; 2021.

Acute inflammatory or infectious processes cause splenomegaly because of an increased demand for defensive activities. An acutely enlarged spleen secondary to infection may become so filled with erythrocytes that their natural rubbery resilience is lost, and they become fragile and vulnerable to blunt trauma. Splenic rupture is a complication associated with IM; rupture occurs mostly in males between days 4 and 21 of acute illness.

Congestive splenomegaly is accompanied by ascites, portal hypertension, and esophageal varices and is most seen in those with hepatic cirrhosis. Splenic hyperplasia develops in disorders that increase splenic workload and is associated most with various types of anemia (hemolytic) and chronic myeloproliferative disorders (i.e., polycythemia vera).

Infiltrative splenomegaly is caused by engorgement by the macrophages with indigestible materials associated with various "storage diseases." Tumors and cysts cause actual growth of the spleen. Neoplastic involvement of the spleen is rare except in myeloid and lymphoid tumors.[16]

Clinical Manifestations

The most common physical symptom is vague abdominal discomfort.[104] Abdominal bloating, distended abdomen, anorexia, and/or early satiety may occur.[104] Those individuals with acute infection may present with fever, rigors, malaise, and focal infectious symptoms. Cirrhosis is the main cause of congestive splenomegaly; other causes include, for example, hepatitis. Other symptoms include those from anemia (lightheadedness and dyspnea), easy bruising, bleeding, or petechiae.[104] Overactivity of the spleen results in hematologic alterations that affect all blood components. Sequestering of red blood cells, granulocytes, and platelets results in a reduction of all circulating blood cells. The spleen may sequester up to 50% of the red blood cell population, thereby upsetting the normal physiologic concentration of red blood cells in the circulation. The rate of splenic pooling is directly related to spleen size and the degree of increased blood flow through it. Sequestering exposes the red blood cells to splenic conditions that accelerate destruction, further contributing to the decreased red blood cell concentration. Anemia is the result of these combined activities. Anemia may be further potentiated by an increase in blood volume, which produces a *dilutional effect* on the already reduced concentration of red blood cells. The dilutional effect, as well as the removal and destruction of red blood cells, depends primarily on the degree of splenomegaly.

White blood cells and platelets also are affected by sequestering, although not to the same degree as the red blood cell. Again, the size of the spleen is the determining

factor in the number of cells sequestered.

Evaluation and Treatment

Treatment of splenomegaly is targeted at treating the underlying disease and protecting individuals from complications of splenomegaly itself. Splenic rupture is a serious and feared complication of splenomegaly.[104] Treatment includes splenectomy; however, it may not always be indicated. A splenectomy is considered necessary to alleviate the destructive effects on red blood cells. Clinical indicators should determine the need for splenectomy, not necessarily specific conditions. Splenectomy for splenic rupture is no longer considered mandatory because of the possibility of overwhelming sepsis after removal. Repair and preservation are now considered before the decision to remove the spleen. Splenectomy also may be performed as treatment for hairy cell leukemia, Felty syndrome, agnogenic myeloid metaplasia, thalassemia major, Gaucher disease, hemodialysis, splenomegaly, splenic venous thrombosis, and thrombotic thrombocytopenia purpura (TTP).

Individuals are able to lead normal lives after splenectomy, but blood cell abnormalities often exist after removal of the spleen (i.e., red blood cells become thinner, broader, and wrinkled; white blood cell counts initially increase and then plateau; platelet counts rise after surgery and then stabilize). A major postoperative complication after splenectomy is *overwhelming post-splenectomy infection (OPSI*). It is a rare but rapidly fatal infection. Unless treated in time, OPSI may rapidly progress to septic shock and possibly disseminated intravascular coagulation (DIC). OPSI can be prevented by educating patients, vaccination, and antibiotic prophylaxis.[105]

Hemorrhagic Disorders and Alterations of Platelets and Coagulation

The arrest of bleeding, or **hemostasis**, depends on adequate numbers of platelets, normal levels of coagulation factors, and absence of defects in vessels walls. The spectrum of abnormal bleeding varies widely from massive bleeds, such as rupture of large vessels like the aorta, to small bleeds in skin or mucosal membranes. Diminished or excessive levels of coagulation factors can lead to defective hemostasis or spontaneous and unnecessary clotting. (Hemostasis is discussed in Chapter 28.) Diminished hemostasis results in either internal or external **hemorrhage**, defined as copious or heavy discharge of blood from blood vessels. A classification of hemorrhagic disorders is included in Table 29.11.

Table 29.11

Classification of Hemorrhagic Disorders

Type of Defect	Example	Manifestation
Defects of primary hemostasis	Platelet defects or von Willebrand disease	Usually present with small bleeds in skin or mucosal membrane; bleeds are usually petechiae (<3-mm min hemorrhages) or purpuras (>3-mm red-purple discolorations); common in capillaries; also includes epistaxis (nose bleeds), GI bleeds, or excessive menstruation
Defects of secondary hemostasis	Coagulation factor defects	Bleeds into soft tissue, muscle, or joints; intracranial bleeds may occur
Generalized defects of small vessels	Palpable purpura and ecchymoses	Extravasated blood creates a palpable mass (or palpable purpura), ecchymoses (simply called a *bruise*), or a larger palpable lesion (or hematoma); systemic disorders disrupt small blood vessels, called vasculitis

Purpuric disorders, red or purple discolored spots on skin, occur when there is a deficiency of normal platelets necessary to plug damaged vessels or prevent leakage from the tiny tears that occur daily in capillaries. More serious internal bleeding occurs from events that simply overwhelm hemostatic mechanisms, such as rupture of large blood vessels, trauma, and diseases associated with massive hemorrhage including abdominal aneurysm (also see the Anemias of Blood Loss section). Between these smaller bleeds and massive bleeds are deficiencies of coagulation factors found with the hemophilias (see Chapter 30). Disorders that result in spontaneous clotting can develop from genetic disorders of the clotting system components or from acquired diseases that activate clotting. These disorders are known collectively as **thromboembolic disease**. Additionally, any disorder of the blood that predisposes to clotting of blood or **thrombosis** is called **hypercoagulability (thrombophilia)**.

Disorders of Platelets

Quantitative or qualitative abnormalities of platelets can interrupt normal blood coagulation and prevent hemostasis. The quantitative abnormalities are *thrombocytopenia*, a decrease in the number of circulating platelets, and *thrombocythemia*, an increase in the number of platelets. Qualitative disorders affect the structure or function of individual platelets and can coexist with the quantitative disorders. Qualitative disorders usually prevent platelet adherence and aggregation, preventing formation of a platelet plug.

Thrombocytopenia

Thrombocytopenia is defined as a platelet count less than 150,000 platelets/μL of blood.[106] Hemorrhage associated with minor trauma does not appreciably increase until the count falls below 50,000 platelets/μL. Spontaneous bleeding without trauma can occur with counts ranging from less than 10,000 platelets /μL to less than 20,000/μL and surgical bleeding with counts below 50,000/μL.[107] Counts less than 10,000 platelets/μL can result in skin manifestations (e.g., petechiae, ecchymoses, and larger purpuric spots) or frank bleeding from mucous membranes. Severe spontaneous bleeding may result if the count is less than 10,000 platelets/μL and can be fatal if it occurs in the GI tract, respiratory tract, or CNS. Thrombocytopenia is associated with risk of thrombosis in conditions like heparin-induced thrombocytopenia (HIT), antiphospholipid antibody syndrome (APS), DIC, thrombotic microangiopathy (TMA), and paroxysmal nocturnal hemoglobinuria (PNH).[107] Common causes of thrombocytopenia are included in Box 29.4. Normal platelet counts vary by age, sex, and ethnicity. Women, young people, and non-Hispanic blacks have slightly higher platelet counts.[108]

Box 29.4

Common Causes of Thrombocytopenia

Primary immune thrombocytopenia (primary ITP)

- Drug-induced immune thrombocytopenia:
  - Heparin-induced thrombocytopenia (HIT)
  - Quinine
  - Sulfonamides, ampicillin, vancomycin, piperacillin
  - Acetaminophen, ibuprofen, naproxen
  - Cimetidine
  - Glycoprotein IIb/IIIa inhibitors
  - Other over the counter remedies, supplements, foods like African bean, sesame seeds, walnuts, and beverages (herbal teas and cranberry juice)
- Drug-induced non-immune thrombocytopenia. Valproic acid, daptomycin, linezolid cause thrombocytopenia by dose-dependent suppression of platelet production.
- Infections:
  - Viral: HIV, hepatitis C, Epstein-Barr virus, parvovirus, mumps, varicella, rubella, Zika viral infections
  - Sepsis causes bone marrow suppression.
  - Helicobacter pylori
  - Leptospirosis, brucellosis, anaplasmosis, and other tick-borne infections are associated with thrombocytopenia.

    - Malaria, babesiosis intracellular parasite infections are associated with both thrombocytopenia and hemolytic anemia
    - Hypersplenism due to chronic liver disease
    - Chronic alcohol abuse
- Nutrient deficiencies (folate, vitamin B12, copper)
- Autoimmune disorders: systemic lupus erythematosus, rheumatoid arthritis
- Pregnancy. Mild thrombocytopenia presents in gestational thrombocytopenia; moderate-severe thrombocytopenia can occur in preeclampsia and HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome

Other Causes Include

- Myelodysplasia
- Malignancy: cancer with chronic DIC, cancer with marrow suppression (leukemia, lymphoma, solid tumors)
- Paroxysmal nocturnal hemoglobinuria (PNH)
- Thrombotic microangiopathy (TMA)
    - Thrombotic thrombocytopenic purpura (TTP)
    - A hemolytic uremic syndrome (HUS) caused by Shiga toxin-producing organism (E. coli and Shigella), seen in children.
    - Drug-induced TMA: quinine, specific chemotherapy agents
    - Antiphospholipid antibody syndrome
- Aplastic anemia
- Inherited thrombocytopenia. Often seen in children, rare in adults
- Von Willebrand disease type 2
- Alport syndrome
- Wiskott-Aldrich syndrome
- Fanconi syndrome.
- Thrombocytopenia-absent radius syndrome
- Bernard–Soulier syndrome
- May-Hegglin anomaly

Data from Jinna S, Khandhar PB. *Thrombocytopenia*. Treasure Island, FL: StatPearls Publishing; 2020.

Before the diagnosis of thrombocytopenia is made, **pseudothrombocytopenia** must be ruled out. This phenomenon occurs in approximately 1 in 1000 to 1 in 10,000 laboratory samples and results from an error in platelet counting when a blood sample is analyzed by an automated cell counter. Platelets in the blood sample may become nonspecifically agglutinated by immunoglobulins in the presence of ethylenediaminetetraacetic acid (EDTA), a preservative in banked blood. The agglutinated platelets are not counted, thus giving an apparent, but false, thrombocytopenia. Thrombocytopenia also may be falsely diagnosed because of a

dilutional effect observed after massive transfusion of platelet-poor packed cells to treat a hemorrhage. This occurs when more than 10 units of blood have been transfused within a 24-hour period. The hemorrhage that necessitated the transfusion also accelerates the loss of platelets, contributing to the pseudothrombocytopenic state. Splenic sequestering of platelets in hypersplenism (congestive) also induces an apparent thrombocytopenia, as does hypothermia (less than 25°C [77°F]), which is reversed when temperatures return to normal, suggesting an increased platelet sequestration in response to chilling.

Pathophysiology

Thrombocytopenia results from decreased platelet production, increased destruction, or both. The condition may be either congenital or acquired and may be either primary or secondary to other acquired or congenital conditions. Thrombocytopenia secondary to congenital conditions occurs in many different diseases, although each is relatively rare.

Acquired thrombocytopenia is more common and may occur as a result of decreased platelet production secondary to viral infections (e.g., EBV, rubella, CMV, HIV), drugs (e.g., valproic acid, daptomycin, certain chemotherapeutic agents, chronic ethanol abuse), nutritional deficiencies (vitamin B_{12} or folic acid in particular), chronic renal failure, bone marrow suppression (e.g., AA), radiation therapy, or bone marrow infiltration by cancer. Most common forms of thrombocytopenia are the result of increased platelet destruction. Examples include HIT idiopathic (immune) TTP, TTP, and DIC (discussed in the Disorders of Coagulation section). The spleen can also hold on to too many platelets; it normally stores about one-third of the body's platelets.[106] Dilutional thrombocytopenia presents after massive fluid resuscitation and massive blood transfusion.[107]

Heparin-induced thrombocytopenia

Heparin is a common cause of drug-induced thrombocytopenia. Approximately 4% of individuals treated with unfractionated heparin develop HIT. The incidence is lower (about 0.1%) with the use of low-molecular-weight heparin. HIT is an immune-mediated, adverse drug reaction caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation through platelet Fc γIIa receptors (Fig. 29.30) (see Chapter 9). The release of additional platelet factor 4 from activated platelets and activation of thrombin lead to increased platelet consumption and a decrease in platelet counts beginning 5 to 10 days after administration of heparin.

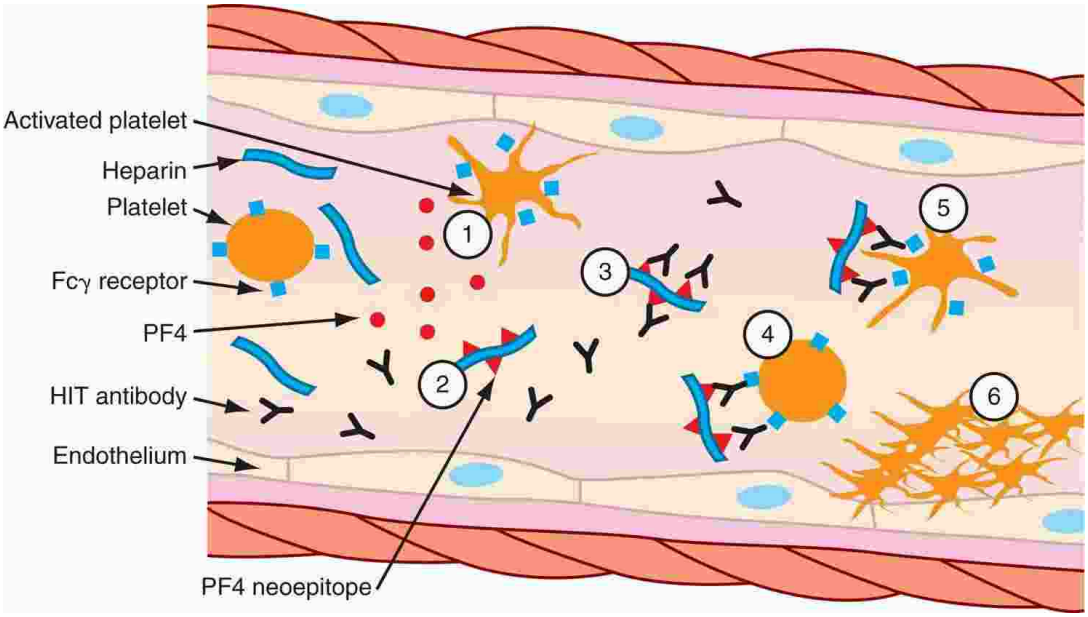

FIG. 29.30 Pathogenesis of Heparin Induced Thrombocytopenia (HIT).
(1) Activated platelets release procoagulant proteins from α-granules, including platelet factor 4 (PF4). Administered heparin binds PF4 *(2)*, which undergoes a conformational change and expresses a new antigen (neoepitope). Individuals with HIT produce an immunoglobulin G (IgG) antibody that specifically reacts *(3)* with multiple identical neoepitopes on the heparin-PF4 complex. The reaction forms heparin-PF4-IgG immune complexes. Platelets express FcγRIIa receptors (Fcγ receptor) that react *(4)* with the Fc portion of IgG in immune complexes. Cross-linking of Fc receptors *(5)* results in FcγRIIa-dependent platelet activation. The activated platelets mediate a series of events that lead to further activation of the coagulation cascade, resulting in thrombin generation. Further release of PF4 from newly activated platelets leads to a cycle of continuing platelet activation and *(6)* formation of a primary clot. The reaction can be enhanced by the release of platelet-derived microparticles that are rich in surface phosphatidylserine and increase activation of coagulation and by the binding of heparin-PF4 complexes and HIT-IgG to the vascular endothelium (not shown).

An illustration shows the pathogenesis of heparin induced thrombocytopenia. 1. An activated platelet. 2. A heparin with P F 3 neoepitope. 3. H I T antibodies attracted to the heparin with P F 3 neoepitope. 4. H I T antibodies bind a platelet with F C gamma receptors to a heparin with P F 4 neoepitope. 5. The platelet, bound

to the heparin, becomes activated. 6. Platelet proliferates, forming a clot.

Clinical Manifestations

The hallmark of HIT is thrombocytopenia. A decrease of approximately 50% in the platelet count is observed in more than 95% of individuals. However, 30% or more of those with thrombocytopenia are also at risk for venous or arterial thrombosis because a *prothrombotic state* is caused by antibody binding to platelets, inducing activation, aggregation, and consumption (thus the term *thrombocytopenia* in the syndrome name) of platelets. Venous thrombosis is more common and results in DVT and pulmonary emboli. Arterial thrombosis affects the lower extremities, causing limb ischemia. Arterial thrombosis may lead to cerebrovascular accidents and myocardial infarctions. Other major arteries also may be affected (e.g., renal, mesenteric, upper limb). Although platelet counts are low, bleeding is uncommon.

Evaluation and Treatment

Diagnosis is primarily based on clinical observations. Evaluation of persons with isolated thrombocytopenia includes a CBC, a peripheral blood smear, and HIV and HCV tests. Liver enzymes and coagulation tests are done in those with liver disease. A bone marrow biopsy is indicated in conditions when the cause of thrombocytopenia is unclear, and when a hematologic disorder is suspected.[107]

The individual presents with dropping platelet counts after 5 days or longer of heparin treatment. On average, platelet counts may fall to 60,000/μL. Because most individuals have undergone surgery and the onset of symptoms, including thrombosis, may be delayed until after release from the hospital, other possible causes of thrombocytopenia (e.g., infection, other drug reactions) must be considered. Tests are available to measure anti-heparin–platelet factor 4 antibodies. The sensitivity of this test is extremely high (>90%), but the specificity is less because of false-positive reactions (e.g., those receiving dialysis). Treatment is the withdrawal of heparin and use of alternative anticoagulants.

Repeat and routine monitoring is done in asymptomatic, mild thrombocytopenic individuals. Thrombocytopenic emergency conditions that require immediate action include suspected HIT, TTP, HUS, drug-induced ITP, pregnancy with severe thrombocytopenia, bleeding with severe thrombocytopenia, urgently needed invasive procedure in the presence of severe thrombocytopenia, leukopenia, and AA.[107]

Immune thrombocytopenia purpura

The most common cause of thrombocytopenia secondary to increased platelet destruction is **immune thrombocytopenic purpura (ITP)**. ITP may be acute or chronic. The acute form presents in childhood and typically lasts 1 to 2 months with a complete remission. In some children, however it may last for up to 6 months and may progress to the chronic condition in 7% to 28% of children (see Chapter 30). Acute

ITP is usually secondary to infections (particularly viral) or other conditions that lead to large amounts of antigen in the blood, such as drug allergies or SLE. HIV-associated disease is now the most common cause of ITP, especially in males between 20 and 50 years of age.[109] Sometimes an identical form of autoimmune thrombocytopenia is associated with CLL, lymphomas, IM, and other infections.[109] The antigen usually forms immune complexes with circulating antibody (anti-platelet IgG antibodies); it is thought that the immune complexes bind to Fc receptors on platelets, leading to their destruction in the spleen. The acute form of ITP usually resolves as the source of antigen is resolved (infection) or removed (drugs).

Chronic ITP is caused by autoantibodies against platelet-specific antigens. This form is more commonly observed in adults, being most prevalent in women between 20 and 40 years of age, although it can be found in all ages. The chronic form tends to get progressively worse. It can occur from a variety of predisposing conditions or exposures (secondary) or have no known risk factors (primary). The autoantibodies are generally of the IgG class and are against one or more of several platelet glycoproteins (e.g., GPIIb/IIIa, GPIIb/IX, GPIa/IIa). The antibodies bind directly to the platelet antigens, after which the antibody-coated platelets are recognized and removed from the circulation by macrophages in the spleen.

Clinical Manifestations

Initial manifestations range from minor bleeding problems (development of petechiae and purpura) over the course of several days to major hemorrhage from mucosal sites (epistaxis, hematuria, menorrhagia, bleeding gums). Rarely will an individual present with intracranial bleeding or other sites of internal bleeding.

During pregnancy, a woman with ITP may have a newborn that is also thrombocytopenic. If the fetal platelets express the same antigen as the mother, the maternal antibody will coat the platelets, potentially resulting in thrombocytopenia in utero. A variant of neonatal thrombocytopenia *(neonatal alloimmune thrombocytopenia)* occurs when the mother does not have ITP but makes IgG antibodies against an antigen inherited from the father found on fetal platelets but not on maternal platelets.

Evaluation and Treatment

Diagnosis of ITP is based on a history of bleeding and associated symptoms (weight loss, fever, headache). Physical examination includes notations on the type, location, and severity of bleeding. In addition, evidence of infections (bacterial, HIV and other viral), medication history, family history, and evidence of thrombosis are assessed. Other diagnostic tests include CBC and peripheral blood smear. Unlike some other forms of thrombocytopenia, there is usually no evidence of splenectomy. Testing for antiplatelet antibodies is usually not helpful. Although most cases of ITP are associated with elevated levels of IgG on platelets, other forms of thrombocytopenia also have a high incidence of platelet-associated antibodies; thus, the specificity is low (49% to 66%).[110] In addition, some cases of ITP will not present with elevated platelet-associated antibodies. The sensitivity is 78% to 92%; therefore, a negative test does not rule out ITP.

The acute form of ITP usually resolves without major clinical consequences, but the chronic form, like many autoimmune diseases, is variable with multiple remissions and exacerbations. Treatment is palliative, not curative, and focuses on prevention of platelet destruction. Initial therapy for ITP is glucocorticoids (e.g., prednisone), which suppress the immune response and prevent sequestering and further destruction of platelets. If steroid therapy is ineffective, other reagents have been used. Treatment with intravenous immunoglobulin (IVIG) is used to prevent major bleeding. The response rate is 80%, but the effects are transient, lasting only days to a few weeks. Anti-Rh_o(D) immune globulin (anti-D) has been used with limited success to treat individuals who are Rh-positive. Newer drug therapies are now available.

If other therapies are ineffective, splenectomy is considered to remove the site of platelet destruction. However, splenectomy is not without risks and approximately 10% to 20% of individuals who undergo a splenectomy suffer a relapse and require further treatment. In that situation, it is thought that the liver has become the site for platelet destruction. If splenectomy is unsuccessful and life-threatening thrombocytopenia persists, more aggressive immunosuppressive medications are usually recommended. Because of potential complications, these medications are reserved for individuals who are severely thrombocytopenic and refractive to other therapies. Zidovudine is effective in raising platelet counts in those with HIV-associated ITP.[109]

Thrombotic thrombocytopenia purpura

Thrombotic thrombocytopenia purpura (TTP; also known as Moschcowitz disease) is a multisystem disorder characterized by TMA (small or microvessel disease) in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation. Aggregation may lead to increased platelet consumption and organ ischemia. TTP is relatively uncommon, occurring in about 5 per 1 million individuals per year. The incidence is increasing and does appear to be an actual increase and not just the result of improved recognition. One suspected etiologic factor for TMA, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome is drug-induced, and a recent report found definite evidence from three drugs: quinine, cyclosporine, and tacrolimus.

There are two types of TTP: familial and acquired idiopathic. The familial type is the rarer type and is usually chronic, relapsing, and typically seen in children. When the disease is recognized and treated early, the child experiences predictable recurring episodes at approximately 3-week intervals that are responsive to treatment. Acquired TTP is more common and more acute and severe. It occurs mostly in females in their thirties and is rarely observed in infants or older adults.

Platelet aggregation and microthrombi formation is found throughout the entire vascular system, causing damage to multiple organs. The most susceptible organs for damage include the kidney, brain, and heart. Also affected are the pancreas, spleen, and adrenal glands. The thrombi are composed of platelets with minimal fibrin and red cells, differentiating them from thrombi secondary to intravascular coagulation. Most cases of TTP are related to a dysfunction of the plasma metalloprotease

ADAMTS13 (Fig. 29.31A and B). This enzyme is responsible for digesting large precursor molecules of von Willebrand factor (vWF) produced by endothelial cells into smaller molecules. Defects in ADAMTS13 result in expression of large-molecular-weight vWF on the endothelial cell surface and the formation of large aggregates of platelets, which can break off and form occlusions in smaller vessels.[111] People with TTP (about 80%) have less than 5% of normal plasma ADAMTS13 levels. Although deficiency of ADAMS-13 is necessary to cause TTP, it is not sufficient to induce the clinical syndrome.[111] The hypothesis of a "second trigger" helps to explain that such conditions as infections, pregnancy, and inflammation increase plasmatic vWF level moving to overt TTP.[111,112] Most individuals with familial TTP are homozygous for mutations in ADAMTS13. Acquired TTP of unexplained origin is associated in individuals with an IgG autoantibody against ADAMTS13.

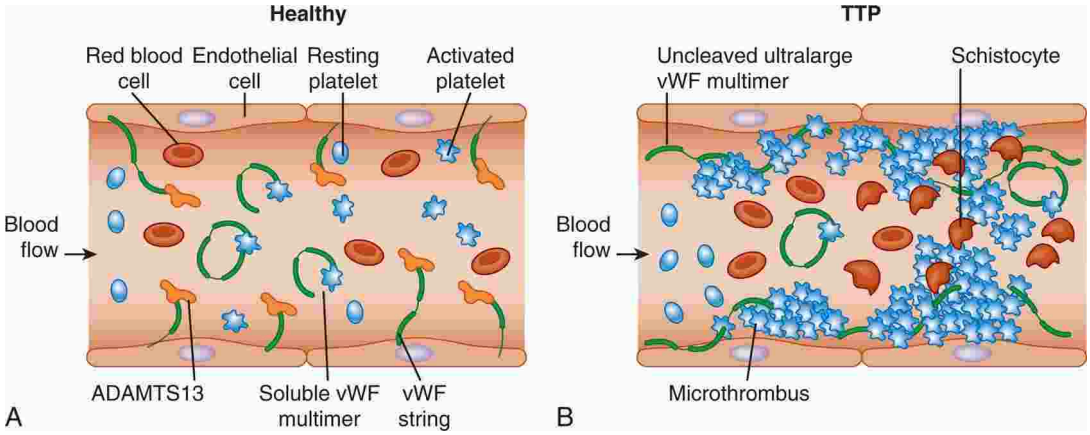

FIG. 29.31 Thrombotic Thrombocytopenic Purpura.
(A) A microvessel (arteriole or capillary) in a healthy individual. Normal proteolysis by ADAMTS13 of ultra-large von Willebrand factor *(vWF)* strings anchored to or secreted from stimulated microvascular endothelial cells. (B) A microvessel in thrombotic thrombocytopenic purpura *(TTP)*. Cleavage of secreted or anchored ultralarge vWF is severely reduced when ADAMTS13 activity is less than 10% of normal level. The results include excessive microthrombi formation, shear stress injury to red blood cells (schistocytes) flowing through microvessels that are partially occluded by platelet clumps (producing hemolysis), and perhaps damage from activation of the alternative complement pathway on the uncleaved ultralarge vWF strings. (From Hovinga JAK, Coppo P, Lämmle B, et al. Thrombotic thrombocytopenic purpura. *Nature Reviews Disease Primers*, 2017;3:17020.)

Left panel, A. An illustration of a health capillary identifies the following structures: red blood cell, endothelial cell, resting platelet, activated platelet, A D A M T S 13, soluble v W F multimer, and c W F string. Blood flows from the left to the right. Right panel, B. An illustration of a T T P capillary identifies the following structures: uncleaved ultra large v W F multimer, schistocyte, and microthrombus. Blood flows from the left to the right.

Clinical Manifestations

Chronic relapsing TTP is a rare familial form of TTP observed in children and usually recognized and successfully treated (see Chapter 30). The acquired **acute idiopathic TTP** is much more common and more severe. Early diagnosis and treatment are

essential because TTP may prove fatal within 90 days of onset. TTP is clinically related to and must be distinguished from other thrombotic microangiopathic conditions, including hemolytic uremic syndrome (HUS), malignant hypertension, preeclampsia, and pregnancy induced HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelet count) syndrome.

Acute idiopathic TTP is characterized by a *pathognomonic pentad* (characteristic for a particular disease; group of five). However, only 20% to 30% of those with acute idiopathic TTP present with the classic pentad. These include (1) extreme thrombocytopenia (less than 20,000 platelets/μL), (2) intravascular hemolytic anemia, (3) ischemic signs and symptoms most often involving the CNS (about 65% present with memory disturbances, behavioral irregularities, headaches, or coma), (4) kidney failure (affecting about 65% of individuals), and (5) fever (present in about 33% of individuals with TTP). It is not mandatory that all five be present to begin treatment.

Evaluation and Treatment

The initial findings may be very nonspecific and include weakness, headache, confusion, nausea, vomiting, and diarrhea.[111] The more prevalent findings are a significant thrombocytopenia (usually <30,000/μL of blood) and microangiopathic hemolytic anemia.[110] Both findings are associated with their relative signs of cutaneous and mucosal bleeding, weakness, and dyspnea.[111] A routine blood smear usually shows fragmented red cells *(schistocytes)* produced by shear forces when red cells are in contact with the fibrin mesh in clots that form in the vessels. As a result of tissue injury, serum levels of LDH may be very high, and low-density lipoprotein (LDL) levels may be elevated. The presence of an LDH level 1 times the upper normal value, a cardiac troponin level greater than 0.25 ng/mL on diagnosis, and older age are associated with treatment refractoriness and death.[111,113,114] Tests for antibody on red cells are negative, excluding immune hemolytic anemia.

Importantly, prompt treatment can significantly reduce the death rate. Therapeutic plasma exchange (TPE) with fresh frozen plasma, which replenishes functional ADAMTS13, is the treatment of choice, achieving a 70% to 85% response rate. Additionally, steroids (glucocorticoids) are administered. In the absence of major organ damage, this approach may lead to complete recovery with no long-term complications. The anti-CD20 monoclonal antibody rituximab has shown some success in people who are refractory to plasma exchange. In other individuals rituximab is started immediately. Relapse does occur, generally within the first year of treatment, although recurrences have been reported as late as 20 years after treatment.[115] The transfusion of platelets is debated, and studies suggest this may be harmful. The studies lack rigor; they should not be used to make a liberal policy for transfusion. The use of platelets should be limited to individuals with overt bleeding or before invasive procedures.[111] Individuals who do not respond to conventional treatment may be candidates for splenectomy; however, postoperative hemorrhage remains a dangerous complication. Immunosuppression therapy has been successful in some individuals.

Thrombocythemia

Thrombocythemia (also called thrombocytosis) is defined as a platelet count greater than 450,000/μL of blood. Thrombocythemia may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/μ. Then intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

Pathophysiology

Essential (primary) thrombocythemia (ET) is a chronic, MPN characterized by excessive platelet production resulting from a defect in the bone marrow megakaryocyte progenitor cells. Abnormal blood clotting commonly occurs in individuals with essential thrombocythemia causing many clinical manifestations. Other disease features include leukocytosis, splenomegaly, thrombosis, bleeding, microcirculatory symptoms, itching (or pruritus), and risk of leukemic or bone marrow fibrotic transformation. The most mutated genes in ET are the *JAK2* (in 60%), calreticulin *CALR* (in 20%), or *MPL* (in 3%).[116] The *JAK2* mutation induces overactivity in cell signaling from JAK2 protein. JAK2, a tyrosine kinase, is an essential player downstream of cytokine receptors, such as the TPO (affects platelet proliferation) and erythropoietin (EPO, affects erythrocyte proliferation) receptors. More simply, both EPO and TPO convey their signals and consequent proliferation through JAK2. Along with increased platelets, there may be a concomitant increase in the number of red cells, indicating a myeloproliferative disorder; however, the increase in red cells is not to the extent seen in PV. Red blood cells in ET tend to aggregate and adhere to the endothelium and contribute to the blockage of flow in the microvasculature and altered interactions between platelets and the vascular endothelium. The *JAK2* is more common in middle-aged individuals, with most cases occurring between ages 50 and 60 years.[116] There is no known sex preference, however, a Mayo clinic retrospective study (n = 1076) showed a higher incidence in women (67%).[116] There also is a rare hereditary type of ET called *familial essential thrombocythemia (FET)* that is inherited in an autosomal dominant pattern.

Secondary thrombocythemia may occur after splenectomy because platelets that normally would be stored in the spleen remain in circulating blood. The increase in platelets may be gradual, with thrombocythemia not occurring for up to 3 weeks after splenectomy. Reactive thrombocythemia may occur during some inflammatory conditions, such as rheumatoid arthritis and cancers. In these conditions, excessive production of some cytokines (e.g., IL-6, IL-11) may induce increased production of TPO in the liver, resulting in increased megakaryocyte proliferation. Reactive thrombocythemia also may occur during a variety of physiologic conditions, such as after exercise.

Clinical Manifestations

Clinical manifestations vary among individuals. Those with ET are at risk for large-vessel arterial or venous thrombosis, although the most common complication is **microvasculature thrombosis** leading to ischemia in the fingers, toes, or cerebrovascular regions. The primary presenting symptoms of microvasculature

thrombosis are erythromelalgia, headache, and paresthesia. Other constitutional symptoms include night sweats, weight loss, and splenomegaly.[116] **Erythromelalgia** is unilateral or bilateral warm, congested, red hands and feet with painful burning sensations, particularly in the forefoot sole and one or more toes. The lower extremities are affected more often, and only one side may be involved. The pain is initiated by standing, exercise, or warmth and relieved by elevation and cooling. In extreme situations, acrocyanosis (bluish or purple coloring of hands or feet) and gangrene may result.

Arterial thrombosis is more common than venous thrombosis and may involve the coronary and renal arteries. DVT of the lower extremities and pulmonary embolism are the major sites for venous involvement. Other common venous sites include intra-abdominal venous thrombosis (portal and hepatic). People with prior history of thrombotic events have a much higher chance of developing a cerebral, cardiac, or peripheral arterial thrombus and, less often, developing a pulmonary embolism or DVT. The IPSET-revised score also considers the *JAK2*V617F mutation as well as classical risk variables.[117] Conversion to acute leukemia is found in less than 10% of persons with ET.[118] Symptoms related to microvascular thrombosis in the CNS include headache, dizziness with paresthesia, transient ischemic attacks (TIAs), strokes, visual disturbances, and seizures. Major thrombotic events, not directly related to the platelet count, occur in about 20% to 30% of individuals with ET. Prior history of thrombotic events, advanced age, and duration of thrombocytosis are predictors of future thrombotic complications. Individuals older than age 60 are at greatest risk.

Although thrombosis is the more common symptom, hemorrhage can also occur. Sites for bleeding include the GI tract, skin, mucous membranes, urinary tract, gums, teeth sockets after extraction, joints, eyes, and brain. GI bleeding may be mistaken for a duodenal ulcer. Hemorrhage is not severe and generally occurs in the presence of very high platelet counts; transfusions are required only occasionally. Bleeding and clotting may occur simultaneously, and individuals will not necessarily be "bleeders" or "clotters."

Evaluation and Treatment

Initial diagnosis is not difficult, and as many as two-thirds of cases are diagnosed from a routine CBC. Secondary thrombocytosis also may occur as a moderate rise in the platelet count that resolves with treatment or resolution of the underlying condition. The WHO criteria for the diagnosis of ET require the following four criteria be met: (1) sustained platelet count of at least 450×10^9/L; (2) bone marrow biopsy showing proliferation of enlarged mature megakaryocytes and no increase of granulocyte or erythrocyte precursors; (3) failure to meet the criteria of PV, myelofibrosis, CML, or other myelodysplastic syndrome; and (4) presence of *JAK2*V617F,*CALR*, or *MPL* mutation.[119] Because ET can be mistaken for CML, careful differentiation is necessary because treatment varies significantly.

Treatment of ET is directed toward preventing thrombosis or hemorrhage. Reducing the platelet count remains a significant treatment issue. Hydroxyurea, a

nonalkylating myelosuppressive agent, has been the drug of choice to suppress platelet production. However, there are persistent concerns that long-term use may cause progression to other myelodysplastic disorders, particularly AML or myelofibrosis, although this has not been proven.[120] Another drug used to treat ET is IFN. IFN has a response rate of 80% but may not be effective for everyone because of side effects. Anagrelide interferes with platelet maturation rather than production, thus not interfering with red and white cell growth and development. Low-dose aspirin may be effective to alleviate erythromelalgia and transient neurologic manifestations. ET is not necessarily considered life-threatening but, in those older than age 60 and who have had previous incidences of thrombosis, complications are more common and have a higher risk of mortality. The most important determinant of survival among individuals with ET is age, with a median survival ranging from 8.1 years among those older than 70 years of age to 34.7 years among those younger than 40 years of age.[116]

Alterations of Platelet Function

Qualitative alterations in platelet function are characterized by an increased bleeding time in the presence of a normal platelet count. Associated clinical manifestations include spontaneous petechiae and purpura, and bleeding from the GI tract, genitourinary tract, pulmonary mucosa, and gums. Congenital alterations in platelet function *(thrombocytopathies)* are quite rare and may be categorized into several types of disorders (also see Chapter 30).

Acquired disorders of platelet function are more common than the congenital disorders and may be categorized into three principal causes: (1) drugs, (2) systemic inflammatory conditions, and (3) hematologic alterations.

Multiple drugs are known to interfere with platelet function in several ways: inhibition of platelet membrane receptors, inhibition of prostaglandin pathways, and inhibition of phosphodiesterase activity. Aspirin is the most used drug that affects platelets. It irreversibly inhibits cyclooxygenase function for several days after administration. Nonsteroidal anti-inflammatory drugs also affect cyclooxygenase, although in a reversible fashion.

Systemic disorders that affect platelet function are chronic renal disease, liver disease, cardiopulmonary bypass surgery, and severe deficiencies of iron or folate and antiplatelet antibodies associated with autoimmune disorders. Hematologic disorders associated with platelet dysfunction include CMPDs, MM, leukemias, myelodysplastic syndromes, and dysproteinemias.

Disorders of Coagulation

Disorders of coagulation are usually caused by defects or deficiencies of one or more of the clotting factors. (Normal function of the clotting factors is described in Chapter 28) Qualitative or quantitative abnormalities interfere with or prevent the enzymatic reactions that transform clotting factors, circulating as plasma proteins, into a stable fibrin clot (see Fig. 28.17). Some clotting factor defects are inherited and involve a

single factor, such as the hemophilias and von Willebrand disease, caused by deficiencies of specific clotting factors. Other coagulation defects are acquired and tend to result from deficient synthesis of clotting factors by the liver. Causes include liver disease and dietary deficiency of vitamin K.

Other coagulation disorders are attributed to pathologic conditions that trigger coagulation inappropriately, engaging the clotting factors and causing detrimental clotting within blood vessels. For example, any cardiovascular abnormality that alters normal blood flow by acceleration or deceleration or obstruction can create conditions in which coagulation proceeds within the vessels. An example of this is thromboembolic disease, in which blood clots obstruct blood vessels. Coagulation is also stimulated by the presence of *tissue factor* that is released by damaged or dead tissues. **Vasculitis**, or inflammation of the blood vessels, along with vessel damage activates platelets, which in turn activates the coagulation cascade. In extensive or prolonged vasculitis, blood clot formation can suppress mechanisms that normally control clot formation and dissolution, leading to clogging of the vessels. In each of these acquired conditions, normal hemostatic function proves detrimental to the body by consuming coagulation factors excessively or by overwhelming normal control of clot formation and breakdown (fibrinolysis) (see Fig. 28.19).

Impaired Hemostasis

Impaired hemostasis, or the inability to promote coagulation and the development of a stable fibrin clot, is commonly associated with liver dysfunction, which may be caused by either specific liver disorders or lack of vitamin K.

Vitamin K deficiency

Vitamin K, a fat-soluble vitamin, is required for the synthesis and regulation of prothrombin, the procoagulant factors (VII, IX, X), and the anticoagulant factors within the liver (proteins C and S). Unknown is the contribution of vitamin K to the overall supply by the intestinal flora. The primary source of vitamin K is found in green leafy vegetables. The most common cause of vitamin deficiency is parenteral nutrition in combination with antibiotics that destroy normal gut flora. Rarely is the deficiency caused by a lack of dietary intake; however, bulimia can suppress vitamin K–dependent activity. Parenteral administration of vitamin K is the treatment of choice and usually results in correction of the deficiency within 8 to 12 hours. Fresh frozen plasma also may be administered but is usually reserved for individuals with life-threatening hemorrhages or those who require emergency surgery.

Liver disease

Liver disease (e.g., acute or chronic hepatocellular diseases, cirrhosis), vitamin K deficiency, or liver surgery includes hemostatic derangements with defects in the clotting or fibrinolytic systems and platelet function. The hepatic (parenchyma) cells produce most of the factors involved in hemostasis; therefore, damage to the liver frequently results in diminished production of factors involved in clotting. Factor VII level is the first to decline after liver damage because of its rapid turnover. Factor IX

levels are less affected and do not decline until the liver destruction is well advanced. The liver also is a major site for production of plasminogen and α_2-antiplasmin of the fibrinolytic system, as well as TPO and the metalloprotease ADAMTS13. Diminished TPO may lead to thrombocytopenia from decreased platelet production. Decreased production of ADAMTS13 results in increased levels of large precursor molecules of vWF, which leads to the formation of large aggregates of platelets.

With severe liver disease, such as cirrhosis, most clotting factors are significantly depressed. Levels of clotting system regulators, such as antithrombin, protein C, protein S, and fibrinogen, also are diminished. The fibrinolytic system is commonly active because of plasmin inhibitor and other activators that are unaffected. Thrombocytopenia occurs in affected individuals because of diminished TPO and ADAMTS13, as well as increased sequestration (pooling) of platelets in the spleen, which is frequently enlarged in cirrhosis and is associated with portal hypertension. Thus, these individuals may appear to have a condition similar to DIC (see the Consumptive Thrombohemorrhagic Disorders section).

Treatment of hemostasis alterations in liver disease must be comprehensive to cover all aspects of dysfunctions. Fresh frozen plasma administration is the treatment of choice; however, not all individuals tolerate the volume needed to adequately replace all deficient factors. Alternative modalities include the addition of exchange transfusions and platelet concentration to plasma administration.

Consumptive Thrombohemorrhagic Disorders

Consumptive thrombohemorrhagic disorders are a heterogeneous group of conditions that demonstrate the entire spectrum of hemorrhagic and thrombotic pathologic findings. Symptoms range from the subtle to the devastating and generally are intermediary disease processes that complicate a vast number of primary disease states. These disorders are also characterized by confusion and controversy related to their diagnosis, treatment, and management. No one definition can cover all possible varieties of these disorders; however, DIC is most used in the clinical setting to describe a pathologic condition associated with hemorrhage and thrombosis.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is an acquired clinical syndrome characterized by widespread activation of coagulation resulting in formation of fibrin clots in medium and small vessels or microvasculature throughout the body. DIC can be acute, subacute, or chronic. DIC is secondary to a wide variety of well-defined clinical conditions, specifically those capable of activating the clotting cascade (see Pathophysiology and Box 29.5).[121] Widespread clotting may lead to blockage of blood flow to organs, resulting in multiple organ failure. The excess clotting may result in consumption of platelets and clotting factors, leading to tendency to bleed despite widespread clots.

Box 29.5

Clinical Conditions Associated With Disseminated Intravascular Coagulation

Sepsis or Severe Infection

Potentially from any microorganism, including malaria

Trauma

Serious head injury
Head injury
Fat metabolism
Burns

Liver Diseases

Fulminant hepatitis
Severe liver cirrhosis

Heat Stroke

Organ Destruction
Severe pancreatitis

Malignancy

Solid tumors
Hematologic cancers

Obstetrical Calamities

Preeclampsia or eclampsia
Placental abruption
Amniotic fluid embolism
HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome
Acute fatty liver
Sepsis during pregnancy

Vascular Abnormalities

Hemangioma
Leaking or ruptured aneurysm (such as in the aorta)
Aortic aneurysm

Kasabach-Merritt syndrome
Other vascular malformations

Severe Toxic or Immunologic Reactions

Snake bite
Recreational drug use
Severe transfusion reaction
Transplant rejection

Data from Gando S, Levi M, Toh C-H. Disseminated intravascular coagulation. *Nature Reviews Disease Primers*, 2016;2:16037.

The clinical course of DIC is largely determined by the stimulus intensity, host response, and comorbidities and ranges from an acute, severe, life-threatening process that is characterized by massive hemorrhage and thrombosis to a chronic, low-grade condition. The chronic condition includes subacute hemorrhage and diffuse microcirculatory thrombosis. DIC may be localized to one specific organ or generalized, involving multiple organs.

The diagnosis of DIC has been challenging because of the complexity and wide variations in clinical manifestations. Diagnostic criteria have been established and include a systemic thrombohemorrhagic disorder with laboratory evidence of (1) clotting activation, (2) fibrinolytic activation, (3) coagulation inhibitor consumption, and (4) biochemical evidence of end-organ damage or failure.

Sepsis is the most common condition associated with DIC. Gram-negative microorganisms, as well as some gram-positive microorganisms, fungi, protozoa (malaria), and viruses (influenza, herpes), are capable of precipitating DIC by causing damage to the vascular endothelium. Gram-negative endotoxins are the primary cause of endothelial damage. The adenocarcinomas most frequently associated with DIC include the lung, pancreas, colon, and stomach. Direct tissue damage (e.g., massive trauma, extensive surgery, severe burns) also results in release of tissue factor (TF), an initiator of DIC, by the endothelium. Severe trauma, especially to the brain, can induce DIC. DIC occurs in about two-thirds of individuals with a systemic inflammatory response (SIRS) to trauma. Some complications of pregnancy also are associated with DIC; incidences range from 50% for women with placental abruptions to less than 10% for severe preeclampsia. Other causes of DIC have been identified, most notably blood transfusion. Transfused blood dilutes the clotting factors, as well as circulating naturally occurring antithrombins. In hemolytic transfusion reactions, the endothelium is damaged by complement-mediated reactions.

Pathophysiology

The pathophysiology of DIC is complex. DIC results from abnormally widespread and ongoing activation of clotting—*coagulopathy*—in small and midsize vessels that alters the microcirculation, leading to ischemic necrosis in various organs, particularly the kidney and lung. Concomitantly, DIC can be caused by the imbalance between the

coagulant system and the fibrinolytic system (which generates plasmin) to maintain normal circulation (Fig. 29.32). DIC can cause widespread deposition of fibrin in the microcirculation that leads to ischemia, microvascular thrombotic obstruction, and organ failure (Fig. 29.33).

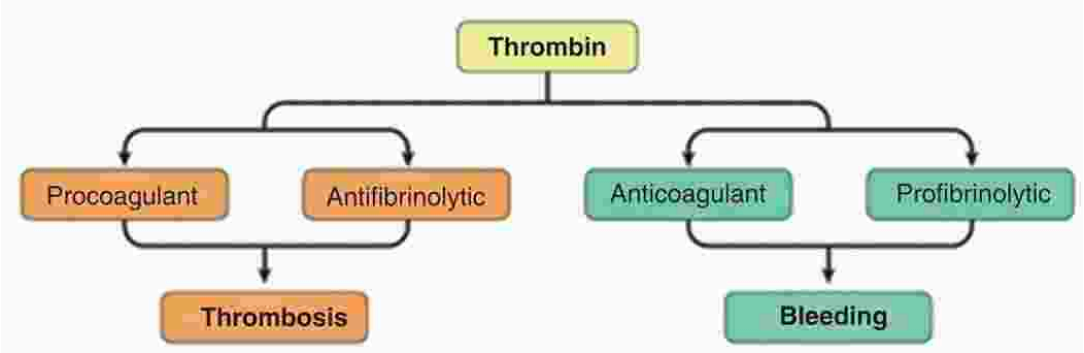

FIG. 29.32 Imbalance Between the Coagulant System and the Fibrinolytic System.
Increased thrombin generation in disseminated intravascular coagulation leads to bleeding and/or thrombosis depending on the presiding change of the dynamic balance in both coagulant and fibrinolytic outcomes. (From Gando S, Levi M, Toh CH. Disseminated intravascular coagulation. *Nature Reviews Disease Primers*, 2016;2(1). https://doi.org/10.1038/nrdp.2016.37.)

A hierarchy chart shows the imbalance between the coagulant system and the fibrinolytic system. Thrombin: thrombosis (procoagulant and antifibrinolytic) and bleeding (anticoagulant and profibrinolytic).

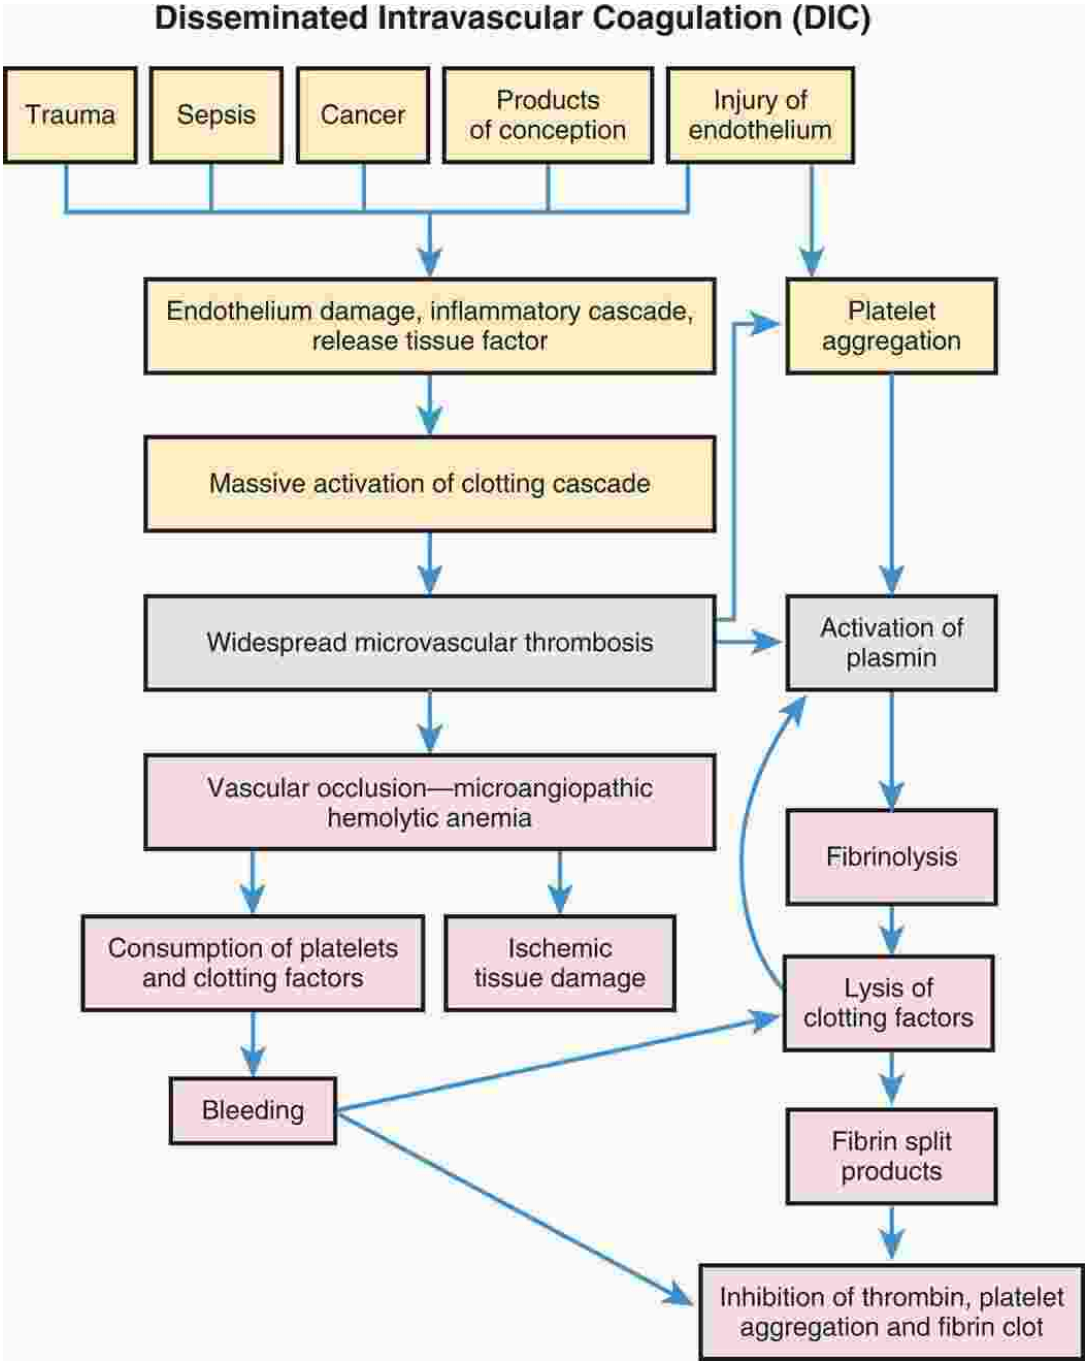

FIG. 29.33 Pathophysiology of Disseminated Intravascular Coagulation.
See text.

A flowchart represents the pathophysiology of disseminated intravascular coagulation. 1. Trauma. Leads to 6. 2. Sepsis. Leads to 6. 3. Cancer. Leads to 6. 4. Products of conception. Leads to 6. 5.

Injury of endothelium. Leads to 6 and 13. 6. Endothelium damage, inflammatory cascade, release tissue factor. Leads to 7. 7. Massive activation of clotting cascade. Leads to 8. 8. Widespread microvascular thrombosis. Leads to 9, 13, and 14. 9. Vascular occlusion–microangiopathic hemolytic anemia. Leads to 10 and 11. 10. Consumption of platelets and clotting factors. Leads to 12. 11. Ischemic tissue damage. 12. Bleeding. Leads to 16 and 18. 13. Platelet aggregation. Leads to 14. 14. Activation of plasmin. Leads to 15. 15. Fibrinolysis. Lead to 16. 16. Lysis of clotting factors. Leads to 14 and 17. 17. Fibrin split products. Leads to 18. 18. Inhibition of thrombin, platelet aggregation, and fibrin clot.

Seemingly paradoxical, DIC involves both widespread clotting and bleeding because of simultaneous procoagulant activation, fibrinolytic activation, and consumption of platelets and coagulation factors, which results directly in serious bleeding (see Fig. 29.33).

DIC is not a disease but is secondary to a variety of conditions (see Box 29.5) because of activation of the clotting cascade. The common pathway for DIC appears to be excessive and widespread exposure to TF. This may occur by several mechanisms:

1. Damage to the vascular endothelium results in exposure to TF.
2. When stimulated by inflammatory cytokines, endothelial cells and monocytes express surface TF.
3. Endotoxin triggers the release of many cytokines that can both promote and cause progression of DIC.
4. Sepsis is associated with many cytokines, interleukins, and platelet activating factor (PAF) that promote DIC as well as activate endothelial cells that stimulate thrombi development.
5. TF may be released directly into the bloodstream from circulating white blood cells.

TF binds clotting factor VII, which leads to conversion of prothrombin to thrombin and formation of fibrin clots (see Fig. 28.18). This pathway appears to be the primary route by which DIC is initiated.

Not only is the clotting system extensively activated in DIC, but also the activities of the predominant natural anticoagulants (TF pathway inhibitor, antithrombin III, protein C) are greatly diminished. During DIC, the activation of clotting is prolonged and is a result of certain conditions (e.g., bacteremia or endotoxemia); thrombin generation is increased and is insufficiently balanced by impaired anticoagulant systems, such as antithrombin and protein C. The overall result is fibrin generation and deposition in the vascular system. In early DIC, plasmin (naturally occurring clot

busting or fibrinolytic agent) produced from endothelial cells causes fibrinolysis to maintain circulation. Bleeding can occur with excess fibrinolytic activity. However, fibrinolysis becomes blunted by high levels of plasminogen activator inhibitor-1 (PAI-1), a fibrinolytic inhibitor. Over time the activity of plasmin is diminished by PAI-1. Although some fibrinolytic activity remains, the level is inadequate to control the systemic deposition of fibrin. The slow breakdown of fibrin by plasmin produces **fibrin split products (FSPs)** (also known as **fibrin degradation products [FDPs]**). These products are powerful anticoagulants that are normally removed from blood by fibronectin and macrophages. FSPs, along with thrombin, induce further cytokine release from monocytes, contributing to endothelial damage and TF release. During DIC, the presence of FSPs is prolonged. Low levels of fibronectin suggest a poor prognosis.

Although thrombosis is generalized and widespread, individuals with DIC are paradoxically at risk for hemorrhage. Hemorrhage is secondary to the abnormally high consumption of clotting factors and platelets, as well as the anticoagulant properties of FSPs, which interfere with fibrin mesh formation or polymerization. Both thrombin and FSPs have a high affinity for platelets and cause platelet activation and aggregation—an event that occurs early in the development of DIC—which facilitates microcirculatory coagulation and obstruction in the initial phase. However, platelet consumption exceeds production, resulting in a thrombocytopenia that increases bleeding.

Activation of clotting also leads to activation of other inflammatory pathways, including the kallikrein-kinin and complement systems (see Chapter 7). With sepsis, TNF first reaches a peak, followed by an increase in IL-6 and IL-1.[121] Other cytokines are released and produce **cytokine release syndrome (CRS)**, which is a life-threatening complication induced by hyperinflammatory responses.[122] Activation of these systems contributes to increased vascular permeability, hypotension, and shock. Activated complement components also induce platelet destruction, which initially contributes to the thrombosis and later to the thrombocytopenia.

The deposition of fibrin clots in the circulation interferes with blood flow, causing widespread organ hypoperfusion. This condition may lead to ischemia, infarction, and necrosis, further potentiating and complicating the existing DIC process by causing further release of TF and eventually organ failure. Manifestations of multisystem organ dysfunction and failure ultimately result.

In addition to initiation of clotting by TF, DIC may be precipitated by direct proteolytic activation of factor X. This has been described as "thrombin mimicry" and is the result of proteases directly converting fibrinogen to fibrin. These proteases may come from snake venom, some tumor cells, or the pancreas and liver, where they are respectively released during episodes of pancreatitis and various stages of liver disease. Direct proteolytic activity appears to be independent of any type of damage to the endothelium or tissue.

Whatever initiates the process of DIC, the cycle of thrombosis and hemorrhage persists until the underlying cause of the DIC is removed or appropriate therapeutic interventions are used.

Clinical Manifestations

Clinical signs and symptoms of DIC present a wide spectrum of possibilities, depending on the underlying disease process that initiates DIC and whether the DIC is acute or chronic (see Box 29.5). Most symptoms are the result of either bleeding or thrombosis. Acute DIC presents with rapid development of hemorrhaging (oozing) from venipuncture sites, arterial lines, or surgical wounds or development of ecchymotic lesions (purpura, petechiae) and hematomas. Other sites of bleeding include the eyes (sclera, conjunctiva), the nose, and the gums. Most individuals with DIC demonstrate bleeding at three or more unrelated sites, and any combination may be observed. Shock of variable intensity, out of proportion to the amount of blood loss, also may be observed. Hemorrhaging into closed compartments of the body can occur and may precede the development of shock.

Manifestations of thrombosis are not always as evident, even though it is often the first pathologic alteration to occur. The initial observations may be bleeding and sometimes very extensive hemorrhage. Several organ systems are susceptible to microvascular thrombosis associated with dysfunction: cardiovascular, pulmonary, central nervous, renal, and hepatic systems. Acute and accurate clinical interpretations are critical to preventing progression of DIC that may lead to multisystem organ dysfunction and failure. (Multiple organ dysfunction and failure are discussed further in Chapter 48.) Indicators of multisystem dysfunction include changes in level of consciousness or behavior, confusion, seizure activity, oliguria, hematuria, hypoxia, hypotension, hemoptysis, chest pain, and tachycardia. Symmetric cyanosis of fingers and toes (blue finger/toe syndrome), nose, and breast may be observed and indicates macrovascular thrombosis. This may lead to infarction and gangrene that may require amputation. Jaundice also is observed and most likely results from red cell destruction rather than liver dysfunction.

Individuals with chronic or low-grade DIC do not present with the overt manifestations of hemorrhaging and thrombosis but instead have subacute bleeding and diffuse thrombosis; these individuals are described as having *compensated DIC*, or *non-overt DIC*. The major characteristic of this state is an increased turnover and decreased survival time of the components of hemostasis: platelets and clotting factors. Occasionally, diffuse or localized thrombosis develops, but this is infrequent.

Evaluation and Treatment

Persons with DIC should be treated at hospitals with appropriate critical care and subspecialty expertise, such as hematology, blood bank, or surgery.[123] Individuals who present without those capabilities and who are able to be transferred should be referred immediately to a hospital that has those resources.[123] No single laboratory test can be used to effectively diagnose DIC. Diagnosis is based primarily on clinical symptoms and confirmed by a combination of laboratory tests. The person must present with a clinical condition that is known to be associated with DIC. The most used combination of laboratory tests usually confirms thrombocytopenia or a rapidly decreasing platelet count on repeated testing, prolongation of clotting times, the presence of FSPs, and decreased levels of coagulation inhibitors. Platelet counts below

100,000/μL or a progressive decrease in platelet counts is very sensitive for DIC, although not greatly specific. These changes usually indicate consumption of platelets.

The standard coagulation tests (e.g., prothrombin time [PT], activated partial thromboplastin time [aPTT]) also have a high degree of sensitivity, but they are not highly specific for DIC. As a result of consumption of circulating clotting factors, these tests are usually abnormal, ranging from shortened to prolonged times. However, conditions other than DIC may prolong clotting times.

Detection of FSPs is more specific for DIC. Detection of D-dimers is a widely used test for DIC. A **D-dimer** is a molecule produced by plasmin degradation of cross-linked fibrin in clots. D-Dimers in the blood can be quantified using ELISA tests that include commercially available and highly specific monoclonal antibody against the D-dimer. Agglutination tests for other FSPs are available. Levels of FSPs are elevated in the plasma in 95% to 100% of cases; however, they are less specific and only document the presence of plasmin and its action on fibrin. ELISAs for markers of thrombin activity are sometimes used.

Levels of coagulation inhibitors (e.g., antithrombin III [AT-III], protein C) can be measured by assays that rely on function or by ELISAs that quantify the amount of the specific inhibitor. AT-III levels can provide key information for diagnosing and monitoring therapy of DIC. Initial levels of functional AT-III are low in DIC because thrombin is irreversibly complexed with activated clotting factors and AT-III.

Treatment of DIC is directed toward (1) eliminating the underlying pathologic condition, (2) controlling ongoing thrombosis, and (3) maintaining organ function. Elimination of the underlying pathologic condition is the initial intervention in the treatment phase in order to remove the trigger for activation of clotting. Once the stimulus is gone, production of coagulation factors in the liver leads to restoration of normal plasma levels within 24 to 48 hours.

Control of thrombosis is more difficult to attain. Heparin has been used for this; however, its use is controversial because its mechanism of action is binding to and activating AT-III, which is deficient in many types of DIC. Currently, heparin is indicated only in certain types of situations related to DIC.[123] For instance, heparin seems to be effective in DIC caused by a retained dead fetus or associated with acute promyelocytic leukemia. Organ function is compromised by microthrombi, and there is a risk of losing an extremity because of vascular occlusion; therefore, heparin is also indicated in these conditions. Heparin's usefulness, however, for DIC that is precipitated by septic shock has not been established and so is contraindicated in that instance; heparin is also contraindicated when there is evidence of postoperative bleeding, peptic ulcer, or CNS bleeding.

Replacement of deficient coagulation factors, platelets, and other coagulation elements is gaining recognition as an effective treatment modality. Their use is not without controversy, however, because a major concern with replacement therapy is the possible risk of adding components that will increase the rate of thrombosis. Clinical judgment is the key factor in determining whether replacement is to be used as a treatment modality. Several clinical trials are evaluating replacement of anticoagulants (i.e., AT-III, protein C). Antifibrinolytic drugs also are used in treatment

but are limited to instances of life-threatening bleeding that have not been controlled by blood component replacement therapy.

Maintenance of organ function is achieved by fluid replacement to sustain adequate circulating blood volume and maintain optimal tissue and organ perfusion. Fluids may be required to restore blood pressure, cardiac output, and urine output to normal parameters.

Thromboembolic Disorders

Certain conditions within the blood vessels predispose an individual to develop clots spontaneously. Close to 100,000 people die each year of blood clots, and 1 in 4 people who have the clot in their lungs—*a pulmonary embolism*—die without warning (see Chapter 35). *Venous thromboembolism* (VTE) affects about 900,000 Americans each year, and 3 in 10 people who have a clot will have another episode within 10 years. Blood clots can happen to anyone, and they are often preventable. Early diagnosis is critical to prevent death.[124] A stationary clot attached to the vessel wall is called a **thrombus** (Fig. 29.34). A thrombus is composed of fibrin and blood cells and can develop in either the arterial or the venous system. **Arterial thrombi** form under conditions of high blood flow and are composed mostly of platelet aggregates held together by fibrin strands. **Venous thrombi** form under conditions of low flow and are composed mostly of red cells with larger amounts of fibrin and few platelets.

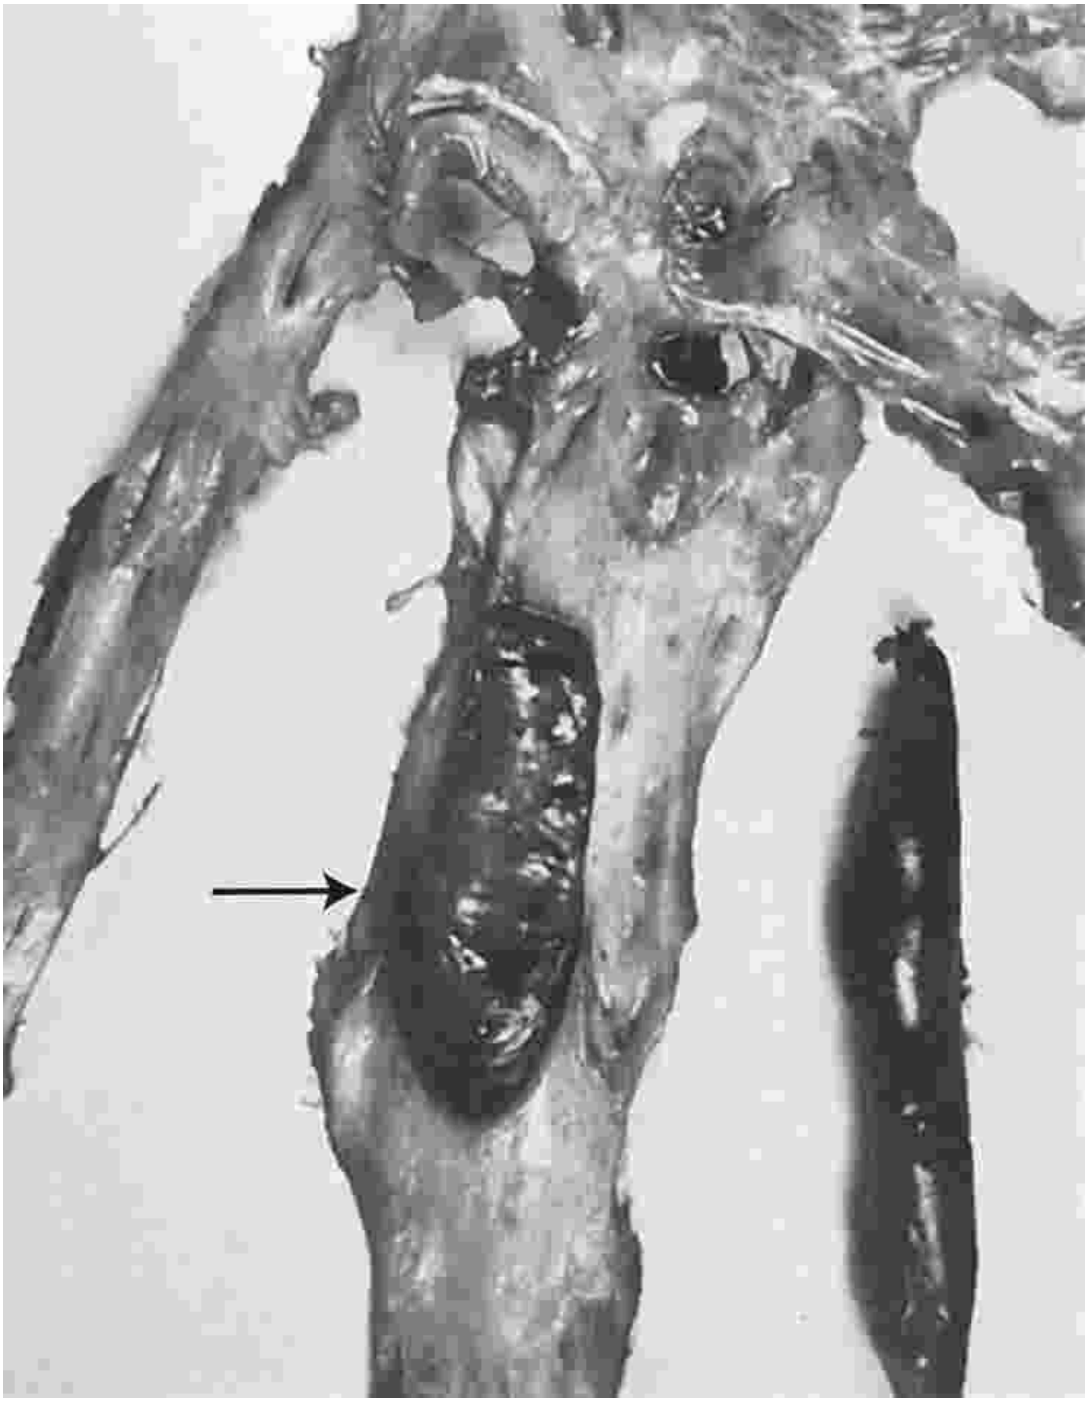

FIG. 29.34 Thrombus.
Thrombus arising in valve pocket at upper end of superficial femoral vein *(arrow)*. Postmortem clot on the right is shown for comparison. (From McLachlin J, Paterson JC. Some basic observations on venous thrombosis and pulmonary embolism. *Surgery, Gynecology and Obstetrics*, 1951;93(1):1–8.)

A thrombus eventually reduces or obstructs blood flow to tissues or organs, such as the heart, brain, or lungs, depriving them of essential nutrients critical to survival. A thrombus also has the potential to detach from the vessel wall and circulate within the bloodstream (referred to as an **embolus**). The embolus may become lodged in smaller blood vessels, blocking blood flow into the local tissue or organ and leading to ischemia. A **pulmonary embolism** (**PE**) is life-threatening and can cause sudden death.[124] Episodes of thromboembolism are life-threatening depending on the *site* of vessel occlusion. Risk factors for **venous thromboembolism (VTE**), include older age, malignancy, inflammatory disorders (e.g., 4.7% risk in those with rheumatoid arthritis), and inherited thrombophilia.[125]**Deep vein thrombosis (DVT**) for lower extremity ranges from 88 to 112/100,000 person-years and increases with age.[125]**Postthrombotic syndrome** is persistent symptoms, signs of chronic venous insufficiency, or both and occurs in 25% to 50% of patients 3 to 6 months after DVT diagnosis.[125] Catheter-directed fibrinolysis with or without mechanical thrombectomy is appropriate in those with iliofemoral obstruction, severe symptoms, and a low risk of bleeding.[125] Newer direct oral anticoagulants including rivaroxaban, apixaban, dabigatran, and edoxaban are considered noninferior to warfarin (absolute rate of recurrent VTE or VTE-related death, 2.0% vs. 2.2%).[125] Major bleeding occurs in 1.1% of individuals treated with direct oral anticoagulants versus 1.8% treated with warfarin.[125]

More aggressive therapy may be indicated for such conditions as pulmonary embolism, coronary thrombosis, or thrombophlebitis. Streptokinase, tissue plasminogen activator (t-PA), and urokinase activate the fibrinolytic system and are administered to accelerate the lysis of known thrombi. These drugs are known as fibrinolytic or thrombolytic therapy and are prescribed with a high degree of caution because they can cause hemorrhagic complications.

The risk for developing spontaneous thrombi is related to several factors, referred to as the **Virchow triad**: (1) injury to the blood vessel endothelium, (2) abnormalities of blood flow (turbulence or stasis), and (3) hypercoagulability of the blood (see Chapter 32).

Endothelial injury to blood vessels can result from atherosclerosis (plaque deposits on arterial walls) (see Chapter 32). Atherosclerosis initiates platelet adhesion and aggregation, promoting the development of atherosclerotic plaques that enlarge, causing further damage and occlusion. Other causes of vessel endothelial injury may be related to hemodynamic alterations associated with hypertension and turbulent blood flow. Injury is also caused by radiation injury, exogenous chemical agents (e.g., toxins from cigarette smoke), endogenous agents (e.g., cholesterol), bacterial toxins or endotoxins, or immunologic mechanisms.

Sites of turbulent blood flow in the arteries and stasis of blood flow in the veins increase the risk for thrombus formation. In areas of turbulence, platelets and endothelial cells may be activated, leading to thrombosis. In sites of stasis, platelets may remain in contact with the endothelium for prolonged lengths of time, and clotting factors that would normally be diluted with fresh flowing blood are not

diluted and may become activated. The most common clinical conditions that predispose to venous stasis and subsequent thromboembolic phenomena are major surgery (e.g., orthopedic surgery), acute myocardial infarction, CHF, limb paralysis, travel, spinal injury, malignancy, advanced age, the postpartum period, and bed rest longer than 1 week. Turbulence and stasis occur with ulcerated atherosclerotic plaques, hyperviscosity (polycythemia), and conditions with deformed red cells (e.g., sickle cell anemia).

Hypercoagulability, *or thrombophilia*, increases the risk for venous thrombosis. Hypercoagulability is differentiated according to whether it results from primary (hereditary) or secondary (acquired) causes (see Chapter 32).

Hereditary thrombophilias

Thrombophilias can result from both inherited conditions and, more commonly, acquired conditions. Several inherited conditions increase the risk of developing thrombosis, and most are autosomal dominant. Thus, individuals who are homozygous for the mutation are at greatest risk for thrombosis. These include mutations in platelet receptors, coagulation proteins, fibrinolytic proteins, and other factors. The mutations that have been most strongly linked as risk factors for venous thrombosis or for arterial thrombosis involving coronary artery disease or stroke include those that affect fibrinogen, prothrombin (G20210A variant), and factor V (factor V Leiden) of the coagulation system. Other inherited thrombophilias are risk factors mostly for venous thrombosis and in some cases arterial ischemic stroke, including deficiencies in protein C and protein S.[126,127] Other hereditary thrombophilias are less common.

Tests to diagnose inherited thrombophilias include PT; partial thromboplastin time; and levels of protein C, protein S, and AT-III. More elaborate tests to detect precise mutations in factor V, prothrombin, or MTHFR may be indicated. Management is based on the underlying defect and may include long-term anticoagulation.[128]

Acquired hypercoagulability

Deficiencies in proteins S and C and AT-III may be acquired and contribute to a hypercoagulable state. Conditions associated with an acquired protein deficiency include DIC, liver disease, infection, DVT, acute respiratory distress syndrome, L-asparaginase therapy, HUS, and TTP. The postoperative state also predisposes an individual to protein C or S deficiency; however, its role in contributing to DVT remains unclear.

Acquired hypercoagulable states include *antiphospholipid syndrome (APS*). APS is an autoimmune syndrome characterized by autoantibodies against plasma membrane phospholipids and phospholipid-binding proteins. As with most autoimmune diseases, the predominantly affected individual is female and of reproductive age. Those with APS are at risk for both arterial and venous thrombosis (Fig. 29.35) and a variety of obstetric complications, including pregnancy loss and preeclampsia/eclampsia. In severe cases the individual may die from recurrent major thrombus formation. The pathophysiology is related to autoantibodies directly

reacting with platelets or endothelial cells (increasing the risk for thrombosis) or the placental surface (resulting in damage to the placenta). The predominant diagnostic tests measure prolongation of laboratory blood coagulation tests related to an antibody inhibitor (lupus anticoagulant) and specific ELISAs for antibodies against phospholipids (e.g., anticardiolipin antibody) or proteins that bind to phospholipids (e.g., β_2-glycoprotein I). Highly effective therapy (i.e., unfractionated or low-molecular-weight heparin with low-dose aspirin) is available to prevent the obstetric complications.

FIG. 29.35 Arterial Thrombosis Associated Antiphospholipid Antibodies.
A 12-year-old girl with systemic lupus erythematosus and antiphospholipid antibodies with painful cutaneous vasculitis of the

right foot. Arterial thrombosis documented by angiography resulted in cyanosis of the large toe. Symptoms resolved with treatment with heparin and corticosteroids. (From Kliegman R, et al. *Nelson textbook of pediatrics*, 18th edition. Philadelphia: Saunders; 2007.)

Summary Review

Anemia

1. Anemia is defined as a reduction in the number or volume of circulating red cells or a decrease in the quality or quantity of hemoglobin.
2. The most common classification of anemias is based on changes in the cell size—represented by the cell suffix *-cytic*—and changes in the cell's hemoglobin content—represented by the suffix *-chromic*.
3. Clinical manifestations of anemia can be found in all organs and tissues throughout the body. Decreased oxygen delivery to tissues causes fatigue, dyspnea, dizziness, compensatory tachycardia, and organ dysfunction.
4. Posthemorrhagic anemia is caused by acute blood loss, often caused by trauma. Complete recovery is possible if acute blood loss is not severe.
5. Macrocytic (megaloblastic) anemias are characterized by unusually large stem cells (megaloblasts) in the marrow that mature into very large erythrocytes (macrocytic). Macrocytic anemias are caused most by deficiency of vitamin B_{12} or folate. Pernicious anemia can be fatal, usually because of heart failure, unless vitamin B_{12} replacement is given (lifelong replacement is required). Folate deficiency anemia is treated with folate supplements, but long-term therapy is not necessary if dietary adjustments are made to increase folate intake.
6. Microcytic-hypochromic anemias are characterized by abnormally small red cells with unusually reduced hemoglobin content. The most common cause is iron deficiency.
7. Iron deficiency anemia (IDA) is the most common nutritional disorder worldwide. The causes of IDA include (1) dietary deficiency, (2) impaired absorption, (3) increased requirement, (4) chronic blood loss, (5) impaired absorption, and (6) chronic diarrhea.
8. IDA usually develops slowly, with a gradual, insidious onset of nonspecific symptoms, including fatigue, weakness, shortness of breath, and pale earlobes, palms, and conjunctivae. Once the source of blood loss is identified and corrected, iron replacement therapy can be initiated.
9. Normocytic-normochromic anemias are characterized by insufficient numbers of normal erythrocytes.
10. Anemia of inflammation is caused by inflammatory cytokines which increase hepcidin levels. The increased levels reduce iron absorption, sequester iron in macrophages, and suppress erythropoietin production. Altogether these

changes cause decreased production of red blood cells and impaired iron utilization in people with chronic systemic diseases or chronic inflammation. It is a common anemia found in hospitalized individuals and is usually in the mild to moderate range of anemias.

11. Aplastic anemia is caused by a reduction in the effective production of mature cells by the bone marrow, causing a reduction or absence of all three blood cell types (pancytopenia). Hemolytic anemia is the premature accelerated destruction of erythrocytes.

Myeloproliferative Red Cell Disorders

1. Myeloproliferative disorders involve an overproduction of cells resulting from abnormal regulation of hematopoietic stem cells. Polycythemia is an excessive red cell production.
2. Polycythemia vera is a slow-growing blood cancer in which the bone marrow makes too many red blood cells. It is a stem cell disorder with hyperplastic and neoplastic bone marrow alterations characterized by abnormal uncontrolled proliferation of erythrocytes, frequently with increased white blood cells and platelets. Polycythemia is responsible for most of the clinical symptoms, including increased blood volume and viscosity.
3. Treatment of polycythemia vera includes frequent phlebotomies and aspirin in low-risk individuals. Hydroxyurea is the drug of choice for myelosuppression. Polycythemia vera may spontaneously convert to acute myelogenous leukemia.
4. Hereditary hemochromatosis is a common inherited disorder of iron metabolism characterized by increased gastrointestinal iron absorption with subsequent iron deposition in the liver, pancreas, heart, joints, and endocrine glands. Periodic phlebotomy is effective at removing excess iron.

Alterations of Leukocyte Function

1. Quantitative alterations of leukocytes (too many or too few) can be caused by bone marrow dysfunction or premature destruction of cells in the circulation. Many quantitative changes in leukocytes occur in response to invasion by microorganisms.
2. Leukocytosis is a condition in which the leukocyte count is higher than normal and is usually a response to physiologic stressors and pathologic conditions, such as malignancies and hematologic disorders.
3. Leukopenia is present when the leukocyte count is lower than normal and is caused by radiation, anaphylactic shock, autoimmune disease, immune deficiencies, and certain drugs. A decrease in neutrophils increases the risk for infection.
4. Granulocytosis (or neutrophilia) is an increase in circulating granulocytes—neutrophils, eosinophils, or basophils—that occurs in response to infection

and inflammation. Granulocytopenia (or neutropenia), a significant decrease in the number of neutrophils, is often caused by chemotherapeutic agents, severe infection, and radiation. Agranulocytosis is a complete absence of granulocytes in the blood.

5. Eosinophilia (increase in circulating eosinophils) results most commonly from allergic disorders and parasitic invasion. Eosinopenia (decrease in circulating eosinophils) is generally caused by the migration of eosinophils into inflammatory sites.
6. Basophilia (increase in circulating basophils) is rare and generally is a response to inflammation and immediate hypersensitivity reactions. Basopenia (decrease in circulating basophils) is seen in hyperthyroidism, acute infection, ovulation and pregnancy, and long-term steroid therapy.
7. Monocytosis (increase in circulating monocytes) is often transient and occurs during the late or recuperative phase of infection. Monocytopenia (decrease in circulating monocytes) is rare but may occur with hairy cell leukemia and prednisone therapy.
8. Lymphocytosis is an increase in the number or proportion of lymphocytes in the blood and is most caused by viral infections. Lymphocytopenia is a decrease in the number of circulating lymphocytes and is associated with neoplasias, immune deficiencies, and destruction by drugs, viruses, or radiation.
9. Infectious mononucleosis (IM) is an acute, self-limiting infection of B lymphocytes most associated with the Epstein-Barr virus (EBV), which is transmitted from person-to-person (salivary secretions), breastfeeding, and sexual contact (cervical and seminal fluid). The classic symptoms of IM are pharyngitis, lymphadenopathy, and fever. The proliferation of infected B cells may be uncontrolled and lead to B-cell and T-cell lymphomas. Treatment of IM consists of rest and symptomatic treatment.
10. The common pathologic feature of all forms of leukemia is an uncontrolled proliferation of malignant leukocytes, overcrowding the bone marrow and resulting in decreased production and function of the other blood cell lines.
11. The classification of leukemias is complex, because the once discrete categories of lymphoma and leukemia have been blurred.
12. The World Health Organization (WHO) groups lymphoid neoplasms into five categories defined by cell of origin: (1) precursor B-cell neoplasms (immature B cells), (2) peripheral B-cell neoplasms (mature B cells), (3) precursor T-cell neoplasms (immature T cells), (4) peripheral T-cell and NK (natural killer)-cell neoplasms (mature T cells and NK cells), and (5) Hodgkin lymphoma (Reed-Sternberg cell and variants).
13. Acute leukemia is characterized by undifferentiated or immature cells. The onset of disease is abrupt and rapid, and, without treatment, disease progression results in a short survival time. In chronic leukemia, the predominant cell is more differentiated but does not function normally, with a relatively slow progression.

14. All leukemias have certain pathophysiologic features in common. Abnormal immature white blood cells, called leukemic blasts, fill the bone marrow and spill into the blood. The blasts overcrowd the marrow and cause cellular proliferation of the other cell lines to cease. Leukemic blasts induce a *senescent phenotype* in stromal cells within the bone marrow microenvironment. Blast cell longevity is promoted by adipocytes.
15. Acute leukemias include acute lymphocytic leukemia (ALL) and acute myelogenous leukemia (AML).
16. Increased risk for ALL has been linked to prenatal exposure to x-rays, postnatal exposure to ionizing radiation, past treatment with chemotherapy, certain chemical exposures, certain viral infections, age, race/ethnicity, gender, and certain genetic conditions. AML can arise in people de novo, those with an underlying hematological disorder, or as a consequence of prior treatment. It is the most frequently reported secondary cancer after high doses of chemotherapy for HL, NHL, MM, ovarian cancer, and breast cancer.
17. The major clinical manifestations of acute leukemia include fatigue caused by anemia, bleeding caused by thrombocytopenia, fever secondary to infection, anorexia, and weight loss.
18. Treatment varies depending on the type of leukemia and includes chemotherapy, radiation therapy, stem cell transplant, and other drug therapy.
19. Chronic leukemias include chronic lymphocytic leukemia (CLL) and chronic myelogenous leukemia (CML).
20. CLL is a disorder of structurally mature but immunologically immature lymphocytes. In adults, CLL is the most common leukemia in the Western world.
21. Exposures associated with CLL include pesticides, deltamethrin and herbicides, Agent Orange, and radon. The role of ionizing radiation is controversial. Hypogammaglobulinemia is common in CLL and can precede the diagnosis. Genetic studies strongly imply involvement of inheritable susceptibility alleles that promote or prevent disease. CLL has the highest incidence of familial association.
22. CML is classified as a myeloproliferative neoplasm, is a slowly progressing disease with increased numbers of granulocytic precursors in the bone marrow, which usually includes elevated proportions of eosinophils and basophils. Megakaryocytes are also increased in the bone marrow and some with dysphasia.
23. The only known cause of CML is exposure to ionizing radiation.
24. CLL involves malignant transformation and accumulation of B lymphocytes and rarely involves chromosomal translocations.
25. The Philadelphia chromosome is present in more than 90% to 95% of persons diagnosed with CML.
26. Most individuals with chronic leukemia are asymptomatic at the time of diagnosis, but the most common finding is lymphadenopathy.

27. Treatments for progressing CLL include chemotherapy and in selected individuals stem cell transplantation. In early disease antileukemic therapy is frequently unnecessary. Treatments for CML do not cure the disease, but include chemotherapy, biologic response modifiers, and stem cell transplant.

Alterations of Lymphoid Function

1. Lymphadenopathy is enlarged lymph nodes. Lymphadenopathy results from four types of conditions: (1) neoplastic disease, (2) immunologic or inflammatory conditions, (3) endocrine disorders, or (4) lipid storage diseases.
2. Lymphomas consist of a diverse group of neoplasms that develop from the proliferation of malignant lymphocytes in the lymphoid system. The WHO classification of lymphomas based on the cell type it originated from include Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). Classification based on morphology and cell lineage include B-cell neoplasms, T-cell neoplasms, and natural killer (NK) cell neoplasms. Two *basic* categories of lymphomas are HL and NHL.
3. In general, lymphomas are the result of genetic mutations or viral infection. Globally, however, the incidence of lymphoma is increased in more developed countries. Malignant transformation produces a cell with uncontrolled and excessive growth that accumulates in the lymph nodes and other sites, producing tumor masses.
4. HL is a malignant lymphoma that progresses from one group of lymph nodes to another and is characterized by abnormal cells called Hodgkin and Reed-Sternberg cells (HRS). EBV has been linked to the pathogenesis of HL. Only a few people that have been infected with EBV develop HL. Genome-wide studies have identified genetic risk variants mostly in immune-related genes.
5. The neoplastic HRS cells originate from a germinal center or post-germinal center B cell. The HRS cells secrete and release cytokines that result in accumulation of inflammatory cells in the tumor microenvironment, which produces the local and systemic effects.
6. An enlarged, painless lymph node, most commonly in the neck, is an initial sign of HL; however, asymptomatic lymphadenopathy can progress undetected for years.
7. Treatment of HL includes chemotherapy and radiation options. Treatment with chemotherapy or radiation therapy, or both, may increase the risk of second cancers, cardiovascular disease, and other health problems months or years after treatment.
8. The NHLs are a heterogeneous group of lymphoid tissue neoplasms. NHL is a progressive clonal expansion of B cells, T cells, or NK cells, with B cells accounting for the majority of NHLs. Oncogenes may be activated by chromosomal translocation or by deletion of tumor-suppressor genes. Certain subtypes may have altered genomes by oncogenic viruses.

9. Risk factors for NHL include being older, male, or white with immunosuppression, certain viruses, *Helicobacter pylori*, autoimmune and chronic inflammatory disorders, occupational exposures, for example certain pesticides, and radiation exposure. Previous treatment of both radiation and chemotherapy increases risk of NHL.
10. The key pathogenic mechanisms include immunosuppression and chronic antigen stimulation, which increases B-cell proliferation leading to random genetic mistakes notably immunoglobulin rearrangement.
11. Generally, with NHL, the swelling of lymph nodes is painless, and the nodes enlarge and transform over a period of months or years. The cervical, axillary, inguinal, and femoral lymph node chains are the most affected sites.
12. Treatment for NHL may include chemotherapy, radiation therapy, monoclonal antibody therapy, and watchful waiting.
13. Burkitt leukemia/lymphoma (BL) is a B-cell NHL. It is highly aggressive and is the fastest growing human tumor. There are three main types of BL: endemic (common in Africa and linked to EBV), nonendemic (occurs worldwide), and immunodeficiency-related (found in individuals with AIDS). The rapidly growing tumor involves the jaw and facial bones and sometimes the abdomen.
14. Virtually all cases of BL are associated with chronic EBV infection.
15. Treatment for BL is aggressive multidrug regimens, such as combination chemotherapy.
16. Multiple myeloma (MM) is a clonal plasma cell cancer characterized by the neoplastic proliferation of plasma cells producing a monoclonal immunoglobulin. The plasma cells proliferate in the bone marrow. The multiple malignant tumor masses of plasma cells are scattered throughout the skeletal system (lytic bone lesions) and sometimes found in soft tissue. The common presentation of MM is characterized by elevated levels of calcium in the blood, renal failure, anemia, and lytic bone lesions.
17. Multiple mutations in different pathways alter the intrinsic biology of the plasma cell, generating the features of myeloma. The exact cause of MM is unknown, but risk factors include overweight or obesity, Agent Orange, possibly other certain chemicals, and a history of monoclonal gammopathy of undetermined significance (MGUS). MM has been observed in some irradiated populations.
18. Treatment options for MM include combinations of chemotherapy; other drug therapy; targeted therapy; high-dose chemotherapy with stem cell transplant; biologic therapy; radiation therapy; and, sometimes, surgery.

9.5 Alterations of Splenic Function

1. Splenomegaly (enlargement of the spleen) may be considered normal in certain individuals, but its presence is associated with various diseases.
2. Splenomegaly results from (1) acute inflammatory or infectious processes, (2) congestive disorders, (3) infiltrative processes, and (4) tumors or cysts.

3. Hypersplenism (overactivity of the spleen) results from splenomegaly. Hypersplenism results in sequestering of the blood cells, causing increased destruction of red blood cells, leukopenia, and thrombocytopenia.

Hemorrhagic Disorders and Alterations of Platelets and Coagulation

1. The arrest of bleeding is called hemostasis. Copious or heavy discharge of blood from blood vessels is called hemorrhage.
2. Quantitative or qualitative abnormalities of platelets can interrupt normal blood coagulation and prevent hemostasis.
3. Thrombocytopenia is characterized by a platelet count below 150,000/μL of blood; a count less than 50,000/μL increases the potential for hemorrhage associated with minor trauma. A count less than 10,000 platelets/μL can cause spontaneous bleeding without trauma.
4. Thrombocytopenia exists in primary or secondary forms and can be congenital or acquired. Acquired thrombocytopenia is associated with viral infections, drugs, nutritional deficiencies, chronic renal failure, cancer, radiation therapy, and bone marrow hypoplasia.
5. Common forms of thrombocytopenia include heparin-induced thrombocytopenia, idiopathic (immune) thrombocytopenia purpura, thrombotic thrombocytopenia purpura, and disseminated intravascular coagulation.
6. Thrombocythemia is characterized by a platelet count more than 450,000 platelets/μL of blood and is symptomatic when the count exceeds 1 million/μL, at which time the risk for intravascular clotting (thrombosis) is high.
7. Thrombocythemia is a myeloproliferative neoplasm characterized by excessive platelet production resulting from a defect in the bone marrow megakaryocyte progenitor cells. It also can include an increase in red blood cell production.
8. Qualitative alterations in normal platelet function prevent platelet plug formation and may result in prolonged bleeding times. Acquired disorders of platelet function are more common than congenital disorders.
9. Disorders of coagulation are usually caused by defects or deficiencies of one or more clotting factors. Coagulation is stimulated by the presence of tissue factor that is released by damaged or dead tissues.
10. Coagulation is impaired when there is a deficiency of vitamin K because of insufficient production of prothrombin and synthesis of clotting factors VII, IX, and X, often associated with liver diseases.
11. Disseminated intravascular coagulation (DIC) is an acquired clinical syndrome characterized by widespread activation of coagulation, resulting in formation of fibrin clots in medium and small vessels or microvasculature throughout the body. Widespread clotting may lead to blockage of blood flow to organs, resulting in multiple organ failure. The excessive clotting may result in

consumption of platelets and clotting factors, leading to a tendency to bleed despite widespread clots.

12. DIC is secondary to a wide variety of clinical conditions, with sepsis being the most common. Massive cytokine release can produce cytokine release syndrome (CRS) which is life-threatening induced by a hyperinflammatory process.
13. For a diagnosis of DIC, the person must present with a clinical condition that is known to be associated with DIC. The most used combination of laboratory tests usually confirms thrombocytopenia, or a rapidly decreasing platelet count on repeated testing, prolongation of clotting times, the presence of fibrin split products, and decreased levels of coagulation inhibitors.
14. Treatment of DIC is directed toward (1) eliminating the underlying pathologic condition, (2) controlling ongoing thrombosis, and (3) maintaining organ function.
15. Thromboembolic disease results from a fixed (thrombus) or moving (embolus) clot that blocks flow within a vessel, denying nutrients to tissues distal to the occlusion; death can result when clots obstruct blood flow to the heart, brain, or lungs.
16. The Virchow triad refers to three factors that influence the risk of developing spontaneous thrombi: (1) injury to the blood vessel endothelium, (2) abnormalities of blood flow, and (3) hypercoagulability of the blood.

Emerging Science Box

Traumatic Coagulopathy

Emerging is the understanding that persons with bleeding trauma are already developing complications of coagulopathy upon hospital admission. Onequarter to one-third of hemorrhaging trauma patients suffer from traumatic coagulopathy. The presence of coagulopathy is related to an increased risk of multiple organ failure and death (see Chapter 48). Terms for coagulopathy that accompanies trauma include acute traumatic coagulopathy, early coagulation of trauma, acute coagulopathy of trauma-shock, trauma-induced coagulopathy, and trauma-associated coagulopathy. Acute coagulopathy associated with traumatic injury is now recognized as a multifactorial condition caused by preexisting factors such as age, genetic background, comorbidities and medications (e.g., oral anticoagulants), and trauma-related factors such as bleeding-induced shock, tissue-related thrombin-thrombomodulin-complex generation, coagulation factor consumption, and activation of the anticoagulant and fibrinolytic pathways. One of the primary mechanisms of the coagulopathy is activation of protein C system.

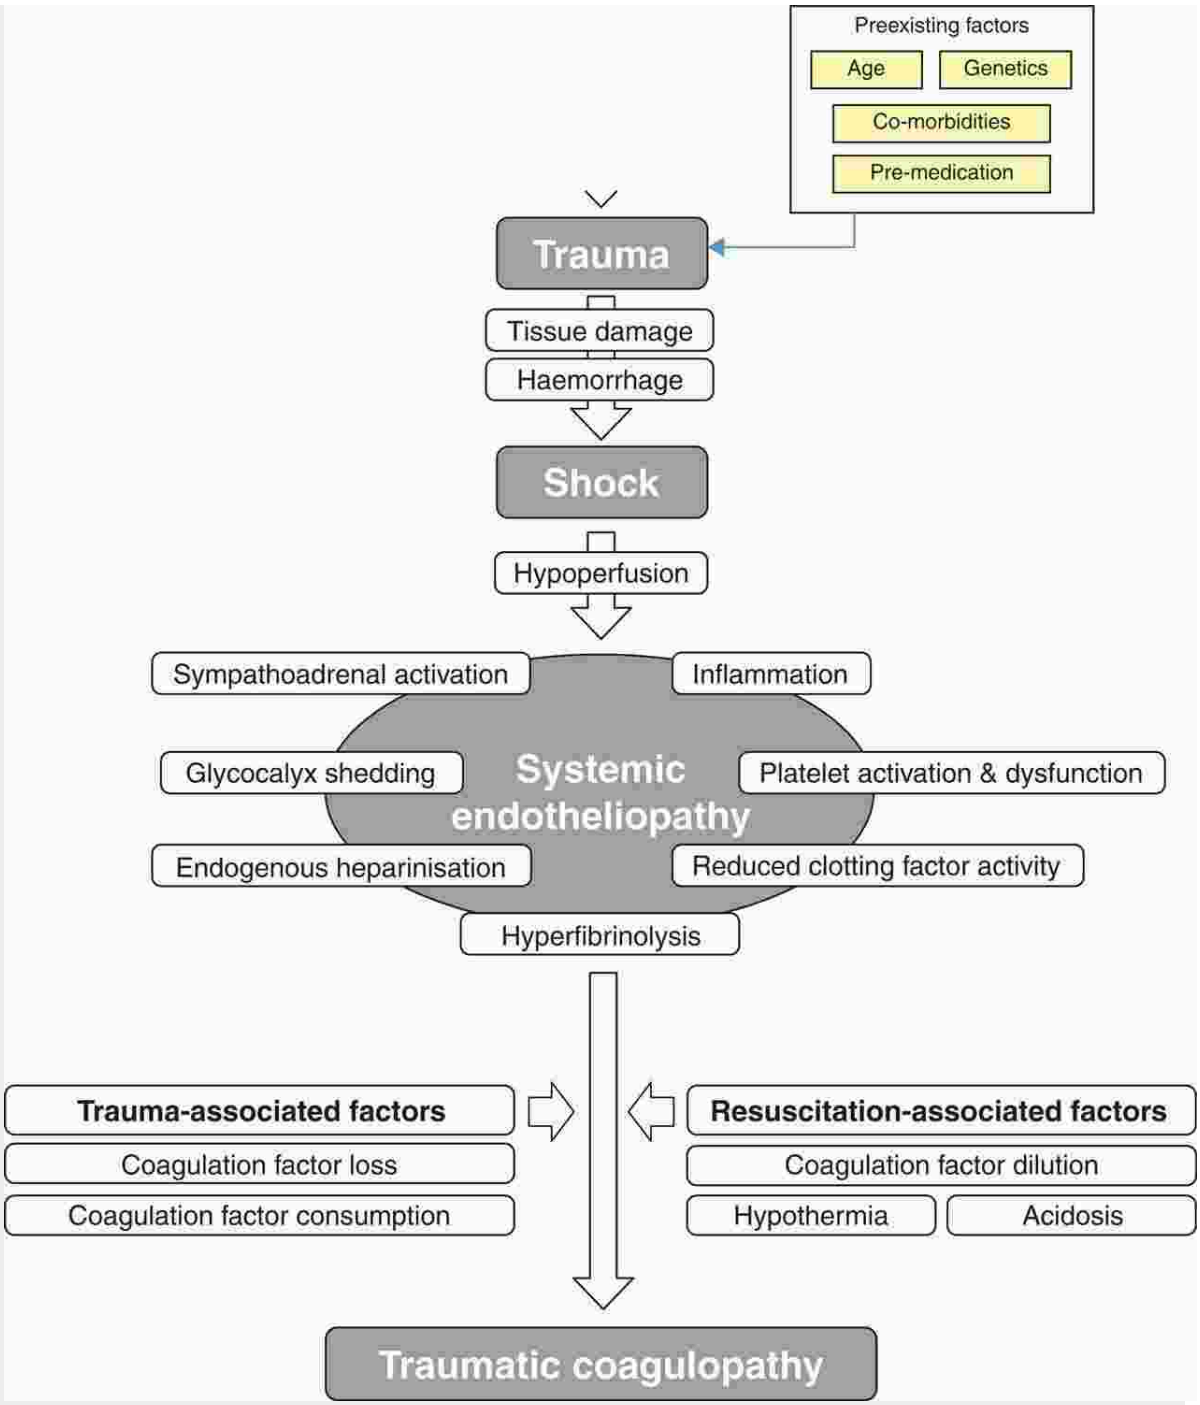

Figure adapted from Spahn DR, et al: the European guideline on the management of major bleeding and coagulopathy following trauma: Fifth edition, Crit Care 23:98,2019. https://ccforum.biomedcentral.com/articles/10.1186/s13054-019-2347-3/figures/1.

In addition to its contribution to uncontrolled bleeding, traumatic coagulopathy and trauma-associated inflammation combine to exacerbate organ dysfunction and thromboembolic complications. The early phase of the process is characterized by hemorrhage, and the late phase (6–24 h after injury) by a hypercoagulability.

Adding to this complexity, structural damage and metabolic changes in erythrocytes cause them to contribute to coagulopathy by their adherence to the endothelium, activation of platelets, exposure of prothrombotic factors, release of prothrombotic microparticles, and resistance to thrombolysis (see Chapter 28). Recent guidelines recommend that individuals be transferred directly to trauma centers to improve outcomes. Treatments for traumatic coagulopathy include tranexamic acid, fresh frozen plasma, and coagulation factor concentrates.

Emerging Science Box

Immunotherapy

Immunotherapy can stimulate or direct an individual's own immune system to target cancer cells. Several types of drugs, biologic, and cellular therapies can activate or suppress specific immune responses. Examples include immune checkpoint inhibitors ([ICIs], e.g., CTLA-4, PD-1, or PD-L1 antibodies), cytokines, immunomodulating agents (e.g., lenalidomide), monoclonal antibodies to tumor antigens (e.g., CD26), cancer vaccines based on tumor-mutated antigens (neo-antigens), oncolytic viruses (OVs), adoptive cell transfer (ACT), and chimeric antigen receptor (CAR) T-cell therapies. Immunotherapies have the potential to induce durable responses and even in some cases cure persons with certain forms of cancer that previously had extremely poor prognosis such as metastatic melanoma. Some of these approaches have therapeutic potential across many forms of cancer, while others are highly specific to a molecular subtype. Genomic sequencing or other precision oncology approaches are used to identify alterations in a person's cancer amenable to targeted or personalized therapies. Other approaches include harvesting a person's immune cells and engineering them to recognize the person's cancer cells via gene therapy and genome editing. Key opportunities include identifying predictive biomarkers of response, while challenges for immunotherapies include navigating unique toxicities (e.g., immune-related adverse events) and ensuring equitable access, given the unprecedented financial burden associated with many of these treatments.

Neoplastic Disorders, 1010
- Leukemia, 1010
- Lymphomas, 1013

This chapter briefly explains fetal and neonatal hematopoiesis and postnatal changes in the blood as a foundation for understanding the pathophysiology of specific blood disorders in childhood. Among the diseases that affect erythrocytes are acquired disorders, such as iron deficiency anemia (IDA), hemolytic disease of the newborn, and anemia of infectious disease; and inherited disorders, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, hereditary spherocytosis, sickle cell disease, and the thalassemias. Disorders of coagulation and platelets include inherited hemorrhagic diseases, such as the hemophilias, and antibody-mediated hemorrhagic diseases, which include immune thrombocytopenia, autoimmune neonatal thrombocytopenias, and autoimmune vascular purpuras. Finally, leukocyte disorders, such as leukemia and the lymphomas (non-Hodgkin lymphoma as well as Hodgkin lymphoma), are discussed.

Fetal and Neonatal Hematopoiesis

As the developing embryo becomes too large for oxygenation of tissues by simple diffusion, the production of erythrocytes begins within the vessels of the yolk sac. Shortly after 2 weeks of gestation, circulating erythrocytes play a significant role in delivering oxygen to the tissues. At approximately the eighth week of gestation, the site of erythrocyte production shifts from the vessels to the liver sinusoids, and the production of leukocytes and platelets begins in the liver and spleen. Erythropoiesis in the liver and, to a lesser extent, in the spleen and lymph nodes, peaks at approximately 4 months. Hepatic blood formation declines steadily thereafter but does not disappear entirely during the remainder of gestation. By the fifth month of gestation, hematopoiesis begins to occur in the bone marrow and increases rapidly until hematopoietic (red) marrow fills the entire bone marrow space. By the time of delivery, the marrow is the only significant site of hematopoiesis.

In neonates and young infants, hematopoietic marrow progressively fills the bony cavities of the entire axial skeleton (skull, vertebrae, ribs, and sternum), the long bones of the limbs, and many intramembranous bones. (These structures are described in Chapter 43). Fatty (yellow) marrow gradually replaces hematopoietic marrow in some bones. During childhood, hematopoietic tissue retreats centrally to the vertebrae, ribs, sternum, pelvis, scapulae, skull, and proximal ends of the femur and humerus.

In diseases characterized by hemolysis, erythrocyte production can increase as much as 12 times the normal level because erythropoietin causes hematopoietic marrow to increase in volume. Initially, hematopoietic marrow expands from the ends of the long bones toward the middle of the shafts, replacing fatty marrow. Next, blood cell production begins to occur outside the marrow cavities, especially in the liver and spleen. Extramedullary hematopoiesis is more likely to occur in children than in adults because the bony cavities of children already are filled with red marrow (Fig. 30.1), which is the reason hemolytic disease causes especially pronounced enlargement of the spleen and liver in children.

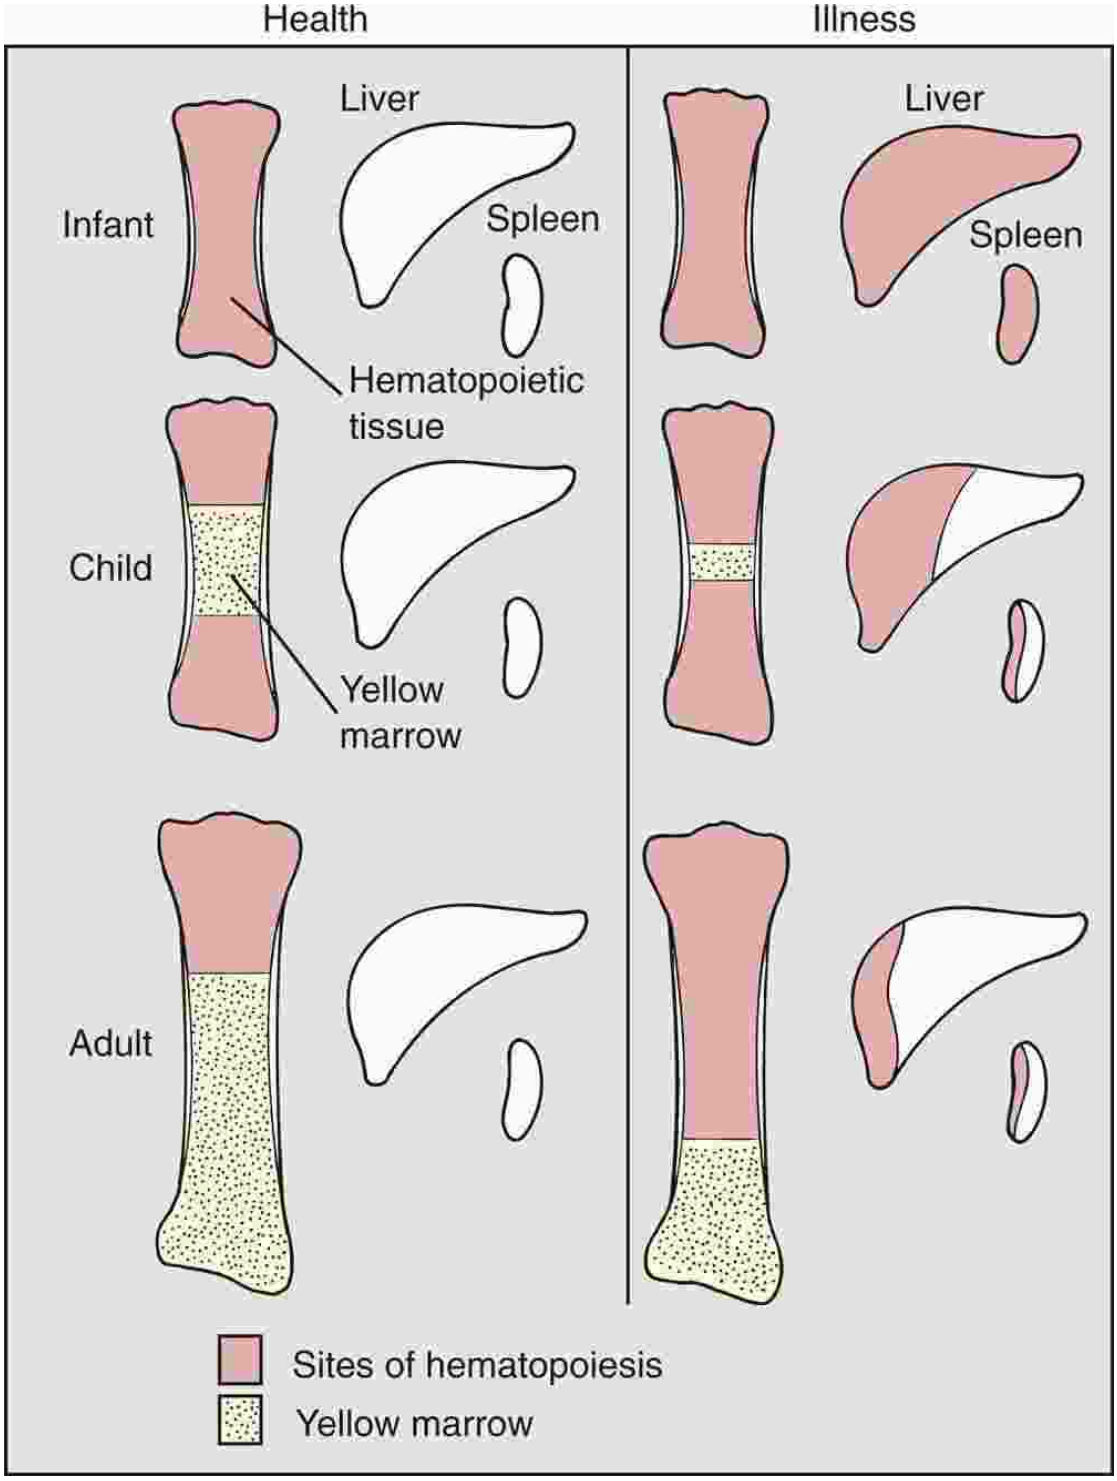

FIG. 30.1 Sites of Hematopoiesis in Health and Illness.
With normal maturation, red marrow is partly replaced by yellow marrow in the shafts of the long bones. In adults, red marrow is largely restricted to the proximal ends of the femur and humerus. In response to hemolysis, red marrow replaces yellow marrow in the long bones. In infants, whose long bones already are filled with red marrow, additional hematopoiesis takes place in the liver and spleen. In children and

adults, red marrow can replace yellow marrow in response to hemolysis, necessitating less hematopoiesis in the liver and spleen.

A series of illustration sets compare the sites of hematopoiesis in infant, child, and adult. Each illustration set shows a long bone, the liver, and the spleen. â€¢ Healthy infant: The entire bone comprises hematopoietic tissue. The liver and spleen are normal. â€¢ Sick infant: The bone, liver, and spleen comprise hematopoietic tissue. â€¢ Healthy child: The upper and lower segments of the bone comprise hematopoietic tissue. The central part of the bone comprises yellow marrow. The liver and spleen are normal. â€¢ Sick child: The yellow marrow in the bone is narrow, compared to that in the healthy child. Half the liver and half the spleen comprise hematopoietic tissue. â€¢ Healthy adult: Three-fourths of the bone comprises hematopoietic tissue. The liver and spleen are normal. â€¢ Sick adult: One-fourths of the bone comprises hematopoietic tissue. A very small segment of the liver and about half the spleen comprises hematopoietic tissue.

The erythrocytes undergo striking changes during gestation, particularly during the first two trimesters, at which time they nearly double in numbers and in hemoglobin content. A proportionate increase in hematocrit level also occurs. By the end of gestation, the erythrocyte count has more than tripled, but the size of each erythrocyte has decreased.

A biochemically distinct type of hemoglobin is synthesized during fetal life. The three **embryonic hemoglobin** molecules **(Gower 1, Gower 2, and Portland)** have different combinations of alpha, epsilon, zeta, and gamma chains, and **fetal hemoglobin (HbF)** molecules are composed of two α and two γ chains of polypeptides. Adult hemoglobin HbA_1 molecules are composed of two α chains and two β chains, and adult hemoglobin HbA_2 molecules are composed of 2 α chains and two δ chains. (The structure of an adult hemoglobin molecule is illustrated in Fig. 28.13 and types of hemoglobin are defined in Table 28.5). A transcriptional regulation mechanism promotes γ-chain synthesis and inhibits β- and δ-chain synthesis in utero. This results in production of embryonic or fetal hemoglobin. After birth, γ-chain synthesis is inhibited, whereas β- and δ-chain synthesis is facilitated, resulting in production of adult hemoglobin types.

Fetal hemoglobin has greater affinity for oxygen than does adult hemoglobin because it interacts less readily with an enzyme (2,3-diphosphoglycerate [2,3-DPG]) that inhibits hemoglobin-oxygen binding. The decreased inhibitory effects of 2,3-DPG enable fetal blood to transport oxygen despite the relative lack of oxygen in the intrauterine environment. The increased affinity for oxygen enables HbF to bind with maternal oxygen in the placental circulation.

During the first trimester, nearly all of the hemoglobin in the fetus is embryonic, but some HbA can be detected. Therefore, some disorders of adult hemoglobin, such as sickle cell anemia and thalassemia major, can be identified as early as 16 to 20 weeks of gestation. In the 6-month fetus, HbF constitutes 90% of the total hemoglobin. This percentage then declines. At birth, neonatal hemoglobin consists of 70% HbF, 29% HbA, and 1% HbA_2. Between 6 and 12 months of age, normal adult hemoglobin percentages are established (see Chapter 28).

Postnatal Changes in the Blood

Blood cell counts tend to rise to higher than adult levels at birth and then decline gradually throughout childhood. Table 30.1 lists normal ranges during infancy and childhood. The immediate rise in values is the result of the accelerated hematopoiesis during fetal life, the increased numbers of cells that result from the trauma of birth, and the cutting of the umbilical cord. These events surrounding the birth also

are accompanied by the presence of large numbers of immature erythrocytes and leukocytes (particularly granulocytes) in peripheral blood (see Chapter 28). As the infant develops over the first 2 to 3 months of life, the numbers of these immature blood cells decrease.

Table 30.1

Hematologic Values During Infancy and Childhood (US-Based Reference Values)

Age	Hemoglobin (g/dL) Range	Hematocrit (%) Range	Reticulocytes (%) Range	MCV (fl) Range	Leukocytes (WBC/mm^3) Range	Neutrophils (%) Range	Lymphocyte (%) Range
0–30 days	15.0–24.0	44–70	0.4–1.2	99–115	9.1–34.0	57–67	25–33

fl, Femtoliters; *MCV*, mean corpuscular volume; *WBC*, white blood cells.

From Kliegman RM, et al., eds. *Nelson textbook of pediatrics*, 21st edition. Philadelphia: Saunders; 2020.

Average blood volume in the full-term neonate is 85 mL/kg of body weight. The premature infant has a proportionately larger blood volume of 90 to 100 mL/kg of body weight. In both full-term and

premature infants, blood volume relative to body weight decreases during the first few months. By 3 years of age, a child's average blood volume is 75 to 77 mL/kg, which is similar to that of older children and adults.

Erythrocytes

The hypoxic intrauterine environment stimulates erythropoietin production in the fetus. This accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) of the newborn. After birth, the oxygen from the lungs saturates arterial blood, and the amount of oxygen delivered to the tissues increases. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease. The very active rate of fetal erythropoiesis is reflected by the large numbers of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. The number of reticulocytes decreases abruptly during the first few days after birth, which is associated with decreased erythropoietin production.[1] Finding an elevated reticulocyte count after the first week of life is rare. A decrease in extramedullary hematopoiesis also occurs at this time. In the peripheral blood, the erythrocyte count drops for 6 to 8 weeks after birth. During this period of rapid growth, the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, the normal erythrocyte life span is 60 to 80 days; in premature infants it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—120 days (see Mechanisms of hemolysis are described in Chapter 28).

In the premature infant, the postnatal decrease in hemoglobin and hematocrit values is more marked than in the full-term infant. In the preschool and school-age child, hemoglobin, hematocrit, and red blood cell (RBC) count values rise gradually. In males and females, these values first begin to diverge in adolescence. In the female, the gradual hemoglobin level increase continues into early puberty, at which time it stabilizes. In the male, the hemoglobin level increase keeps pace with growth and maturation and eventually surpasses that of the female. This higher value of hemoglobin level in the mature male is related to androgen secretion.

Metabolic processes within the erythrocytes of neonates differ significantly from those of erythrocytes in the normal adult. The relatively young population of erythrocytes in the newborn consumes more glucose than do erythrocytes in adults. Several enzymes that regulate glucose consumption are increased in the erythrocytes of neonates, with a subsequent increase in the rate of glycolysis.

Leukocytes and Platelets

The lymphocytes of children tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. The significance of these differences is unknown. One possible explanation is that children tend to have more frequent viral infections, which are associated with atypical lymphocytes. Even minor infections, in which the child fails to exhibit clinical manifestations of illness, or administration of immunizations may result in lymphocyte changes.[2]

The lymphocyte count is high at birth and continues to rise in some healthy infants during the first year of life. A steady decline occurs throughout childhood and adolescence until lower adult values are reached. Whether these developmental variations are physiologic or are a pathologic response to frequent viral infections and immunizations in children is not known.

In healthy neonates, the neutrophil count peaks 6 to 12 hours after birth and then declines over the next few days of life.[3] Neutrophil counts also are slightly higher in female neonates compared with males. After 2 weeks of life, neutrophil counts fall to within or below normal adult ranges. By approximately 4 years of age, the neutrophil count is similar to that of an adult. White children have slightly higher counts than black children.[4]

The eosinophil count is elevated in the first year of life relative to children, teenagers, or adults.[5,6] Monocyte counts are elevated through the preschool years and then decrease to adult levels. No relationship between age and basophil count has been found. Platelet counts in full-term neonates are comparable to platelet counts in adults and remain so throughout infancy and childhood.[5]

Disorders of Erythrocytes

Anemia is the most common blood disorder in children. Although anemia is not a disease state in and of itself, its presence may be associated with an underlying pathophysiologic process. Like anemia in adults, anemias occurring in children result from inadequate erythropoiesis or early destruction of erythrocytes. Iron deficiency is the most common cause of inadequate erythropoiesis. Iron deficiency can result from insufficient dietary intake or chronic loss of iron caused by bleeding. The **hemolytic anemias** of childhood are either inherited, acquired, or both. They may be divided into disorders that result from destruction caused by (1) intrinsic abnormalities of the erythrocytes and (2) damaging factors external to the erythrocytes.

The most dramatic form of acquired congenital hemolytic anemia is hemolytic disease of the fetus and newborn (HDFN), also termed *erythroblastosis fetalis*. HDFN is an alloimmune disorder in which the maternal blood and fetal blood are antigenically incompatible, causing the mother's immune system to produce antibodies against fetal erythrocytes. Fetal erythrocytes that have been bound to maternal antibodies are recognized as foreign or defective by the fetal mononuclear phagocyte system and are removed from the circulation by phagocytosis, usually in the fetal spleen. (For a complete discussion of HDFN, see Hemolytic Disease of the Fetus and Newborn.) Other acquired hemolytic anemias—some of which begin in utero—include those caused by infections or the presence of toxins.

The inherited forms of hemolytic anemia result from intrinsic defects of the child's erythrocytes, any of which can lead to erythrocyte destruction by the mononuclear phagocyte system. Structural defects include abnormal RBC size and abnormalities of plasma membrane structure (spherocytosis). Intracellular defects include enzyme deficiencies, the most common of which is **glucose-6-phosphate dehydrogenase (**G6PD) **deficiency**; and defects of hemoglobin synthesis, which manifest as sickle cell disease or thalassemia, depending on which component of hemoglobin is defective. These and other causes of childhood anemia, some more common than others, are listed in Table 30.2.

Table 30.2

Anemias of Childhood

Cause	Examples of Anemic Condition
Blood Loss	
Trauma Gastrointestinal lesion Parasitic infestation Hemorrhagic disease	Iron deficiency anemia
Decreased Red Cell Production or Hemoglobin Synthesis	
Decreased stem cell population in marrow (congenital or acquired pure red cell aplasia)	Normocytic-normochromic anemia
Decreased erythropoiesis despite normal stem cell population in marrow (infection, inflammation, cancer, chronic renal disease, congenital dyserythropoiesis)	Normocytic-normochromic anemia
Deficiency of a Factor or Nutrient Needed for Erythropoiesis	
Cobalamin (vitamin B_{12}), folate	Megaloblastic anemia
Iron	Microcytic-hypochromic anemia
Increased or Premature Hemolysis	
Alloimmune disease (maternal-fetal Rh, ABO, or minor blood group incompatibility)	Autoimmune hemolytic anemia
Autoimmune disease (idiopathic autoimmune hemolytic anemia, symptomatic systemic lupus erythematosus, lymphoma, drug-induced autoimmune processes)	Autoimmune hemolytic anemia
Inherited defects of plasma membrane structure (spherocytosis, elliptocytosis, stomatocytosis) or cellular size or both (pyknocytosis)	Hemolytic anemia
Infection (bacterial sepsis, congenital syphilis, malaria, cytomegalovirus infection, rubella, toxoplasmosis, disseminated herpes)	Hemolytic anemia
Intrinsic and inherited enzymatic defects (deficiencies) of G6PD, pyruvate kinase, 5′-nucleotidase, glucose phosphate isomerase	Hemolytic anemia
Inherited Defects of Hemoglobin Synthesis	
Structurally abnormal globins	Sickle cell anemia
Deficient globin synthesis	Thalassemia
Other Anemias	
Disseminated intravascular coagulation (see Chapter 29)	Hemolytic anemia

Cause	Examples of Anemic Condition
Galactosemia	Hemolytic anemia
Prolonged or recurrent respiratory or metabolic acidosis	Hemolytic anemia
Blood vessel disorders (cavernous hemangiomas, large vessel thrombus, renal artery stenosis, severe coarctation of aorta)	Hemolytic anemia

Cause	Examples of Anemic Condition
Blood Loss	
Trauma Gastrointestinal lesion Parasitic infestation Hemorrhagic disease	Iron deficiency anemia
Decreased Red Cell Production or Hemoglobin Synthesis	
Decreased stem cell population in marrow (congenital or acquired pure red cell aplasia)	Normocytic-normochromic anemia
Decreased erythropoiesis despite normal stem cell population in marrow (infection, inflammation, cancer, chronic renal disease, congenital dyserythropoiesis)	Normocytic-normochromic anemia
Deficiency of a Factor or Nutrient Needed for Erythropoiesis	
Cobalamin (vitamin B_{12}), folate	Megaloblastic anemia
Iron	Microcytic-hypochromic anemia
Increased or Premature Hemolysis	
Alloimmune disease (maternal-fetal Rh, ABO, or minor blood group incompatibility)	Autoimmune hemolytic anemia
Autoimmune disease (idiopathic autoimmune hemolytic anemia, symptomatic systemic lupus erythematosus, lymphoma, drug-induced autoimmune processes)	Autoimmune hemolytic anemia
Inherited defects of plasma membrane structure (spherocytosis, elliptocytosis, stomatocytosis) or cellular size or both (pyknocytosis)	Hemolytic anemia
Infection (bacterial sepsis, congenital syphilis, malaria, cytomegalovirus infection, rubella, toxoplasmosis, disseminated herpes)	Hemolytic anemia
Intrinsic and inherited enzymatic defects (deficiencies) of G6PD, pyruvate kinase, 5′-nucleotidase, glucose phosphate isomerase	Hemolytic anemia
Inherited Defects of Hemoglobin Synthesis	
Structurally abnormal globins	Sickle cell anemia
Deficient globin synthesis	Thalassemia
Other Anemias	
Disseminated intravascular coagulation (see Chapter 29)	Hemolytic anemia
Galactosemia	Hemolytic anemia
Prolonged or recurrent respiratory or metabolic acidosis	Hemolytic anemia
Blood vessel disorders (cavernous hemangiomas, large vessel thrombus, renal artery stenosis, severe coarctation of aorta)	Hemolytic anemia

ABO; Type A, type B, type O blood; *G6PD*; glucose-6-phosphate dehydrogenase.

Acquired Disorders

Iron Deficiency Anemia

IDA is the most common nutritional disorder worldwide, with the highest incidence occurring between 6 months and 2 years of age. Its prevalence in the United States is greatest among toddlers, adolescent girls, and women of childbearing age. Iron is *critical* to the developing child, especially for normal brain development. Without it, the damage from the periods of IDA is irreversible. The clinical manifestations of IDA are mostly related to inadequate hemoglobin synthesis. The incidence of IDA is not related to gender or race; however, socioeconomic factors are important because they affect nutrition.

IDA can result from (1) dietary lack of iron, (2) problems with iron absorption, (3) blood loss, and (4) increased requirement for iron. During the first few years of life, IDA most often results from inadequate iron intake. During childhood and adolescence, blood loss is the most common cause of IDA. Chronic IDA from occult (hidden) blood loss may be caused by a gastrointestinal lesion, parasitic infestation, or hemorrhagic disease. A reasonable hypothesis for infants and young children who develop IDA is that they have chronic intestinal blood loss induced by exposure to a heat-labile protein in cow's milk. Such exposure causes an inflammatory gastrointestinal reaction that damages the mucosa and results in diffuse microhemorrhage. Growing evidence indicates that cellular components of both innate and adaptive immunity play significant roles during the pathogenesis of cow's milk allergy.[7,8]

Dietary lack of iron is less common in developed countries, where iron is readily absorbed from heme found in meat. In developing countries, food may be less available. Although iron is found in plants, it is a more poorly absorbed form.[9] In the United States, rates of IDA have remained relatively unchanged over the past 10 years.[10] Infants are at increased risk for IDA because milk has only very small amounts of iron. The bioavailability of iron from breast milk, however, is higher than that from cow's milk. In developed countries, including the United States, excessive consumption of cow's milk remains an important predisposing factor for severe IDA.[11] Presently, only low-quality evidence for use of micronutrient powders in pregnant women and in the general population is available.[12,13] Impaired absorption is found in the context of chronic diarrhea, fat malabsorption, and celiac disease. Evidence also is emerging from international studies regarding genetic polymorphisms that may contribute to altered iron absorption in cases of refractory IDA with a familial component.[14,15]

Children in developing countries are often affected by chronic parasite infestations that result in blood and iron loss greater than dietary intake. However, a recent systematic review addressing outcomes of anti-helminthic treatments in adolescent girls and women failed to show an effect on anemia and iron deficiency.[16] Newer evidence is emerging related to a potential protective benefit of iron deficiency against malaria in parts of the world where malaria is endemic.[17] Additional research is needed to establish causality and to determine interventions to minimize adverse health consequences of IDA while maintaining the protective benefit. The association of IDA with lead (Pb) poisoning remains controversial. The role of *Helicobacter pylori* infection in relation to IDA is an area of ongoing investigation. While gastric colonization with *H. pylori* containing the sabA gene is associated with IDA, an understanding of its underlying pathophysiology is limited.[18]

Pathophysiology

No matter the cause, a deficiency of iron produces a hypochromic-microcytic anemia. In the early stages, however, the body may respond by increasing RBC activity in the bone marrow, which may temporarily prevent the development of anemia. As the body's iron stores are depleted, anemia develops (also see Chapter 29). Alterations in hepcidin have an essential role in diseases involving disturbances of iron metabolism (see Chapters 28 and 29). Low serum levels of ferritin and transferrin saturation lead to lowered hemoglobin and hematocrit levels (see Mechanisms of iron depletion are described in Chapter 29).

Clinical Manifestations

The symptoms of mild anemia—listlessness and fatigue—may go unnoticed in infants and young children, who are unable to describe these symptoms. Clinical indicators of anemia also are nonspecific, such as general irritability, decreased activity tolerance, weakness, and lack of interest in play, and may be attributed to other causes. As a result, parents may not note persistent changes in the child's behavior until moderate anemia has developed. In mild to moderate IDA (hemoglobin level of 6 to 10 g/dL),

compensatory mechanisms of tissue oxygenation, such as increased amounts of 2,3-DPG within erythrocytes and a shift of the oxyhemoglobin dissociation curve, may be so effective that few clinical manifestations are apparent. Other clinical manifestations, such as pallor, anorexia, tachycardia, and systolic murmurs, are often not present until hemoglobin levels fall below 5 g/dl.

Other symptoms and signs of chronic IDA include splenomegaly, widened skull sutures, decreased physical growth, developmental delays, *pica* (a behavior in which nonfood substances, such as clay or ice, are eaten). Weight is not necessarily an indicator of IDA because children may be obese, underweight, or normal weight. Consequences of IDA are significant and may include altered neurologic and intellectual function, especially involving attention span, alertness, and learning ability.

Evaluation and Treatment

The evaluation and treatment of IDA are similar in children and adults (see Chapter 29). The diagnosis of IDA is confirmed by laboratory tests. These tests include hemoglobin, hematocrit, serum iron, ferritin levels and the total iron binding capacity. Obtaining a thorough history of the child's present illness and dietary history and performing a complete physical examination also are essential to the evaluation and subsequent clinical management of IDA. Oral administration of a simple ferrous salt is usually sufficient. Taking iron supplements with a vitamin C source helps promote absorption.[19] If liquid iron supplements are used, they should be given with a straw or a dropper placed back on the tongue to prevent staining the teeth. Iron therapy is continued for at least 2 months after erythrocyte indexes have returned to normal to replenish iron stores.[20]

Dietary modification is required to prevent recurrences of IDA.

Intake of iron-rich foods is increased, and the intake of cow's milk may be restricted, with the exact amount restricted to 16 to 32 ounces per day depending on the child's age. Limiting milk intake makes the child hungrier for other iron-rich foods and prevents gastrointestinal blood loss in children whose anemia is aggravated or caused by inflammatory reactions to proteins in cow's milk.

Hemolytic Disease of the Fetus and Newborn

The most common cause of hemolytic anemia in newborns is alloimmune disease. **Hemolytic disease of the fetus and newborn (HDFN) (erythroblastosis fetalis)** can occur only if antigens on fetal erythrocytes differ from antigens on maternal erythrocytes. The antigens present on erythrocytes are determined genetically. They may be type A, B, or O, and they may or may not include Rh antigen D. Erythrocytes that express Rh antigen D are called Rh-positive; those that do not are called Rh-negative. The frequency of Rh negativity is higher in whites (15%) than in blacks (5%), and it is rare in Asians. Maternal-fetal incompatibility exists if mother and fetus differ in ABO blood type or if the fetus is Rh-positive and the mother is Rh-negative. (The antigenic properties of erythrocytes are described in Chapter 9).

Most cases of HDFN are caused by ABO incompatibility, which occurs if the mother and fetus have different ABO blood types. Although ABO incompatibility occurs in about 20% to 25% of all pregnancies, only 1 in 10 cases of ABO incompatibility results in HDFN. About 1 in 3 cases of HDFN is caused by Rh incompatibility, which occurs when the fetus is Rh-positive and the mother is Rh-negative. Rh incompatibility occurs in less than 10% of pregnancies and rarely causes HDFN in the first incompatible fetus. Typically, erythrocytes from the first incompatible fetus cause the mother's immune system to produce antibodies. These antibodies then can affect the fetuses of subsequent incompatible pregnancies. Even after five or more pregnancies, however, only 5% of women have babies with hemolytic disease. Some minor blood antigens also may be involved.

Pathophysiology

Three conditions must be present for HDFN to occur:

1. the mother's blood contains preformed antibodies against fetal erythrocytes or produces them when exposed to fetal erythrocytes,
2. sufficient amounts of antibody (usually immunoglobulin G [IgG] class) cross the placenta and enter fetal blood, and

3. IgG binds with sufficient numbers of fetal erythrocytes to cause widespread antibody-mediated hemolysis or splenic removal (antibody-mediated cellular destruction is described in Chapter 9).

In most cases of HDFN, the mother has blood type O, and the fetus has blood type A or B. Maternal antibodies may be formed against type B fetal erythrocytes if the mother has blood type A or against type A fetal erythrocytes if the mother has blood type B.

ABO incompatibility can cause HDFN even if fetal erythrocytes do not escape into the maternal circulation during pregnancy because the blood of most adults already contains anti-A or anti-B antibodies. These antibodies are produced on exposure to certain foods or infection by gram-negative bacteria. As a result, IgG against type A or B erythrocytes is usually already present in maternal blood and can enter the fetal circulation during the first incompatible pregnancy. Anti-O antibodies do not exist because type O erythrocytes are not antigenic.

Anti-Rh antibodies, on the other hand, form only in response to the presence of Rh-positive erythrocytes from the fetus in the blood of an Rh-negative mother. This exposure typically occurs when fetal blood is mixed with the mother's blood at the time of delivery. Exposure may also occur through transfused blood, and, rarely, previous sensitization of the mother by her own mother's incompatible blood.

The first Rh-incompatible pregnancy generally presents no difficulties for the fetus because few fetal erythrocytes cross the placental barrier during the pregnancy. When the placenta detaches at birth, many fetal erythrocytes often enter the mother's bloodstream. If the mother is Rh-negative and the fetus is Rh-positive, the mother produces anti-Rh antibodies. The capacity of the mother's immune system to produce anti-Rh antibodies depends on many factors, including her genetic capacity to make antibodies against the Rh antigen D, the amount of fetal-to-maternal bleeding, and the occurrence of any bleeding earlier in the pregnancy. These anti-Rh antibodies persist in the mother's bloodstream for a long time. If the next offspring is Rh-positive, the mother's anti-Rh antibodies can enter the bloodstream of the fetus and destroy the erythrocytes. Antibodies against Rh antigen D are of the IgG class and easily cross the placenta.

Antibody-coated fetal erythrocytes are usually destroyed through extravascular hemolysis, primarily by phagocytic cells in the spleen. As hemolysis proceeds, the fetus becomes anemic. Erythropoiesis accelerates, particularly in the liver and spleen. Immature nucleated cells (erythroblasts) are released into the bloodstream, hence the name ***erythroblastosis fetalis***. The degree of anemia depends on several factors: (1) the length of time the antibody has been in the fetal circulation, (2) the concentration of the antibody, and (3) the ability of the fetus to compensate for increased hemolysis. During the pregnancy, unconjugated (indirect) bilirubin, which forms during the breakdown of hemoglobin, is transported across the placental barrier into the maternal circulation and is excreted by the mother. **Hyperbilirubinemia**, an increase in bilirubin concentration in the blood occurs in the neonate shortly after birth because lipid-soluble unconjugated bilirubin is no longer excreted through the placenta.

HDFN is typically more severe in Rh incompatibility than in ABO incompatibility. ABO incompatibility may resolve after birth without life-threatening complications. Maternal-fetal incompatibility in which a mother with type O blood has a child with type A or B blood usually is so mild that it does not require treatment.

Rh incompatibility is more likely to result in severe or even life-threatening anemia, death in utero, or damage to the central nervous system (CNS). Severe anemia alone can cause death because of cardiovascular complications. Extensive hemolysis can result in increased levels of unconjugated bilirubin in the neonate's circulation. If bilirubin levels exceed the liver's ability to conjugate and excrete bilirubin, it can be deposited in the brain, a condition known as **kernicterus**, causing cellular damage and, eventually, death if the neonate does not receive exchange transfusions.

Fetuses that do not survive anemia in utero are usually stillborn with gross edema in the entire body, a condition called **hydrops fetalis**. Death can occur as early as 17 weeks' gestation and results in spontaneous abortion.

Clinical Manifestations

Neonates with mild HDFN may appear healthy or slightly pale, with slight enlargement of the liver or spleen. Pronounced pallor, splenomegaly, and hepatomegaly indicate severe anemia, which predisposes

the neonate to cardiovascular failure and shock. Life-threatening symptoms as a consequence of Rh incompatibility, however, are rare, largely because of the routine use of Rh immunoglobulin.

Because the maternal antibodies remain in the neonate's circulatory system after birth, erythrocyte destruction can continue causing hyperbilirubinemia and **icterus neonatorum (neonatal jaundice)** that occurs shortly after birth. Without replacement transfusions, in which the child receives Rh-negative erythrocytes, the bilirubin can be deposited in the brain, causing a condition termed **kernicterus**. If kernicterus develops, it can cause cerebral damage, including intellectual disabilities, cerebral palsy, high-frequency deafness, and even death (**icterus gravis neonatorum**).[21]

Evaluation and Treatment

Fetuses and neonates with ABO incompatibility typically do not require additional monitoring or treatment. Fetuses and infants at risk for HDFN because of Rh incompatibility may require additional monitoring and treatment. Routine evaluation of fetuses at risk for HDFN includes the Coombs test. The indirect Coombs test measures antibody in the mother's circulation and indicates whether the fetus is at risk for HDFN. The direct Coombs test measures antibody already bound to the surfaces of fetal erythrocytes. It is used primarily to confirm the diagnosis of antibody-mediated HDFN. If a prior history of fetal hemolytic disease is present, additional diagnostic tests are done to determine risk with the current pregnancy. These include maternal antibody titers, fetal blood sampling, amniotic fluid spectrophotometry, and ultrasound fetal assessment.[22]

Prevention is the key to managing HDFN that results from Rh incompatibility. Immunoprophylaxis through the use of Rh immune globulin (RhoGAM), a preparation of antibody against Rh antigen D (anti-D Ig), prevents an Rh-negative woman from producing antibodies. If an Rh-negative woman is given Rh immune globulin within 72 hours of exposure to Rh-positive erythrocytes, she will not produce antibody against the D antigen. As a result, the next Rh-positive baby she conceives will be protected. Updated United States and United Kingdom guidelines also state that if anti-D Ig is not given within 72 hours, every effort should be made to administer it within 10 days.[23,24]

The injected (anti-D Ig) antibodies remain in the mother's bloodstream long enough to prevent her immune system from producing its own anti-Rh antibodies but not long enough to affect subsequent offspring. The mother must be given Rh immune globulin injections after the birth of each Rh-positive baby and after a miscarriage. The mother also must be especially careful not to receive a transfusion containing Rh-positive blood because this would stimulate production of anti-Rh antibodies.

If antigenic incompatibility of the mother's erythrocytes is not discovered in time to administer Rh immune globulin and a child is born with HDFN, treatment consists of exchange transfusions in which the neonate's blood is replaced with new Rh-positive blood that is not contaminated with anti-Rh antibodies. This treatment is instituted during the first 24 hours of extrauterine life to prevent kernicterus. Phototherapy also is used to reduce the toxic effects of unconjugated bilirubin.

Jaundice and indirect hyperbilirubinemia are reduced when the infant is exposed to high-intensity light in the visible spectrum from 460 to 490 nm.[25] Bilirubin in the skin absorbs light energy, which converts the toxic unconjugated bilirubin into its conjugated water-soluble form that is excreted in the bile. Phototherapy also causes autosensitization that results in oxidation reactions. Breakdown products from the oxidation reactions are excreted by the liver and kidney without need for conjugation. The therapeutic effect of phototherapy depends on the light energy emitted in the effective wavelengths, the distance between the infant and the light source, and the amount of skin exposed. The rate of hemolysis and the infant's ability to excrete bilirubin also are factors in determining the effectiveness of phototherapy in lowering serum bilirubin levels.

Anemia of Infectious Disease

Infections of the newborn, often initially acquired by the mother and transmitted to the fetus, may result in a hemolytic anemia with clinical manifestations similar to those of HDFN. Congenital syphilis, toxoplasmosis, cytomegalic inclusion disease, rubella, coxsackievirus B infection, herpesvirus infection, and bacterial sepsis can cause hemolytic anemia in the neonate.

The exact mechanism of anemia caused by congenital infections is unclear. In some instances, it is related to direct injury of erythrocyte membranes or erythrocyte precursors by the infectious

microorganism. In other instances, it results from traumatic destruction of erythrocytes during their passage through inflamed capillaries.

Anemia in Critically Ill Children

Anemia is a common occurrence in critically ill children (see Chapter 49). The causes are numerous and include decreased erythropoietin activity, poor iron use by the body, and blood loss from diverse conditions and consequences of treatment. A topic of ongoing discussion is whether transfusion of blood products, particularly packed RBCs, improves outcomes in critically ill children because of problems related to blood storage. New research is ongoing and needed to understand these problems, the development of new blood transfusion strategies, and blood substitutes.[26]

Inherited Disorders

A number of inherited and intrinsic erythrocyte conditions are known to cause hemolytic disease or increased hemolysis (see Table 30.2). These conditions may result from enzymatic abnormalities that disrupt metabolic processes and prevent normal biochemical balance within the cell, alterations of hemoglobin structure or synthesis, or plasma membrane defects accompanied by changes in erythrocyte size or shape.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited disorder caused by a genetic defect in the RBC enzyme G6PD, which is involved in the normal processing of carbohydrates. It is the most common disorder of RBCs, estimated to affect 200 to 400 million people worldwide. The deficiency occurs most often in tropical and subtropical regions of the Eastern Hemisphere including the Mediterranean region, Africa, the Middle East, and Asia. G6PD deficiency is an X-linked recessive disorder, most fully expressed in homozygous males, although partial expression is possible in heterozygous females because of mosaicism resulting from X-inactivation. (X-linked inheritance is discussed in Chapter 4). More than 200 mutations have been identified in the G6PD gene, almost all of which result in changes in single amino acids. The consequences of these mutations are decreased quantities of the G6PD enzyme or an enzyme with abnormal structure and function. The type of mutation that is present will determine the degree of deficiency and the associated clinical manifestations.[27]

G6PD is responsible for the first step in a pathway that converts glucose to ribose-5-phosphate. These initial chemical reactions usually produce another enzyme, nicotinamide adenine dinucleotide phosphate (NADPH), which helps protect cells from oxidative stress from reactive oxygen species. The deficiency of G6PD leads to damaged RBCs that can hemolyze, or rupture and break down prematurely.

Pathophysiology

G6PD enables erythrocytes to maintain normal metabolic processes despite injury from oxidative stressors. As a result, G6PD deficiency is usually asymptomatic unless exposure to a source of oxidative stress occurs. Deficient or abnormal enzyme function can cause abnormalities in the hexose monophosphate shunt or glutathione metabolism that impairs the ability of RBCs to protect themselves against oxidative stress injuries. Such injury can cause both an intravascular and an extravascular hemolysis. Sources of oxidative stress include exposure to certain classes of drugs (sulfonamides, nitrofurantoins, antimalarial agents, salicylates, or naphthaquinolones), ingestion of fava beans (a dietary staple in some Mediterranean areas and parts of Africa), hypoxemia, fever, acidosis, or infection. Infections associated with initiation of hemolysis include viral hepatitis, pneumonia, and typhoid fever. Erythrocyte damage in affected children begins after intense or prolonged exposure to one or more sources of oxidative stress and ceases when the stressors are removed. In black males, the G6PD defect becomes more pronounced as the erythrocyte ages. In other population groups the defect is profound even in young erythrocytes. A fetus with G6PD deficiency may experience an episode of hemolysis if the mother ingests a substance with oxidant properties, such as a salicylate (aspirin).

In the absence of G6PD, oxidative stressors damage hemoglobin and the plasma membranes of erythrocytes and possibly interfere with the activities of other enzymes within the cell. Hemoglobin is oxidized progressively to methemoglobin, sulfmethemoglobin, and denatured globin-glutathione complexes. Exposure to oxidizing substances results in the precipitation of insoluble hemoglobin inclusions, called *Heinz bodies*, within the cell. Plasma membrane damage and the presence of Heinz bodies cause hemolysis, primarily in the spleen.

Clinical Manifestations

In infants, G6PD deficiency may present as icterus neonatorum. The most common clinical manifestation of G6PD deficiency is acute hemolytic anemia, usually after infections or the ingestion of certain oxidative drugs or foods. Ingestion of fava beans can produce a severe hemolytic reaction in children with G6PD deficiency.

Hemolytic episodes are characterized by pallor, icterus, dark urine, back pain, and, in severe cases, shock, cardiovascular collapse, and death. When the child is not exposed to sources of oxidative stress, the child does not have anemia, and erythrocyte survival is normal.

Evaluation and Treatment

Reduced G6PD activity in erythrocytes is required for diagnosis. Immediately after a hemolytic episode, reticulocytes and young erythrocytes are evident. Because young erythrocytes have significantly higher enzyme activity than do older cells, laboratory evaluation should not be performed after a crisis. Doing so can result in a low to normal range, a false-negative result. Testing for suspected G6PD deficiency should be done when hemoglobin and reticulocytes are normal. G6PD deficiency also can be detected by electrophoretic analysis.

Prevention of hemolysis is the most important therapeutic measure. Prevention includes avoiding medications and dietary substances associated with hemolysis. Because of the high frequency of G6PD deficiency in areas of the world that are endemic for malaria, the World Health Organization (WHO) currently recommends testing for G6PD deficiency before administration of antimalarial medications in these regions.[28] When hemolysis occurs, supportive treatment may include blood transfusions and oral iron therapy. Spontaneous recovery generally follows treatment.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is an inherited disorder caused by defects in the membrane skeleton of RBCs. The changes cause RBCs to become spherical, less deformable, and vulnerable to destruction. Mutations in at least five genes that produce proteins necessary for the RBC membrane (*ANK1, EPB42, SLC4A1, SPTA1*, and *SPTB*) result in the HS phenotype. Proteins produced by these genes act as transporters for molecules in and out of the cells, attach to other proteins, and maintain the RBC's biconcave disc shape. Thus, these proteins help the cells to be flexible for RBC mobility from large blood vessels to capillaries. Altered RBC cell membranes result in a more rigid and spherical cell shape. These misshapen cells, or **spherocytes**, are vulnerable to destruction or hemolysis particularly in the splenic vessels. Ultimately, these damaged cells are removed from circulation in the spleen.

Pathophysiology

HS is transmitted as an autosomal dominant trait in about 75% of cases. The defect results from properties of its specialized membrane skeleton, which lies close to the internal surface of the plasma membrane. The affected proteins include spectrins and ankyrin, and their intrinsic defects in the membrane cause less deformability and increased vulnerability to splenic sequestration and destruction.

The spleen is intimately involved in the hemolytic process. The spherocyte is relatively rigid and passes with difficulty through the small openings between the splenic cords and sinuses initiating macrophage response. Circulation of blood to the spleen creates repeated circulation through a metabolic environment that results in sequestration and destruction of spherocytes.

Clinical Manifestations

The presenting signs of HS are anemia, jaundice, and splenomegaly, which can be mild to severe depending on the individual's physiologic compensation. In these cases, the reticulocyte count will be elevated. In infancy, hemolytic anemia and hyperbilirubinemia may be severe.[29] Infants and children may have life-threatening anemia with clinical symptoms ranging from difficulty feeding, circumoral pallor, tachycardia, nasal flaring, and diaphoresis to lethargy. They also are at increased risk for gallstones because of the presence of extra bile pigment from hemolysis. Infection (specifically parvovirus),[30] fever, and stress stimulate the spleen to destroy more RBCs than usual, leading to a worsening anemia in a child with baseline anemia. The parvovirus also infects erythroid progenitor cells in the bone marrow resulting in an aplastic crisis.[31]

Evaluation and Treatment

Ascertaining a family history of spherocytosis is important. Laboratory findings include spherocytes in the peripheral blood smear *(spherocytosis)*, elevated reticulocyte count (with or without anemia), indirect hyperbilirubinemia, and a positive osmotic fragility test. An osmotic fragility test is performed by placing RBCs in a saline solution for 24 hours. Spherocytes do not tolerate saline solutions; as a result, they burst more readily than normal RBCs. In addition, flow cytometry can detect reductions in RBC transmembrane proteins. Band 3 Protein Reduction testing can confirm the diagnosis of HS. Treatment of HS is based on disease severity and some children or adolescents may require RBC transfusions; however, this is somewhat rare. Management includes regular monitoring for anemia and splenomegaly. Daily folic acid supplementation supports the increased production of healthy RBCs. In the past, splenectomy was the first line of treatment. Currently, however, splenectomy is only recommended for those children more than 5 years of age with severe anemia or splenomegaly. Some children who develop gallstones may undergo splenectomy and cholecystectomy. Partial splenectomy, in which only a portion of the spleen is removed, is being performed on children with HS to decrease the risk of postsplenectomy complications.[31]

Sickle Cell Disease

Sickle cell disease is a group of autosomal recessive disorders characterized by the production of an atypical type of hemoglobin, **hemoglobin S (HbS; sickle hemoglobin)** within the erythrocytes. The hemoglobin molecule consists of four protein subunits called α-globin and two subunits called β-globin. The hemoglobin B *(HbB)* gene provides instructions for making protein β-globin. HbS is formed as a result of a genetic point mutation (missense mutation) in β**-globin** in which one amino acid (valine) replaces another (glutamic acid) (Fig. 30.2**)**. Abnormal versions of β-globin can cause erythrocytes to distort into a sickle shape. Other mutations in the *HbB* gene lead to other versions of β-globin, such as hemoglobin C (HbC) and hemoglobin E (HbE). *HbB* gene mutations also can affect the quantity of β-globin, such as low levels of β-globin found in β-thalassemia.

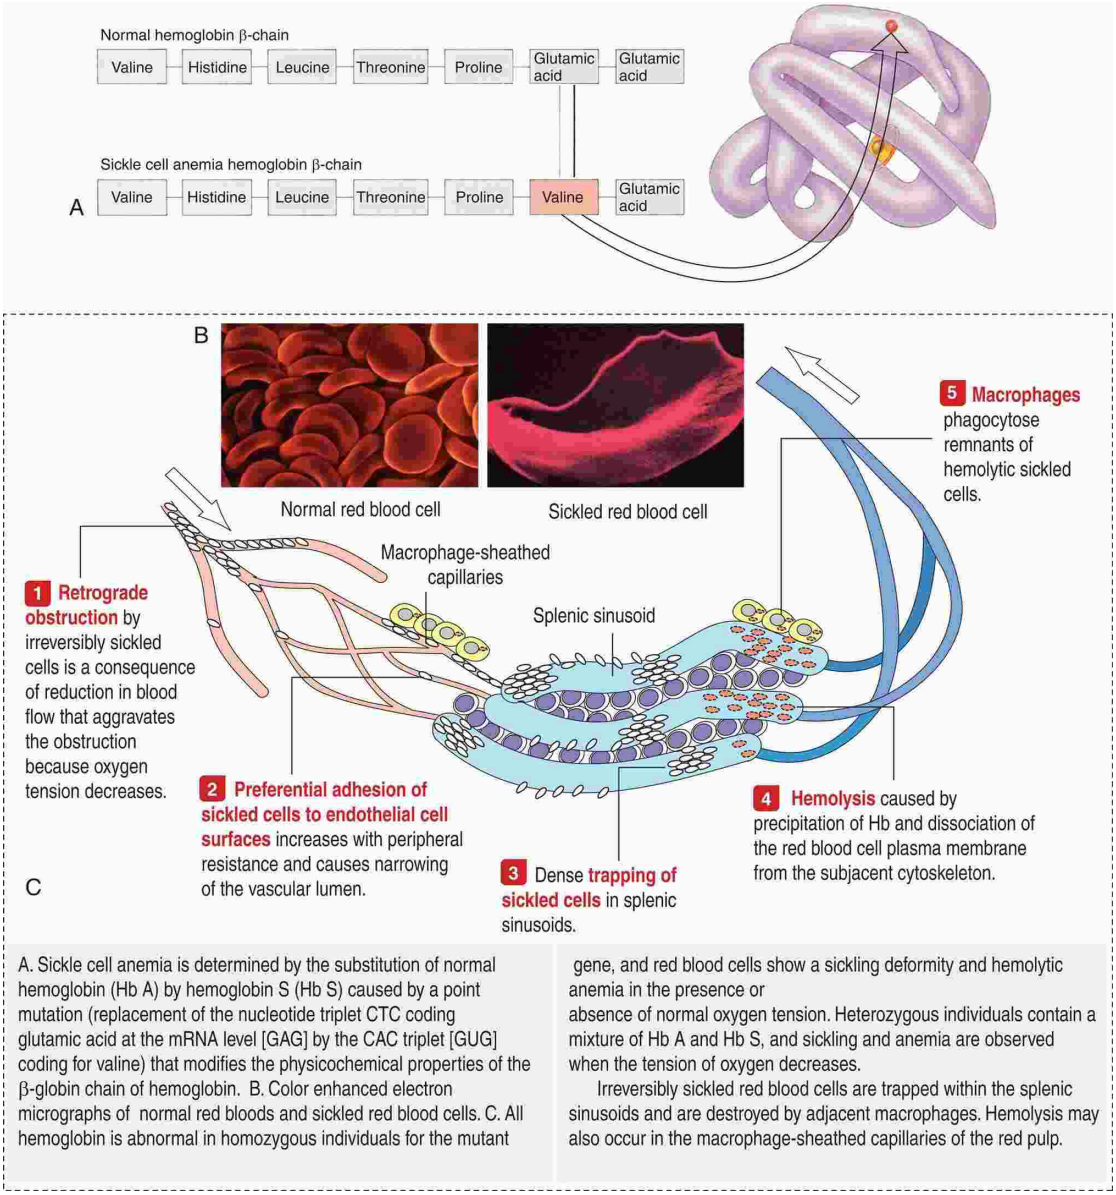

FIG. 30.2 Brief Summary of Sickle Cell. (From Kierzenbaum AL, Tres LL. *Histology and cell biology: An introduction to pathology*, 4th edition. Philadelphia: Saunders; 2015.)

Top panel, A. The illustration shows the structure of a normal hemoglobin beta-chain and a sickle cell anemia hemoglobin beta-chain. The normal hemoglobin beta-chain shows the following sequence: valine, histidine, leucine, threonine, proline, glutamic acid, and glutamic acid. The sickle cell anemia hemoglobin beta-chain shows the following sequence: valine, histidine, leucine, threonine, proline, valine, and glutamic acid. Bottom panel, B. Two adjacent photomicrographs show a cluster of normal red blood cells on the left and a sickle red blood cell on the right. An accompanying illustration, C, shows and labels the following structures: macrophage-sheathed capillaries and splenic sinusoid. The sequence of mechanisms is as follows. 1. Retrograde obstruction

by irreversibly sickled cells is a consequence of reduction in blood flow that aggravates the obstruction because oxygen tension decreases. 2. Preferential adhesion of sickled cells to endothelial cell surfaces increases with peripheral resistance and causes narrowing of the vascular lumen. 3. Dense trapping of sickled cells in splenic sinusoids. 4. Hemolysis caused by precipitation of Hb and dissociation of the red blood cell plasma membrane from the subjacent cytoskeleton. 5. Macrophages phagocytose remnants of hemolytic sickled cells. Blood flows from the left to the right. Text below reads as follows. Sickle cell anemia is determined by the substitution of normal hemoglobin (H b A) by hemoglobin S (H b S) caused by a point mutation (replacement of the nucleotide triplet C T C coding glutamic acid at the m R N A level [G A G] by the C A C triplet [G U G] coding for valine) that modifies the physicochemical properties of the beta¬-globin chain of hemoglobin. All hemoglobin is abnormal in homozygous individuals for the mutant gene, and red blood cells show a sickling deformity and hemolytic anemia in the presence or absence of normal oxygen tension. Heterozygous individuals contain a mixture of H b A and H b S, and sickling and anemia are observed when the tension of oxygen decreases. Irreversibly sickled red blood cells are trapped within the splenic sinusoids and are destroyed by adjacent macrophages. Hemolysis may also occur in the macrophage-sheathed capillaries of the red pulp.

The most prevalent types of sickle cell disease are sickle cell anemia, sickle cell–thalassemia disease, and sickle cell–HbC disease (Table 30.3). (See Chapter 4 for a discussion of genetic inheritance of disease.) SCD is inherited in an autosomal recessive pattern in which each parent carries one copy of the mutated gene. **Sickle cell anemia (SCA; HbSS)**, a homozygous form, is the most severe.[32] The most prevalent SCD genotypes include homozygous hemoglobin SS (HbSS, or sickle cell anemia) and the compound heterozygous conditions hemoglobin Sβ^0-thalassemia (Hbβ^0-thalassemia), hemoglobin Sβ-thalassemia (HbSβ^+-thalassemia), and hemoglobin SC disease (HbSC).[33] HbSS and HbSβ^0-thalassemia are clinically similar and are, therefore, commonly referred to as *sickle cell anemia (SCA);* these genotypes are associated with the most severe clinical manifestations. **Sickle cell trait (HbAS)**, in which the child inherits HbS from one parent and normal hemoglobin (HbA) from the other. This heterozygous carrier state rarely has clinical manifestations and is not regarded as a form of SCD. All forms of SCD are lifelong conditions.[34]

Table 30.3

Inheritance of Sickle Cell Disease

Hemoglobin Inherited From First Parent	Hemoglobin Inherited From Second Parent	Form of Sickle Cell Disease in Child
HbS (an abnormal hemoglobin)	HbS	Sickle cell anemia: homozygous inheritance in which child's hemoglobin is mostly HbS, with remainder HbF (fetal hemoglobin)
HbS	Defective or insufficient α- or β-chains of HbA (alpha- or beta-thalassemia)	Sickle cell–thalassemia disease (heterozygous inheritance of HbS and alpha- or beta-thalassemia)
HbS	HbC or D (both abnormal hemoglobins)	Sickle cell–hemoglobin C (or D) disease (heterozygous inheritance of hemoglobin S and either C or D)
HbS	Normal hemoglobins (mostly HbA)	Sickle cell trait, carrier state (heterozygous inheritance of HbS and normal hemoglobin)

Sickle cell disease affects millions of people worldwide and is most common among persons with ancestry from sub-Saharan Africa. Although less common, it also is present among individuals with ancestry from Mediterranean countries, the Arabian Peninsula, parts of India, and Spanish-speaking areas of South America. Approximately 100,000 individuals living in the United States have SCD,[33] and most infants with SCD born in the United States are now identified by routine neonatal screening. In the United States, sickle cell anemia is most common in black people, with a reported incidence of around 1 in 365 live births.[33] In the general population, the risk of two black parents having a child with sickle cell anemia is 0.7%. Sickle cell–HbC disease occurs in 1 in 800 births, and sickle cell–thalassemia is even less common (1 in 1700 births).

Between 1 and 3 million Americans and more than 100 million individuals worldwide are estimated to be heterozygous carriers for the sickle cell trait (HbAS).[34] Sickle cell trait is present in 7% to 13% of African Americans. Its prevalence in African countries, such as Nigeria and the Democratic Republic of Congo, may be as high as 30%.[35] The sickle cell trait may provide protection against lethal forms of malaria. This results in a genetic advantage for carriers who reside in regions of the world that are endemic for malaria, such as sub-Saharan Africa and some Mediterranean countries.

Under conditions of decreased oxygen tension and dehydration, HbS stretches and elongates. Repeated cycles of deoxygenation and oxygenation cause the HbS molecule to polymerize and stiffen. These polymers can damage the RBC structure, leading to sickle-shaped RBCs. This change causes several pathologic consequences: the sickle-shaped RBCs die prematurely leading to hemolytic anemia, microvascular obstruction, and ischemic tissue damage (Fig. 30.3).

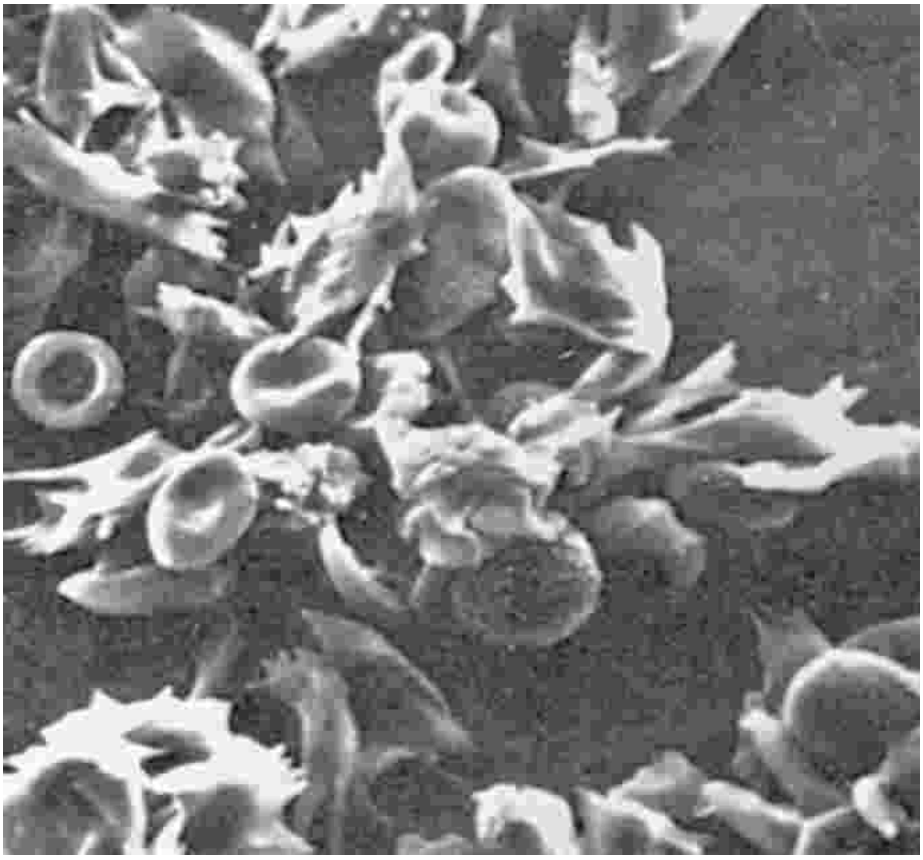

FIG. 30.3 Scanning Electron Micrograph of Normal and Sickle-Shaped Red Blood Cells Together.
The irregularly shaped cells are the sickle cells; the circular cells are the normal blood cells. (From Raven PH, Johnson GB. *Biology*, 3rd edition. St. Louis: Mosby; 1992.)

Two effective disease therapies for SCD are hydroxyurea and chronic transfusion.[32] The role of curative treatments including hematopoietic stem cell transplantation (HSCT) and gene therapy (GT) for SCD are increasing. See Emerging Science Box: Gene Therapy for Sickle Cell. Although data are encouraging, additional studies are needed to assess efficacy and long-term outcomes.[36]

Pathophysiology

The sickling process is an occasional, intermittent phenomenon that can be triggered or sustained by one or more of the following stressors: decreased oxygen tension (PO_2) of the blood (e.g., hypoxemia), acidosis (decreased pH), increased plasma osmolality, decreased plasma volume, and low temperature (Fig. 30.4). Low temperatures can precipitate sickle crisis, presumably because of vasoconstriction.[37]

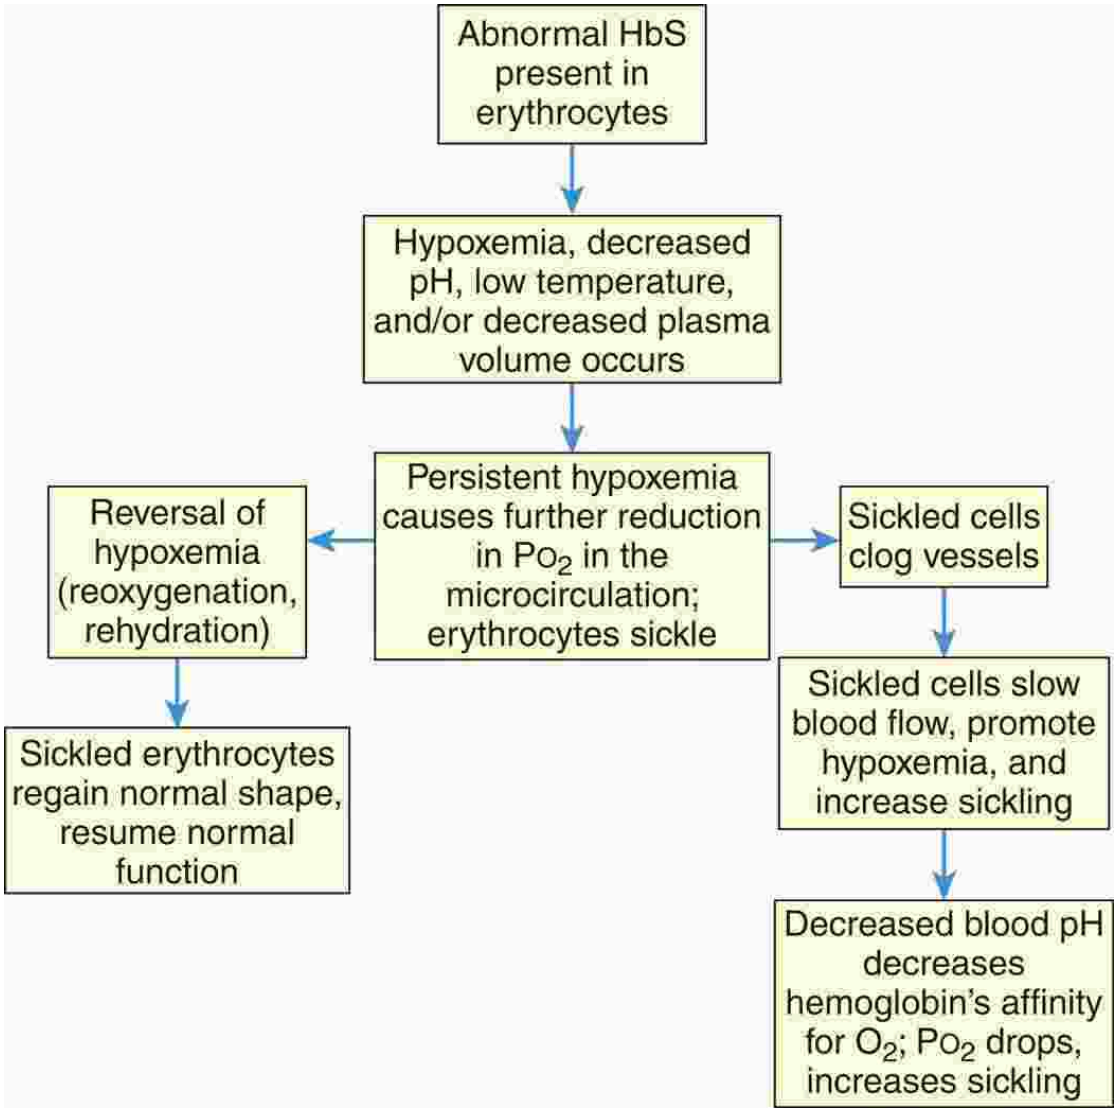

FIG. 30.4 Sickling of Erythrocytes.

A flowchart shows the sequence of sickling of erythrocytes. 1. Abnormal H b S present in erythrocytes. Leads to 2. 2. Hypoxemia, decreased p H, low temperature, and or decreased plasma volume occurs. Leads to 3. 3. Persistent hypoxemia causes further reduction in partial pressure of oxygen in the microcirculation; erythrocytes sickle. Leads to 4 and 6. 4. Reversal of hypoxemia (reoxygenation, rehydration). Leads to 5. 5. Sickled erythrocytes regain normal shape, resume normal function. 6. Sickled cells clog vessels. Leads to 7. 7. Sickled cells slow blood flow, promote hypoxemia, and increase sickling. Leads to 8. 8. Decreased blood p H decreases hemoglobin's affinity for oxygen; partial pressure of oxygen drops, increases sickling.

The pathophysiology of the sickling process includes erythrocyte derangement, chronic hemolysis (hemolytic anemia), microvascular occlusions, and tissue damage. HbS is soluble and usually causes no

problem when it is properly oxygenated; therefore, deoxygenation is probably the most important variable in determining the occurrence of sickling. Other significant variables that affect sickling include interaction of HbS with other types of hemoglobin in the cell, mean cell hemoglobin concentration (MCHC), intracellular pH, and transit times of erythrocytes through the microcirculation. Among individuals who are heterozygous for sickle cell trait, the presence of other types of Hb prevents sickling except under conditions of severe hypoxia.

As the sickling process begins, intracellular dehydration increases the MCHC, which increases sickling. A decrease in pH reduces the oxygen affinity of hemoglobin, resulting in a further increase in the quantity of deoxygenated HbS regardless of the oxygen tension. These changes, in turn, increase the sickling process. Inflammation in the microcirculation will slow erythrocyte transit times because blood flow is sluggish with adhesion of leukocytes to activated endothelial cells. Increased osmolality of the plasma draws water out of the erythrocytes. The result is sickling by raising the relative HbS content in erythrocytes. Investigators are studying the optimal intravenous fluid to increase erythrocyte deformability and biomechanical properties.[38]

Sickling causes damage to erythrocytes through several mechanisms, including (1) *membrane derangements* occur because as HbS units (polymers) grow they protrude through the membrane skeleton by only the lipid layer, causing changes in membrane structure: (2) membrane derangement leads to *changes in ionic flow* with an influx in Ca^{++} ions, which induces cross-linking of membrane proteins and activation of an ion channel that induces the efflux of K^+ and H_2O; and (3) with time the damaged *cells are converted to end-stage*, nondeformable or stiff and irreversibly sickled cells (Fig. 30.5). Recent studies have shown that elevated red cell levels of the enzyme *sphingosine kinase 1 (SPH1)* underlie sickling and disease progression by increasing *sphingosine 1-phosphate (S1P)* production in the blood.[39,40]**S1P level**, a bioactive lipid enriched in red cells, is elevated in red cells and plasma of mice and humans with SCD.[40] S1P also is a signaling molecule that regulates diverse biologic functions including inflammation.[41] Additionally, investigators demonstrated that the compound 5 C can inhibit *SPHK1* and, thus, has antisickling properties.[42] These data are important for identifying the structure of the sickling process to assess potential new therapeutics.

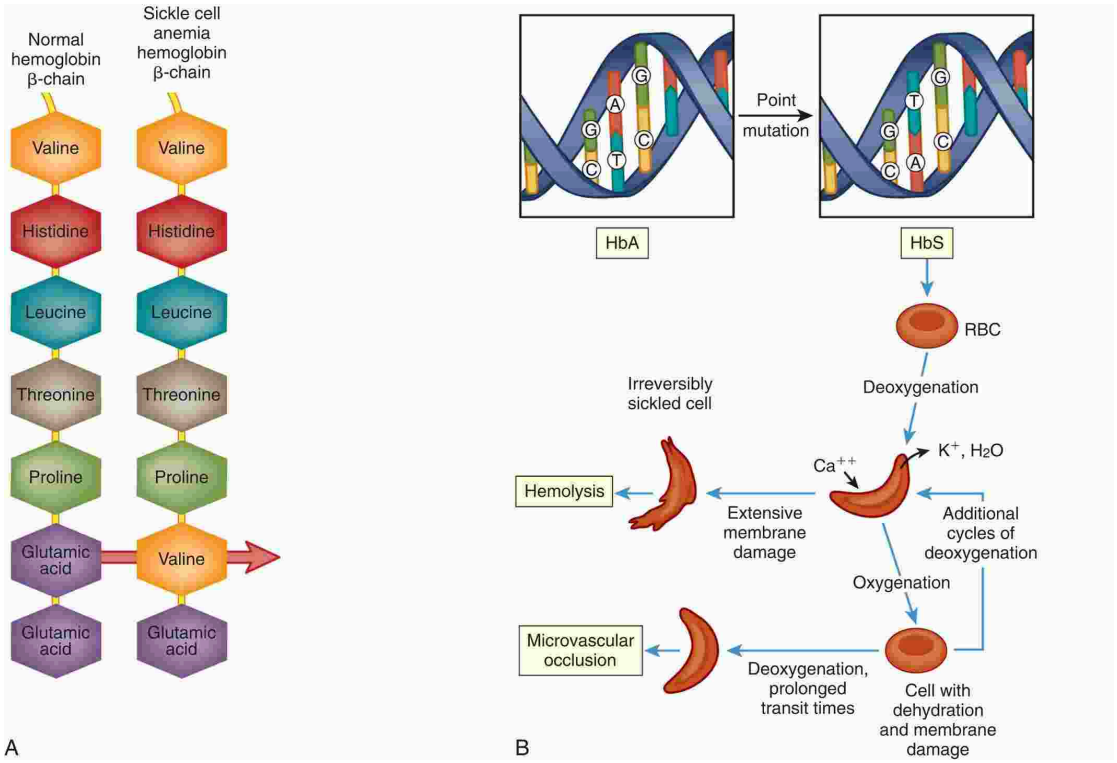

FIG. 30.5 Sickle Cell Disease Pathogenesis.
See text for discussion. (A and B, Adapted from Kumar V, Abbas AK, Aster JC. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Elsevier Saunders; 2015.)

Left panel, A. The illustration shows a normal hemoglobin beta-chain and sickle cell anemia hemoglobin beta-chain. The normal hemoglobin beta-chain shows the following sequence: valine, histidine, leucine, threonine, proline, glutamic acid, and glutamic acid. The sickle cell anemia hemoglobin beta-chain shows the following sequence: valine, histidine, leucine, threonine, proline, valine, and glutamic acid. Right panel, B. The illustration shows the point mutation of H b A to H b S in a D N A helical structure with G C, T A, and G C. The sequence of pathogenesis is as follows. â€¢ R B C undergoes deoxygenation. â€¢ Cell absorbs calcium ions and releases potassium ions and water. â€¢ Hemolysis: Deoxygenated cell undergoes extensive membrane damage and becomes an irreversibly sickled cell. â€¢ Microvascular occlusion: Deoxygenated cell undergoes oxygenation and becomes cell with dehydration and membrane damage. Deoxygenation and prolonged transit times of dehydrated cell results in microvascular occlusion. â€¢ Cyclic mechanism: Deoxygenated cell undergoes oxygenation resulting in a dehydrated cell. Dehydrated cell undergoes additional cycles of deoxygenation.

Some cells remain sickled even with full oxygenation and are vulnerable to hemolysis. Polymerization of sickled hemoglobin is central to the disorder. **Polymerization** stiffens the sickled erythrocyte, changing it from a flexible, beneficial cell to an inflexible one where HbS molecules stack into polymers

that starve and damage tissues. The pathogenesis of SCD derives from the tendency of HbS molecules to stack into polymers even when deoxygenated and assemble into needle-like fibers within cells, producing the distorted crescent-like sickle or holly-leaf shape (see Figs. 30.2 and 30.3**)**. Sickled cells undergo hemolysis in the spleen or become sequestered there, causing blood pooling and infarction of splenic vessels. The anemia that follows triggers erythropoiesis in the marrow and, in extreme cases, in the liver.[43,44]

The pathogenesis of **microvascular occlusions**, a main feature of SCD is not fully understood. This process is responsible for the most serious and urgent manifestations of SCD. Microvascular occlusions are not related to the quantity of irreversibly sickled cells in the blood. Rather, they are dependent on understated RBC membrane damages and other local factors, such as inflammation or vasoconstriction, that tend to decrease blood flow or arrest red cells through the microcirculation.[45] Sickled RBCs express higher than normal amounts of adhesion molecules and are sticky. During inflammatory reactions, leukocyte release of meditators increases the expression of adhesion molecules on endothelial cells. These reactions further promote sickled erythrocytes to become arrested during movement through the microvasculature.[45] The sluggish and stagnant red cells within the inflamed vascular vessels result in extended exposure to low oxygen tension, sickling, and vascular obstruction. Lysed sickle erythrocytes release hemoglobin. This free hemoglobin can bind and inactivate nitric oxide (NO), which is a powerful vasodilator and inhibitor of platelet aggregation. A decrease in blood pH reduces hemoglobin's affinity for oxygen leading to an increasing fraction of deoxygenated HbS at any oxygen tension and predisposition to sickling. As less oxygen is taken up by hemoglobin in the lungs, the P_{O_2} drops, promoting additional sickling.

Sickling usually is not permanent. Most sickled erythrocytes regain a normal shape after reoxygenation, a return of the P_{O_2} to normal, and rehydration. Irreversible sickling is caused by permanent plasma membrane damage, which in turn is caused by sickling. In persons with sickle cell anemia, in which the erythrocytes contain a high percentage of HbS (75% to 95%), up to 30% of the erythrocytes can become irreversibly sickled.

The extent, severity, and clinical manifestations of sickling depend to a great extent on the percentage of hemoglobin that is HbS. That is why homozygous inheritance of HbS produces the severest form of SCD—sickle cell anemia. The presence of sickle cell trait rarely results in sickling because these individuals also produce normal HbF and HbA which do not contribute to sickling at all. Anemia persists because HbF does not live 120 days.

Clinical Manifestations

The clinical manifestations of sickle cell disease can vary. Some individuals have mild symptoms; others suffer from repeated vasoocclusive crises. The clinical manifestations of sickle cell disease usually do not appear until the infant is at least 6 months old. At this time, postnatal concentrations of HbF decrease, causing concentrations of HbS to rise (Fig. 30.6). Two key attributes of SCD contribute to its presentation: the first is its nature to be a chronic disease with acute exacerbations; the second is that it is a condition affecting RBCs that supply oxygen to all cells of the body. As a consequence, SCD can affect any part of the body. Sites of specific dysfunction are shown in Fig. 30.7.

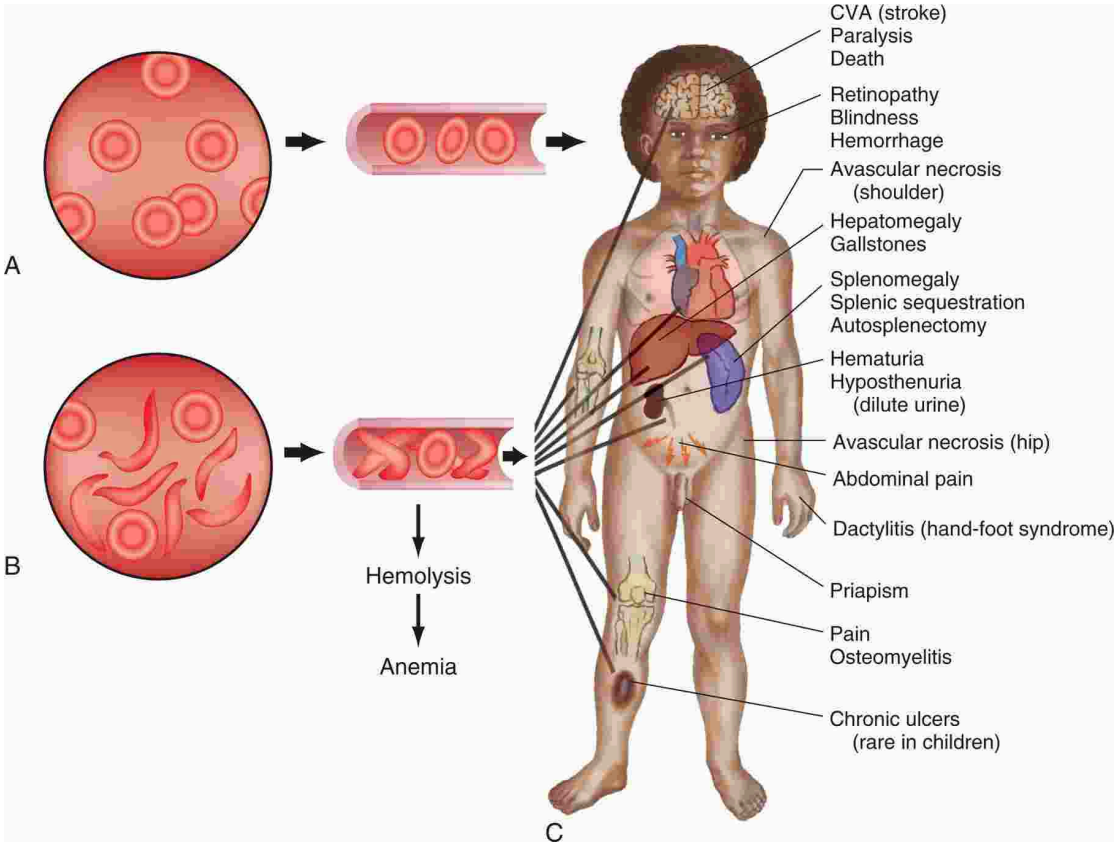

FIG. 30.6 Differences between effects of normal (A) and sickled (B) red blood cells on blood circulation and selected consequences in a child. (C) Tissue effects of sickle cell anemia. *CVA*, Cerebrovascular accident. (A and B, Adapted from Hockenberry MJ, et al., eds. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

Top-left panel, A. The illustration shows normal red blood cells. Top-right panel, B. The illustration shows sickle and normal red blood cells. Right panel, C. An illustration of the anterior view of the human body identifies the following tissue effects from the top to the bottom. â€¢ C V A (stroke), paralysis, and death. â€¢ Retinopathy, blindness, and hemorrhage. â€¢ Avascular necrosis (shoulder). â€¢ Hepatomegaly and gallstones. â€¢ Splenomegaly, splenic sequestration, and autosplenectomy. â€¢ Hematuria and hyposthenuria (dilute urine). â€¢ Avascular necrosis (hip). â€¢ Abdominal pain. â€¢ Dactylitis (hand-foot syndrome). â€¢ Priapism. â€¢ Pain and osteomyelitis. â€¢ Chronic ulcers (rare in children).

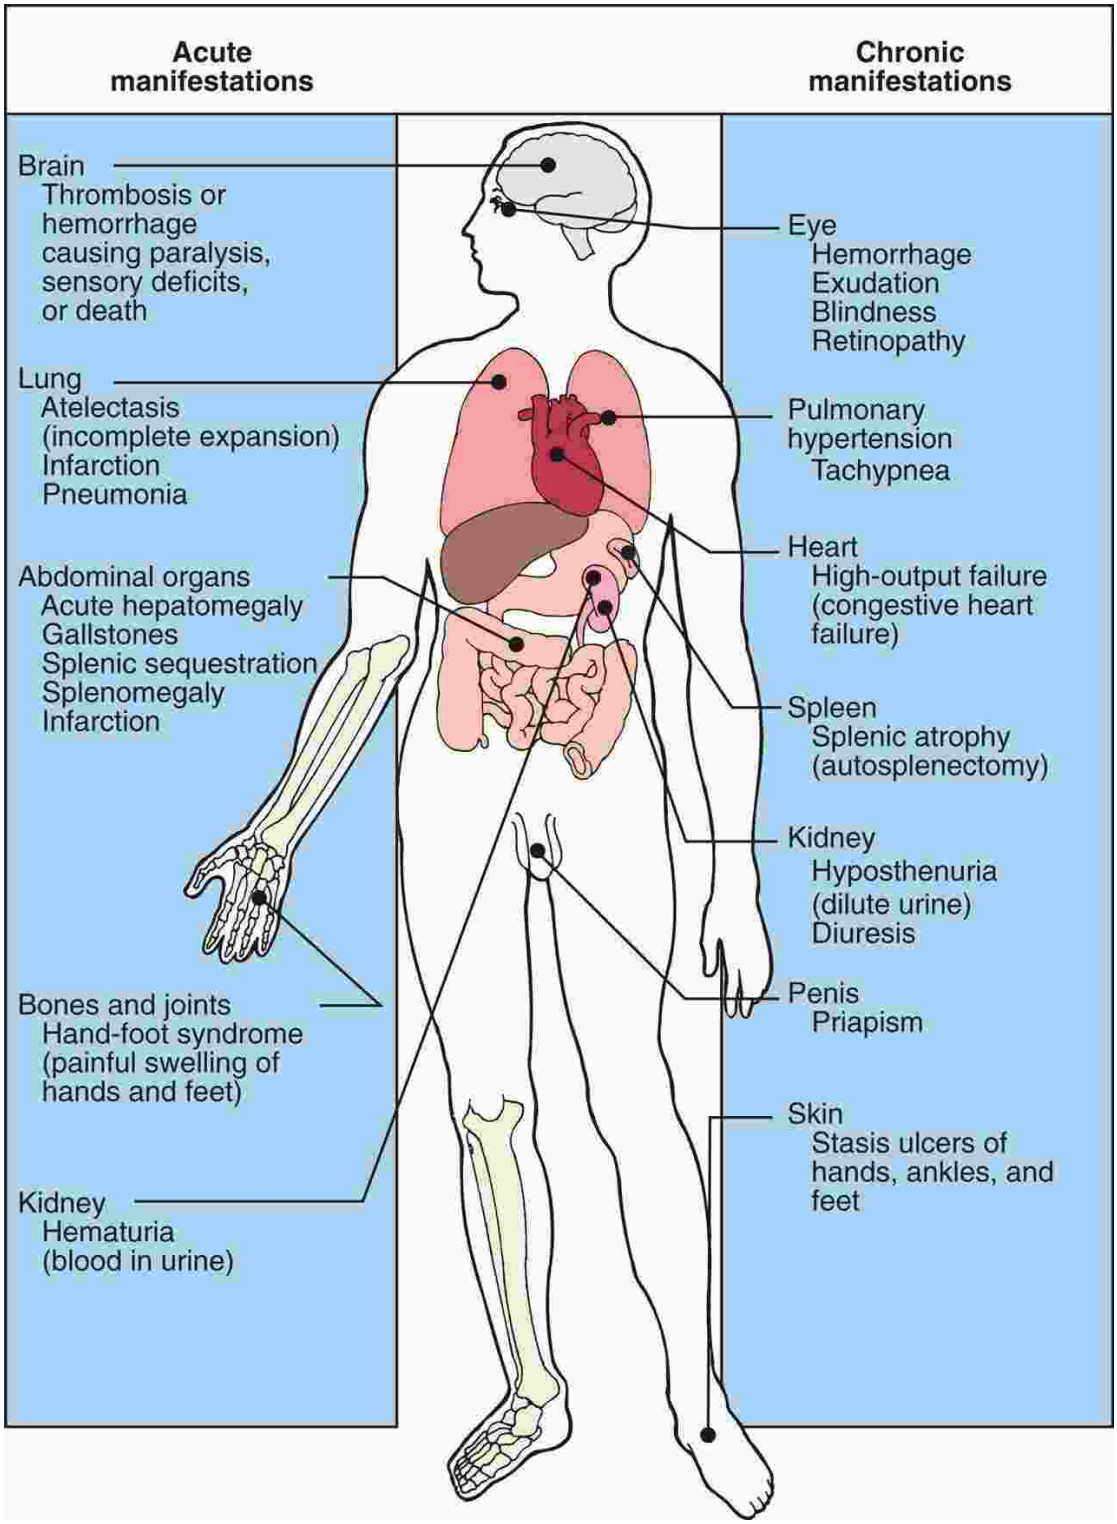

FIG. 30.7 Clinical Manifestations of Sickle Cell Disease.

An illustration of the anterior view of the human body shows acute and chronic manifestations by organ. Acute manifestations are as follows. â€¢ Brain: thrombosis or hemorrhage causing paralysis; sensory deficits or death. â€¢

Lung: atelectasis (incomplete expansion); infarction; and pneumonia. â€¢ Abdominal organs: acute hepatomegaly; gallstones; splenic sequestration; splenomegaly; and infarction. â€¢ Bones and joints: hand-foot- syndrome (painful swelling of hands and feet). â€¢ Kidney: hematuria (blood in urine). Chronic manifestations are as follows. â€¢ Eye: hemorrhage; exudation; blindness; and retinopathy. â€¢ Pulmonary: hypertension and tachypnea. â€¢ Heart: high-output failure (congestive heart failure). â€¢ Spleen: splenic atrophy (autosplenectomy). â€¢ Kidney: hyposthenuria (dilute urine) and diuresis. â€¢ Penis: priapism. â€¢ Skin: stasis ulcers of hands, ankles, and feet.

The general manifestations of hemolytic anemia from the sickling process include pallor, fatigue, jaundice, and irritability. Extensive sickling can precipitate four types of acute manifestations, often referred to as *crises*: (1) vaso-occlusive crisis, (2) aplastic crisis, (3) sequestration crisis, or rarely (4) hyperhemolytic crisis.

Vasoocclusive crisis (pain crisis). This type of crisis involves hypoxic injury and infarction that can cause severe pain in the microcirculation. The frequency of this type of crisis is variable and unpredictable because it may develop spontaneously or be precipitated by infection, exposure to cold, dehydration, low P_{O_2}, acidosis (low pH), or localized hypoxemia. Vaso-occlusive crises are extremely painful, and the specific cause of this sensory pain is not well characterized.[46,47]

As blood flow is obstructed by sickled cells, vasospasm occurs, and a logjam effect blocks all blood flow through the vessel. Unless the process is reversed, thrombosis and infarction of local tissue occur. Vasoocclusive crisis may last for days or even weeks, with an average duration of 4 to 6 days. The most common sites include bones, lungs, spleen, liver, brain, and penis. Painful bone crises are common in young children and are difficult to distinguish from acute osteomyelitis. These bone alterations can manifest as painful swelling of the hands and feet (*hand-foot syndrome* or *dactylitis*).

A high-risk type of vaso-occlusive crisis involving the lungs is known as **acute chest syndrome**. It typically presents with fever, cough, chest pain, and accumulations of lung infiltrates. The complications in the lungs create a worsening cycle of hypoxemia, sickling, and vaso-occlusion. Acute chest syndrome remains a leading cause of death among people with SCD.[48,49]*Priapism*, or prolonged erection of the penis, can lead to hypoxic damage and erectile dysfunction. Vaso-occlusion in vessels to the brain can result in stroke. Chronic vaso-occlusion in vessels to the kidneys results in end-stage renal disease.

Aplastic crisis. This type of crisis involves profound anemia caused by a transient cessation in RBC production despite a need for new RBCs. In sickle cell anemia, erythrocyte survival is only 10 to 20 days; however, the bone marrow is typically able to compensate to replace RBCs that are lost through hemolysis. Aplastic crisis is often precipitated by a viral infection, such as parvovirus B1. The virus causes temporary shutdown of RBC production with an accompanying sudden drop in hemoglobin level with an extremely low reticulocyte count. This type of crisis typically lasts 7 to 10 days.

Sequestration crisis. This type of crisis is typically seen only in children less than 5 years of age. It occurs when large amounts of sickled RBCs become acutely pooled in the liver and spleen. Because the spleen can hold as much as one-fifth of the body's blood supply, hypovolemia and, sometimes shock, can occur (see Chapter 49). The risk of mortality is high if the condition is not recognized and managed appropriately. Clinical management may include exchange transfusions.[32] Approximately half of children who experience sequestration crises will have recurrent episodes.

Hyperhemolytic crisis. This type of crisis, associated with an accelerated rate of RBC destruction, is unusual, but it may occur in association with certain drugs or infections. It is characterized by anemia, jaundice, and reticulocytosis. The concomitant presence of G6PD deficiency (see Glucose-6-Phosphate Dehydrogenase Deficiency) contributes to hyperhemolytic episodes, especially when combined with infections. It has also been reported as an acute or chronic reaction following a blood transfusion.

Infection is the most common cause of death related to sickle cell disease. Infection is also an important cause of disease-related morbidity, particularly for children with impaired splenic function.

Sepsis and meningitis develop in as many as 10% of children with sickle cell anemia during the first 5 years of life. Splenic congestion and poor blood flow compromise splenic function and lead to splenic infarction. As a consequence, the risk of infection from *Pneumococcus pneumoniae* and *Haemophilus influenzae* is increased.

Glomerular disease, characterized by damage to the glomeruli allowing protein and often RBCs to leak into the urine, is caused by sickling of RBCs in the kidneys. Extensive damage to the glomeruli results in nephropathy that may progress to renal failure. The earliest manifestation of SCD in the kidney is hyposthenuria, or the inability of the tubules of the kidneys to concentrate urine. As a result, the specific gravity of the urine tends to be very low. In young children, hyposthenuria can result in bed-wetting. Proteinuria also is an early manifestation of nephropathy associated with sickle cell disease.

Cholecystitis, inflammation of the gallbladder, occurs when a gallstone blocks the cystic duct. It can also be caused by hemolysis resulting in an increase of bilirubin concentration, which in turn causes the formation of gallstones in the gallbladder. The presence of gallstones can cause right upper quadrant pain, nausea, vomiting, and an elevated white blood cell count and alkaline phosphatase level. Cholecystectomy may be required.

Sickle cell–hemoglobin C (HbC) disease is usually milder than sickle cell anemia. HbC results when lysine is substituted for glutamic acid in the amino acid chain. HbC is less soluble than HbA; however, it does not polymerize under conditions of decreased oxygen tension as does HbS. The main clinical problems are related to vasoocclusive crises, which are thought to result from higher hematocrit values and viscosity. In older children, sickle cell retinopathy, renal necrosis, and aseptic necrosis of the femoral heads can occur along with obstructive crises.

Sickle cell–thalassemia has the mildest clinical manifestations of all the sickle cell diseases. Individuals with sickle cell–thalassemia have mutations in each allele coding for hemoglobin. One mutation results in HbS formation, and the other is associated with β-thalassemia, which results in decreased production of hemoglobin. Even though most of the child's hemoglobin is HbS (60% to 90%), normal hemoglobins (HbA and HbF) also are present. The normal hemoglobins, particularly HbF, inhibit sickling. The erythrocytes tend to be small (microcytic) and to contain relatively little hemoglobin (hypochromic). As a result, these cells are less likely to occlude the microcirculation, even when in a sickled state.

Evaluation and Treatment

The parents' hematologic history and clinical manifestations may suggest that a child has sickle cell disease, but hematologic tests are necessary to confirm the diagnosis. If the sickle solubility test confirms the presence of HbS in peripheral blood, hemoglobin electrophoresis will be performed to provide information about the amount of HbS in erythrocytes. Prenatal diagnosis can be made by chorionic villus sampling (CVS) as early as 8 to 10 weeks' gestation or by amniotic fluid analysis at 15 weeks' gestation (Fig. 30.8). Hemoglobinopathies, including sickle cell disease, are now included as part of routine newborn screening in all 50 states and the District of Columbia.

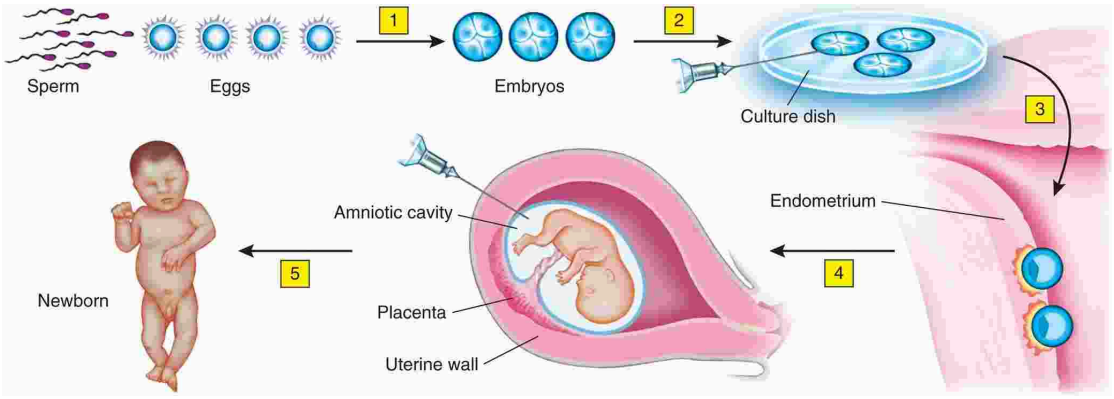

FIG. 30.8 Prepregnancy Sickle Cell Test.
This technique has potential for detection of other inherited diseases. *(1)* Fertilization produces several embryos. *(2)* The embryos are tested for the presence of the gene. *(3)* The embryos without the gene are implanted. *(4)* Amniocentesis confirms whether the fetus (or fetuses) has the sickle cell gene. *(5)* Woman has a normal child.

An illustrated flowchart shows the prepregnancy sickle cell test. The illustration shows sperm and eggs. Fertilization of sperm and eggs leads to embryos (1). The illustration shows embryonic cells in a culture dish (2). The embryos are implanted in the endometrium (3). The embryo develops into a fetus (4). A syringe collects sample from the amniotic cavity. Birth of a newborn (5). The placenta and the uterine wall are identified. The illustration shows a newborn.

Advances in identification of SCD and supportive care have led to decreased morbidity and improved survival of children with SCD. Supportive care emphasizes preventing consequences of anemia and avoiding crises, including adequate hydration, infection prevention, and pain management. Genetic counseling and psychologic support are important for the child and family.

Health maintenance activities are key to reduce the risk of crises and other aspects of disease-related morbidity. In addition to regular childhood vaccines, children with SCD should receive vaccination against pneumococcus and other encapsulated microorganisms. Children under 5 years of age may also be prescribed prophylactic penicillin to further reduce the risk of infection.[32] Because of the high infection-related mortality, individuals with SCD and their families should be instructed to seek immediate medical attention in the event of fever. Evidence-based guidance for screening for nephropathy, hypertension, retinopathy, pulmonary disease, and the risk of stroke have been published by the National Heart, Lung, and Blood Institute.[32]

Sickle cell trait typically does not affect life expectancy or interfere with daily activities. On rare occasions, however, severe hypoxia caused by shock, vigorous exercising at high altitudes, flying at high altitudes in unpressurized aircraft, or undergoing anesthesia may precipitate vasoocclusive episodes in persons with sickle cell trait. Persons with sickle cell trait are at risk for hyphema with traumatic injury to the eye. Untreated hyphema may result in glaucoma and potential vision loss. In 2010, the National Collegiate Athletic Association implemented testing for sickle cell trait for all incoming student athletes. While having sickle cell trait does not disqualify the individual from participation in athletics, the goal of this testing is to ensure the safety of student athletes.[50]

Treatment advances since the late 1980s have significantly decreased morbidity and mortality in children with SCD. Aggressive management of fever, early diagnosis of *acute chest syndrome* (hypoxia, anemia, progressive multilobar pneumonia, fat emboli), and proper pain management can improve quality of life and prognosis for these children. Treatment of SCD consists of supportive care aimed at

preventing consequences of anemia and avoiding crises. Crises can be prevented by avoiding fever, infection, acidosis, dehydration, constricting clothes, and exposure to cold. Immediate correction of acidosis and dehydration with appropriate intravenous fluids is imperative. Infections require aggressive antibiotic therapy, and infections can be reduced by vaccination. Oxygen is not needed unless the child becomes hypoxic. Pain associated with SCD is very complex, requiring accurate assessment and multimodal management.[51,52]

A common treatment for sickle cell disease is hydroxyurea. Hydroxyurea inhibits deoxyribonucleic acid (DNA) synthesis, which causes an increase in HbF concentration. HbF will not sickle. It also provides an anti-inflammatory effect by decreasing leukocyte production. These outcomes are thought to decrease mechanisms that lead to crises.

Two new medications were approved by the US Food and Drug Administration for use in individuals with sickle cell disease in 2019.[32] Voxelotor is an oral medication approved for individuals 12 years of age and older. It is proposed to inhibit HbS polymerization and the sickling process by modifying the affinity between hemoglobin and oxygen.[53] Crizanlizumab is a monoclonal antibody against the adhesion molecule P-selectin. P-selectin is involved in the underlying process by which blood cells adhere to blood vessel walls, thereby contributing to vaso-occlusion.[54] Crizanlizumab is administered as an IV infusion.

Transfusion therapy can decrease morbidity and mortality associated with sickle cell disease, particularly in those at increased risk for stroke.[32] Despite these benefits, it can result in iron overload in the liver, heart, and endocrine glands causing disruption of normal function, including delayed physical and sexual development and heart disease. Chelation therapy to remove excess iron is often required for individuals with SCD who require chronic transfusion of RBCs

HSCT offers the only cure for sickle cell disease; however, it is not without important risks. Observational studies to date have demonstrated improved survival and prevention of long-term complications. Additional studies are needed to evaluate benefits and risks by comparing individuals based on disease severity.[55] Current research is seeking to reduce the toxicities associated with transplantation while optimizing long-term outcomes. Clinical trials evaluating the feasibility of GT using an RNA viral vector are presently underway. One type of trial seeks to inhibit the BCL11a gene with the goal of increasing hemoglobin F production, thereby creating a sickle cell trait phenotype.[56]

Thalassemias

The **alpha-** and **beta-thalassemias** are autosomal recessive disorders that result in impaired synthesis of one of the two chains—α or β—of adult hemoglobin (HbA). The disorder was named **thalassemia**, which is derived from the Greek word for *sea*, because it was initially described in people with origins near the Mediterranean Sea. Beta-thalassemia, in which synthesis of the β-globin chain is slowed or defective, is most prevalent among Greek, Italian, some Arab, and Sephardic Jewish people. Alpha-thalassemia, in which the α chain is affected, is most common among Chinese, Vietnamese, Cambodian, and Laotian people. Both alpha- and beta-thalassemias are common among black people.

Beta-thalassemias are more common than alpha-thalassemias. The classification is based on the genes that control α- or β-chain synthesis. It also is based on the combination of mutations within these genes and whether they are homozygous or heterozygous. The anemia associated with both alpha- and beta-thalassemia is a microcytic-hypochromic hemolytic anemia.

Pathophysiology

The **β-thalassemias** are caused by mutations in the *HBB* gene that decrease the synthesis of β-globin chains and lead to anemia, tissue hypoxia, and RBC hemolysis. The β-thalassemias are classified into three types depending on the severity of symptoms: thalassemia major, intermedia, or minor. Both **beta-thalassemia major (Cooley anemia)** and **beta-thalassemia intermedia** are inherited in an autosomal recessive pattern in which both copies of the *HBB* gene in each cell have mutations; however, beta thalassemia major is more severe. β-globin chain production is moderately depressed in the heterozygous form, **beta-thalassemia minor**, and is known as beta-thalassemia trait. In a small

percentage of families, the *HBB* gene mutation, associated with beta-thalassemia major, is inherited in an autosomal dominant manner.[57]

The mutations associated with beta-thalassemia are classified as (1) β^0 mutations or absent β-globin synthesis and (2) β^+ mutations with reduced amounts of β-globin synthesis. More than 200 different causative mutations have been identified, and most are point (missense) mutations. The clinical classification of β-thalassemias is based on the severity of the anemia, which is dependent on the type of mutation (β^0 or β^+ allele) and whether the individual is homozygous or heterozygous for mutations.[57] Individuals who have β-thalassemia major, a β^0/β^0 genotype, will lack HbA and have severe anemia. Those with β^+/β^+ or β^0/β^+ genotypes, β-thalassemia intermedia, may produce small amounts of HbA. β-Chain production is depressed in the heterozygous form, thalassemia minor (β^0 or β^+ allele); and anemia, if present, is mild. The predominant type of hemoglobin is HbF and typically comprises more than 90% of the total hemoglobin among individuals who are homozygous for mutations. HbA_2 levels are variable among individuals who are homozygous but may be increased among individuals with beta thalassemia minor.[58]

The depression of β-chain synthesis that occurs in beta-thalassemia results in erythrocytes having a reduced amount of hemoglobin and accumulations of free α chains (Fig. 30.9). Free α-chains are unstable and easily precipitate in the cell. Most erythroblasts that contain precipitates are destroyed by mononuclear phagocytes in the marrow. Destruction results in ineffective erythropoiesis and anemia. Some of the precipitate-carrying cells mature and enter the bloodstream. These cells are destroyed prematurely in the spleen, resulting in mild hemolytic anemia.

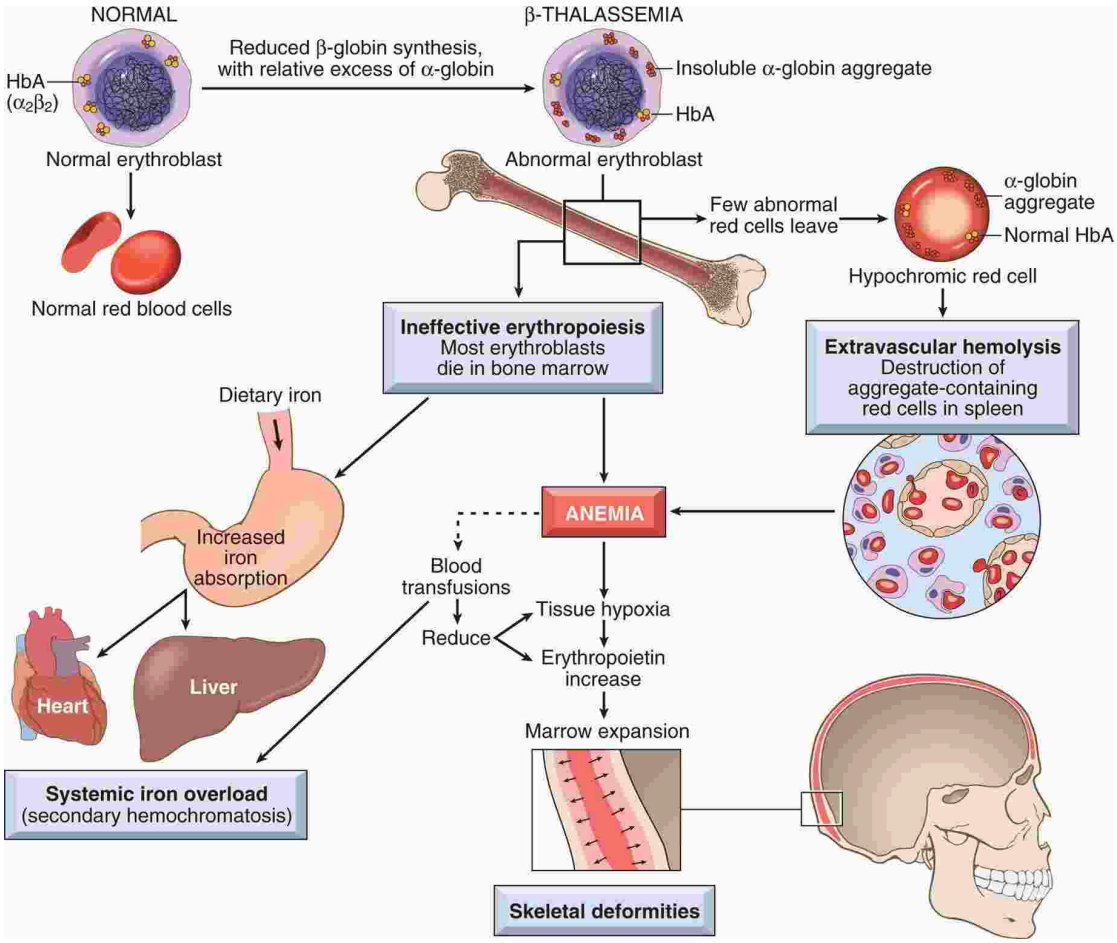

FIG. 30.9 Pathogenesis of β-Thalassemia Major.
The aggregates of unpaired α-globin chains are a hallmark of the disease. Blood transfusions can diminish the anemia, but they add to the systemic iron overload.
(From Kumar V, Abbas AK, Aster JC. *Robbins and Cotran pathologic basis of disease*, 9th edition. Philadelphia: Elsevier Saunders; 2015.)

An illustrated flowchart shows the pathogenesis of beta-thalassemia major. â€¢ The illustration shows a normal cell with H b A (alpha sub 2 beta sub 2). â€¢ Normal erythroblast results in normal red blood cells. â€¢ Normal cell undergoes reduced beta-globin synthesis, with relative excess of alpha-globin, leading to beta-thalassemia. â€¢ The illustration of the abnormal erythroblast shows a cell with insoluble alpha-globin aggregate and H b A. â€¢ The illustration shows a bone. Few abnormal red cell leave the bone, forming a hypochromic red cell with alpha-globin aggregate and normal H b A. â€¢ Hypochromic red cell leads to extravascular hemolysis (destruction of aggregate-containing red cells in spleen), leading to anemia. â€¢ Ineffective erythropoiesis in bone marrow leads to most erythroblasts dying in bone marrow, resulting in anemia. â€¢ Ineffective erythropoiesis leads to increased iron absorption (from dietary iron), which leads to systemic iron overload (secondary hemochromatosis) in heart and liver. â€¢ Anemia leads to tissue

hypoxia, which leads to erythropoietin increase, which leads to marrow expansion and skeletal deformities. â€¢ Blood transfusions reduce tissue hypoxia and erythropoietin. â€¢ Blood transfusions leads to systemic iron overload.

The **alpha** (α)**thalassemias** result from deletions involving the *HBA1* and *HBA2* genes. These genes provide instructions for making a protein called **α-globin**, a subunit of hemoglobin. The different types of α-thalassemia result from mutations in one or more of the four alleles involved in producing α-globin. These alleles include the two copies of the *HBA1* gene and the two copies of the *HBA2* gene that are present in each cell. The characteristic features of α-thalassemia are anemia, weakness, fatigue, and other more severe complications. The four types of α-thalassemia include

1. ***Hb Bart syndrome*** is the most severe form of α-thalassemia and is caused by loss-of-function mutations in all four α-globin alleles. In an attempt to compensate, Hb Barts, which contains γ-globin chains, is produced. These γ-globin chains have a high affinity for oxygen; however, they do not deliver oxygen to the tissues of the developing fetus. As a result, hydrops fetalis develops, and signs of fetal distress may become evident in the third trimester of pregnancy. Although most cases are fatal, intrauterine transfusions may save the baby.[59]
2. HbH disease results from a loss-of-function in three of the four α-globin alleles. These individuals have an excess of beta-globin chains within the RBCs that form beta-4 tetramers, known as *hemoglobin H* (HbH). HbH also does not carry oxygen effectively, which leads to anemia and other related consequences.[59,60]
3. **Alpha thalassemia minor** or alpha thalassemia trait occurs when mutations are present in two alleles. Although the amount of α-globin will be reduced, some normal hemoglobin will still be produced and therefore cause fewer health problems. Affected individuals may have microcytic RBCs and slight anemia.[59]
4. Silent α-thalassemia carrier results from a mutation in one of the four α-globin alleles. These individuals typically have no related clinical manifestations but can pass the mutated allele on to their children.[59]

Clinical Manifestations

Beta-thalassemia minor causes mild to moderate microcytic-hypochromic anemia. The degree of reticulocytosis depends on the severity of the anemia. Hemolysis of immature, and therefore fragile, erythrocytes may cause a slight elevation in serum iron and indirect bilirubin levels. Persons with beta-thalassemia minor may be asymptomatic; however, they may experience mild splenomegaly, bronze coloring of the skin, and hyperplasia of the bone marrow. These individuals are less likely to experience life-threatening complications.

If untreated, persons with beta-thalassemia major may become quite ill and have impaired physical growth and development. Skeletal changes begin in infancy and include spinal impairment that impedes linear growth and causes subsequent upper and lower limb-length discrepancy. Deformity of the facial bones in response to hyperplastic marrow results in a characteristic chipmunk-like facial appearance, as the nasal bridge, mandible, and maxilla widen. Osteopenia, osteochondrosis, or both also may develop. The severe anemia resulting from this condition can cause a significant cardiovascular burden with high-output congestive heart failure. For persons with thalassemia that require regular transfusions, progressive hemosiderosis will occur. If not managed carefully from infancy into adulthood, death may occur. Today, careful management with regular blood transfusions and compliance with chelation therapy can increase the life span significantly.

Persons who inherit the mildest form of α-thalassemia (silent α-thalassemia trait) usually are symptom free or have mild microcytosis. Alpha-thalassemia minor has clinical manifestations similar to those of beta-thalassemia minor: mild microcytic-hypochromic anemia, reticulocytosis, bone marrow hyperplasia, increased serum iron concentrations, and mild to moderate splenomegaly.

The clinical manifestations of HbH disease are variable based on the specific characteristics of the mutations that are present in the three affected alleles.

Alpha-thalassemia major (Hb Barts) causes **hydrops fetalis**, whereby the developing fetus suffers from severe tissue anoxia and may develop fulminant intrauterine congestive heart failure. Signs of fetal distress became evident by the third trimester of pregnancy. In the past, severe tissue anoxia led to death in utero; now many such infants are saved by intrauterine transfusions.

Evaluation and Treatment

Evaluation of thalassemia is based on the familial disease history, clinical manifestations, and blood tests. Diagnostic tests include peripheral blood smears that show a microcytic, hypochromic anemia and target cells. Hemoglobin electrophoresis typically indicates decreased amounts of HbA and increased amounts of HbF after age 12 months and may be useful in diagnosing beta thalassemia. However, to diagnose α-thalassemia, targeted deletion analysis is recommended.

Prenatal diagnosis may be performed, and families with an affected fetus will be referred for genetic counseling. Identification of thalassemia is now included as part of routine newborn screening for hemoglobinopathies in all 50 states and the District of Columbia. Molecular genetic testing of at-risk siblings should be offered to allow for early diagnosis and appropriate treatment. Women with thalassemia intermedia who have never received a blood transfusion or who received a minimal quantity of blood are at risk for severe alloimmune anemia if blood transfusions are required during pregnancy.[61] Treatment for thalassemia is largely supportive. Typical treatment involves a regular transfusion program and chelation therapy to reduce transfusion iron overload. Individuals with milder forms of thalassemia rarely require transfusion. These individuals are at risk for iron overload secondary to increased intestinal absorption of iron from ineffective erythropoiesis.[61] Optimal clinical management may decrease the need for splenectomy. Treatment of thalassemia intermedia is based on the individual's symptoms, and splenectomy may be performed for those who are more symptomatic. These individuals may also require sporadic red cell transfusions, folic acid supplementation, and iron chelation.[61] The only available definitive cure for thalassemia major is allogeneic HSCT from a matched family or unrelated donor or cord blood transplantation from a related donor.[61] In addition, on-going clinical trials are investigating the use of GT strategies for thalassemia.[62,63]

Disorders of Coagulation and Platelets

Inherited Hemorrhagic Disease

Table 30.4 provides a summary of the coagulation factors and deficiencies associated with clinical bleeding. Not all the disorders are discussed in this chapter because some are extremely rare (congenital dysfibrinogenemias), and others have no clinical significance. For example, Hageman factor deficiency is a condition with profound laboratory deficiency of factor XII yet is associated with no clinical defects in humans.

Table 30.4

The Coagulation Factors

Clotting factors	Synonym	Disorder
I	Fibrinogen	Congenital deficiency (afibrinogenemia) and dysfunction (dysfibrinogenemia)
II	Prothrombin	Congenital deficiency or dysfunction
V	Labile factor, proaccelerin	Congenital deficiency (parahemophilia)
VII	Stable factor or proconvertin	Congenital deficiency
VIII	Antihemophilic factor (AHF)	Congenital deficiency is hemophilia A (classic hemophilia)
IX	Christmas factor	Congenital deficiency is hemophilia B
X	Stuart-Power factor	Congenital deficiency
XI	Plasma thromboplastin antecedent	Congenital deficiency, sometimes referred to as hemophilia C
XII	Hageman factor	Congenital deficiency is *not* associated with clinical symptoms
XIII	Fibrin-stabilizing factor	Congenital deficiency

Hemophilias

Awareness of a serious bleeding disorder in males was documented nearly 2000 years ago in the Babylonian Talmud, which exempted those boys having male relatives prone to excessive bleeding from the rite of circumcision. In 1803, the first description of this disorder appeared in the medical literature, where it was noted to be X-linked and associated with joint bleeding and crippling.

The hemophilias are a group of inherited bleeding disorders resulting from mutations in the genes responsible for coagulation factors. Until 1952 the term *hemophilia* was reserved for deficiency of factor VIII (antihemophilic factor). Since then, two additional coagulation proteins, factor IX (plasma thromboplastin component) and factor XI (plasma thromboplastin antecedent), have been identified. Deficiencies in these two clotting factors are associated with similar clinical manifestations and are regarded as hemophilia B and hemophilia C, respectively. Collectively, inherited deficiencies of these three plasma clotting factors—VIII, IX, XI—account for 90% to 95% of the hemorrhagic bleeding disorders.

Types of hemophilia

Hemophilia has a wide range of clinical severity. The most prevalent types of hemophilia are **hemophilia A (classic hemophilia** or **factor VIII deficiency**) and **hemophilia B (Christmas disease or factor IX deficiency**). **Hemophilia A** results from mutations in the *F8* gene, which codes for factor VIII, an essential cofactor for factor IX in the coagulation cascade. It is the most common hereditary disease associated with life-threatening bleeding. **Hemophilia B** results from a mutation in the *F9* gene, which codes for factor IX. Because both factors VIII and IX function together to activate factor X, hemophilias A and B are clinically indistinguishable. The alterations or deficiencies of these coagulation factors decrease the ability to form blood clots in response to injury. The decreased or ineffective blood clotting leads to continuous bleeding.

Hemophilias A and B occur with varying degrees of clinical severity, depending on concentrations of clotting factor VIII or IX in the blood. Severe hemophilia (concentration of clotting factors less than 1%

of normal) is associated with spontaneous bleeding. This manifestation of hemophilia is associated with mutations that eliminate the activity of factors VIII or XI. In moderate hemophilia (1% to 5% of normal), bleeding may occur with injury, trauma, or surgery; in the mild form (6% to 50% of normal), bleeding typically occurs only after severe trauma or surgery. Moderate and mild hemophilia are associated with mutations that reduce but do not eliminate the activity of these coagulation factors.[63]

Hemophilia is equally prevalent across racial groups. The incidence of hemophilia A is approximately 1 in 5000 male births. Hemophilia B is five times less common, with an incidence of approximately 1 in 20,000 male births.[64] Hemophilia C, which results from a deficiency of Factor XI is inherited as an autosomal recessive condition and is extremely rare. It affects approximately 1 in 1,000,000 individuals.[65] The worldwide prevalence of severe hemophilia is estimated to be around 400,000 people. A recent meta-analysis of worldwide registry data, however, suggests that approximately 1,125,000 males are living with hemophilia, with manifestations ranging from mild to severe disease.[66]

Pathophysiology

As X-linked recessive conditions, hemophilias A and B are most frequently inherited from a mother who is heterozygous, that is, a carrier, for a mutation in either the *F8* or *F9* gene. Approximately 30% of cases, however, result from a new mutation. This new mutation can occur in either a carrier female or in an affected male. Multiple types of genetic mutations are associated with hemophilias A and B. More than 2000 unique mutations have been identified for hemophilia A,[67] and more than 1000 mutations have been described for hemophilia B.[68] The type of mutation also affects the phenotype, or severity, of the disease. Mutations tend to be identical among affected members of a given family; however, mutations often differ across families.[69]

The *F8* and *F9* genes are located on the long arm of the X chromosome. A mutation in either of these genes typically results in either deficient or abnormal function of the corresponding clotting factor. Because males have only one copy of the X chromosome, the mutation results in the clinical manifestations of hemophilia. Females who are heterozygous carriers typically do not experience excessive bleeding. However, 50% of female carriers have lower than normal clotting factor levels. Those females without a sufficient quantity of normal functioning clotting factor may have bleeding similar to a male with mild hemophilia. Because X-inactivation, or lyonization (see Chapter 4), is a random process, phenotypes of females who are heterozygous carriers can vary. Although very uncommon, it is plausible for a female to be homozygous for mutations in the *F8* or *F9* gene and therefore have hemophilia.

Inversions in introns 1 and 22 of the factor VIII gene are the most frequently observed mutations and account for the most severe cases of hemophilia A.[68] Point mutations, in which a single base in the DNA is inserted in the place of another base, are another type of mutation that causes hemophilia. This type of mutation comprises the majority of unique mutations associated with hemophilia.[67] When a point mutation gives rise to a de novo stop codon (nonsense mutation), translation of the protein ceases, and a shortened version of the protein is synthesized. Usually, the protein is destroyed intracellularly and never reaches the plasma. A point mutation defect also is associated with severe hemophilia, that is, with coagulant activity levels below 1%. Point mutations resulting in the substitution of one amino acid for another can cause phenotypes of varying severity. The altered amino acid chain can destroy protein function, activation, or folding; inhibit intracellular processing; or cause protein clearance.[69]

Clinical Manifestations

The clinical manifestations and severity of hemophilia depend largely on the level of factor VIII and IX activity. Children with severe hemophilia also manifest prolonged bleeding times at different ages. Many boys with hemophilia are circumcised without excessive bleeding. Normal hemostasis is achieved in these infants because clotting is activated through the extrinsic coagulation cascade, which does not involve factors VIII, IX, or XI.

During the first year of life, spontaneous bleeding often is minimal, but hematoma formation may result from immunizations and from firm holding (e.g., under the arms), and joint bleeding may occur.

Most children with severe hemophilia initiate prophylactic factor administration around the time they become mobile (e.g., crawling, pulling to stand).

Joint bleeding, or **hemarthrosis**, is the most characteristic type of bleeding in hemophilia. The joints most often affected are the knees, ankles, and elbows.[70] Hemarthrosis causes pain, limits joint mobility, and predisposes the child to degenerative joint changes. Bleeding into muscles, usually from trauma, also can occur. Oral bleeding is common in the setting of traumatic injury to the mouth or dental surgery. Spontaneous painless hematuria is relatively common in hemophilia; it does not result in significant blood loss but requires evaluation. Hematuria accompanied by pain requires prompt evaluation and treatment. Spontaneous epistaxis may also occur. Although troublesome, it tends to be a minor complication.

Recurrent bleeding—spontaneous and after minor trauma—is a lifelong problem. Intracranial bleeding, bleeding of internal organs, and bleeding into the tissues of the neck, chest, or abdomen are all life-threatening. Delayed or suboptimal treatment of these bleeding episodes may lead to permanent brain injury, loss of organ function, or death.

Evaluation and Treatment

Because hemophilia most often manifests as an inherited disease, a positive family history may expedite a diagnosis of hemophilia. When a mother who is a known or suspected carrier is pregnant, prenatal genetic testing through CVS or amniocentesis may reveal a diagnosis of hemophilia. In the absence of a positive family history, a personal bleed history, laboratory testing, family history, and physical assessment contribute to a thorough evaluation and accurate diagnosis. In general, those with hemophilia A or B will have a prolonged partial thromboplastin time (PTT) and the prothrombin time (PT) will be normal. Measuring factor VIII and factor IX levels also is necessary for diagnosis.

Most children with hemophilia A can be treated with recombinant factor VIII, and most children with hemophilia B can be treated with recombinant factor IX. Recombinant factor is reconstituted in a small volume of diluent, administered by slow intravenous push, and raises the factor level almost immediately.

Primary prophylaxis consists of regular infusions of factor VIII or IX with the goal of preventing joint bleeding. It is usually given to children with severe hemophilia. A 5-year, multicenter trial, which has now become the standard of care,[71,72] found prophylaxis initiated in children between 6 and 30 months of age to be effective in the prevention of joint bleeding, structural joint damage, and frequency of bleeding in boys with factor VIII deficiency. Recent multisite trials have demonstrated the safety and efficacy of pegylated, recombinant factors VIII and IX. These pegylated products have extended half-lives and require less frequent dosing.[73,74] Newer generation products are fully produced in human cell lines and help reduce the risk of the development of inhibitors that limit the efficacy of the infused product.[75] Recently approved substitution therapies using monoclonal antibodies have shown great promise in the management of bleeding in hemophilia. Ongoing investigation of rebalancing therapies and GT may transform disease severity and management.

von Willebrand Disease

von Willebrand disease is an inherited condition with variable clinical manifestations and hematologic findings resulting from a deficiency or dysfunction in von Willebrand factor. von Willebrand factor binds factor VIII and platelets to the blood vessel wall as part of the clotting process. As a result, factor VIII activity may be decreased in individuals with von Willebrand disease. Over 80% of cases of von Willebrand disease demonstrate an autosomal dominant pattern of inheritance; however, some cases demonstrate an autosomal recessive or compound heterozygous pattern. The pattern of inheritance depends on the type of mutation that is present.[67] The clinical management of von Willebrand disease will depend on the underlying subtype that is present.

Congenital Hypercoagulability and Thrombosis

Hereditary bleeding disorders, such as hemophilia, have been recognized and treated for centuries; however, the counterpart of these disorders, **thrombophilia**, has not been recognized until the past 50 years. The inherited thrombophilic conditions generally are caused by defects in the clotting factors that

inhibit clot formation; thus, the balance between bleeding and clotting is directed toward the clotting aspects of hemostasis. In general, thromboses in children in the absence of some type of triggering event such as a vascular access catheter, infection, or heart disease are rare and comprise less than 5% of thrombotic events in children. For these spontaneous events, approximately 60% have some type of hereditary basis.[76] A recent study investigating genetic mutations in 115 adolescents and young adults presenting with thrombotic events identified single-gene mutations in two-thirds of this sample, and some individuals had more than one mutation.[77] Ongoing studies are needed to further investigate the specific roles of these mutations as well as the clinical management of children and adolescents who present with a thrombotic event. Current guidance supports testing for inherited thrombophilia if (1) identification of a thrombophilic mutation or defect might explain the basis for the event, (2) a positive test would have implications for the child or adolescent's clinical management, or (3) testing might help identify asymptomatic family members and provide guidance in avoiding risk factors for future thrombotic events.[78]

Defects in specific proteins (C and S) and antithrombin (AT) and resistance to activated protein C (APC) and hyperhomocysteinemia are the main recognized causes of inherited thrombophilia. Both proteins C and S inhibit coagulation and depend on vitamin K for synthesis in the hepatocytes of the liver. Decreased levels of either of these proteins interfere with the normal homeostatic balance of procoagulant and anticoagulant activity at the endothelial level. Protein C and S deficiency states predispose affected individuals to thrombosis, especially venous thrombosis of the lower extremities.

Protein C deficiency is inherited in an autosomal dominant manner and results from mutations in the *PROC* gene. Its prevalence is approximately 0.2% to 0.4% in the general population. Genetic mutations may result in quantitative (type I) or qualitative (type II) deficiencies of protein C. *Type I deficiencies* involve a reduction in both biologic and immunologic activity of protein C. Type I is caused by deletion of the entire gene. *Type II deficiencies* are less common and result in decreased functional levels of protein C activity despite the presence of a normal level of protein C.[79]

Individuals who are heterozygous for protein C mutations have levels that are 50% to 60% of normal. They may develop superficial thrombophlebitis, deep venous thrombosis, or pulmonary embolism in their late teens and early 20 s. Individuals with homozygous mutations have less than 1% of normal levels of protein C and tend to develop thrombosis of the cutaneous vessels with large areas of skin necrosis. Arterial thrombosis is rare among individuals with protein C deficiency.

Neonatal purpura fulminans is a fatal syndrome found in neonates who are homozygous or compound heterozygous for types I and II protein deficiency. Ecchymosis becomes apparent on the first day of life and develops around the head, trunk, and extremities and often is accompanied by cerebral thrombosis and infarction. The ecchymotic areas often coalesce, and ulceration and necrosis develop. Treatment is largely supportive and includes administration of fresh frozen plasma (FFP) and heparinization; however, the condition is often fatal.

Treatment for protein C deficiency depends on the clinical manifestations. Individuals who are asymptomatic may not require therapy unless a strong family history of thrombosis is present. Heparin is the treatment for acute episodes of thrombosis caused by protein C deficiency. The need for long-term therapy is varied and will be individualized to the person with attention to prior family history. Supplemental protein C concentrates (human) also are available and have been approved for use in children.[80]

Protein S deficiency results from mutations in the *PROS1* gene and is similar to protein C deficiency. Its autosomal dominant pattern of inheritance is also similar. The severity of the clinical manifestations varies. Approximately 60% to 80% of affected individuals will develop a venous thrombosis at some point during their lives.[81]

Protein S deficiency exists in three forms: type I, type II, and type III.[82] *Type I* deficiency is identified as a quantitative deficiency and manifests as low levels of total protein S antigen and free protein S antigen. *Type II* deficiency is identified as a qualitative deficiency with normal levels of free and total protein S antigen but reduced protein S activity. *Type III deficiency* results in low free protein S levels; however, the total plasma concentration of protein S is normal. Type III deficiency has not been established as a risk factor for venous or arterial thromboembolism.

The clinical manifestations of Protein S deficiency vary across individuals. Approximately half of individuals who are heterozygous for mutations will experience a thrombotic event before age 55. Other manifestations include superficial thrombophlebitis and pulmonary emboli. Although clots may occur spontaneously in individuals with protein S deficiency, risk factors, such as increasing age and immobility, can raise the risk of thrombus formation.

Homozygotes demonstrate severe manifestations of the condition and may develop a form of purpura fulminans in the neonatal period. The homozygous state also may lead to intrauterine death. Treatment with heparin, warfarin (Coumadin), and protein C concentrate is similar to that for protein C deficiency.

Antithrombin III (AT III) deficiency is inherited as an autosomal dominant condition. Most individuals are heterozygous for a mutation. AT III deficiency results from mutations in the *SERPINC1* gene and exists in forms type I and type II. Type I is a quantitative deficiency of the AT III antigen resulting from decreased production. Type II is characterized by decreased functional activity. Normal levels of AT III are present; however, their activity is reduced.[83]

Individuals with AT III deficiency are at risk for early development of venous thrombosis and pulmonary embolism. These events often occur in the middle to late teens, but they can occur as early as 10 years of age. The deep veins of the lower extremities are usually involved, most commonly the iliofemoral vein. Other sites include the mesenteric veins, vena cava, renal veins, and retinal veins. Cerebral thromboses also have been described, and arterial thrombotic events are rare. In some cases, thrombosis is precipitated by surgery, trauma, pregnancy, oral contraceptives, and infection.

The treatment of choice for AT III deficiency is heparin. Antiplatelet agents (e.g., aspirin, dipyridamole) may be used, as well as AT III concentrates.

Antibody-Mediated Hemorrhagic Disease

Antibody-mediated hemorrhagic diseases are caused by the immune response. Antibody-mediated destruction of platelets or antibody-mediated inflammatory reactions to allergens damage blood vessels and cause seepage into tissues. The thrombocytopenic purpuras may be intrinsic or idiopathic. They also may be transient phenomena transmitted from mother to fetus. The inflammatory, or "allergic," purpuras, although rare, occur in response to allergens in the blood. All of these disorders first appear during infancy or childhood.

Primary Immune Thrombocytopenia

Primary **immune thrombocytopenia (ITP)** (previously referred to as **idiopathic thrombocytopenic purpura**) is the most common of the thrombocytopenic purpuras of childhood. It is a disorder of platelet consumption in which autoantibodies bind to the plasma membranes of platelets. Antibody binding causes platelet sequestration and destruction by mononuclear phagocytes in the spleen and other lymphoid tissues at a rate that exceeds the ability of the bone marrow to produce them. The destruction of platelets is triggered by drugs, infections, lymphomas, or an unknown cause.

ITP is defined further based on the phases of the illness and established criteria for evaluating the response to therapy.[84] Specific phases include *newly diagnosed ITP*, within 3 months of diagnosis; *persistent ITP*, describing individuals with 3 to 12 months of diagnosis who have not achieved remission or complete response off therapy; *chronic ITP*, symptoms lasting longer than 12 months; and *severe ITP*, the presence of bleeding that requires treatment either at diagnosis or following initiation of treatment.

Pathophysiology

The autoantibodies that produce the destruction are often of the IgG class and are usually against the platelet membrane glycoproteins (IIb-IIIa or Ib-IX). Approximately 70% of cases of ITP are preceded by a viral illness (e.g., cytomegalovirus [CMV], Epstein-Barr virus [EBV], parvovirus, or respiratory tract infection), suggesting that viral sensitization has occurred. The typical interval between infection and onset of purpura is 1 to 3 weeks.

Clinical Manifestations

Bruising and a generalized petechial rash often develop acutely about 1 to 3 weeks after a viral illness. Petechiae can develop into ecchymoses. Asymmetric bruising is typical and is found most often on the legs and trunk. Hemorrhagic bullae of the gums, lips, and other mucous membranes may be prominent. Epistaxis (nose bleeding) may be severe and difficult to control. Except for signs of bleeding, the child appears well. The principal changes are found in the spleen, bone marrow, and blood. The acute phase of the disease associated with spontaneous hemorrhages lasts 1 to 2 weeks, but thrombocytopenia often persists. Intracranial hemorrhage is the most serious complication of ITP; however, the incidence is less than 1%. In some cases, the onset of ITP is more gradual, and clinical manifestations consist of moderate bruising and a few petechiae.

Evaluation and Treatment

Laboratory examination reveals an isolated low platelet count. The few platelets observed on a peripheral smear are large, reflecting increased bone marrow production. The Ivy bleeding time is prolonged. Bone marrow aspiration is not recommended for children with typical features of ITP. The primary management for children newly diagnosed with ITP, with no or mild bleeding (skin manifestations), is only observation regardless of the platelet count. When non-life-threatening mucosal bleeding or diminished quality of life is present, a short burst of corticosteroids is recommended.[84]

Even without treatment, the prognosis for children with ITP is excellent: 75% recover completely within 3 months. After the initial acute phase, spontaneous clinical manifestations subside. By 6 months after onset, 80% to 90% of affected children have regained normal platelet counts. ITP that persists longer than 12 months in children is considered chronic. Thrombopoietin receptor agonists (TPO-RA) are recommended for the management of children with ITP who are unresponsive to first-line therapies.[84]

Autoimmune Neonatal Thrombocytopenias

Antibody-mediated thrombocytopenic purpura occurs in neonates in either autoimmune or alloimmune form. Both forms are characterized by the immunologic destruction of platelets by autoantibodies (IgG) against tissue-specific antigens expressed by the platelets (i.e., platelet-specific antigens).

Autoimmune neonatal thrombocytopenia was first noted in the early 1950s when it was observed that mothers with ITP often delivered infants who were transiently thrombocytopenic. Neonatal thrombocytopenia was observed in approximately 50% of infants at risk and lasted an average of 1 month. As platelet counts returned to normal, a concomitant drop in the level of maternal antiplatelet antibody on the child's platelets occurred. The antibody is directed against antigens common to maternal and neonatal platelets. The prognosis generally is favorable, and the frequency of intracranial hemorrhage is rare (1% to 3% of cases). Medical management of affected infants is to prevent the severe thrombocytopenia that can cause significant morbidity by administering intravenous immunoglobulins.

Neonatal alloimmune thrombocytopenia purpura (NAIT) is less common and is estimated to occur in 1 to 2 per 1000 live births. NAIT is caused by maternal immunization against fetal paternally derived platelet-specific antigens (similar to rhesus [Rh] disease). The mother has a normal platelet count, whereas the fetus can be severely thrombocytopenic.

The diagnosis of NAIT is confirmed by detection in the maternal serum of antibody that reacts with platelets from the infant and father but not with platelets from the mother. In approximately 75% to 85% of cases, NAIT recurs in subsequent pregnancies. Purpura usually develops in the affected infant shortly after delivery, and intracranial, renal, and gastrointestinal hemorrhages are possible. The mortality rate from intracranial hemorrhage has been estimated at 10% to 15%. Management of the newborn with NAIT includes an immediate cranial ultrasound because of the significant risk of intracranial hemorrhage. Severely thrombocytopenic newborns (<10,000/μl) or newborns with intracranial or visceral hemorrhages should receive a matched platelet transfusion (maternal or homozygous human platelet antigen 1b [HPA-1b] donor) as soon as possible. If maternal platelets are used, they must be processed to remove platelet alloantibodies. Newborn thrombocytopenia is difficult to predict because newborn platelet counts do not correlate with maternal platelet counts or antiplatelet antibody titers.[85]

Most of the life-threatening clinical manifestations of transient neonatal thrombocytopenia and NAIT can be avoided through cesarean delivery. If the mother has antiplatelet disease, however, surgery can

result in hemorrhage and serious maternal morbidity. Maternal morbidity resulting from NAIT during pregnancy is low (less than 5%): the principal maternal risk is bleeding from surgical incisions during cesarean delivery. The incidence of transient thrombocytopenia in infants born to mothers with NAIT is about 50%. If all deliveries were cesarean, half the mothers would undergo cesarean delivery unnecessarily. Conversely, if all deliveries were vaginal, half the infants—those with thrombocytopenia—would be at risk for intracranial bleeding. Therefore, in the absence of any clear benefit to the neonate (given the low rate of intracranial hemorrhage in infants born to mothers with ITP), cesarean delivery should be reserved for the usual obstetric indications.

Autoimmune Vascular Purpura

Autoimmune vascular purpura (allergic purpura) is caused by antibody-mediated injury of blood vessel walls, typically arterioles and capillaries. The exact cause of the inflammatory reaction is unknown but is believed to result from exposure to foreign proteins or chemicals in the blood such as microorganisms, drugs, or other chemicals.

Autoimmune vascular purpura usually is seen in young children. Its incidence decreases among adolescents and adults and occurs only rarely in older adults. The average age at onset is 5 years, with a slightly higher proportion of males affected. Purpura occurs as vessel integrity is disrupted by inflammatory processes, causing effusion of serosanguineous exudate to perivascular tissues.

Clinical manifestations include headache, anorexia, fever, abdominal pain, constipation, arthralgias and urticaria, and erythema that are located symmetrically on the proximal portions of the extremities, particularly on the legs and buttocks, and may be accompanied by itching or paresthesias. Abdominal pain results from hemorrhage into the bowel, which may lead to colic, nausea, and vomiting. These symptoms may precede the appearance of skin lesions. The pain usually is midabdominal but may radiate to other parts of the abdomen. Joint pain and tenderness may be present, but hemarthrosis does not occur. Periarticular swelling and edema of the hands and feet are common and may precede the onset of abdominal pain and purpura. Subacute glomerulonephritis occurs in some cases but usually is reversible.

The characteristic skin lesions (purpura and cutaneous manifestations of allergy), accompanied by a history of joint and abdominal pain, are suspicious for diagnosis. Laboratory test results often reveal no major abnormalities. Attacks may last several weeks and may recur at odd intervals and with changing manifestations with each episode. Treatment, if necessary, consists of symptom management, often with analgesics and non-steroidal anti-inflammatory medications.

Neoplastic Disorders

Leukemia

Leukemia is cancer of the blood-forming tissues, such as the bone marrow, that most often produces abnormal white blood cells called **leukemic cells**. Once in the blood, leukemic cells can spread to other organs, such as the lymph nodes, spleen, and brain. Leukemia is the most common malignancy in children and adolescents. Of the types of acute childhood leukemia, 75% to 80% of leukemias in children are derived from the lymphoid line and are classified as *acute lymphoblastic leukemia (ALL)*. The remaining 20% to 25% are derived from the myeloid line and are classified as *acute myeloid leukemia (AML)* and *related neoplasms*. The related neoplasms include acute promyelocytic, myelomonocytic, and myelomonoblastic leukemias, as well as the very rare erythroid leukemia.[86] A very small percentage of acute leukemias have characteristics of both the lymphoid and myeloid line and are classified as acute leukemia of ambiguous lineage. Chronic leukemias are rare in children and account for fewer than 5% of cases. Leukemia accounts for 25% of cases of cancer in black children and 34% of cases of cancer in white children.

In the United States, over 50% of all cases of ALL are diagnosed in individuals less than 20 years of age with new cases most prevalent among children between 2 and 6 years of age.[86] The incidence of ALL is greatest among children aged 2 to 3 years (>90 cases per 1 million per year) with rates decreasing to fewer than 30 cases per million by age 8. Since 1975, the incidence of ALL has gradually increased.[87] New cases of leukemia have been rising on average 0.3% a year in the last 10 years. ALL affects more

white and Hispanic than black children and more males than females. The incidence of ALL is also higher in Western and industrialized nations.[88] ALL is more common in boys than girls and among Hispanic and white children than among black and Asian American children. AML is slightly more common during the first 2 years of life and during the teenage years. It occurs about equally among boys and girls of all races; however, recent studies suggest increasing rates among Asian children and those of Hispanic ethnicity.[89,90]

Types of Leukemia

A number of different classifications are used for the leukemias. First, acute leukemia is differentiated from chronic leukemia. Second, the cell line determines whether lymphoid cells or myeloid cells are involved. In acute leukemia, this difference separates ALL from AML and vice versa. Categories of ALL are further identified based on their presumed origin from bursa-equivalent cells (B cells) of cases of ALL and thymic cells (T cells) of normal lymphocytes. B-cell ALL comprises 80% to 85% of cases of ALL, and approximately 15% to 20% of cases are T-cell ALL. (See Chapter 29 for a discussion of leukemias in adults.)

Cytogenic studies of leukemic cells are performed routinely at most major treatment centers during the diagnostic process. Abnormal morphologic characteristics, as well as abnormalities in the number of copies of chromosomes, are often found in leukemic cells. **Hyperdiploidy** (the presence of greater than the diploid [46] number of chromosomes) is associated with a good prognosis. Common translocations associated with ALL are TEL-AML1, MLL rearrangements, and BCR-ABL. TEL-AML1 is the most common abnormality (in 20% to 30% of cases) and occurs when the *TEL* gene on chromosome 12p13 fuses with the *AML1* gene on chromosome 21q22. TEL-AML1 is associated with a favorable outcome. MLL rearrangements are translocations between the *MLL* gene on chromosome 11q23 and other partner chromosomes. One of the most noted MLL rearrangements involves chromosome 4 as the partner chromosome t(4;11). This specific MLL rearrangement occurs most frequently among leukemia in infants less than 1 year of age and is associated with a poor prognosis despite intensive therapy.[91] A translocation involving the long arms of chromosomes 9 and 22, t(9;22)(q34;q11), also described as the **Philadelphia chromosome**, occurs in more than 95% of cases of chronic myeloid leukemia (CML) yet is also present in about 2% to 3% of cases of ALL.[86] The specific breakpoint, however, varies in CML and ALL. The translocation results in the generation of the *BCR-ABL* fusion gene. The bcr-abl protein that is produced by this fusion gene results in unregulated tyrosine kinase activity.

Classification of childhood leukemia has become a complex but essential process to determine treatment. The WHO has developed a classification scheme based on a comprehensive system that uses morphology, immunophenotyping, cytogenetic, and clinical features.[86] Immunophenotyping using flow cytometry is used to distinguish between lymphoblastic and nonlymphoblastic leukemia. Molecular cytogenetic techniques, such as fluorescence in situ hybridization (FISH), allow for further detection of specific genetic abnormalities associated with leukemia subtypes. Next-generation sequencing (NGS) techniques, including whole genome and whole exome sequencing, are supporting further investigation of the molecular basis of childhood leukemia as well as planning treatment.[92] (See Emerging Science Box: Molecular Characterization of Childhood Leukemia and Treatment Considerations.)

Etiology

The exact cause of most childhood cancer, including leukemia, is unknown. The occurrence of leukemia in monozygotic twins is estimated as being as high as 25%. About 5% of all childhood cancers are caused by inherited mutations. Genetic mutations that predispose the child to cancer development can occur during fetal development. Genetic conditions associated with leukemia include Down syndrome, neurofibromatosis, Li-Fraumeni syndrome, Shwachman-Diamond syndrome, Bloom syndrome, Fanconi anemia, and ataxia-telangiectasia.[93] AML in children is sometimes associated with loss or deletion of chromosome 7 in the leukemia cells. AML can develop from preexisting myeloproliferative disorders that also are preleukemia syndromes, such as myelodysplastic syndrome. Epigenetic modifications, including DNA methylation, have been proposed as mediating events between environmental exposures and subsequent disease development.[94,95]

Multiple types of exposures have been investigated in relation to the development of leukemia. Many studies have shown that exposure to ionizing radiation (prenatal exposure to x-rays and postnatal exposure to high doses) can lead to the development of childhood leukemia and possibly other cancers.[96] There is recent concern for performing computed tomography (CT) scans in children. The increased use of these scans combined with wide variability in radiation doses has resulted in many children receiving a high dose of radiation.[97] Studies of other possible environmental risk factors, including parental exposure to cancer-causing chemicals, prenatal exposure to pesticides, childhood exposure to common infectious agents, and living near a nuclear power plant, have so far produced inconsistent results. Higher risks of cancer have not been seen in children of individuals treated for sporadic cancer (cancer not caused by an inherited mutation).[98,99]

Exposure to prenatal and postnatal smoking has also been investigated in relation to the development of leukemia and other childhood cancers. A recent meta-analysis identified an association between the development of ALL and paternal smoking in both the preconception and prenatal periods.[100] Paternal smoking before, during, and after a pregnancy was identified as contributing to an increased risk of both ALL and AML in another recent meta-analysis; however, maternal smoking was not.[101]

Prenatal exposure to pesticides is hypothesized to increase the risk of childhood leukemia by resulting in oxidative stress leading to the generation of free radicals that induce breaks in the DNA of early hematopoietic stem cells. Results of recent meta-analyses support associations between parental exposure to pesticides and other potential environmental toxins before or during pregnancy and subsequent development of childhood leukemia.[102,103]

Chemicals such as benzene have been associated with the development of AML in adults. Recent meta-analyses provide evidence of a possible association between benzene exposure, occurring in the context of traffic-related air pollution and childhood leukemia.[104,105] Previous treatment with chemotherapy for other cancer types is also a risk factor for developing ALL and AML.[91]

Studies investigating other types of exposures have had inconclusive results. Leukemic "clusters" that represent a greater number of leukemia cases occurring in a particular geographic location have raised speculation about environmental factors or infectious patterns of transmission. Follow-up studies, however, have not provided evidence of increased risk in the context of these exposures.[106,107]

Pathophysiology

ALL involves immature B (pre-B) or T (pre-T) cells called **lymphoblasts**. As leukemia develops, the bone marrow becomes dense with lymphoblasts that replace the normal marrow and disrupt normal function. Many of the chromosomal abnormalities documented in ALL cause dysregulation of the expression and function of transcription factors required for normal B-cell and T-cell development.[108,109] The mutations can include both gain of function and loss of function that are required for normal development.

AML is caused by acquired oncogenic mutations that impair differentiation, resulting in the accumulation of immature myeloid blasts in the marrow and other organs. Epigenetic alterations are frequent in AML and have a central role. The bone marrow crowding by blast cells produces marrow failure and complications, including anemia, thrombocytopenia, and neutropenia. AML is very heterogeneous because myeloid cell differentiation is very complex. Leukemia, whether ALL or AML, is typically distinguished from lymphoma by the presence of greater than 20% leukemic blasts in the bone marrow.

Clinical Manifestations

The onset of leukemia may be abrupt or insidious. Children with leukemia may present with symptoms only a few weeks before diagnosis. Regardless of how leukemia develops, the most common symptoms reflect consequences of bone marrow failure. These include decreased levels of RBCs and platelets, as well as changes in white blood cells. Pallor, fatigue, petechiae, purpura, bleeding, and fever generally are present. Approximately 45% of children present with a hemoglobin level below 7 g/dL. Three-quarters of children with ALL have platelet counts less than 100,000/mm^3 at diagnosis, and 28% have platelet counts less than 20,000/mm^3. Epistaxis, excessive bruising, and hematuria may occur in children

with severe thrombocytopenia. Half of all children newly diagnosed with AML have platelet counts less than 50,000/mm^3. Disseminated intravascular coagulation occurs more commonly with AML, particularly with promyelocytic leukemia. The granules in the leukemic promyelocytes likely possess thromboplastin activity.

Fever can be present as a result of (1) infection associated with the decrease in functional neutrophils and (2) hypermetabolism associated with the ongoing rapid growth and destruction of leukemic cells. In most children with ALL, the total white blood count at diagnosis is less than 10,000/mm^3, and with AML, most present with white cell counts less than 50,000/mm^3. In a few children, however, the peripheral white blood count at presentation may be greater than 100,000/mm^3. White blood cell counts greater than 200,000/mm^3 can cause leukostasis, an intravascular clumping of cells resulting in infarction and hemorrhage, usually in the brain and lung. The three most important favorable prognostic factors are age at diagnosis (2 to 10 years), initial leukocyte count (<50,000/mm^3), and initial response to treatment.

Renal failure as a result of hyperuricemia (high uric acid levels) can be associated with ALL, particularly at diagnosis or during the initial phase of treatment. Uric acid levels rise as an end product of purine metabolism from cellular destruction. Because the major excretory pathway is through the kidney, urates can precipitate in renal tubules or ureters and can lead to oliguria and acute renal failure. Renal failure is typically preventable if uric acid levels are monitored, and initial management is aimed at optimal hydration and blockage of further uric acid formation by administration of the drug allopurinol. Rasburicase, a medication that directly inhibits existing uric acid, may be administered to children with elevated uric acid levels and deemed at increased risk for renal failure.[110]

Extramedullary invasion with leukemic cells can occur in nearly all body tissue. Most children with ALL have some extramedullary involvement at diagnosis. Leukemic invasion of tissue other than bone marrow is believed to represent metastatic infiltration. Hepatosplenomegaly and lymphadenopathy, resulting from extramedullary hematopoiesis, occur in nearly half of children with ALL, but they are less common in children with AML.

The CNS is a common site of infiltration of extramedullary leukemia. Less than 10% of children with ALL, however, will have CNS involvement at diagnosis. The most common symptoms of CNS involvement relate to increased intracranial pressure, causing early morning headaches, nausea, vomiting, irritability, and lethargy. Gonadal involvement with testicular infiltration also may occur.

Leukemic infiltration into bones and joints is common. Reports of bone or joint pain actually lead to the diagnosis of leukemia in some children. In most children, bone pain is characterized as migratory, vague, and without areas of swelling or inflammation. In some cases, however, joint pain is the primary symptom, and some swelling is associated with the pain. Occasionally, these children are initially misdiagnosed as having rheumatoid arthritis. Other organs reported to be sites of leukemic invasion include the kidneys, heart, lungs, thymus, eyes, skin, and gastrointestinal tract. Skin involvement is more common in AML than in ALL.

Evaluation and Treatment

Leukemia is diagnosed through blood tests and examination of peripheral blood smears. A bone marrow aspiration is usually performed to further characterize the leukemia. The **blast cell** is the hallmark of acute leukemia (Fig. 30.10A). The blast cell is a relatively undifferentiated cell characterized by diffusely distributed nuclear chromatin, with one or more nucleoli and basophilic cytoplasm (Fig. 30.10B).

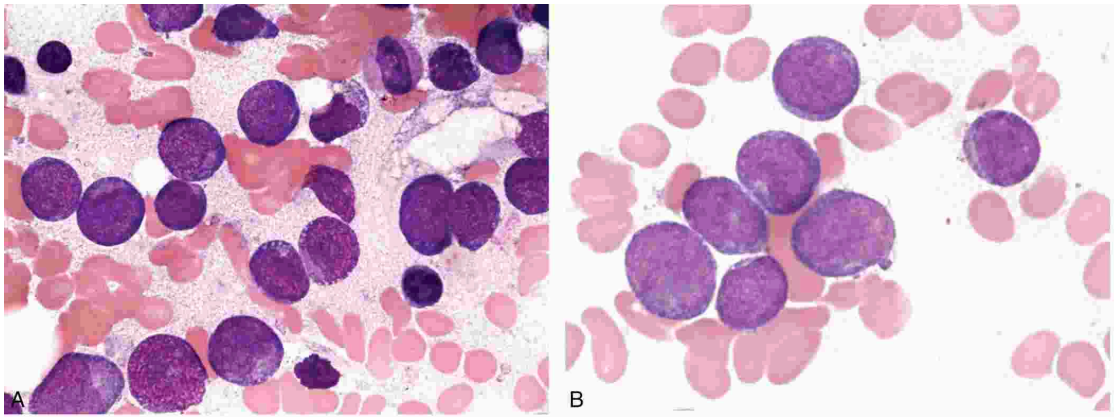

FIG. 30.10 Blast Cells Acute Myeloid Leukemia Without Maturation.
(A) Bone marrow smear with numerous blast cells and (B) blast cells (shown in purple) with basophilic cytoplasm. (From Naeim F, Nagesh Rao P, Song SX, et al. Acute myeloid leukemia, not otherwise specified. *Atlas of Hematopathology*, 2018; 345–374. https://doi.org/10.1016/b978-0-12–809843-1.00022-x.)

Two photomicrographs of bone marrow smears A and B show the morphology of acute myeloid leukemia. Photomicrograph A shows large blast cells with a low nucleus. Photomicrograph B shows numerous blasts cell with round nuclei.

Healthy children have less than 5% blast cells in the bone marrow and none in the peripheral blood. In ALL, the bone marrow often is replaced by 80% to 100% blast cells. The bone marrow, at the time of diagnosis, is typically considered hypercellular and is composed of a homogeneous population of cells. Counts of normally developing RBCs, granulocytes, and platelets are typically reduced. Occasionally, the marrow appears hypocellular, making the diagnosis difficult to differentiate from aplastic anemia. When this occurs, bone marrow biopsy or biopsy of extramedullary sites is necessary to confirm the diagnosis.

Approximately 85% of children with ALL will become 5-year survivors of their illness. Chemotherapy, using a combination of medications, is the treatment of choice for acute leukemia. Radiation of the CNS is used only in selected cases. Identification of various risk groups among children with ALL has led to the development of different intensities of drug protocols. As a result, treatment can be targeted specifically for a particular risk group. For example, enhanced technologies to detect minimal residual disease have improved the ability to identify children who are at increased risk of relapse. These children are then able to receive intensified treatment with emerging therapeutic approaches, including bi-specific antibodies earlier in their course of treatment.[111] Children who experience relapses of ALL may receive hematopoietic stem cell transplants. Treatment with chimeric antigen receptor T cells (CAR-T cells) is also showing promise.[93]

AML is more difficult to treat than ALL. Combination chemotherapy is the most common approach to treatment. Those children with unfavorable cytogenetic markers and those who experience a relapse of their disease will often undergo HSCT.[112]

CML accounts for less than 5% of childhood leukemias. Biologically targeted therapies, specifically tyrosine kinase inhibitors (TKIs), are becoming the mainstay of treatment, specifically for individuals whose disease has the *BCR/ABL* translocation.[112] TKIs are administered orally, and several are now approved for use in children. Treatment requires continued adherence to the medication regimen, and the health impact of long-term TKI therapy is not yet known.

Lymphomas

Lymphoma (Hodgkin lymphoma [HL] and non-Hodgkin lymphoma [NHL]) develops from the proliferation of malignant lymphocytes in the lymphoid system (see Chapters 14 and 29). Lymphomas arise from discrete tissue masses and involve some recognizable stage of lymphocyte B- or T-cell differentiation. The WHO provides a classification scheme for lymphoma that was updated in 2016 (also see Chapter 29).[113]

Lymphomas are the third most common type of childhood cancer, behind leukemia and CNS tumors, and represent about 11% of all cases of childhood cancer. Around 1800 children younger than 20 years of age are diagnosed with lymphoma in the United States each year.[114] NHL (including Burkitt lymphoma) occurs more often than Hodgkin lymphoma. Either group of diseases is rare before the age of 5 years, and the relative incidence increases throughout childhood. Boys are more likely to be diagnosed with lymphoma than are girls. Children with inherited or acquired immunodeficiency syndromes, such as Wiskott-Aldrich syndrome, ataxia-telangiectasia, and Bloom syndrome, are at particular risk for developing NHL.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphomas (NHLs) are cancers of immune cells. NHLs are a large and diverse group of tumors. NHL typically arises at extranodal sites and spreads in a noncontiguous or unpredictable manner. Some tumors develop more slowly, whereas others develop more quickly and aggressively. Some mature B-cell lymphomas present more like leukemia. Childhood NHL typically becomes evident as a diffuse disease and can be further subdivided into four major types: (1) mature B-cell non-Hodgkin lymphoma (Burkitt and Burkitt-like lymphoma and Burkitt leukemia); (2) lymphoblastic lymphoma; and (3) anaplastic large cell lymphoma.[115] The common types of NHL in children are different from those in adults. The most common types of NHL in children are Burkitt lymphoma (40%), lymphoblastic lymphoma (25% to 30%), and large cell lymphoma (10%).

Pathophysiology

Burkitt lymphoma will be discussed as an example of the pathogenesis of NHL in children. Burkitt lymphoma includes three clinical variants: sporadic, endemic, and immunodeficiency associated. Each of these variants is associated with translocations of the *MYC* gene on chromosome 8 that lead to increased MYC protein levels.[115] MYC is a transcription factor, meaning that it influences the rate of transcription of DNA into messenger RNA. Overexpression of MYC further increases the expression of genes required for aerobic glycolysis, called the *Warburg effect* (see Chapter 12). Many Burkitt lymphomas are associated with latent infection of the EBV.[116] EBV is present in nearly all cases of endemic Burkitt lymphoma, which occur mostly among individuals living in areas of the world where malaria is highly prevalent. Malaria is believed to reduce resistance to EBV, thereby increasing susceptibility to lymphoma. EBV is also present in 15% to 20% of sporadic cases of Burkitt lymphoma and about 25% of tumors associated with human immunodeficiency virus (HIV) infection.[116,117] Other immunodeficiency conditions that increase the risk for Burkitt and other NHLs include receipt of a solid organ transplant, Wiskott-Aldrich syndrome, ataxia-telangiectasia, and Bloom syndrome.

Clinical Manifestations

NHL can arise from any lymphoid tissue. Signs and symptoms therefore are specific for the involved site. Some children have such widespread involvement that no original site can be determined. Because some childhood NHL is rapidly progressive, symptoms are often present only a few weeks before diagnosis is made. Rapidly enlarging lymphoid tissue and painless lymphadenopathy are common in about one-third of children with abdominal sites of involvement, usually representing a gastrointestinal origin for the disease. Symptoms often include abdominal pain and vomiting, but a palpable mass is not always present. The other common site of childhood NHL is the chest region. Associated signs of NHL include swelling of the lymph nodes in the neck, underarm, stomach, or groin; trouble swallowing; a painless lump or swelling in a testicle; weight loss for unknown reason; night sweats; and possibly trouble breathing. Involvement of facial bones, particularly the jaw, is common in endemic Burkitt lymphoma.

Evaluation and Treatment

Diagnosis is made by physical exam and health history, followed by a needle biopsy of disease sites, usually the involved lymph nodes, tonsils, spleen, liver, bowel, or skin. Burkitt lymphoma is very aggressive and responds well to treatment. With intensive chemotherapy, most children and young adults can be cured.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is a group of lymphoid neoplasms that, unlike NHL, arises in a single chain of lymph nodes and spreads first in a contiguous way to lymphoid tissue. HL is characterized by the presence of Hodgkin and Reed-Sternberg cells (HRS), which are large cells that come from the germinal center of B cells (Fig. 30.11). HL is a common type of cancer in young adults and adolescents but rare in childhood. The WHO has identified five types of HL: (1) nodular sclerosis, (2) mixed cellularity, (3) lymphocyte rich, (4) lymphocyte depletion, and (5) lymphocyte predominance (also see Chapter 29). Similar expression of HRS cells occurs in the first four types; therefore, they are considered the *classic* types. In the lymphocyte predominance type, the HRS cell is distinctive but different than the others. Risk factors for HL include having EBV, being infected with HIV or other immunologic disorders (immunodeficiencies, autoimmune lymphoproliferative syndrome), having a personal history of mononucleosis, and having a parent or sibling with a personal history of HL.[118] Relatively few cases of HL are diagnosed in children before age 5 years, and HL is much more prevalent among males than females (M:F = 5.3) in this age group. Among adolescents 15 to 19 years of age, however, the incidence of HL is slightly greater in females (M:F = 0.8). The incidence of HL gradually increases through age 11 years, with a marked increase through adolescence that continues into the 30 s.

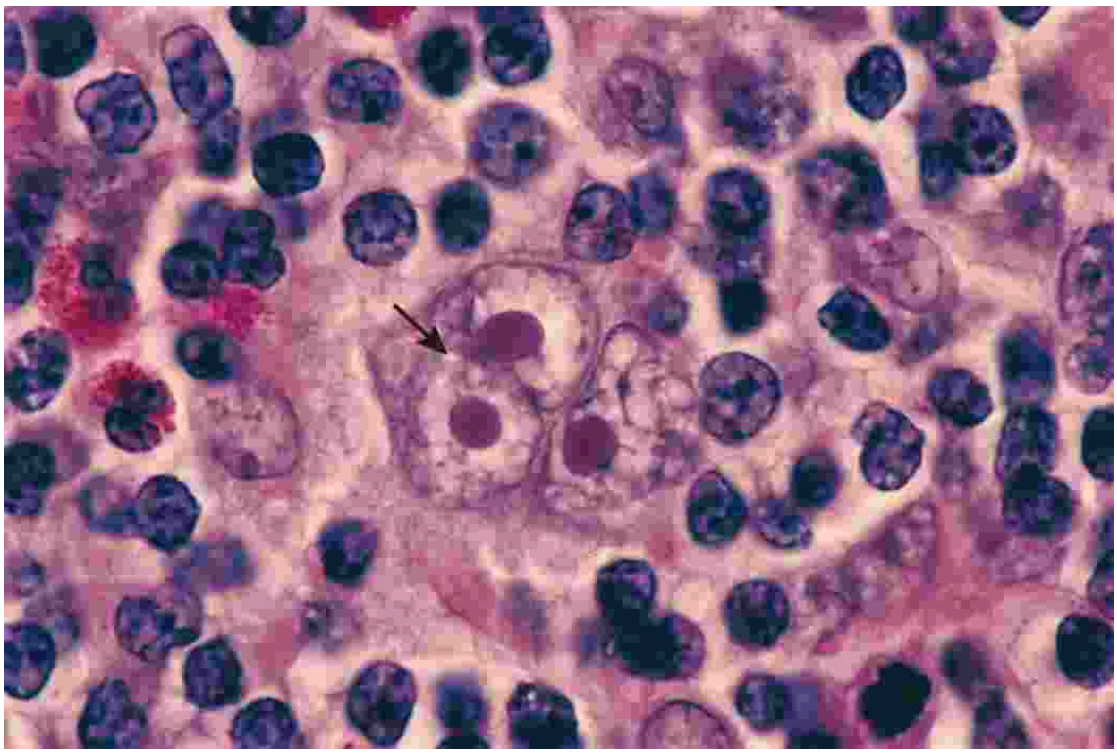

FIG. 30.11 Diagnostic Reed-Sternberg Cell.
A large multinucleated or multilobated cell with inclusion body–like nucleoli *(arrow)* surrounded by a halo of clear nucleoplasm. (From Damjanov I, Linder J. *Pathology: A color atlas*. St. Louis: Mosby; 2000.)

Pathophysiology

The HRS cells fail to express most of the normal B-cell markers, as well as those of T-cells. The causes of the genetic rearrangements or reprogramming are not fully known but are thought to be the result of widespread epigenetic changes.

The abnormal pattern of gene expression in HRS cells suggests that the activity of many transcription factors is also altered.[119] NGS studies have identified mutations in signaling pathways, including transcription factor nuclear factor-kappa B (NF-κB) and other epigenetic regulators. Abnormalities in the activation of NF-κB may be influenced by EBV infection. NF-κB is involved in many biologic processes, including inflammation, immunity, cell growth, differentiation, and apoptosis. EBV-infected B cells, resembling Reed-Sternberg cells, are found in lymph nodes in individuals with infectious mononucleosis, suggesting that the EBV proteins may have a role in changes of the B cells into HRS cells.[120] Altered expression of major histocompatibility class antigens may allow HRS cells to avoid the normal host immune response.[121]

Clinical Manifestations

Painless lymphadenopathy in the lower cervical chain, with or without fever, is the most common symptom in children. These nodes are firm and rubbery and may be sensitive to palpation if they have grown rapidly. Other lymph nodes and organs also may be involved (Fig. 30.12). At least two-thirds of individuals have mediastinal involvement that may cause symptoms ranging from a nonproductive cough to tracheal or bronchial compression leading to airway obstruction. Extranodal primary sites in Hodgkin lymphoma are rare. Systemic symptoms at the time of diagnosis may include fatigue, anorexia, weight loss, malaise, drenching night sweats, and pruritus. Intermittent fever is present in 30% of children, and weight loss may be present.

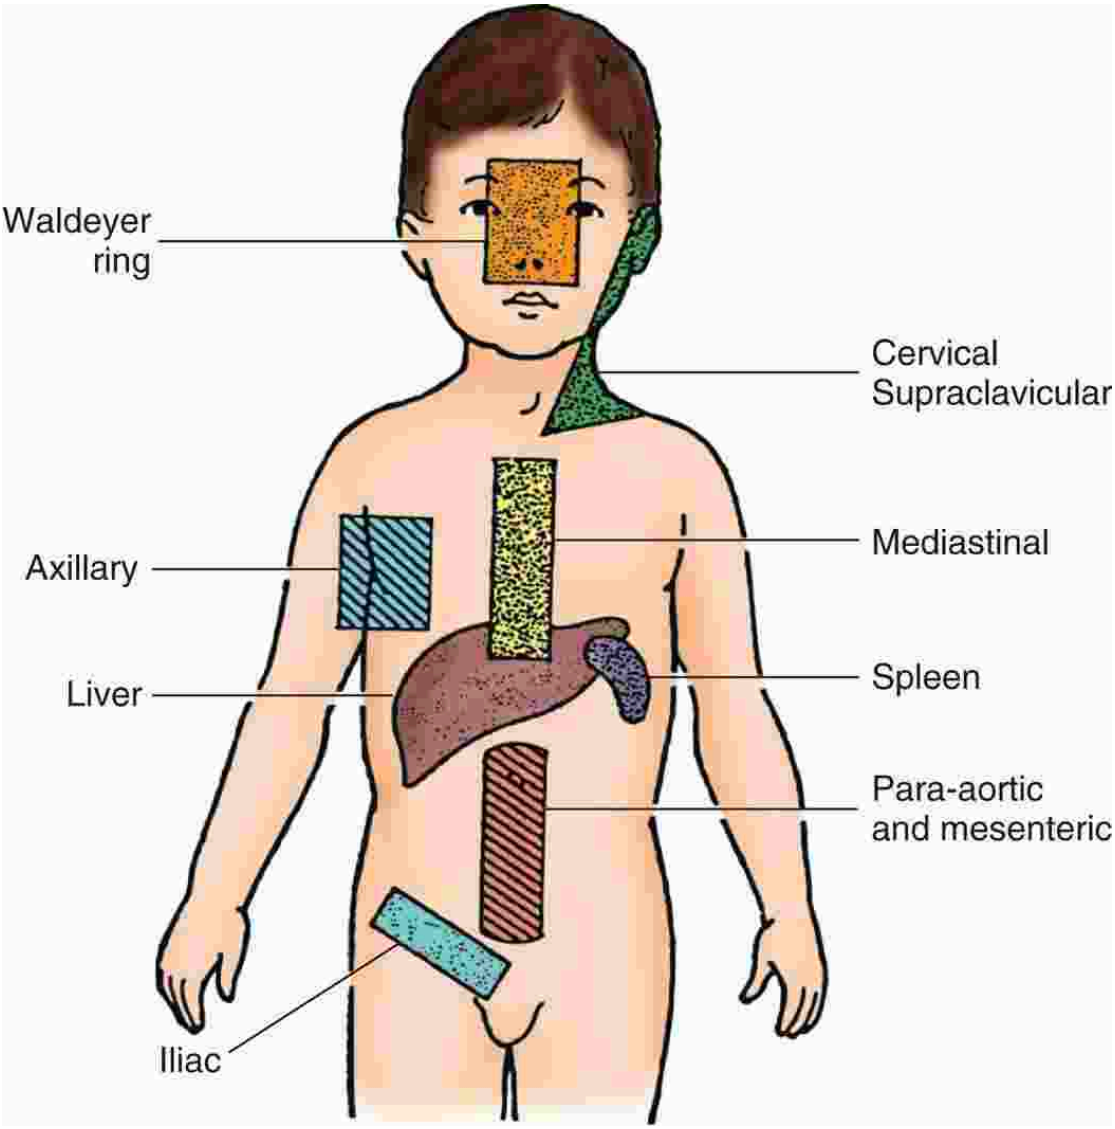

FIG. 30.12 Main Areas of Lymphadenopathy and Organ Involvement in Hodgkin Lymphoma. (From Hockenberry MJ, et al., eds. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2015.)

An illustration of the anterior view of the human body shows the main areas of lymphadenopathy and organ involvement in Hodgkin lymphoma: Waldeyer ring, cervical supraclavicular, mediastinal, axillary, liver, spleen, para-aortic and mesenteric, and iliac.

Evaluation and Treatment

The Ann Arbor staging system considers extent and location of disease, as well as substage classifications that consider systemic symptoms (presence of fever of 38°C [100.4°F] for 3 consecutive days, drenching night sweats, or unexplained loss of 10% or more of body weight in the 6 months preceding diagnosis), extranodal manifestations, or bulky disease. Combination chemotherapy used

with or without low-dose radiation has been an effective treatment, with long-term cure rates reported from 90% to 95%.[118]

Historically, survivors had a much greater risk of developing a secondary cancer, such as lung cancer, melanoma, and breast cancer. Treatment protocols have been modified to minimize the use of radiotherapy and use less toxic chemotherapy. Targeted therapies, including monoclonal antibodies such as brentuximab vedotin and immune checkpoint inhibitors, may have a greater role in treating Hodgkin lymphoma.

Summary Review

Disorders of Erythrocytes

1. Anemia is the most common blood disorder in children. Like the anemias of adulthood, the anemias of childhood are caused by ineffective erythropoiesis or premature destruction of erythrocytes.
2. Iron deficiency anemia (IDA) is the most common nutritional disorder worldwide. Its incidence is greatest among children between 6 months and 2 years of age. Iron is critical for the developing child and without it, damage from the periods of IDA is irreversible.
3. Regardless of its cause, IDA produces a hypochromic-microcytic anemia. Symptoms of mild anemia are often nonspecific, so parents may not notice changes until moderate anemia has developed.
4. Hemolytic disease of the fetus and newborn (HDFN) results from incompatibility between the maternal and the fetal Rh factors or blood type (ABO). Maternal antibodies (anti-Rh antibodies) form in response to the presence of fetal incompatible (Rh-positive) erythrocytes in the blood of an Rh-negative mother. The maternal antibodies then enter the fetal circulation and cause hemolysis of fetal erythrocytes. ABO incompatibility can cause HDFN even if fetal erythrocytes do not escape into the maternal circulation during pregnancy.
5. The key to treatment of HDFN resulting from Rh incompatibilities lies in prevention or immunoprophylaxis.
6. Sickle cell disease is a group of disorders characterized by the production of abnormal hemoglobin S (HbS) within the erythrocytes. It is most common among people with ancestry from sub-Saharan Africa.
7. Sickle cell disease is an inherited, autosomal recessive disorder expressed as sickle cell anemia, sickle cell–thalassemia disease, or sickle cell–HbC disease, depending on mode of inheritance. Sickle cell anemia, in which the individual is homozygous for HbS, is the most severe. Sickle cell–thalassemia and sickle cell–HbC disease are compound heterozygous forms in which the child inherits HbS from one parent or another type of abnormal hemoglobin from the other parent. All forms of sickle cell disease are lifelong conditions.
8. Sickle cell trait, in which the child inherits HbS from one parent and normal hemoglobin (HbA) from the other, is a heterozygous carrier state that rarely has clinical manifestations.
9. Sickle cell disease causes a change in the shape of red blood cells into the sickle shape. Sickling is triggered by decreased oxygen or dehydration. Most sickled erythrocytes regain a normal shape after reoxygenation and rehydration.
10. The alpha- and beta-thalassemias are inherited autosomal recessive disorders. These conditions result in an impaired rate of synthesis of one of the two chains—α or β—of adult hemoglobin (HbA).

Disorders of Coagulation and Platelets

1. Hemorrhagic diseases can be either inherited (hemophilias) or antibody-mediated (primary immune thrombocytopenia [ITP]).
2. The hemophilias are a group of inherited bleeding disorders resulting from mutations in the genes responsible for coagulation factors.

3. Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are caused by mutations in the genes coding for factors VIII and IX, factors essential in the coagulation cascade. Because factors VIII and IX function together, hemophilia A and B are clinically indistinguishable. Hemophilia A is the most common hereditary disease associated with life-threatening bleeding.
4. Hemophilias A and B are inherited as X-linked recessive conditions. Approximately one-third of cases, however, are the result of a spontaneous mutation in the involved gene.
5. The antibody-mediated hemorrhagic diseases are a group of disorders caused by the immune response. Antibody-mediated destruction of platelets or antibody-mediated inflammatory reactions to allergens damage blood vessels and cause seepage into tissues.
6. ITP is the most common disorder of platelet consumption in which antiplatelet antibodies bind to the plasma membranes of platelets. ITP results in platelet sequestration and destruction by mononuclear phagocytes at a rate that exceeds the ability of the bone marrow to produce them.

Neoplastic Disorders

1. Leukemia is cancer of the blood-forming tissues, such as the bone marrow, that most often produces abnormal white blood cells called leukemic cells.
2. About 75% of childhood leukemias are acute lymphoblastic leukemia (ALL). The remaining cases are classified as acute myeloid leukemia (AML) and related neoplasms. Chronic leukemias are rare in children.
3. The cause of most childhood cancer, including leukemia, is unknown. About 5% of all childhood cancers are caused by inherited mutations. Genetic mutations that predispose the child to cancer development can occur during fetal development.
4. Exposure to ionizing radiation can lead to the development of childhood leukemia and possibly other cancers.
5. ALL causes dysregulation of the expression and function of transcription factors required for normal B- and T-cell development.
6. Epigenetic alterations are frequent in AML and have a central role in its development.
7. The onset of leukemia may be abrupt or insidious. The most common symptoms reflect consequences of bone marrow failure and can include decreased levels of red blood cells and platelets, as well as changes in white blood cells.
8. The lymphomas of childhood are Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).
9. Lymphomas are proliferations of malignant lymphocytes that arise from discrete tissue masses. Lymphoid neoplasms involve some recognizable stage of lymphocyte B- or T-cell differentiation.
10. Some lymphomas occasionally have leukemic presentations, and evolution to leukemia is not unusual during the progression of incurable lymphoma.
11. The lymphomas of childhood are Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).
12. NHLs are cancers of immune cells. Children with inherited or acquired immunodeficiency syndromes have an increased risk of developing NHL.
13. The most common types of NHL in children are Burkitt lymphoma, lymphoblastic lymphoma, and large cell lymphoma. Most Burkitt lymphomas are latently infected with the Epstein-Barr virus (EBV).
14. HL is a group of lymphoid cancers. HL arises in a single chain of lymph nodes and spreads first in a contiguous way to lymphoid tissue.
15. HL is characterized by the presence of Reed-Sternberg cells, which are large cells derived from the germinal center of B cells.

Emerging Science BoxGene Therapy for Sickle Cell

Historically, the clinical management of sickle cell disease has been largely supportive. With the advancement of technology and supportive care strategies, curative treatments, including

hematopoietic stem cell transplant and gene therapy are emerging. Gene therapy for sickle cell disease involves editing one of two genes of interest in the individual's hematopoietic stem cells using CRISPR/Cas9 technology. Editing a gene of interest allows its function and expression to be changed. Currently available clinical trials that include gene therapy for sickle cell disease are targeting two genes of interest: HBB and BCL11A, each of which has a different role in the phenotypic expression of sickle cell disease.

HBB provides the code for the beta-globin protein. A point mutation in HBB results in the production of hemoglobin S, which is associated with the sickling process. Gene editing replaces the incorrect base, thymine, with the correct base adenine. When this sequence is introduced into the individual's hematopoietic stem cells, they will then produce the correct beta-globin protein.

BCL11A is a transcription factor. Under normal conditions, expression of the BCL11A gene is responsible for the transition to the production of adult hemoglobin rather than fetal hemoglobin. Current gene editing techniques modify the expression of BCL11A so that it reverts back to producing fetal hemoglobin rather than adult hemoglobin. By producing fetal hemoglobin, the sickling process is prevented.

The gene therapy process involves the removal of some of the individual's hematopoietic stem cells to allow for gene editing. After the gene sequence of interest, HBB or BCL11A, is edited, a virus is used as a vector to introduce it into the harvested stem cells. The individual receives chemotherapy to create space for the newly modified stem cells. The stem cells are then infused back into the individual with the goal that the cells will express the newly edited version of the gene of interest.

Emerging Science BoxMolecular Characterization of Childhood Leukemia and Treatment Considerations

The presence of the Philadelphia chromosome, which involves a translocation between chromosomes 9 and 22 has been well-described in a subset of children with acute lymphoblastic leukemia. This translocation results in the formation of the *BCR-ABL* fusion gene. The protein produced by this gene results in unregulated tyrosine kinase activity within the cell. Historically, cure rates for children with Philadelphia positive (Ph+) acute lymphoblastic leukemia (ALL) have been poor. The use of tyrosine kinase inhibitors, in combination with chemotherapy, have resulted in improved cure rates.

In recent years, another molecular subtype of ALL that involves altered tyrosine kinase activity has been discovered. This subtype has been designated Philadelphia chromosome-like ALL or Ph-like ALL. It is present in approximately 12% of children and 21% of adolescents with ALL. It is also more prevalent among children and adolescents of Hispanic ethnicity and those with Down syndrome. As with Ph+ ALL, Ph-like ALL has been associated with poorer outcomes. Although the pattern of gene expression in Ph-like ALL is similar to that of Ph+ ALL, the bcr-abl protein is not produced. Ph-like ALL is genetically heterogeneous and is further defined by its gene expression profile and underlying tyrosine kinase alteration. Determining the tyrosine kinase alteration that is present can then guide the selection of a tyrosine kinase inhibitor to be used as part of the child's treatment.

Tyrosine kinase inhibitors differ from traditional chemotherapy in that they block intracellular signals rather than interfere with DNA synthesis. Tyrosine kinase inhibitors are also administered orally. Although this group of medications is associated with improved survival, treatment outcomes can depend on the individual's adherence to the prescribed treatment. Optimizing outcomes for individuals affected with this subtype of leukemia involves early identification of its molecular characteristics and then supporting affected children, adolescents, and their families in adhering to the prescribed treatment.

Chapter Outline

OUTLINE

Circulatory System, 1020

Heart, 1020
- Structures that Direct Circulation Through the Heart, 1021
- Structures that Support Cardiac Metabolism: Coronary Circulation, 1026
- Structures that Control Heart Action, 1028
- Factors Affecting Cardiac Output, 1036

Systemic Circulation, 1039
- Structure of Blood Vessels, 1039
- Factors Affecting Blood Flow, 1043
- Regulation of Blood Pressure, 1045
- Regulation of the Coronary Circulation, 1049

Lymphatic System, 1050

Tests of Cardiovascular Function, 1051
- Cardiac and Coronary Artery Evaluation, 1051
- Systemic Vascular Evaluation, 1054

Aging and the Cardiovascular System, 1054

The functions of the circulatory system include delivery of oxygen, nutrients, hormones, immune system components, and other substances to body tissues and removal of the waste products of metabolism. Delivery and removal are achieved by an extensive array of tubes—the blood and lymphatic vessels—connected to a pump—the heart. The heart continuously pumps blood through the

blood vessels in collaboration with other systems, particularly the nervous and endocrine systems, which are intrinsic regulators of the heart and blood vessels. Immune system components, nutrients, and oxygen are supplied by the immune, digestive, and respiratory systems; gaseous wastes of metabolism are expired through the lungs; and other wastes are removed by the kidneys and digestive tract.

http://evolve.elsevier.com/Rogers/pathophysiology/

The vascular **endothelium** also is a key component of the circulatory system and is sometimes considered a separate endocrine organ. This endothelium is a multifunctional tissue whose health is essential to normal vascular, immune, and hemostatic system function. Endothelial dysfunction is a critical factor in the development of vascular and other diseases (see Chapter 32).

Circulatory System

The heart is composed of two conjoined pumps moving blood through two separate circulatory systems in sequence: one pump supplies blood to the lungs, whereas the second pump delivers blood to the rest of the body. Structures on the right side, or **right heart, pump** blood through the lungs. This system is termed the **pulmonary circulation** and is described in Chapter 34. The left side, or left heart, sends blood throughout the **systemic circulation**, which supplies all of the body except the lungs (Fig. 31.1). These two systems are serially connected; thus the output of one becomes the input of the other.

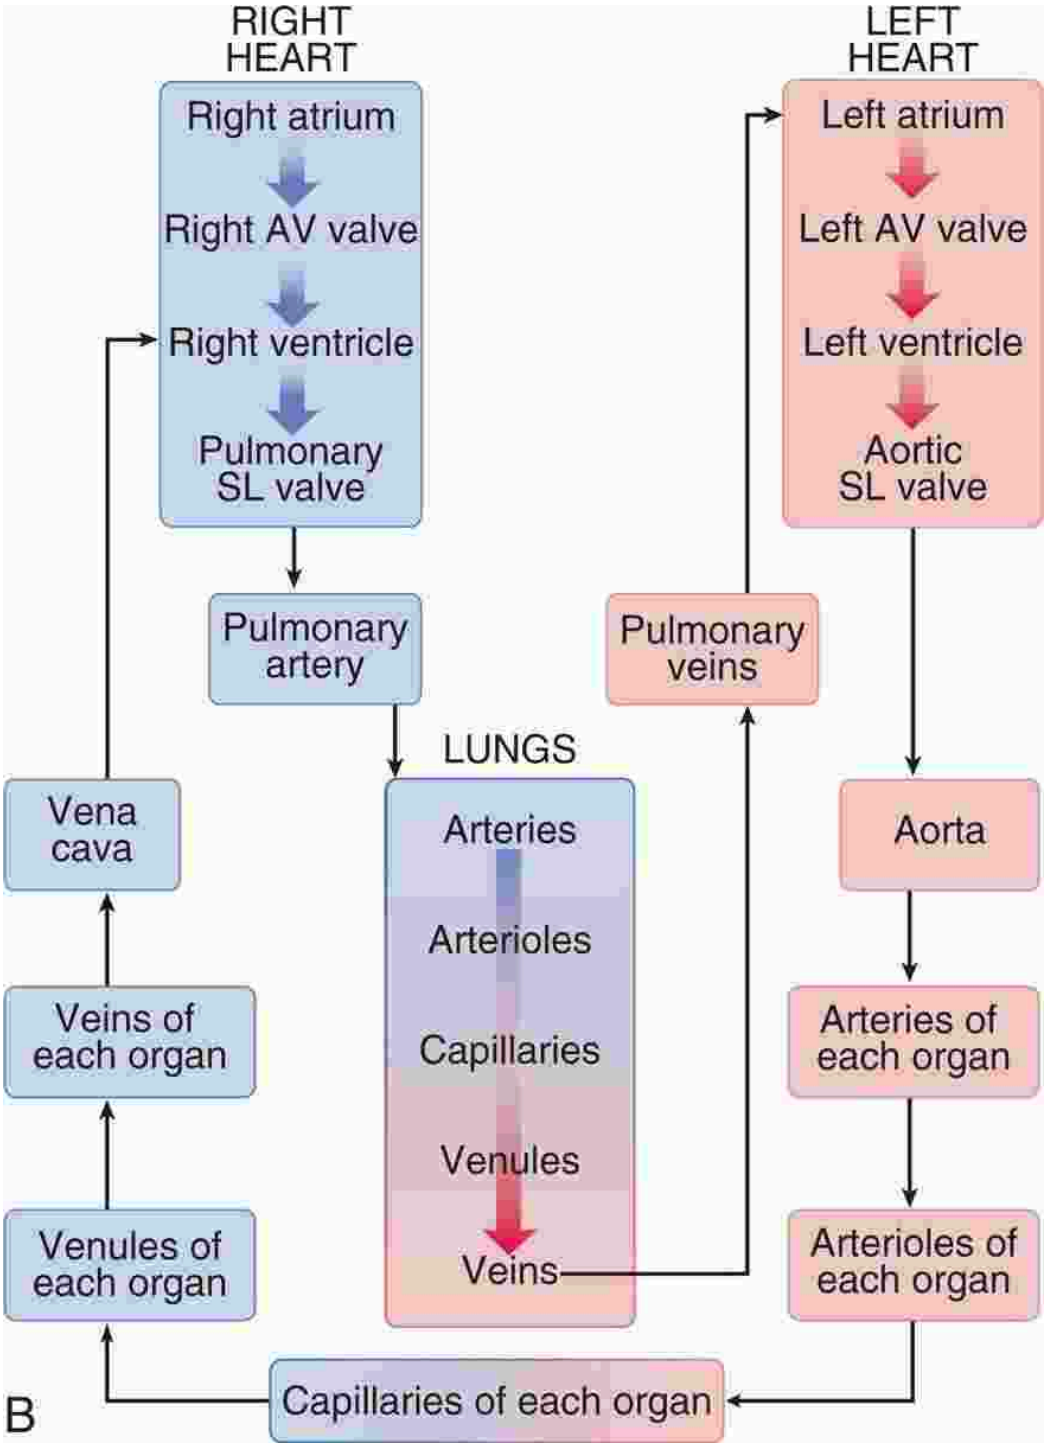

FIG. 31.1 Diagram of the Pulmonary and Systemic Circulatory Systems and Flow Chart of the Direction of Blood Flow.
(A) The right heart pumps unoxygenated blood *(blue)* through the pulmonary circulation, where

oxygen enters the blood and carbon dioxide is exhaled, and the left heart pumps oxygenated *(red)* blood to and from all the other organ systems in the body. **(B)** Blood flow begins at the left ventricle of the heart; the blood flows to the arteries, arterioles, capillaries of each body organ, venules, veins, right atrium, right ventricle, pulmonary artery, lung capillaries, pulmonary veins, and left atrium and then returns to the left ventricle. (B, Adapted from Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

Left panel, A. The illustration shows the pulmonary and the systemic circulatory system and the arrow mark in the system and the blood flow is indicated by arrow marks. The following structures in the pulmonary circulation system are labeled: right pulmonary artery, right pulmonary vein, right lung capillaries, left pulmonary artery, left pulmonary vein, and left lung capillaries. The following structures in the systemic circulation system are labeled: liver circulation, vena cava, aorta, hepatic portal vein, systemic circulation, intestinal capillaries, renal capillaries, and systemic capillary beds. Right panel, B. The cycle shows the direction of the blood flow. The sequence of the flow is as follows. •Capillaries of each organ. •Venules of each organ. •Veins of each organ. •Vena cava. •Right heart (right atrium, right A V valve, right ventricle,

and pulmonary S L valve). •Lungs (arteries, arterioles, capillaries, venules, and veins) •Pulmonary veins. •Left heart (left atrium, left A V valve, left ventricle, and aortic S L valve). •Aorta. •Arteries of each organ. •Arterioles of each organ. •Capillaries of each organ.

Arteries carry blood from the heart to all parts of the body, where they branch into **arterioles** and even smaller vessels, ultimately becoming a fine meshwork of **capillaries**. Capillaries allow the closest contact and exchange between the blood and the interstitial space, or interstitium—the environment in which cells live. **Venules** and then **veins** next carry blood from the capillaries back to the heart. Some of the plasma or liquid part of the blood passes through the walls of the capillaries into the interstitial space. This fluid, called *lymph*, is returned to the cardiovascular system by vessels of the **lymphatic system**. The lymphatic system is a critical component of the immune system as described in Chapters 7 and 8.

Heart

The adult heart is about the size of a fist and weighs between 250 and 350 g. The heart lies obliquely (diagonally) in the **mediastinum**, the area above the diaphragm and between the lungs. Heart structures can be categorized by function:

1. *Structural support of heart tissues and circulation of pulmonary and systemic blood through the heart*. This category includes the heart wall and fibrous skeleton enclosing and supporting the heart and dividing it into four chambers; the valves directing flow through the chambers; and the great vessels conducting blood to and from the heart.
2. *Maintenance of cardiac metabolism*. This category includes all the vessels of the **coronary circulation**—the arteries and veins

that serve the metabolic needs of all the heart cells—and the heart's lymphatic vessels.

3. *Stimulation and control of heart action*. Among these structures are the nerves and specialized muscle cells that direct the rhythmic contraction and relaxation of the heart muscles, propelling blood throughout the pulmonary and systemic circulatory systems.

Structures that Direct Circulation Through the Heart

The complex anatomy and physiology of the heart serve to accept blood from the venous system and propel it unidirectionally through the right heart into the lungs, then through the left heart and out into the systemic arterial circulation (Fig. 31.2A). This process ensures the delivery of oxygenated blood into the systemic circulation and maintains tissue **perfusion**.

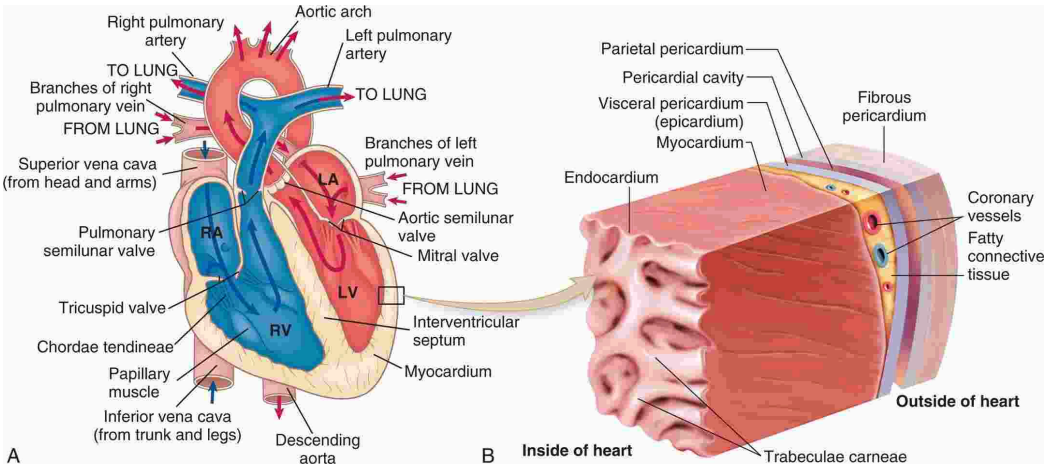

FIG. 31.2 Structures that Direct Blood Flow Through the Heart and Wall of the Heart. **(A)** The *arrows* indicate the path of blood through the chambers, valves, and major vessels. **(B)** This section of the heart wall shows the fibrous pericardium, the parietal and visceral layers of the serous pericardium (with the pericardial space between them), the myocardium, and the endocardium. Note the fatty connective tissue between the visceral layer of the serous pericardium (epicardium) and the myocardium. Note also that the endocardium covers tubular projections of myocardial muscle tissue called trabeculae. (Revised from Applegate E. *The anatomy and physiology learning system*, 4th edition. St. Louis: Saunders; 2011.)

Left panel, A. An illustration shows a cross-section of the heart. The flow of blood is traced as follows: from the lung through the branches of left pulmonary vein to the left atrium, through the mitral vale to the left ventricle and into the aortic arch. The blood also flows from the superior vena cava (from head and

arms) to the right atrium, into the right ventricle, and into the lung. Other structures identified on the illustration, clockwise from the right include: aortic semilunar valve, interventricular septum, myocardium, descending aorta, inferior vena cave (from trunk and legs), papillary muscle, chordae tendineae, pulmonary semilunar valve, and branches of right pulmonary vein. Right panel, B. The illustration shows a magnified view of the heart and identifies the following layers from the inside of the heart to the outside of the heart: endocardium, myocardium, coronary vessels, fatty connective tissue, visceral pericardium (epicardium), parietal pericardium, pericardial cavity, and fibrous pericardium.

Heart Wall

The three layers of the heart wall—the **epicardium**, **myocardium**, and **endocardium**—are enclosed in a double-walled membranous sac, the **pericardium** (see Fig. 31.2B). The **pericardial sac** has several functions: provides stability of the heart within the thorax, reduces friction between the heart and the mediastinal structures, limits the size of the heart chambers, provides a barrier to the spread of infection, and it contains pain receptors and mechanoreceptors that can cause reflex changes in blood **pressure** and **heart rate**.[1] The fibrous pericardium is composed of tough connective tissue that surrounds but does not attach to the heart. Within this outer layer are the parietal pericardium which adheres to the internal surface of the fibrous pericardium, and the visceral pericardium which adheres

to the heart (see Fig. 31.2B). These two layers are separated by a fluid-containing space called the **pericardial cavity**. The **pericardial fluid** (about 20 mL) is secreted by cells of the mesothelial layer of the pericardium and lubricates the membranes that line the pericardial cavity, enabling them to slide smoothly over one another with minimal friction as the heart beats. The amount and character of the pericardial fluid are altered if the pericardium is inflamed (see Chapter 32).

The smoothness of the outer layer of the heart, the epicardium, also minimizes the friction between the heart wall and the pericardial sac. The thickest layer of the heart wall, the myocardium, is composed of cardiac muscle and is anchored to the heart's fibrous skeleton. The thickness of the myocardium varies tremendously from one heart chamber to another. Thickness is related to the amount of **resistance** the muscle must overcome to pump blood from the different chambers. The heart muscle cells, cardiomyocytes, provide the contractile force needed for blood to flow through the heart and into the pulmonary and systemic circulations. About 0.5% to 1% of the cardiomyocytes are replaced annually; thus over a lifetime only about half of these muscle cells are replaced.[2] There is great interest in finding therapies that will increase the rate of **cardiomyocyte** replacement for persons who have suffered a myocardial infarction or have heart failure from another cause because the limited myocyte turnover is insufficient to restore contractile function (see Emerging Science Box: Myocardial Regeneration).[3]

Emerging Science Box Myocardial Regeneration

Myocardial infarction causes the loss of some of the muscle cells needed to maintain cardiac output, thus increasing the risk of heart failure in survivors. Given that heart failure is a growing problem with a poor prognosis in both the United States and internationally, finding an effective therapy is a critical need.

To replace the approximately 1 billion cardiomyocytes that are estimated to be lost with a myocardial infarction, researchers have identified four possible approaches: (1) accelerating the rate of heart cell division, (2) inserting new cells into the heart, (3) stimulating the heart muscle precursor cells already in the heart, and (4) reprogramming other cells so that they will become cardiomyocyte precursor cells. To stimulate adult heart cells to enter the cell cycle and thus accelerate cell division, various signaling molecules, such as neuregulin and fibroblast growth factor 1, have been used with some success. Currently the most promising cell types that have been injected into the heart include cells from the bone marrow, cardiac-derived cells taken from myocardial biopsies, and human pluripotent stem cells. Although there are cardiac progenitor or precursor cells in the heart, their rate of division is not adequate to replace lost tissue after an infarction. Some of the methods being investigated to stimulate these cardiomyocytes or other progenitor cells in the heart include treatment with peptides that act as growth factors, and some types of modified ribonucleic acids (RNAs) that produce vascular endothelial growth factor (VEGF). Reprogramming from one cell type into a pluripotent stem cell has been attempted with fibroblasts with some success. Each of these four approaches to replacing cardiomyocytes after injury comes with its own set of risks and challenges. Associated risks include increasing the chances for tumor development, damage to other organs, and myocardial scarring.

A barrier to using embryonic cells to replace adult heart tissue is that energy metabolism of the embryonic and adult heart is quite distinct. During embryonic development the relatively hypoxic embryonic heart utilizes anaerobic glycolysis as a main source of energy, whereas adult cardiomyocytes utilize the oxygen-dependent mitochondrial oxidative phosphorylation as an energy source. Therefore, to further advance this field, it is necessary to study changes in oxygenation of cardiomyocytes.

The internal lining of the myocardium, the endocardium, is composed of connective tissue and squamous cells (see Fig. 31.2B). This lining is continuous with the endothelium that lines all the arteries, veins, and capillaries of the body, creating a continuous, closed circulatory system.

Great Vessels

Blood moves into and out of the heart through several large veins and arteries (see Fig. 31.2A). The right heart receives venous deoxygenated blood from the systemic circulation through the superior and inferior venae cavae, which join and then enter the **right atrium**. Blood leaving the **right ventricle** enters the pulmonary circulation through the **pulmonary artery**, which divides into right and left branches to transport deoxygenated blood from the right heart to the lungs. The pulmonary arteries branch further into the

pulmonary capillary beds, where oxygen and carbon dioxide exchange occurs (see Fig. 31.1B).

Four **pulmonary veins**, two from the right lung and two from the left lung, carry oxygenated blood from the lungs to the left side of the heart. The oxygenated blood moves through the **left atrium** and ventricle, out into the **aorta** that subsequently branches into the systemic arteries that supply the body.

Chambers of the Heart

The heart has four chambers: the left atrium, the right atrium, the right ventricle, and the **left ventricle**. These chambers form two pumps in series: the right heart is a low-pressure system pumping blood through the lungs, and the left heart is a high-pressure system pumping blood to the rest of the body (see Fig. 31.2A). The atria are smaller than the ventricles and have thinner walls. The ventricles have a thicker myocardial layer and constitute much of the bulk of the heart. The wall of the right ventricle is about 4 to 5 mm thick, and that of the more muscular left ventricle is 8 to 12 mm thick.[1] The ventricles are formed by a continuum of muscle fibers originating from the fibrous skeleton at the base of the heart.

The wall thickness of each cardiac chamber depends on the amount of pressure or resistance it must overcome to eject blood. The two atria have the thinnest walls because they are low-pressure chambers that serve as storage units and channels for blood that is emptied into the ventricles. Normally, there is little resistance to flow from the atria to the ventricles. The ventricles, on the other hand, must propel the blood all the way through the pulmonary or systemic vessels. The ventricular myocardium must be strong enough to pump against pressures within the pulmonary or systemic vessels. The mean pulmonary artery pressure, the force the right ventricle must overcome, is only 15 mm Hg, whereas the mean arterial pressure the left ventricle must pump against is about 92 mm Hg. Because the pressure is markedly higher in the systemic circulation, the wall of the left ventricle is about three times thicker than that of the right ventricle.

The right ventricle is shaped like a crescent or triangle, enabling a bellows-like action that efficiently ejects large volumes of blood through the **pulmonary semilunar valve** into the low-pressure pulmonary system. The larger left ventricle is bullet shaped, which allows it to generate enough pressure to eject blood through a relatively larger **aortic semilunar valve** into the high-pressure systemic circulation.

The ventricles are structurally more complex than the atria. Each ventricle contains muscle fibers that divide it roughly into an **inflow tract**, which receives blood from the atrium, and an **outflow tract**, which sends blood to the circulation (see Fig. 31.2A).

Blood normally does not flow between the chambers of the right and left sides of the heart. The atria are separated by the interatrial septum, and the ventricles by the interventricular septum. However, because the fetus does not depend on the lungs for oxygenation, there is an opening before birth between the right and left atria, called the foramen ovale, that facilitates circulation. This opening closes functionally at the time of birth as the higher pressure in the left atrium pushes a flap, the septum primum, over the hole. In 75% to 80% of infants these septa are permanently fused within the first year of life (see Chapter 33).

Valves of the Heart

Four valves in the heart direct **blood flow** in one direction through the heart chambers (Fig. 31.3). The **atrioventricular(AV) valves** are termed such because they fall between the atria and ventricles. The AV valve openings are composed of tissue flaps called *leaflets* or *cusps*, which are attached at the upper margin to a ring in the heart's fibrous skeleton and by the **chordae tendineae** at the lower end to the papillary muscles (see Fig. 31.2A). The papillary muscles, extensions of the myocardium, help hold the cusps together and downward at the onset of ventricular contraction, thus preventing their backward expulsion or **prolapse** into the atria. The AV valve in the right heart is called the **tricuspid valve** because it has three cusps. The tricuspid opening (orifice) has the largest diameter of all

the heart valves.[1] The left atrioventricular valve is a bicuspid (two-cusp) valve called the **mitral valve**. The tricuspid and mitral valves function as a unit because the atria, fibrous rings, valvular tissue, chordae tendineae, papillary muscles, and ventricular walls are connected. Collectively, these six structures are known as the **mitral and tricuspid complex**. Damage to any one of the six components of this complex can alter function significantly and contribute to heart failure.

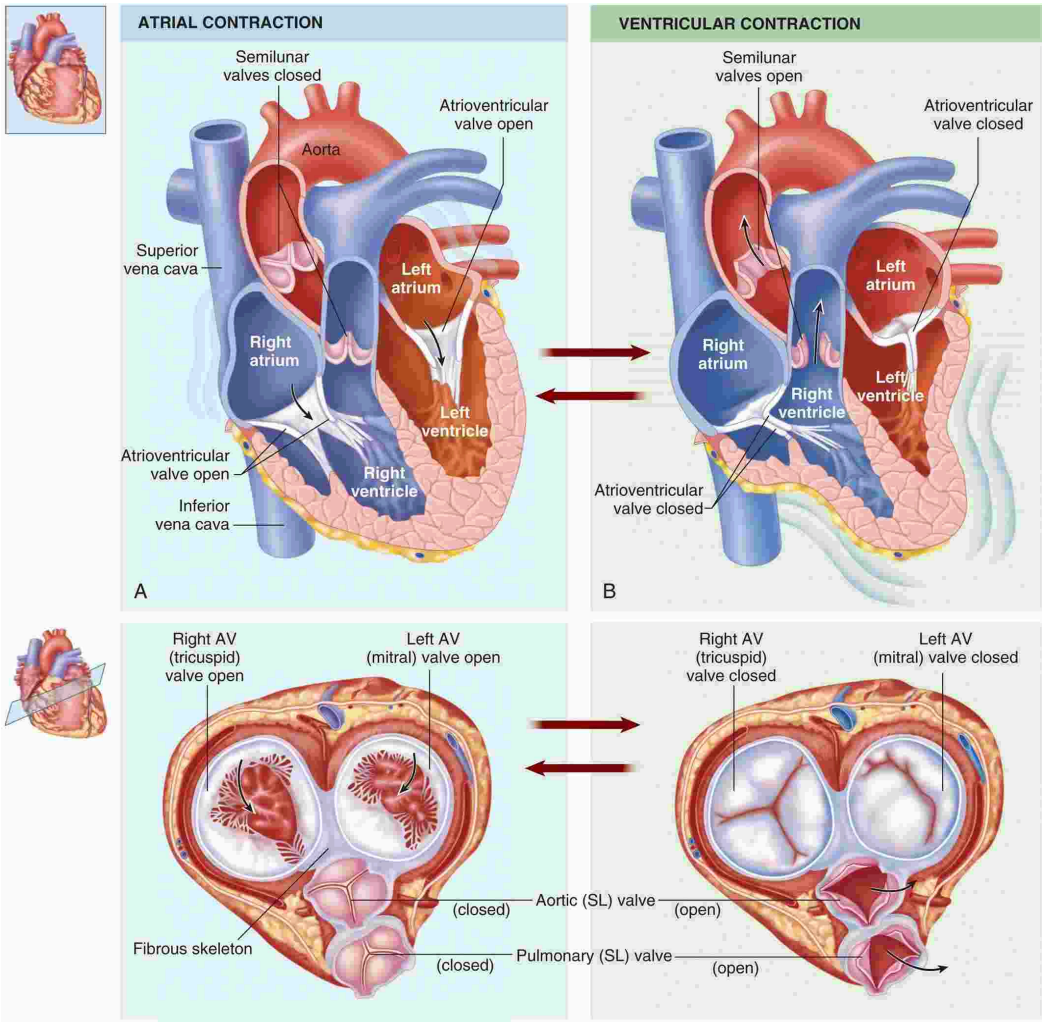

FIG. 31.3 Blood Flow Through the Heart During a Single Cardiac Cycle.
(A) During diastole, blood flows into atria, the atrioventricular valves are pushed open, and blood begins to fill the ventricles. Atrial systole squeezes the blood remaining in the atria into the ventricles. **(B)** During ventricular systole, the ventricles contract, pushing the blood out through the semilunar valves into the pulmonary artery (right ventricle) and the aorta (left ventricle). (From Patton KT, Thibodeau GA. *Structure & function of the body*, 15th edition. St. Louis: Elsevier; 2016.)

Left panel, A. A coronal cross-section and an axial cross-section of the heart illustrate atrial contraction and the arrows indicate the flow of blood. The following structures on the coronal cross-section are labeled, clockwise from the top: aorta, left atrium, atrioventricular valve open, left ventricle, right ventricle, inferior vena cava, atrioventricular valve open, right atrium, superior vena cava, and semilunar valves closed. The following structures on the axial cross-section are labeled, clockwise from the top: left A V (mitral) valve open, aortic (S L) valve close, pulmonary (S L) valve closed, fibrous skeleton, and right A V (tricuspid) valve open. Left panel, A. A coronal cross-section and an axial cross-section of the heart illustrate ventricular contraction and the arrows indicate the flow of blood. The following structures on the coronal cross-section are labeled, clockwise from the top: atrioventricular valve closed, left atrium, left ventricle, atrioventricular valve closed, right ventricle, right atrium, and semilunar valves open. The following structures on the axial cross-section are labeled, clockwise from the top: left A V (mitral) valve closed, aortic (S L) valve open, pulmonary (S L) valve open, and right A V (tricuspid) valve closed.

The other two valves in the heart are called the **semilunar valves**. These valves have three cup-shaped cusps that arise from the fibrous

skeleton. Blood leaves the right ventricle through the pulmonary semilunar valve, and it leaves the left ventricle through the aortic semilunar valve (see Figs. 31.2 and 31.3).

Fibrous Skeleton of the Heart

Four rings of dense fibrous connective tissue provide a firm anchorage for the attachments of the atrial and ventricular musculature, as well as the valvular tissue (see Fig. 31.3). The fibrous rings are adjacent and form a central, fibrous supporting structure collectively termed the *annuli fibrosi cordis*.

Intracardiac Pressures

Four heart valves, four chambers, and the pressure gradients they maintain ensure that blood only flows one way through the heart. When the ventricles are relaxed, the two AV valves open and blood flows from the relatively higher pressure in the atria to the lower pressure in the ventricles. As the ventricles contract, ventricular pressure increases and causes these valves to close and prevent backflow into the atria. The semilunar valves of the heart open when intraventricular pressure exceeds aortic and pulmonary pressures, and blood flows out of the ventricles and into the pulmonary and systemic circulations. After ventricular contraction and ejection, intraventricular pressure decreases and the pulmonary and aortic semilunar valves close when the pressure in the vessels is greater than the pressure in the ventricles, thus preventing backflow into the right and left ventricles, respectively. The actions of the heart valves are shown in Figs. 31.2 and 31.3. Normal intracardiac pressures are shown in Table 31.1.

Table 31.1

Normal Intracardiac Pressures

	Mean (mm Hg)	Range (mm Hg)
Right atrium	4	0–8
Right ventricle		
Systolic	24	15–28
End-diastolic	4	0–8
Left atrium	7	4–12
Left ventricle		
Systolic	130	90–140
End-diastolic	7	4–12

	Mean (mm Hg)	Range (mm Hg)
Right atrium	4	0–8
Right ventricle		
Systolic	24	15–28
End-diastolic	4	0–8
Left atrium	7	4–12
Left ventricle		
Systolic	130	90–140
End-diastolic	7	4–12

Cardiac pressure curves depicted in Fig. 31.4 include left atrial, left ventricular, and aortic pressures. Left atrial pressures increase during systole as the atrium receives blood from the superior and inferior venae cavae, and peaks during atrial contraction. In addition, a small bump in atrial pressure occurs early in systole as the closed mitral valve bulges into the left atrium during ventricular contraction. Left ventricular pressure increases rapidly during systole as the ventricle contracts, then falls rapidly as blood flows into the aorta and ventricular volume decreases. Aortic pressure rises and then falls after blood from the left ventricle is distributed to

the systemic arterial circulation during diastole. This is reflected clinically in the difference between systolic and diastolic blood pressures when measured in the arm with a blood pressure cuff.

FIG. 31.4 Composite Chart of Heart Function. This chart is a composite of several diagrams of heart function (cardiac pumping cycle, blood pressure, blood flow, volume, heart sounds, venous pulse, and an electrocardiogram [ECG]), all on the same time scale.

Five sets of graphs represent the rhythm of the cardiac pumping cycle depending on pressure, aortic blood flow, ventricular volume, heart sounds, venous pulse, and electrocardiogram, all on the same time scale and the on top indicates atrial systole, Isovolumetric contraction, reduced ejection, isovolumetric relaxation, rapid ventricular filling, and reduced ventricular filling diastasis depending on pressure. The horizontal axis represents the time given in seconds. The first graph represents the cardiac rhythm depending on pressure. The vertical axis represents the pressure given millimeters per mercury, which shows three graphs labeled left ventricular pressure, aortic pressure, and left atrial pressure. Arrow marks indicate that the aortic valve opens, the mitral valve opens, the mitral valve closes, and the aortic valve closes. The second graph depicts the cardiac rhythm depending on aortic blood flow, with the vertical axis representing aortic valve flow given in liters per minute, and the curve is plotted from (0.1, 0), reaching the peak at (0.2, 5), and falls at (0.5, 0). The third graph depicts the cardiac rhythm

depending on ventricular volume, with the vertical axis representing ventricular volume given in milliliters. The curve is plotted from (0, 38) slopes down at (0.3, 20), and rises at (0.4, 20) reaching (0.8, 38). The fourth graph depicts the wave pattern of cardiac rhythm depending on heart sounds, venous pulse, and electrocardiogram. The wave pattern of heart sounds represents four-phase at points 1, 0.1; 2, 0.4; 3, 0.6; and 4, 0.1. The wave pattern for venous plus represents three-phase at points a, 0.1; c, 0.2; and v, 0.5. The wave pattern for electrocardiogram represents P at 0; Q at 0.1, R at 0.15; S at 0.2, T at 0.35. All data are approximate.

Venous pressure pulses (like that seen in the jugular vein of the neck) are composed of three waves. The **a wave** is generated by atrial contraction, which actively fills the right ventricle in end-diastole. The **c wave** occurs after the a wave during early systole and represents the bulging of the closed tricuspid valve into the right atrium. The **v wave** corresponds to the passive increase in pressure and volume of the right atrium as it fills in late systole and early diastole. Other aspects of falling venous pressure are defined. The **x descent** follows the c wave and reflects movement of the lower portion of the right atrium toward the right ventricle during the final phases of ventricular systole The **y descent** corresponds to the abrupt termination of the downstroke of the v wave during early **diastole** after the tricuspid valve opens and the right ventricle starts to fill passively.

Blood Flow during the Cardiac Cycle

The pumping action of the heart consists of contraction and relaxation of the heart muscle, or myocardium. Each ventricular contraction and the relaxation that follows it constitute one **cardiac cycle** (Fig. 31.5). During the period of relaxation, termed diastole, blood fills the ventricles. The ventricular contraction that follows, termed systole, propels the blood out of the ventricles and into the pulmonary and systemic circulations. Contraction of the left ventricle occurs slightly earlier than contraction of the right ventricle.

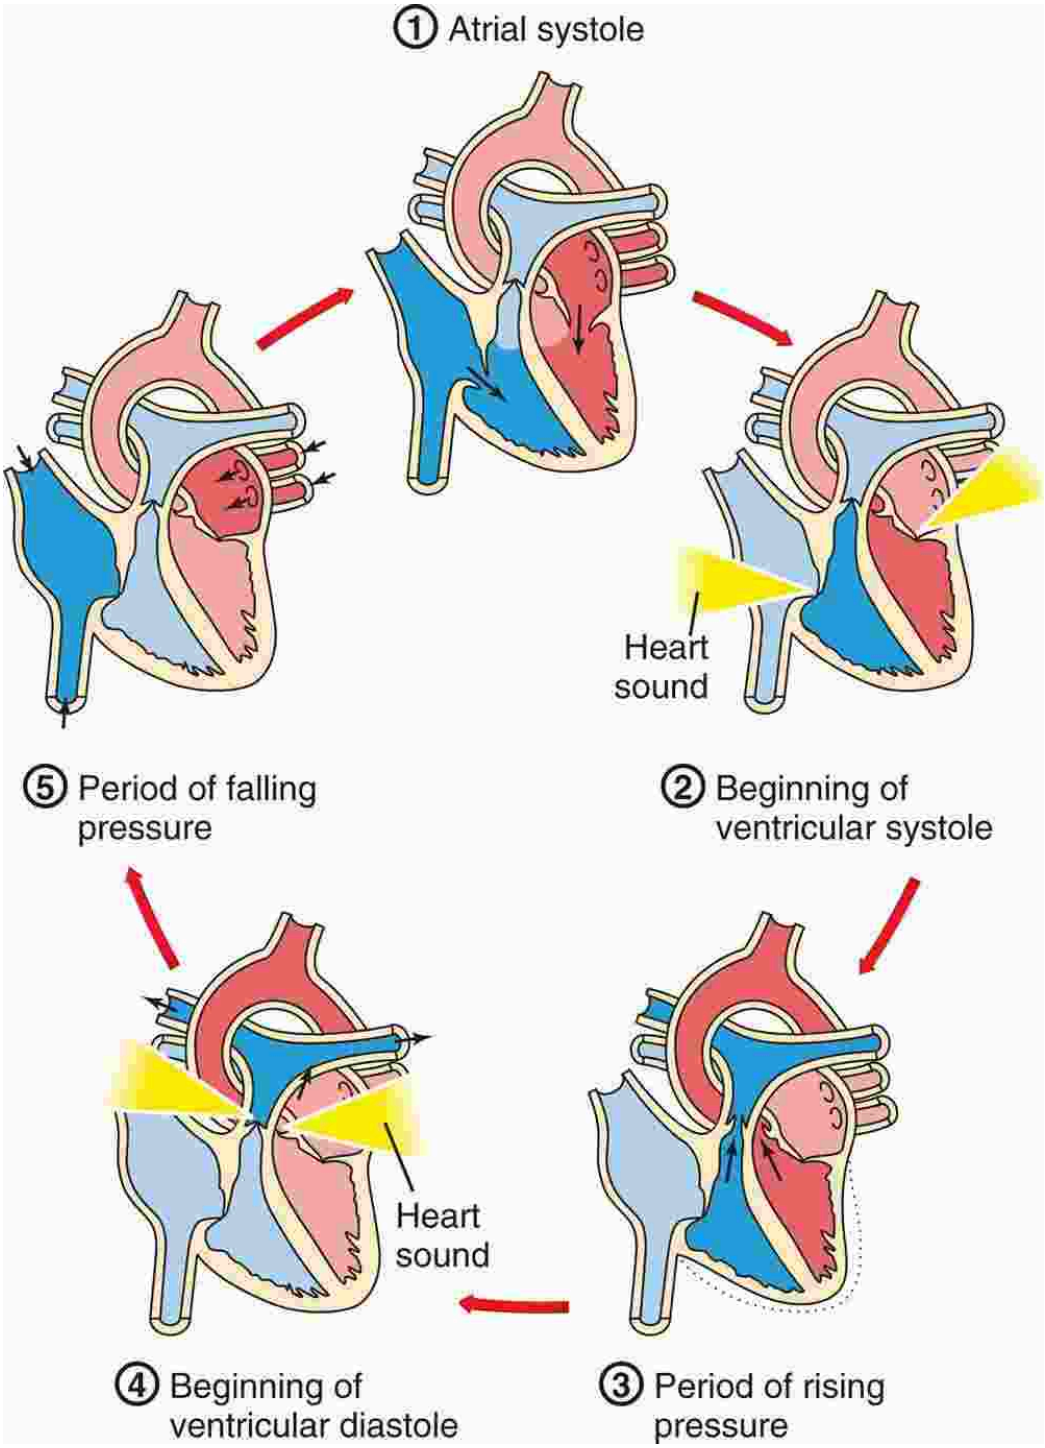

FIG. 31.5 The Five Phases of the Cardiac Cycle.

1, Atrial systole. The atria contract, pushing blood through the open tricuspid and mitral valves into the ventricles. The semilunar valves are closed.

2, Beginning of ventricular systole. The ventricles contract, increasing pressure within the ventricles. The tricuspid and mitral valves close, causing the first heart sound. *3*, Period of rising pressure. The semilunar valves open when pressure in the ventricle exceeds that in the arteries. Blood spurts into the aorta and pulmonary arteries. *4*, Beginning of ventricular diastole. Pressure in the relaxing ventricles drops below that in the arteries. The semilunar valves snap shut, causing the second heart sound. *5*, Period of falling pressure. Blood flows from the veins into the relaxed atria. The tricuspid and mitral valves open when pressure in the ventricles falls below that in the atria. (Adapted from Solomon E. *Introduction to human anatomy and physiology*, 4th edition. St. Louis: Saunders; 2016.)

A cycle diagram shows the five phases of the cardiac cycle as follows. 1. Atrial systole. 2. Beginning of ventricular systoles. 3. Period of rising pressure. 4. Beginning of ventricular diastole. 5. Period of falling pressure.

During ventricular systole, blood from the veins of the systemic circulation enters the thin-walled right atrium from the superior and inferior venae cavae (see Figs. 31.2 and 31.3). Venous blood from the coronary circulation enters the right atrium through the **coronary sinus**. The right atrium fills, which, along with the falling right ventricular pressures, allows the right AV (tricuspid) valve to open and fill the right ventricle during ventricular diastole (occasionally called *atrial systole*). The same sequence of events occurs a split second earlier in the **left heart**. The four pulmonary veins, two from

the right lung and two from the left lung, carry blood from the pulmonary circulation to the left atrium. As the left atrium fills and left ventricular pressure falls, the mitral valve opens and blood flows into the left ventricle. Left atrial contraction, termed *atrial kick*, provides significant increases in the volume of blood entering the left ventricle at the end of diastole. Filling of the right and left ventricles occurs during one period of diastole. Five phases of the cardiac cycle can be identified (see Figs. 31.4 and 31.5). The cardiac cycle is said to *begin* with the opening of the mitral and tricuspid valves and atrial contraction, and to *end* with the closing of the mitral and tricuspid valves and passive ventricular filling. As blood is pushed through the inflow and outflow tracts of the ventricles, it flows around the **crista supraventricularis**—the muscle that separates the inflow from the outflow tracts—and is mixed by passing through the strands of the **trabeculae carneae**.

Structures that Support Cardiac Metabolism: Coronary Circulation

The myocardium and other heart structures are supplied with oxygen and nutrients by the coronary circulation, which is the part of the systemic circulation that occurs within the blood vessels of the heart muscles. The **coronary arteries** originate at the upper edge of the aortic semilunar valve cusps (Fig. 31.6A and B) and receive blood through openings in the aorta called the **coronary ostia**. The **cardiac veins** empty into the right atrium through another ostium, the opening of a large vein called the coronary sinus (see Fig. 31.6C). (The Regulation of the Coronary Circulation section describes the regulation of this mechanism, which is similar to regulation of flow through systemic and pulmonary vessels.)

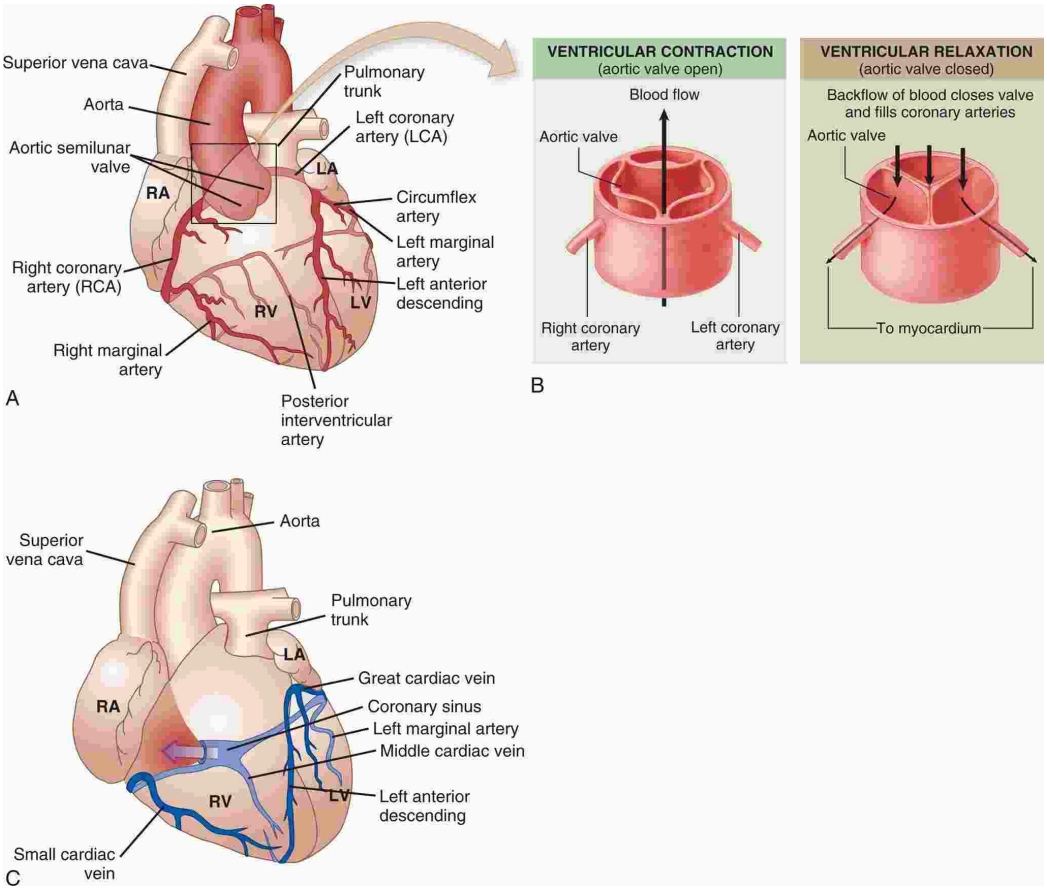

FIG. 31.6 Coronary Circulation.
(A) Arteries. **(B)** Coronary artery openings from the aorta. **(C)** Veins. Both A and C are anterior views of the heart. Vessels near the anterior surface are more darkly colored than vessels of the posterior surface seen through the heart. (A and C, From Patton KT, Thibodeau GA. *Anatomy & physiology*, 7th edition. St. Louis: Mosby; 2010. B, Patton KT, Thibodeau GA. *The human body in health & disease*, 6th edition. St. Louis: Mosby; 2014.)

Top-left panel, A. An illustration of the heart shows and labels the following structures, clockwise from the top: pulmonary trunk, left coronary artery (L C A), circumflex artery, left marginal artery, left

anterior descending, posterior interventricular artery, right marginal artery, right coronary artery (R C A), aortic semilunar valve, aorta, and superior vena cava. Top-right panel, B. Two illustrations showing a magnified view of the aorta illustrate ventricular contraction and ventricular relaxation. • Ventricular contraction, aortic valve open. Blood flows into the aortic valve. • Ventricular relaxation, aortic valve closed. Backflow of blood closes valve and fills coronary arteries. Blood flows into the right and left coronary artery and to myocardium. Bottom panel, C. An illustration of the heart shows and labels the following structures, clockwise from the top: aorta, pulmonary trunk, great cardiac vein, coronary sinus, left marginal artery, middle cardiac vein, left anterior descending, small cardiac vein, and superior vena cava.

Coronary Arteries

The major coronary arteries, the **right coronary artery (RCA)** and the **left coronary artery (LCA)** (see Fig. 31.6A), traverse the epicardium, myocardium, and endocardium and branch to become arterioles and then capillaries. The LCA arises from a single ostium behind the left cusp of the aortic semilunar valve. It generally divides into the left **anterior descending (LAD) artery** (supplies blood to portions of the left and right ventricles and much of the interventricular septum), and the **circumflex artery** (supplies blood to the left atrium and the lateral wall of the left ventricle). The RCA originates from an ostium

behind the right aortic cusp. It branches into the conus (supplies blood to the upper right ventricle), right marginal branch (supplies the right ventricle to the apex), and posterior descending branch (supplies smaller branches to both ventricles). Because women's hearts weigh proportionally less than men's hearts, the coronary arteries are smaller in women.

Collateral Arteries

Collateral arteries are connections, or *anastomoses*, between branches of the same coronary artery or connections of branches of the right coronary artery with branches of the left. The epicardium contains more collateral vessels than the endocardium. New collateral vessels are formed through two processes: **arteriogenesis** (new artery growth branching from preexisting arteries) and **angiogenesis** (growth of new capillaries within a tissue). This collateral growth is stimulated by **shear stress**, an increased blood flow speed within and just beyond areas of **stenosis**, or narrowing, as well as the production of growth factors and cytokines. The collateral circulation assists in supplying blood and oxygen to myocardium that has become ischemic following gradual stenosis of one or more major coronary arteries (coronary artery disease). Unfortunately, diabetes, which predisposes to coronary artery disease, also impedes collateral formation because of increased production of antiangiogenic factors, such as endostatin and angiostatin. Current research is focused on identifying whether some factors that stimulate collateral growth might be useful treatments for myocardial ischemia.[4]

Coronary Capillaries

The heart requires an extensive capillary network to function. Blood travels from the arteries to the arterioles and then into the capillaries, where oxygen and other nutrients enter the myocardium while waste products enter the blood. At rest, the heart extracts 70% to 80% of the oxygen delivered to it, and coronary blood flow is directly

correlated with myocardial oxygen consumption. Any alteration of the cardiac muscles dramatically affects blood flow in the capillaries. For example, in ventricular hypertrophy (enlargement of the ventricular myocardium), the capillary network does not expand along with muscle fiber size. Therefore, the same number of capillaries must now perfuse a larger area. This results in decreased exchange of oxygen and nutrients.

Coronary Veins and Lymphatic Vessels

After passing through the capillary network, blood from the coronary arteries drains into the cardiac veins located alongside the arteries. Most of the venous drainage of the heart occurs through veins in the visceral pericardium. The veins then feed into the **great cardiac vein** and coronary sinus on the posterior surface of the heart, between the atria and ventricles, in the coronary sulcus (see Fig. 31.6C).

There is an extensive system of lymphatic capillaries and collecting vessels within the layers of the myocardium and the valves. With cardiac contraction, the lymphatic vessels drain fluid to lymph nodes in the anterior mediastinum that empty into the **superior vena cava**. The **cardiac lymphatics** maintain tissue fluid homeostasis, allow immune cells to move in and out of the heart tissue, aid in nutritional lipid transport, and participate in reverse cholesterol transport (see Emerging Science Box: Coronary Lymphatics in Health and Disease).[5]

Emerging Science BoxCoronary Lymphatics in Health and Disease

The primary function of the cardiac lymphatic vasculature is to maintain tissue fluid homeostasis and prevent edema formation. Cardiac lymphatics also have several other essential functions. For example, the heart and coronary vessels rely on the lymphatics for transport of lipids and lipoproteins (cholesterol) in and out of cardiac and coronary tissues. Also crucial is the role of the

lymphatics in modulating the inflammatory response to injury and pathogens. Cardiac lymphatics regulate innate and adaptive immune responses, and macrophages in the lymphatic system contribute to the regeneration of cardiac tissue after myocardial infarction. Without adequate lymphatic function, edema and chronic immune responses contribute to fibrotic remodeling of the myocardium. In atherosclerotic cardiovascular disease, myocardial infarction, and heart failure, lymphatics are disrupted and the generation of new lymphatic vessels is decreased. Recently, pharmacologic stimulation of lymphangiogenesis has been shown to improve cardiac function and reduce myocardial fibrosis during heart failure development after myocardial infarction. Methods under investigation for stimulating cardiac lymphangiogenesis include injection of vascular endothelial growth factor-C (VGEF-C), adenovirus vector-mediated VEGF-C gene therapy, and intravenous epicardium-specific peptide adrenomedullin administration. Early results are promising.

Structures that Control Heart Action

Life depends on continuous repetition of the cardiac cycle (systole and diastole), which requires the transmission of electrical impulses,

termed **cardiac action potentials**, through the myocardium.[6] (Action potentials are described in Chapters 1 and 3.) As an electrical impulse passes from cell to cell (fiber to fiber) in the myocardium, it stimulates an intracellular process that results in fiber shortening—that is, muscular contraction or systole. Between action potentials, the fibers relax and return to their resting length, causing diastole. The muscle fibers of the myocardium are electrically coupled so that action potentials pass from cell to cell very rapidly and efficiently. The myocardial structures that allow the action potentials to move so rapidly through the heart are the gap junctions in the **intercalated discs**. In the intercalated discs, the channel-forming proteins, called **connexins**, form pores in the gap junctions.[7] As a result of these structures plus the heart's **conduction system**, an action potential generated in one part of the myocardium passes very quickly throughout the heart, causing rapid, organized, sequential contraction of the atria and then the ventricles.

The myocardium contains its own conduction system—a collection of specialized cells that enable the myocardium to generate and transmit action potentials without input from the nervous system (Fig. 31.7). Cells that initiate signals are called pacemakers. The pacemaker cells are concentrated at two sites in the myocardium, called *nodes:* the **sinoatrial node** and the atrioventricular node. The cardiac cycle is stimulated by these nodes of specialized cells. Although the heart is innervated by the autonomic nervous system (both sympathetic and parasympathetic fibers), neural impulses are not needed to maintain the cardiac cycle. Thus the heart will beat in the absence of any innervation, one of the many factors that allow heart transplantation to be successful. The cardiac cycle is adjusted to the physical needs of the body by the autonomic fibers.

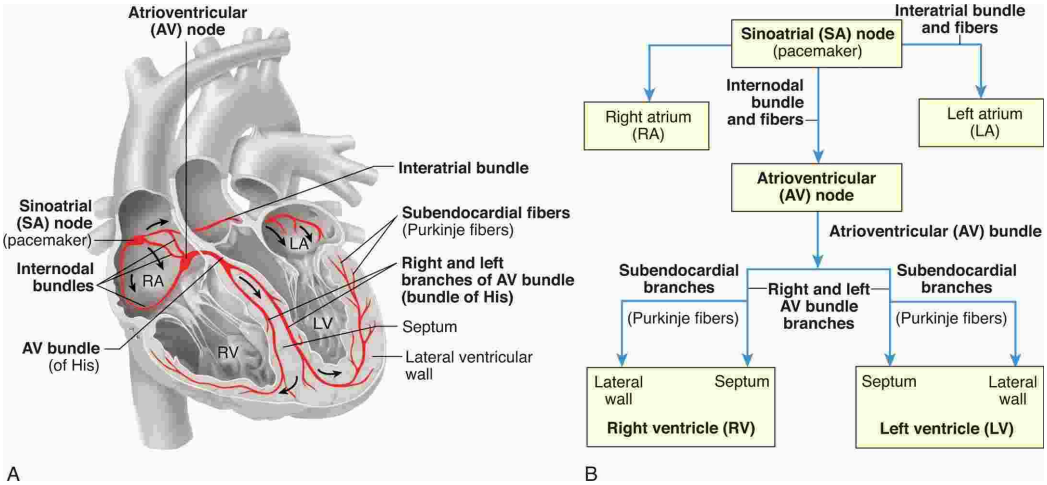

FIG. 31.7 Conduction System of the Heart. Specialized cardiac muscle cells *(boldface type)* in the wall of the heart rapidly initiate or conduct an electrical impulse throughout the myocardium. Both the sketch of the conduction system **(A)** and the flowchart **(B)** show the origin and path of conduction. The signal is initiated by the SA node (pacemaker) and spreads to the rest of the right atrial myocardium directly, to the left atrial myocardium by way of a bundle of interatrial conducting fibers, and to the AV node by way of three internodal bundles. The AV node then initiates a signal that is conducted through the ventricular myocardium by way of the AV bundle (of His) and subendocardial branches (Purkinje fibers). (From Patton KT, Thibodeau GA. *The human body in health & disease*, 7th edition. St. Louis: Mosby; 2018.)

Left panel, A. An illustration of the coronal cross-section of the heart shows and labels the following structures, clockwise from the top: atrioventricular (A V) node, interatrial bundle, subendocardial fibers (Purkinje fibers), right and left branches of A V

bundle (bundle of His), septum, lateral ventricular wall, A V bundle (of His), internodal bundles, and sinoatrial (S A) node (pacemaker). Right panel, B. A flowchart tracks the conduction path. 1. Sinoatrial (S A) node (pacemaker). Leads to 2, 3 (through interatrial bundle and fibers), and 4 (through internodal bundle and fibers). 2. Right atrium (R A). 3. Left atrium (L A). 4. Atrioventricular (A V) node. Leads to 5 (through atrioventricular bundle). 5. Right ventricle (R V): lateral wall and septum. 6. Left ventricle (L V): lateral wall and septum.

Heart action is also influenced by substances delivered to the myocardium in coronary blood. Nutrients and oxygen are needed for cellular survival and normal function. Hormones and biochemical substances, including medications, can affect the strength and duration of myocardial contraction and the degree and duration of myocardial relaxation. Normal or appropriate function depends on the supply of these substances, which is why coronary artery disease can seriously disrupt heart function.

Conduction System

Normally, electrical impulses arise in the sinoatrial (SA) node (sinus node), the usual **pacemaker** of the heart. The SA node is located at the junction of the right atrium and superior vena cava, just superior to the tricuspid valve (see Fig. 31.7). It sits only 1 mm beneath the visceral pericardium, making it vulnerable to injury and disease, especially pericardial inflammation. The SA node is nourished by the sinus node artery, which passes through the center of the node. The SA node is heavily innervated by both sympathetic and parasympathetic nerve fibers. In the resting adult the SA node

generates about 60 to 100 action potentials per minute, depending on the age and physical condition of the person. Each action potential travels rapidly from cell to cell and through the atrial myocardium as well as through interatrial and internodal fibers, carrying the action potential onward to the **atrioventricular (AV) node**, as well as causing both atria to contract, beginning systole (see Fig. 31.7).

The AV node, located in the right atrial wall superior to the tricuspid valve and anterior to the ostium of the coronary sinus, conducts the action potentials onward to the ventricles. It is innervated by nerves from the autonomic parasympathetic ganglia that serve as receptors for the vagus nerve and cause slowing of impulse conduction through the AV node.

Conducting fibers from the AV node converge to form the **bundle of His (atrioventricular bundle)**, within the posterior border of the interventricular septum. The bundle of His then gives rise to the right and left bundle branches. The **right bundle branch (RBB)** is thin and travels without much branching to the right ventricular apex. Because of its thinness and relative lack of branches, the RBB is susceptible to interruption of impulse conduction by damage to the endocardium. The **left bundle branch (LBB)** divides into two branches, or fascicles. The left anterior bundle branch (LABB) passes the left anterior **papillary muscle** and the base of the left ventricle and crosses the aortic outflow tract. Damage to the aortic valve or the left ventricle can interrupt this branch. The left posterior bundle branch (LPBB) travels posteriorly, crossing the left ventricular inflow tract to the base of the left posterior papillary muscle. This branch spreads diffusely through the posterior inferior left ventricular wall. Blood flow through this portion of the left ventricle is relatively nonturbulent, so the LBB is somewhat protected from injury caused by wear and tear.

The **Purkinje fibers** are the terminal branches of the RBB and LBB (see Fig. 31.7). They extend from the ventricular apexes to the fibrous rings and penetrate the heart wall to the outer myocardium. The first areas of the ventricles to be excited are portions of the interventricular septum. The septum is activated from both the RBB and the LBB. The extensive network of Purkinje fibers promotes the

rapid spread of the impulse to the ventricular apexes. The basal and posterior portions of the ventricles are the last to be activated.

Cardiac excitation

From the SA node, the impulse that begins systole spreads throughout the right atrium at a conduction velocity of about 35 cm/s.[8] The action potential is delayed in the region of the AV node, possibly because of electrophysiologic differences in the cells that comprise the AV region. Conduction velocity within the node is about 10 cm/s, markedly slower than conduction through the atria. The delay between atrial and ventricular excitation permits an additional boost to ventricular filling by atrial contraction (atrial kick). From the AV node the impulse travels from the AV bundle and through the bundle branches to the Purkinje fibers. Conduction velocities in the AV and Purkinje fibers are the most rapid in the heart.

Ventricular activation occurs sequentially in three phases: (1) septal activation, (2) apical activation, and (3) basal (upper) and posterior activation. The first areas of the ventricles to be excited are portions of the interventricular septum. The septum is activated from both the RBB and the LBB, although the impulse travels from left to right. The extensive network of Purkinje fibers promotes the rapid spread of the impulse to the ventricular apexes. *Activation* traverses the heart wall from the inside outward (from the endocardium to the epicardium). The basal and posterior portions of the ventricles are the last to be activated. *Deactivation*, which begins in diastole, occurs in the opposite direction, spreading from the outside inward (epicardium to endocardium). All areas of the ventricle recover at about the same time.

Propagation of cardiac action potentials

Electrical activation of the muscle cells, termed **depolarization**, is caused by the movement of ions, including sodium, potassium, calcium, and chloride, across cardiac cell membranes. Deactivation, called **repolarization**, occurs the same way. (Movement of ions

across cell membranes is described in Chapter 1; electrical activation of muscle cells is described in Chapter 43.)

Movement of ions into and out of the cell creates an electrical (voltage) difference across the cell membrane, called the *membrane potential*. The resting membrane potential of myocardial cells is between −80 and −90 mV, whereas that of the SA node is between −50 and −60 millivolts and that of the AV node is between −60 and −70 mV.[8] During depolarization, the inside of the cell becomes less negatively charged as positive ions move inside. In cardiac cells, as in other excitable cells, when the resting membrane potential (in millivolts) becomes less negative with depolarization and reaches the threshold potential for cardiac cells, a cardiac action potential is fired. The various phases of the cardiac action potential are related to changes in the permeability of the cell membrane to sodium, potassium, chloride, and calcium. *Threshold* is the point at which the cell membrane's selective permeability to these ions is temporarily disrupted, leading to an "all or nothing" depolarization. Drugs that alter the movement of these ions (e.g., calcium) have profound effects on the action potential and can alter heart rate. If the resting membrane potential becomes more negative because of a decrease in the extracellular potassium concentration (hypokalemia), it is termed *hyperpolarization*.

Normal myocardial cell depolarization and repolarization occur in five phases numbered 0 through 4 (Fig. 31.8). Phase 0 consists of depolarization. This phase lasts 1 to 2 ms and represents rapid sodium entry into the cell. Phase 1 is early repolarization, in which calcium slowly enters the cell. Phase 2, also called the *plateau*, is a continuation of repolarization, with slow entry of calcium and sodium into the cell. Potassium is moved out of the cell during phase 3, with a return to resting membrane potential in phase 4.[8] The time between action potentials corresponds to diastole.

(Modified from Koeppen BM, Stanton BA. *Berne and Levy Physiology*, 6th edition. Philadelphia: Mosby; 2010.)

Illustration A depicts the action potential of a ventricle indicating four phases and points are as follows. (0, minus 40), (1, 20), (3, minus 40), (4, minus 90). All data are approximate. Illustration B depicts the action potential of S A node indicating two phases and points are as follows. (4, minus 60), (0, 30), (3, minus 40). All data are approximate. Illustration C depicts the action potential of the atrium indicating four phases and points are as follows. (0, minus 30), (1, 10), (3, minus 40), (4, minus 80). All data are approximate.

The phases of depolarization and repolarization occur somewhat differently in the SA and AV node cells, a difference that enables these cells to generate cardiac action potentials independently. The cells of the Purkinje fibers, atria, and ventricles begin with a negative resting membrane potential and proceed to a rapid upstroke, or depolarization (phase 0), a rapid early repolarization (phase 1), a plateau (phase 2), and a rapid later repolarization (phase 3) (see Fig. 31.8 A and C). The fast inward current of phase 0 is mediated by sodium ions flowing through "fast channels" in the cell membrane and causes the rapid upstroke of the action potential in Purkinje fibers, atria, and ventricles. In contrast, the cells of the SA and AV nodes begin with a less negative resting membrane potential, proceed to a slow upstroke (phase 0), and usually lack a plateau

(phase 2) (see Fig. 31.8B). The slow inward current, mediated by calcium through transient and long-lasting channels and sodium ions flowing through "slow channels" of the cell membrane, is responsible for the action potential of the SA node and the AV node. Hence, drugs that block calcium have profound effects on the slow inward current and can alter heart rate. Slow channel-blocking drugs, such as verapamil, are used to treat a variety of cardiovascular disorders.

The **absolute refractory period**, during which no new cardiac action potential can be initiated by a stimulus, no matter the strength, follows depolarization. The absolute refractory period corresponds to the time needed for the reopening of channels that permit sodium and calcium influx (phase 0 through half of phase 3). A **relative refractory period** occurs near the end of repolarization. During this time, the membrane can be depolarized again but only by a greater than normal stimulus. Abnormal refractory periods as a result of disease can cause abnormal heart rhythms or dysrhythmias, including ventricular fibrillation and cardiac arrest (see Chapter 32).

The electrocardiogram

An electrocardiogram originates from myocardial cell electrical activity as recorded by skin electrodes and is the summation of all the cardiac action potentials (Fig. 31.9). The **P wave** represents atrial depolarization. The **PR interval** is a measure of time from the onset of atrial activation to the onset of ventricular activation. The PR interval represents the time necessary for electrical activity to travel from the sinus node through the atrium, AV node, and His-Purkinje system to activate ventricular myocardial cells. The **QRS complex** represents the sum of all ventricular muscle cell depolarization. The configuration and amplitude of the QRS complex may vary considerably among individuals. During the **ST interval**, the entire ventricular myocardium is depolarized. The **QT interval** is sometimes called the *electrical systole* of the ventricles but the time it takes varies inversely with the heart rate. The **T wave** represents ventricular repolarization.

(A) Normal ECG. Depolarization and repolarization. **(B)** ECG intervals among P, QRS, and T waves. **(C)** Schematic representation of ECG and its relationship to cardiac electrical activity. *AV*, Atrioventricular; *LA*, left atrium; *LBB*, left bundle branch; *LV*, left ventricle; *RA*, right atrium; *RBB*, right bundle branch; *RV*, right ventricle.

Illustration A depicts the tracing for E C G deflections. The horizontal represents the time given in seconds and the vertical axis represents the voltage in millivolt. The E C G tracing comprises P which indicates the atrial depolarization, QRS which indicates the ventricular depolarization and atrial depolarization, and T which indicates the ventricular repolarization. Illustration B depicts the tracing for E C G which shows the E C G intervals among P, QRS, and T waves. The horizontal represents the time given in seconds and the vertical axis represents the voltage in millivolt. The E C G tracing shows the P R interval between 0.12 to 0.20 s, Q R S under 0.10 s, S T interval, and T Illustration B depicts the relationship between cardiac electrical activity and E C G which shows the S A node in right atrium and A V node in left atrium relates to P, depolarization of right

ventricle relates to S T, and repolarization of left ventricular relates to T.

Automaticity

Automaticity, or the property of generating spontaneous depolarization to threshold, enables the SA and AV nodes to generate cardiac action potentials without any external stimulus. Cells capable of spontaneous depolarization are called **automatic cells**. The automatic cells of the cardiac conduction system can stimulate the heart to beat even when it is transplanted and thus has no innervation. Spontaneous depolarization is possible in automatic cells because the membrane potential of these special cells does not actually "rest" during the phase 4 return to the resting membrane potential. Instead, it slowly depolarizes toward threshold during the diastolic phase of the cardiac cycle. Because threshold is approached during diastole, return to the resting membrane potential in automatic cells is called **diastolic depolarization**. The electrical impulse normally begins in the SA node because its cells depolarize more rapidly than other automatic cells.

Rhythmicity

Rhythmicity is the regular generation of an action potential by the heart's conduction system. The SA node sets the pace because normally it has the fastest rate of depolarization. The SA node depolarizes spontaneously 60 to 100 times per minute. If the SA node is damaged, the AV node can become the heart's pacemaker at a rate of about 40 to 60 spontaneous depolarizations per minute. Eventually, however, conduction cells in the atria usually take over from the AV node. Purkinje fibers are capable of spontaneous depolarization but at an even slower rate than the AV node. Therefore the Purkinje fibers only function as pacemakers when the SA and AV nodes are diseased or there is interruption to movement of electrical current through the heart.

Cardiac Innervation

Sympathetic and parasympathetic nerves

Although the heart's nodes and conduction system are able to generate action potentials independently, the autonomic nervous system influences both the *rate* of impulse generation (firing), depolarization, and repolarization of the myocardium, and the *strength* of atrial and ventricular contraction. Autonomic neural transmission produces changes in the heart and circulatory system faster than metabolic or humoral agents. Speed is important, for example, in stimulating the heart to increase its pumping action with increased physical activity or during times of stress and fear—the so-called fight or flight response. Although increased delivery of oxygen, glucose, hormones, and other blood-borne factors sustains increased cardiac activity, the rapid initiation of increased activity depends on the sympathetic and parasympathetic fibers of the autonomic nervous system.

Sympathetic and parasympathetic nerve fibers innervate all parts of the atria and ventricles and the SA and AV nodes. Efferent sympathetic and parasympathetic fibers join at the **cardiac plexus**, a neural junction located at the root of the aorta in front of the trachea. The **cardiovascular center** in the brainstem responds to input from higher brain centers and from sensory receptors in the periphery and modulates sympathetic and parasympathetic nerve activation (Fig. 31.10) In general, sympathetic stimulation increases electrical conductivity and the strength of myocardial contraction, and vagal parasympathetic nerve activity does the opposite, slowing the conduction of action potentials through the heart and reducing the strength of contraction. Thus the sympathetic and parasympathetic nerves affect the speed of the cardiac cycle (heart rate, or beats per minute). Sympathetic nervous activity enhances myocardial performance. Stimulation of the SA node by the sympathetic nervous system rapidly increases heart rate. The sympathetic nervous system may also induce an increased influx of calcium (Ca^{2+}), which increases the contractile strength of the heart and the speed of electrical impulses through the heart muscle and the nodes.

Finally, sympathetic nerves influence the diameter of the coronary vessels. Increased sympathetic discharge dilates the coronary vessels by causing the release of vasodilating metabolites resulting from increased myocardial contraction.

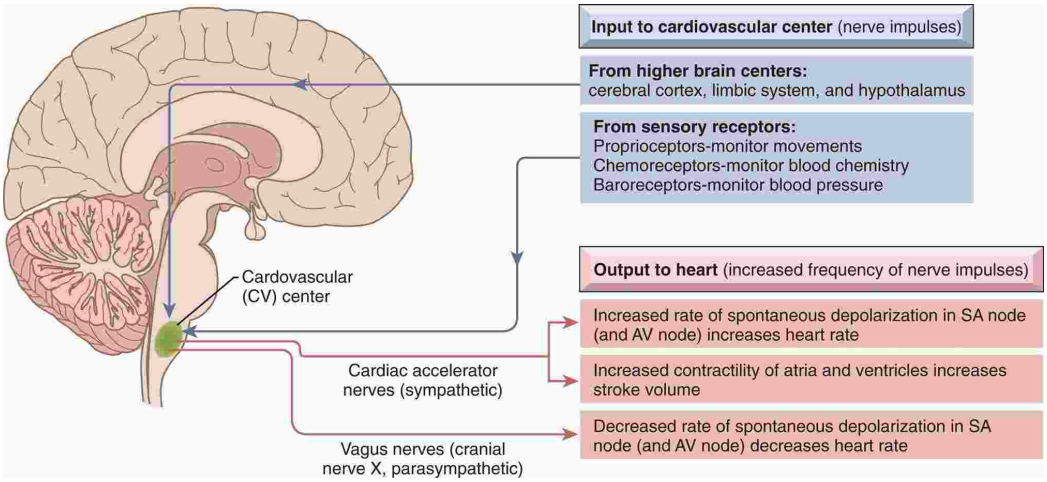

FIG. 31.10 Autonomic Innervation of the Cardiovascular System.
Input to the cardiovascular center and output to the heart.

A right lateral illustration of the brain highlights the cardiovascular (C V) center at the base of the brain. The inputs to the cardiovascular center (nerve impulses) are as follows. • From higher brain centers: cerebral cortex, limbic system, and hypothalamus. • From sensory receptors: Proprioceptors-monitor movements, chemoreceptors-monitor blood chemistry, and baroreceptors-monitor blood pressure. The outputs to the heart (increased frequency of nerve impulses) are as follows. • Cardiac accelerator nerves (sympathetic): Increased rate of spontaneous depolarization in S A node (and A V node) increases heart rate. Increased contractility of atria and ventricles increases stroke volume. • Vagus nerves

(cranial nerve X, parasympathetic): Decreased rate of spontaneous depolarization in S A node (and A V node) decreases heart rate.

The parasympathetic nervous system affects the heart through the vagus nerve, which releases acetylcholine. Receptors for acetylcholine are found in the myocardium and coronary vessels of the heart. Acetylcholine causes a decreased heart rate, slows conduction through the AV node, and reduces myocardial contraction strength.

Adrenergic receptor function

Sympathetic neural stimulation of the myocardium and coronary vessels depends on the presence of G-protein–coupled adrenergic receptors, which bind specifically with neurotransmitters of the sympathetic nervous system. The effects of sympathetic stimulation depend on whether the α- or β-adrenergic receptors are most plentiful on cells of the effector tissue and whether the neurotransmitter is norepinephrine or **epinephrine**. Individual variations in receptor structure also influence receptor responsiveness.[9] There are five types of adrenergic receptors: β_1, β_2, β_3, α_1, and α_2. (Each of the α-adrenergic receptors also has three subtypes, so some sources indicate that there are nine types of adrenergic receptors.) Overall, cardiovascular structures have more β- than α-receptors; therefore, effects mediated by the β-receptors predominate. Norepinephrine is released by postsynaptic sympathetic nerve endings in the heart, whereas epinephrine is mainly released by the adrenal medulla and reaches the heart through the bloodstream.

The β_1-receptors are found mostly in the heart, specifically the conduction system (AV and SA nodes, Purkinje fibers) and the atrial and ventricular myocardium. The β_2-receptors are found in the heart and also on vascular smooth muscle. Stimulation of both the β_1- and

β_2-receptors results in an increase in heart rate (chronotropy) and force of myocardial contraction (inotropy).[6] In addition, stimulation of the β_2-receptors results in **vasodilation** because of the location of the receptors on vascular smooth muscle. Overall β_1 and β_2 stimulation enables the heart to pump more blood, and β_2 stimulation also increases coronary blood flow. In the heart, stimulation of β_3-receptors found in the myocardium and coronary vessels opposes the effects of β_1- and β_2-receptor stimulation and decreases **myocardial contractility** (negative inotropic effect).[9] Thus, β_3-receptors may provide a "safety mechanism" to prevent overstimulation of the heart by the sympathetic nervous system.

Norepinephrine binding with α_1-receptors, all of which are postsynaptic in the systemic and coronary arteries, causes smooth muscle contraction and thus **vasoconstriction**. One of the subtypes of α_2-receptors is located on the sympathetic ganglia and nerve terminals. The effect of norepinephrine on these receptors is to inhibit release of more norepinephrine, which promotes vasodilation, thus providing another safety mechanism to prevent excess blood pressure elevation. Dysfunction of α- and β-adrenergic receptors can occur in many conditions (e.g., diabetes, hypertension) and has been implicated in the pathogenesis of many cardiac diseases, including heart failure, myocardial ischemia, and dysrhythmias (see Chapter 32).

Myocardial Cells

Cardiomyocytes are composed of long, narrow fibers that contain bundles of longitudinally arranged myofibrils; a nucleus; mitochondria; an internal membrane system (the sarcoplasmic reticulum); cytoplasm (sarcoplasm); and a plasma membrane (the sarcolemma), which encloses the cell (Fig. 31.11).[6] Cardiac and skeletal muscle cells also have an "external" membrane system made up of transverse tubules (T tubules) formed by inward pouching of

the sarcolemma. The sarcoplasmic reticulum forms a network of channels that surrounds the muscle fiber.

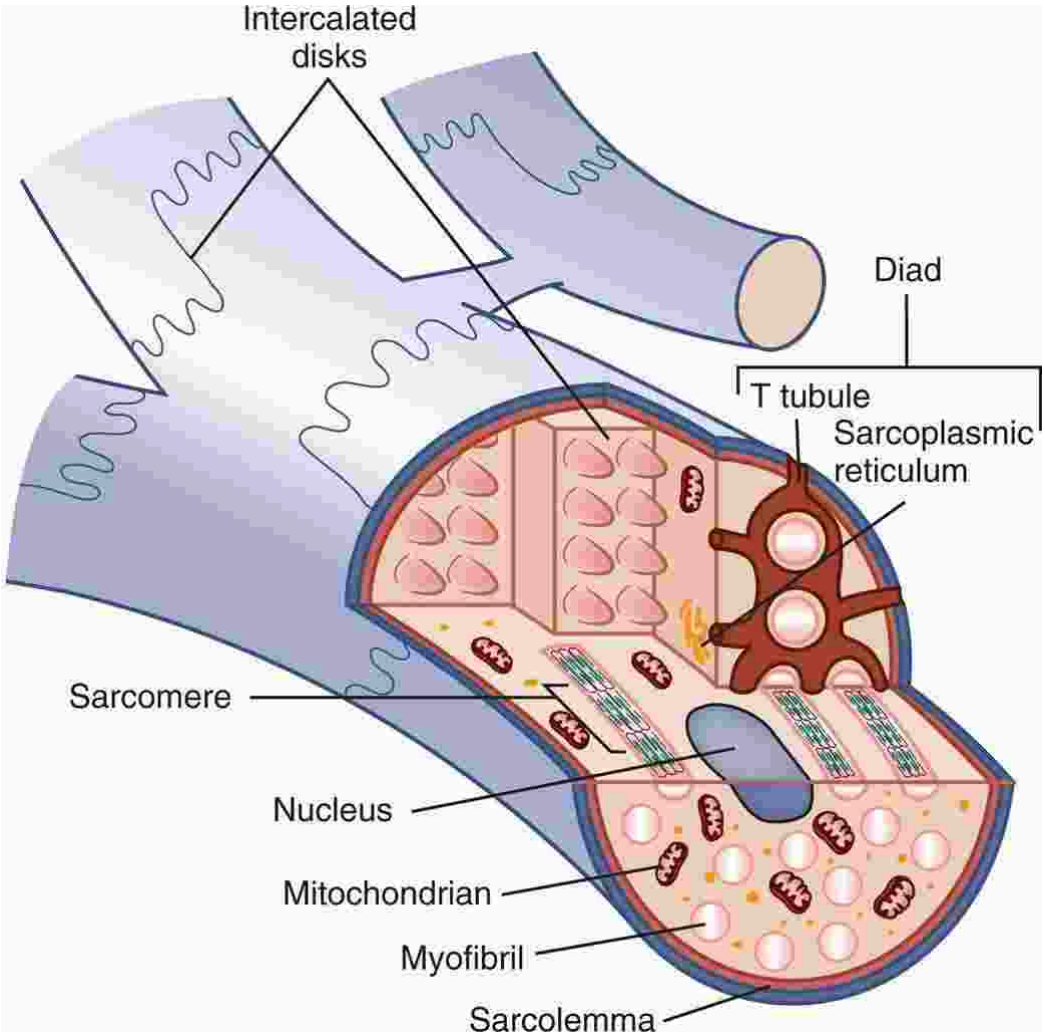

FIG. 31.11 Cardiac Muscle Fiber.
Unlike other types of muscle fibers, cardiac muscle fibers are typically branched with junctions, called intercalated discs, between adjacent myocytes. Like skeletal muscle cells, cardiac muscle cells contain sarcoplasmic reticula and T tubules, although these structures are not as highly organized as in skeletal muscle fibers.

A cutaway illustration of the cardiac muscle fiber shows and labels the following structures: intercalated disks, T tubule, sarcoplasmic reticulum,

sarcomere, nucleus, mitochondrion, myofibril, and sarcolemma.

Because the myofibrils in both cardiac and skeletal fibers consist of alternating light and dark bands of protein, the fibers appear striped, or striated. The dark and light bands of the myofibrils create repeating longitudinal units, called *sarcomeres*, which are between 1.6 and 2.2 μm long (Fig. 31.12). The length of these sarcomeres determines the limits of myocardial stretch at the end of diastole and subsequently the force of contraction during systole. Alterations in **sarcomere** size are seen in both physiologic and pathologic myocardial hypertrophy.

Illustration B shows the structure of the thin myofilament in the sarcomere with labels indicating F-actin strands, troponin, active sites, tropomyosin, and actin molecules. Illustration C shows the structure of the thin myofilament of sarcomere with labels indicating myosin, myosin head, and shaft. Illustration D shows the structure of the myosin molecule with label indicating myosin head.

There are a number of differences between cardiac and muscle cells. Cardiac cells are arranged in branching networks throughout the myocardium, whereas skeletal muscle cells tend to be arranged in parallel units throughout the length of the muscle. Cardiac fibers

have only one nucleus, whereas skeletal muscle cells have many nuclei. Differences between cardiac and skeletal muscle often relate to heart function. Some of these functions include:

1. *Transmit action potentials quickly from cell to cell*. Myocardial cells are all electrically and mechanically connected within the wall of a particular heart chamber. Electrical impulses are transmitted rapidly from cardiac fiber to cardiac fiber because the network of fibers connects at intercalated discs, which are thickened portions of the sarcolemma. The intercalated discs contain three junctions: desmosomes, or macula adherens; fascia adherens, which mechanically attach one cell to another; and gap junctions, which allow the electrical impulse to spread from cell to cell through a low-resistance pathway (see Fig. 31.12A). Changes in the function of these junctional elements may cause an increased risk of arrhythmias.[10]
2. *Maintain high levels of energy synthesis*. Unlike skeletal muscle, the heart cannot rest and is in constant need of energy, which is supplied by molecules such as adenosine triphosphate (ATP). Therefore, the cytoplasm surrounding the bundles of myofibrils in each cardiomyocyte contains a large number of mitochondria (25% to 35% of cell volume, versus 3% to 8% of cell volume in skeletal muscle). Cardiac muscle cells have more mitochondria than skeletal muscle cells to provide the necessary respiratory enzymes for aerobic metabolism and supply quantities of ATP sufficient for the constant action of the myocardium.
3. *Gain access to more ions, particularly sodium and potassium, in the extracellular environment*. Cardiac fibers contain more T tubules than do skeletal muscle fibers (see Fig. 31.11). This increased closeness to the T tubules gives each myofibril in the myocardium faster access to molecules needed for the transmission of action potentials, a process that involves transport of sodium and potassium through the walls of the

T tubules. Because the T tubule system is continuous with the extracellular space and the interstitial fluid, it facilitates the rapid transmission of the electrical impulses from the surface of the sarcolemma to the myofibrils inside the fiber. This rapid transmission activates all the myofibrils of one fiber simultaneously. The sarcoplasmic reticulum is located around the myofibrils. As an action potential is transmitted through the T tubules, it induces the sarcoplasmic reticulum to release its stored calcium, thus activating the contractile proteins **actin** and **myosin**.

The sarcomere

Within each myocardial sarcomere are myosin and actin molecules that are grouped together to form filaments. Myosin molecules resemble golf clubs with two large, ovoid heads at one end of the shaft (see Fig. 31.12D). The bi-lobed heads contain an actin-binding site and a site of ATPase activity. About 200 myosin molecules are bundled together with their heads facing outward, forming a single thick filament. Actin molecules resemble beads, and they are strung into two chains that wind around each other, forming a thin filament (see Fig. 31.12C).

Several proteins are also present in the sarcomere. A **tropomyosin molecule** (a relaxing protein) lies alongside actin molecules. **Troponin**, another relaxing protein, associates with the tropomyosin molecule. The troponin complex itself has three components. *Troponin T* aids in binding of the troponin complex to actin and tropomyosin; *troponin I* inhibits the ATPase of actomyosin; and *troponin C* contains binding sites for the calcium ions involved in contraction. *Troponin T* and *I* molecules are released into the bloodstream during myocardial injury. They can be measured to evaluate if a myocardial infarction or other damage has occurred. The sarcomere also contains a giant elastic protein, **titin**, which attaches myosin to the **Z line**, acts as a spring, and influences myocardial stiffness. The titin structure affects myocardial diastolic filling and has been found to play a role in heart failure.[11]

Where thick filaments overlap with thin filaments, a central dark band is formed, called the anisotropic band, or **A band** (see Fig. 31.12B). The light bands of the sarcomere, called isotropic bands or **I bands**, contain only actin molecules and no myosin. The center of the sarcomere is a less dense region called the **H band**, which contains only myosin molecules and no actin. Thick filaments are held together by M-protein molecules that form a central thin, dark **M line**.[7] Thin filaments of actin extend from each side of the Z line, a dense fibrous structure at the center of each I band. The area from one Z line to the next Z line defines one sarcomere.

Myocardial metabolism

Cardiomyocytes depend on the constant production of ATP, which is synthesized within the mitochondria mainly from glucose, fatty acids, and lactate. If the myocardium is underperfused because of coronary artery disease, anaerobic metabolism must be used for energy (see Chapter 1). Energy produced by metabolic processes fuels muscle contraction and relaxation, electrical excitation, membrane transport, and synthesis of large molecules. Normally, the amount of ATP produced supplies sufficient energy to pump blood throughout the system.

Cardiac work is expressed as **myocardial oxygen consumption ($M\dot{V}O2$)**, which is closely correlated with total cardiac energy requirements. The $M\dot{V}O_2$ is determined by three major factors: (1) the amount of wall stress during systole, estimated by measuring the **systolic blood pressure**; (2) the duration of systolic wall tension, measured indirectly by the heart rate; and (3) the contractile state of the myocardium, which is not measured clinically.

The coronary arteries deliver oxygen (O_2) to the myocardium. Approximately 70% to 75% of this O_2 is used immediately by cardiac muscle, leaving little O_2 in reserve. Because the O_2 content of the blood and the amount of O_2 extracted from the blood cannot be increased under normal circumstances, any increased energy needs can be met only by increasing coronary blood flow. The $M\dot{V}O_2$ increases with exercise and decreases with hypotension and

hypothermia. As myocardial metabolism and consumption of O_2 increase, the concentration of local vasoactive metabolic factors increases. Some of these (e.g., adenosine, nitric oxide, and prostaglandins) dilate coronary arterioles, thus increasing coronary blood flow. Aging reduces the efficiency of myocardial metabolism and may contribute to the development of heart failure.[12]

Myocardial Contraction and Relaxation

Myocardial contractility is a change in developed tension at a given resting fiber length, which basically is the ability of the heart muscle to shorten. Each sarcomere serves as the basic contractile unit of a muscle cell. The outward-facing heads of myosin molecules are called *cross-bridges* because they can form force-generating bridges by binding with exposed actin molecules. Once bound, the myosin molecules effectively pull the thin filaments toward the center of the sarcomere, shortening the sarcomere and resulting in contraction. This process is known as the **cross-bridge theory of muscle contraction** (Fig. 31.13). Anatomically, contraction occurs when the sarcomere shortens, causing adjacent Z lines to move closer together. The width of the A band, which contains the thick myosin filaments, is unchanged whereas the I band becomes narrower as the overlap between the thick and thin filaments increases. The degree of shortening depends on the amount of overlap between the thick and thin filaments.

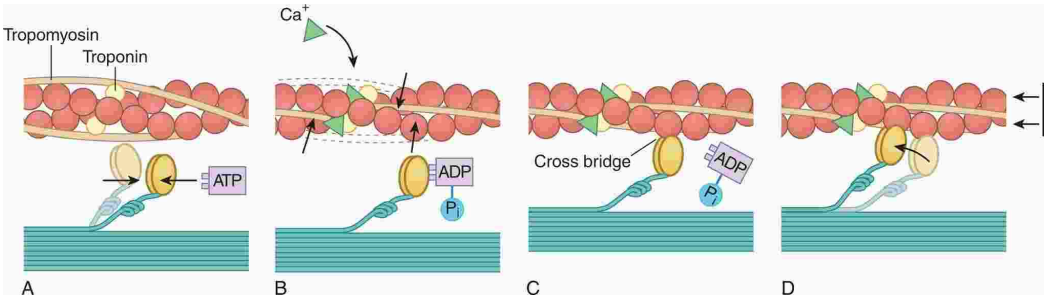

FIG. 31.13 Cross-Bridge Theory of Muscle Contraction.
(A) Each myosin cross-bridge in the thick filament moves into a resting position after an adenosine triphosphate *(ATP)* molecule binds and transfers its energy. **(B)** Calcium ions released from the sarcoplasmic reticulum bind to troponin in the thin filament, allowing tropomyosin to shift from its position blocking the active sites of actin molecules. **(C)** Each myosin cross-bridge then binds to an active site on a thin filament, displacing the remnants of ATP hydrolysis—adenosine diphosphate *(ADP)* and inorganic phosphate *(P_i)*. **(D)** The release of stored energy from step A provides the force needed for each cross-bridge to move back to its original position, pulling actin along with it. Each cross-bridge will remain bound to actin until another ATP molecule binds to it and pulls it back into its resting position (A). (Adapted from *Thibodeau GA, Patton KT. Anatomy & physiology*, 4th edition. St. Louis: Mosby; 1999.)

Cross-bridge cycling

The ovoid head-end of the myosin contains a binding site for actin and a separate enzymatic site that catalyzes the breakdown of ATP to adenosine diphosphate (ADP) and inorganic phosphate (P_i) (see Fig. 31.13). This reaction releases the chemical energy stored in ATP. The splitting of ATP occurs on the myosin molecule before it attaches

to actin, but the ADP and inorganic phosphate released remain bound to the active site on myosin.

The binding of this high-energy myosin-actin to form a cross-bridge releases the energy stored in myosin (i.e., ADP and P_i), producing the force necessary for movement of the cross-bridge. With the attachment of actin to myosin at the cross-bridge, the myosin head molecule undergoes a position change, exerting traction on the rest of the myosin bridge, causing the thin filaments to slide past the thick filaments (see Fig. 31.13D). During contraction each cross-bridge undergoes several cycles of attachment, movement, and dissociation from the thin filaments. The rate of cross-bridge cycling is linked to systolic function and **cardiac output**.[13]

Calcium and excitation-contraction coupling

Excitation-contraction coupling is the process by which an action potential arriving at the muscle fiber plasma membrane triggers the cycle, leading to cross-bridge formation and contraction. Cycle activation depends on calcium availability, and the amount of force developed is regulated by how much the concentration of calcium ions increases within the cardiomyocytes. Calcium enters the myocardial cell from the interstitial fluid after electrical excitation that increases membrane calcium permeability. Two types of calcium channels are identified in cardiac tissues. The *L-type*, or long-lasting, channels are the predominant type of calcium channels and are the channels blocked by **calcium channel–blocking drugs** (verapamil, nifedipine, diltiazem). The major effect of these medications is to decrease the strength of cardiac contraction. The *T-type*, or transient, channels are much less abundant in the heart and are not blocked by currently available calcium channel–blocking drugs and are being investigated.

Calcium entering the cell triggers the release of additional calcium from the two storage sites within the sarcomere. Calcium ions then diffuse toward the myofibrils, where they bind with troponin. The calcium-troponin complex interaction facilitates the contraction

process (see Fig. 31.13). In the resting state, troponin is bound to actin and the tropomyosin molecule covers the sites where the myosin heads bind to actin, thereby preventing interaction between actin and myosin. Calcium binds to troponin, which ultimately results in tropomyosin moving troponin, thus uncovering the binding sites. Myosin and actin can now form cross-bridges, and ATP can be dephosphorylated to adenosine diphosphate (ADP). Under these circumstances, sliding of the thick and thin filaments can occur, and the muscle contracts.

Myocardial relaxation

Relaxation is as vital to optimal cardiac function as contraction, and calcium, troponin, and tropomyosin also facilitate relaxation. After contraction, free calcium ions are actively pumped out of the cell back into the interstitial fluid or taken back into storage by the sarcoplasmic reticulum and tubule system. As the concentration of calcium within the sarcomere decreases, troponin releases its bound calcium. The tropomyosin complex moves and blocks the active sites on the actin molecule, preventing cross-bridge formation with the myosin heads. If the ability of the myocardium to relax is impaired, it can lead to increased diastolic filling pressures and eventually heart failure (see Chapter 32).

Factors Affecting Cardiac Output

Cardiac performance can be evaluated by measuring the cardiac output. Cardiac output is calculated by multiplying the heart rate in beats per minute by the **stroke volume** (volume of blood ejected during systole) in liters per beat. Normal adult cardiac output is about 5 L/min at rest, given a heart rate of about 70 beats/min and a normal stroke volume of about 70 mL.

With each heartbeat, the ventricles eject much of their blood volume, and the percentage of total end-diastolic ventricular volume ejected per beat is called the **ejection fraction**. The ejection fraction is calculated by dividing the stroke volume by the end-diastolic volume. The **end-diastolic volume** of the normal ventricle is about

70 to 80 mL/m^2, and the normal ejection fraction of the resting heart, measured with gated myocardial perfusion imaging, was 66% ± 8% for women and 58% ± 8% for men. The ejection fraction is increased by factors that increase contractility, such as increased sympathetic nervous system activity. A decrease in the ejection fraction may indicate ventricular failure. The effects of aging on cardiovascular function are summarized in Table 31.2.

Table 31.2

Cardiovascular Function in Elderly Adults

Determinant	Resting Cardiac Performance	Exercise Cardiac Performance[a]
Cardiac output	Unchanged	Decreases because of a decrease in maximum heart rate
Heart rate	Slight decrease	Increases less than in younger people
Stroke volume	Slight increase	No change
Ejection fraction	Unchanged	Decreased
Afterload	Increased	Increased
End-diastolic volume	Unchanged	Increased
End-systolic volume	Unchanged	Increased
Contraction	Decreased velocity	Decreased
Myocardial wall stiffness	Increased	Increased
Maximum oxygen consumption	Not applicable	Decreased
Plasma catecholamines	—	Increased

[a]Changes in healthy men and women up to age 80 years as compared to those 20 years of age.

Data from Lakatta EG, et al. Aging and cardiovascular disease in the elderly. In: Fuster V, et al., eds. *Hurst's the heart*, 13th edition. Philadelphia: McGraw-Hill; 2011.

The factors that determine cardiac output are (1) **preload**, (2) **afterload**, (3) myocardial contractility, and (4) heart rate. Preload, afterload, and contractility all affect stroke volume (Fig. 31.14).

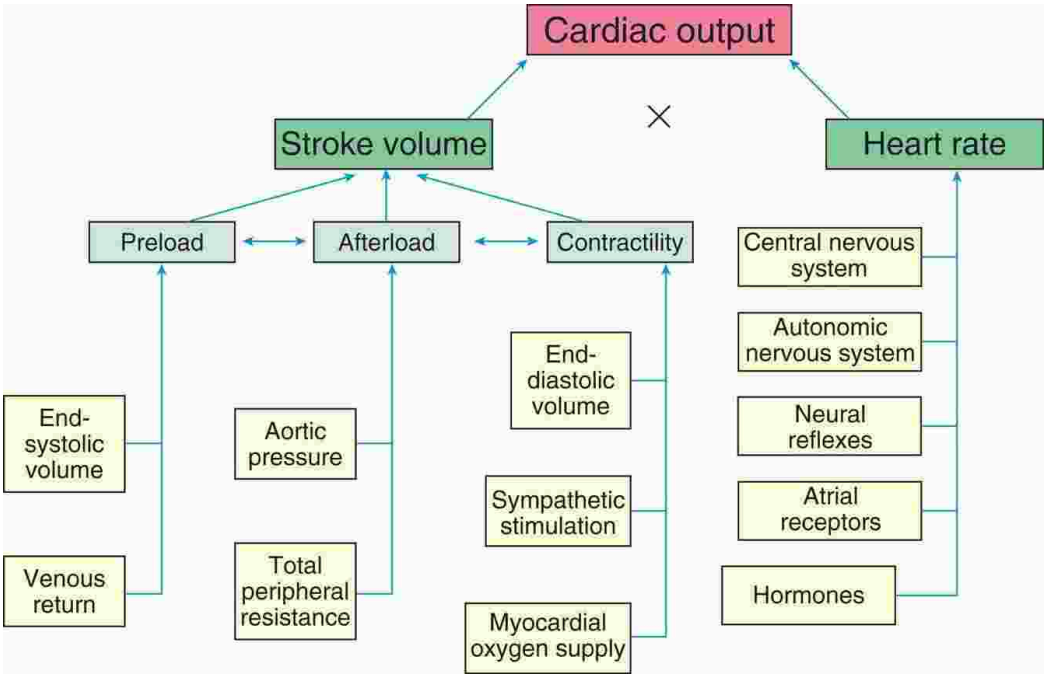

FIG. 31.14 Factors Affecting Cardiac Performance.
Cardiac output, the amount of blood (in liters) ejected by the heart per minute, depends on the heart rate (beats per minute) and stroke volume (milliliters of blood ejected during ventricular systole).

A flowchart lists the factors affecting cardiac performance. • End-systolic volume and venous return affects preload. • Total peripheral resistance and aortic pressure affects afterload. • Myocardial oxygen supply, sympathetic stimulation, and end diastolic volume affects contractility. • Preload, afterload, and contractility are interrelated which impacts stroke volume. • Hormones, atrial receptors,

neural reflexes, autonomic nervous system, and central nervous system affect heart rate.

Preload

Preload is the volume and pressure inside the ventricle at the end of diastole (ventricular end-diastolic volume [VEDV] and pressure [VEDP]). Preload is determined by two primary factors: (1) the amount of blood left in the ventricle after systole (end-systolic volume) and (2) the amount of venous blood returning to the ventricle during diastole. *End-systolic volume* is dependent on the strength of ventricular contraction and the resistance to ventricular emptying. *Venous return* is dependent on blood volume and flow through the venous system and the atrioventricular valves. Clinically, preload is estimated by measuring the central venous pressure (CVP) for the right side of the heart and the pulmonary artery wedge pressure (cross-sectional pressure) for the left side. Normal values for these two estimates are 1 to 5 mm Hg and 4 to 12 mm Hg, respectively. Heart failure can occur because of an increase in preload (VEDV), which causes a decline in stroke volume and also increases VEDP (see Chapter 32). Increased VEDP causes pressures to increase or "back up" into the pulmonary or systemic venous circulation, increasing plasma outflow through the vessel walls, causing fluid to accumulate in lung tissues (pulmonary edema) or in peripheral tissues (peripheral edema).

Frank-starling law of the heart

Cardiac muscle, like other muscle, increases its strength of contraction when it is stretched up to a certain point. The **Frank-Starling law of the heart**, or the length-tension relationship of cardiac muscle, relates resting sarcomere length, expressed as the volume of blood in the heart at the end of diastole (end-diastolic volume), to tension generation, described as development of left ventricular pressure. Thus, the volume of blood in the heart at the

end of diastole (the length of its muscle fibers) is directly related to the force of contraction during the next systole. Although the change in pressure is related to the volume of the ventricle and, consequently, to the length of the ventricular muscle fibers, preload (i.e., filling pressure) is commonly used as an index of ventricular volume. The length-tension mechanism is the main mechanism by which the normal right and left ventricles maintain equal minute outputs even though their stroke outputs may vary considerably during normal respiration. For example, changes in volume occur when an individual assumes a reclining position after being in a standing position; the volume of blood returning to the heart temporarily increases. The right ventricle stretches to accommodate this increase in volume and thereby increases its force of contraction. A larger stroke volume (i.e., the amount of blood ejected per beat) is pumped to the lungs, generating higher pressures. Pulmonary vascular pressure increases, causing a rise in the left ventricular filling pressure or preload. Left ventricular volume and pressure increase. The left ventricle pumps a larger stroke volume, and arterial vascular pressure rises.

The mechanical function of the heart is characterized by a number of length-tension curves (Fig. 31.15). Factors that increase contractility, such as sympathetic nerve stimulation, cause the heart to operate on a higher length-tension curve (curve *A* in Fig. 31.15). A higher tension or increase in ventricular stroke volume is generated without a necessary change in **left ventricular end-diastolic volume (LVEDV)** or fiber length. Heart failure (curve *C* in Fig. 31.15) is characterized by a lower length-tension curve. The Frank-Starling law of the heart may not apply to dilated or failing hearts because their fibers are already stretched beyond their optimal length. The failing heart responds to increased filling or stretch with a progressive decline in the force of contraction. Thus at the same left ventricular end-diastolic volume (LVEDV) as curves *A* and *B* (see Fig. 31.15), the force of contraction of stroke volume is decreased (Fig. 31.15C).

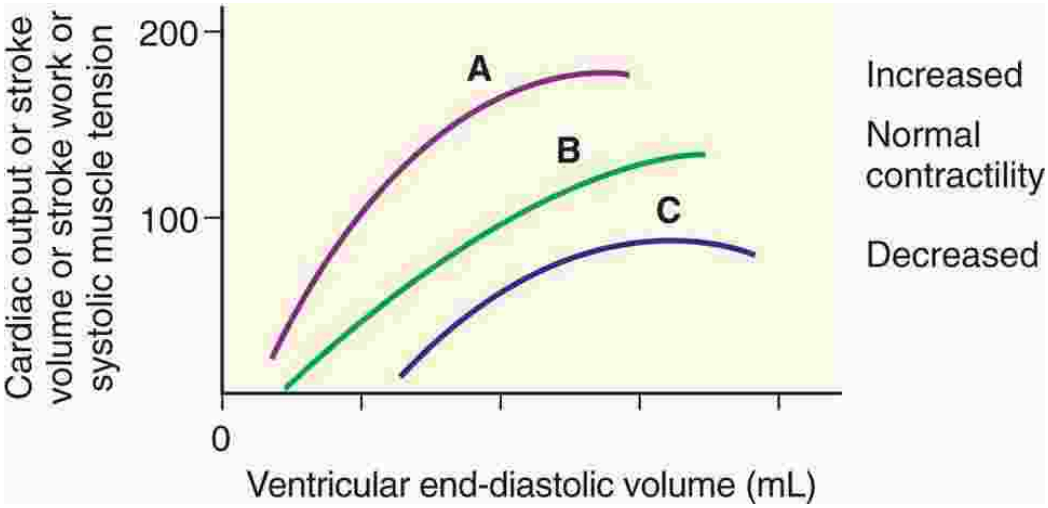

FIG. 31.15 Frank-Starling Law of the Heart. The relationship between length and tension in the heart. The end-diastolic volume determines the end-diastolic length of ventricular muscle fibers and is proportional to tension generated during systole, as well as to cardiac output, stroke volume, and stroke work. A change in myocardial contractility causes the heart to perform on a different length-tension curve. **(A)** Increased contractility; **(B)** normal contractility; **(C)** heart failure or decreased contractility. (See text for further explanation.)

A graph shows the effect of changes in myocardial contractility on the Frank-Starling curve. The horizontal axis represents the ventricular end-diastolic volume given in milliliters. The vertical axis represents the cardiac output or stroke volume or stroke work or systolic muscle tension, ranging from 0 to 200. The curve shifts downward and to the right as contractility is decreased. Stroke volume in

response to increased left ventricular end-diastolic volume in heart failure.

The cross-bridge arrangement with the sarcomere partially accounts for the length-tension mechanism of cardiac muscle. According to the Frank-Starling law, the longer the initial resting length of the cardiac muscle fiber (optimal length is between 2.2 and 2.4 mm), the greater the strength of contraction. At 2.2 mm an optimal number of active cross-bridges exist between actin and myosin. However, if the fibers are stretched beyond 2.2 to 2.4 mm, the force of contraction decreases because actin and myosin become partially disengaged, disrupting many of the cross-bridges. Excessive stretching, to about 3.65 mm, causes actin and myosin to become completely disengaged so that tension (force of contraction) drops to zero. The relationship between stretch and contraction can be compared with that of a rubber band. Up to a certain point, the more the rubber band is stretched the farther it will fly when one end is released; beyond that point, however, the rubber band will break but, of course, the myocardium does not actually break.

Laplace law

Laplace law states that wall tension is related directly to the product of intraventricular pressure and internal radius, and inversely related to the wall thickness as shown in the Laplace equation:where T = wall tension, p = intraventricular pressure, r = internal radius of the sphere, and μm = wall thickness. In other words, the amount of tension generated in the ventricular wall (or any chamber or vessel) to produce a given intraventricular pressure depends on the size (radius and wall thickness) of the ventricle.

Laplace law is useful for understanding aneurysm formation, distensibility in blood vessels, and the effects of ventricular dilation on myocardial contraction. Dilation is an important factor in heart failure (see Chapter 32). With a dilated ventricle, myocardial fibers in the wall must develop greater tension to produce a given pressure

within the ventricle. The disadvantage of dilation is that the increased force, or tension, in the myocardial fibers required to develop a given pressure inside a dilated ventricle decreases the rate of fiber shortening, thereby decreasing the ability of the ventricle to eject blood.

Afterload

Ventricular afterload is the resistance to ejection of blood from the ventricle. It is the load the muscle must move during contraction. The aortic systolic pressure is an index of afterload. Pressure in the ventricle must exceed the aortic pressure before blood can be pumped out during **systole**. Low aortic pressures (decreased afterload) enable the heart to contract more rapidly and efficiently, whereas high aortic pressures (increased afterload) slow contraction and cause higher workloads against which the heart must function to eject blood. Increased aortic pressure is usually the result of increased **systemic vascular resistance (SVR)**, sometimes referred to as **total peripheral resistance (TPR)**. In individuals with hypertension, increased SVR means that afterload is chronically elevated, resulting in increased ventricular workload and hypertrophy of the myocardium. SVR is calculated by dividing the mean arterial pressure by the cardiac output; the normal range is 700 dyne/s/cm^{-5}. The most sensitive measure of afterload is SVR. In some individuals, changes in afterload are the result of aortic valvular disease.

Myocardial Contractility

Stroke volume, or the volume of blood ejected per beat during systole, also depends on the *force* of contraction, myocardial contractility, or the degree of myocardial fiber shortening. Three major factors determine the force of contraction (see Fig. 31.14):

1. *Changes in the stretching of the ventricular myocardium caused by changes in VEDV (preload)*. As discussed previously, increased

venous return to the heart distends the ventricle, thus increasing preload, which increases the stroke volume and, subsequently, cardiac output, up to a certain point. However, an excessive increase in preload leads to decreased stroke volume.

2. *Alterations in the inotropic stimuli of the ventricles*. Hormones, neurotransmitters, or medications that affect contractility are called inotropic agents. The most important endogenous positive inotropic agents are epinephrine and norepinephrine released from the sympathetic nervous system. The most important negative **inotropic agent** is acetylcholine released from the vagus nerve. Many medications have positive or negative inotropic properties that can have significant effects on cardiac function. In sepsis, a variety of cytokines, including tumor necrosis factor-alpha (TNF-α), and interleukin-1β, have been shown to impair myocardial contractility.[14]
3. *Adequacy of myocardial oxygen supply*. O_2 and carbon dioxide levels (tensions) in the coronary blood also influence contractility. With severe hypoxemia (arterial O_2 saturation less than 50%), contractility is decreased. Moderate degrees of hypoxemia may increase contractility by enhancing the myocardial response to circulating catecholamines.

Preload, afterload, and contractility all interact with one another to determine stroke volume and cardiac output (see Fig. 31.14). Changes in any one of these factors can result in deleterious effects on the others, resulting in heart failure (see Chapter 32).

Heart Rate

As described previously, SA node activity is the primary determinant of the heart rate. The average heart rate in healthy adults is about 70 beats/min; in children it is typically greater. This rate diminishes by 10 to 20 beats/min during sleep and can accelerate to more than 100 beats/min during muscular activity or emotional

excitement. In well-conditioned athletes, the resting heart rate is normally about 50 to 60 beats/min. In highly trained or elite athletes, the resting heart rate can be below 50 beats/min; these athletes also have a greater stroke volume and lower peripheral resistance in active muscles than they had before training. The control of heart rate includes activity of the central nervous system, autonomic nervous system, neural reflexes, atrial receptors, and hormones (see Fig. 31.14).

Heart rate variability

Heart rate varies naturally with many factors such as exercise, anxiety, temperature, and hormones (e.g., estrogen). This ability of the heart to change rate is called **heart rate variability (HRV)** and is a measure of cardiac autonomic function. For example, heart rate varies with respiration, the rate increasing with inspiration and decreasing with expiration. This normal alteration in rhythm pattern, called **sinus arrhythmia**, is caused by changes that occur within the chest cavity because of respiration. Inspiration results in stretch and an associated increase in firing of the SA node that increases heart rate. The stretch is reduced with expiration and the SA node firing rate slows, resulting in a decrease in heart rate. Adequate amounts of HRV in response to physiologic conditions is believed to be an important indicator of health.

Many pathophysiologic factors are linked to decreased HRV, including neurologic disease (e.g., parkinsonian syndrome, multiple sclerosis), cardiovascular disease (e.g., coronary artery disease, heart failure), inflammation, alcohol and drug consumption, occupational exposures, exposure to electromagnetic fields, air pollution, and others.[15] Recent studies have documented the relationship between psychological stress, lack of effective coping mechanisms, and mental health disorders with decreased heart rate variability.[16] A decrease in HRV may indicate that the individual is vulnerable to complications from their underlying conditions. For example, a decrease in HRV is associated with a higher risk of cardiovascular events and mortality in individuals with cardiovascular disease.[17]

Cardiovascular control centers in the brain

The **cardiovascular vasomotor control** center is in the medulla and pons areas of the brainstem, with additional areas in the hypothalamus, cerebral cortex, and thalamus. The hypothalamic centers regulate cardiovascular responses to changes in temperature, the cerebral cortex centers adjust cardiac reaction to a variety of emotional states, and the brainstem control center regulates heart rate and blood pressure.

The nerve fibers from the cardiovascular control center synapse with autonomic neurons that influence the rate of firing of the SA node. As previously discussed, an increased heart rate occurs with sympathetic (adrenergic) stimulation. When the parasympathetic nerves to the heart are stimulated (primarily via the vagus nerve), the heart rate slows and the sympathetic nerves to the heart, arterioles, and veins are inhibited. At rest, the heart rate in healthy individuals is primarily under the control of parasympathetic stimulation. Administration of drugs that block parasympathetic function (anticholinergic) or physical interruption of the vagus nerve causes significant tachycardia (abnormally fast heart rate) because this inhibitory parasympathetic influence is lost.

Neural reflexes

Output from the **baroreceptor reflexes** influences short-term regulation of the vascular smooth muscle of resistance arteries, myocardial contractility, and heart rate, all components of blood pressure control. The baroreceptors or pressoreceptors are located in the aortic arch and carotid arteries. If blood pressure decreases, the baroreceptor reflex accelerates the heart rate, increases myocardial contractility, and increases vascular smooth muscle contraction in the arterioles, thus raising blood pressure. This reflex is critical to maintaining adequate tissue perfusion. When the blood pressure increases, the baroreceptors increase their rate of discharge, sending neural impulses over a branch of the glossopharyngeal nerve (cranial nerve IX) and through the vagus nerve to the cardiovascular control centers in the medulla. These reflexes increase parasympathetic

activity and decrease sympathetic activity, causing the resistance arteries to dilate, decreasing myocardial contractility and the heart rate. The role of baroreceptors in influencing blood pressure is discussed in more detail later in this chapter.

Atrial receptors

Mechanoreceptors that influence the heart rate exist in both atria. They are located where the veins, venae cavae, and pulmonary veins enter their respective atria. The **Bainbridge reflex** is the name for the changes in the heart rate that may occur after intravenous infusions of blood or other fluid. The change in heart rate is thought to be caused by a reflex mediated by these atrial volume receptors that are innervated by the vagus nerve (volume receptors are thought to respond to increased plasma volume). Although this reflex can be elicited in humans, its relevance is uncertain at this time. Stimulation of these atrial receptors also increases urine volume, presumably because of a neurally mediated reduction in antidiuretic hormone. In addition, peptides of the atrial natriuretic family are released from atrial tissue in response to the increases in blood volume. These peptides have diuretic and natriuretic (salt excretion) properties, resulting in decreased blood volume and pressure. The atrial natriuretic peptides also have been shown to relax vascular smooth muscle and oppose myocardial hypertrophy, leading to measurement of blood levels to evaluate clinical status and raising interest in their use as therapeutic agents (see Chapter 32).

Hormones and biochemicals

Hormones and other biochemically active substances affect the arteries, arterioles, venules, capillaries, and contractility of the myocardium. Norepinephrine, mainly released as a neurotransmitter from the adrenal medulla, dilates vessels of the liver and skeletal muscle and also causes an increase in myocardial contractility. Epinephrine dilates vessels of the liver and skeletal muscle and causes an increase in myocardial contractility. Some adrenocortical

hormones, such as hydrocortisone, increase the effects of the catecholamines—norepinephrine and epinephrine.

Thyroid hormone, specifically triiodothyronine, causes increases in both heart rate and contractility, resulting in an increase in cardiac output; it also decreases systemic vascular resistance. Triiodothyronine acts directly on the cardiac myocytes to cause gene transcription and cellular changes that result in more calcium release from the sarcoplasmic reticulum.[18] Awareness of these changes helps to understand the cardiovascular changes that occur with thyroid diseases. Growth hormone, working together with insulin-like growth factor-1 (IGF-1), also has been shown to increase myocardial contractility.[19] Decreases in levels of growth hormone or thyroid hormone may result in bradycardia (heart rate below 60 beats/min), reduced cardiac output, and low blood pressure. (Other hormones are discussed in the Regulation of Blood Pressure section.)

Systemic Circulation

The arteries and veins of the systemic circulation are illustrated in Fig. 31.16. Oxygenated blood leaves the left side of the heart through the aorta and flows into the systemic arteries. These arteries branch into small arterioles, which branch into the smallest vessels, the capillaries, where nutrient and waste product exchange between the blood and tissues occurs. Blood from the capillaries then enters tiny venules that join to form the larger veins, which return venous blood to the right heart (see Fig. 31.1B). **Peripheral vascular system** is the term used to describe the part of the systemic circulation that is outside of the chest or abdomen, consisting primarily of the vessels that supply blood to the extremities. Cerebrovascular system is the term used to describe the vessels that supply blood to the neck, head, and brain.

Bottom panel, B. An illustration of the anterior view of person shows and identifies the following veins, clockwise from the top right: occipital angular, facial, external jugular, internal jugular, left brachiocephalic, left subclavian, axillary, cephalic, great cardiac, basilic, long thoracic, splenic, brachial, inferior mesenteric, ulnar, common

iliac, internal iliac, radial, digital, femoral, popliteal, digital, venous dorsal arch, posterior tibial, anterior tibial, fibular, small saphenous, great saphenous, femoral, external iliac, common iliac, median cubital (basilic), superior mesenteric, hepatic portal, hepatic, inferior vena cava, small cardiac, right pulmonary, superior vena cava, right subclavian, and right brachiocephalic.

Structure of Blood Vessels

Blood vessel walls are composed of three layers: (1) the **tunica intima** (innermost, or intimal, layer), (2) the **tunica media** (middle, or medial, layer), and (3) the **tunica externa** or adventitia (outermost, or external, layer), which also contains nerves and lymphatic vessels. These layers are illustrated in Fig. 31.17. Blood vessel walls vary in thickness, depending on the thickness or absence of one or more of these three layers. Cells of the larger vessel walls are nourished by the **vasa vasorum**, small vessels located in the tunica externa, and innervated by perivascular nerves. The vasa vasorum arises from the blood vessel itself or from other vessels nearby.

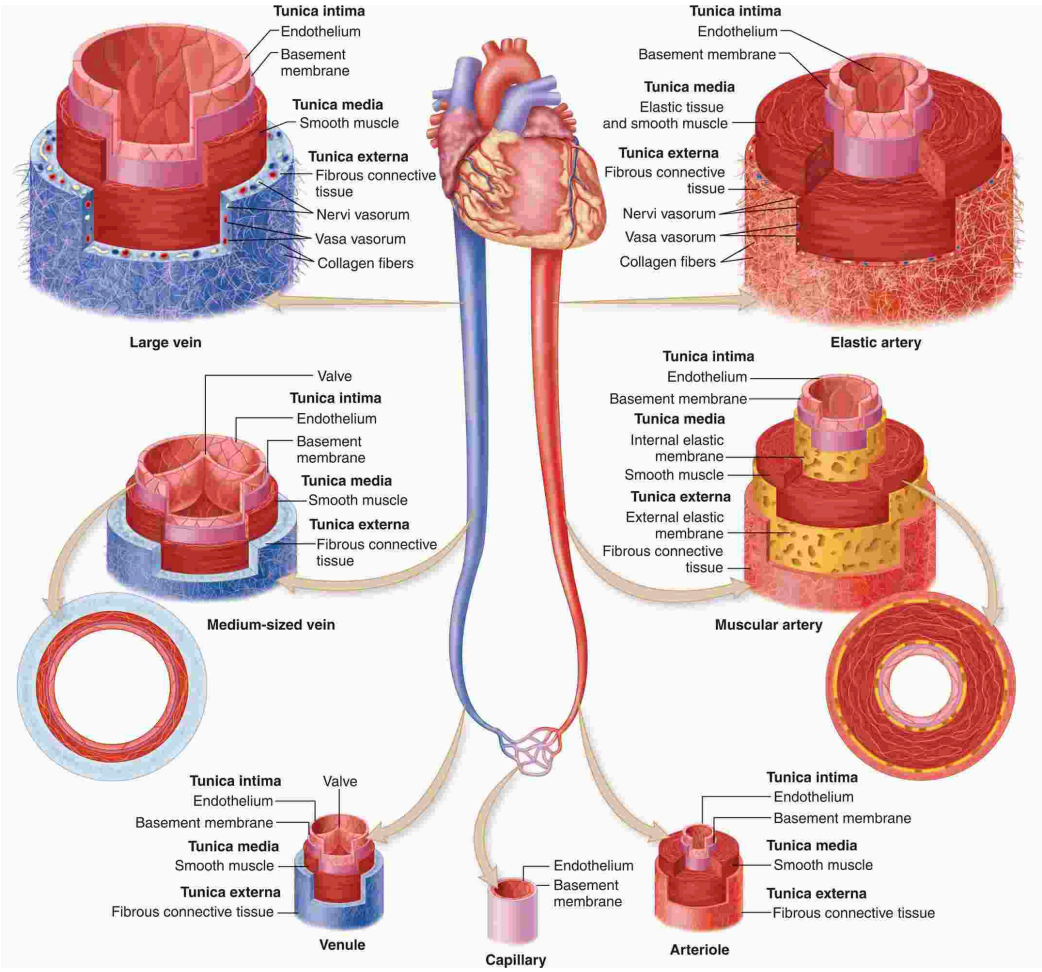

FIG. 31.17 Structure of Blood Vessels, and an Artery and Vein.
Structure of blood vessels. The tunica externa of the veins are color-coded *blue* and the arteries *red*. (From Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Elsevier; 2019.)

An illustration of the heart and accompanying magnified views of arteries and veins shows and labels its different structures. Top-left. The illustration shows a cutaway view of the large vein and identifies the following structures from the inside to the outside: tunica intima (endothelium,

basement membrane), tunica media (smooth muscle), and tunica externa (fibrous connective tissue, nervi vasorum, vasa vasorum, and collage fibers). Top-right. The illustration shows a cutaway view of the elastic artery and identifies the following structures from the inside to the outside: tunica intima (endothelium, basement membrane), tunica media (elastic tissue and smooth muscle), and tunica externa (fibrous connective tissue, nervi vasorum, vasa vasorum, and collagen fibers). Middle-left. The illustration shows a cutaway view of a medium-sized vein and identifies the following structures from the inside to the outside: valve, tunica intima (endothelium, basement membrane), tunica media (smooth muscle), and tunica externa (fibrous connective tissue). Middle-right. The illustration shows a cutaway view of the muscular artery and identifies the followings structures from the inside to the outside: tunica intima (endothelium, basement membrane), tunica media (internal elastic membrane, smooth muscle), and tunica externa (external elastic membrane, fibrous connective tissue). Bottom-left. The illustration shows a cutaway view of the venule and identifies the following structures from the inside to the outside: tunica intima (endothelium, basement membrane), tunica media (smooth muscle), and tunica externa (fibrous connective

tissue). Bottom-center. The illustration shows a capillary and labels its endothelium and basement membrane. Bottom-right. The illustration shows a cutaway view of the arteriole and identifies the following structures from the inside to the outside: tunica intima (endothelium, basement membrane), tunica media (smooth muscle), and tunica externa (fibrous connective tissue).

Adults are capable of growing new blood vessels through three processes, all of which are important in wound healing but also contribute to tumor growth. The three processes are angiogenesis, arteriogenesis, and **vasculogenesis**. Both angiogenesis and arteriogenesis occur by growth of new vessels that branch from existing vessels. Angiogenesis is branching of small vessels, such as capillaries, whereas arteriogenesis occurs by branching from larger vessels, such as arterioles. Vasculogenesis is a term that refers to the growth of vessels from progenitor or stem-like cells that originate in the bone marrow and other body tissues.

Arterial Vessels

An **artery** is a thick-walled, pulsating blood vessel transporting blood away from the heart. In the systemic circulation, arteries carry oxygenated blood. When the iron in hemoglobin is oxygenated, it turns bright red, which is why arterial vessels are often color-coded red in illustrations (see Fig. 31.17). Arterial walls are composed of elastic connective tissue, fibrous connective tissue, and smooth muscle. There are two types of arteries: elastic and muscular. **Elastic arteries** have a thick tunica media with more elastic fibers than smooth muscle fibers. Elastic arteries are located close to the heart and include the aorta and its major branches and the pulmonary trunk. Elasticity allows the vessel to absorb energy and stretch as blood is ejected from the heart during systole. During diastole,

elasticity promotes recoil of the arteries, maintaining blood pressure within the vessels.

Muscular arteries, consisting of the medium and small size arteries, are farther from the heart than the elastic arteries. They contain more muscle fibers and fewer elastic fibers than the elastic arteries and they function to distribute blood to arterioles throughout the body (see Fig. 31.17). Because their smooth muscle can contract or relax, they play a role in blood flow control and in directing flow to body parts with the highest need at any point in time. For example, during exercise more blood is sent to the skeletal muscles, while after a meal more blood is directed to the gut and liver. Contraction narrows the vessel **lumen** (the internal cavity of the vessel), which diminishes flow through the vessel (vasoconstriction). When the smooth muscle layer relaxes, more blood flows through the vessel lumen (vasodilation).

An artery becomes an arteriole where the diameter of its lumen narrows to less than 0.5 mm. Arterioles are mainly composed of smooth muscle and regulate the flow of blood into the capillaries by constricting or dilating to either slow or increase the flow of blood into the capillaries (Fig. 31.18). The thick smooth muscle layer of the arterioles is a major determinant of the resistance blood encounters as it flows through the systemic circulation.

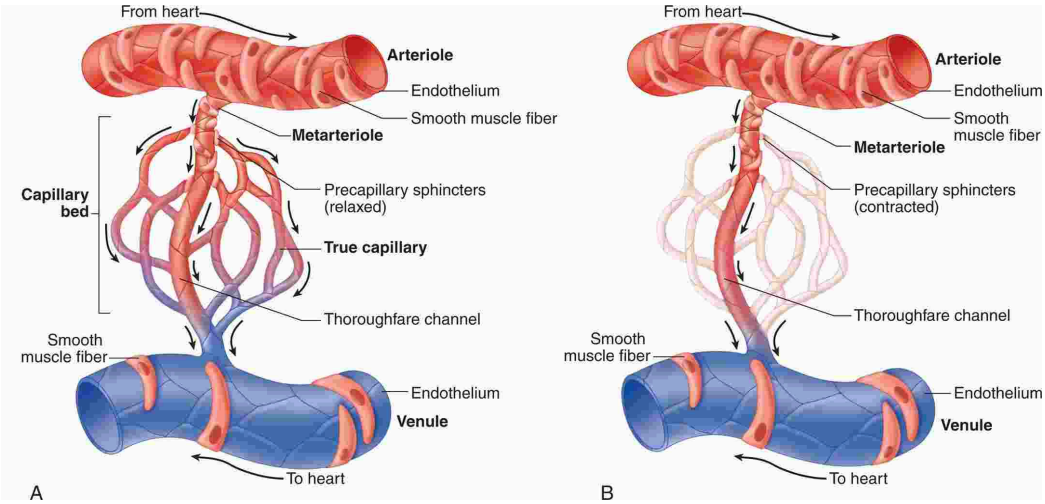

FIG. 31.18 Microcirculation.
Control of local blood flow through a capillary network is regulated by altering the tone of precapillary sphincters surrounding arterioles and metarterioles. **(A)** Sphincters are relaxed, permitting blood flow to enter the capillary bed. **(B)** With sphincters contracted, blood flows from the metarteriole directly into the thoroughfare channel, bypassing the capillary bed. (From Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Mosby; 2019.)

Left panel, A. An illustration shows the arteriole, the capillary bed, and the venule. The endothelium and smooth muscle fiber of the arteriole are labeled. Blood flow from the heart and through the arteriole. The capillary bed comprises precapillary sphincters (relaxed), true capillary, and thoroughfare channel. The endothelium and the smooth fiber of the venule are labeled. Blood from the venule flows to the heart. Blood flows from arteriole to metarteriole followed by capillary bed. Right panel, B. An illustration

shows the arteriole, the metarteriole, and the venule. The endothelium and the smooth muscle fiber of the arteriole are labeled. Blood from the heart flows through the arteriole, into the venule and to the heart. The endothelium and the smooth muscle fiber of the venule are labeled. Precapillary sphincters (contracted) and thoroughfare channel.

The capillary network is composed of connective channels called **metarterioles** and "true" capillaries (see Fig. 31.18). Metarterioles have discontinuous smooth muscle cells in their tunica media, whereas capillaries have no smooth muscle cells. There is a ring of smooth muscle called the **precapillary sphincter** at the point where capillaries branch from metarterioles. As the sphincters contract and relax, they regulate blood flow through the capillary beds. The precapillary sphincters help to maintain arterial pressure and regulate selective flow to vascular beds.

Capillaries are composed solely of a layer of **endothelial cells** surrounded by a basement membrane (see Fig. 31.17). Their thin walls and unique structure make possible the rapid exchange of water; small soluble molecules; some larger molecules, such as albumin; and cells of the innate and adaptive components of the immune system between the blood and the interstitial fluid. Based on their structure, three types of capillaries have been described: *continuous*, *sinusoid*, and *fenestrated*. In the renal glomerulus, for example, the endothelial cells contain oval windows or pores termed **fenestrations**, which are covered by a thin diaphragm. Sinusoid capillaries are found in the liver and bone marrow.

Substances pass between the capillary lumen and the interstitial fluid (1) through junctions between endothelial cells, (2) through fenestrations in endothelial cells, (3) in vesicles moved by active transport across the endothelial cell membrane, or (4) by diffusion through the endothelial cell membrane (Fig. 31.19B). A single

capillary may be only 0.5 to 1 mm in length and 0.01 mm in diameter, but the capillaries are so numerous their total surface area may be more than 600 m^2 (about 100 football fields).

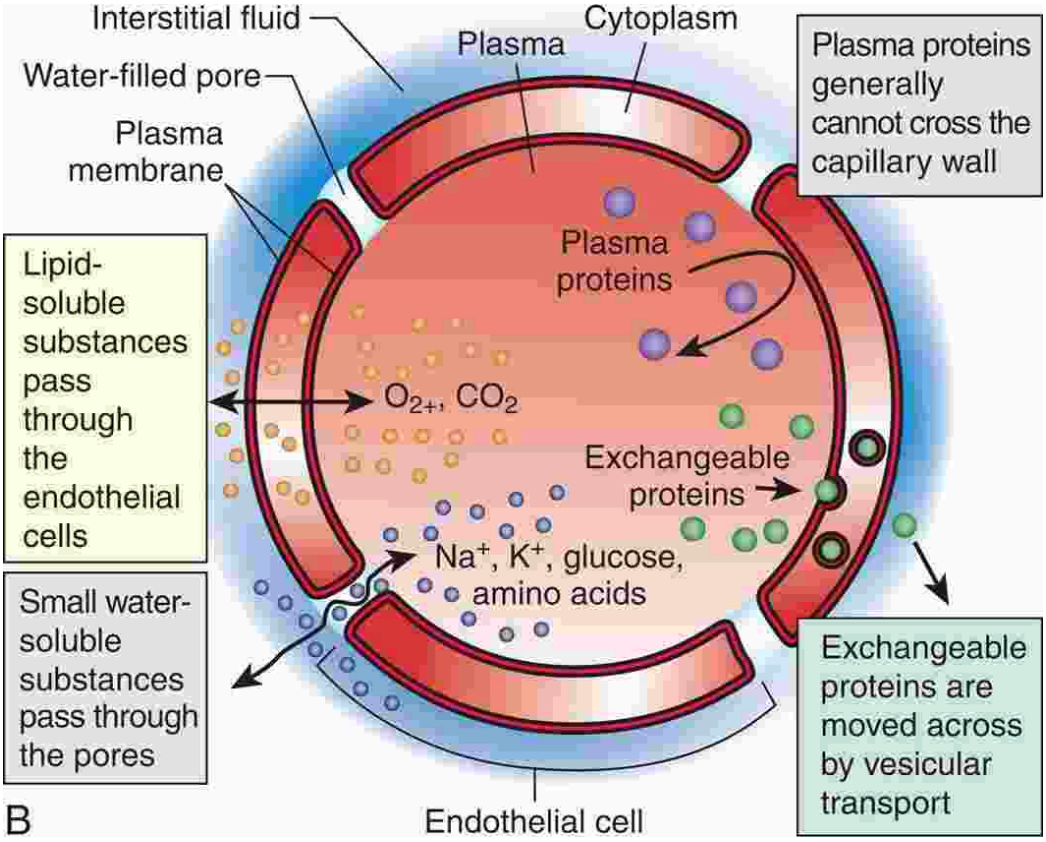

FIG. 31.19 Vascular Endothelium.
(A) This shows the endothelial cells in context with the entire blood vessel. The endothelial cells arrange themselves as a single-layer lining that has numerous critical functions (see Table 31.3).
(B) The endothelium supports numerous functions through synesis and release of vasoactive fibers.

Left panel, A. The illustration shows a cutaway view of a blood vessel and identifies the following layers from the inside to the outside: endothelium, basement membrane, tunic intima, tunica media, tunica adventitia, nerve, and vasa vasorum. Right panel, B. The illustration shows a cross-section of the blood vessel. The structure identified on the

illustration are as follows: plasma membrane, water-filled pore, interstitial fluid, plasma, cytoplasm, and endothelial cell. The functions of the endothelium are as follows. Plasma protein generally cannot cross the capillary wall. Exchangeable proteins are moved across by vesicular transport. Small water-soluble substances pass through the pores. Lipid-soluble substances pass through the endothelial cells.

Endothelium

The vascular endothelium, or blood vessel lining, is important to several body functions and is sometimes considered a separate endocrine organ. All tissues depend on a blood supply, and the blood supply depends on endothelial cells, which form the lining, or endothelium, of the blood vessel (see Fig. 31.19). In addition to substance transport, the vascular endothelium has important roles in coagulation, antithrombogenesis, and fibrinolysis; immune system function; tissue and vessel growth and wound healing; and **vasomotion**, the contraction and relaxation of vessels. Table 31.3 summarizes some of the more important endothelial functions. Because of its varying roles, the actual structure of the endothelium may vary in different vascular beds. For example, within lymph nodes the endothelial cells of specialized venules, called *high endothelial venules*, are uniquely structured to support the movement of lymphocytes from the blood into the **lymph node**.[20] Endothelial injury and dysfunction are central processes in many of the most common and serious cardiovascular disorders, including hypertension and atherosclerosis (see Chapter 32).

Table 31.3

Functions of the Endothelium

Function	Actions Involved
Filtration and permeability	Facilitates transport of large molecules via vesicular transport movement through intercellular junctions Facilitates transport of small molecules via movement of vesicles, through opening of tight junctions, and across cytoplasm
Vasomotion	Stimulates vascular relaxation through production of nitric oxide, prostacyclin, and other vasodilators Stimulates vascular constriction through production of endothelin-1 and of angiotensin II by the action of endothelial angiotensin-converting enzyme on angiotensin I
Hemostatic balance	Endothelial surface is normally antithrombotic and maintains a balance between procoagulant and anticoagulant factors, as well as profibrinolytic and antifibrinolytic factors

Function	Actions Involved
	Anticoagulant factors include prostacyclin, nitric oxide, antithrombin, thrombomodulin, tissue factor pathway inhibitor, and heparins Procoagulant factors include tissue factor (factor VII), factor VIII, factor V, and plasminogen activator inhibitor-1 (PAI-1) Profibrinolytic factors are tissue- and urokinase-type plasminogen activating factor and PAI-1 Antifibrinolytic factor is tissue plasminogen activator
Inflammation/immunity	Expresses chemotactic agents and adhesion molecules that support white blood cells (including monocytes, neutrophils, and lymphocytes) moving into tissues Expresses receptors for oxidized lipoproteins, allowing them to enter vascular intima
Angiogenesis/vessel growth	Releases growth factors, such as endothelin-1, and heparins for vascular smooth muscle cells
Lipid metabolism	Expresses receptors for lipoprotein lipase and low-density lipoproteins

Function	Actions Involved
	(LDLs)

Veins

Compared with arteries, veins are thin walled with more fibrous connective tissue and have a larger diameter (see Fig. 31.17). A given vein is larger than the artery that lies within the same sheath. Veins also are more numerous than arteries. The smallest venules downstream from the capillaries have an endothelial lining and are surrounded by connective tissue. The largest venules have some smooth muscle fibers in their thin tunica media. The venous tunica

externa has less elastic tissue than that in arteries, so veins do not recoil as much or as rapidly after distention. Like arteries, veins receive nourishment from tiny vasa vasorum.

Some veins, typically in the legs, contain valves to facilitate the one-way flow of blood toward the heart (Fig. 31.20). These valves are folds of the tunica intima and resemble the semilunar valves of the heart. Backflow in veins of the legs is stopped as the flaps of the valves fill with blood and block the vessel. The position of the valves also facilitates blood flow in the proper direction during venous compression. When a person stands up, contraction of the skeletal muscles of the legs compresses the deep veins of the legs and assists the flow of blood toward the heart and against the force of gravity. This important mechanism of venous return is called the **muscle pump** (see Fig. 31.20B).

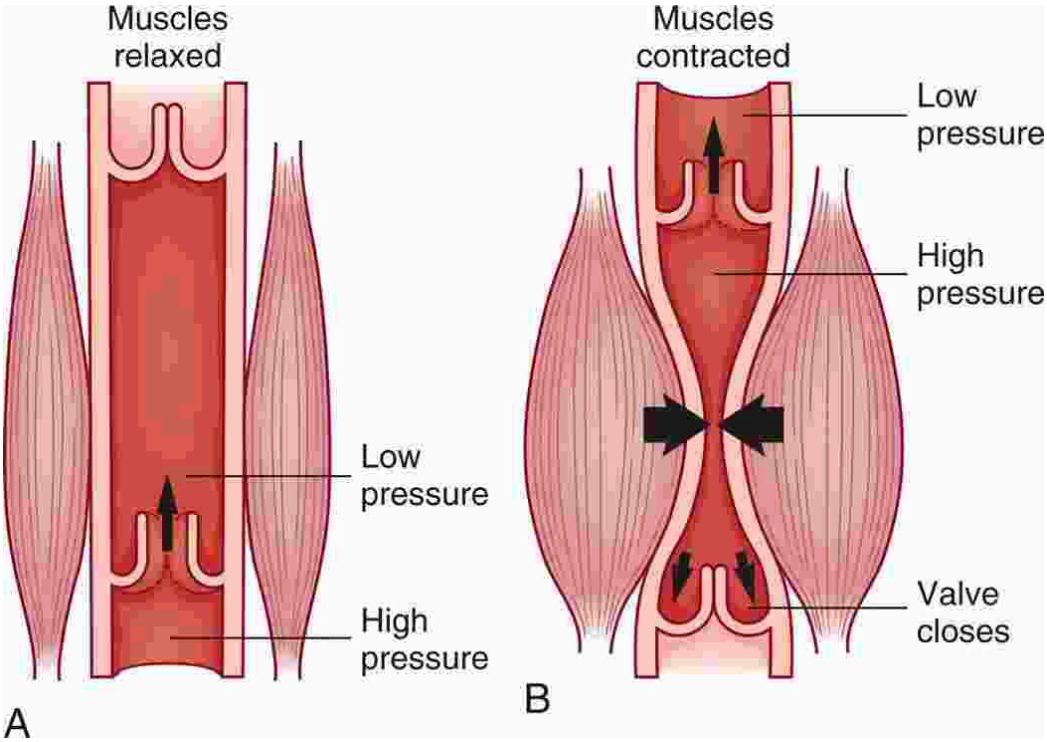

FIG. 31.20 Venous Valves and the Muscle Pump.
In veins, one-way valves aid circulation by preventing backflow of venous blood when pressure in a local area is low. **(A)** Blood is moved toward the heart as valves in the veins are forced open by pressure from volume of blood downstream and the neighboring muscles are relaxed. **(B)** When pressure below the valve drops, blood begins to flow backward but fills the "pockets" formed by the valve flaps, pushing the flaps together and thus blocking further backward flow. Contraction in the adjacent muscles and the valves of the systemic veins assist in the return of unoxygenated blood to the right heart.

Left panel, A. The illustration shows a vein when the muscles are relaxed. The vein is normal with blood from high-pressure zone flowing through the

opening and into the low-pressure zone. Right panel, B. The illustration shows a vein when the muscles are contracted. The vein is constricted with blood from the high-pressure zone flowing through the opening and into the low-pressure zone.

Factors Affecting Blood Flow

Blood flow, the amount of fluid moved per unit of time, is usually expressed as liters or milliliters per minute (L/min or mL/min). Factors that influence blood flow include pressure, resistance, velocity, laminar versus **turbulent** flow, and compliance, with the most important of these being pressure and resistance.

Pressure and Resistance

Pressure in a liquid system is the force exerted on the liquid per unit area and is expressed clinically as millimeters of mercury (mm Hg), or torr (1 torr = 1 mm Hg). Blood flow to an organ depends partly on the pressure difference between the arterial and venous vessels supplying that organ. Fluid moves from the arterial "side" of the capillaries where the pressure is higher to the venous side where the pressure is lower.

Resistance is the opposition to blood flow. Most opposition to blood flow results from the diameter and length of the vessels. Changes in blood flow through an organ result from changes in the vascular resistance within the organ because of increases or decreases in vessel diameter and the opening or closing of vascular channels. Resistance in a vessel is inversely related to blood flow—that is, increased resistance leads to decreased blood flow. The **Poiseuille law** indicates that resistance is directly related to tube length and blood **viscosity** and inversely related to the radius of the tube to the fourth power (r^4). Resistance to flow cannot be measured directly, but it can be calculated if the pressure difference and flow

volumes are known. Resistance to blood flow in a single vessel is determined by the radius and length of the blood vessel and by the blood viscosity.

The most important factor determining resistance *in a single vessel* is the radius or diameter of the vessel's lumen. Small changes in the lumen's radius or diameter lead to large changes in vascular resistance. Because vessel length is relatively constant but lumen size is quite variable, length is not as important as lumen size in determining flow through a single vessel. Clinically, vasoconstriction of arterioles will decrease blood flow to organs perfused by those vessels, whereas vasodilation will increase perfusion. Vasoconstriction or vasodilation of multiple arterioles leads to changes in TPR that may cause a rise of fall in systemic blood pressure.

Blood vessel radius is usually the key factor in determining the TPR because viscosity, the consistency of the fluid, is relatively constant. Thick fluids move more slowly and cause greater resistance to flow than thin fluids—just think of honey as compared to water. The viscosity of blood depends on the red cell content. The greater the percentage of red cells in the blood, the more viscous the blood. This relationship is expressed as the **hematocrit**. A high hematocrit value reduces flow through the blood vessels, particularly the microcirculation (arterioles, capillaries, venules). An elevated hematocrit level is relatively rare. Conditions with elevated hematocrits include a lack of body water, cyanotic congenital heart disease (see Chapter 33), or polycythemia (see Chapter 29), and can lead to increased cardiac work as a result of increased vascular resistance.

Resistance to flow through a *system of vessels*, or **total resistance**, depends not only on characteristics of individual vessels, but also on whether the vessels are arranged in *series* (end to end) or in *parallel* (side to side) and on the total cross-sectional area of the system. Vessels arranged in parallel provide less resistance than vessels arranged in series. Blood flowing through the distributing arteries, beginning with branches off the aorta and ending at arterioles in the capillary bed, encounters more resistance than blood flowing

through the capillary bed itself, where flow is distributed among many short, tiny branches arranged in parallel (Fig. 31.21). The total cross-sectional area of the arteriolar system is greater than that of the arterial system, yet the greater number of arterioles arranged in series leads to great resistance to flow in the arteriolar system. In contrast, the capillary system has a larger number of vessels arranged in parallel than the arteriolar system, and the total cross-sectional area is much greater; thus there is lower resistance overall through the capillary system. The resulting slow velocity of flow in each capillary is optimal for capillary-tissue exchange.

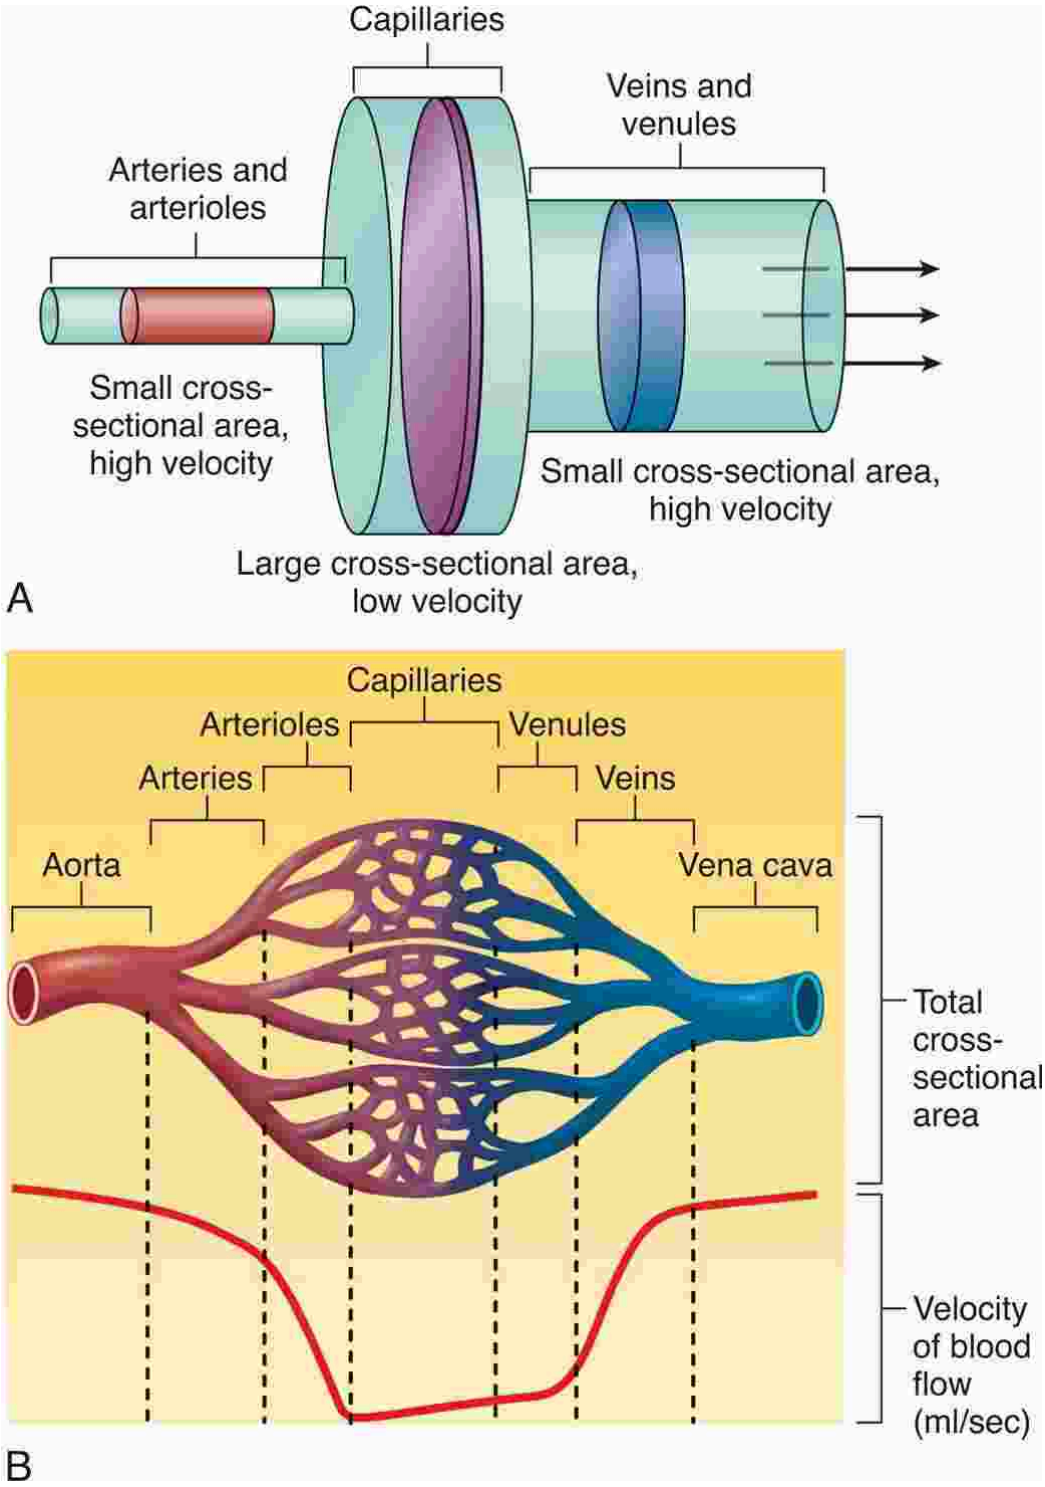

FIG. 31.21 Relationship Between Cross-Sectional Area and Velocity of Blood Flow. **(A)** Small and large cross-sectional areas and their relationship to velocity changes. **(B)** Total

cross-sectional area of different kinds of blood vessels with velocity of blood flow (mL/s). Blood flows with great speed in the large arteries. However, branching of arterial vessels increases the total cross-sectional area of the arterioles and capillaries, reducing the flow rate. When capillaries merge into venules and venules merge into veins, the total cross-sectional area decreases, causing the flow rate to increase.
(From Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Elsevier; 2019.)

Top panel, A. An illustration compares the size of the arteries, capillaries, and veins. Arteries and arterioles: small cross-sectional area, high velocity. Capillaries: large cross-sectional area, low velocity. Veins and venules: small cross-sectional area (larger than that of arteries and arterioles), high velocity. Arrows from the left to the right, along the vessels represent the flow. Bottom panel, B. An illustration shows and labels the following structures, from the left to the right: aorta, arteries, arterioles, capillaries, venules, veins, and vena cava. The upper part of the illustration represents total cross-sectional area. The lower part of the illustration represents velocity of blood flow in milliliters per second. The curve is high and stable initially, falls and is roughly stable for a while, and rises to stabilize at the original level.

Velocity

Blood velocity, or speed, is the *distance* blood travels in a unit of time, usually centimeters per second (cm/s). It is directly related to blood flow (the *amount* of blood moved per unit of time) and inversely related to the cross-sectional area of the vessel in which the blood is flowing (see Fig. 31.21). As blood moves from the aorta to the capillaries, the total cross-sectional area of the vessels increases and the velocity decreases.

Laminar Versus Turbulent Flow

Flow through a tubular system can be either laminar or turbulent. Blood flow through the vessels, except where vessels split or branch, is usually laminar. In **laminar flow**, concentric layers of molecules move "straight ahead," with each layer flowing at a slightly different velocity (Fig. 31.22A). The cohesive attraction between the fluid and the vessel wall prevents the molecules of blood that are in contact with the wall from moving at all. The next thin layer of blood is able to slide slowly past the stationary layer and so on until, at the center, the blood velocity is greatest. Large vessels have room for a large center layer; therefore they have less resistance to flow and greater flow and velocity than smaller vessels.

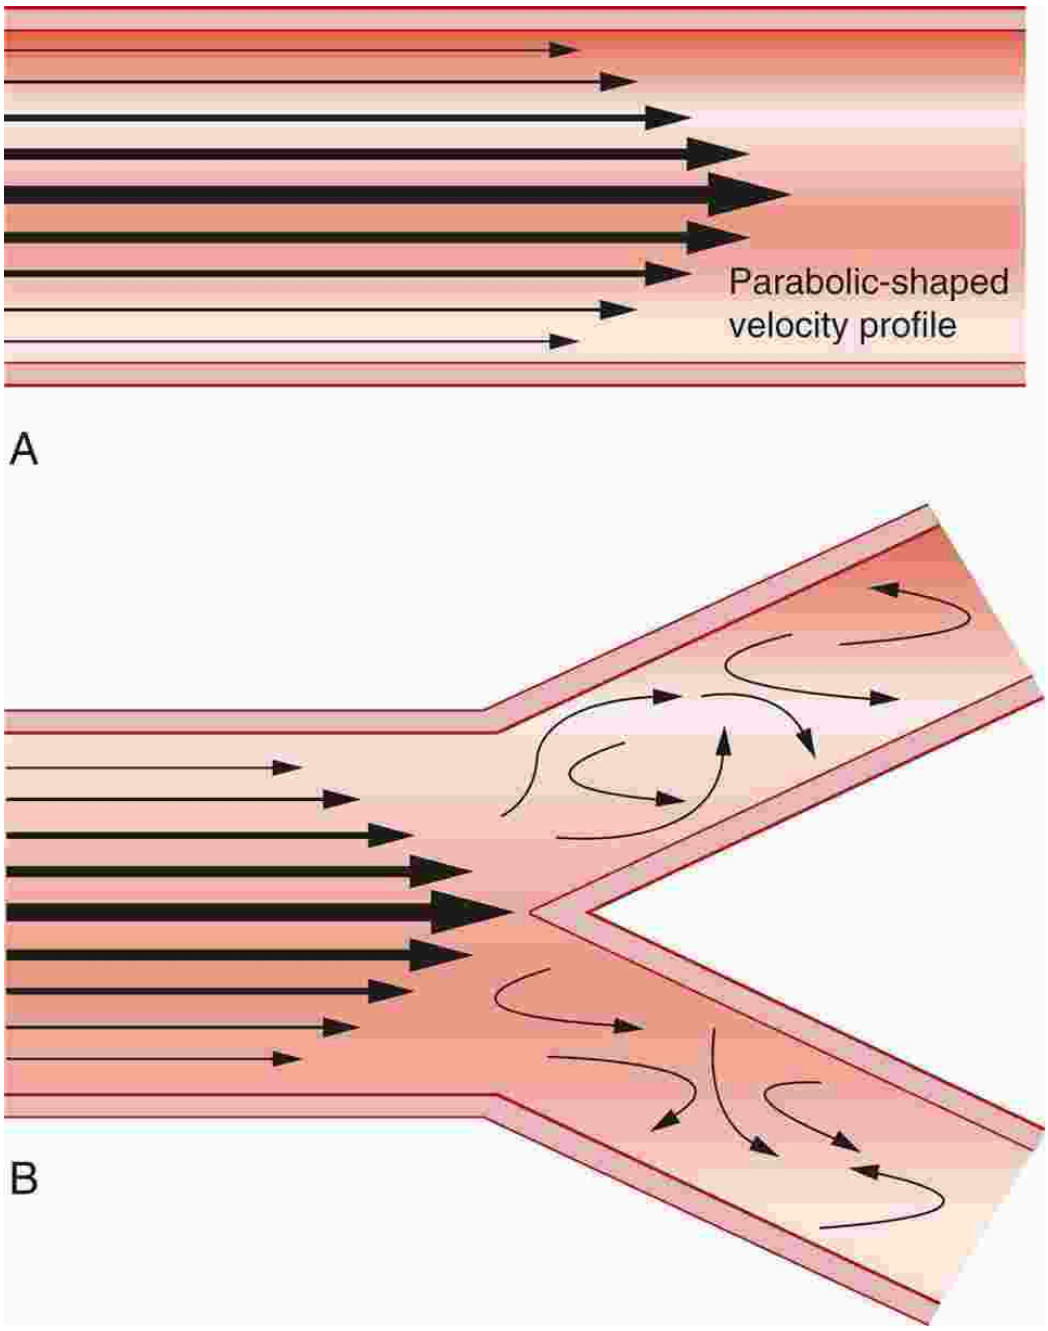

FIG. 31.22 Laminar and Turbulent Blood Flow. **(A)** Laminar flow. Fluid flows in long, smooth-walled tubes as if it is composed of a large number of concentric layers. **(B)** Turbulent flow. Turbulent flow is caused by numerous small currents flowing crosswise or oblique to the long axis of the vessel, resulting in flowing whorls and eddy currents.

Top panel, A. The illustration shows a linear tube tracing a parabolic-shaped velocity profile. Bottom panel, B. The illustration shows a branched tube tracing a parabolic-shaped velocity profiles at the trunk and random velocity profiles in the branches.

Where flow is obstructed, the vessel turns or branches, or blood flows over rough surfaces, the flow becomes turbulent with whorls or eddy currents that produce noise, causing a bruit (vascular murmur) to be heard on auscultation (see Fig. 31.22B). Resistance increases with turbulence, which frequently occurs in areas with atherosclerotic plaque (e). **Wall shear stress (WSS)** is the complex interaction between the vessel wall's endothelial layer and blood hemodynamics. Much investigation is on the consequences of lower WSS and the promotion of atherosclerotic plaque development distal to an induced stenosis.[21] Clarifying WSS and the perivascular changes with inflammation, macrophage activation, medial thinning, and plaque disruption is critical to understanding the pathogenesis of atherosclerosis.

Vascular Compliance

Vascular compliance is the increase in volume a vessel can accommodate with a given increase in pressure. Compliance depends on factors related to the nature of a vessel wall, such as the ratio of elastic fibers to muscle fibers in the wall. Elastic arteries are more compliant than muscular arteries. The veins are more compliant than either type of artery because they have less smooth muscle, and they can serve as storage areas for the circulatory system.

Compliance determines a vessel's response to pressure changes. For example, a large volume of blood can be accommodated by the venous system with only a small increase in pressure. In the less compliant arterial system, where smaller volumes and higher

pressures are normal, even small changes in blood volume can cause significant changes in arterial pressure.

Stiffness is the opposite of compliance. Several conditions and disorders can cause stiffness, with the most common being aging and atherosclerosis (see Chapter 32). Increases in stiffness of arterial walls increases peak arterial pressure at a given volume of blood.

Regulation of Blood Pressure

Arterial Pressure

The arterial blood pressure is determined by the cardiac output multiplied by the peripheral resistance (Fig. 31.23). The systolic blood pressure is the highest arterial blood pressure after ventricular contraction or systole. The **diastolic blood pressure** is the lowest arterial blood pressure that occurs during ventricular filling or diastole. The **mean arterial pressure (MAP)**, which is the average pressure in the arteries throughout the cardiac cycle, depends on the elastic properties of the arterial walls and the mean volume of blood in the arterial system. MAP can be approximated from the measured values of the systolic (P_s) and diastolic (P_d) pressures as follows:

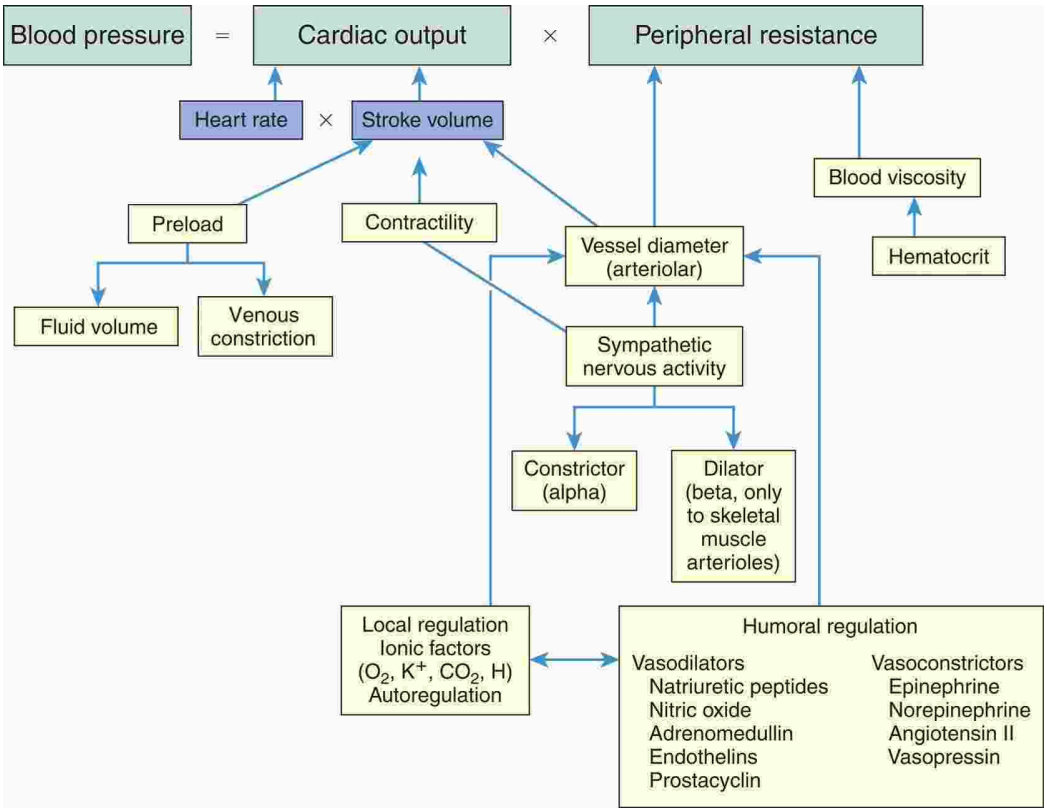

FIG. 31.23 Factors Regulating Blood Pressure.
O_2, Oxygen; K^+, potassium; CO_2, carbon dioxide; *H*, hydrogen.

An equation and an accompanying flowchart show the factors regulating blood pressure. The equation reads: blood pressure equals cardiac output (heart rate multiplied with stroke volume) multiplied with peripheral resistance (P R) or hypertension equals increased C O and or increased P R. • In hypertension increased preload leads to increased fluid volume and venous constriction. • Increased contractility affects the cardiac output. • Vessel diameter (arteriolar) and blood viscosity impact the peripheral resistance. The flowchart shows the

following pathways. 1. Humoral regulation (vasodilators and vasoconstrictors). Interrelated with 2. Leads to 3. 2. Local regulation, ionic factors (oxygen, potassium ions, carbon dioxide, and hydrogen), autoregulation. Leads to 3. 3. Vessel diameter (arteriolar). Impacts the peripheral resistance. 4. Sympathetic nervous activity. Leads to 3, 5, and 6. 5. Constrictor (alpha). 6. Dilator (beta, only to skeletal muscle arterioles). Vasodilators include natriuretic peptides, nitric oxide, adrenomedullin, endothelins, and prostacyclin. Vasoconstrictors include epinephrine, norepinephrine, angiotensin 2, and vasopressin.

The normal range for MAP is 70 to 110 mm Hg. The difference between the systolic pressure and the diastolic pressure ($P_s - P_d$) is called the **pulse pressure** and typically is between 40 and 50 mm Hg. The pulse pressure is directly related to arterial wall stiffness and stroke volume.

During a wide range of physiologic conditions, including changes in body position, muscular activity, and circulating blood volume, arterial pressure is regulated within a fairly narrow range to maintain tissue perfusion, or blood supply to the capillary beds. The major factors and relationships that regulate arterial blood pressure are summarized in Fig. 31.23.

Effects of Cardiac Output

The cardiac output (minute volume) of the heart can be changed by alterations in the heart rate, stroke volume (volume of blood ejected during each ventricular contraction), or both. An increase in cardiac output without a decrease in peripheral resistance will cause the

MAP and flow rate to increase. The higher arterial pressure increases blood flow through the arterioles. On the other hand, a decrease in the cardiac output causes a drop in the MAP and arteriolar flow if peripheral resistance stays constant (Table 31.4).

Table 31.4

Factors that Affect Mean Arterial Pressure and Capillary Flow

	Mean Arterial Pressure	Capillary Flow

Effects of Total Peripheral Resistance

Total resistance in the systemic circulation, known as either SVR or TPR, is primarily a function of arteriolar diameter. If cardiac output remains constant, arteriolar constriction raises the MAP by reducing the flow of blood into the capillaries, whereas arteriolar dilation has the opposite effect. Reflex control of total cardiac output and peripheral resistance includes (1) sympathetic stimulation of the heart, arterioles, and veins; and (2) parasympathetic stimulation of the heart (Fig. 31.24). The cardiovascular center in the medulla receives input from arterial baroreceptors and chemoreceptors throughout the vascular system and then modifies vagal and sympathetic output to control heart rate and contractility, plus vascular diameter. Vasoconstriction is regulated by an area of the brainstem that maintains a constant (tonic) output of norepinephrine from sympathetic fibers in the peripheral arterioles. This tonic activity is essential for maintenance of blood pressure.

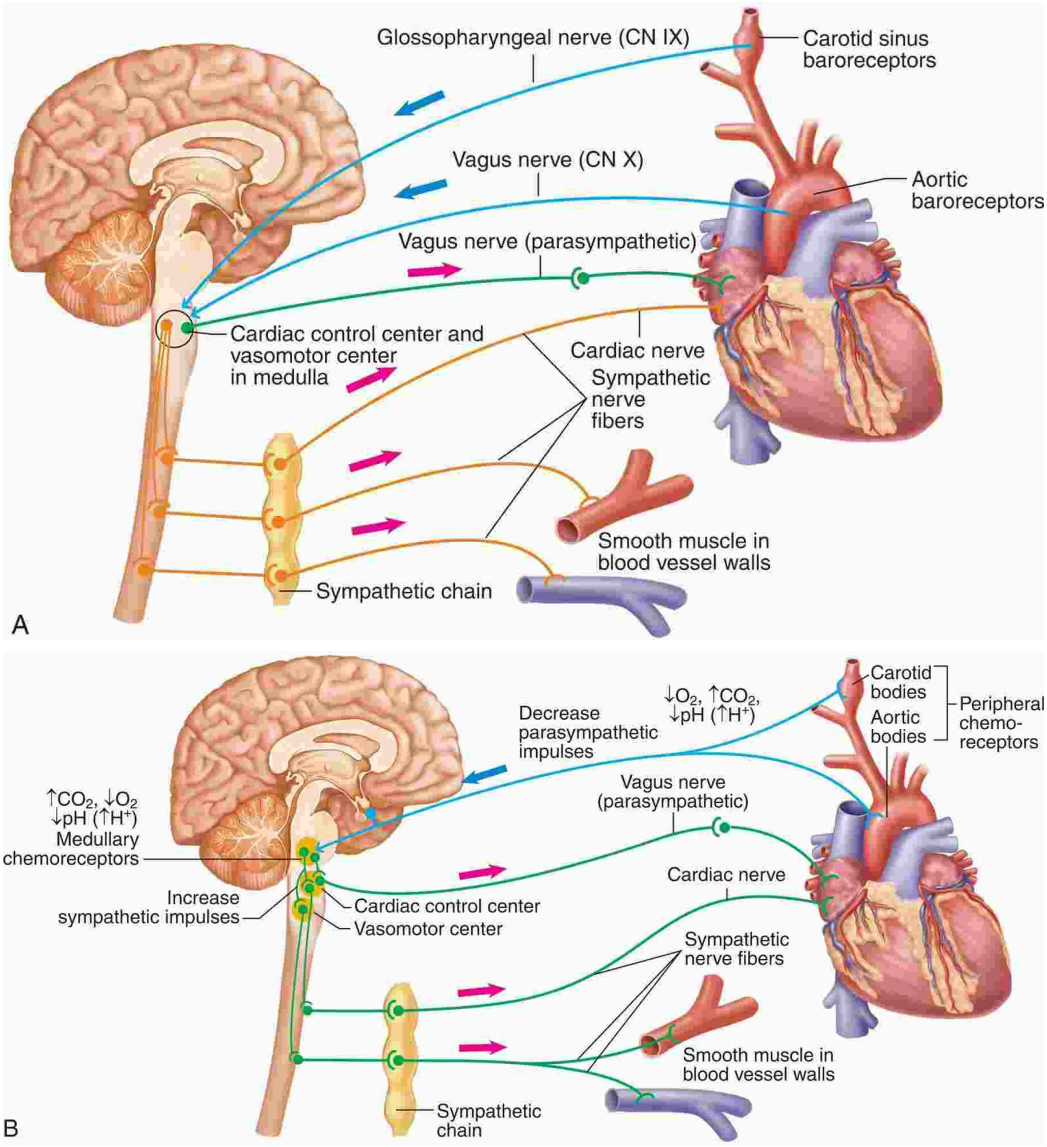

FIG. 31.24 Baroreceptors and Chemoreceptor Reflex Control of Blood Pressure.
(A) Baroreceptor reflexes. **(B)** Vasomotor chemoreflexes. *CN*, Cranial nerve; O_2, oxygen; CO_2, carbon dioxide; H^+, hydrogen. (Modified from Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Elsevier; 2019.)

Top panel, A. An illustration of the brain and the heart shows the baroreceptor reflexes. The reflexes

are as follows. • Carotid sinus baroreceptors, through glossopharyngeal nerve (C N 9) to cardiac control center and vasomotor center in medulla. • Carotid sinus baroreceptors, through vagus nerve (C N 10) to cardiac control center and vasomotor center in medulla. • Cardiac control center and vasomotor center in medulla, through vagus nerve (parasympathetic) to heart. • Sympathetic chain to cardiac nerve, sympathetic nerve fibers, and smooth muscle in blood vessel walls. Bottom panel, B. An illustration of the brain and the heart shows the vasomotor chemoreflexes. • Peripheral chemoreceptors (carotid bodies, aortic bodies): decreased oxygen, increased carbon dioxide, decreased p H (increased hydrogen ions) result in decreased parasympathetic impulses. • Medullary chemoreceptors: increased carbon dioxide, decreased oxygen, decreased p H (increased hydrogen ions). • Increase sympathetic impulses. • Cardiac control center through vagus nerve (parasympathetic) to heart. • Sympathetic chain to cardiac nerve, sympathetic nerve fibers, and smooth muscle in blood vessel walls.

Baroreceptors

As discussed previously, baroreceptors are stretch receptors located predominantly in the aorta and in the carotid sinus (see Fig. 31.24A).

They respond to pressure-related changes in smooth muscle fiber length by altering their rate of discharge and supply sensory information to the cardiovascular center in the brainstem. When activated (stretched), the baroreceptors decrease cardiac output by lowering the heart rate, stroke volume, and peripheral resistance, and thus lower blood pressure.

Arterial chemoreceptors

Specialized areas within the medulla oblongata, aortic arch, and carotid arteries are sensitive to concentrations of O_2, carbon dioxide (CO_2), and hydrogen ions (pH) in the blood (see Fig. 31.24B). Although these chemoreceptors are most important for respiratory control, they also transmit impulses to the medullary cardiovascular centers that regulate blood pressure. A decrease in arterial oxygen concentration (hypoxemia), an increase in arterial $PaCO_2$ concentration, or to a lesser extent a decrease in arterial blood pH causes a reflexive increase in heart rate, stroke volume, and blood pressure.

Effects of hormones

Hormones influence blood pressure regulation through their effects on vascular smooth muscle and blood volume. By constricting or dilating the arterioles in organs, hormones can (1) increase or decrease the blood flow in response to the body's needs, (2) redistribute blood volume during hemorrhage or shock, and (3) regulate heat loss. The key vasoconstrictor hormones include angiotensin II, antidiuretic hormone (ADH; vasopressin), epinephrine, and norepinephrine. The main vasodilator hormones are the atrial natriuretic hormones, nitric oxide, **adrenomedullin**, and **endothelins**. By causing fluid retention or loss, aldosterone, ADH, and the natriuretic hormones can influence stroke volume and thus blood pressure. A variety of other hormones, including adipokines and insulin, may be related to the hypertension that occurs with chronic conditions, such as adiposity and diabetes

mellitus. However, these factors have not been clearly demonstrated to play a role in blood pressure regulation in healthy individuals.

Vasoconstrictor hormones

The vasoconstrictor hormones include epinephrine; norepinephrine; angiotensin II, which is part of the renin-angiotensin-aldosterone system (RAAS) (see Chapters 5 and 32); and ADH. Epinephrine, the catecholamine hormone released from the adrenal medulla, causes vasoconstriction in most vascular beds except the coronary, liver, and skeletal muscle circulations. Norepinephrine mainly acts as a neurotransmitter; however, some also is released from the adrenal medulla. When the RAAS is activated, angiotensin II (ANG II) binds to the AT_1 receptor and serves as a potent vasoconstrictor. Other RAAS pathways oppose this action (see Fig. 32.2). High levels of aldosterone also can increase vascular tone.

ADH and aldosterone also affect blood pressure by increasing blood volume through their influence on fluid reabsorption in the kidney and by stimulating thirst. ADH causes the reabsorption of water from tubular fluid in the distal tubule and collecting duct of the nephron. Aldosterone, the end product of the RAAS, stimulates the reabsorption of sodium, chloride, and water from the same locations in the kidney (Fig. 31.25; also see Chapters 3 and 22).

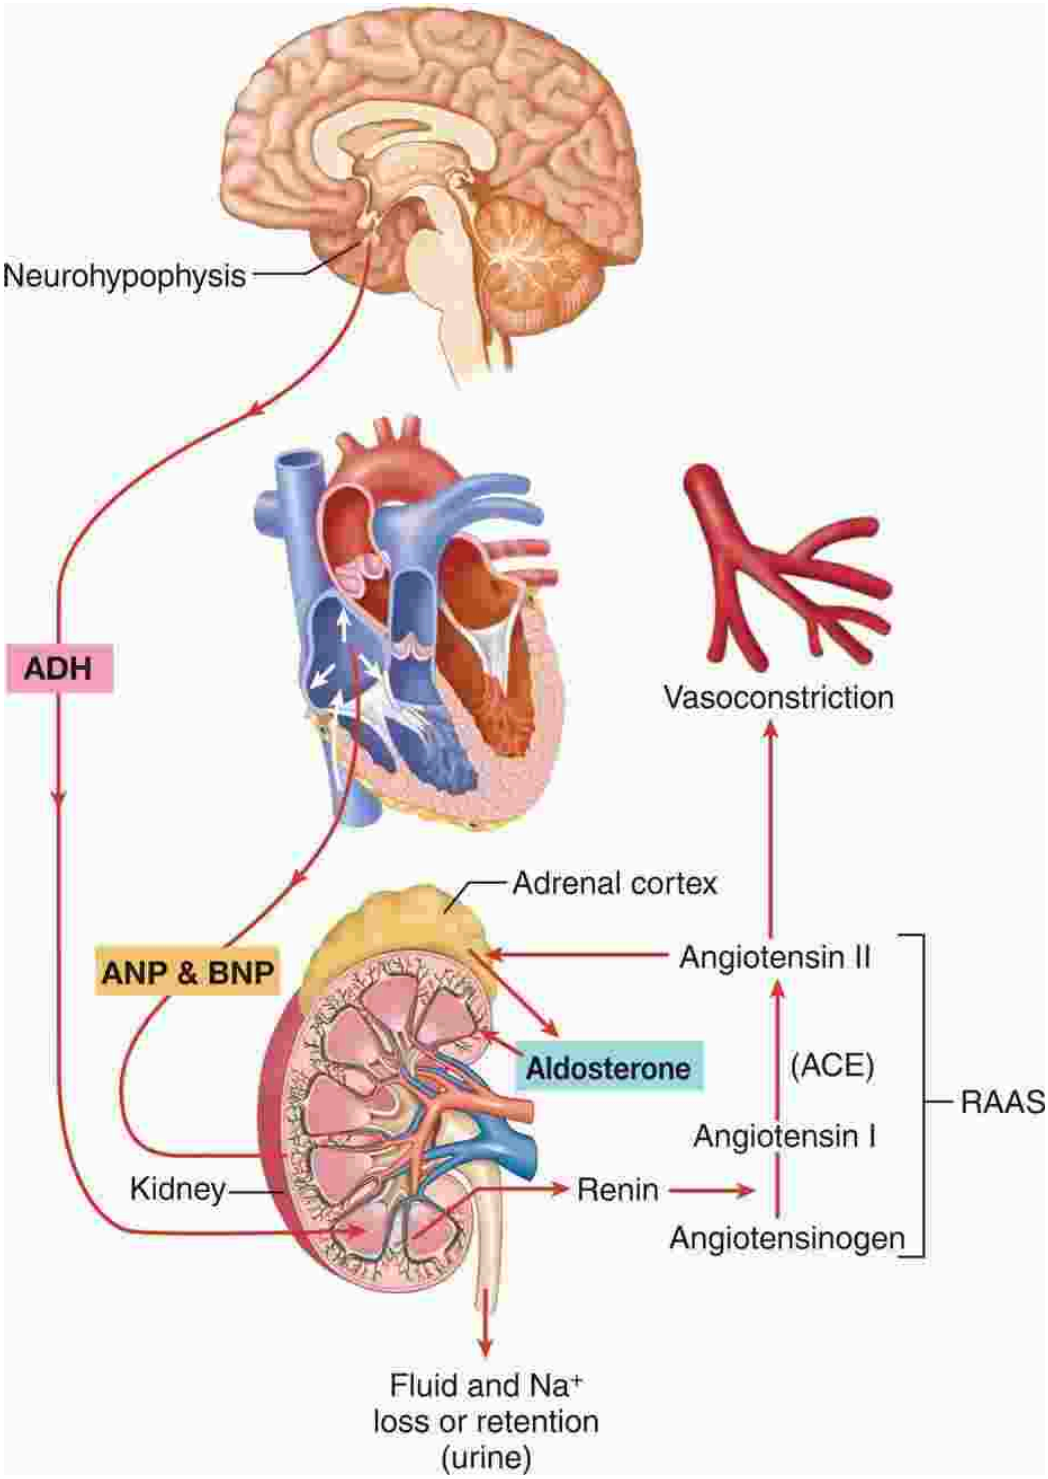

FIG. 31.25 Three Mechanisms That Influence Total Plasma Volume.
Antidiuretic hormone *(ADH)* mechanism and renin-angiotensin-aldosterone system *(RAAS)* to

increase water and sodium retention by the kidney and thus increase total plasma volume. Atrial natriuretic peptide *(ANP)* and B-type natriuretic peptide *(BNP)* antagonize these mechanisms by promoting water and sodium loss, thus promoting a decrease in total plasma volume. *ACE*, Angiotensin-converting enzyme; Na^+, sodium. (Modified from Patton, K. T. [2019]. *Anatomy & physiology* [10th ed.]. St Louis: Elsevier.) ACE, Angiotensin-converting enzyme; *Na*+, sodium. (Modified from Patton KT. *Anatomy & physiology*, 10th edition. St. Louis: Elsevier; 2019.)

An illustration shows the three mechanisms influencing total plasma volume. • A D H from neurohypophysis triggers the kidney. • A N P and B N P from the heart trigger the kidney. • Fluid and sodium ions loss or retention (urine). • Renin converts angiotensinogen to angiotensin 1 and angiotensin 1 is converted to angiotensin 2 in the presence of A C E which results in vasoconstriction. • R A S S: angiotensin 1 to A C E to angiotensin 2 to adrenal cortex that releases aldosterone to the kidney. • R A S S to vasoconstriction.

Vasodilator hormones

There are numerous vasodilator hormones, most of which have other important effects on blood volume and vascular function. The **natriuretic peptides (NPs)** include atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), C-type natriuretic peptide (CNP),

and urodilatin. These hormones function as both vasodilators and regulators of sodium and water excretion (natriuresis and diuresis) (see Chapter 3). ANP and BNP are released from myocytes in heart. Increased pressure or diastolic volume in the heart stimulates the release of these peptide hormones which then stimulate secretion of sodium and water from the kidney (see Fig. 31.25). Serum levels of BNP are increased in many types of cardiac disease including heart failure, hypertension, pulmonary embolism, valvular heart disease, and chronic coronary artery disease, and can be used to predict prognosis. Neprilysin is a drug that prevents the degradation of the natriuretic peptides and can be used in combination with other medications for the treatment of severe acute heart failure (see Chapter 32).[22] Many studies are underway to develop other medications that can mimic the positive effects of the natriuretic peptides.[23]

Other vasodilating mediators include **nitric oxide (NO)**, adrenomedullin (ADM), the endothelins, and prostacyclin. These mediators are being investigated to determine if they or their inhibitors might be useful drugs for the treatment of cardiovascular diseases or if their levels might be useful in determining the prognosis of persons with known disease. Nitric oxide (NO) is a soluble gas continuously synthesized in endothelial cells by the enzyme nitric oxide synthase (NOS). NO has a wide range of biologic properties that maintain vascular homeostasis, including modulation of vascular dilator tone, regulation of local cell growth, and protection of the vessel from injurious consequences of platelets and cells circulating in blood. NO plays a crucial role in the normal endothelial function. An emerging list of conditions, including those commonly associated as risk factors for atherosclerosis such as hypertension, hypercholesterolemia, smoking, diabetes mellitus, and heart failure, is associated with diminished release of nitric oxide into the arterial wall because of impaired synthesis or excessive oxidative degradation (Fig. 31.26).[24,25] Adrenomedullin (ADM), a peptide with powerful vasodilatory activity, is present in numerous tissues. It has been found to have numerous cardiovascular effects,

including a role in fetal cardiovascular system development and vasodilation. ADM is released by endothelial cells in conditions of vascular wall stress and plays a role in controlling vascular tone and blood pressure.[26] The endothelins are a family of three structurally similar peptides (ET-1, ET-2, and ET-3) and four receptors produced in cells in the vascular smooth muscle, the endothelium, the kidneys, and other organs. Understanding the physiologic and pathologic roles of these peptides has been complicated by the fact that endothelin binding to some receptors causes vasodilation and natriuresis, whereas binding to other receptors causes the opposite response—vasoconstriction plus sodium and water retention. Inhibitors to ET-1 have been approved for the treatment of pulmonary hypertension (see Chapter 35).

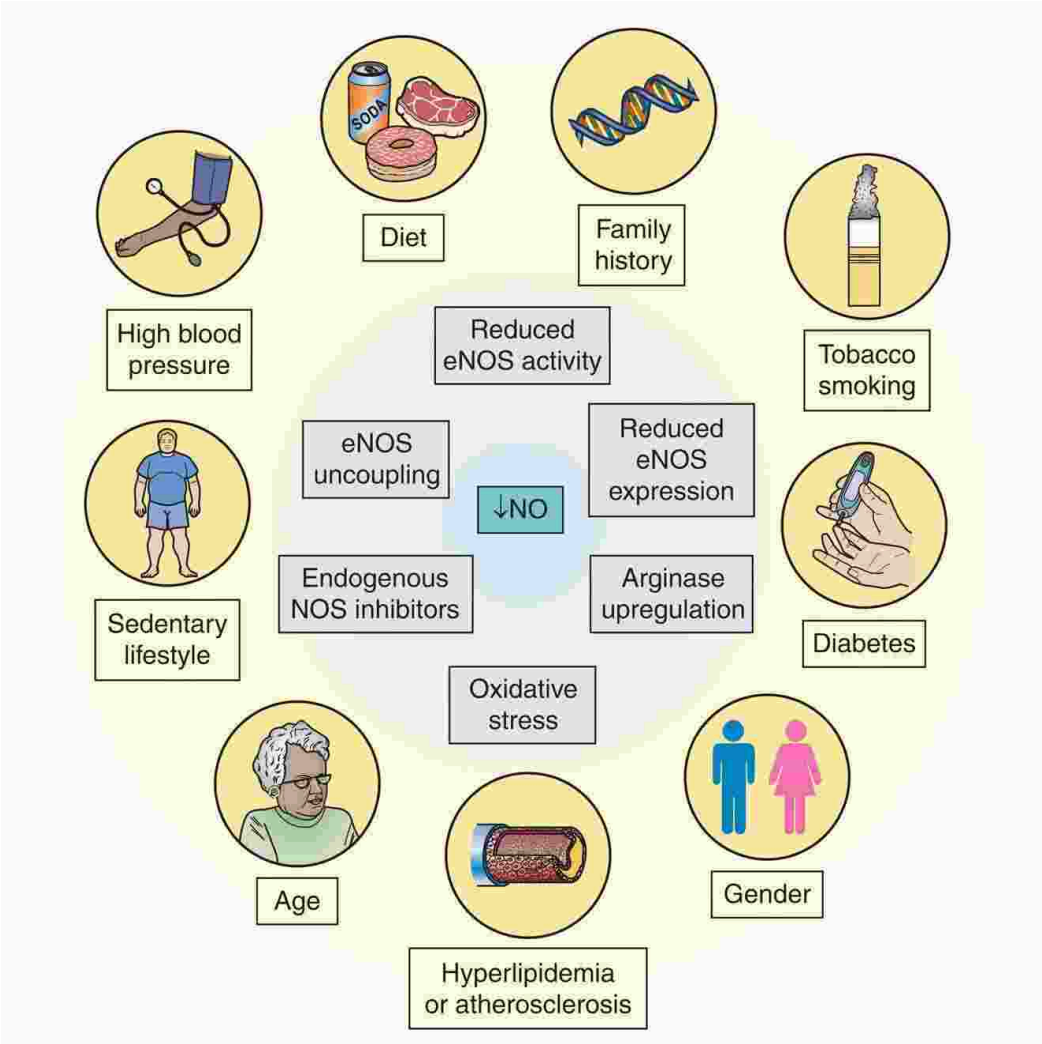

FIG. 31.26 Lifestyle Factors Associated With Reduced Bioavailability of Nitric Oxide (NO). *eNOS*, Endothelial nitric oxide synthase. (Adapted from Lundberg JO, Gladwin MT, Weitzberg E. Strategies to increase nitric oxide signalling in cardiovascular disease. *Nature Review Drug Discovery*, 2015;14:623–641.)

An illustration lists the lifestyle factors associated with reduced bioavailability of nitric oxide: diet, family history, tobacco smoking, diabetes, gender, hyperlipidemia or atherosclerosis, age, sedentary lifestyle, high blood pressure. Reduced nitric oxide

also leads to reduced e N O S activity, reduced e N O S expression, arginase upregulation, oxidative stress, endogenous N O S inhibitors, and e N O S uncoupling.

Prostacyclin is a vasodilator that is produced by the actions of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. It has the additional properties of opposing clot formation (antithrombotic), decreasing platelet activity, and inhibiting the release of growth factors from macrophages and the endothelial cells. Nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit these cyclooxygenases have been associated with cardiovascular disease risk in healthy people and in those with a known cardiovascular disease.[27]

Venous Pressure

The main determinants of venous blood pressure are (1) the volume of fluid within the veins and (2) the compliance (distensibility) of the vessel walls. The venous system typically accommodates about 66% of the total blood volume at any time, with venous pressure averaging less than 10 mm Hg. The systemic arteries accommodate about 11% of the total blood volume, with an average arterial pressure (blood pressure) of about 100 mm Hg; the remainder of the blood volume is within the heart, capillaries, and pulmonary circulation.

The sympathetic nervous system controls venous compliance. The walls of the veins are highly innervated by sympathetic fibers that control venous smooth muscle. Rather than constriction that would occur in the arteries, smooth muscle contraction in the veins results in stiffening of the vessel walls. This stiffening reduces venous distensibility and increases venous blood pressure, thus forcing more blood through the veins and into the right heart.

Two other mechanisms that increase venous pressure and venous return to the heart are (1) the skeletal muscle pump and (2) the respiratory pump. During skeletal muscle contraction, the veins

within the muscles are partially compressed, causing decreased venous capacity and increased return to the heart (see Fig. 31.20B). The respiratory pump acts during inspiration, when the veins of the abdomen are partially compressed by the downward movement of the diaphragm. Increased abdominal pressure moves blood toward the heart.

Regulation of the Coronary Circulation

Coronary blood flow is directly proportional to the perfusion pressure and inversely proportional to the vascular resistance of the coronary bed. **Coronary perfusion pressure** is the difference between pressure in the aorta and pressure in the coronary vessels. Thus, aortic pressure is the driving pressure for the arteries and arterioles that perfuse the myocardium. Vasodilation and vasoconstriction maintain coronary blood flow despite stresses imposed by the constant contraction and relaxation of the heart muscle and despite shifts (within a physiologic range) of coronary perfusion pressure.

Several unique anatomic factors influence coronary blood flow. Because of their anatomic location, the aortic valve cusps can obstruct coronary blood flow by occluding the openings of the coronary arteries during systole. Also during systole, the coronary arteries are compressed by ventricular contraction. The resulting **systolic compressive effect** is particularly evident in the subendocardial layers of the left ventricular wall and can greatly increase resistance to coronary blood flow, with the result that most left ventricular coronary blood flow occurs during diastole. During the period of systolic compression, when flow is slowed or stopped, **myoglobin**, a protein in heart muscle that binds O_2, provides the supply of O_2 to the myocardium. Myoglobin's O_2 levels are replenished during diastole.

Autoregulation

Autoregulation (automatic self-regulation) enables organs to regulate blood flow by altering the resistance (diameter) in their

arterioles. Autoregulation in the coronary circulation maintains the blood flow at a nearly constant rate at perfusion pressures (MAP) between 60 and 140 mm Hg when other influencing factors are held constant. Thus autoregulation helps to ensure constant coronary blood flow despite shifts in the perfusion pressure within the stated range.

Given that blood flow is directly related to pressure and inversely related to resistance, for flow to stay constant as pressure decreases, resistance also has to decrease; therefore the mechanisms underlying autoregulation must be related to control of smooth muscle contraction in the arteriolar walls.

Autonomic Regulation

Although the coronary vessels themselves contain sympathetic (α- and β-adrenergic) and parasympathetic neural receptors, coronary blood flow during regular activity is regulated locally by the factors that cause autoregulation. During exercise, however, the vasodilating effects of β_2-receptors on the smaller coronary resistance arteries are responsible for about 25% of any increase in blood flow. At the same time, α-adrenergic receptors in larger arteries cause vasoconstriction to direct the blood flow to the inner layers of the myocardium.

Lymphatic System

The **lymphatic system** is a one-way network of lymphatic vessels and the lymph nodes (Figs. 31.27 and 31.28) that is important for immune function, fluid balance, and transport of lipids, hormones, and cytokines and is considered to be part of the circulatory system. Every day about 3 liters of fluid filters out of venous capillaries in body tissues and is not reabsorbed (Fig. 31.29). This fluid becomes the lymph that is carried by the lymphatic vessels to the chest, where it enters the venous circulation. The lymphatic vessels run in the same sheaths with the arteries and veins. (Lymph nodes and lymphoid tissues are described in Chapters 8 and 28.) The lymphatic capillaries are closed at the distal ends, as shown in Fig. 31.29.

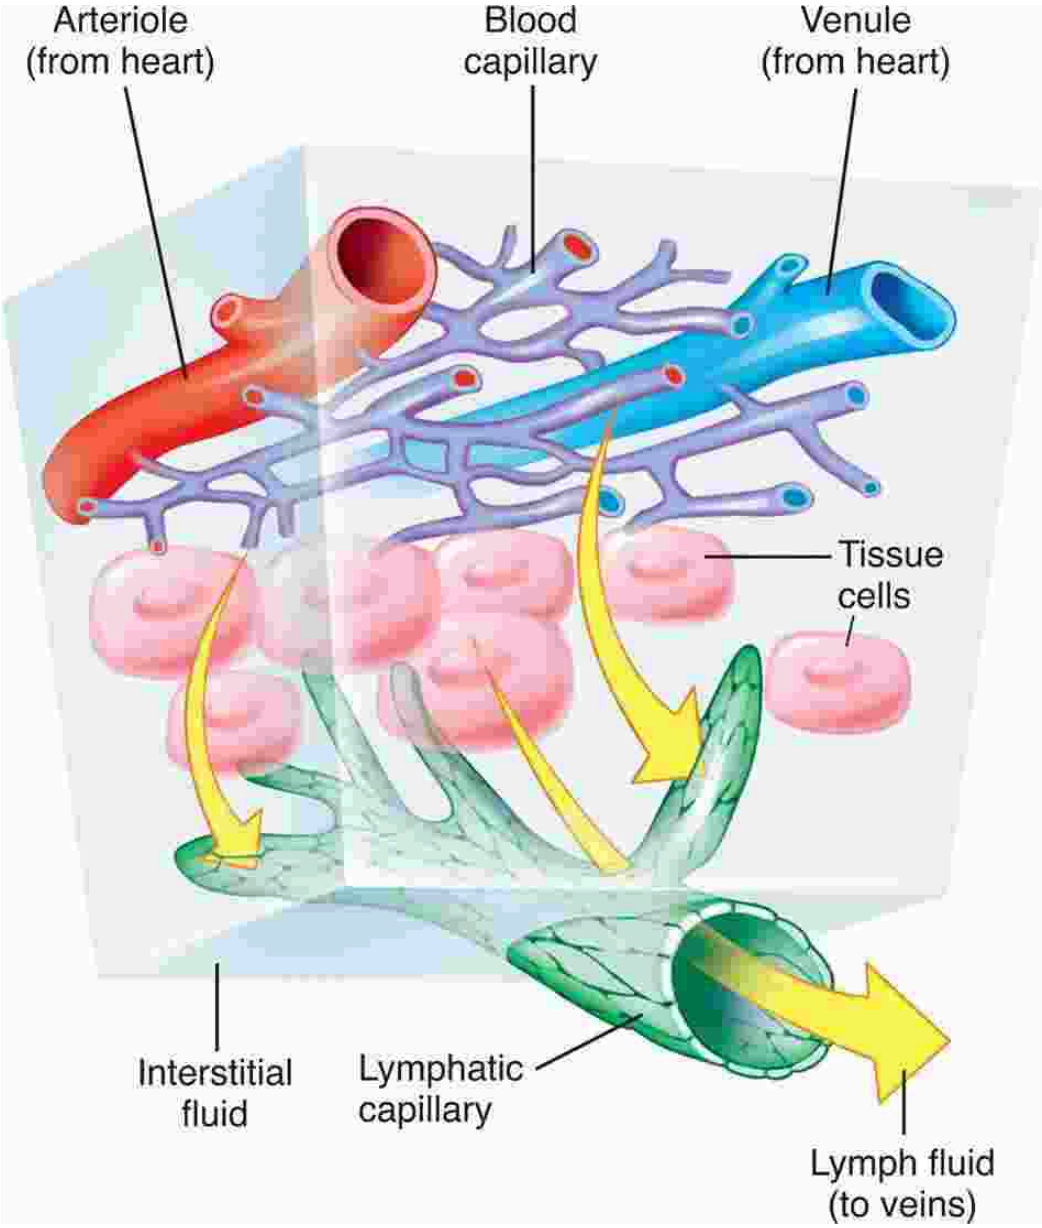

FIG. 31.27 Role of the Lymphatic System in Fluid Balance.

Fluid from plasma flowing through the capillaries moves into interstitial spaces. Although most of this interstitial fluid is either absorbed by tissue cells or reabsorbed by blood capillaries, some of the fluid tends to accumulate in the interstitial spaces. This lymph then diffuses into the lymphatic vessels that carry it to the lymph nodes and then into the systemic venous blood. Green

is used to diagram the lymphatic vessels although the lymphatic vessels, particularly the smaller ones, are almost transparent. (Modified from Thibodeau GA, Patton KT. *Structure & function of the body*, 13th edition. St. Louis: Elsevier; 2008.)

An illustration of the cross-section of the lymphatic system in fluid balance shows and labels the following structures, from the top to the bottom: arteriole (from heart), blood capillary, venule (from heart), tissue cells, interstitial fluid, lymphatic capillary, and lymph fluid (to veins). Arrows from the blood capillaries flow through and out of the lymphatic capillary indicate the direction of the flow.

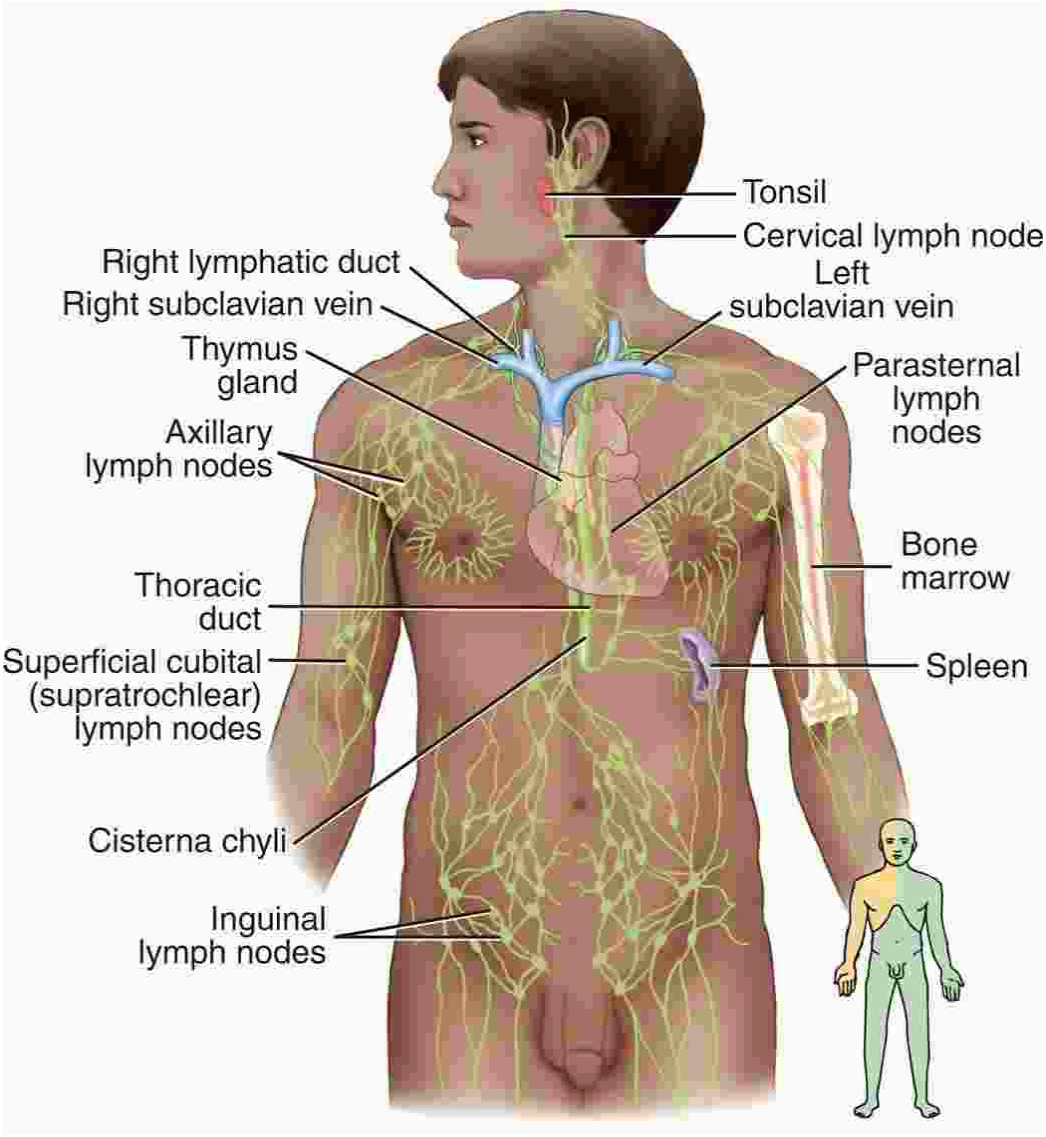

FIG. 31.28 Principal Organs of the Lymphatic System. (From VanMeter KC, Hubert RJ. *Microbiology for the healthcare professional*. St. Louis: Mosby; 2010.)

An illustration of the anterior view of a person shows and identifies the principal organs of the lymphatic system, clockwise from the top-right: tonsil, cervical lymph node, left subclavian vein, parasternal lymph nodes, bone marrow, spleen, inguinal lymph nodes, cisterna chyli, superficial cubital (supratrochlear)

lymph nodes, thoracic duct, axillary lymph nodes, thymus gland, right subclavian vein, and right lymphatic duct.

FIG. 31.29 Lymphatic Capillaries. **(A)** Schematic representation of lymphatic capillaries. **(B)** Anatomic components of microcirculation.

Top panel, A. The illustration shows the lymphatic capillaries. The flow of blood from heart is as follows: from heart to arteriole to arterial capillaries to venous capillaries to venule to heart. The lymphatic capillaries enmeshed with the capillaries connects to the lymph vessel, which leads to the venous system. Bottom panel, B. The illustration shows a magnified view of the microcirculation. The illustration shows anchoring filaments binding the capillaries and the lymph vessel. Fluid exchange occurs capillaries to lymph vessel.

In this pumpless system, a series of valves ensures one-way flow of the excess interstitial fluid (now called *lymph*) toward the heart. Lymph consists primarily of water and small amounts of dissolved proteins, mostly albumin, that are too large to be reabsorbed into the less permeable blood capillaries. Lymph also carries two types of immune system cells: lymphocytes and antigen-presenting cells. The antigen-presenting cells are carried to the next lymph node in the system, whereas lymphocytes traffic between lymph nodes. Once within the lymphatic system, lymph travels through **lymphatic venules** and veins that drain into one of two large ducts in the thorax: the **right lymphatic** duct and the **thoracic duct**. The right lymphatic duct drains lymph from the right arm and the right side of the head and thorax, whereas the larger thoracic duct receives lymph from the rest of the body (see Fig. 31.28). The right lymphatic

duct and the thoracic duct drain lymph into the right and left subclavian veins, respectively.

Lymphatic veins are thin walled like the veins of the cardiovascular system. In larger lymphatic veins, endothelial flaps form valves similar to those in blood-carrying veins. The valves allow lymph to flow in only one direction, because lymphatic vessels are compressed intermittently by skeletal muscle contraction, pulsating expansion of the artery in the same sheath, and contraction of the smooth muscles in the walls of the lymphatic vessels.

As lymph is transported toward the heart, it is filtered through thousands of bean-shaped lymph nodes clustered along the lymphatic vessels (see Fig. 31.28). Lymph enters the nodes through **afferent lymphatic vessels**, filters through the sinuses in the node, and leaves by way of **efferent lymphatic vessels**. Lymph flows slowly through a node, allowing phagocytosis of foreign substances within the node and delivery of lymphocytes. (Phagocytosis is described in Chapter 7.)

Tests of Cardiovascular Function

Assessment of the individual with suspected cardiovascular disorders begins with a thorough history for determination of risk factors and symptoms. A careful physical examination looking for evidence of tissue ischemia, pulmonary congestion, and cardiac dysfunction is next. Blood samples are taken and sent for a variety of tests. For many individuals, these basic steps will be complemented with methods that measure heart and vascular function with greater specificity. Cardiac function can be evaluated using indicators calculated from pressures and flow rates in the heart and vessels. Table 31.5 defines the indicators most often used in the clinical setting. The normal values for several testing methods are different for men and women.

Table 31.5

Indicators of Cardiac Function

Indicator	Definition[a]	Common Cause of Abnormality
Heart rate (HR)	Number of heartbeats (cardiac cycles) per minute	Ischemia, electrolyte disturbances, drug toxicity
	Normal adult value: 70 beats/min	
Cardiac output (CO)	Amount of blood (in L) moved by the heart in 1 min	Decrease indicates heart failure
	Normal range: 4–8 L/min	Increase indicates decreased systemic vascular resistance, common in sepsis
Cardiac index (CI)	Relationship between cardiac output and body surface area (BSA, in m^2)	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 2.8–4.2 L/min/m^2	
Stroke volume (SV)	Amount of blood (in mL) ejected by the left ventricle during	Decrease indicates heart failure

Indicator	Definition[a]	Common Cause of Abnormality
	systole (i.e., per beat)	Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 60–100 mL/beat	
Stroke volume index (SVI)	Relationship between stroke volume and body surface area	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 33–47 mL/beat/m^2	
Ejection Fraction (EF)	Percentage of total ventricular end-diastolic volume ejected with each beat	Decrease indicates heart failure
	Normal range 50%–75%	
Oxygen consumption index (V2)	Amount of oxygen (in mL) consumed per minute in relation to BSA	Decrease: sedation, anesthesia, hypothermia Increase: elevated temperature, sepsis, seizures

Indicator	Definition[a]	Common Cause of Abnormality
Stroke work index (SWI)	Amount of work (expressed as done) by the left or right ventricle per systole per square meter of BSA	Decreases within specific ranges indicate cardiogenic or hypovolemic shock (see Chapter 48)
	Normal value: 35 g/m^2	Increase: elevated systemic vascular resistance
Systemic mean arterial pressure (MAP)	Mean blood pressure (in mm Hg) in the systemic arteries	Elevated: epinephrine release, diseases of arteries, primary hypertension Decreased: cardiac failure, decreased vascular resistance of sepsis
	Normal range: 70–100 mm Hg	
Pulmonary vascular resistance (PVR)	Relationship among cardiac output, preload, and afterload, expressed as units of force of resistance per	Increased: acute respiratory distress syndrome (ARDS), pneumonia, primary pulmonary hypertension,

Indicator	Definition[a]	Common Cause of Abnormality
	second per centimeter of water	congestive heart failure Decreased: late shock
	Normal value: <250 dynes/s/cm^{-5}	
Systemic vascular resistance (SVR)	Same definition as for PVR Normal range: 770–1500 dynes/s/cm^{-5}	Increased: epinephrine release Decreased: inflammatory response

Indicator	Definition[a]	Common Cause of Abnormality
Heart rate (HR)	Number of heartbeats (cardiac cycles) per minute	Ischemia, electrolyte disturbances, drug toxicity
	Normal adult value: 70 beats/min	
Cardiac output (CO)	Amount of blood (in L) moved by the heart in 1 min	Decrease indicates heart failure
	Normal range: 4–8 L/min	Increase indicates decreased systemic vascular resistance, common in sepsis
Cardiac index (CI)	Relationship between cardiac output and body surface area (BSA, in m^2)	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 2.8–4.2 L/min/m^2	
Stroke volume (SV)	Amount of blood (in mL) ejected by the left ventricle during systole (i.e., per beat)	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 60–100 mL/beat	
Stroke volume index (SVI)	Relationship between stroke volume and body surface area	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 33–47 mL/beat/m^2	
Ejection Fraction (EF)	Percentage of total ventricular end-diastolic volume ejected with each beat	Decrease indicates heart failure
	Normal range 50%–75%	
Oxygen consumption index (V2)	Amount of oxygen (in mL) consumed per minute in relation to BSA	Decrease: sedation, anesthesia, hypothermia Increase: elevated temperature, sepsis, seizures
Stroke work index (SWI)	Amount of work (expressed as done) by the left or right ventricle per systole per square meter of BSA	Decreases within specific ranges indicate cardiogenic or hypovolemic shock (see Chapter 48)
	Normal value: 35 g/m^2	Increase: elevated systemic vascular resistance
Systemic mean arterial pressure (MAP)	Mean blood pressure (in mm Hg) in the systemic arteries	Elevated: epinephrine release, diseases of arteries, primary hypertension Decreased: cardiac failure, decreased vascular resistance of sepsis
	Normal range: 70–100 mm Hg

	Normal value: <250 dynes/s/cm^{-5}	
Systemic vascular resistance (SVR)	Same definition as for PVR Normal range: 770–1500 dynes/s/cm^{-5}	Increased: epinephrine release Decreased: inflammatory response

[a]Values given are for adults at rest.

Cardiac and Coronary Artery Evaluation

Many sophisticated tests are used to evaluate and diagnose cardiac or coronary artery diseases, and new ones are being developed each year. Some of the more commonly used modalities include chest x-ray, electrocardiography, echocardiography, stress testing, single-photon emission computed tomography (SPECT), computed

tomography (CT), magnetic resonance imaging (MRI), electrophysiology studies, and catheterization with angiography.

Chest Radiograph Examination

Chest x-rays allow for the examination of the size and contour of the heart and related structures. Evidence of chamber enlargement, pericardial disease, pulmonary edema, valvular calcification, ventricular hypertrophy, and pathology of the great vessels may be visualized. Chest x-ray also is useful to assess for appropriate placement of invasive cardiac conduction devices and for any complications caused by these devices (e.g., pneumothorax or hemothorax; see Chapter 35). A chest x-ray examination is a routine part of a cardiac examination.

Electrocardiography

Electrocardiography, typically a 12-lead electrocardiogram (ECG), gives information about heart rate and rhythm; the effects of activities of daily life, exercise, electrolytes, drugs, and disease on electrical activity in the heart; and the electrical orientation of the cardiac muscle (see Fig. 31.9). An ECG provides no direct information about the contractile state or mechanical performance of the heart.

Serial 12-lead ECGs are of primary importance in establishing the presence of myocardial ischemia and infarction or conduction defects and dysrhythmias. This examination has become part of the routine hospital preadmission/admission assessment, even when the admitting diagnosis is not cardiac in nature, because it establishes baseline information about the electrical function of the heart. Also, recent ECGs can be compared with ECGs obtained from the same individual in the past. Changes in the ECG over time assist in determining the cause, amount, or nature of changes in cardiac anatomy and physiology. Ambulatory electrocardiographic or Holter monitoring is used to evaluate rhythm changes that may occur in persons during activities of daily living. Cell phone

technology also is rapidly advancing to enable ECG recording and relaying to healthcare providers.

Echocardiography

Echocardiography is the most widely used noninvasive modality for evaluating the structures of the heart. Ultrasound beams reflected by cardiovascular structures produce shapes that can be visualized and can allow for recognition of altered cardiac anatomy. It is used to evaluate for suspected coronary artery disease, heart failure, valvular disease, infective endocarditis, cardiomyopathies, pericardial disease, prosthetic valve function, congenital heart disease, and aortic diseases. Through the use of one-dimensional (M-mode), two-dimensional, and three-dimensional echocardiographic techniques and combining them with Doppler and color flow imaging, accurate assessments of cardiac output, ejection fraction, and valvular function can be obtained.[28] Advances in technology now allow both intracardiac and transesophageal echocardiography for evaluation of the heart anatomy and physiology.

Exercise or Stress Testing

Cardiac activity during exercise is examined during a stress test when an intervention is used to increase myocardial work. Stress testing elicits signs and symptoms of heart disease and coronary artery disease that may not appear at rest. Echocardiography or continuous 12-lead ECG and blood pressure measurements are obtained before, during, and after the study. Cardiac stress from exercise is usually induced by having the individual walk on a treadmill. Other, less frequently used forms of exercise include static exercise (hand ergometry or chemical stress), stair climbing (the Stairmaster's double two-step), arm ergometry, and bicycle ergometry. The individual exercises until the maximal heart rate for gender and age is reached or until other subjective or objective indicators of cardiac dysfunction or distress appear. Subjective indicators include chest pain, extreme fatigue, extreme dyspnea, leg

pain, or the individual's request to stop the test. Objective criteria include ST-segment elevation or depression, SA node or atrial dysrhythmias, AV node dysrhythmias, ventricular dysrhythmias, elevated or decreased blood pressure, signs of cerebral hypoxia, and signs of circulatory insufficiency.[29] One limitation of this test is that it cannot be used in persons whose capacity for exercise is limited.

Stress testing also may be used to evaluate either fitness for noncardiac surgery or progress in recovery after myocardial infarction or cardiac surgery. Graded exercise in individuals with low- to moderate-risk chest pain evaluated in an emergency department can be used as a prognostic indicator of adverse cardiac events. When a differential diagnosis for chest pain has been difficult to determine, stress testing may help distinguish coronary artery insufficiency from other causes of pain. The risks associated with stress testing include dysrhythmias, myocardial infarction, and death. The risk is greater when the test is performed soon after an acute ischemic event.

Stress testing with ECG monitoring may not be sensitive enough to detect and localize areas of the myocardium at risk for ischemia and infarction. Currently, most stress testing includes the injection of a radiotracer that is absorbed by active heart cells. When the heart is scanned, during and after stress testing, areas where the radiotracer is not taken up by ischemic cells can be seen and those locations indicate areas of myocardial damage.

Single-Photon Emission Computed Tomography

Single-photon emission computed tomography (SPECT) is typically used to evaluate individuals for coronary artery disease and myocardial ischemia during stress testing. A radiotracer (usually thalium-201 or technetium) is injected intravenously and is absorbed and retained for a while by healthy myocytes.[30] Photons are emitted from the radiotracer in the myocardium in proportion to perfusion of the tissue. A gamma camera visualizes the photons, and views are taken from 360 degrees by CT, which digitizes the information and provides a three-dimensional view of myocardial perfusion. Data

about where the myocardium absorbs the tracer normally, slowly, or not at all can be correlated with existing myocardial disease and can help quantify ischemic risk. A new development, high-speed SPECT, has the advantage of taking less time and, thereby, requiring less radiotracer, which decreases radiation exposure for the person being examined Positron emission tomography (PET) scanning also can be used to assess myocardial perfusion and metabolism.[30]

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are used to evaluate cardiac anatomy and physiology. Techniques such as ECG gating (timing of data gathering to the cardiac cycle), electron beam CT, and spiral CT have improved the ability of tomography to visualize cardiac structures.[31] The high resolution of CT can provide information about calcification of coronary vessels and cardiac valves. Information about coronary artery calcification is being used to improve risk classification for coronary artery disease. It also is a tool for evaluating large-vessel disease. Concerns and debate continue, however, about the radiation risks and use of variable protocols.

MRI is based on the principle that the frequency of energy (resonant frequency) given up by a nucleus is exactly proportional to the surrounding magnetic field. The anatomy and physiology of the great blood vessels and myocardium are depicted in three dimensions with excellent resolution. Ventricular function can be evaluated using indexes of ventricular function, such as ejection fraction. Rapidly moving sequences (MRI) can determine regional wall motion and myocardial deformation. Flow direction and velocity also can be quantitatively determined. Stress testing also can be done with MRI using the drug dobutamine to increase the cardiac workload instead of exercise.[32]

Electrophysiology Studies

In-depth evaluation of electrical conduction within the heart can provide important information about the nature and causes of dysrhythmias, such as atrial and ventricular tachycardias and heart block. This evaluation is often referred to as *electrophysiologic mapping* of the myocardium. There are many types of electrophysiology studies that are specific to certain conduction disorders but they have the common goal of documenting abnormal conduction pathways.[33] Furthermore, the techniques used may also allow for ablation of unwanted pathways or the appropriate placement of pacemakers and implantable defibrillators. Mapping can include the use of echocardiography and CT scanning.

One example of an electrophysiology study is AV bundle electrocardiography. Two electrode-tipped catheters are inserted percutaneously into the femoral vein, floated up the **inferior vena cava**, and positioned in or near the right atrium during AV bundle (His bundle) electrocardiography. AV bundle electrocardiography can detect secondary sites of impulse generation (ectopic foci), as well as accessory pathways of conduction. Other conduction defects and the effects of drugs on conduction also can be illuminated. Risks related to this procedure can be grave and include dysrhythmias, death, vessel or heart perforation, clot or plaque embolization, and kidney failure.

Cardiac Catheterization and Angiography

One or both sides of the heart can be examined using cardiac catheterization. This invasive procedure requires the use of fluoroscopy and strict sterile techniques and takes place in a specially equipped catheterization laboratory. Local anesthetic is administered, and a catheter is introduced percutaneously into the vasculature and passed caudally into the atrium and ventricle. For a right-heart catheterization, the catheter is placed in either the jugular, subclavian, brachial, or femoral veins. The femoral artery is commonly used for a left-heart study. Once the catheter has been guided into the heart chambers, pressures are recorded, blood

samples are obtained to examine oxygen content, and a contrast medium is injected to visualize chamber function and valve patency.

Cardiac catheterization provides a means to visualize the chambers of the heart continuously, although for a short time. A great deal of information can be obtained about heart structure and function.[34] Pressures in each chamber and across heart valves can be precisely measured, along with timing of events in the cardiac cycle. Of particular value is the ability to compare the oxygen content of blood in each heart chamber. Risks for this procedure that have decreased over time include the development of dysrhythmias. Death can occur secondary to cardiac arrest after ventricular fibrillation.

Fluoroscopic visualization of the coronary arteries and left-heart structures using contrast dye is called coronary angiography or arteriography. Like cardiac catheterization, this study takes place in a catheterization laboratory using local anesthesia and a sterile field. A catheter is threaded into the left ventricle through the femoral artery. A ventriculogram generally is performed first. Contrast dye is injected into the apex of the ventricle, and the next few cardiac cycles are visualized and filmed. Like cardiac catheterization, coronary angiography is used to gain information about the structure and function of the ventricles and related valves. After the ventriculogram, catheters are introduced individually into the ostia of the coronary arteries. When the catheter is in position, a small volume of contrast dye is mechanically and rapidly injected into the artery and the results are visualized and filmed. Dye injection is repeated with the individual tilted at various angles to afford views of the artery other than the anteroposterior view.

The risks of coronary angiography are similar to those of cardiac catheterization, with exceptions. As the blood supply to the cardiac muscle is briefly interrupted when dye is introduced into the coronary arteries, angina (chest pain) caused by ischemia (lack of oxygen) is much more common. Coronary artery spasms also can occur. Interrupted flow also causes decreased heart rate

(bradycardia), as well as some tachydysrhythmias, hypotension, and ST-segment depression.

Systemic Vascular Evaluation

The systemic vascular system can be studied by a variety of techniques in order to evaluate for adequate flow rates, vascular obstruction, and structural defects. These techniques include Doppler ultrasonography, CT and MRI, venography, and arteriography.

Arterial Pressure Pulse Waveform Analysis

Pulsation, described by the flow of blood through an artery during the cardiac cycle, can be drawn as a waveform plotting pressure against time (Fig. 31.30). The waveform can be obtained noninvasively by placing a transducer on the skin over the carotid artery while the individual's head is turned slightly away from the transducer. The amplitude and shape of arterial waveforms can provide information about the elasticity of the arterial wall, or its inverse—the stiffness of the wall.

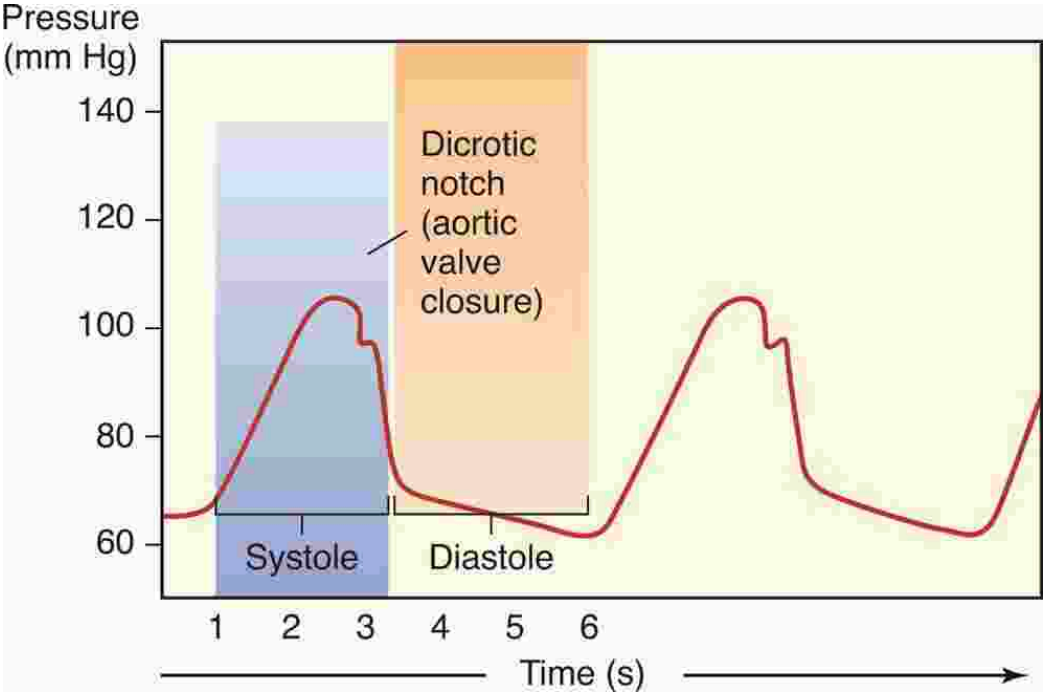

FIG. 31.30 Arterial Pressure Pulse Waveforms.

A graph shows the arterial pressure pulse waveform plotting pressure against time, indicating the dicrotic notch within the systole. The horizontal axis represents time in seconds. The vertical axis represents the pressure in millimeters of mercury. The waveform shows an alternating upstroke and downstroke with the dicrotic notch in a regular pattern.

Doppler Ultrasonography Studies

A Doppler study is done using a microphone that amplifies and records the sounds made by blood flowing in peripheral vessels. The Doppler microphone is placed over the vessel to be studied, and sounds related to obstructions to flow, vessel wall mobility, and

heart murmurs are transmitted through a lubricating gel to the microphone. The audio findings can be digitized into visual findings that can be analyzed for flow velocity and volume. These studies are useful in the evaluation for abnormalities of venous flow (e.g., deep venous thrombosis) and arterial flow (e.g., embolism). Ultrasound also is used to calculate the thickness of arterial walls, yielding a reading called *intimal-medial thickness*. Carotid intimal-medial thickness is used to assess for atherosclerosis.[28]

Computed Tomography and Magnetic Resonance Imaging

CT and MRI are used to evaluate the systemic circulation, providing information about the structure of the great vessels. Either can be used to evaluate for aneurysms and dissections of the thoracic or abdominal aorta. CT also is used to assess for vessel calcification and provide some insights into the risk for stroke and myocardial infarction through evaluation of the carotid and coronary vessels.

Venography and Arteriography

Radiopaque dye can be injected through intravenous or intraarterial catheters to allow for visualization of the internal structure, diameter, and patency of veins and arteries. Venography is performed primarily in the lower extremity to assess for the presence of thrombi in the large veins of the leg. Arteriography (angiography) can be used in almost any vascular system, including the great vessels and the pulmonary, coronary (see previously in this chapter), cerebral, mesenteric, renal, hepatic, and peripheral arteries. Risks include rupture, dissection, thrombosis, embolization, or organ infarction involving the arterial system being studied.

Aging and the Cardiovascular System

Cardiovascular disease is the most common cause of morbidity and mortality in older adults in Western society and in much of the rest

of the world (see Chapter 32). Age is a key driver of cardiovascular risk, in large measure due to the increased prevalence of risk factors such as hypertension, hyperlipidemia, and sedentary lifestyle in older individuals. For example, lipoprotein removal from tissues is decreased with aging, contributing to the risk of cardiovascular disease.[35] The most relevant age-associated physiologic changes in cardiovascular performance include myocardial and blood vessel stiffening, changes in neurogenic control over vascular tone, increased occurrence of atrial fibrillation, and loss of exercise capacity plus left ventricular hypertrophy and fibrosis. These changes pose considerable consequences with increased demand for flow, with changes in posture, or with disease. Cardiovascular aging occurs at the cellular level and includes genomic instability, epigenetic changes, inflammation and mitochondrial oxidative stress, and endothelial senescence.[36]

Arterial stiffening occurs with aging even in the absence of clinical hypertension. It can, however, be an important contributor to systolic hypertension and its associated risks for cardiovascular events, dementia, and death. These changes result from alterations within the vascular media, including age-associated changes in cross-linking of collagen, an increase in the amount of collagen, deposition of calcium, and changes in the nature of elastin, the extracellular matrix, inflammatory molecules, endothelial cell function, and reactive oxygen species. The increased arterial stiffness may not be related strictly to an age-associated change in vascular structure but may be caused by changes in baroreceptor activity. Baroreceptor activity may decrease with age, slowing physiologic adjustment to changes in blood pressure and posture. In persons older than age 60, pulse pressure, which is directly influenced by arterial stiffness, is a better predictor of cardiovascular disease than either diastolic or systolic blood pressure (see Chapter 32).

Left ventricular hypertrophy and fibrosis also are more common in the aging population, even in the absence of high blood pressure. As the arterial system becomes stiffer the ventricles must work harder to pump blood throughout the body, thus contributing to

hypertrophy. Fibrosis, calcification, and increase in stiffness also impact valvular function, particularly the function of the atrioventricular valves. These changes make valvular disease a greater risk for the elderly, along with an increased risk of heart failure related to the left ventricular hypertrophy and stiffness.

Stress testing is used to uncover functional capacity losses that are not apparent at rest. In contrast to the subtle age effects on resting cardiac tests, more dramatic changes occur during exercise. Table 31.2 summarizes age-associated changes at rest and during exercise. Overall, long-term exercise conditioning in older individuals increases aerobic capacity, improves left ventricular function, and decreases arterial stiffness so that cardiovascular diseases may be prevented or delayed in older adults. Although the risks and benefits of pharmacologic and invasive strategies must always be assessed carefully, lack of cardiovascular health is a strong predictor of disability in the elderly,[37] and many older adults can live longer and healthier lives if appropriate preventive and treatment regimens are offered, even quite late in life.

The advent of genomic medicine and a deeper exploration of molecular changes with aging continue to enhance understanding of the myriad changes in people's bodies as they age.[36] The ongoing hope is that as understanding of the causative factors related to cardiovascular decline with aging improves, therapeutics that arrest or slow these changes may be developed.

Summary Review

Circulatory System

1. The circulatory system is part of the body's transport and communication systems. It delivers O_2, nutrients, metabolites, hormones, neurochemicals, proteins, and blood cells, including lymphocytes and leukocytes, throughout the body and carries metabolic wastes to the kidneys, lungs, and liver for excretion.

2. The circulatory system consists of the heart and the blood and lymphatic vessels and is made up of two separate but conjoined, serially connected pump systems: the pulmonary circulation and the systemic circulation. The lymphatic system is a one-way network consisting of lymphatic vessels and lymph nodes.
3. The low-pressure pulmonary circulation is driven by the right side of the heart; its function is to deliver blood to the lungs for oxygenation.
4. The higher-pressure systemic circulation is driven by the left side of the heart and functions to provide oxygenated blood, nutrients, and other key substances to body tissues and transport waste products to the lungs, kidneys, and liver for excretion.
5. The lymphatic vessels collect fluids from the interstitium and return the fluids to the circulatory system; lymphatic vessels also deliver antigens, microorganisms, and cells to the lymph nodes.

Heart

1. The heart consists of four chambers (two atria and two ventricles), four valves (two atrioventricular valves and two semilunar valves), a muscular wall, a fibrous skeleton, a conduction system, nerve fibers, systemic vessels (the coronary circulation), and openings where the great vessels enter the atria and ventricles.
2. The heart wall, which encloses the heart and divides it into chambers, is made up of three layers: the epicardium (outer layer), the myocardium (muscular layer), and the endocardium (inner lining). The heart lies within the pericardium, a double-walled sac.
3. The myocardial layer of the two atria, which receive blood entering the heart, is thinner than the myocardial layer of the

ventricles, which have to be stronger to squeeze blood out of the heart.

4. The right and left sides of the heart are separated by portions of the heart wall called the *interatrial septum* and the *interventricular septum*.
5. Deoxygenated (venous) blood from the systemic circulation enters the right atrium through the superior and inferior venae cavae. From the right atrium, the blood passes through the right atrioventricular (tricuspid) valve into the right ventricle. In the ventricle, the blood flows from the inflow tract to the outflow tract and then through the pulmonary semilunar valve (pulmonary valve) into the pulmonary artery, which delivers it to the lungs for oxygenation.
6. Oxygenated blood from the lungs enters the left atrium through the four pulmonary veins (two from the left lung and two from the right lung). From the left atrium, the blood passes through the left atrioventricular valve (mitral valve) into the left ventricle. In the ventricle, the blood flows from the inflow tract to the outflow tract and then through the aortic semilunar valve (aortic valve) into the aorta, which delivers it to systemic arteries of the entire body.
7. There are four heart valves. The atrioventricular valves ensure one-way flow of blood from the atria to the ventricles. The semilunar valves ensure one-way blood flow from the right ventricle to the pulmonary artery and from the left ventricle to the aorta. The valves are supported by a fibrous skeleton.
8. The pumping action of the heart consists of two phases: diastole, during which the myocardium relaxes and the ventricles fill with blood; and systole, during which the myocardium contracts, forcing blood out of the ventricles. A cardiac cycle consists of one systolic contraction and the diastolic relaxation that follows it. Each cardiac cycle represents one heartbeat.
9. Coronary circulation provides O_2 and nutrients to the myocardium and other heart structures. Oxygenated blood

enters the coronary arteries through openings from the aorta, and deoxygenated blood from the coronary veins enters the right atrium through the coronary sinus.

10. The conduction system of the heart generates and transmits electrical impulses (cardiac action potentials) that stimulate systolic contractions. The autonomic nerves (sympathetic and parasympathetic fibers) can adjust heart rate and force of contraction, but they do not originate the heartbeat.
11. The normal electrocardiogram is the sum of all cardiac action potentials. The P wave represents atrial depolarization; the QRS complex is the sum of all ventricular cell depolarizations. The ST interval occurs when the entire ventricular myocardium is depolarized.
12. Cardiac action potentials are generated by the sinoatrial node at a rate of 60 to 100 impulses per minute. The impulses can travel through the conduction system of the heart, stimulating myocardial contraction as they go.
13. Each cardiac action potential travels from the SA node to the AV node to the bundle of His (atrioventricular bundle), through the bundle branches, and finally to the Purkinje fibers and ventricular myocardium, where the impulse stops. It is prevented from reversing its path by the refractory period of cells that have just been polarized. The refractory period ensures that diastole (relaxation) will occur, thereby completing the cardiac cycle.
14. Cells of the cardiac conduction system have the properties of automaticity and rhythmicity. Automatic cells return to threshold and depolarize rhythmically without an outside stimulus. The cells of the sinoatrial node depolarize faster than other automatic cells, making it the natural pacemaker of the heart. If the SA node is disabled, the next fastest pacemaker, the AV node, takes over.
15. Adrenergic receptor number, type, and function govern autonomic (sympathetic) regulation of heart rate, contractile force, and the dilation or constriction of coronary arteries. The presence of specific receptors on the myocardium and

coronary vessels determines the effects of the neurotransmitters norepinephrine and epinephrine.

16. Unique features that distinguish myocardial cells from skeletal cells enable myocardial cells to transmit action potentials faster (through intercalated discs), synthesize more ATP (because of a large number of mitochondria), and have readier access to ions in the interstitium (because of an abundance of transverse tubules). These combined differences enable the myocardium to work constantly, which is not required by skeletal muscle.
17. Cross-bridges between actin and myosin enable contraction. Calcium ions interacting with the troponin complex help initiate the contraction process. Subsequently, myocardial relaxation begins as troponin releases calcium ions.
18. Cardiac performance is affected by preload, afterload, myocardial contractility, and heart rate.
19. Preload, or pressure generated in the ventricles at the end of diastole, depends on the amount of blood in the ventricle. Afterload is the resistance to ejection of the blood from the ventricle. Afterload depends on pressure in the aorta.
20. Myocardial stretch determines the force of myocardial contraction; thus the greater the stretch, the stronger the contraction up to a certain point. This relationship is known as the Frank-Starling law of the heart.
21. Contractility is the potential for myocardial fiber shortening during systole. It is determined by the amount of stretch during diastole (i.e., preload) and by sympathetic stimulation of the ventricles.
22. The heart rate is determined by the sinoatrial node and by components of the autonomic nervous system, including cardiovascular control centers in the brain, receptors in the aorta and carotid arteries, and hormones, including catecholamines (epinephrine, norepinephrine).

Systemic Circulation

1. Blood flows from the left ventricle into the aorta and from the aorta into arteries that eventually branch into arterioles and capillaries, the smallest of the arterial vessels. O_2, nutrients, and other substances needed for cellular metabolism pass from the capillaries into the tissues, where they are taken up by the cells. Capillaries also absorb metabolic waste products from the tissues.
2. Venules, the smallest veins, receive capillary blood. From the venules, the venous blood flows into larger and larger veins until it reaches the venae cavae, through which it enters the right atrium.
3. Vessel walls have three layers: the tunica intima (inner layer), the tunica media (middle layer), and the tunica externa (the outer layer).
4. Layers of the vessel wall differ in thickness and composition from vessel to vessel, depending on the vessel's size and location within the circulatory system. In general, the tunica media of arteries close to the heart has more elastic fibers (elastic arteries) because these arteries must be able to distend during systole and recoil during diastole. Arteries farther from the heart contain more smooth muscle fibers (muscular arteries) because they constrict and dilate to control blood pressure and volume within specific capillary beds.
5. Blood flow into the capillary beds is controlled by the contraction and relaxation of smooth muscle bands (precapillary sphincters) at junctions between metarterioles and capillaries.
6. Endothelial cells line the blood vessels. The endothelium is a life-support tissue; it functions as a filter (altering permeability), changes in vasomotion (constriction and dilation), and is involved in clotting and inflammation.
7. Blood flow through the veins is assisted by the contraction of skeletal muscles (the muscle pump), and backward flow is

prevented by one-way valves, which are particularly important in the deep veins of the legs.

8. Blood flow is affected by blood pressure, resistance to flow within the vessels, velocity of the blood, anatomic features that may cause turbulent or laminar flow, and compliance (distensibility) of the vessels.
9. The Poiseuille law states that resistance is directly related to tube length and blood viscosity, and inversely related to the radius of the tube.
10. Total resistance, or the resistance to flow within the entire systemic circulatory system, depends on the combined lengths and radii of all the vessels within the system and on whether the vessels are arranged in series (greater resistance) or in parallel (lesser resistance).
11. Blood flow is also influenced by neural stimulation (vasoconstriction or vasodilation) and by autonomic features that cause turbulence within the vascular lumen (e.g., protrusions from the vessel wall, twists and turns, vessel branching).
12. Arterial blood pressure is influenced and regulated by factors that affect cardiac output (heart rate, stroke volume), total resistance within the system, and blood volume.
13. ADH, the RAAS system, and NPs can all alter blood volume and thus blood pressure.
14. Venous blood pressure is influenced by blood volume within the venous system and compliance of the venous walls.
15. Blood flow through the coronary circulation is governed by the same principles as flow through other vascular beds plus two adaptations dictated by cardiac dynamics. First, blood flows into the coronary arteries during diastole rather than systole, because during systole the cusps of the aortic semilunar valve block the openings of the coronary arteries. Second, systolic contraction inhibits coronary artery flow by compressing the coronary arteries.
16. Autoregulation enables the coronary vessels to maintain optimal perfusion pressure despite systolic compression.

17. Myoglobin in heart muscle stores O_2 for use during the systolic phase of the cardiac cycle.

The Lymphatic System

1. The vessels of the lymphatic system run in the same sheaths as the arteries and veins.
2. Lymph (interstitial fluid) is absorbed by lymphatic venules in the capillary beds and travels through ever larger lymphatic veins until it empties through the right lymphatic duct or thoracic duct into the right or left subclavian veins, respectively.
3. As lymph travels toward the thoracic ducts, it passes through thousands of lymph nodes clustered around the lymphatic veins. The lymph nodes are sites of immune function and are ideally placed to sample antigens and cells carried by the lymph from the periphery of the body into the central circulation.

Tests of Cardiovascular Function

1. The evaluation of an individual with known or suspected cardiovascular disease must include a careful history and physical examination including assessment of risk factors, symptoms, vital signs, level of consciousness, mucous membrane color, and cardiopulmonary functioning.
2. Important tests for cardiac disorders are ECG and Holter monitoring, which detect disturbances of impulse generation or conduction.
3. Stress tests elicit clinical manifestations of cardiovascular disease that might not be present at rest.
4. The sensitivity of stress testing is improved by the use of radiotracer imaging techniques such as SPECT.

5. Echocardiography detects structural and functional cardiac abnormalities over time.
6. Cardiac catheterization is used to measure the oxygen content and pressure of blood in the heart's chambers and to inject contrast media for x-ray examination of the size and shape of the chambers and valves. Injection of contrast medium into the coronary arteries (coronary angiography), on the other hand, permits visualization of the coronary circulation and every tissue perfused by the coronary arteries.
7. Evaluation of the systemic vascular system can include arterial pressure pulse waveform analysis, Doppler ultrasonography, venography, and arteriography.

Aging and the Cardiovascular System

1. Cardiovascular disease is the most common cause of morbidity and mortality in older adults in Western society and in much of the rest of the world. In addition, age is a key driver of cardiovascular risk, which explains why it is the primary cause of death in persons older than age 65.
2. The most common cardiovascular disease condition is hypertension followed by coronary atherosclerosis, for which hypertension is a risk factor.
3. It is challenging to determine the normal physiologic changes in cardiac function with aging because many pathologic changes are usually present and physical fitness is variable in older people as well.
4. The most relevant age-associated physiologic changes in cardiovascular performance include myocardial and blood vessel stiffening, changes in neurogenic control over vascular tone, increased occurrence of atrial fibrillation, and loss of exercise capacity plus left ventricular hypertrophy and fibrosis.
5. With active risk reduction, physical activity, and disease management, older adults can have markedly improved

cardiovascular health.

- Dysrhythmias, 1101

Cardiovascular disease is the leading cause of death, both in the United States and worldwide. Disorders of the veins, arteries, and heart comprise the scope of cardiovascular disease. Current understanding of the pathophysiology of cardiovascular disease is focused on genetic, neurohumoral, inflammatory, and metabolic mechanisms that underlie tissue and cellular alterations.

Diseases of the Veins

Varicose Veins and Chronic Venous Insufficiency

A varicose vein is a vein in which blood has pooled, producing distended, tortuous, and palpable vessels (Fig. 32.1). Risk factors include age, female sex, family history of varicose veins, obesity, pregnancy, deep venous thrombosis (DVT), and previous leg injury. Varicose veins typically involve the saphenous veins of the leg and are caused by (1) injury or disease involving the saphenous vein valves or (2) gradual venous distention caused by the action of gravity on blood in the legs.

FIG. 32.1 Varicose Veins of the Leg *(Arrow)*. (From *Robbins SL, Cotran RS, Kumar V, et al. Robbins and Cotran pathologic basis of disease*, 8th edition. Philadelphia: Saunders; 2010. Courtesy Dr. Magruder C. Donaldson, Brigham and Women's Hospital, Boston, MA.)

If a valve is damaged, volume and pressure increase within the vessel. The vein swells as it becomes engorged and surrounding tissue becomes edematous because increased hydrostatic pressure pushes plasma through the stretched vessel wall. Venous distention develops over time, especially in individuals who habitually stand for long periods, wear constricting garments, or cross the legs at the knees, which diminishes the action of the muscle pump (see Fig. 31.20). Genetic factors, female sex, and pregnancy are contributing factors. Eventually the pressure in the vein damages venous valves, rendering them incompetent and unable to maintain normal venous pressure.

Varicose veins and valvular incompetence can progress to chronic venous insufficiency, especially in sedentary obese individuals and those who smoke. Chronic venous insufficiency (CVI) is inadequate venous return over a long period of time. Venous hypertension, circulatory stasis, and tissue hypoxia cause an inflammatory reaction and changes in the extracellular matrix in vessels. Endothelial cells express adhesion molecules bringing leukocytes and fibroblasts to the area. Collagen synthesis increases vascular wall thickening and fibrosclerotic remodeling of the veins. The microcirculation is impaired contributing to more inflammation and tissue hypoxia. Approximately one-third of those with varicose veins develop significant skin changes.[1] Symptoms include edema of the lower extremities and hyperpigmentation of the skin of the feet and ankles. Poor circulation makes tissues vulnerable to trauma and infection resulting in the formation of venous stasis ulcers (Fig. 32.2) and cellulitis.

FIG. 32.2 Venous Stasis Ulcer.
Typical venous ulcer, healed after 11 weeks of compression therapy using high pressure Unna boot bandages. (From Caprini JA, Partsch H, Simman R. Venous ulcers. *Journal of the American College of Clinical Wound Specialists*, 2013;4(3):54–60. doi:10.1016/j.jccw.2013.11.001.)

Evaluation of CVI includes careful physical examination of pulses and skin, followed by Doppler ultrasound and measurement of ankle brachial pressure index. Identification of the underlying cause is crucial to effective management.[2] Treatment of varicose veins and CVI begins conservatively with elevating the legs, wearing compression bandages or stockings, and performing physical exercise. In those with venous ulcers, the choice of compression materials and their proper use is essential to obtaining improvement in symptoms and ulcer healing.[1] Advanced wound care techniques including skin grafting, mesenchymal stem cells, and autologous platelet rich plasma may be indicated for large non-healing ulcers.[2] Invasive management for venous obstruction and dilation includes endovenous ablation, sclerotherapy or surgical ligation, conservative vein resection (phlebectomy), and vein bypass.

Thrombus Formation in Veins

A thrombus is a blood clot that remains attached to a vessel wall. A detached thrombus is a thromboembolus. The Centers for Disease Control and Prevention estimates that venous thrombi and associated thromboembolism affect about 900,000 people and cause nearly 100,000 deaths in the United States per year.[3] Deep venous thrombosis (DVT) occurs primarily in the lower extremity. Venous thrombi are more common than arterial thrombi because flow and pressure are lower in the veins than in the arteries. Three factors (triad of Virchow) promote venous thrombosis: (1) venous stasis, (2) venous endothelial damage, and (3) hypercoagulable states (see Chapter 29).

Venous stasis occurs in conditions that limit flow through the local or systemic venous circulation. For example, immobility (e.g., stroke, spinal cord injury, casting) prevents the muscular pump (see Fig. 31.20) from increasing blood flow from the lower extremity to the inferior vena cava and right atrium. Similarly, heart failure results in increased diastolic filling pressures causing reduced venous return. Accumulation of clotting factors and platelets leads to thrombus formation in the vein, often near a venous valve. Further platelet aggregation leads to the thrombus propagating (growing) proximally.

Damage to endothelial cells can occur due to trauma (e.g., orthopedic injury or surgery), the use of caustic intravenous medications, or the use of invasive

venous procedures (e.g., peripherally inserted central catheters). The healthy vascular endothelium serves as a barrier between the blood and the prothrombotic subendothelium. It also expresses several anticoagulant factors including protein C receptors and tissue factor pathway inhibitor. In the presence of endothelial damage, endothelial cells lose their anticoagulant properties and instead express adhesion molecules that promote inflammatory cell and platelet activation.[4] Polymorphonucleocytes infiltrate the vessel wall and produce neutrophil extracellular traps (NETs) (see Chapter 7) that cause additional inflammatory damage to the endothelium and promote clotting.

Many individuals develop DVT because of transient or prolonged hypercoagulability states. Pregnancy is associated with both hypercoagulability and venous stasis in the lower extremities. Active cancer is estimated to be the cause of approximately 20% of all cases of venous thromboembolism, especially hematologic malignancies and those involving the pancreas, stomach, lung, brain, ovaries, and kidneys.[5] In malignancy-related DVT, a hypercoagulable state is created by the cancer cells themselves. Tissue factor produced by cancer cells activates coagulation, fibrin synthesis, and platelet activation. Many cancer cells also produce plasminogen activator inhibitor-1 which inhibits the fibrinolytic system.[6] Some infections also are associated with hypercoagulability and venous thromboembolism. For example, systemic inflammation that results from infections such as bacterial sepsis or SARS-CoV-2 induced Coronavirus Disease 2019 (COVID-19) are associated with a high risk for the development of DVT.[7,8] Inherited hypercoagulability states increase the risk for DVT, especially in association with other risk factors, such as immobility or pregnancy. The most common inherited hypercoagulability state is factor V Leiden mutation, which affects 3% to 8% of the population and is estimated to be the cause of 20% to 25% of venous thromboembolism cases. Factor V Leiden results from a single point mutation in the Factor V gene which causes an inadequate anticoagulant response to activated protein C.[9] Individuals may develop DVT without apparent cause or after a relatively minor risk event such as airplane travel. This mutation also increases the risk of DVT recurrence after treatment. Other inherited hypercoagulability states are caused by prothrombin mutations and deficiencies of protein C, protein S, and antithrombin.

Venous thrombosis is often asymptomatic and affected individuals may be unaware that they are at risk for serious complications until they develop symptoms of thromboembolism to the lungs (pulmonary embolism, see Chapter 35). In some cases, venous inflammation causes pain and redness of the overlying tissues and skin. If the thrombus creates significant obstruction to venous blood flow, increased pressure in the vein behind the clot may lead to edema of the extremity. Most thrombi will eventually dissolve without

treatment; however, untreated DVT is associated with a high risk of thromboembolization. Persistent venous obstruction may lead to CVI and postthrombotic syndrome with associated pain, edema, and ulceration of the affected limb.[4]

Because DVT is usually asymptomatic and difficult to detect clinically, prevention is important in at-risk individuals. Risk stratification algorithms are used to identify and manage at-risk individuals. Common approaches to prevention include early ambulation, pneumatic compression devices, and prophylactic anticoagulation. If thrombosis is suspected, a serum D dimer is measured. If it is negative, the diagnosis of DVT is unlikely. If the D-dimer is elevated, diagnosis of DVT is confirmed by a Doppler ultrasonography. Current guidelines recommend that uncomplicated DVT should be managed at home rather than in the hospital unless there is limb-threatening venous obstruction, high risk of bleeding, or severe pain.[10] Direct oral anticoagulants (e.g., dabigatran, apixaban, edoxaban, rivaroxaban) have been shown to have a favorable benefit-to-risk ratio and are rapidly becoming the treatments of choice.[10] Thrombolytic therapy (intravenous or catheter directed) or placement of an inferior vena cava filter may be indicated in selected individuals. Treatment is continued for 3 to 6 months at which time anticoagulation may be discontinued, or continued indefinitely for those with irreversible underlying risk factors.[10]

Superior Vena Cava Syndrome

Superior vena cava syndrome (SVCS) is a progressive occlusion of the superior vena cava (SVC) that leads to venous distention in the upper extremities and head. The most common cause is bronchogenic cancer followed by lymphomas and metastasis of other cancers. The incidence of device-related thromboses as a cause of SVCS is increasing.[11] Other less common causes include tuberculosis, mediastinal fibrosis, and cystic fibrosis. The SVC is a relatively low-pressure vessel that lies in the closed thoracic compartment; therefore space-occupying lesions can easily compress the SVC. The SVC is surrounded by lymph nodes and abuts the right mainstem bronchus, which commonly becomes involved in thoracic cancers which may compress the SVC during tumor growth. The SVC also can be occluded by the presence of large thrombi. Invasive therapies (pacemaker wires, central venous catheters, and pulmonary artery catheters) with associated thrombosis now account for nearly half of cases of SVCS.

Clinical manifestations of SVCS are edema and venous distention in the upper extremities and face, including the ocular beds. Affected persons complain of a feeling of fullness in the head or tightness of shirt collars, necklaces, and rings. Cerebral edema may cause headache, visual disturbance,

and impaired consciousness. The skin of the face and arms may become purple and taut, and capillary refill time is prolonged. Respiratory distress may be present because of bronchial compression. In infants, SVCS can lead to hydrocephalus.

Diagnosis is made by chest x-ray, Doppler studies, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound. SVCS is an oncologic emergency. Treatment for malignant disorders can include radiation therapy, surgery, chemotherapy, and the administration of diuretics, steroids, and anticoagulants, as necessary. Treatment for moderate to severe nonmalignant causes may include endovascular therapy such as balloon angioplasty or bypass surgery using various grafts. Severe symptoms require thrombolysis, balloon angioplasty, placement of intravascular stents, and/or surgery.[11]

Diseases of the Arteries

Hypertension

Hypertension is consistent elevation of systemic arterial blood pressure. It results from a sustained increase in peripheral vascular resistance (PVR), an increase in circulating blood volume and cardiac output, or both. Hypertension is defined as a sustained systolic blood pressure (SBP) of 130 mm Hg or a diastolic blood pressure (DBP) of 80 mm Hg or greater (Table 32.1). According to the American Heart Association, 51.7% of men and 42.8% of women over the age of 20 in the United States have hypertension, and the lifetime risk for developing hypertension is between 70% and 86%, with white females having the lowest risk and black males the highest risk.[12] Most affected individuals do not have their hypertension under control. Between 2007 and 2017, hypertension-related deaths in the United States increased from 18.3 per 100,000 to 23.0 per 100,000, probably related to increasing rates of obesity and diabetes.[13] The chance of developing primary hypertension increases with age, although children are being diagnosed with increasing frequency (see Chapter 33). The prevalence of hypertension is higher in Blacks and in those with diabetes. Those who fall into the category called elevated blood pressure (SBP 120 to 129 mm Hg and DBP < 80 mm Hg) are at risk for developing hypertension unless lifestyle modification is instituted. All stages of hypertension are associated with increased risk for target organ disease events, such as myocardial infarction (MI), kidney disease, and stroke.

Table 32.1

Classification of Blood Pressure for Adults Age 18 Years and Older

Category	Systolic (mm Hg)		Diastolic (mm Hg)
Normal	<120	AND	<80
Elevated	120–129	AND	<80
Stage 1 hypertension	130–139	OR	80–89
Stage 2 hypertension	≥140	OR	≥90
Hypertensive crisis	≥180	AND/OR	>120

Data from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension*. 2018;71(6):e13–e115.

Most cases (90% to 95%) of hypertension are diagnosed as primary hypertension (also called essential or idiopathic hypertension). Secondary hypertension is caused by an underlying disease process or medication that raises PVR or cardiac output. This form of hypertension accounts for only 5% to 10% of cases.[14] Examples include renal vascular or parenchymal disease, adrenocortical tumors, adrenomedullary tumors (pheochromocytoma), and drugs (oral contraceptives, corticosteroids, antihistamines). If the cause is identified and removed before permanent structural changes occur, blood pressure returns to normal.

Primary Hypertension

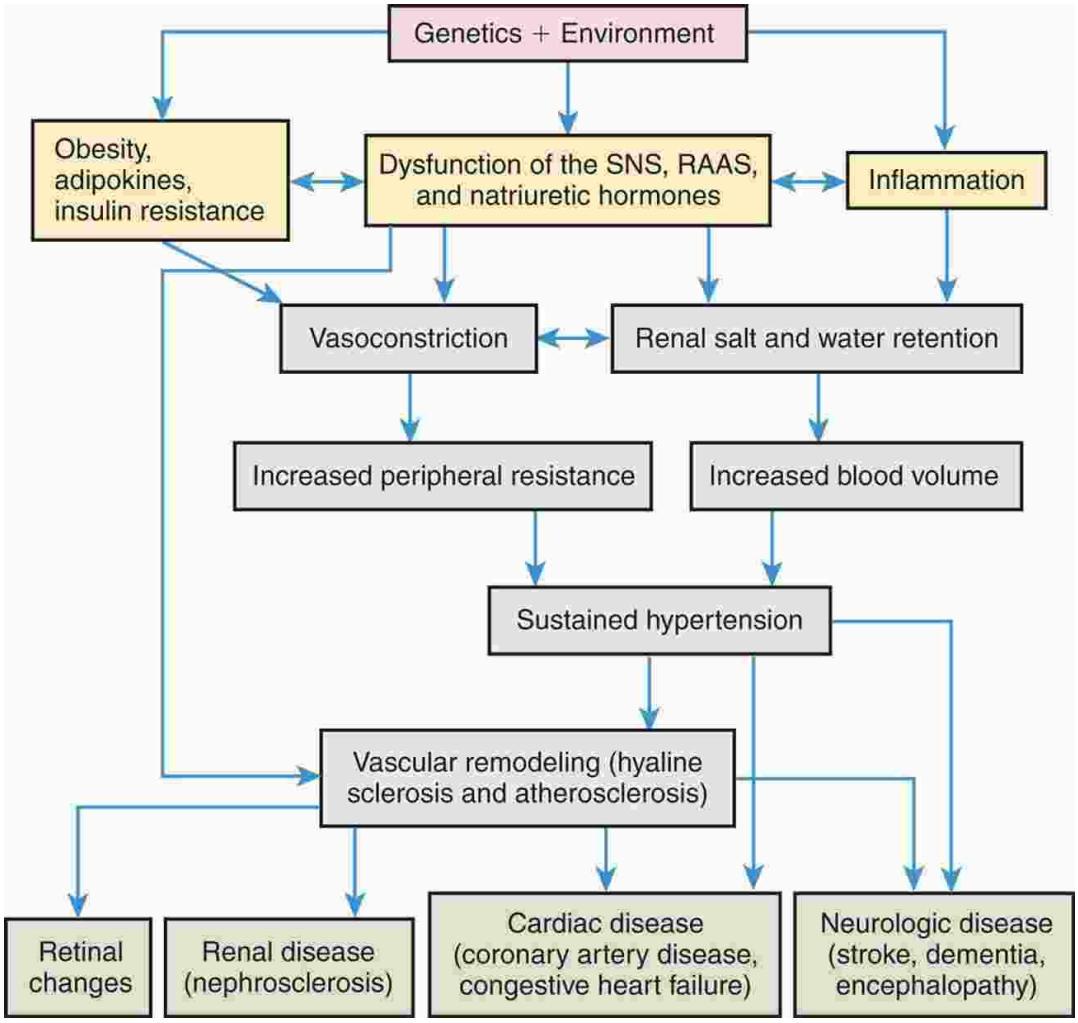
A specific cause for primary hypertension has not been identified. Primary hypertension is the result of a complicated interaction of genetics and the environment mediated by a host of neurohumoral effects that influence intravascular volume and PVR (Algorithm 32.1). Genetic predisposition to hypertension is thought to be polygenic and associated with epigenetic changes influenced by diet and lifestyle. Genetic risks include defects in renal sodium excretion, insulin sensitivity, activity of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS), and cell membrane sodium or calcium transport. Risk factors for primary hypertension relate to

age, sex, race, and dietary factors (see *Risk Factors:* Primary Hypertension). Many of these factors are also risk factors for other cardiovascular disorders. In fact, obesity, hypertension, dyslipidemia, and glucose intolerance often are found together in a condition called the metabolic syndrome (see Chapter 22).

Risk Factors

Primary Hypertension

Family history
Advancing age
Cigarette smoking
Obesity
Heavy alcohol consumption
Sex (men > women before age 55, women > men after 55)
Black race
High dietary sodium intake
Low dietary intake of potassium, calcium, magnesium
Glucose intolerance and diabetes



ALGORITHM 32.1 **Pathophysiology of Hypertension.** Numerous genetic vulnerabilities have been linked to hypertension and these, in combination with environmental risks, cause neurohumoral dysfunction (sympathetic nervous system *[SNS]*, renin-angiotensin-aldosterone *[RAA]* system, natriuretic hormones) and promote inflammation and insulin resistance. Insulin resistance, obesity-related adipokine alterations, and neurohumoral dysfunction contribute to sustained systemic vasoconstriction and increased peripheral vascular resistance. Inflammation contributes to renal dysfunction, which, in combination with the neurohumoral alterations, results in renal salt and water retention and increased blood volume. Increased peripheral vascular resistance and increased blood volume are two primary causes of sustained hypertension. Sustained

hypertension leads to blood vessel sclerosis and associated damage to the retina, kidney, heart, and brain.

A flowchart shows the pathophysiology of hypertension. 1. Genetics and environment. Leads to 2, 3, and 4. 2. Obesity, adipokines, and insulin resistance. Interrelated with 3. Leads to 5. 3. Dysfunction of the S N S, R A A S, and natriuretic hormones. Interrelated with 4. Leads to 5, 6, and 10. 4. Inflammation. Leads to 6. 5. Vasoconstriction. Interrelated with 6. Leads to 7. 6. Renal salt and water retention. Leads to 8. 7. Increased peripheral resistance. Leads to 9. 8. Increased blood volume. Leads to 9. 9. Sustained hypertension. Leads to 10, 13, and 14. 10. Vascular remodeling (hyaline sclerosis and atherosclerosis). Leads to 11, 12, 13, and 14. 11. Retinal changes. 12. Renal disease (nephrosclerosis). 13. Cardiac disease (coronary artery disease, congestive heart failure). 14. Neurologic disease (stroke dementia, encephalopathy).

Pathophysiology

Multiple mechanisms contribute to the pathophysiology of hypertension including changes in the SNS, the RAAS, and natriuretic peptides. Inflammation, endothelial dysfunction, obesity-related hormones, and insulin resistance also contribute. Increased vascular volume is related to a decrease in renal excretion of salt, often referred to as a shift in the pressure-natriuresis relationship (Fig. 32.3). This means that for a given blood pressure, individuals with hypertension tend to secrete less salt in their urine.

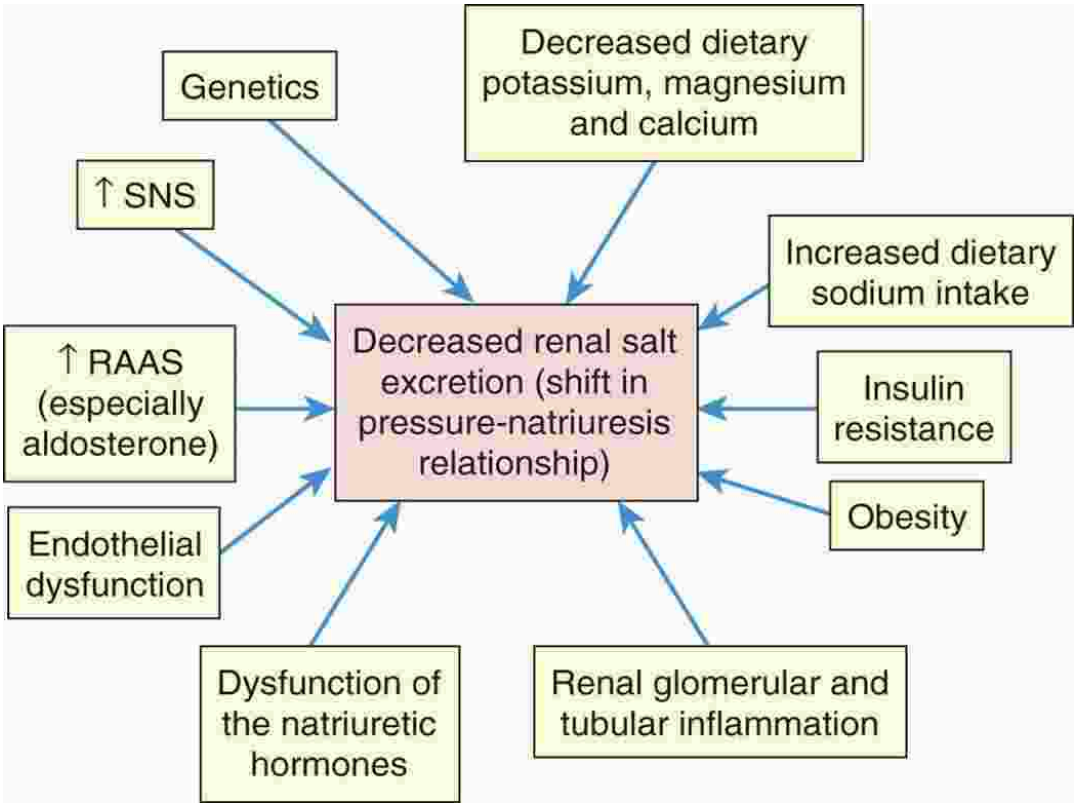


FIG. 32.3 Factors that Cause a Shift in the Pressure-Natriuresis Relationship.
Numerous factors have been implicated in the pathogenesis of sodium retention in individuals with hypertension. These factors cause less renal excretion of salt than would normally occur with increased blood pressure. This is called a shift in the pressure-natriuresis relationship and is thought to be a central process in the pathogenesis of primary hypertension. *RAAS*, Renin-angiotensin-aldosterone system; *SNS*, sympathetic nervous system.

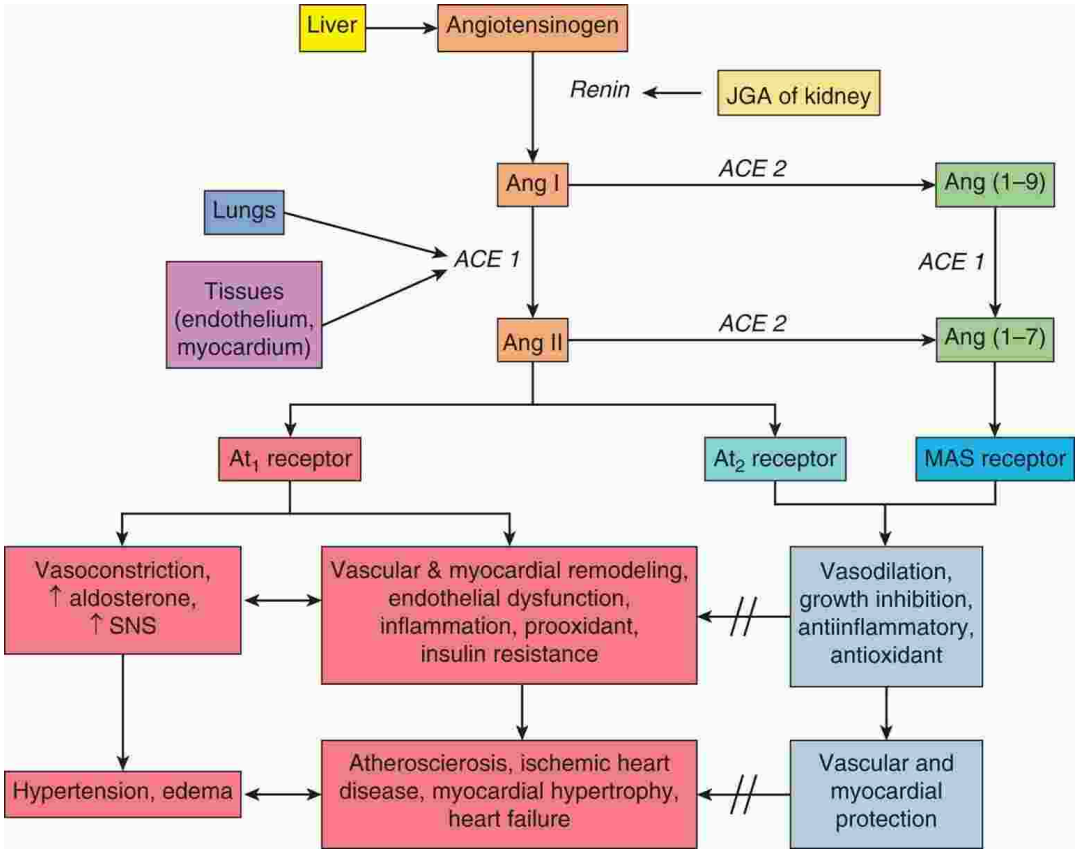
An illustration lists the various factors leading to decreased renal salt (shift in pressure-natriuresis relationship). • Increased dietary sodium intake. • Insulin resistance. • Obesity • Renal glomerular and tubular inflammation. • Dysfunction of the natriuretic hormones. • Endothelial dysfunction. • Increased R A A S (especially aldosterone). •

Increased S N S. • Genetics. • Decreased dietary potassium, magnesium, and calcium.

As described in Algorithm 32.1, genetic and environmental risks lead to changes in neurohormones, insulin resistance, and inflammation. Obesity contributes to these changes through changes in adipokines and increased inflammation. The combination of all of these factors cause sodium and water retention and peripheral vasoconstriction leading to sustained hypertension and organ damage.

Increased SNS activity causes accelerated heart rate and systemic vasoconstriction. These changes increase both cardiac output and peripheral vascular resistance, thus raising the blood pressure. Additional mechanisms of SNS-induced hypertension include structural changes in blood vessels (vascular remodeling), renal sodium retention (shift in pressure-natriuresis curve), insulin resistance, increased renin and angiotensin levels, and procoagulant effects.

In hypertensive individuals, overactivity of the classical pathway of the RAAS directly causes salt and water retention and increased vascular resistance (Algorithm 32.2). This RAAS pathway begins when angiotensinogen is synthesized in the liver and is released into the blood. There it is cleaved to angiotensin I (Ang I) by renin which is secreted from the juxtaglomerular apparatus (JGA) in the kidney. Angiotensin-converting enzyme 1 (ACE1) in the lung and in tissues catalyzes the formation of angiotensin II (Ang II). Ang II binds with several receptors, the most important of which are AT1 and AT2. AT1 receptor binding results in vasoconstriction (increases vascular resistance) and aldosterone secretion by the adrenal cortex (increases salt and water retention) leading to hypertension and edema. AT1 receptor binding by Ang II also activates the SNS and acts as a growth factor contributing to vascular and myocardial remodeling, inflammation, insulin resistance, and platelet activation. Vascular remodeling is structural change in vessel walls that results in permanent increases in PVR and contributes to atherogenesis. Taken together, these effects contribute to atherosclerosis, ischemic heart disease, myocardial hypertrophy, and heart failure. Medications such as ACE inhibitors, angiotensin receptor blockers (ARBs), and aldosterone blockers oppose the activity of the RAAS and are effective in reducing blood pressure and protecting against target organ damage.



ALGORITHM 32.2 The Renin-Angiotensin-Aldosterone System and Its Effects on Tissues

The classical pathway of the renin-angiotensin-aldosterone system (RAAS) begins when angiotensinogen is synthesized in the liver and is released into the blood. There it is cleaved to angiotensin I *(Ang I)* by renin which is secreted from the juxtaglomerular apparatus *(JGA)* in the kidney. Angiotensin-converting enzyme 1 *(ACE1)* in the lung and in tissues catalyzes the formation of angiotensin II *(Ang II)*. Ang II binds with several receptors, the most important of which are AT1 and AT2. AT1 receptor binding results in vasoconstriction (increases vascular resistance) and aldosterone secretion by the adrenal cortex (increases salt and water retention) leading to hypertension and edema. AT1 receptor binding by Ang II also acts as a growth factor leading to vascular and myocardial remodeling as well as inflammation and insulin resistance. Taken together, these effects contribute to atherosclerosis, ischemic heart disease, myocardial hypertrophy and heart failure. In contrast, Ang II binding to the AT2 receptor causes vasodilation, decreased remodeling

and has anti-inflammatory and antioxidant effects. Another pathway of the RAAS uses the enzyme ACE2 to form Angiotensin (1–7) from Angiotensin (1–9). Ang (1–7) binds to the MAS receptor and provides additional protection against the negative vascular and myocardial effects of Ang II. *SNS*, Sympathetic nervous system.

In contrast, when Ang II binds to the AT2 receptor, it functions to oppose the effects of AT1 stimulation. Ang II binding to the AT2 receptor causes vasodilation and decreased remodeling and has anti-inflammatory and antioxidant effects. An imbalance between these two receptor pathways is linked to primary hypertension (see Algorithm 32.2). A second RAAS pathway uses angiotensin converting enzyme 2 (ACE2) to create Ang (1–7) which binds to MAS receptors in vascular, cardiac, and pulmonary tissues. It serves to downregulate AT1 receptors, promotes antihypertensive vasodilation, and reduces cardiovascular remodeling.[15] MAS receptor binding by Ang (1–7) also provides cerebrovascular and metabolic protective effects. In addition, the ACE2 pathway is highly expressed in lungs with the ability to mitigate cardiopulmonary diseases such as inflammatory lung disease associated with COVID-19.[16] New therapies aimed at potentiating the ACE2 pathway are in development.[17]

Dysfunction of the natriuretic hormones plays an important role in the pathogenesis of hypertension. These hormones include atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. Together they modulate renal sodium (Na^+) excretion and require adequate potassium, calcium, and magnesium intake to function properly. ANP and BNP are released when there is mechanical stretch of the myocardium. After binding to the natriuretic receptor, they stimulate salt and water loss by the kidney (natriuresis), contribute to arteriolar vasodilation, and reduce RAAS activation.[18] Dysfunction of these hormones, along with alterations in the RAA system and the SNS, causes a shift in the pressure-natriuresis relationship leading to increased blood volume and blood pressure. Decreased activity of the natriuretic peptides also is linked to vascular and cardiac remodeling. With inadequate natriuretic function, there is a compensatory increase in natriuretic peptide serum levels. High levels of these peptides therefore indicate dysfunction and are linked to an increased risk for ventricular hypertrophy, atherosclerosis, and heart failure in individuals with hypertension. Salt restriction combined with adequate intake of dietary potassium, magnesium, and calcium improves natriuretic peptide function. Diuretics promote renal salt and water excretion and are a mainstay of hypertensive treatment. Drugs that block the degradation of the natriuretic peptides by blocking the enzyme

neprilysin are currently used in combination with angiotensin receptor blockers (ARNi) (e.g., sacubitril/valsartan) for the treatment of heart failure, and are being evaluated for the treatment of hypertension, but may be associated with decreased cognitive function.[19,20]

Innate and adaptive immunity with associated inflammation play a role in the pathogenesis of hypertension. Activation of immunity results in chronic inflammation with damage to endothelial cells, decreased production of vasodilators (such as nitric oxide), vascular remodeling, and smooth muscle contraction. The contributions of diet, obesity, insulin resistance, and activation of the RAAS to the development of hypertension are likely to be mediated in part by increased systemic inflammation.[21] Neuroinflammation is linked to increased SNS activity.[22] Inflammation also contributes to insulin resistance, decreased natriuresis, and autonomic dysfunction.

Obesity accounts for 65% to 75% of primary hypertension.[23] Obesity and increased caloric intake contribute to adipocyte dysfunction and ectopic fat deposition throughout the cardiovascular system. Adipocytes secrete adipokines, including leptin and adiponectin. The primary function of leptin is to interact with the hypothalamus to control body weight through appetite inhibition and increased metabolic rate (see Chapter 23). Adiponectin is a protein produced by adipose tissue but is reduced in obesity. With obesity, increased leptin and decreased adiponectin have been found to increase sympathetic nervous system and renin-angiotensin-aldosterone system activity, contribute to insulin resistance, decrease renal sodium excretion, promote inflammation, and stimulate myocyte hypertrophy. Other adipokines that are altered in obesity-related cardiovascular diseases include resistin, omentin, visfatin, and perivascular adipose tissue–derived relaxing factor. Obesity also is linked with endothelial dysfunction which contributes to vasoconstriction and arterial remodeling. Taken together, these obesity-related changes result in vasoconstriction, salt and water retention, and renal dysfunction that contribute to the development of hypertension. Weight loss is an essential treatment for obesity-related hypertension. In severe obesity, bariatric surgery has been shown to cause long-standing remission of hypertension in many individuals, although those with severe hypertension requiring multiple medications are less likely to benefit.[24,25]

Insulin resistance is common in hypertension, even in individuals without clinical diabetes. Insulin resistance is associated with decreased endothelial release of nitric oxide and other vasodilators. It also affects renal function and causes renal salt and water retention. Insulin resistance promotes overactivity of the SNS and RAAS. The interactions among obesity, hypertension, insulin

resistance, and lipid disorders in metabolic syndrome result in a high risk of cardiovascular disease.[26]

Given the complexity of all the factors that contribute to its pathophysiology, primary hypertension is now being considered a metabolic disease that results from the interaction of genes, diet, neurohormones, adipokines, immune cytokines, and gut microbiota (see Emerging Science Box: Hypertension as a Metabolic Disease). These discoveries are leading to new approaches to hypertension

Emerging Science BoxHypertension as a Metabolic Disease

As the complex mechanisms that link obesity with hypertension are being elucidated, there is increasing appreciation for the concept of hypertension as a metabolic disorder. This concept derives from an increased understanding of the many ways that diet, gut function and microbiota, neurohormones, and adipose tissue composition and function work together to influence cardiovascular health and disease. For example, it is now believed that high salt intake not only causes hypertension in genetically predisposed individuals, it also may directly contribute to the development of obesity and diabetes. Furthermore, a high-salt diet causes gut microbiota dysbiosis, alters nutrient uptake from the intestines, and negatively impacts gastrin-induced natriuresis. There are interactions between the gut, the brain, adipose tissue, and the kidney that affect vascular tone. Obesity is not only linked to changes in adipokines such as leptin and adiponectin, but there are other hormones released from adipose tissue that are linked to changes in fat deposition and vascular function including apelin, omentin, and visfatin. Further complicating these relationships is the discovery that visceral and perivascular adipose tissue are independently associated with insulin resistance, dyslipidemia, and hypertension even in individuals with a healthy body mass index (BMI). Changes in glucocorticoid function are linked to obesity-related hypertension, and may be associated with stress even in perinatal development. Inflammatory and immune cells are also impacted by obesity-related metabolic changes resulting in chronic inflammation and immune-mediated damage to blood vessels and to renal tissue. These complex interactions reinforce the benefits of lifestyle interventions (diet, exercise, weight loss) and provide multiple potential opportunities for future hypertension therapies aimed at specific mechanisms of metabolic dysfunction.

Complicated hypertension

As hypertension becomes more severe and chronic, tissue damage can occur in the blood vessels and tissues leading to target organ damage in the heart, kidney, brain, and eyes. Cardiovascular complications of sustained hypertension include left ventricular hypertrophy, angina pectoris, heart failure, coronary artery disease, myocardial infarction, and sudden death.[14] Myocardial hypertrophy is mediated by the SNS and RAAS. Hypertrophy is characterized by a myocardium that is thickened, scarred, and less able to relax during diastole, leading to heart failure with preserved ejection fraction. Over time, the increased size of the heart muscle increases demand for oxygen delivery, the contractility of the heart is impaired, and the individual is at risk for myocardial infarction and heart failure with reduced ejection fraction. Vascular complications include hyaline sclerosis and accelerated atherosclerosis that can affect perfusion to any vascular bed. Hypertension also can contribute to the formation, dissection, and rupture of aneurysms (outpouchings in vessel walls). Renal manifestations of complicated hypertension include nephrosclerosis, renal arteriosclerosis, and renal insufficiency or failure. Microalbuminuria (small amounts of protein in the urine) occurs in many individuals with HTN and is now recognized as an early sign of impending renal dysfunction and increased risk for cardiovascular events. Complications specific to the retina include retinal vascular sclerosis, exudation, and hemorrhage. Cerebrovascular complications include transient ischemia, stroke, cerebral thrombosis, aneurysm, hemorrhage, and dementia. The pathologic effects of complicated hypertension are summarized in Table 32.2.

Table 32.2

Pathologic Effects of Sustained, Complicated Primary Hypertension

Site of Injury	Mechanism of Injury	Pathologic Effect
Heart		
Myocardium	Increased workload combined with diminished blood flow through coronary arteries	Left ventricular hypertrophy, myocardial ischemia, heart failure
Coronary arteries	Accelerated atherosclerosis (coronary artery disease)	Myocardial ischemia, myocardial infarction, sudden death
Kidneys	Reduced blood flow, increased arteriolar pressure, RAAS and SNS stimulation, and inflammation	Glomerulosclerosis and decreased glomerular filtration, end-stage renal disease
Brain	Reduced blood flow and oxygen supply; weakened vessel walls, accelerated atherosclerosis	Transient ischemic attacks, cerebral thrombosis, aneurysm, hemorrhage, acute brain infarction
Eyes (retinas)	Retinal vascular sclerosis, increased retinal artery pressures	Hypertensive retinopathy, retinal exudates and hemorrhages
Aorta	Weakened vessel wall	Dissecting aneurysm
Arteries of lower extremities	Reduced blood flow and high pressures in arterioles, accelerated atherosclerosis	Intermittent claudication, gangrene

RAAS, Renin-angiotensin-aldosterone system; *SNS*, sympathetic nervous system.

Clinical Manifestations

The early stages of hypertension have no clinical manifestations other than elevated blood pressure; for this reason, hypertension is called a silent disease. Some hypertensive individuals never develop signs, symptoms, or complications, whereas others become very ill, and hypertension can be a cause of death. If elevated blood pressure is not detected and treated, it becomes established, setting the stage for the complications of hypertension that begin to appear during the fourth, fifth, and sixth decades of life.

Most clinical manifestations of hypertensive disease are caused by complications that damage organs and tissues outside the vascular system. Besides elevated blood pressure, the signs and symptoms therefore tend to be specific for the organs or tissues affected. Evidence of heart disease, renal insufficiency, central nervous system dysfunction, impaired vision, impaired mobility, vascular occlusion, or edema can all be caused by sustained hypertension.

Evaluation and Treatment

Diagnosis of hypertension requires the measurement of blood pressure on at least two separate occasions, averaging two readings at least 2 minutes apart, with the following conditions: the person is seated, the arm is supported at heart level, the person must be at rest for at least 5 minutes, and the person should not have smoked or ingested any caffeine in the previous 30 minutes. Diagnostic tests for further evaluation of hypertension may include ambulatory 24-hour blood pressure monitoring to detect night-time blood pressure variations and the presence of white-coat or masked hypertension (blood pressures that are elevated or normal only during office blood pressure measurement) in selected individuals.[27] Other evaluative studies should include measurement of electrolytes, glucose, and lipids, and an electrocardiogram (ECG). Individuals who have elevated blood pressure are assumed to have primary hypertension unless their history, physical examination, or initial diagnostic screening indicates secondary hypertension. Once the diagnosis is made, a careful evaluation for other cardiovascular risk factors and for end-organ damage should be done (e.g., echocardiography, carotid ultrasound, renal evaluation).

Treatment of primary hypertension depends on its severity. Management begins with lifestyle modification including exercise, and dietary modifications including reducing salt intake, smoking cessation, and weight loss. In 2021 the American College of Cardiology recommended that individuals with Stage 1 hypertension who are at low risk for cardiovascular disease but who do not respond to lifestyle modification should consider beginning pharmacologic therapy.[28] Pharmacologic treatment is recommended for individuals with Stage 1 hypertension who have existing or are at high risk for atherosclerotic

cardiovascular disease, and for those who have Stage 2 hypertension. The 2017 American College of Cardiology/American Heart Association guidelines recommend medications including diuretics, ACE inhibitors or ARBs, and calcium channel blockers.[27] These guidelines were largely affirmed by the International Society of Hypertension in 2020.[29] The choice of medications depends upon several factors including race and ethnicity, gender, age, and comorbidities such as heart disease, diabetes, and renal disease. Combinations of different types of antihypertensive medications may be indicated. Careful follow-up to support continued adherence, determine the response, and monitor for potential side effects of these medications is important. Other therapies for selected individuals include mineralocorticoid receptor antagonists and renal denervation.

Treatment goals include returning blood pressure to normotensive levels in most individuals, which can reduce the risk for stroke, dementia, and cardiovascular complications.[27,30] Older adults with hypertension also benefit from blood pressure reduction treatments but should be managed carefully with treatment goals adjusted by age and underlying comorbidities.[27]

Hypertensive crisis

Hypertensive crisis (malignant hypertension) is rapidly progressive hypertension in which systolic pressure is ≥180 mm Hg and/or diastolic pressure is ≥120 mm Hg and is associated with advanced bilateral retinopathy, encephalopathy, or microangiopathy.[27] It can occur in those with primary hypertension, but the reason some people develop this complication and others do not is unknown. Other causes include complications of pregnancy, cocaine or amphetamine use, reaction to certain medications, adrenal tumors, and alcohol withdrawal. High arterial pressure renders the cerebral arterioles incapable of regulating blood flow to the cerebral capillary beds. High hydrostatic pressures in the capillaries cause vascular fluid to exude into the interstitial space. Retina exhibit hemorrhages, cotton wool spots, and papilledema. If blood pressure is not reduced, cerebral edema and cerebral dysfunction (encephalopathy) increase until death occurs. Besides encephalopathy, hypertensive crisis can cause hemolysis and thrombocytopenia, angiopathy, myocardial infarction, cardiac failure with pulmonary edema, aortic dissection, uremia, and cerebrovascular accident (stroke) and is considered a medical emergency. A rapid evaluation for underlying cause and cardiovascular and neurologic complications is indicated, with rapid institution of medications such as beta- or alpha-blockers, calcium channel blockers, and nitrates.[27] It is likely that in many cases, individuals who

present with hypertensive crisis have poorly controlled underlying chronic hypertension, and careful follow-up and management is crucial.

Orthostatic (Postural) Hypotension

The term orthostatic (postural) hypotension (OH) refers to a decrease in SBP of at least 20 mm Hg or a decrease in DBP of at least 10 mm Hg within 3 minutes of moving to a standing position. It is a common condition in individuals accessing community and primary care clinics (prevalence 17% to 19%) and affects nearly one third of individuals in residential care or nursing homes, especially those with dementia and Parkinson disease.[31] OH affects men more often than women, and usually occurs between the ages of 40 and 70 years. It is a significant risk factor for falls and associated injury and for increased mortality.

OH is often associated with disorders that affect autonomic nervous function. Normally when an individual stands, the gravitational changes on the circulation are compensated by a baroreceptor-mediated reflex that stimulates the SNS. This causes arteriolar and venous constriction and increased heart rate upon standing. Other compensatory mechanisms include mechanical factors, such as the closure of valves in the venous system, contraction of the leg muscles, and a decrease in intrathoracic pressure. These mechanisms are dysfunctional or inadequate in individuals with orthostatic hypotension; consequently, upon standing, blood pools in the lower extremities and normal arterial pressure cannot be maintained.

Orthostatic hypotension may be acute or chronic. Acute orthostatic hypotension is common in older adults and occurs when the normal regulatory mechanisms are inadequate as a result of (1) altered body chemistry, (2) drug action (e.g., antihypertensives, antidepressants), (3) prolonged immobility, (4) starvation, (5) physical exhaustion, (6) volume depletion (e.g., dehydration, diuresis, potassium or sodium depletion), or (7) any condition that results in venous pooling (e.g., pregnancy, extensive varicosities of the lower extremities).

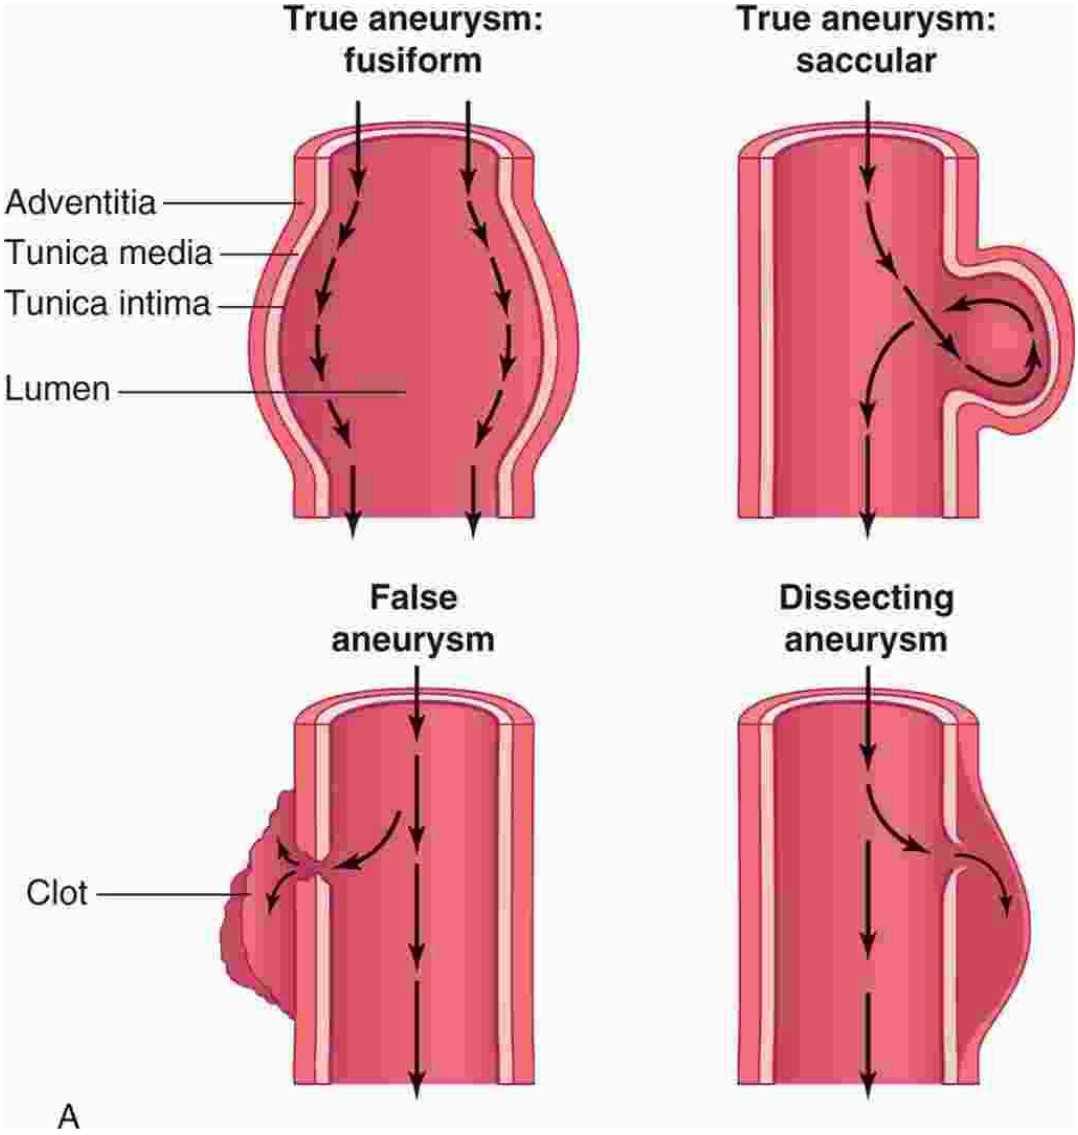
Chronic orthostatic hypotension may be (1) secondary to a specific disease or (2) primary (idiopathic). Secondary causes include neurogenic OH which results from diseases of the central or peripheral nervous systems that affect autonomic function (e.g., spinal cord injury, Parkinson disease, multiple system atrophy, intracranial tumors, cerebral infarcts, Wernicke encephalopathy, and peripheral neuropathies). Other causes of secondary OH are adrenal insufficiency and metabolic disorders (e.g., diabetes, porphyria). Cardiovascular autonomic neuropathy is a common cause of OH in persons with diabetes affecting up to 20% of diabetic individuals and is often overlooked.[32] Chronic OH also can occur in those taking antihypertensive medications. It is interesting to note that

although OH is common in older individuals being treated for hypertension, those who undergo intensive treatment and achieve good control of their systolic blood pressure are less likely to develop OH than those who are treated less intensively, likely due to favorable effects of improved blood pressure on autonomic function.[33] Many other medications also can cause OH including nitrates, antidepressants, phosphodiesterase inhibitors, and dopamine agonists.[32]

OH can be asymptomatic. In those with symptoms, it often is characterized by dizziness, blurring or loss of vision, and syncope. In neurogenic OH, symptoms often worsen during exercise and after meals. When possible, acute OH and secondary chronic OH are managed by correction of the underlying condition. Chronic primary OH and irreversible secondary OH are managed with a combination of nondrug and drug therapies.[34] Nonpharmacologic interventions include avoidance of caffeine and alcohol, increased fluid and salt intake, frequent small low-glycemic meals, sleeping with the head of the bed raised, and waist-high stockings or abdominal binders. Pharmacologic management includes mineralocorticoids (e.g., fludrocortisone) and vasoconstrictors (e.g., midodrine, droxidopa). Norepinephrine reuptake inhibitors are being studied.[32]

Aneurysm

An aneurysm is a localized dilation or outpouching of a vessel wall or cardiac chamber. True aneurysms involve weakening in all three layers of the arterial wall (Fig. 32.4A). Most are fusiform and circumferential, whereas *saccular aneurysms* are basically spherical in shape. False aneurysms are an extravascular hematoma that communicates with the intravascular space. A common cause of this type of lesion is a leak between a vascular graft and a natural artery.



True aneurysm: fusiform
True aneurysm: saccular
Adventitia
Tunica media
Tunica intima
Lumen
False aneurysm
Dissecting aneurysm

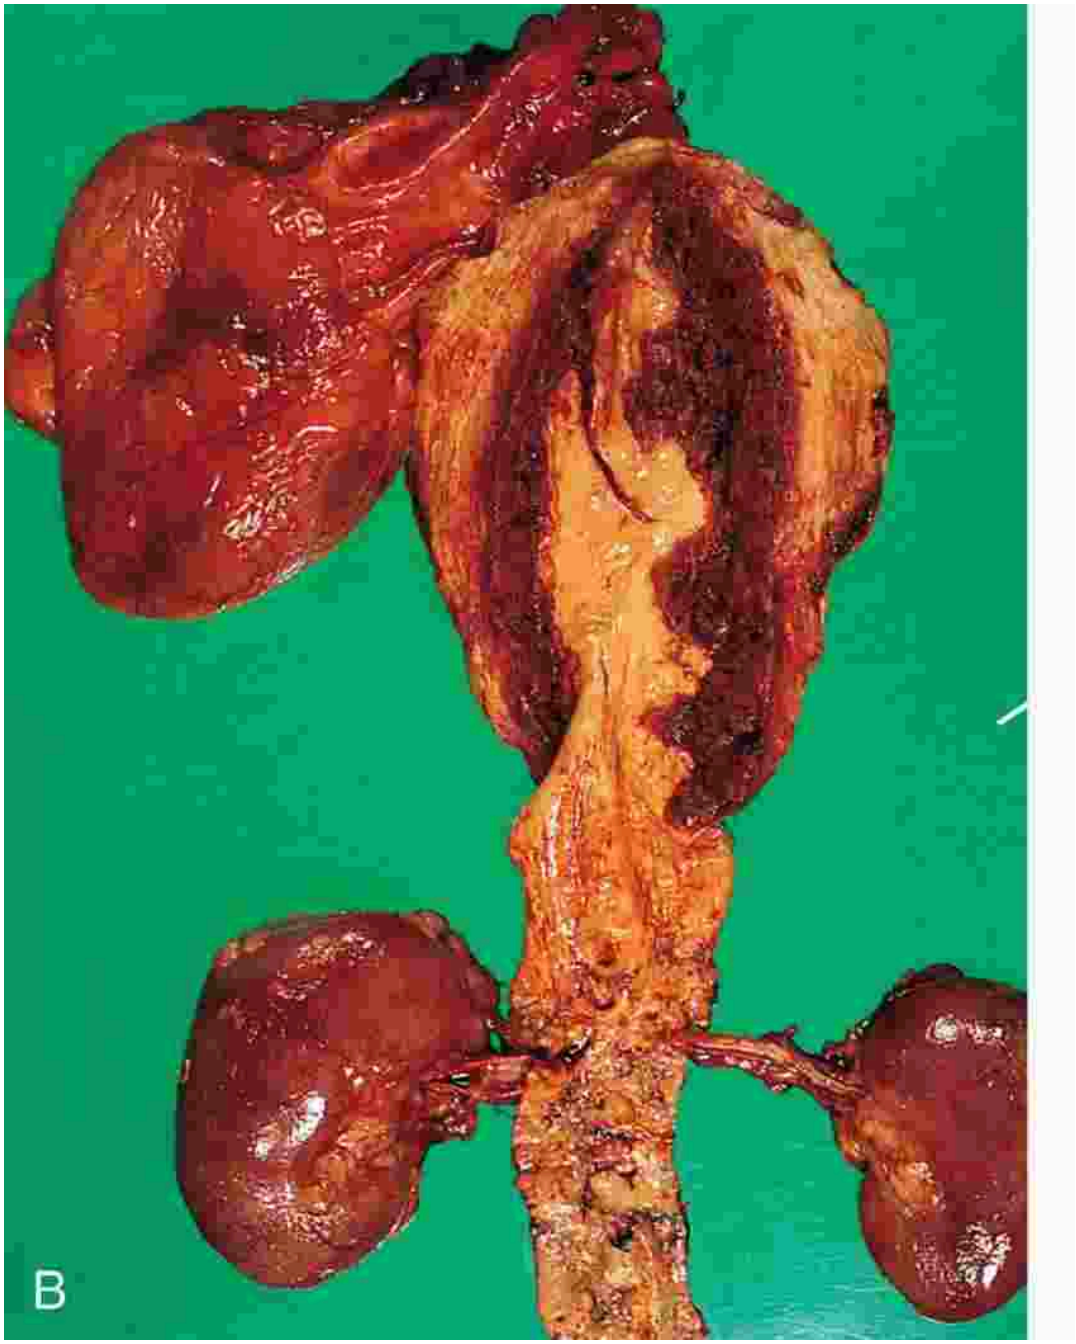

FIG. 32.4 Longitudinal Sections Showing Types of Aneurysms.
(A) True aneurysms are caused by bulging of all three layers of the vessel wall and can be circumferential (fusiform) or can form a bulge on one side of the vessel (saccular). False aneurysms are a collection of clotted blood just outside of the vessel due to a break all the way through the vessel wall, usually caused by trauma. Dissecting aneurysms result from a partial break in the vessel wall such that blood is pushed

between the tunica media and the adventitia. (B) Dissecting aneurysm of thoracic aorta *(arrow)*. (B, From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Left panel, A. True aneurysm: fusiform. Illustration shows labels for adventitia, tunica media, tunica intima, and lumen. Arrows along the inner walls represent the flow. True aneurysm: saccular. Illustration shows bulging of outer three layers on one side. Arrows, representing the flow, are traced along the wall, looping through the bulge, and flowing further down. False aneurysm. Illustration shows formation of clot. Arrows along the center of the longitudinal section represent direction of flow. Part of the flow also enters the clot. Dissecting aneurysm. Illustration shows broken tunica media and tunica intima on one side. Arrows along the center of the longitudinal section represent direction of flow. Part of the flow also enters the broken section. Right panel, B. Specimen of thoracic aorta shows enlarged artery with extra growth of tissue.

Vascular aneurysms most commonly occur in the thoracic or abdominal aorta, and in the cerebrovascular system. Major risk factors for aneurysm formation include hypertension and atherosclerosis. Chronic hypertension results in mechanical and shear forces that contribute to inflammation and remodeling resulting in weakening of the vessel wall. Atherosclerotic plaque formation also causes inflammatory changes that erode the vessel wall. Additional risk factors include gene polymorphisms that are linked to the production of growth factors, myosin, and proteases.[35] Infections, such as syphilis, collagen disorders (such as Marfan syndrome), and traumatic injury to the chest or abdomen, also can cause aortic aneurysms. There are rare inherited syndromes that are characterized by aneurysm formation at an early age.

The aorta is particularly susceptible to aneurysm formation because of constant stress on the vessel wall and the absence of penetrating vasa vasorum in the media layer. Chronic inflammation of the wall of the aorta is considered the primary cause of aortic aneurysms leading to weakening of the intima and medial layers. Neutrophils, macrophages, and T and B lymphocytes enter the

aortic wall, and cytokines produced by these cells cause an inflammatory response. Proteases are released that destroy tissues and contribute to extracellular matrix remodeling, apoptosis and calcification of vascular smooth muscle cells, and decreased wall elasticity.[36] These chronic inflammatory changes are potentiated in individuals with atherosclerosis and hypertension, which are found in more than half of all individuals with aneurysms.

Formation of a cardiac ventricular wall aneurysm most often occurs when intraventricular tension stretches noncontracting infarcted muscle. Acutely infarcted myocardium is characterized by a weak and thin layer of necrotic tissue that bulges with each contraction. With time the aneurysm becomes more fibrotic, but continues to bulge with each systole, thus acting as a "reservoir" and reducing stroke volume.

Clinical manifestations of aneurysms depend on where the aneurysm is located. Aortic aneurysms often are asymptomatic until they rupture and then cause severe pain and hypotension. Thoracic aortic aneurysms can cause dysphagia (difficulty swallowing) and dyspnea (breathlessness). An aneurysm that impairs flow to an extremity causes symptoms of ischemia. Cerebral aneurysms, which often occur in the circle of Willis, are associated with signs and symptoms of increased intracranial pressure and stroke. (Cerebral aneurysms are described in Chapter 18.) Aneurysms in the heart present with dysrhythmias, heart failure, and embolism of clots to the brain or other vital organs.

The diagnosis of an aneurysm is usually confirmed by ultrasonography, CT, MRI, or angiography. Medical treatment for small asymptomatic aortic aneurysms includes cessation of smoking, reduction of blood pressure, and initiation of cholesterol lowering medications (statins) and antiplatelet drugs. None of these treatments can fully prevent the progression of these aneurysms, and their growth must be monitored closely. Potential new medical therapies being explored include the diabetes drug metformin, blockers of specific inflammatory pathways, and stem cells.[36] For aneurysms that are dilating rapidly or have become large, either open or endovascular surgical repair is indicated and usually includes replacement with a prosthetic graft.[37]

Aortic aneurysms can be complicated by the acute aortic syndromes, which include aortic dissection, hemorrhage into the vessel wall, or vessel rupture. Dissection of the layers of the arterial wall occurs when there is a tear in the intima and blood is pushed between the tunica media and the adventitia of the wall of the artery (see Fig. 32.4B). Dissections can involve any part of the aorta (ascending, arch, or descending) and can disrupt flow through arterial branches. Symptoms include severe pain in the neck, jaw, chest, back, or abdomen. Emergent evaluation and surgical intervention are critical. Chest CT

angiography is the diagnostic technique of choice.[38] Surgical intervention is often emergent.

Thrombus Formation in Arteries

As in venous thrombosis, arterial thrombi develops when intravascular conditions promote activation of coagulation or when there is stasis of blood flow. These conditions include those in which there is intimal irritation or roughening (such as in percutaneous or surgical procedures and trauma), inflammation, infection, low intravascular volume and pressures, or obstructions that cause blood stasis and pooling within the vessels. Damage to the endothelium leads to activation of the clotting cascade and platelet adherence. An anatomic change in an artery (such as an aneurysm) can contribute to thrombus formation, particularly if the change results in a pooling of arterial blood. Valvular thrombi are most commonly associated with inflammation of the endocardium (endocarditis) and rheumatic heart disease. Widespread arterial thrombus formation can occur in shock when systemic inflammation activates the intrinsic and extrinsic pathways of coagulation, resulting in microvascular thrombosis throughout the systemic arterial circulation (see Chapter 48).

Arterial thrombi pose two potential threats to the circulation. First, the thrombus may grow large enough to occlude the artery, causing ischemia in tissue supplied by the artery. Second, the thrombus may dislodge, becoming a thromboembolus that travels through the vascular system until it occludes flow into a distal systemic vascular bed.

Diagnosis of arterial thrombi is usually accomplished through the use of Doppler ultrasonography and angiography. Pharmacologic treatment involves the administration of anticoagulants or thrombolytics. A balloon-tipped catheter can be used to remove or compress an arterial thrombus.

Embolism

Embolism is the obstruction of a vessel by an embolus—a bolus of matter circulating in the bloodstream. The embolus may consist of a dislodged thrombus; an air bubble; an aggregate of amniotic fluid; an aggregate of fat, bacteria, or cancer cells; or a foreign substance. The types of emboli are summarized in Table 32.3. Most emboli arise from venous or arterial thrombi and travel in the bloodstream until they reach a vessel through which they cannot pass. Pulmonary emboli originate on the venous system (mostly from the deep veins of the legs) or in the right heart; arterial emboli most commonly originate in the left heart and are associated with thrombus formation

associated with MI, valvular disease, left heart failure, endocarditis, and dysrhythmias.

Table 32.3

Types of Emboli

Type	Characteristics
Arteries	
Arterial thromboembolism	Dislodged thrombus; source is usually from heart; most common sites of obstruction are lower extremities (femoral and popliteal arteries), coronary arteries, and cerebral vasculature
Veins	
Venous thromboembolism	Dislodged thrombus; source is usually from lower extremities; obstructs branches of pulmonary artery
Air embolism	Bolus of air displaces blood in vasculature; source usually room air entering circulation through IV lines; trauma to chest also may allow air from lungs to enter vascular space
Amniotic fluid embolism	Bolus of amniotic fluid; extensive intra-abdominal pressure attending labor and delivery can force amniotic fluid into bloodstream of mother; introduces antigens, cells, and protein aggregates that trigger inflammation, coagulation, and immune responses
Bacterial embolism	Aggregates of bacteria in bloodstream; source is subacute bacterial endocarditis or abscess
Fat embolism	Globules of fat floating in bloodstream associated with trauma to long bones; lungs in particular are affected
Foreign matter	Small particles or fibers introduced during trauma or through an IV or intra-arterial line; coagulation cascade is initiated and thromboemboli form around particles

Embolism causes ischemia or infarction in tissues distal to the obstruction, producing organ dysfunction and pain. Infarction and subsequent necrosis of a central organ are life-threatening. For example, occlusion of a coronary artery will cause an MI whereas occlusion of a cerebral artery causes a stroke (see Chapter 18).

Peripheral Vascular Diseases

Thromboangiitis Obliterans (Buerger Disease)

Thromboangiitis obliterans (Buerger disease) is a highly inflammatory autoimmune disease of the peripheral arteries. It is strongly associated with smoking. Thromboangiitis obliterans is characterized by the formation of thrombi filled with inflammatory and immune cells. Inflammatory cytokines and toxic oxygen free radicals contribute to accompanying vasospasm. Over time, these thrombi become organized and fibrotic and result in permanent occlusion of small- and medium-sized arteries in the feet and sometimes in the hands.

The chief symptom of thromboangiitis obliterans is pain and tenderness of the affected part, usually affecting more than one extremity. Clinical manifestations include rubor (redness of the skin), which is caused by dilated capillaries under the skin, and cyanosis, which is caused by tissue ischemia. Chronic ischemia causes the skin to become thin and shiny and serious ulcers may occur. In advanced disease, profound ischemia of the extremities can cause gangrene necessitating amputation. Thromboangiitis obliterans also has been associated with cerebrovascular disease (stroke), mesenteric disease, and rheumatic symptoms (joint pain).

Diagnosis of thromboangiitis obliterans is made by identification of the following common features—age <45 years, smoking history, evidence of peripheral ischemia—and by exclusion of other causes of arterial insufficiency. The most important part of treatment is cessation of cigarette smoking. Other measures include vasodilators and exercises aimed at improving circulation to the foot or hand. Endovascular procedures can improve outcomes in selected individuals. Stem cell therapy for skin ulcers have been shown to improve healing and symptoms.[39,40]

Raynaud Phenomenon

Raynaud phenomenon (RP) is characterized by attacks of vasospasm in the small arteries and arterioles of the fingers and, less commonly, the toes. Approximately 90% of individuals with RP have primary Raynaud phenomenon, which is a common vasospastic disorder of unknown origin affecting up to 5% of adults.[41] Genetic factors have been implicated. Secondary

Raynaud phenomenon is associated with systemic diseases, particularly collagen vascular disease (progressive systemic sclerosis [scleroderma]), vasculitis, malignancy, pulmonary hypertension, chemotherapy, cocaine use, hypothyroidism, thoracic outlet syndrome, trauma, serum sickness, or long-term exposure to environmental conditions such as cold temperatures or vibrating machinery in the workplace. Blood vessels in affected individuals demonstrate dysfunctional autonomic vascular thermoregulation.[41] In addition, endothelial dysfunction with an imbalance in endothelium-derived vasodilators (e.g., nitric oxide) and vasoconstrictors (e.g., endothelin-1) is seen. Platelet activation also may play a role. It tends to affect young women and is characterized by vasospastic attacks triggered by brief exposure to cold, vibration, or emotional stress. Genetic predisposition may play a role in its development.

The clinical manifestations of the vasospastic attacks of either disorder are changes in skin color and sensation caused by ischemia. Attacks tend to be bilateral, and manifestations usually begin at the tips of the digits and progress to the proximal phalanges. Vasospasm causes pallor, numbness, and the sensation of coldness in the digits. Sluggish blood flow resulting from ischemia may cause the skin to appear cyanotic. Rubor, throbbing pain, and paresthesias follow as blood flow returns. Skin color returns to normal after the attack, but frequent, prolonged attacks interfere with cellular metabolism, causing the skin of the fingertips to thicken and the nails to become brittle. In severe, chronic Raynaud phenomenon, ischemia can eventually cause ulceration and gangrene.

The diagnosis of RP is based on clinical presentation and nailfold capillaroscopy or infrared thermography. A search for underlying secondary causes should be conducted. Treatment of RP begins with avoidance of stimuli that trigger attacks (e.g., cold temperatures, emotional stress) and cessation of cigarette smoking to eliminate the vasoconstricting effects of nicotine. If attacks of vasospasm become frequent or prolonged, vasodilators (e.g., calcium channel blockers, alpha blockers, ACE inhibitors) are administered.[41] Sympathectomy or botulinum injection may be indicated in severe cases.

Atherosclerosis

Arteriosclerosis is a condition characterized by thickening and hardening of the vessel wall. Atherosclerosis is a form of arteriosclerosis that is caused by the accumulation of lipid-laden macrophages within the arterial wall, which leads to the formation of a lesion called a plaque. Atherosclerosis is a pathologic process that can affect vascular systems throughout the body and is the leading cause of peripheral artery disease, CAD, and cerebrovascular disease.

(Atherosclerosis of the coronary arteries is described later in this chapter, and atherosclerosis of the cerebral arteries is described in Chapter 18.)

Pathophysiology

Atherosclerosis is an inflammatory disease that begins with injury to the endothelial cells that line artery walls.[42] Pathologically, the lesions progress from endothelial injury and dysfunction to fatty streak to fibrotic plaque to complicated lesion (Fig. 32.5). Possible causes of endothelial injury include the common risk factors for atherosclerosis, such as smoking, hypertension, diabetes, increased levels of low-density lipoprotein (LDL), decreased levels of high-density lipoprotein (HDL), and autoimmunity. Other "nontraditional" risk factors include increased serum markers for inflammation and thrombosis (e.g., high-sensitivity C-reactive protein [hs-CRP]), troponin I, adipokines, infection, and air pollution. These risk factors are discussed in more detail in the following section on CAD (see the section on Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes).

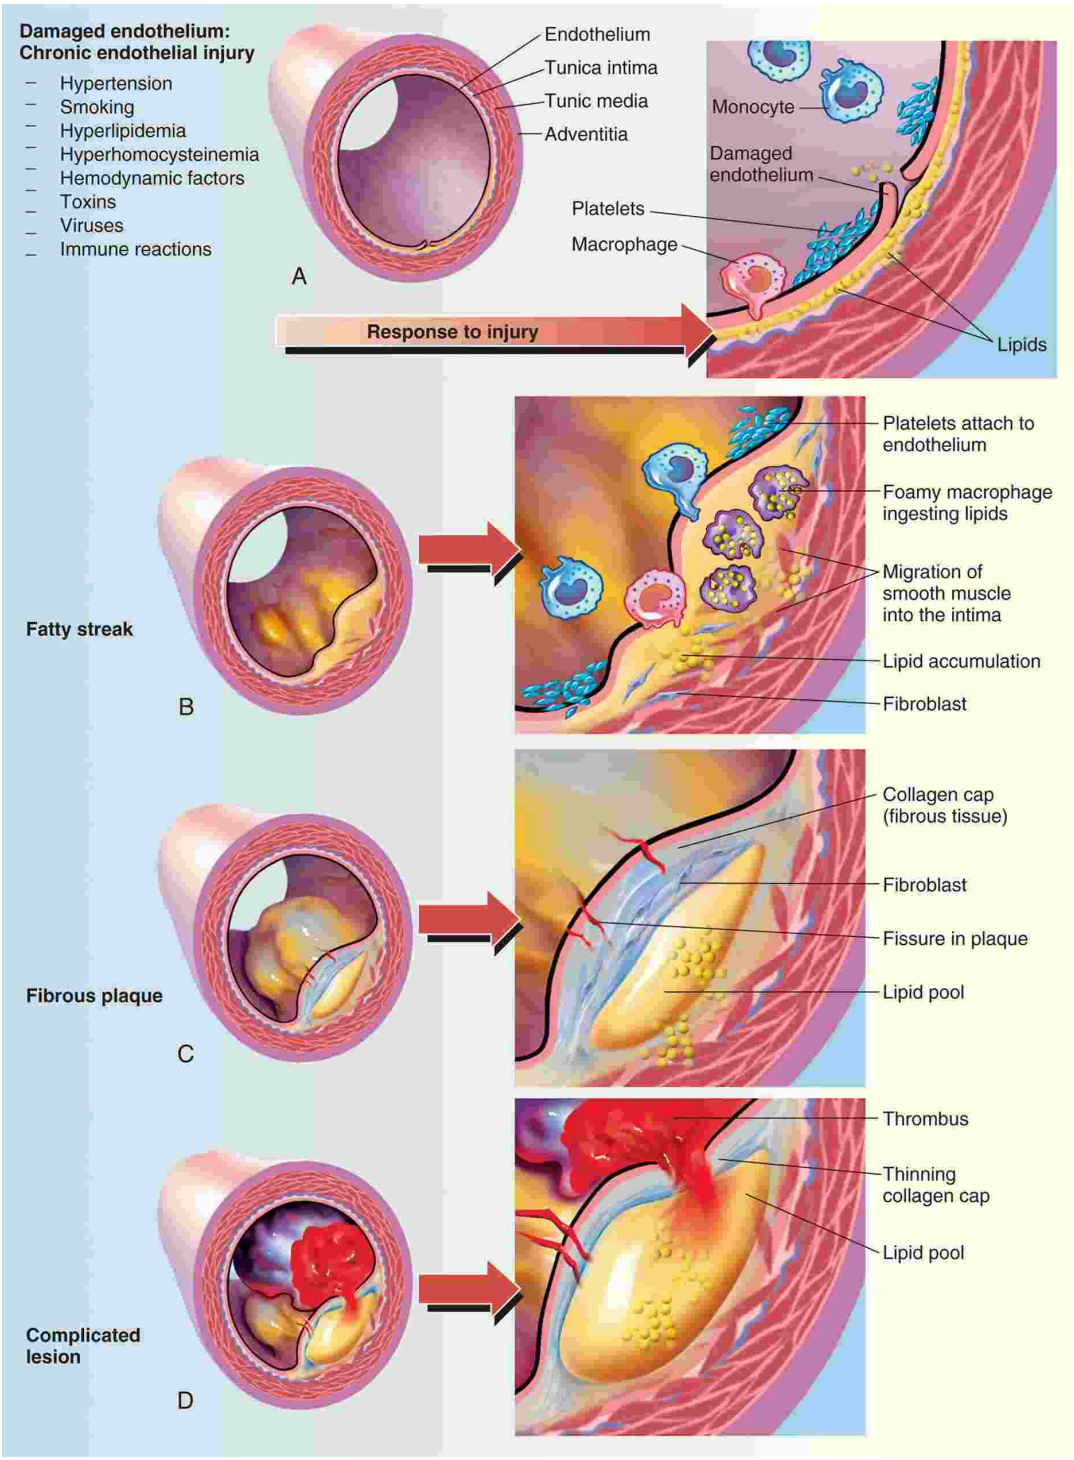

FIG. 32.5 Progression of Atherosclerosis.
(A) Damaged endothelium. (B) Diagram of fatty streak and lipid core formation (see Fig. 32.6 for a diagram of oxidized low-density lipoprotein [LDL]). (C) Diagram of fibrous plaque. Raised plaques are visible: some are yellow; others are white. (D) Diagram of complicated lesion; thrombus is red;

collagen is blue. Plaque is complicated by red thrombus deposition.

Panel a. Illustration of vessel shows labels as follows: endothelium, tunica intima, tunic media, and adventitia. The symptoms of damaged endothelium: chronic endothelial injury are hypertension, smoking, hyperlipidemia, hyperhomocysteinemia, hemodynamic factors, toxins, viruses, and immune reactions. An arrow labeled response to injury points toward a cross-section that shows labels as follows: monocyte, damaged endothelium, platelets, macrophage, and lipids. Panel b. Illustration labeled fatty streak shows buildup of plaque inside endothelium. Cross-section of fatty streak shows labels as follows: platelets attach to endothelium, foamy macrophage ingesting lipids, migration of smooth muscle into the intima, lipid accumulation, and fibroblast. Panel c. Illustration labeled fibrous plaque shows blue and yellow deposits. Cross-section of fibrous plaque shows labels as follows: collagen cap (fibrous tissue), fibroblast, fissure in plaque, and lipid pool. Panel d. Illustration labeled complicated lesion shows build-up of plaque and blood clot. Cross-section of complicated lesion shows labels as follows: thrombus, thinning collagen cap, and lipid pool.

Injured endothelial cells become inflamed. Inflamed endothelial cells cannot make normal amounts of antithrombic and vasodilating cytokines and express adhesion molecules that bind macrophages and other inflammatory and immune cells (Fig. 32.6). Macrophages release numerous inflammatory cytokines (e.g., tumor necrosis factor-alpha [TNF-α], interferons, interleukins, C-reactive protein) and enzymes that further injure the vessel wall.[43] Toxic oxygen free radicals generated by the inflammatory process cause oxidation (i.e., addition of oxygen) of LDL that has accumulated in the vessel intima. Oxidized LDL causes additional adhesion molecule expression with the

recruitment of monocytes that differentiate into macrophages. These macrophages penetrate into the intima, where they engulf oxidized LDL, and are then called foam cells. When they accumulate in significant amounts, they form a lesion called a fatty streak (see Figs. 32.6 and 32.7). Once formed, fatty streaks produce more toxic oxygen free radicals, and secrete additional inflammatory mediators resulting in progressive damage to the vessel wall. In addition, oxidized LDL and foam cells serve as damage-associated molecular patterns (DAMPs; see Chapter 7) and activate macrophage release of inflammatory cytokines and recruit autoreactive T cells leading to autoimmune vascular injury.[44–46] Selected lipid lowering and antihypertensive medications may improve atherosclerotic disease progression through their antiinflammatory effects (see Emerging Science Box: Lipid-Lowering and Antihypertensive Medication Effects on Atherosclerosis-Associated Inflammation). Increasing understanding of the pivotal role of inflammation and autoimmunity in the pathogenesis of atherosclerosis has led to significant research into potential antiinflammatory treatments.[42,47]

Emerging Science BoxLipid-Lowering and Antihypertensive Medication Effects on Atherosclerosis-Associated Inflammation

Atherosclerosis and coronary artery disease are the result of chronic inflammatory and immune processes involving the vessel wall. The use of several types of lipid-lowering and antihypertensive drugs is associated with a decreased risk for coronary artery disease and associated ischemic events. There is increasing evidence that the positive effects of these medications are related not only to their lowering of serum lipid levels or blood pressure, but also to their antiinflammatory effects within the vasculature. The most widely used lipid lowering medications are the HMG-CoA reductase inhibitors, which are collectively referred to as statins. Statins not only decrease LDL synthesis, but also have multiple other effects including improved nitric oxide production by the vascular endothelium, inhibition of smooth muscle cell proliferation, decreased T cell activation, decreased vascular inflammation, and decreased C-reactive protein levels in the serum. Statins also have been shown to contribute to fibrotic and calcific stabilization of plaques, thus reducing their likelihood for rupture. Treatment with the proprotein convertase subtilisin/Kexin Type 9 (PCSK9) antibodies inhibits degradation of the LDL receptor and thus lowers serum LDL. In addition, this drug inhibits macrophage uptake of oxidized LDL thus reducing foam cell formation, and inhibits activation of the inflammatory nuclear factor kappa B (NF-κB). The antihypertensive medications angiotensin converting enzyme (ACE)

inhibitors suppress autoreactive T lymphocytes and lower levels of interleukin 6. Beta blockers decrease production of toxic oxygen radicals by neutrophils and decrease the number of activated macrophages. Successful treatment specifically targeting inflammation in atherosclerotic coronary artery disease has been achieved with blockade of interleukin 1 beta (IL-1β) by canakinumab, a human monoclonal IL-1β antibody. Canakinumab reduces cardiovascular events and mortality in individuals who have a history of myocardial infarction and an elevated C-reactive protein. However, individuals treated with canakinumab have an increased risk for serious infection. Agonists of CD (cluster of differentiation) 31—a molecule expressed by inflammatory cells—has been found to promote the healing of injured arteries in animals. Attempts to advance vaccination strategies to modulate the adaptive immune component of atherogenesis are underway. Modulation of the gut microbiome to reduce systemic inflammation provides another approach to the prevention and treatment of atherosclerosis. Many other antiinflammatory treatments for atherosclerosis and coronary artery disease are being researched.

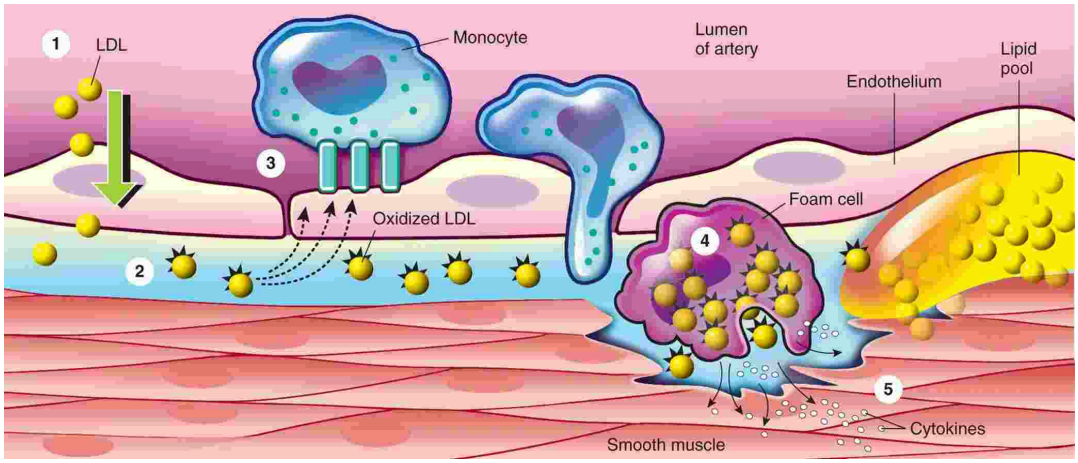

FIG. 32.6 Low-Density Lipoprotein Oxidation.
(1) Low-density lipoprotein *(LDL)* enters the arterial intima through an intact endothelium. *(2)* In hypercholesterolemia, the influx of LDL exceeds the eliminating capacity and an extracellular pool of LDL is formed. *(3)* Intimal LDL oxidized through the action of free oxygen radicals generates proinflammatory cytokines that induce endothelial expression of the adhesion molecules. Monocytes bind to the adhesion molecules and differentiate into macrophages, which then *(4)* internalize oxidized LDL and become foam cells. *(5)* Foam cells accumulate forming a fatty streak and release many inflammatory cytokines that damage the vessel wall. (Modified from Crawford MH, Dim Arco JP, Paulus WJ. *Cardiology*, 3rd edition. London: Mosby; 2010.)

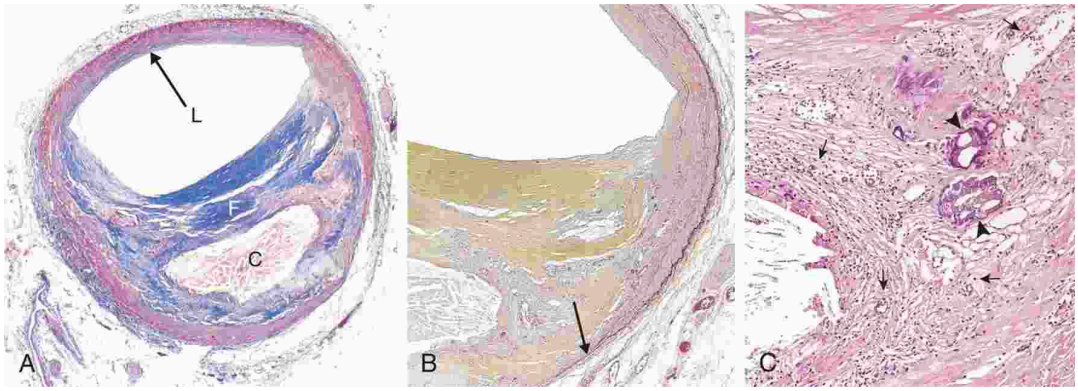

FIG. 32.7 Histologic Features of Atheromatous Plaque in the Coronary Artery.
(A) Overall architecture demonstrating fibrous cap *(F)* and a central necrotic (largely lipid) core *(C)*. The lumen (*L*) has been moderately narrowed. Note that a segment of the wall is plaque free *(arrow)*, so that there is an eccentric lesion. In this section, collagen has been stained blue (Masson trichrome stain). (B) Higher power photograph of a section of the plaque shown in (A) stained for elastin *(black)*, demonstrating that the internal and external elastic membranes are destroyed and the media of the artery is thinned under the most advanced plaque *(arrow)*. (C) Higher magnification photomicrograph at the junction of the fibrous cap and core, showing scattered inflammatory cells, calcification *(arrowhead)*, and neovascularization *(small arrows)*. (From Kumar V, Abbas A, Aster J. *Robbins basic pathology*, 9th edition. St. Louis: Saunders; 2007.)

Macrophages also release growth factors that stimulate smooth muscle cell proliferation. Smooth muscle cells in the region of endothelial injury proliferate, produce collagen, and migrate over the fatty streak, forming an atherosclerotic plaque (see Fig. 32.7).[48] The plaque may calcify, protrude into the vessel lumen, and obstruct blood flow to distal tissues (especially during exercise), which may cause symptoms (e.g., angina or intermittent claudication).

Many plaques are "unstable," meaning they are prone to rupture. These plaques are clinically silent and do not affect luminal blood flow significantly until they erode and rupture (see the section on Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes). Rupture of unstable plaques occurs due to the degradative effects of inflammatory cytokines and enzymes, wall stress, and neurohumoral changes.[49] Plaques that have ruptured are called complicated plaques. Once rupture occurs, exposure of underlying

tissue results in platelet adhesion, initiation of the clotting cascade, and rapid thrombus formation. The thrombus may suddenly occlude the affected vessel, resulting in ischemia and infarction. Aspirin or other antithrombotic agents are used to prevent this complication of atherosclerotic disease.

Clinical Manifestations

Atherosclerosis presents with symptoms and signs that result from inadequate perfusion of tissues because of obstruction of the vessels that supply them. Partial vessel obstruction may lead to transient ischemic events, often associated with exercise or stress. As the lesion becomes complicated, increasing obstruction with superimposed thrombosis may result in tissue infarction. Obstruction of peripheral arteries can cause significant pain and disability. CAD caused by atherosclerosis is the major cause of myocardial ischemia. Atherosclerotic obstruction of the vessels supplying the brain is the major cause of stroke. Often, more than one vessel will become involved with this disease process such that an individual may present with symptoms from several ischemic tissues at the same time, and disease in one area may indicate that the individual is at risk for ischemic complications elsewhere.

Evaluation and Treatment

In evaluating individuals for the presence of atherosclerosis, obtaining a complete health history (including risk factors and symptoms of ischemia) is essential. Physical examination may reveal arterial bruits and evidence of decreased blood flow to tissues. Laboratory data that include measurements of levels of lipids, blood glucose, and hs-CRP are also indicated. Judicious use of x-ray films, electrocardiography, ultrasonography, nuclear scanning, CT, MRI, and angiography may be necessary to identify affected vessels, particularly coronary vessels.

Current management of atherosclerosis is focused on detection and treatment of preclinical lesions with drugs aimed at stabilizing and reversing plaques before they rupture. Once a lesion obstructs blood flow, the primary goal in the management of atherosclerosis is to restore adequate blood flow to the affected tissues. If an individual has presented with acute ischemia (e.g., MI, stroke), interventions are specific to the diseased area (discussed further under those topics). In situations in which the disease process does not require immediate intervention, management focuses on reduction of risk factors and prevention of plaque progression. This includes implementation of an exercise program, cessation of smoking, and control of contributing factors such as hypertension, diabetes, and dyslipidemia. Management of atherosclerotic risk factors is discussed further in the Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes section.

Peripheral Artery Disease

Peripheral artery disease (PAD) refers to atherosclerotic disease of arteries that perfuse the limbs, especially the lower extremities. PAD affects an estimated 6.5 million Americans aged > 40 years.[12] The risk factors for PAD are the same as those previously described for atherosclerosis. It is especially prevalent in smokers and older adults with diabetes.

Lower extremity ischemia resulting from arterial obstruction in PAD can be gradual or acute. In most individuals, gradually increasing atherosclerotic changes in arterial walls is associated with endothelial cell dysfunction, decreases in endogenous vasodilators such as endothelin -1, and the tendency for thrombosis.[50] This leads to obstruction to arterial blood flow and exercise-related ischemia. In the iliofemoral vessels, this may result in leg pain with ambulation called intermittent claudication. If a thrombus forms over the atherosclerotic lesion, complete obstruction of blood flow can occur acutely, causing severe pain, loss of pulses, and skin color changes in the affected extremity. Critical limb ischemia may lead to gangrene.

Evaluation for PAD requires a careful history and physical examination that focuses on finding evidence of atherosclerotic disease (e.g., bruits), determining a difference in blood pressure measured at the ankle versus the arm (ankle-brachial index), and measuring blood flow using duplex ultrasound, CT angiography, or magnetic resonance angiography. Treatment begins with risk factor reduction including smoking cessation, exercise, diabetes and hypertension management, and treatment for dyslipidemia.[50] Symptomatic PAD should be managed with vasodilators in combination with antiplatelet medications. Newer vasodilators such as cilostazol and anticoagulants such as rivaroxaban may be indicated.[51,52] If acute or refractory symptoms occur, emergent invasive catheterization followed by percutaneous or surgical revascularization may be needed.

Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes

Coronary artery disease (CAD) caused by atherosclerosis is the primary cause of heart disease in the United States. CAD can diminish the myocardial blood supply until deprivation impairs myocardial metabolism enough to cause myocardial ischemia, a local state in which the cells are temporarily deprived of blood supply. The cells remain alive but cannot function normally. Persistent ischemia or the complete occlusion of a coronary artery causes the acute coronary syndromes, including MI *(heart attack)*.

Development of Coronary Artery Disease

An estimated 20.1 million Americans have coronary heart disease, which constitutes a prevalence of 7.2% in adults over 20 years of age and 22% to 34% in those over 80. In 2018, coronary heart disease was the leading cause of death attributable to cardiovascular disease in the United States, with mortality reaching over 365,000 deaths.[12] Risk factors for CAD are the same as those for atherosclerosis and can be categorized as conventional (major) versus nontraditional (novel) and as modifiable versus nonmodifiable. Conventional or major risk factors for CAD that are nonmodifiable include (1) advanced age, (2) male sex or women after menopause, and (3) family history. Aging and menopause are associated with increased exposure to risk factors and poor endothelial healing. Family history may contribute to CAD through genetics and shared environmental exposures. Modifiable major risks include (1) dyslipidemia, (2) hypertension, (3) cigarette smoking, (4) diabetes and insulin resistance, (5) obesity, (6) sedentary lifestyle, and (7) atherogenic diet. Fortunately, modification of these factors can dramatically reduce the risk for CAD.

Genes

An individual's risk of developing CAD and MI is impacted by both genetic and lifestyle factors. Recent studies have identified 37 genes that are likely causal for CAD.[53] Inheritance of genetic risks for dyslipidemia, diabetes, hypertension, and other risk factors is common. Epigenetic patterns are affected by the environment and can modulate gene expression. For example, dietary changes can alter the expression of genes related to dyslipidemia and the development of atherosclerotic lesions.[54]

Dyslipidemia

Using data from 2015-2018, it is estimated that over 90 million, or 38 %, of American adults have dyslipidemia.[12] The link between CAD and abnormal levels of lipoproteins is well documented. The term lipoprotein refers to lipids, phospholipids, cholesterol, and triglycerides bound to carrier proteins. The cycle of lipoprotein synthesis is complex. Dietary fat is packaged into particles known as chylomicrons in the small intestine. Chylomicrons primarily contain triglycerides. Some of the triglycerides may be removed and either stored by adipose tissue or used by muscle as an energy source. The chylomicron remnants, composed mainly of cholesterol, are taken up by the liver. A series of chemical reactions in the liver results in the production of several lipoproteins that vary in density and function. These include very-low-density lipoproteins (VLDLs) composed primarily of triglycerides and protein; LDLs, composed

mostly of cholesterol and protein; and HDLs, composed mainly of phospholipids and protein. Although lipoproteins are necessary for many physiologic functions, they can accumulate in abnormal amounts in the serum.

Dyslipidemia (or dyslipoproteinemia) refers to abnormal concentrations of serum lipoproteins as defined by the Third Report of the National Cholesterol Education Program.[55] (Table 32.4). These abnormalities are the result of a combination of genetic and dietary factors. Primary or familial dyslipoproteinemias result from genetic defects that cause abnormalities in lipid-metabolizing enzymes and abnormal cellular lipid receptors.[56] Secondary causes of dyslipidemia include the existence of several common systemic disorders, such as diabetes, hypothyroidism, pancreatitis, and renal nephrosis, as well as the use of certain medications, such as some diuretics, glucocorticoids, interferons, and antiretrovirals.

Table 32.4

Criteria for Dyslipidemia[a]

	Optimal	Near-Optimal	Desirable	Low	Borderline	High	Very High
Total cholesterol			<200		200–239	≥240	
Low-density lipoprotein	<100	100–129			130–159	160-189	≥190
Triglycerides			<150		150–199	200-499	≥500
High-density lipoprotein				<40		≥60	

[a]All units are milligrams per deciliter.

Data from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. Executive summary of the third report of the National Cholesterol Education Program (NCEP) expert panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III). *JAMA*. 2001;285:2486–2497.

LDL is responsible for the delivery of cholesterol to the tissues, and an increased serum concentration of LDL is a strong indicator of coronary risk.

Serum levels of LDL are normally controlled by hepatic receptors that bind LDL and limit liver synthesis of this lipoprotein. Genetic predisposition to dyslipidemias, in combination with a high dietary intake of saturated fats, result in excess amounts of LDL in the bloodstream. Excess LDL migration into the vessel wall, oxidation, and phagocytosis by macrophages are key steps in the pathogenesis of atherosclerosis (see Fig. 32.6). LDL also plays a role in endothelial injury, inflammation, and immune responses that have been identified as being important in atherogenesis. The term *LDL* actually describes several types of LDL molecules. Measurement of LDL subfractions allows for a better prediction of coronary risk. For example, LDL-C and apolipoprotein B (structural protein found in both LDL and VLDL) measurements allow for the detection of the small, dense LDL particles that are the most atherogenic. Guidelines from the American Heart Association and the American College of Cardiology focus on treating dyslipidemia in the context of other risk factors.[57] Diet and medication are the mainstays of treatment for elevated LDL. The most commonly used medications are the 3-hydroxy-3-methyl-glutaryl-CoA reductase medications (statins); however, side effects limit their use in some individuals. New medications, such as the proprotein convertase subtilisin/kexin 9 (PCKS9) inhibitors, also effectively lower LDL. Lipid-lowering medications may have other beneficial effects on the vasculature (see Emerging Science Box: Lipid-Lowering and Antihypertensive Medication Effects on Atherosclerosis-Associated Inflammation).

Low levels of HDL cholesterol are an indicator of increased coronary risk, whereas high levels of HDL are associated with a significant reduction in coronary risk independent of age, smoking history, LDL levels, blood pressure, or weight.[58] HDL is responsible for "reverse cholesterol transport," which returns excess cholesterol from the tissues to the liver for processing or elimination in the bile. HDL also participates in endothelial repair and decreases thrombosis. It can be fractionated into several particle densities (HDL-2 and HDL-3) that have different effects on vascular function. Exercise, weight loss, fish oil consumption, and moderate alcohol use result in modest increases in HDL level. Pharmacologic interventions to increase HDL levels have largely been ineffective in reducing CAD risk.[59] Recent studies suggest that it is not only the serum levels of HDL that are key to determining CAD risk, but rather HDL functionality, which is harder to measure.[60] One approach is measurement of the cholesterol efflux capacity (an indirect measure of reverse cholesterol transport) which has been found to be inversely associated with atherosclerotic risk.[61]

Other lipoproteins associated with increased cardiovascular risk include elevated levels of serum VLDLs (triglycerides) and increased lipoprotein(a)

levels. Triglycerides are associated with an increased risk for CAD, especially in combination with other risk factors such as diabetes. Lipoprotein(a) (Lp[a]) is a genetically determined molecular complex between LDL and a serum glycoprotein called apolipoprotein A and has been shown to be an important risk factor for atherosclerosis, especially in women. Lipoprotein(a) potentially contributes to cardiovascular disease through proatherogenic, proinflammatory, and prothrombotic effects.[62] Emerging therapies targeting elevated levels of Lp(a) may improve the management of individuals with CAD.[63]

Hypertension

Hypertension is responsible for a two- to threefold increased risk of atherosclerotic cardiovascular disease. It contributes to endothelial injury, a key step in atherogenesis. It also can cause myocardial hypertrophy, which increases myocardial demand for coronary flow (see Algorithm 32.2). Overactivity of the RAAS commonly found in hypertension also contributes to the genesis of atherosclerosis, and treatment of hypertension with medications that block the RAAS reduces CAD risk.

Cigarette smoking

Both direct and passive (environmental) smoking increase the risk of CAD. Smoking has a direct effect on endothelial cells and the generation of oxygen free radicals that contribute to atherogenesis. Nicotine stimulates the release of catecholamines (epinephrine and norepinephrine), which increase heart rate and peripheral vascular constriction. As a result, blood pressure increases, as do cardiac workload and oxygen demand. Cigarette smoking is associated with an increase in LDL levels and a decrease in HDL levels. The risk of CAD increases with heavy smoking and decreases when smoking is stopped.

Diabetes mellitus

Insulin resistance and diabetes mellitus are extremely important risk factors for CAD (see Chapter 22). Type 2 diabetes is associated with chronic vascular inflammation resulting from hyperglycemia, insulin resistance, and elevated levels of circulating insulin. Insulin resistance and diabetes have multiple effects on the cardiovascular system, including damage to the endothelium, thickening of the vessel wall, increased thrombosis, glycation of vascular proteins, and decreased production of endothelial-derived vasodilators, such as nitric oxide. Diabetes also is associated with dyslipidemia. Good diabetic control is linked to reduced risk for CAD.[64]

Obesity/adipokines/sedentary lifestyle

A sedentary lifestyle not only increases the risk of obesity but also has an independent effect on increasing CAD risk. Abdominal obesity has a strong link with increased CAD risk and is related to inflammation, insulin resistance, decreased HDL level, and increased blood pressure. Adipokines are a group of hormones released from adipose cells. Obesity causes increased levels of leptin and decreased levels of adiponectin that are associated with inflammation, endothelial injury, and thrombosis. Obesity-related changes in adipokines have been linked to hypertension, diabetes, and heart failure, as well as CAD. Excessive accumulation of perivascular adipose tissue leads to the paracrine release of vasoconstrictors and growth factors which have deleterious effects on vascular smooth muscle endothelial cells.[65] Perivascular fat tissue also affects local adipokine levels (especially leptin), as well as releases proinflammatory signals and promotes atherosclerotic plaque formation.[66,67] Weight loss, exercise, and healthy diet improve adipokine levels. Bariatric surgery procedures, such as gastric bypass, can provide sustained improvement in risk factors for cardiovascular disease, such as hypertension, dyslipidemia, and diabetes in selected individuals.[68,69]

Atherogenic diet

Diet plays a complex role in atherogenic risk. Diets high in salt, fats, trans-fats, and carbohydrates all have been implicated. There are many recommendations regarding diet modification to reduce coronary risk; one of the most effective is called the Mediterranean diet.

The traditional Mediterranean diet is characterized by a high intake of olive oil, fruits, nuts, vegetables, and cereals; moderate intake of fish and poultry; low intake of dairy products, red meat, processed meats, and sweets; and moderate intake of wine consumed with meals. The beneficial effects of the Mediterranean diet are hypothesized to include modulation of many different biologic components of cardiovascular health such as epigenetic control of genes associated with cardiovascular risk, modification of the gut microbiome, antiinflammatory and immune effects, and improvement in metabolic factors such as glucose tolerance and lipid metabolism. Dietary guidance to improve cardiovascular health had been published by the American Heart Association.[70]

Nontraditional risk factors

Nontraditional risk factors for CAD have been identified that can help with clinical decision-making about how best to manage individuals who also have established CAD or significant traditional risk factors.

Markers of inflammation and ischemia

Of the numerous markers of inflammation that have been linked to an increase in CAD risk, high-sensitivity C-reactive protein (hs-CRP) is the most important clinically. hs-CRP is a protein synthesized in the liver and is used as an indirect measure of atherosclerotic plaque–related inflammation. The primary use of hs-CRP is as an aid to decision-making about pharmacologic interventions for individuals with other risk factors for coronary disease.

Troponin I (TnI) is a serum protein whose measurement is used as a sensitive and specific diagnostic test to help identify myocardial injury during acute coronary syndromes. Highly sensitive TnI assays are used in individuals without a history of CAD to assess risk for future CHD events, mortality, and heart failure.

Chronic kidney disease

In individuals with chronic kidney disease (CKD), a decline in glomerular filtration rate is associated with an increasing risk for CAD. CKD is associated with dyslipidemia, endothelial injury, and vascular calcification, which contribute to atherogenesis.

Air pollution and ionizing radiation

Exposure to air pollution, especially roadway exposures, is strongly correlated with coronary risk. Fine particulate matter is the major cardiovascular risk component of air pollution and is considered the most important risk factor contributing to global cardiovascular mortality.[71] It is postulated that toxins in pollution contribute to macrophage activation, oxidation of LDL, thrombosis, and inflammation of vessel walls. Exposure to even low levels of ionizing radiation also has been linked to increased risk for CAD. Reducing exposure to air pollutants can reduce cardiovascular risk.[72]

Medications

Medications may contribute to CAD through their effect on lipid metabolism (e.g., protease inhibitors, diuretics, antirejection medications), clotting (e.g., estrogens and progesterones), or other effects on vascular function and tone. Nonsteroidal antiinflammatory drugs (NSAIDs) are linked to an increase in CAD-related ischemic events that can occur within weeks of beginning their use.[73] Likely mechanisms include increases in toxic oxygen radicals, vasoconstrictors, and thrombosis.

The microbiome

The microbiome is increasingly being recognized for its influence on cardiovascular disease risk. The impact of the microbiome on atherogenesis is likely related to its effects on underlying risk factors, as well as its role in

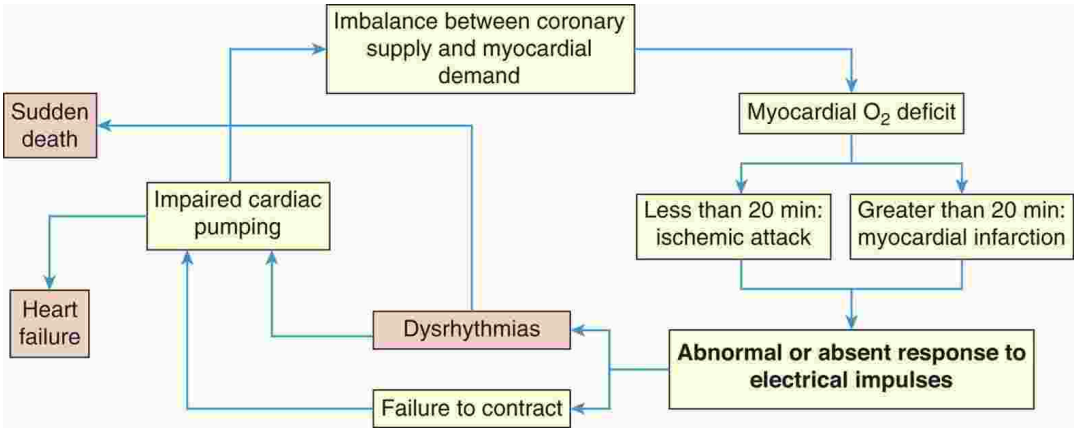
modulating innate and adaptive immunity. Differences in the composition of the microbiome between those with CAD and healthy individuals have been documented. Changes in the microbiome have been found to have significant effects on the development of traditional risk factors for cardiovascular disease, such as diabetes and obesity. The identification of microbiota-controlled metabolites, such as trimethylamine N-oxide (TMAO), is shedding light on the link between diet and these risk factors.[74,75]

Transient Myocardial Ischemia

As described previously, CAD can diminish the myocardial blood supply causing ischemia. The process of atherosclerotic plaque progression can be gradual, which usually results in transient myocardial ischemic syndromes when demand for blood supply exceeds supply, but perfusion is restored before there is permanent damage to the heart muscle. Ischemia also can occur with coronary vasospasm even in the absence of atherosclerosis.

Pathophysiology

Myocardial ischemia develops if the flow or oxygen content of coronary blood is insufficient to meet the metabolic demands of myocardial cells (Algorithm. 32.3). Imbalances between coronary blood supply and myocardial demand can result from a number of conditions. The most common cause of decreased coronary blood flow and resultant myocardial ischemia is the formation of atherosclerotic plaques in the coronary circulation (CAD). As the plaque increases in size, it may partially occlude the vessel lumen, thus limiting coronary flow and causing ischemia especially during exercise. While these large plaques are often considered "stable," individuals with chronic atherosclerotic changes are still at risk for adverse events. Myocardial ischemia also can result from other causes of decreased blood and oxygen delivery to the myocardium, such as coronary spasm, hypotension, dysrhythmias, and decreased oxygen-carrying capacity of the blood (e.g., anemia, hypoxemia). Common causes of increased myocardial demand for blood include tachycardia, exercise, hypertension (hypertrophy), and valvular disease.



ALGORITHM 32.3 Cycle of Myocardial Ischemic Events. Factors that decrease coronary artery blood flow (e.g., atherosclerosis) or increase demand for myocardial blood supply (e.g., exercise) cause myocardial ischemia. Both transient and prolonged ischemia can cause abnormal or absent myocyte responses to electrical impulses through the myocardium leading to dysrhythmias or decreased contractility. Decreased ability of the heart to pump blood results in heart failure and decreased coronary perfusion, further compromising the supply of blood to the heart. Dysrhythmias may also lead to sudden death.

A flowchart shows the cycle of myocardial ischemic events. 1. Imbalance between coronary supply and myocardial demand. Leads to 2. 2. Myocardial oxygen deficit. Leads to 3 or 4. 3. Less than 20 minutes: ischemic attack. Leads to 5. 4. Greater than 20 minutes: myocardial infraction. Leads to 5. 5. Abnormal or absent response to electrical impulses. Leads to 6 or 7. 6. Dysrhythmias. Leads to 8 or 10. 7. Failure to contract. Leads to 8. 8. Impaired cardiac pumping. Leads to 1 or 9. 9. Heart failure. 10. Sudden death.

Factors that decrease coronary artery blood flow (e.g., atherosclerosis) or increase demand for myocardial blood supply (e.g., exercise) cause myocardial ischemia. Both transient and prolonged ischemia can cause abnormal or absent myocyte responses to electrical impulses through the myocardium leading to dysrhythmias or decreased contractility. Decreased ability of the heart to pump

blood results in heart failure and contributes to decreased coronary perfusion, further compromising the supply of blood to the heart. Dysrhythmias also may lead to sudden death.

Myocardial cells become ischemic within 10 seconds of coronary occlusion, thus hampering pump function and depriving the myocardium of a glucose source necessary for aerobic metabolism. Anaerobic processes take over, and lactic acid accumulates. After several minutes, the heart cells lose the ability to contract and cardiac output decreases. Cardiac cells remain viable for approximately 20 minutes under ischemic conditions. If blood flow is restored, aerobic metabolism resumes, contractility is restored, and cellular repair begins. If perfusion is not restored, myocardial infarction occurs.

Individuals with transient myocardial ischemia present clinically in several ways. Chronic coronary obstruction results in recurrent predictable chest pain called *stable angina*. Abnormal vasospasm of coronary vessels results in unpredictable chest pain called *vasospastic (Prinzmetal) angina*. Myocardial ischemia that does not cause detectable symptoms is called *silent ischemia*.

Stable angina pectoris

Angina is chest pain caused by myocardial ischemia. Atherosclerotic plaques partially obstruct coronary vessels, and affected vessels cannot dilate in response to increased myocardial demand associated with physical exertion or emotional stress. In stable angina pectoris, blood flow is restored with rest and the administration of nitrates, and necrosis of myocardial cells does not occur. The pain of stable angina is caused by the buildup of lactic acid or abnormal stretching of the ischemic myocardium that irritates myocardial nerve fibers. These afferent sympathetic fibers enter the spinal cord from levels C3 to T4, accounting for a variety of locations and radiation patterns of anginal pain. Discomfort may radiate to the neck, lower jaw, left arm, and left shoulder, or occasionally to the back or down the right arm.

Stable angina is typically experienced as transient substernal chest discomfort, ranging from a sensation of heaviness or pressure to moderately severe pain. Individuals often describe the sensation by clenching a fist over the left sternal border. The discomfort may be mistaken for indigestion. Pallor, diaphoresis, and dyspnea may be associated with the pain. Guidelines for the acute evaluation of chest pain recommend a careful symptom history and physical examination followed by diagnostic testing to include ECG, chest radiography, and measurement of serum biomarkers such as troponins.[76]

Many individuals with reversible myocardial ischemia will have a normal physical examination between events. Physical examination of those experiencing myocardial ischemia may disclose rapid pulse rate or extra heart sounds (gallops or murmurs), and pulmonary congestion indicating impaired

left ventricular function. The presence of xanthelasmas (small fat deposits) around the eyelids or arcus senilis of the eyes (a yellow lipid ring around the cornea) suggests severe dyslipidemia and possible atherosclerosis. The presence of peripheral or carotid artery bruits suggests probable atherosclerotic disease and increases the likelihood that CAD is present. Electrocardiography detects distortion of electrical impulses across ischemic myocardium, and can be conducted during exercise stress testing to detect ischemic changes associated with stable angina. Transient ST segment depression and T wave inversion are characteristic signs of stable angina involving the endocardium, although ST elevation indicative of ischemia involving the full myocardial wall (transmural ischemia) may occur (Fig. 32.8). Serum troponin levels remain within normal limits. Stress radionucleotide imaging with single-photon emission computerized tomography (SPECT) is effective at identifying ischemia and estimating coronary risk. Other noninvasive tests for evaluating coronary atherosclerotic lesions include stress echocardiography and coronary CT angiography.[77]

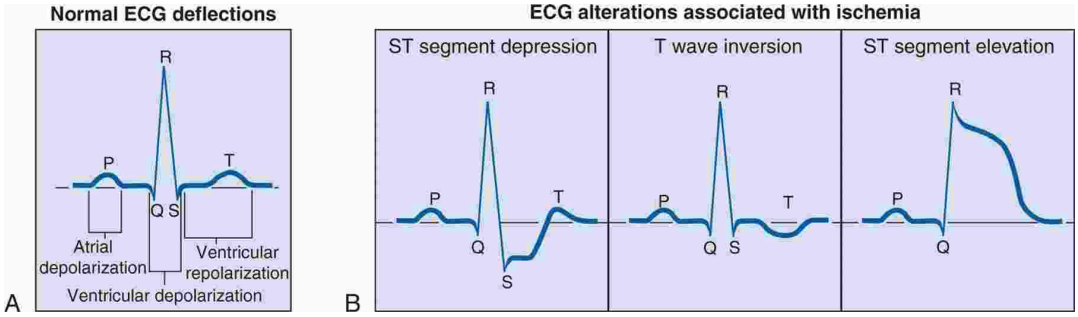


FIG. 32.8 Electrocardiogram *(ECG)* and Ischemia.
(A) Normal ECG. (B) Electrocardiographic alterations associated with ischemia.

Left panel, A. Electrocardiogram labeled normal E C G deflections shows gentle peak labeled P and atrial depolarization, followed by a sharp and tall peak, marked R. The area under Q R S is labeled ventricular depolarization. It is followed by another gentle peak labeled T. Area from S to T is labeled ventricular repolarization. Right panel, B. Electrocardiogram labeled E C G alterations associated with ischemia is as follows: S T segment depression: It shows sharp and tall peak labeled R and depression at S. T wave inversion shows trough labeled T. S T segment elevation shows curve reaches at height labeled R, followed by fluctuations while sloping down.

The primary aims of therapy for myocardial ischemia and stable angina are to increase coronary blood flow, reduce myocardial oxygen consumption, and to reduce the risk for adverse cardiovascular events such as myocardial infarction. Coronary blood flow is improved by reversing vasoconstriction, reducing plaque growth and rupture, and preventing clotting. Myocardial oxygen demand is reduced by manipulation of blood pressure, heart rate, contractility, and left ventricular volume. Several classes of drugs are useful for increasing coronary flow and decreasing myocardial demand, especially nitrates, β-blockers, calcium channel blockers, and sodium ion channel inhibitors (e.g., nicorandil).[77] Antiplatelet medications are used to prevent thrombus formation. Percutaneous coronary intervention (PCI) is a procedure in which stenotic (narrowed) coronary vessels are dilated with a catheter. The use of PCI for

stable angina may be associated with improvements in symptoms but does not reduce the risk for future MI or death.[78] Severe CAD also can be surgically treated by a coronary artery bypass graft (CABG), usually using the saphenous vein from the lower leg.[77,79]

Primary prevention of CAD is key to improving morbidity and mortality in those with stable angina. Primary prevention refers to reduction in CAD risk factors before the occurrence of a major ischemic event such as myocardial infarction, whereas secondary prevention refers to risk reduction after such an event. Primary prevention rests on the calculation of 10-year atherosclerotic cardiovascular disease risk, followed by the development of a comprehensive plan for lifestyle change to include exercise and dietary modifications.[80] Antihypertensive and lipid lowering medications should be prescribed as indicated by current guidelines.[27,28,57] In those individuals with diabetes, metformin, sodium-glucose cotransporter 2 (SGLT2) inhibitors, or a glucagon-like peptide-1 receptor agonist are recommended along with diet and exercise.[80]

It is estimated that half of women with stable angina do not have obstructive CAD, but rather have "microvascular angina," which results from vasoconstriction of small coronary arterioles deep in the myocardium. This form of myocardial ischemia may present with atypical chest pain, palpitations, sense of unease, and severe fatigue rather than typical angina; thus many women with this disorder are misdiagnosed. Small intramyocardial arterioles constrict in MVA due to endothelial dysfunction, decreased endogenous vasodilators, inflammation, changes in adipokines, and platelet activation. Evaluation for microvascular angina relies upon transthoracic Doppler echocardiography and positron emission tomography. The combination of calcium channel blockers or sodium ion channel inhibitors with statins has been shown to be effective in many women.[81]

Vasospastic (Prinzmetal) angina

Vasospastic angina is chest pain attributable to transient ischemia of the myocardium that occurs unpredictably and often at rest. Pain is caused by vasospasm of one or more major coronary arteries and can occur in those with or without coronary artery disease. The spasm may involve the large epicardial coronary arteries, or may occur in the microvasculature. Vasospasm may result from coronary smooth muscle hypercontractility, decreased vagal activity, endothelial dysfunction, magnesium deficiency, inflammation, oxidative stress, and hyperactivity of the SNS.[82] It can be triggered by hyperventilation, mental stress, smoking, alcohol, use of stimulants, or rapid eye movement sleep. Hypokalemia worsens symptoms and outcomes.[83] Vasospastic angina is diagnosed by matching clinical manifestations with documented transient

ischemic changes on ECG. In some individuals, confirmation with coronary angiography combined with administration of a provocative agent (e.g., ergonovine) is needed. Management includes avoidance of triggers and the use of calcium channel blockers or nitrates. Although vasospastic angina is usually a benign condition, it can cause dysrhythmias and infarction, especially in those who also have atherosclerotic coronary lesions.[84]

Another form of vasospastic myocardial ischemia without coronary artery disease is called Takotsubo syndrome (TTS). TTS occurs primarily in postmenopausal women during mental or physical stress and is associated with acute transient heart failure. It is believed to be the result of increased catecholamine levels coupled with increased adrenergic receptor density and sensitivity in the myocardium.[85] It is usually reversible but can cause significant morbidity and mortality (see Emerging Science Box: Takotsubo Syndrome).

Emerging Science BoxTakotsubo Syndrome

Takotsubo syndrome (TTS) is an acute reversible heart failure syndrome associated with acute myocardial ischemia but without obstruction of coronary arteries. TTS usually is preceded by emotional or physical stress and occurs most commonly in postmenopausal women. It occurs in up to 2% of those presenting with suspected acute coronary syndrome. The pathophysiology of TTS includes increased density and sensitivity of adrenergic receptors coupled with a stress-induced catecholamine surge. Direct myocardial toxicity to high levels of adrenergic stimulation plus increased myocardial workload and coronary microvascular vasospasm cause acute ischemia. Inflammation with increased levels of interleukins has also been documented. The diagnosis rests on acute transient myocardial hypokinesis without evidence of epicardial coronary artery disease. There are transient ischemic changes seen on ECG along with modest increases in troponins. Echocardiography typically demonstrates ventricular apical ballooning that extends beyond the distribution of a single coronary artery. MRI may show ventricular dysfunction and edema in a noncoronary regional distribution pattern. Management includes beta blockers such as levosimendan and mechanical circulatory support. TTS carries substantial mortality due to arrhythmias, acute heart failure, cardiogenic shock, cardiac arrest, and thromboembolic events.

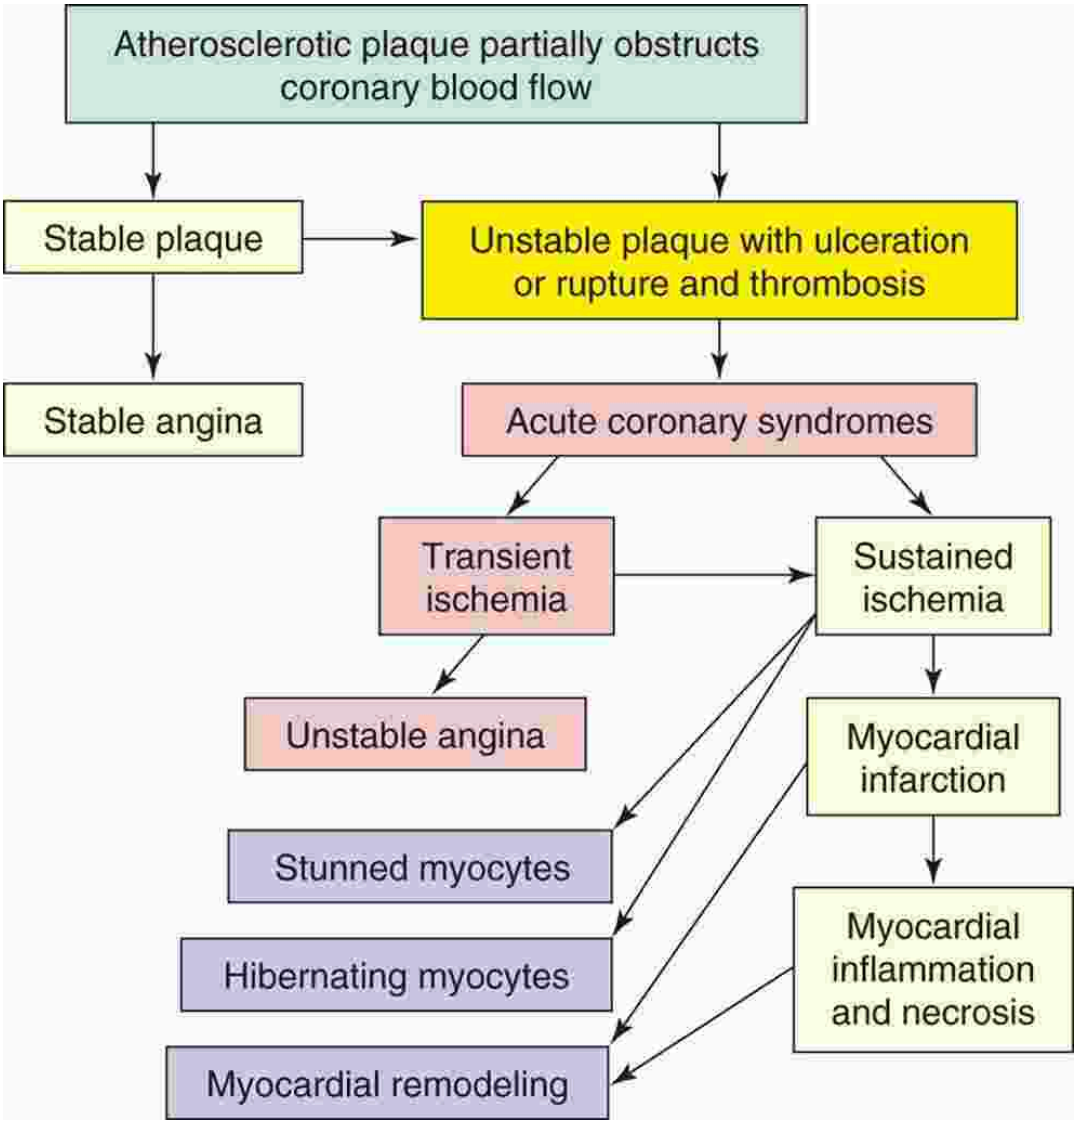
Silent ischemia

Silent ischemia is myocardial ischemia that does not cause detectable symptoms such as angina. Ischemia can be totally asymptomatic, or individuals may complain of fatigue, dyspnea, or a feeling of unease. It is believed to be more common than symptomatic angina.[86] The primary cause of silent ischemia is abnormalities in autonomic innervation, most commonly associated with diabetes mellitus. Other causes include surgical denervation during CABG or cardiac transplantation. Also of interest is silent ischemia occurring in some individuals during mental stress. Chronic stress has been linked to an increase in inflammatory cytokines and a hypercoagulable state that may contribute to acute ischemic events (see Chapter 11). Detection and management of silent ischemia is important because it may be an indicator of future serious cardiovascular events. Treatment is based on the degree of ischemia and the extent of underlying coronary disease.[86]

Acute Coronary Syndromes

The process of atherosclerotic plaque progression can be gradual. However, when there is sudden coronary obstruction caused by thrombus formation over a ruptured atherosclerotic plaque, the acute coronary syndromes result (Algorithm 32.4). Unstable angina is a form of acute coronary syndrome that is a harbinger of impending infarction. Myocardial infarction (MI) results when there is prolonged ischemia causing irreversible damage to the heart muscle. MI can be further subdivided into non-ST elevation MI (non-STEMI) and ST elevation MI (STEMI). Sudden cardiac death can occur as a result of any of the acute coronary syndromes.



ALGORITHM 32.4 Pathophysiology of Acute Coronary Syndromes.

The atherosclerotic process can lead to stable plaque formation and stable angina or can result in unstable plaques that are prone to rupture and thrombus. Thrombus formation on a ruptured plaque that disperses in less than 20 minutes leads to transient ischemia and unstable angina. If the vessel obstruction is sustained, myocardial infarction (MI) with inflammation and necrosis of the myocardium results. In addition, MI is associated with other structural and functional changes, including myocyte stunning and hibernation and myocardial remodeling.

A flowchart shows the pathophysiology of acute coronary syndromes. 1. Atherosclerotic plaque partially obstructs coronary blood flow. Leads to 2 and 12. 2. Unstable plaque with ulceration or rupture and thrombosis. Leads to 3. 3. Acute coronary syndromes. Leads to 4 and 5. 4. Transient ischemia. Leads to 5 and 6. 5. Sustained ischemia. Leads to 7, 8, and 10. 6. Unstable angina. 7. Stunned myocytes. 8. Hibernating myocytes. 9. Myocardial remodeling. 10. Myocardial infarction. Leads to 9 and 11. 11. Myocardial inflammation and necrosis. 12. Stable plaque. Leads to 2 and 13. 13. Stable angina.

An unstable atherosclerotic plaque has a core that is especially rich in deposited oxidized LDL, has a thin fibrous cap, and is prone to rupture (Fig. 32.9). Calcification of these plaques further destabilizes them.[87] These unstable plaques may not extend into the lumen of the vessel and may be clinically silent until they rupture. New methods are emerging for detecting unstable plaques before they rupture, thus identifying those individuals at highest risk for acute coronary syndromes.[88] Plaque rupture occurs because of the effects of shear forces, inflammation with release of multiple inflammatory mediators, secretion of neutrophil- and macrophage-derived degradative enzymes, and apoptosis of cells at the edges of the lesions.[44] Exposure of the plaque substrate activates the clotting cascade. The resulting thrombus can form very quickly (Fig. 32.10A). Vessel obstruction is further exacerbated by the release of vasoconstrictors, such as thromboxane A_2 and endothelin. The thrombus may dissolve when only minimal myocyte damage has occurred (unstable angina), or it may persist causing prolonged ischemia with infarction of the heart muscle (MI) (see Fig. 32.10B).

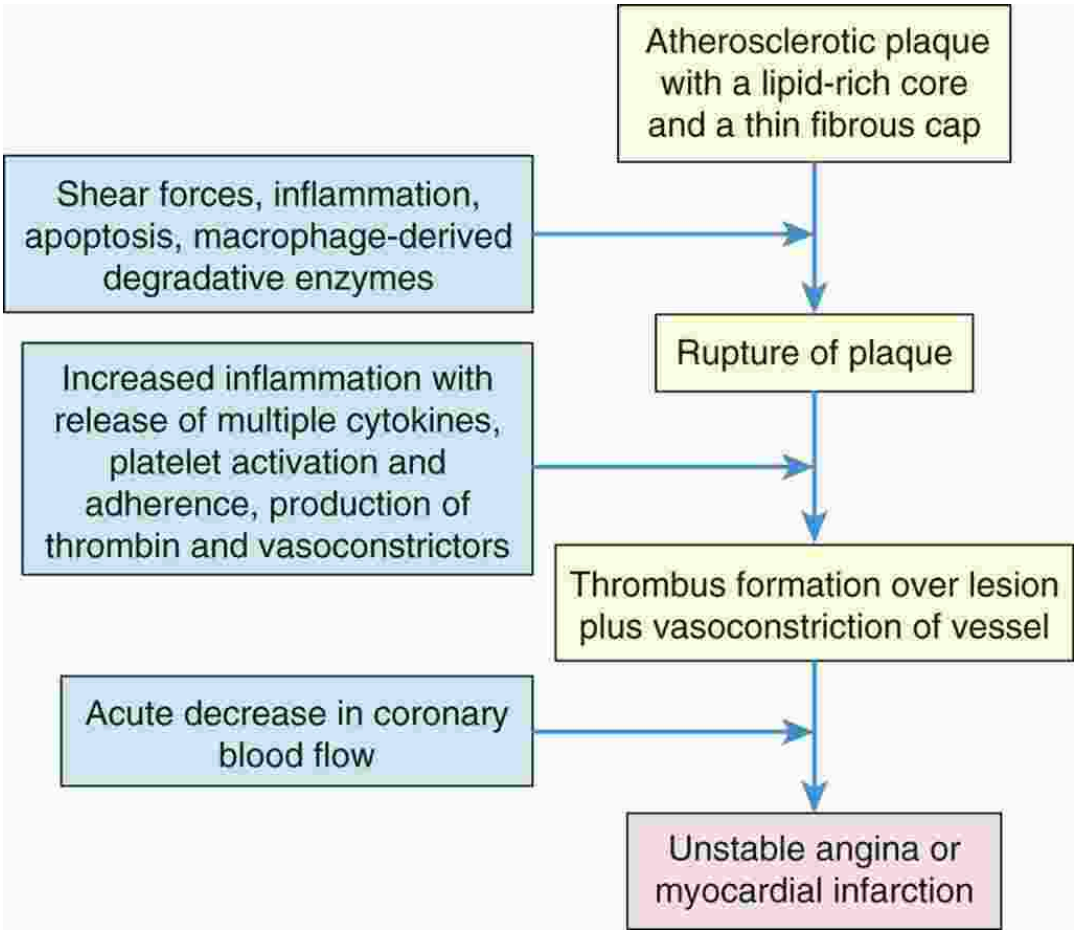


FIG. 32.9 Pathogenesis of Unstable Plaques and Thrombus Formation.

A flowchart represents the pathogenesis of unstable plaques and thrombus formation. 1. Atherosclerotic plaque with a lipid-rich core and a thin fibrous cap. Leads to 3. 2. Shear forces, inflammation, apoptosis, macrophage-derived degradative enzymes. Leads to 3. 3. Rupture of plaque. Leads to 5. 4. Increased inflammation with release of multiple cytokines, platelet activation and adherence, production of thrombin and vasoconstrictors. Leads to 5. 5. Thrombus formation over lesion plus vasoconstriction of vessel. Leads to 7. 6. Acute decrease in coronary blood. Leads to 7. 7. Unstable angina or myocardial infarction.

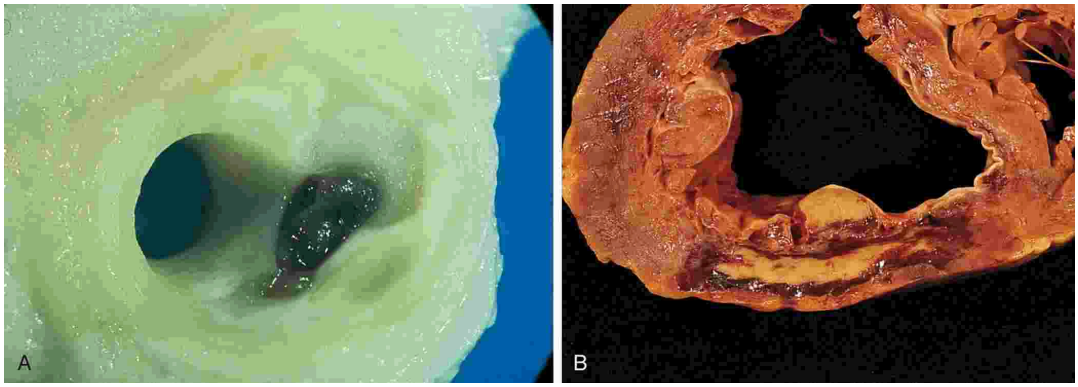

FIG. 32.10 Plaque Disruption and Myocardial Infarction. (A) Plaque disruption. The cap of the lipid-rich plaque has become torn, with the formation of a thrombus, mostly inside the plaque. (B) Myocardial infarction. This infarct is 6 days old. The center is yellow and necrotic with a hemorrhagic red rim. The responsible arterial occlusion is probably in the right coronary artery. The infarct is on the posterior wall. (From Damjanov I, Linder J, eds. *Anderson's pathology*, 10th edition. St. Louis: Mosby; 1996.)

Unstable angina

Unstable angina was once considered a separate type of acute coronary syndrome characterized by reversible myocardial ischemia and the absence of myocardial cell injury. However, the use of highly sensitive measurements of myocardial damage (hs-troponin I) has resulted in the recognition that most individuals with unstable angina do have some myocardial damage. Therefore, unstable angina is the first step in a progressive spectrum of ischemia-related myocardial injury and now is grouped under the classification of non-ST elevation acute coronary syndromes. It is important to recognize this syndrome because it signals that the atherosclerotic plaque has begun to rupture and infarction may soon follow. Unstable angina occurs when a fairly small fissuring or superficial erosion of the plaque leads to transient episodes of thrombotic vessel occlusion and vasoconstriction at the site of plaque damage. This thrombus is labile and occludes the vessel for no more than 10 to 20 minutes, with return of perfusion before large amounts of myocardial necrosis occurs. Unstable angina presents as new-onset angina, angina that is occurring at rest, or angina that is increasing in severity or frequency. Individuals may experience increased dyspnea, diaphoresis, and anxiety as the angina worsens. Physical examination may reveal evidence of ischemic myocardial dysfunction such as pulmonary congestion. The ECG most commonly shows ST segment depression and T wave inversion during pain that

resolve as the pain is relieved. Serum levels of hs-troponin I are often slightly increased. Management of unstable angina requires immediate hospitalization with administration of nitrates and antithrombotics (e.g., aspirin, clopidogrel, abciximab, eptifibatide). Anticoagulants, such as low-molecular-weight heparin (enoxaparin), bivalirudin, or fondaparinux, are also given.[89,90] Beta-blockers, calcium channel blockers, and ACE inhibitors also may be used. Choices are based on symptoms, underlying conditions, and planned interventions. Lipid lowering medications such as statins should be administered. Rapid intervention with PCI also may be indicated if the individual's condition is refractory to medical treatment.[89,90]

Myocardial infarction

When coronary blood flow is interrupted for an extended period, infarction with myocyte necrosis occurs. This results in MI. Plaque progression, disruption, and subsequent clot formation are the same for MI as they are for unstable angina (see Algorithm 32.4 and Figs. 32.9 and 32.10). In this case, however, the thrombus is less labile and occludes the vessel for a prolonged period, such that myocardial ischemia progresses to myocyte necrosis and death. Pathologically, there are two major types of MI: subendocardial infarction and transmural infarction. Clinically, however, MI is categorized as non-ST segment elevation MI (non-STEMI) or ST segment elevation MI (STEMI).

If the thrombus disintegrates before complete distal tissue necrosis has occurred, the infarction will involve only the myocardium directly beneath the endocardium (subendocardial MI) (Fig. 32.11). This type of infarction usually will present with ST segment depression and T wave inversion without ST elevation; therefore, it is termed non-STEMI. It is important to recognize this form of acute coronary syndrome because recurrent clot formation on the disrupted atherosclerotic plaque is likely. If the thrombus lodges permanently in the vessel, the infarction will extend through the myocardium all the way from endocardium to epicardium (transmural MI), resulting in severe cardiac dysfunction (see Fig. 32.11). Transmural myocardial infarction usually will result in ST segment elevation on ECG, so it is called STEMI. Clinically, it is important to identify individuals with STEMI because they are at highest risk for serious complications and should receive definitive intervention without delay.

Pathophysiology

After 8 to 10 seconds of decreased blood flow, myocardial oxygen reserves are used quickly. Glycogen stores decrease as anaerobic metabolism begins. Unfortunately, glycolysis can supply only 65% to 70% of the total myocardial energy requirement and produces much less adenosine triphosphate (ATP) than aerobic processes. Hydrogen ions and lactic acid accumulate, making the myocardium more vulnerable to the damaging effects of lysosomal enzymes and may suppress impulse conduction and contractile function, thereby leading to heart failure.

Oxygen deprivation also is accompanied by electrolyte disturbances, specifically the loss of potassium, calcium, and magnesium from cells. Myocardial cells deprived of necessary oxygen and nutrients lose contractility, thereby diminishing the pumping ability of the heart. Ischemia causes the myocardial cells to release catecholamines, predisposing the individual to serious imbalances of sympathetic and parasympathetic function, irregular heartbeats (dysrhythmia), and heart failure. Catecholamines cause an increase in plasma concentrations of free fatty acids and glycerol, which can have a harmful detergent effect on cell membranes. Norepinephrine elevates blood glucose levels, which also contributes to myocardial dysfunction. Ang II is released during myocardial ischemia and causes peripheral vasoconstriction, coronary spasm, and fluid retention. It also is a growth factor for vascular smooth muscle cells, myocytes, and cardiac fibroblasts, resulting in structural changes in the myocardium called remodeling. Infiltration of inflammatory cells further contributes to tissue injury.

MI results in both structural and functional changes of cardiac tissues (Fig. 32.12). Cardiac cells can withstand ischemic conditions for about 20 minutes before irreversible hypoxic injury causes cellular death (apoptosis) and myocardial infarction. Gross tissue changes at the area of infarction may not become apparent for several hours, despite almost immediate onset (within 30 to 60 seconds) of electrocardiographic changes. Myocyte injury and necrosis result in the release of intracellular enzymes, such as creatine phosphokinase-myocardial bound (CPK-MB), and myocyte proteins, such as the troponins, through the damaged cell membranes into the interstitial spaces. The lymphatics absorb the enzymes and transport them into the bloodstream, where they can be detected by serologic tests.

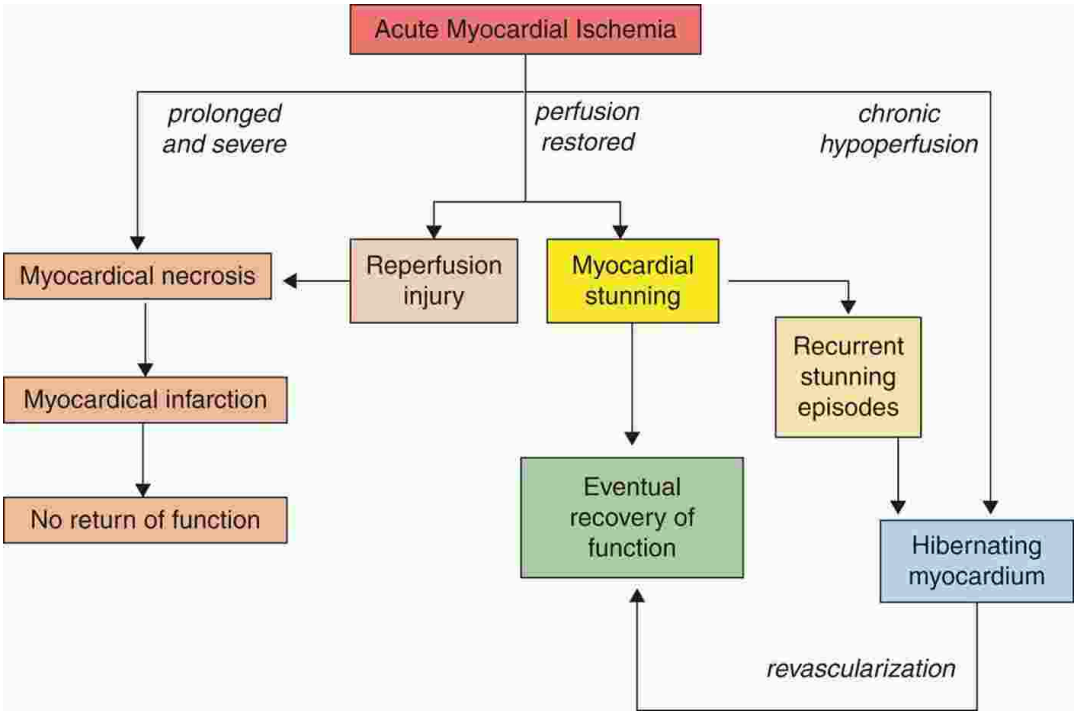

FIG. 32.12 Structural and Functional Changes Associated With Acute Myocardial Ischemia.
Acute myocardial ischemia can result in prolonged and severe hypoperfusion, reperfusion, or chronic hypoperfusion. As a result, an acute coronary syndrome may be characterized by infarction, reperfusion injury, stunning, or hibernating myocardium. Recovery of function is not possible once myocardial tissue is necrosed, however stunned and hibernating myocardium may regain function after days, weeks, or even months, especially after appropriate revascularization procedures. (Adapted from Kloner RA. Stunned and hibernating myocardium: Where are we nearly 4 decades later? *Journal of the American Heart Association*, 2020;9:e015502.)

A flowchart shows the structural and functional changes associated with acute myocardial ischemia. 1. Acute Myocardial ischemia. If prolonged and severe, leads to 2. If perfusion is restored, leads to 5 and 6. If chronic hypoperfusion, leads to 9. 2. Myocardial necrosis. Leads to 3. 3. Myocardial infraction. Leads to 4. 4. No return of function. 5. Reperfusion injury. Leads to 2. 6. Myocardial stunning.

Leads to 7 and 8. 7. Recurrent stunning episodes. Leads to 9. 8. Eventual recovery of function. 9. Hibernating myocardium. If revascularization, leads to 8.

Although restoration of blood flow is crucial to reducing infarct size, reperfusion of the ischemic myocardium triggers a process called reperfusion injury which can contribute as much as 50% to the overall infarct size (see Fig. 32.12).[91] Reperfusion injury involves the release of toxic oxygen free radicals, calcium flux, and pH changes that cause a sustained opening of mitochondrial permeability transition pores (mPTPs) and contribute to resultant cellular death. Ischemia and reperfusion also cause damage to the coronary circulation through endothelial injury, platelet activation, inflammation, and vasoconstriction.[92] Many studies are exploring ways to reduce the extent of injury in ischemia and reperfusion injury during myocardial infarction (see Emerging Science Box: Cardioprotection Therapies for Myocardial Infarction and Reperfusion Injury).

Emerging Science BoxCardioprotection Therapies for Myocardial Infarction and Reperfusion Injury

Outcomes for individuals with myocardial ischemia and infarction have greatly improved through advances in the speed and efficacy of reperfusion strategies such as emergent percutaneous coronary interventions and thrombolytic medications. However, these reperfusion efforts cannot fully reverse established myocardial damage, and may contribute to infarct size through reperfusion injury. Numerous studies are exploring emerging therapies that may provide cardioprotection and reduce the extent of myocardial injury during and after ischemic events. For example, therapeutic angiogenesis using growth factors and progenitor cells has been shown to revascularize ischemic heart tissue. Techniques such as ischemic preconditioning promote neural pathways that have beneficial effects on myocyte resilience and function. Antiinflammatory and anti-immune therapeutics are also being explored. Stem cell approaches are of particular interest to researchers. These approaches include the intracoronary, intravenous, or intramuscular infusion of bone marrow, embryonic, mesenchymal, or cardiac stem cells. More recently, stem cell sheets are being created that are monolayers of stem cells that preserve cell-cell contact and their extracellular matrix resulting in enhanced effectiveness. To date, early animal and a few human clinical trials have shown that stem cell therapy is safe and has the potential to significantly improve cardiac function after myocardial infarction. Many further studies are underway.

Cardiac tissue surrounding the area of necrosed tissue in myocardial infarction also undergoes changes. Myocardial stunning is a temporary loss of contractile function that persists for hours to days after perfusion has been restored (see Fig. 32.12). This pathophysiologic state can occur both after MI and in individuals who suffer ischemia during cardiovascular procedures or during CNS trauma. Stunning is caused by the alterations in electrolyte pumps and calcium homeostasis and by the release of toxic oxygen free radicals and contributes to heart failure, shock, and dysrhythmias.[93] Numerous interventions to limit the amount of stunning are being explored. Hibernating myocardium describes tissue that is persistently ischemic and undergoes metabolic adaptation to prolong myocyte survival until perfusion can be restored. Cardiomyocytes undergo downregulation of calcium-handling and mitochondrial proteins and upregulation of survival and stress proteins.[93] PCI or surgery aimed at reperfusion of hibernating myocardium can restore significant cardiac function (see Fig. 32.12).

Myocardial remodeling is a process that causes myocyte hypertrophy and loss of contractile function in the areas of the heart distant from the site of infarction. It can occur over days, weeks, and months after an acute ischemic event.[94] It is mediated by Ang II, aldosterone, catecholamines, adenosine, and inflammatory cytokines. It contributes to long-term myocardial dysfunction and heart failure. Remodeling can be limited through rapid restoration of coronary flow and the use of renin-angiotensin-aldosterone blockers and β-blockers after MI.

The severity of functional impairment depends on the size of the lesion and the site of infarction. Functional changes can include (1) decreased cardiac

contractility with abnormal wall motion, (2) altered left ventricular compliance, (3) decreased stroke volume and ejection fraction, (4) increased left ventricular end-diastolic pressure (LVEDP), and (5) sinoatrial (SA) node malfunction. Life-threatening dysrhythmias and heart failure often follow MI.

With infarction, ventricular function is abnormal and the EF falls, resulting in increases in ventricular end-diastolic volume (VEDV). If the coronary obstruction involves the perfusion to the left ventricle, pulmonary venous congestion ensues; if the right ventricle is ischemic, increases in systemic venous pressures occur.

MI causes a severe inflammatory response that ends with wound repair (see Chapter 6).[95] Damaged cells undergo degradation, fibroblasts proliferate, and scar tissue is synthesized. Within 24 hours, leukocytes infiltrate the necrotic area, and proteolytic enzymes released from scavenger neutrophils degrade the necrotic tissue. Macrophages remove dead cells and secrete growth factors which help repair myocardial injury.[96] The collagen matrix that is deposited is initially weak, mushy, and vulnerable to reinjury. Unfortunately, it is at this time in the recovery period (10 to 14 days after infarction) that individuals feel more like increasing activities and may stress the newly formed scar tissue. After 6 weeks, the necrotic area is completely replaced by scar tissue, which is strong but cannot contract and relax like healthy myocardial tissue. These cellular and extracellular matrix changes contribute to sustained functional impairment of the heart often resulting in heart failure. Recent studies have shown that cardiac stem cells have regenerative capacity, and stem cell therapy may be a novel approach for cardiac muscle repair and regeneration (see Emerging Science Box: Cardioprotection Therapies for Myocardial Infarction and Reperfusion Injury).[97]

Clinical Manifestations

The first symptom of acute MI is usually sudden, severe chest pain. The pain is similar to that of angina pectoris but more severe and prolonged. It may be described as heavy and crushing, such as a "truck sitting on my chest." Radiation to the neck, jaw, back, shoulder, or left arm is common. Some individuals, especially those who are older or have diabetes, experience no pain, thus having a "silent" infarction. Infarction often simulates a sensation of unrelenting indigestion. Nausea and vomiting may occur because of reflex stimulation of vomiting centers by pain fibers. Vasovagal reflexes from the area of the infarcted myocardium also may affect the gastrointestinal tract.

Various cardiovascular changes are found on physical examination:

1. The SNS is reflexively activated to compensate, resulting in a temporary increase in heart rate and blood pressure.

2. Abnormal extra heart sounds reflect left ventricular dysfunction.
3. Pulmonary findings of congestion, including dullness to percussion and inspiratory crackles at the lung bases, can occur if the individual develops heart failure.
4. Peripheral vasoconstriction may cause the skin to become cool and clammy.

The number and severity of postinfarction complications depend on the location and extent of necrosis, the individual's physiologic condition before the infarction, and the availability of swift therapeutic intervention. Table 32.5 lists the most common complications of MI. Sudden cardiac death can occur in individuals with myocardial ischemia even if infarction is absent or minimal. Risk factors for sudden death are related to an interaction among three factors: ischemia, left ventricular dysfunction, and electrical instability.

Table 32.5

Complications of Myocardial Infarction

Type	Characteristics
Dysrhythmias	Caused by alterations of impulse conduction because of ischemia and electrolyte disturbances; sudden onset of tachycardia or bradycardia, palpitations, syncope, shock, or sudden death
Left ventricular failure	Characterized by pulmonary congestion, reduced myocardial contractility, and abnormal heart wall motion; cardiogenic shock may develop
Pericarditis	Inflammation of the pericardium associated with anterior chest pain that worsens with respiratory effort and pericardial friction rub; occurs 2–3 days after infarction
Dressler postinfarction syndrome	Delayed form of pericarditis that occurs 1 week to several months after acute myocardial infarction and thought to be immunologic response to necrotic myocardium; marked by pain, fever, friction rub, pleural effusion, and arthralgias
Organic brain syndrome	Occurs if blood flow to brain is impaired
Rupture of chordae tendinea	Caused by necrosis of tissue in or around papillary muscles; acute onset of severe valvular regurgitation
Aneurysm and rupture of wall or septae of infarcted ventricle	Aneurysm formation resulting from high chamber pressures and volume pushing against weakened ventricular wall; rupture of ventricular wall or septae between chambers when pressure becomes too great; rapid onset of shock
Systemic arterial thromboembolism	May disseminate from debris and clots that collect inside dilated aneurysmal sacs or from infarcted endocardium; can affect any

Type	Characteristics
	system but especially targets cerebrovascular system with transient ischemic attacks and stroke
Pulmonary thromboembolism	Usually from deep venous thrombi of legs; acute onset of dyspnea and hypoxemia
Sudden death	Dysrhythmias frequently causative, particularly ventricular fibrillation

Evaluation and Treatment

There are several defined categories of myocardial infarction, each with their own criteria for diagnosis.[98] In general, the diagnosis of acute MI is made on the basis of history, physical examination, ECG results, and serial cardiac troponin elevations.

MI can occur in various regions of the heart wall and may be described as anterior, inferior, posterior, lateral, subendocardial, or transmural, depending on the anatomic location and extent of tissue damage from infarction. Twelve-lead ECGs help localize the affected area through identification of changes in ST segments and T waves. The infarcted myocardium is surrounded by a zone of hypoxic injury, which may progress to necrosis or return to normal, and adjacent to this zone of hypoxic injury is a zone of reversible ischemia (Fig. 32.13). A characteristic Q wave often develops on ECG some hours later in STEMI.

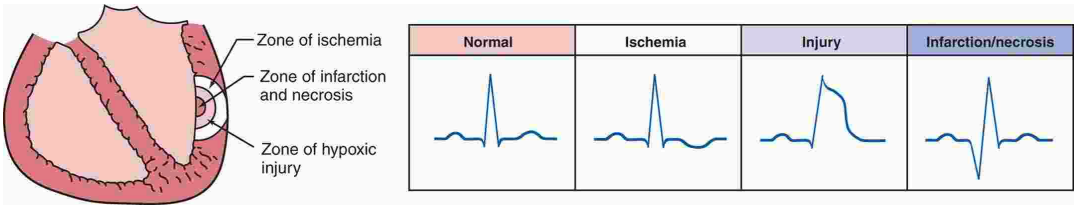

FIG. 32.13 Electrocardiographic Alterations Associated With the Three Zones of Myocardial Infarction.

An illustration of cross-section of the heart indicating the following zones from the inside to the outside: a zone of ischemia, zone of infarction, and zone of hypoxic injury. An accompanying table comprises the electrocardiogram of normal, ischemic, injury, and infarction or necrosis.

Cardiac troponin I (cTnI) is the most specific indicator of MI, and measurement of its level should be performed on admission to the emergency department. cTnI level elevation is detectable 2 to 4 hours after onset of symptoms. Additional measurements within 6 to 9 hours and again at 12 to 24 hours are recommended if clinical suspicion is high and previous samples were negative. Troponin levels also can be used to estimate infarct size and therefore the likelihood of complications. Additional laboratory data may reveal leukocytosis and elevated C-reactive protein (CRP), both of which indicate inflammation. The individual's blood glucose level is usually elevated and the glucose tolerance level may remain abnormal for several weeks.

Acute MI requires admission to the hospital, often directly into a coronary care unit. The individual should be given an aspirin immediately (ticlopidine if allergic to aspirin) along with nitrates and morphine for pain. Continuous monitoring of cardiac rhythms and enzymatic changes is essential, because the first 24 hours after onset of symptoms is the time of highest risk for sudden death. Non-STEMI is treated in the same way as unstable angina including antithrombotics, anticoagulation or PCI, or both.[89] STEMI is best managed with emergent PCI and antithrombotics.[99,100] Hyperglycemia is treated with insulin, and hyperlipidemia with statins. Recent studies suggest that intravenous statins given as a bolus during acute MI management may reduce infarct size, improve systolic contraction, and reduce remodeling.[101] ACE inhibitors should be prescribed as secondary prevention.[79] Individuals who are in shock require aggressive fluid resuscitation, ionotropic drugs, and possible emergent invasive procedures.

Bed rest, followed by gradual return to activities of daily living, reduces the myocardial oxygen demands of the compromised heart. Individuals not receiving thrombolytic or heparin infusion must receive DVT prophylaxis as long as their activity is significantly limited. Stool softeners are given to eliminate the need for straining. Education regarding appropriate diet and caffeine intake, smoking cessation, exercise, and other aspects of risk factor reduction is crucial for secondary prevention of recurrent myocardial ischemia.

Disorders of the Heart Wall

Disorders of the Pericardium

Pericardial disease is a localized manifestation of another disorder, such as infection (bacterial, viral, fungal, rickettsial, or parasitic); trauma or surgery; neoplasm; or a metabolic, immunologic, or vascular disorder (uremia, rheumatoid arthritis, systemic lupus erythematosus, periarteritis nodosa). The pericardial response to injury from these diverse causes may consist of pericarditis, pericardial effusion, or constrictive pericarditis.

Pericarditis

Pericarditis can be categorized as acute, recurrent, or chronic. Acute pericarditis is acute inflammation of the pericardium. The etiology of acute pericarditis is most often idiopathic or caused by viral infection by coxsackie, influenza, hepatitis, measles, mumps, varicella viruses, or human immunodeficiency virus (HIV). Other causes include MI, trauma, neoplasm, bacterial infection (especially tuberculosis), connective tissue disease (especially systemic lupus erythematosus and rheumatoid arthritis), or hypothyroidism. Iatrogenic causes include radiation therapy, cardiac surgery, pacemaker insertion, radiofrequency ablation, transcatheter aortic valve implantation, and PCI.[102] The pericardial membranes become inflamed with the release of inflammatory cytokines such as IL-1, and a pericardial effusion may develop that can be serous, purulent, or fibrinous (Fig. 32.14).

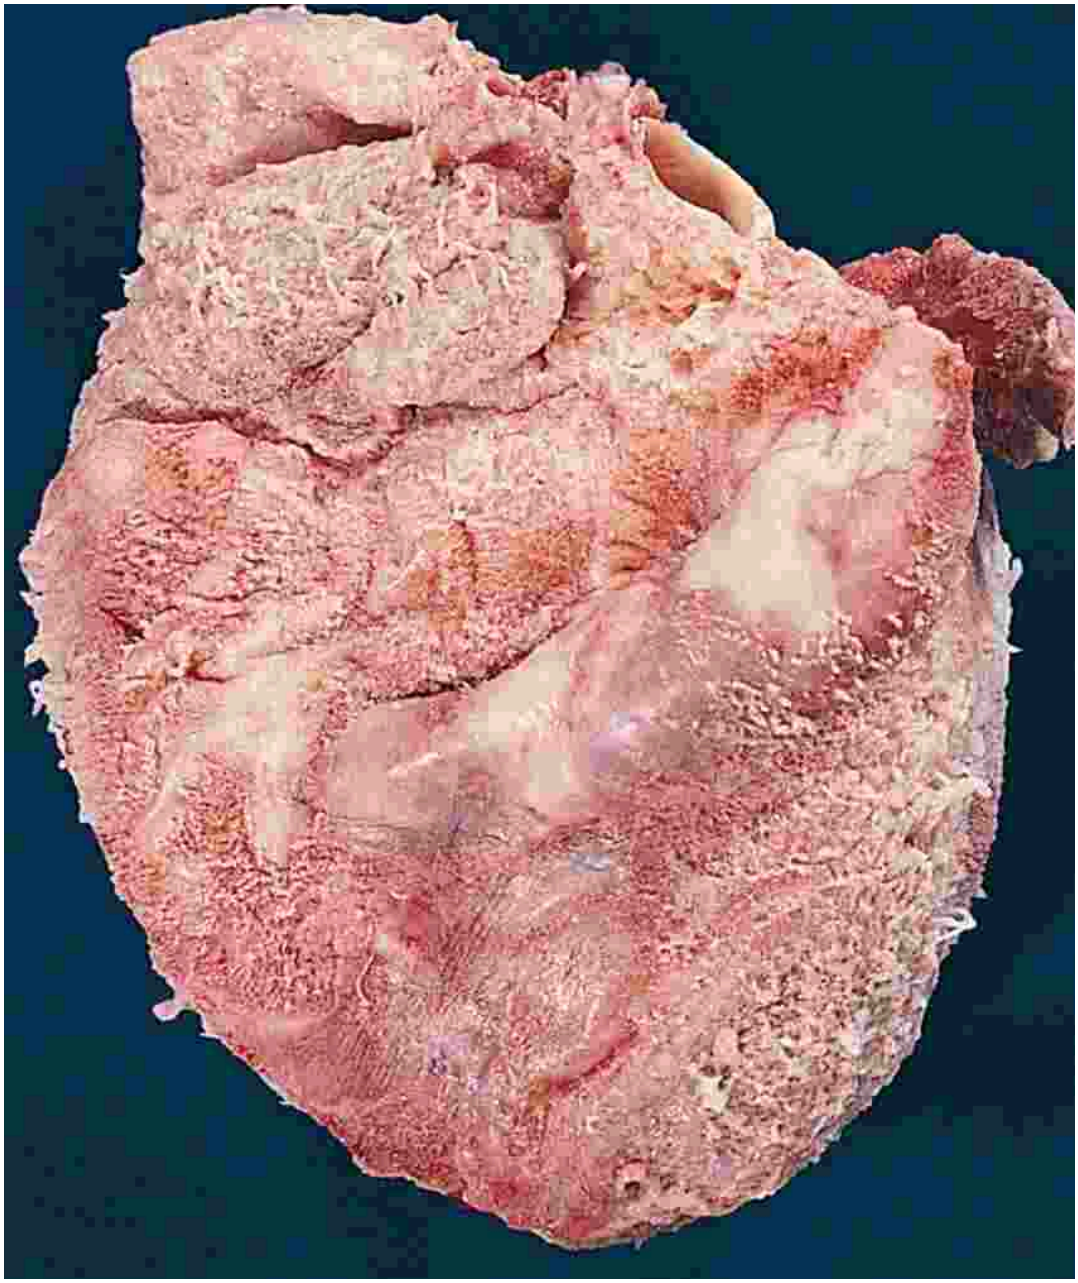

FIG. 32.14 Acute Pericarditis.
Note shaggy coat of fibers covering the surface of heart.
(From Damjanov I, Linder J. *Pathology: A color atlas*. St. Louis: Mosby; 2000.)

Symptoms may follow several days of fever and usually begin with the sudden onset of severe retrosternal chest pain that worsens with respiratory movements and when assuming a recumbent position. The pain may radiate to the back as a result of irritation of the phrenic nerve (innervates the trapezius

muscles) as it traverses the pericardium. Individuals with acute pericarditis also report dysphagia, restlessness, irritability, anxiety, weakness, and malaise.

Physical examination often reveals low-grade fever and sinus tachycardia. An intermittent friction rub—a scratchy, grating sound—may be heard at the cardiac apex and left sternal border and is highly suggestive of pericarditis. The rub is caused by the roughened pericardial membranes rubbing against each other. Evidence of underlying infection or disease may also be evident. ECG findings may reflect inflammatory processes through PR segment depression and diffuse ST segment elevation (sometimes described as "saddle shaped") without Q waves, and they may remain abnormal for days or even weeks. Cardiac troponins may be slightly elevated in some individuals. Echocardiography is the primary imaging modality for diagnosis. Some individuals will require CT or cardiac magnetic resonance (CMR) evaluation. Acute pericarditis requires at least two of the following four criteria for diagnosis: (1) chest pain characteristics of pericarditis, (2) pericardial rub, (3) characteristic electrocardiographic changes, and (4) new or worsening pericardial effusion.[103]

Treatment for uncomplicated acute pericarditis consists of administration of antiinflammatory agents, such as salicylates and NSAIDs, and colchicine.[102] Exploration of the underlying cause is important. Approximately one-third of cases will be complicated by the development of recurrent pericarditis (symptoms return after 4 to 6 weeks without symptoms) and may require the administration of more aggressive antiinflammatory and immunosuppressive medications such as corticosteroids.[103] Other possible sequelae of pericarditis include chronic pericarditis (symptoms persist beyond 3 months), cardiac tamponade, or constrictive pericarditis.

Pericardial Effusion

Pericardial effusion is the accumulation of fluid in the pericardial cavity and can occur in all forms of pericarditis. Many are idiopathic (20%), but other causes, such as neoplasm, infection, renal failure, or hypothyroidism must be considered.[104] Analysis of the fluid obtained through pericardiocentesis allows for identification of the likely source of the fluid. The fluid may be a transudate, such as the serous effusion that develops with left heart failure, overhydration, or hypoproteinemia. More often, however, the fluid is an exudate, which reflects pericardial inflammation like that seen with acute pericarditis, MI, heart surgery, some chemotherapeutic agents, infections, and autoimmune disorders such as systemic lupus erythematosus. (Types of exudate are described in Chapter 7.) If the fluid is serosanguineous, the underlying cause is likely to be tuberculosis, neoplasm, uremia, or radiation, although some remain idiopathic. Effusions of frank blood are generally related to aneurysms, trauma, or

coagulation defects. If chyle leaks from the thoracic duct, it may enter the pericardium and lead to cholesterol pericarditis.

If a pericardial effusion develops gradually, the pericardium can stretch to accommodate large quantities of fluid without compressing the heart. If the fluid accumulates rapidly, however, even a small amount (50 to 100 mL) may create sufficient pressure to cause cardiac compression, a serious condition known as tamponade. In tamponade, the pressure exerted by the pericardial fluid eventually equals or even exceeds diastolic pressure within the heart chambers, which interferes with right atrial filling. This causes increased venous pressure, systemic venous congestion, and signs and symptoms of right heart failure (distention of the jugular veins, edema, hepatomegaly). Decreased atrial filling also leads to decreased ventricular filling, decreased stroke volume, and reduced cardiac output. Life-threatening circulatory collapse may occur.

An important clinical finding is pulsus paradoxus, in which arterial blood pressure during expiration exceeds arterial pressure during inspiration by more than 10 mm Hg. Pulsus paradoxus in the setting of a pericardial effusion indicates tamponade and reflects impairment of diastolic filling of the left ventricle plus reduction of blood volume within all four cardiac chambers.

Other clinical manifestations of pericardial effusion are distant or muffled heart sounds, poorly palpable apical pulse, dyspnea on exertion, and dull chest pain. A chest x-ray film may disclose a "water-bottle configuration" of the cardiac silhouette. An echocardiogram (which often may be done at the bedside) can detect an effusion as small as 20 ml and is a reliable and accurate diagnostic test, although CT scans also may be done.

Treatment of pericardial effusion or tamponade consists of pericardiocentesis (aspiration of excessive pericardial fluid) and treatment of the underlying condition.[104] Persistent pain may be treated with analgesics, antiinflammatory medications, or steroids. Surgery may be required if the underlying cause of tamponade is trauma or aneurysm. A pericardial "window" may be surgically created to prevent tamponade.[105,106]

Constrictive Pericarditis

Constrictive pericarditis, or restrictive pericarditis (chronic pericarditis), is most commonly idiopathic or associated with viral infection, tuberculosis, radiation exposure, collagen vascular disorders, sarcoidosis, neoplasm, uremia, or cardiac surgery. In constrictive pericarditis, fibrous scarring with occasional calcification of the pericardium causes the visceral and parietal pericardial layers to adhere, obliterating the pericardial cavity. The fibrotic lesions encase the heart in a rigid shell (Fig. 32.15). Like tamponade, constrictive pericarditis compresses the heart and eventually reduces cardiac output. Unlike tamponade, however, constrictive pericarditis always develops gradually.

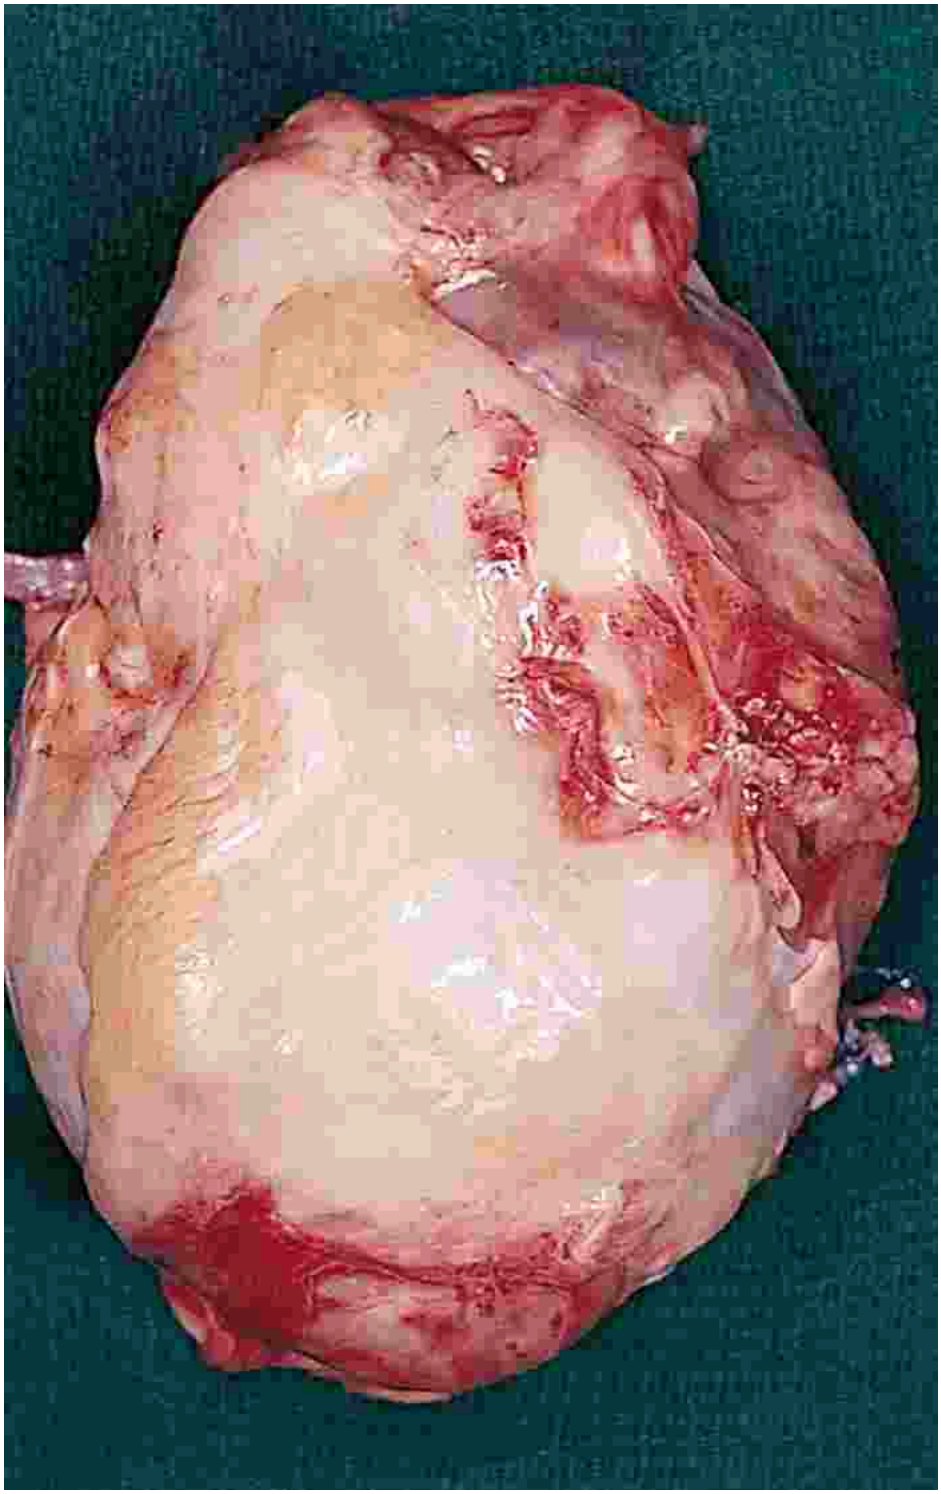

FIG. 32.15 Constrictive Pericarditis.
The fibrotic pericardium encases the heart in a rigid shell. (From Damjanov I, Linder J. *Pathology: A color atlas*. St. Louis: Mosby; 2000.)

Symptoms are exercise intolerance, dyspnea on exertion, fatigue, and anorexia. Clinical assessment shows edema, distention of the jugular vein, hepatic congestion, and systemic hypotension. Restricted ventricular filling may cause a pericardial knock (early diastolic sound).

ECG findings include nonspecific ST and T wave abnormalities and atrial fibrillation (AF). Chest x-ray films often disclose prominent pulmonary vessels and calcification of the pericardium. CT, MRI, and transesophageal echocardiography are used to detect pericardial thickening and constriction and to distinguish constrictive pericarditis from restrictive cardiomyopathy. Pericardial biopsy may be needed to determine the etiology.

Initial treatment for constrictive pericarditis consists of restriction of dietary sodium intake and administration of diuretics to improve cardiac output. Management also may include use of antiinflammatory drugs and treatment of any underlying disorder such as tuberculosis. If these modalities are unsuccessful, surgical excision of the restrictive pericardium is indicated (pericardiectomy).[105]

Disorders of the Myocardium: Cardiomyopathies

The cardiomyopathies are a diverse group of diseases that affect the myocardium. Primary cardiomyopathies are disorders confined to the myocardium. Many primary cardiomyopathies are idiopathic; others are caused by ischemia, hypertension, inherited disorders, infections, toxins, myocarditis, or autoimmunity. Secondary cardiomyopathies occur in the context of disorders that affect other organs as well as the heart, such as infectious disease, toxin exposure, systemic connective tissue disease, infiltrative and proliferative disorders, or nutritional deficiencies. The cardiomyopathies are further categorized as dilated, hypertrophic, or restrictive, depending on their physiologic effects on the heart (Fig. 32.16).

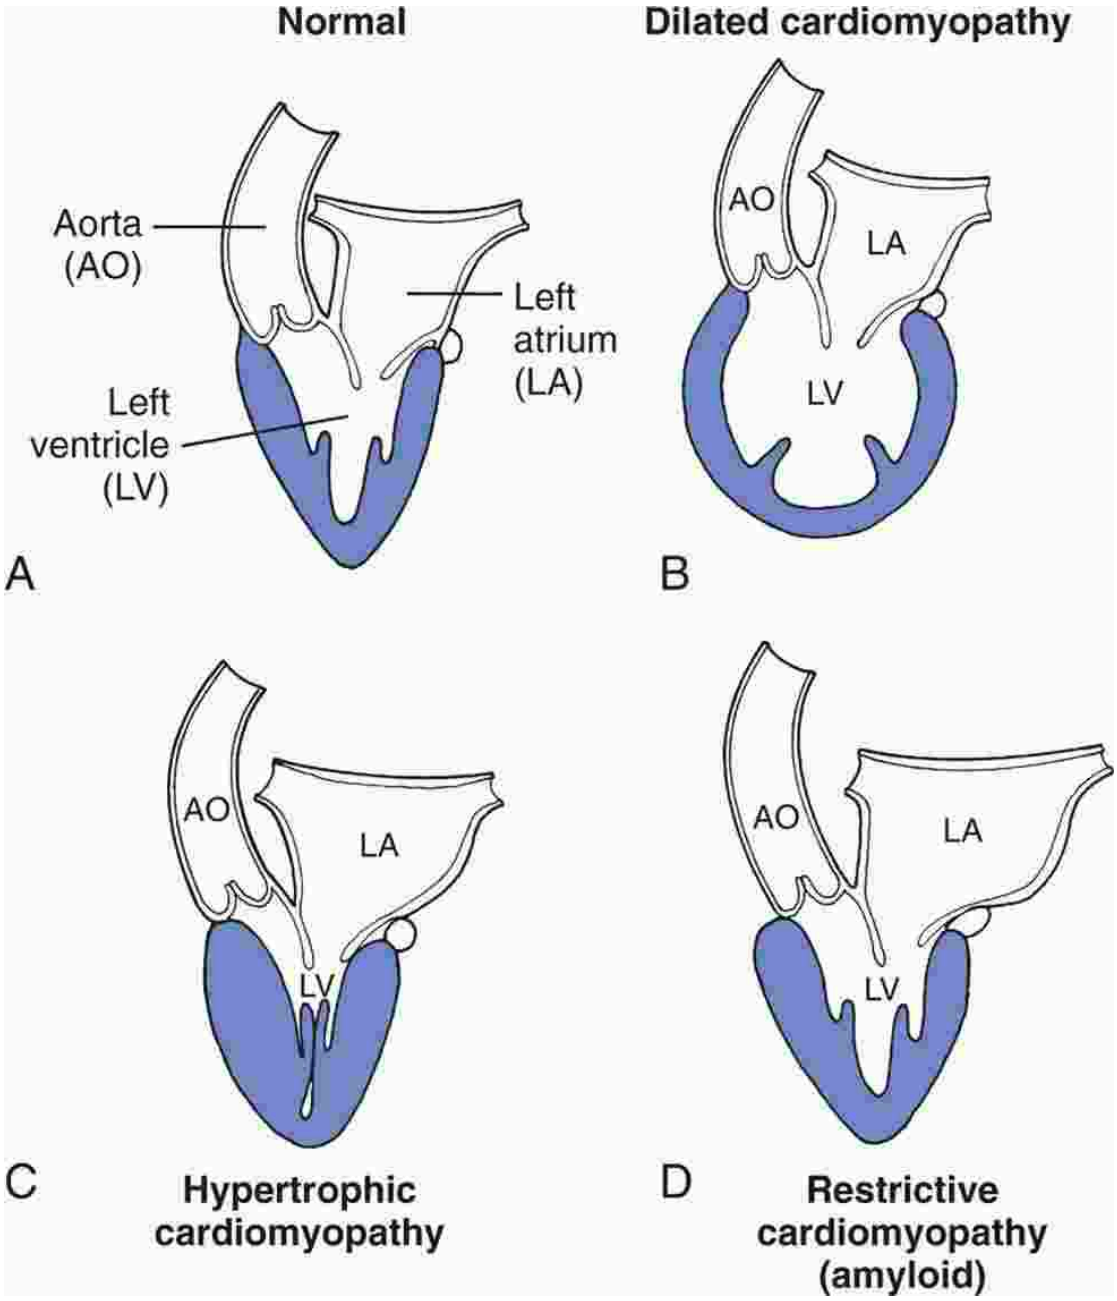

FIG. 32.16 Diagram Showing Major Distinguishing Pathophysiologic Features of the Three Types of Cardiomyopathy.

(A) The normal heart. (B) In the dilated type of cardiomyopathy, the heart has a globular shape and the largest circumference of the left ventricle is not at its base but midway between apex and base. (C) In the hypertrophic type, the wall of the left ventricle is greatly thickened; the left ventricular cavity is small, but the left atrium may be dilated because of poor diastolic relaxation of the ventricle. (D) In the restrictive (constrictive) type, the left ventricular cavity is normal size, but, again, the left atrium is dilated because of the reduced diastolic compliance of the ventricle.

(From Kissane JM, ed. *Anderson's pathology*, 9th edition. St. Louis: Mosby; 1990.)

Top-left panel, Part A, normal. An illustration shows a cross-section of the heart with parts labeled as follows. Aorta (A O), Left ventricle (L V), and Left Atrium (L A). Top-right panel, Part B, dilated cardiomyopathy. An illustration shows a cross-section of the heart with parts labeled as follows. Aorta (A O), Left ventricle (L V), and Left Atrium (L A). Bottom-left panel, Part C, hypertrophic cardiomyopathy. An illustration shows a cross-section of the heart with parts labeled as follows. Aorta (A O), and Left Atrium (L A). Bottom-right panel, Part D, restrictive cardiomyopathy (amyloid). An illustration shows a cross-section of the heart with parts labeled as follows. Aorta (A O), and Left Atrium (L A).

Dilated Cardiomyopathy

Dilated cardiomyopathy most commonly results from ischemic heart disease or valvular disease. Non-ischemic non-valvular causes include diabetes, renal failure, alcohol or drug toxicity, peripartum complications, or infection. It also can be associated with inherited disorders such as muscular dystrophy, and genetic polymorphisms that affect cytoskeletal and sarcomere proteins (including truncated titin proteins) can be identified in up to 35% of individuals.[107] Four different phenotypic groups of dilated cardiomyopathies have been described: (1) mild systolic dysfunction, (2) autoimmune cardiomyopathy, (3) genetic with arrhythmias (atrial fibrillation or non-sustained ventricular tachycardia), and (4) severe systolic dysfunction. Each of these types is characterized by different pathophysiologic mechanisms of metabolism, inflammation, and fibrosis.[108] Dilated cardiomyopathy results in impaired systolic function leading to increases in intracardiac volume, ventricular dilation, and heart failure with reduced EF (Fig. 32.17). Individuals complain of dyspnea, fatigue, and pedal edema. Findings on examination include a displaced apical pulse, S_3 gallop, peripheral edema, jugular venous distention, and pulmonary congestion. Diagnosis is confirmed by chest x-ray and echocardiogram, and management includes standard treatment of heart failure plus prevention of dysrhythmias.[109] Further management is determined by the specific cause of the cardiomyopathy. Ventricular assist devices and heart transplant are required in severe cases.

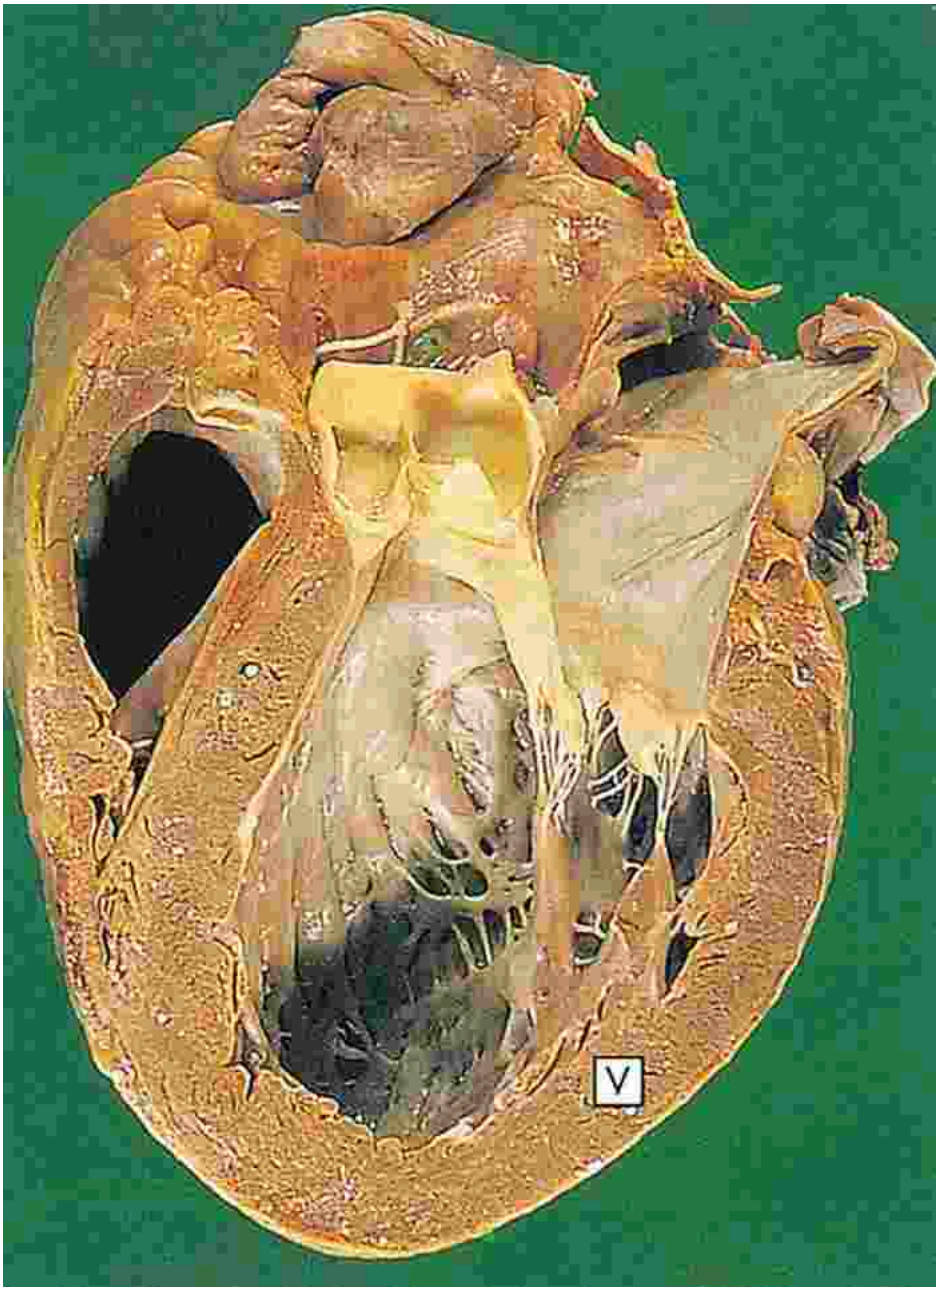

FIG. 32.17 Dilated Cardiomyopathy.
The dilated left ventricle has a thin wall *(V)*. (From Stevens A, Lowe JS, Scott I. *Core pathology*, 3rd edition. London: Mosby; 2009.)

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy refers to two major categories of thickening of the myocardium: (1) hypertrophic cardiomyopathy (hypertrophic obstructive cardiomyopathy, asymmetric septal hypertrophic cardiomyopathy, or subaortic stenosis) and (2) hypertensive or valvular hypertrophic cardiomyopathy.

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the most common inherited cardiac disorder. The prevalence in young adults in the United States is estimated to be 1:200 to 1:500, while diagnosed symptomatic cases occur in about 1:3000 adults.[110] It results from autosomal dominant inheritance of mutations affecting genes encoding for cardiac sarcomere proteins and hypercontractility.[111] HCM is characterized by left ventricular hypertrophy with thickening of the septal wall (Fig. 32.18), which may cause outflow obstruction to the left ventricle outflow tract. Obstruction of left ventricular outflow can occur when the heart rate is increased, and the intravascular volume is decreased such as occurs with exercise. Other abnormalities include myocardial fibrosis with diastolic dysfunction, abnormal mitral valve leaflets with mitral regurgitation, remodeled coronary vessels with myocardial ischemia, and the development of heart failure. Sudden death may occur, although increased awareness and management of HCM have reduced mortality rates to less than 1.0% per year.[110]

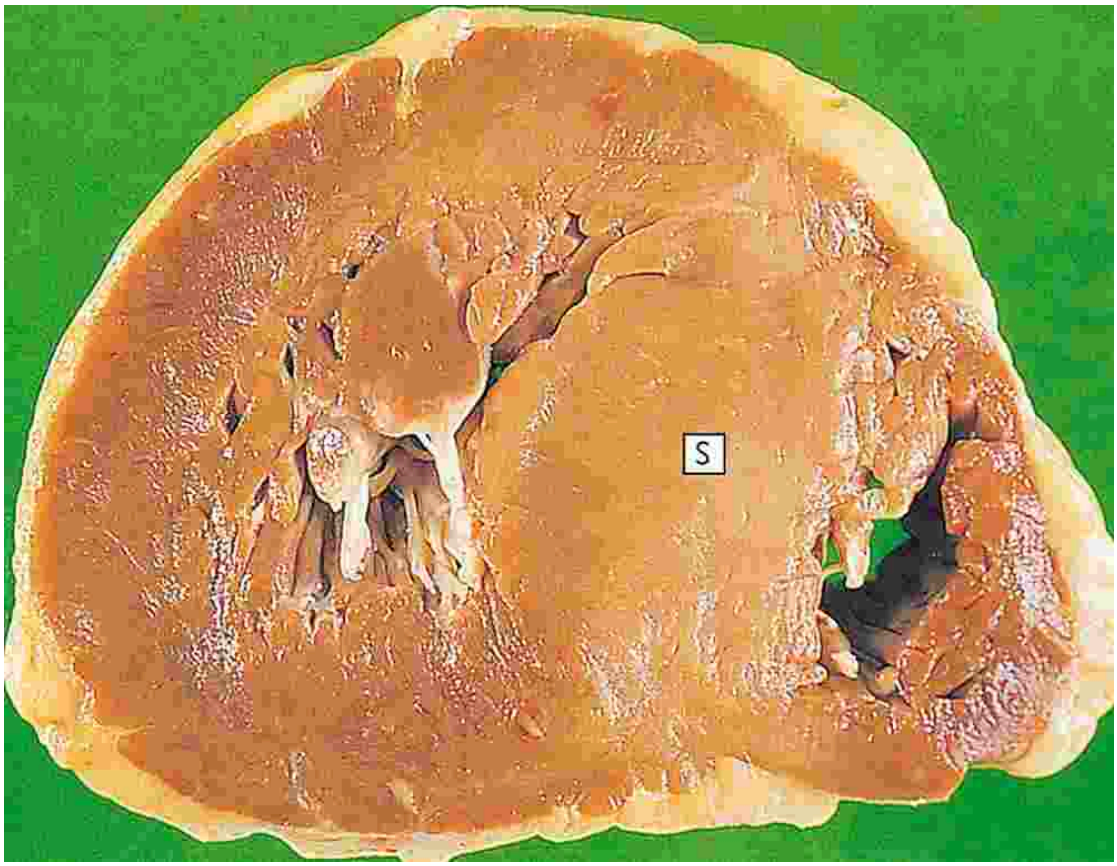

FIG. 32.18 Hypertrophic Cardiomyopathy.
There is marked left ventricular hypertrophy. This often affects the septum *(S)*. (From Stevens A, Lowe JS, Scott I. *Core pathology*, 3rd edition. London: Mosby; 2009.)

Recognition of HCM usually occurs after the development of symptoms such as palpitations, exercise intolerance, syncope, detection of a heart murmur, or abnormal ECG in a young person. Diagnosis is confirmed by echocardiography or MRI. Genetic testing and counseling are recommended for affected individuals and their families. Risk assessment for sudden death based on family history, extent of hypertrophy, development of syncope or heart failure, and presence of arrhythmias should be conducted.

Management begins with extensive discussions and shared decision-making with affected individuals and families about risks for HCM complications, lifestyle changes, and appropriate interventions. Moderate exercise is safe in most cases; however participation in high-intensity sports requires extensive

evaluation and in-depth counseling about risks.[110] Management of symptoms may include beta blockers and calcium channel blockers. Implantable cardioverter defibrillator implantation significantly reduces mortality in high-risk individuals. Heart failure is managed in accordance with general heart failure guidelines.[110] Antiarrhythmic medications may be needed. Transaortic septal myectomy or septal ablation may be indicated in selected individuals. Mavacamten, a cardiac myosin inhibitor, was found to improve cardiac structure and function, symptoms, and quality of life in phase 3 trials for individuals with HCM.[112]

Hypertensive hypertrophic cardiomyopathy and valvular hypertrophic cardiomyopathy

Hypertensive hypertrophic cardiomyopathy and valvular hypertrophic cardiomyopathy occur because of increased resistance to ventricular ejection, which is commonly seen in individuals with hypertension or valvular stenosis (usually aortic). In this case, hypertrophy of the myocytes is an attempt to compensate for increased myocardial workload. Long-term dysfunction of the myocytes develops over time, with diastolic dysfunction appearing first and leading eventually to systolic dysfunction of the ventricle (see the Heart Failure section). Individuals with hypertensive hypertrophic cardiomyopathy may be asymptomatic or may complain of angina, syncope, dyspnea on exertion, and palpitations. Examination may reveal extra heart sounds (especially an S4) and murmurs. Echocardiography and cardiac catheterization can confirm the diagnosis. Management rests on appropriate treatment for the underlying condition.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy is characterized by resistance to filling and increased diastolic pressure of either or both ventricles. Systolic function and wall thickness are normal. It may occur idiopathically or as a cardiac manifestation of systemic diseases, such as amyloidosis, scleroderma, sarcoidosis, lymphoma, and hemochromatosis, or a number of inherited storage diseases. Cardiac amyloidosis is caused by the deposition of excess light chain immunoglobulins leading to ventricular wall thickening and fibrosis.[113] The myocardium becomes rigid and noncompliant, impeding ventricular filling and raising filling pressures during diastole. The most common clinical manifestation of restrictive cardiomyopathy is right heart failure with systemic venous congestion. Cardiomegaly and dysrhythmias are common. A thorough evaluation for the underlying cause should be initiated (and may include myocardial biopsy). Treatment is aimed at managing heart failure and reversing the underlying cause when possible. Death occurs as a result of heart failure or dysrhythmias.

Disorders of the Endocardium

Disorders that involve the endocardium (the innermost lining of the heart wall) damage the cardiac valves. These disorders include valvular heart disease, acute rheumatic fever and rheumatic heart disease, and infective endocarditis.

Valvular Heart Disease

Valvular heart disease can be either congenital or acquired. The acquired forms are more common in adults and result from inflammatory, ischemic, traumatic, degenerative, or infectious alterations of valvular structure and function. Worldwide, the most common cause of acquired valvular dysfunction is degeneration or inflammation of the endocardium secondary to rheumatic heart disease (Table 32.6). In the United States degenerative-calcific disease is the most common cause, and a link between mitral annular calcification and atherosclerotic vascular disease has been established.[114] Structural alterations of the heart valves are caused by remodeling changes in the valvular extracellular matrix and lead to stenosis, incompetence, or both. Previously undiagnosed, mild valvular heart disease is present in approximately half of individuals ≥65 years of age, and the prevalence of undiagnosed moderate or severe valvular heart disease may be as high as 6.4%.[12]

Table 32.6

Clinical Manifestations of Valvular Stenosis and Regurgitation

Manifestation	Aortic Stenosis	Mitral Stenosis	Aortic Regurgitation	Mitral Regurgitation	Tricuspid Regurgitation
Most common cause	Congenital bicuspid valve, degenerative (calcific) changes with aging, rheumatic heart disease	Rheumatic heart disease, mitral annular calcification (MAC)	Infective endocarditis; aortic root disease (connective tissue diseases, Marfan syndrome); dilation of aortic root from hypertension and aging	Myxomatous degeneration (mitral valve prolapse)	Congenital; secondary pulmonar hypertens with cor pulmonal
Cardiovascular outcome (untreated)	Left ventricular hypertrophy followed by left heart failure; decreased coronary blood flow with myocardial ischemia	Left atrial hypertrophy and dilation with fibrillation, followed by right ventricular failure	Left ventricular hypertrophy and dilation, followed by left heart failure	Left atrial hypertrophy and dilation, followed by left heart failure	Right heart failure
Pulmonary effects	Pulmonary edema with dyspnea on exertion	Pulmonary edema with dyspnea on exertion	Pulmonary edema with dyspnea on exertion	Pulmonary edema with dyspnea on exertion	Dyspnea (ma be caused underlyin lung disea
Central nervous system effects	Syncope, especially on exertion	Stroke resulting from emboli (e.g., hemiparesis)	Syncope	None	None
Pain	Angina pectoris	Atypical chest pain	Angina pectoris	Atypical chest pain	Palpitations
Heart sounds	Systolic murmur heard best at right parasternal second intercostal space and	Low, rumbling diastolic murmur heard best at apex and radiating to axilla; accentuated first heart	Diastolic murmur heard best at right parasternal second intercostal space and	Murmur throughout systole heard best at apex and radiating to axilla	Murmur throughou systole heard bes left lower sternal border

Manifestation	Aortic Stenosis	Mitral Stenosis	Aortic Regurgitation	Mitral Regurgitation	Tricuspid Regurgitation
	radiating to neck	sound, opening snap	radiating to neck		

With data from Mann DL, Zipes DP, Libby P, et al., eds. *Braunwald's heart disease: A textbook of cardiovascular medicine*, 10th edition. St. Louis: Elsevier; 2014.

In valvular stenosis, the valve orifice is constricted and narrowed, so blood cannot flow forward and the workload of the cardiac chamber proximal to the diseased valve increases. Pressure (intraventricular or atrial) rises in the proximal chamber to overcome resistance to flow through the valve, necessitating greater exertion by the myocardium and producing myocardial hypertrophy. Although all four heart valves may be affected, those of the left heart (mitral and aortic valves) in adults are far more commonly affected than those of the right heart (tricuspid and pulmonic valves).

In valvular regurgitation (also called insufficiency or incompetence), the valve leaflets, or cusps, fail to shut completely, permitting blood flow to continue even when the valve is presumably closed. During systole or diastole, some blood leaks back into the chamber proximal to the diseased valve, which increases the volume of blood the heart must pump and increases the workload of both the atrium and the ventricle. Increased volume leads to chamber dilation, and increased workload leads to hypertrophy; both lead to cardiac dysfunction over time. For both valvular stenosis and regurgitation, over time. myocardial contractility diminishes, EF drops, diastolic pressure increases, and the ventricles fail from being overworked. Depending on the severity of the valvular dysfunction and the capacity of the heart to compensate, valvular alterations cause a range of symptoms and some degree of incapacitation (see Table 32.6).

In general, valvular disease is suspected when a heart murmur is detected, when symptoms develop, or when incidental findings of valvular abnormalities are detected on noninvasive testing.[115] Diagnosis rests on transthoracic echocardiography (TTE), which can be used to assess the severity of valvular obstruction or regurgitation before the onset of symptoms. CT or MRI may be indicated in certain settings. BNP measurements are obtained to assess cardiac chamber stress. ECG, chest x-ray, and exercise stress testing are often obtained. Cardiac catheterization may be needed if surgical intervention is planned. Valvular lesions are staged and appropriate management is determined by using four general categories: (1) at risk, (2) progressive, (3) asymptomatic severe, and (4) symptomatic severe.[115]

Management of valvular heart disease includes cardiovascular risk reduction and careful medical management. Regular exercise and diet modification to reduce overall cardiovascular risk are crucial. The maintenance of oral health is important to the prevention of infective endocarditis. Medical management most often is focused on reducing cardiac workload and improving systolic function, as well as treating established heart failure.[115] Valvular repair or replacement is indicated for progressive disease. The purpose of valvular repair or replacement is to improve symptoms and prolong survival, as well as to minimize complications such as asymptomatic irreversible heart failure, pulmonary hypertension, stroke, and AF. Anticoagulation either with a non-vitamin K oral anticoagulant or with warfarin is indicated in most individuals with valvular heart disease with or without atrial fibrillation, although warfarin is the antithrombotic of choice for those having undergone valve replacement.[115] Infectious endocarditis prophylaxis is recommended for those with prosthetic valves who are undergoing dental procedures that involve manipulation of gingival tissue or the periapical region of the teeth, or perforation of the oral mucosa.[115]

Aortic stenosis

Aortic stenosis is the most commonly diagnosed form of valvular heart disease, affecting nearly 2% of adults older than 65 years of age and nearly 10% of those over the age of 80.[116] It has three common causes: (1) congenital bicuspid valve, (2) degeneration with aging, and (3) inflammatory damage caused by rheumatic heart disease (Fig. 32.19). Congenital bicuspid aortic valve is found in 1% to 2% of the

population. The valve functions normally at birth, but degenerates with fibrosis and calcification of the valve, causing stenosis as early as age 50. Degenerative aortic valve disease results from progressive deposition of calcium phosphate into all three cusps causing the valves to adhere to one another.[116] In addition, the aortic valve contains numerous inflammatory and immune cells such as macrophages, T lymphocyte, and B lymphocytes that play a causative role in aortic valve degeneration and calcification.[117] Rheumatic (post-inflammatory) aortic stenosis results from chronic inflammation of the valve leading to fibrosis, calcific degeneration, and fusion of the valve cusps. Aortic stenosis is associated with many risk factors for CAD, including hypertension, smoking, and dyslipidemia. Of interest, recent studies have identified a significant reduction in serum levels of zinc in individuals with calcific AS, which suggests a role of zinc metabolism in early valve degeneration.[114]

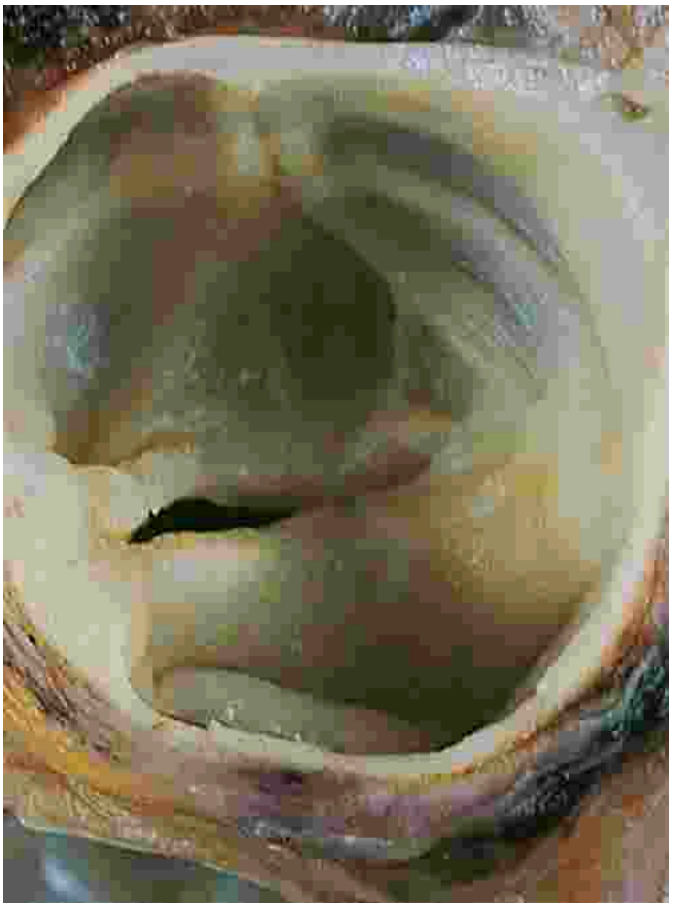

FIG. 32.19 Aortic Stenosis.
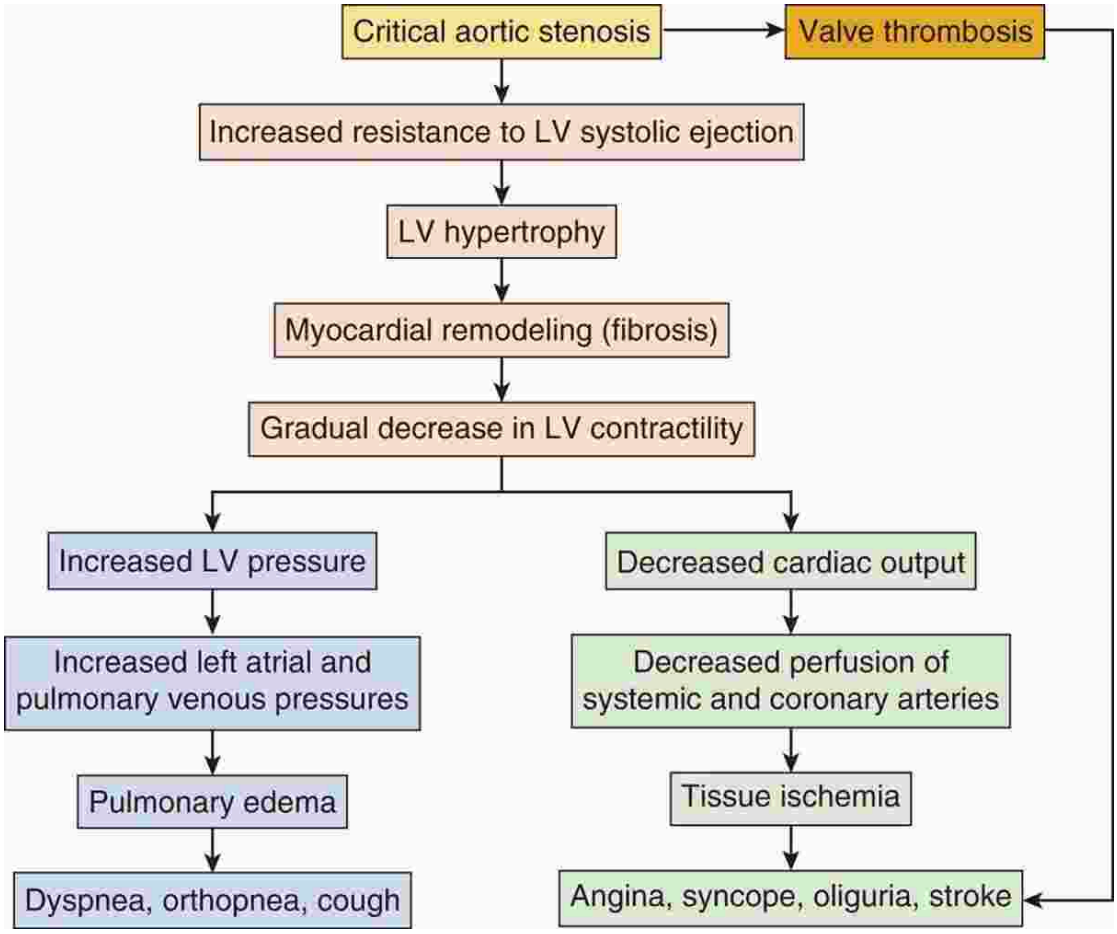
Mild stenosis in valve leaflets of a young adult. (From Damjanov I, Linder J. *Pathophysiology*: A color atlas. St. Louis: Mosby; 2000.)

In aortic stenosis, the orifice of the valve narrows, causing resistance to blood flow from the left ventricle into the aorta (Algorithm 32.5). Outflow obstruction increases pressure within the left ventricle as it tries to eject blood through the narrowed opening. Left ventricular hypertrophy develops to compensate for the increased workload. Remodeling of the LV myocardium with fibrosis leads to a gradual decline in LV function with decreased cardiac output. Untreated aortic stenosis can lead to hypertrophic cardiomyopathy, myocardial ischemia or infarction, oliguria, stroke, heart failure, and pulmonary edema.



ALGORITHM 32.5 **Pathophysiology of Aortic Stenosis.**
LV, Left ventricle.

A flowchart shows the pathophysiology of aortic stenosis. 1. Critical aortic stenosis. Leads to 2 and 3. 2. Valve thrombosis. Leads to 14. 3. Increased resistance to L V systolic ejection. Leads to 4. 4. L V hypertrophy. Leads to 5. 5. Myocardial remodeling (fibrosis). Leads to 6. 6. Gradual decrease in L V contractility. Leads to 7 and 11. 7. Increased L V pressure. Leads to 8. 8. Increased left atrial and pulmonary venous pressures. Leads to 9. 9. Pulmonary edema. Leads to 10. 10. Dyspnea, orthopnea, and cough. 11. Decreased cardiac output. Leads to 11. 12. Decreased perfusion of systemic and coronary arteries. Leads to 12. 13. Tissue ischemia. Leads to 13. 14. Angina, syncope, oliguria, stroke.

Aortic stenosis usually develops gradually. Classic symptoms include angina, syncope, and dyspnea. Clinical manifestations include decreased stroke volume and narrowed pulse pressure (the difference between systolic and diastolic pressures). Heart rate is often slow, and pulses are delayed. Resistance to flow leads to a crescendo-decrescendo systolic heart murmur heard best at the right parasternal second intercostal space and may radiate to the neck. Echocardiography can be used to assess the severity of valvular obstruction before the onset of symptoms. Medical management includes vasodilator therapy to reduce resistance to ventricular ejection. Statins are prescribed for associated CAD, but have not been

shown to prevent progression of AS.[114] Percutaneous placement of a prosthetic valve (transcatheter aortic valve implantation [TAVI]) is indicated for symptomatic and most asymptomatic individuals with severe stenosis. In a meta-analysis of four randomized controlled trials (RCTs) comparing TAVI and surgical valve replacement in low-risk individuals, TAVI was associated with a lower all-cause and cardiovascular mortality along with lower rates of new-onset atrial fibrillation, life-threatening bleeding, and acute kidney injury, but higher rates of paravalvular regurgitation and pacemaker implantation.[118] Surgical valve replacement may be indicated in selected individuals. Untreated aortic stenosis may result in irreversible fibrotic damage to the left ventricle.

Mitral stenosis

Mitral stenosis impairs the flow of blood from the left atrium to the left ventricle. Mitral stenosis is the most common form of rheumatic heart disease. Autoimmunity in response to group A β-hemolytic streptococcal M protein antigens leads to inflammation and scarring of the valvular leaflets. Scarring causes the leaflets to become fibrous and fused, and the chordae tendineae cordis become shortened (Fig. 32.20).

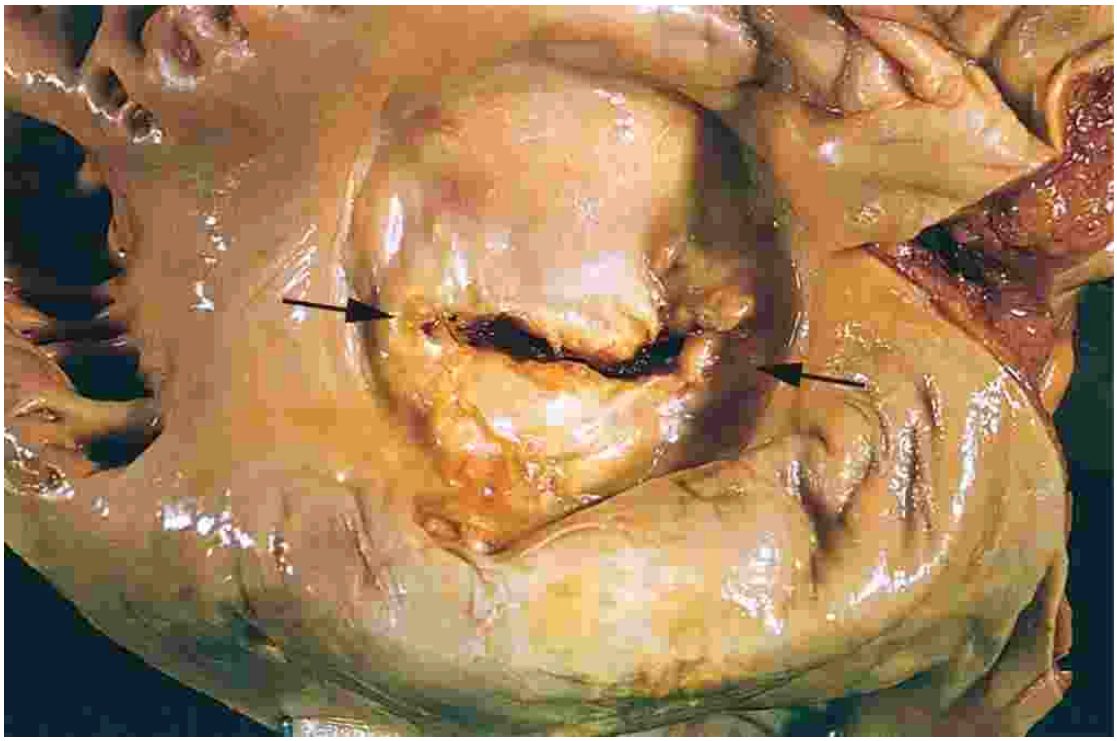


FIG. 32.20 Mitral Stenosis With Classic "Fish Mouth" Orifice *(Arrows)*.

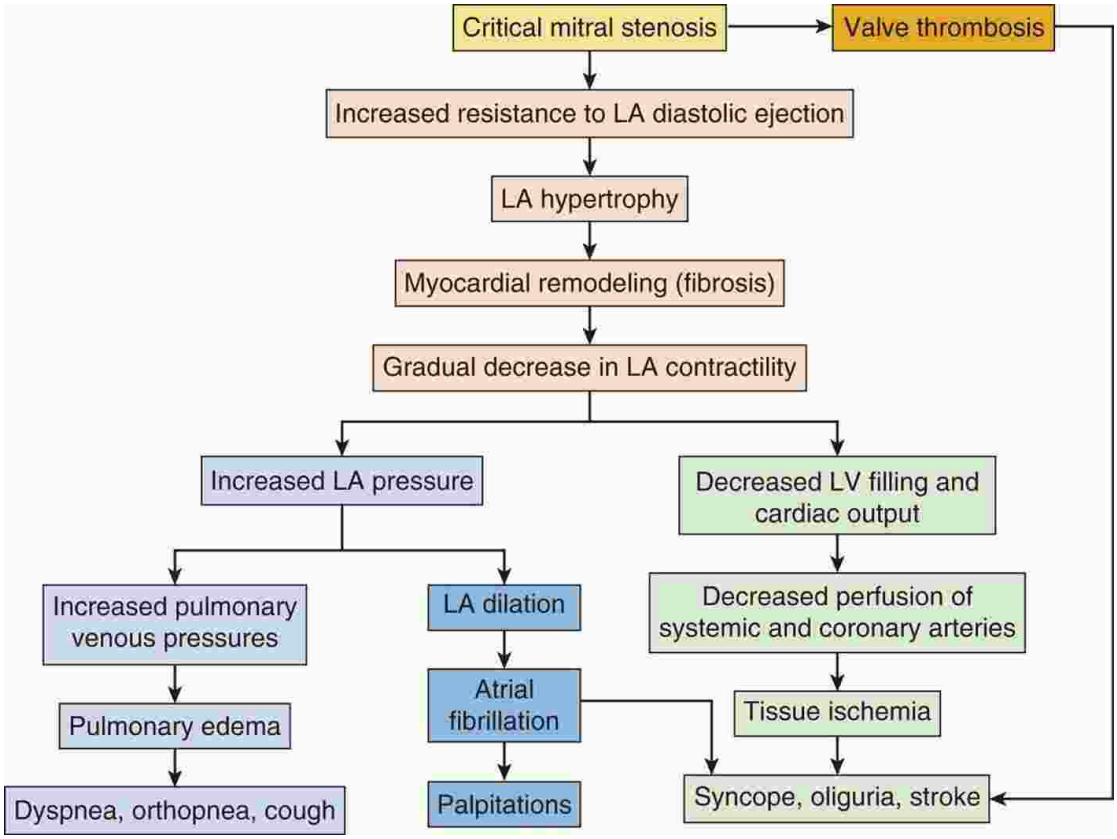
Another cause of narrowing of the mitral orifice is mitral annular calcification (MAC), which is a calcific degeneration of the mitral valve seen in 10% of the U.S. population and affecting up to 40% of those over the age of 70.[119] It is most common in those with risk factors for atherosclerotic coronary artery disease and chronic kidney disease. MAC only occasionally causes significant mitral stenosis by itself but can complicate the care of those with rheumatic mitral valve disease.

Impedance to blood flow results in incomplete emptying of the left atrium and elevated atrial pressure as the chamber tries to force blood through the stenotic valve. Continued increases in left atrial volume and pressure cause atrial dilation and hypertrophy (Algorithm 32.6). The risk of developing AF and dysrhythmia-induced thrombi is high. As mitral stenosis progresses, symptoms of decreased cardiac output occur, especially during exertion. Continued elevation of left atrial pressure and volume

causes pressure to rise in the pulmonary circulation leading to pulmonary hypertension, pulmonary edema, and right ventricular failure.



ALGORITHM 32.6 **Pathophysiology of Mitral Stenosis.**
LA, Left atrium; *LV*, Left ventricle.

A flowchart shows the pathophysiology of mitral stenosis. 1. Critical aortic stenosis. Leads to 2 and 3. 2. Valve thrombosis. Leads to 14. 3. Increased resistance to L V systolic ejection. Leads to 4. 4. L V hypertrophy. Leads to 5. 5. Myocardial remodeling (fibrosis). Leads to 6. 6. Gradual decrease in L V contractility. Leads to 7 and 11. 7. Increased L A pressure. Leads to 8 and 15. 8. Increased pulmonary venous pressures. Leads to 9. 9. Pulmonary edema. Leads to 10. 10. Dyspnea, orthopnea, and cough. 11. Decreased cardiac output. Leads to 11. 12. Decreased perfusion of systemic and coronary arteries. Leads to 12. 13. Tissue ischemia. Leads to 13. 14. Syncope, oliguria, stroke. 15. L A dilation. Leads to 16. 16. Atrial fibrillation. Leads to 14 and 17. 17. Palpitations.

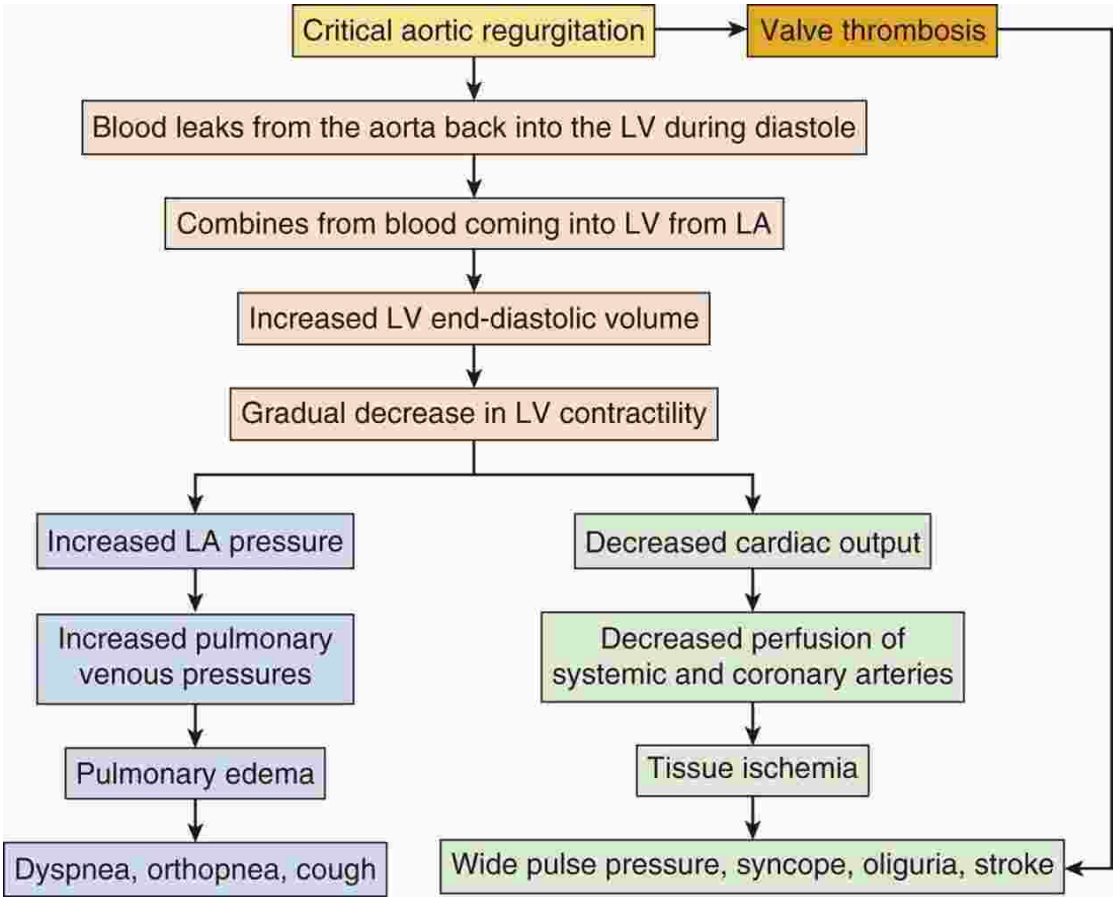
Blood flow through the stenotic valve results in a rumbling decrescendo diastolic murmur heard best over the cardiac apex and radiating to the left axilla. If the mitral valve is forced open during diastole, it may make a sharp noise called an opening snap. The first heart sound (S_1) is often accentuated and somewhat delayed because of increased left atrial pressure. Other signs and symptoms are generally those of pulmonary congestion and right heart failure. Atrial enlargement and valvular obstruction are

demonstrated by chest x-ray films, electrocardiography, and echocardiography. Management includes use of anticoagulation therapy and control of heart rate. Mitral stenosis can often be repaired with clipping leaflets and opening the valve orifice (commissurotomy), or percutaneous balloon commissurotomy, but may require surgical valve replacement in advanced cases.[115,120] While untreated severe calcific mitral stenosis is associated with significant mortality in older adults, surgical or percutaneous interventions are associated with a high risk for procedural complications.[115,121]

Aortic regurgitation

Aortic regurgitation results from an inability of the aortic valve leaflets to close properly during diastole because of abnormalities of the leaflets, the aortic root and annulus, or both. It can be primary, caused by congenital bicuspid valve or degeneration in older adults; or secondary, resulting from chronic hypertension, rheumatic heart disease, bacterial endocarditis, syphilis, connective tissue disorders (e.g., Marfan syndrome and ankylosing spondylitis), appetite-suppressing medications, trauma, valvular surgery, or atherosclerosis. Myxomatous degeneration of the valve causing distortion of the valve leaflets occurs most often in those with hypertension.[122]

During systole, blood is ejected from the left ventricle into the aorta. During diastole, some of the ejected blood flows back into the left ventricle through the leaking valve (Algorithm 32.7). Volume overload occurs in the ventricle because it receives blood from the left atrium and from the aorta during diastole. As the end-diastolic volume of the left ventricle increases, myocardial fibers stretch to accommodate the extra fluid. Compensatory dilation permits the left ventricle to increase its stroke volume and maintain cardiac output. Ventricular hypertrophy also occurs as an adaptation to the increased volume and because of increased afterload created by the high stroke volume and resultant systolic hypertension. Over time, ventricular dilation and hypertrophy eventually cannot compensate for aortic incompetence, and heart failure develops.[122]



ALGORITHM 32.7 **Pathophysiology of Aortic Regurgitation.**
LA, Left atrium; *LV*, Left ventricle.

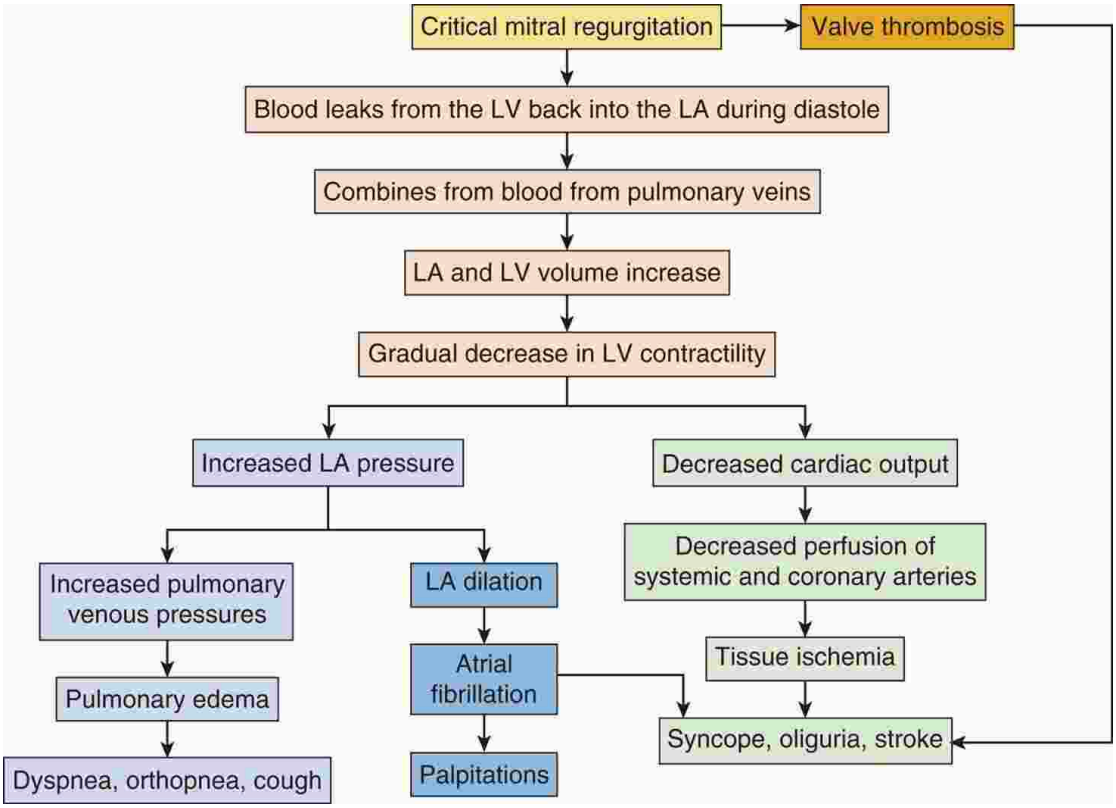
A flowchart shows the pathophysiology of aortic regurgitation. 1. Critical aortic regurgitation. Leads to 2 and 3. 2. Valve thrombosis. Leads to 14. 3. Blood leaks from the aorta back into the L V during diastole. Leads to 4. 4. Combines from blood coming into L V from L A. Leads to 5. 5. Increased L V end-diastolic volume. Leads to 6. 6. Gradual decrease in L V contractility. Leads to 7 and 11. 7. Increased L A pressure. Leads to 8. 8. Increased pulmonary venous pressures. Leads to 9. 9. Pulmonary edema. Leads to 10. 10. Dyspnea, orthopnea, and cough. 11. Decreased cardiac output. Leads to 11. 12. Decreased perfusion of systemic and coronary arteries. Leads to 12. 13. Tissue ischemia. Leads to 13. 14. Wide pulse pressure, syncope, oliguria, stroke.

Clinical manifestations include widened pulse pressure resulting from increased stroke volume and diastolic backflow. Turbulence across the aortic valve during diastole produces a decrescendo murmur in the second, third, or fourth intercostal spaces parasternally and may radiate to the neck. Large stroke volume and rapid runoff of blood from the aorta cause prominent carotid pulsations and bounding peripheral pulses (Corrigan pulse). Other symptoms are usually associated with heart failure that occurs when the ventricle can no longer pump adequately. Dysrhythmias are a common complication of aortic regurgitation. The severity of regurgitation can be estimated by echocardiography, and valve

replacement surgery may be delayed for many years through careful use of vasodilators such as ACE inhibitors and beta blockers.[115,122]

Mitral regurgitation

Mitral regurgitation can be primary (degenerative) because of mitral valve prolapse (MVP), rheumatic heart disease, infective endocarditis, MI, connective tissue diseases (Marfan syndrome), and dilated cardiomyopathy. It also can be secondary (functional) because of ischemic or nonischemic myocardial disease, which damages the chordae tendineae or the mitral annulus. Mitral regurgitation permits backflow of blood from the left ventricle into the left atrium during ventricular systole (Algorithm 32.8). The left atrium and ventricle become dilated and hypertrophied to maintain adequate cardiac output. As the left atrium enlarges, stretching of the atrial myocardium often leads to AF. As mitral valve regurgitation progresses, left ventricular function may become impaired to the point of failure. Eventually, increased atrial pressure leads to pulmonary hypertension and failure of the right ventricle. Most clinical manifestations are caused by heart failure. A characteristic holosystolic (throughout systole) murmur, heard best at the apex and that radiates into the back and axilla, suggests the underlying valvular abnormality, which is then confirmed by echocardiography. Mitral incompetence is usually well tolerated—often for years—until heart failure occurs, at which time transcatheter or surgical repair becomes necessary. Mitral valve replacement for chronic mitral regurgitation should not be performed unless mitral valve repair has been attempted and was unsuccessful.[115] In acute mitral regurgitation caused by MI, surgical repair must be done emergently.



ALGORITHM 32.8 **Pathophysiology of Mitral Regurgitation.**
A, Left atrium; *LV*, Left ventricle.

A flowchart shows the pathophysiology of mitral regurgitation. 1. Critical mitral regurgitation. Leads to 2 and 3. 2. Valve thrombosis. Leads to 14. 3. Blood leaks from the L V back into the L A during diastole. Leads to 4. 4. Combines from blood from pulmonary veins. Leads to 5. 5. L A and L V volume increase. Leads to 6. 6. Gradual decrease in L V contractility. Leads to 7 and 11. 7. Increased L A pressure. Leads to 8 and 15. 8. Increased pulmonary venous pressures. Leads to 9. 9. Pulmonary edema. Leads to 10. 10. Dyspnea, orthopnea, and cough. 11. Decreased cardiac output. Leads to 11. 12. Decreased perfusion of systemic and coronary arteries. Leads to 12. 13. Tissue ischemia. Leads to 13. 14. Syncope, oliguria, stroke. 15. L A dilation. Leads to 16. 16. Atrial fibrillation. Leads to 14 and 17. 17. Palpitations.

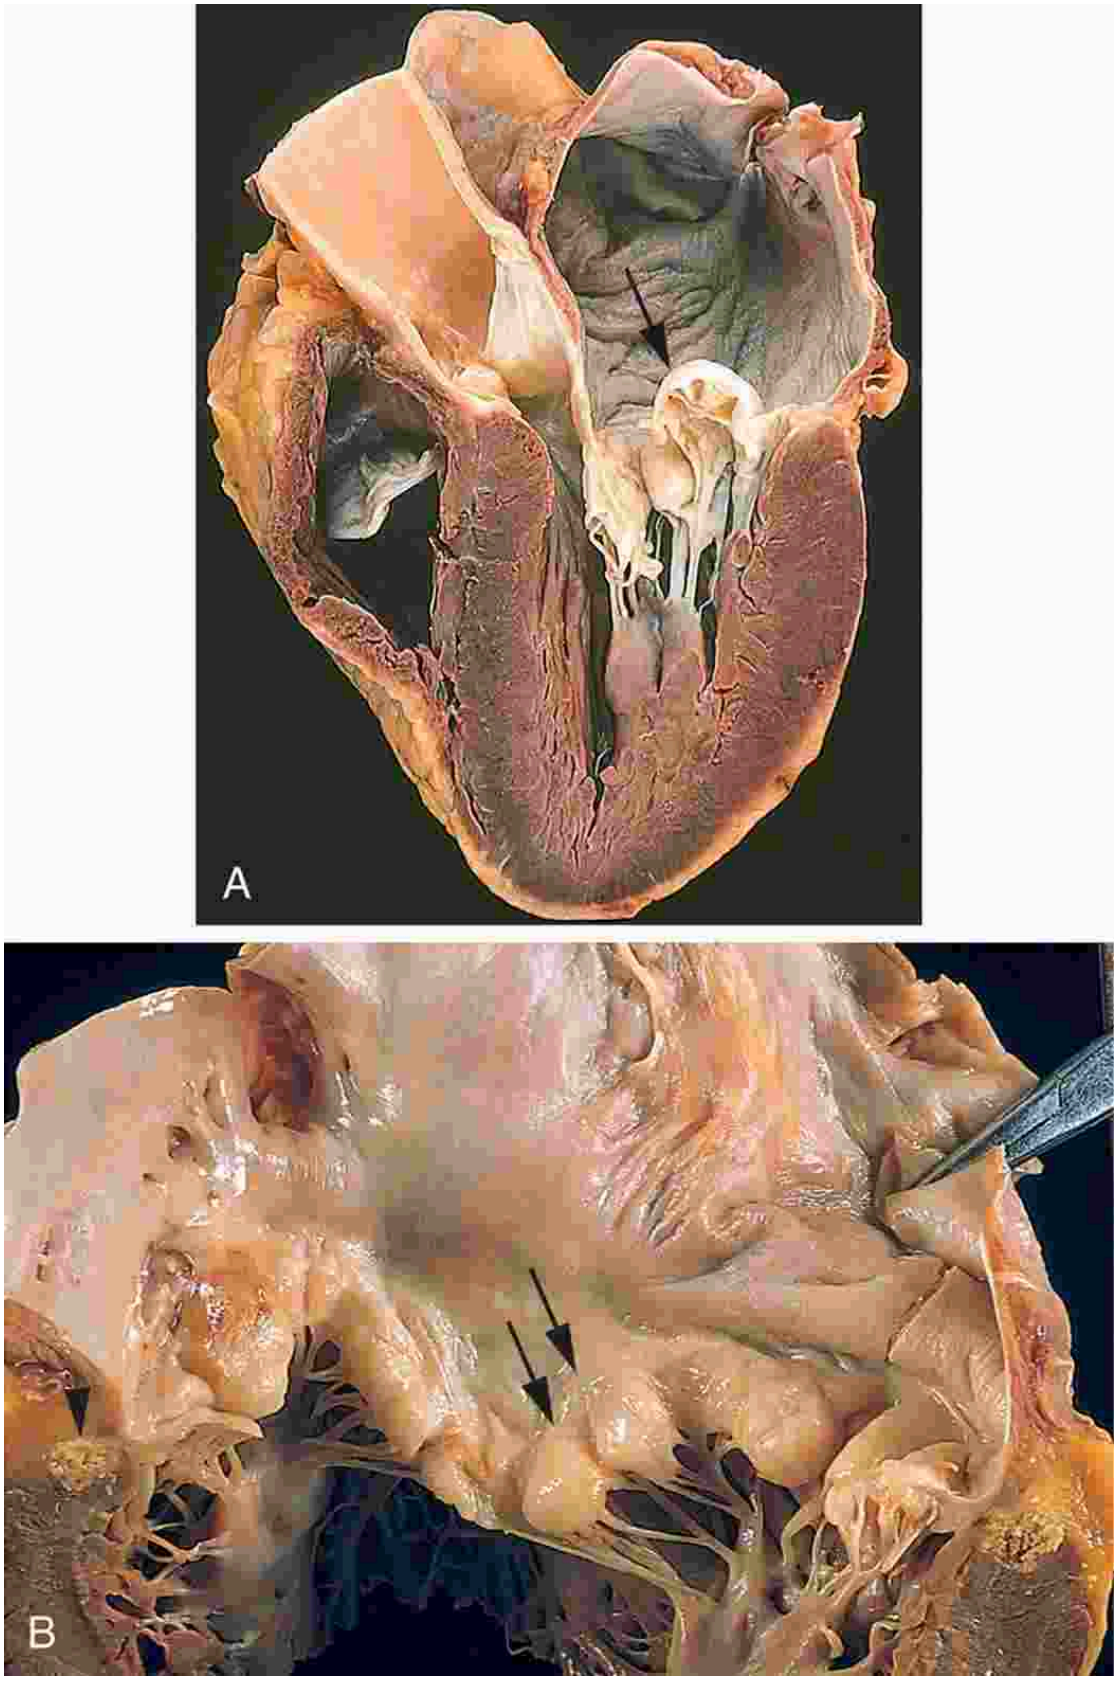
Tricuspid regurgitation

Tricuspid regurgitation is a prevalent valvular disorder and is more common than tricuspid stenosis. Primary tricuspid regurgitation can be caused by congenital defects, rheumatic heart disease, endocarditis, or trauma. However, most cases of tricuspid regurgitation in adults are the result of annular dilatation related to chronic heart failure with pulmonary hypertension and dilation of the right ventricle, which pulls the valve leaflets apart.[123] Tricuspid valve incompetence leads to volume overload in the right atrium and ventricle, increased systemic venous blood pressure, and right heart failure. Management includes guideline-directed medical treatment for heart failure.[115] Some individuals

require surgery, but operative mortality can be high, and new transcatheter approaches are emerging.[114,123] Pulmonic valve dysfunction can have the same consequences as tricuspid valve dysfunction.

Mitral Valve Prolapse Syndrome

In mitral valve prolapse syndrome (MVPS), one or both of the cusps of the mitral valve billow upward (prolapse) into the left atrium during systole (Fig. 32.21). MVP is the most common valve disorder in the United States, with a prevalence of nearly 3% of adults. MVP can be associated with inherited connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta), suggesting that it results from a genetic or environmental disruption of valvular development during the fifth or sixth week of gestation. There also may be a relationship between symptomatic MVP and hyperthyroidism.



A
B

FIG. 32.21 Mitral Valve Prolapse (MVP).
(A) Prolapsed mitral valve. Prolapse permits the valve leaflets to billow back *(arrow)* into the atrium during left ventricular systole. The billowing causes the leaflets to part slightly, permitting regurgitation into the atrium. (B) Looking down into the mitral valve, the ballooning *(arrows)* of the leaflets is seen. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

The most common cause of MVP is myxomatous degeneration of the leaflets. Valve leaflets undergoing abnormal biomechanics undergo degeneration of valve structure and tissue proliferation on the atrial side of the mitral leaflets contributing to prolapse.[114] Cusps become redundant, thickened, and scalloped because of changes in tissue proteoglycans, increased levels of proteinases, and infiltration by myofibroblasts.[124] MVP is the most common cause of mitral regurgitation which occurs if the ballooning valve permits blood to leak into the atrium.

Many cases of MVP are completely asymptomatic. Cardiac auscultation on routine physical examination may disclose a regurgitant murmur or midsystolic click, or echocardiography may demonstrate the condition in the absence of auscultatory findings. Symptomatic MVPs can cause palpitations, tachycardia, atypical chest pain, lightheadedness, syncope, fatigue, weakness, dyspnea, chest tightness, anxiety, depression, and panic attacks. Many symptoms are vague and puzzling and are unrelated to the degree of prolapse. Most individuals with MVP have an excellent prognosis, do not develop symptoms, and do not require any restriction in activity or medical management. Occasionally, β-blockers are needed to alleviate syncope, severe chest pain, or palpitations. If MVP is complicated by mitral regurgitation, it has a 10-year mortality of 19% and mitral valve prolapse-related events (stroke, heart failure, endocarditis, and mitral valve surgery) occur in 20% of individuals by 10 years.[125]

Acute Rheumatic Fever and Rheumatic Heart Disease

Acute rheumatic fever (ARF) is a systemic inflammatory disease caused by a delayed exaggerated immune response to infection by the group A β-hemolytic streptococcus. In its acute form, rheumatic fever is a febrile illness characterized by inflammation of the joints, skin, nervous system, and heart. Although decreasing in incidence in the United States, ARF is the cause of rheumatic heart disease (RHD) later in life, which affects 40 million people worldwide.[126] Acute rheumatic fever occurs most often in children between the ages of 5 and 15 years, whereas RHD is usually diagnosed in adults.

Pathophysiology

ARF can develop only as a complication of pharyngeal infection by group A β-hemolytic streptococcus. Streptococcal skin infections do not progress to acute rheumatic fever because the strains of the microorganism that affect the skin do not have the same antigenic molecules in their cell membranes and do not elicit the same kind of immune response. Acute rheumatic fever is the result of an abnormal humoral and cell-mediated immune response to group A streptococcal cell membrane antigens called M proteins (Fig. 32.22). This immune response cross-reacts with molecularly similar self-antigens in the heart, muscle, brain, and joints (molecular mimicry), causing an autoimmune response that results in diffuse, proliferative, and exudative inflammatory lesions in these tissues.[127] The inflammation may subside before treatment, leaving behind damage to the heart valves. Repeated attacks of acute rheumatic fever cause chronic proliferative changes with resultant tissue scarring, granuloma formation, and thrombosis.

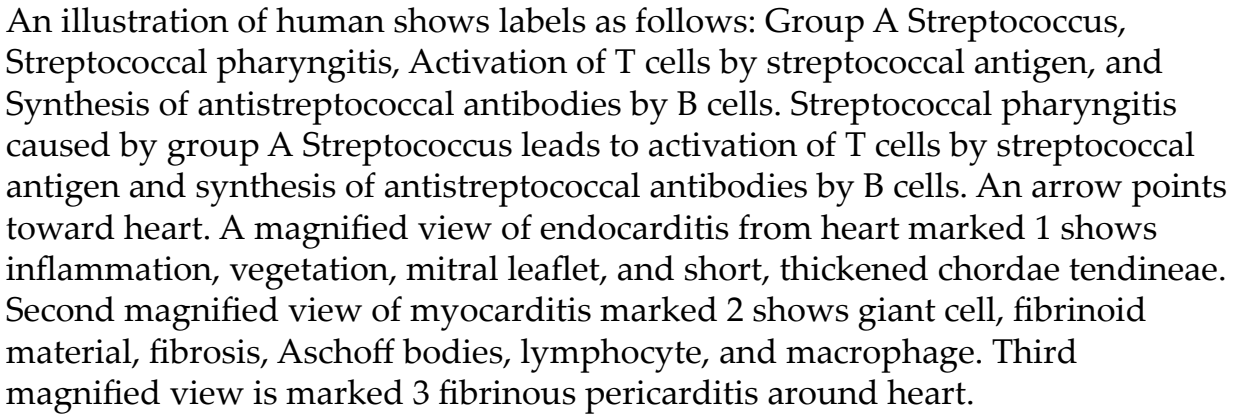
FIG. 32.22 Pathogenesis and Structural Alterations of Acute Rheumatic Heart Disease.
Beginning usually with a sore throat, rheumatic fever can develop only as a sequel to pharyngeal infection by group A β-hemolytic streptococcus. Suspected as a hypersensitivity reaction, it is proposed that antibodies directed against the M proteins of certain strains of streptococci cross-react with tissue glycoproteins in the heart, joints, and other tissues. The exact nature of cross-reacting antigens has been difficult to define, but it appears that the streptococcal infection causes an autoimmune response against self-antigens. Inflammatory lesions are found in various sites; the most distinctive within the heart are called Aschoff bodies. The chronic sequelae result from progressive fibrosis because of healing of the inflammatory lesions and the changes induced by valvular deformities. (From Damjanov I. *Pathology for the health professions*, 4th edition. Philadelphia: Saunders; 2012.)



Approximately 10% of individuals with rheumatic fever develop RHD, usually between the ages of 25 and 34. Valvulitis during clinical or subclinical ARF transitions to chronic valvular lesions that evolve over years.[128] The primary lesion in RHD involves the endocardium. Endocardial inflammation causes swelling of the valve leaflets, with secondary erosion along the lines of leaflet contact. Small, bead-like clumps of vegetation containing platelets and fibrin are deposited on eroded valvular tissue and on the chordae tendineae cordis. These lesions can become progressively adherent, and the leaflets may adhere to each other. Scarring and shortening of the involved structures occur over time.

If inflammation penetrates the myocardium (myocarditis), localized fibrin deposits develop that are surrounded by areas of necrosis. These fibrinoid necrotic deposits are called Aschoff bodies. Pericarditis also can occur, characterized by serofibrinous effusion within the pericardial cavity. Cardiomegaly and left heart failure may occur during episodes of untreated acute or recurrent rheumatic fever. Conduction defects and AF often are associated with rheumatic heart disease.

Clinical Manifestations

The common symptoms of acute rheumatic fever are fever, lymphadenopathy, arthralgia, nausea, vomiting, epistaxis (nosebleed), abdominal pain, and tachycardia. The major clinical manifestations of acute rheumatic fever usually occur singly or in combination 1 to 5 weeks after streptococcal infection of the pharynx. They are (1) carditis: murmur, chest pain, pericardial friction rub, ECG changes, valvular dysfunction; (2) polyarthritis: heat, redness, swelling, and pain that migrate among the large joints of the extremities; (3) chorea: sudden, aimless, irregular, involuntary movements; (4) erythema marginatum: nonpruritic, erythematous macules on the trunk that may fade in the center; and (5) subcutaneous nodules: palpable nodules over bony prominences and extensor tendons.

Evaluation and Treatment

Diagnosis of ARF is based on the Jones Criteria which combine symptoms and signs with laboratory evidence of systemic inflammation (elevated C-reactive protein or erythrocyte sedimentation rate). Echocardiography should be performed on anyone suspected of ARF to determine if subclinical carditis is present.[129] Supportive evidence for the diagnosis of rheumatic fever includes positive throat cultures and measurement of serum antibodies against the hemolytic factor streptolysin O. Several other antibody tests also are available.

Appropriate antibiotic therapy given within the first 9 days of group A β-hemolytic streptococcus infection usually prevents rheumatic fever.[128] Therapy for acute rheumatic fever is aimed at eradicating the streptococcal infection and involves a 10-day regimen of antibiotics. NSAIDs are used as antiinflammatory agents for both carditis and arthritis. Serious carditis may require corticosteroids and diuretics. Because recurrent rheumatic fever occurs in more than half of affected children, continuous prophylactic antibiotic therapy may be necessary for as long as 5 years. RHD may require surgical repair of damaged valves.

Infective Endocarditis

Infective endocarditis is a general term used to describe infection and inflammation of the endocardium —especially the cardiac valves. Over 80% of cases are caused by bacteria, especially streptococci, staphylococci, and enterococci. Other causes include viruses, fungi, rickettsia, and parasites (see *Risk Factors:* Infective Endocarditis).

Risk Factors

Infective Endocarditis

- Acquired valvular heart disease
- Implantation of prosthetic heart valves
- Congenital lesions associated with highly turbulent flow (e.g., ventricular septal defect)
- Previous attack of infective endocarditis
- Intravenous drug use
- Long-term indwelling intravenous catheterization (e.g., for pressure monitoring, feeding, hemodialysis)
- Implantable cardiac pacemakers
- Heart transplant with defective valve

Pathophysiology

The pathogenesis of infective endocarditis requires at least three critical elements:

1. *Endocardial damage*. Trauma, congenital heart disease, valvular heart disease, and the presence of prosthetic valves are the most common risk factors for endocardial damage that leads to infective endocarditis. Turbulent blood flow caused by these abnormalities usually affects the atrial surface of atrioventricular valves or the ventricular surface of semilunar valves. Endocardial damage exposes the endothelial basement membrane, which contains a type of collagen that attracts platelets and thereby stimulates sterile thrombus formation on the membrane. This causes an inflammatory reaction (nonbacterial thrombotic endocarditis).
2. *Adherence of blood-borne microorganisms to the damaged endocardial surface*. Bacteria may enter the bloodstream during injection drug use, trauma, dental procedures that involve manipulation of the gingiva, cardiac surgery, genitourinary procedures and indwelling catheters in the presence of infection, or gastrointestinal instrumentation, or they may spread from uncomplicated upper respiratory tract or skin infections. Bacteria adhere to the damaged endocardium using adhesins.

3. *Formation of infective endocardial vegetations* (Fig. 32.23). Bacteria infiltrate the sterile thrombi and accelerate fibrin formation by activating the clotting cascade. These vegetative lesions can form anywhere on the endocardium but usually occur on heart valves and surrounding structures. Although endocardial tissue is constantly bathed in antibody-containing blood and is surrounded by scavenging monocytes and polymorphonuclear leukocytes, bacterial colonies are inaccessible to host defenses because they are embedded in the protective fibrin clots and biofilms. This also makes them difficult to treat with antibiotics. Embolization from these vegetations can lead to abscesses and characteristic skin changes, such as petechiae, splinter hemorrhages, Osler nodes, and Janeway lesions.

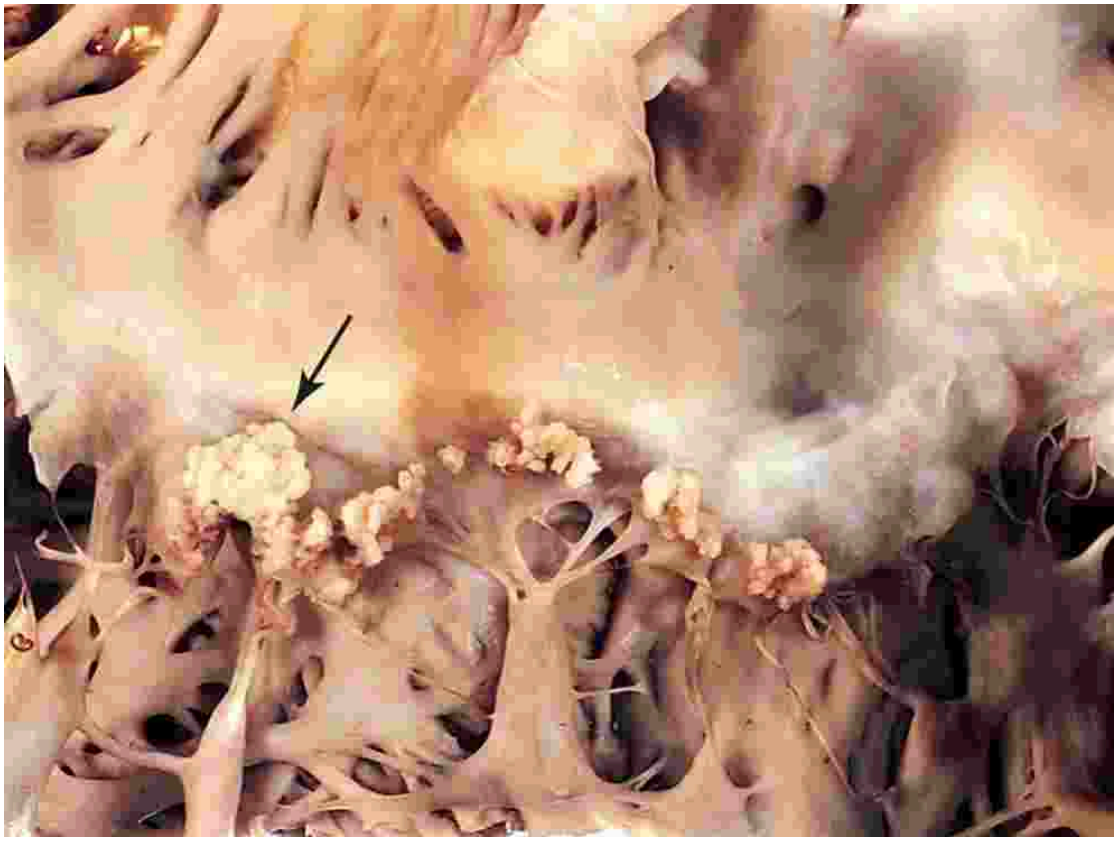


FIG. 32.23 Bacterial Endocarditis of Mitral Valve.
The valve is covered with large, irregular vegetations *(arrow)*. (From Damjanov I, Linder J. *Pathology: A color atlas*. St. Louis: Mosby; 2000.)

Clinical Manifestations

Infective endocarditis causes varying degrees of valvular dysfunction and may be associated with manifestations involving several organ systems, making diagnosis difficult. Signs and symptoms of infective endocarditis are caused by infection and inflammation, systemic spread of microemboli, and immune complex deposition. Microemboli can spread to splenic, renal, pulmonary, peripheral arterial, coronary, bone, CNS, and ocular circulations. The classic findings are fever; new or changed cardiac murmur; and petechial lesions of the skin, conjunctiva, and oral mucosa. Characteristic physical findings include Osler nodes (painful erythematous nodules on the pads of the fingers and toes) and Janeway lesions (nonpainful hemorrhagic lesions on the palms and soles). CNS complications are the most severe extracardiac complications and include stroke, abscess, and meningitis. Other manifestations include weight loss, back pain, night sweats, and heart failure.

Evaluation and Treatment

The Modified Duke criteria for the diagnosis of infective endocarditis include blood cultures positive for bacteria, evidence for endocardial involvement (by echocardiogram or by recognition of a new valvular regurgitation murmur), recognized risk factors, fever, vascular complications, and immunologic phenomena (e.g., Osler nodes).[115] Positron emission tomography (PET) may be required.[130] Serum C-reactive protein is elevated. Antimicrobial therapy is generally given for several weeks, beginning with intravenous and ending with oral administration.[115] Other drugs may be necessary to treat left heart failure secondary to valvular dysfunction. Surgery that involves excision of infected tissue with or without valve replacement may be needed for refractory infections, especially in those individuals who develop acute heart failure, highly resistant infections, or abscesses and emboli.[115,131] Persistent or relapsing infection requires the removal of implanted cardiac devices such as pacemakers, defibrillator systems, and prosthetic valves.[115]

Guidelines for the use of antibiotic prophylaxis before dental procedures to prevent infective endocarditis were updated in 2017.[132] Indications include prosthetic valves (including transcatheter-implanted grafts), prosthetic material used for cardiac valve repair, a history of infective endocarditis, unrepaired cyanotic congenital heart disease, and heart transplant with valvular defect.

Manifestations of Heart Disease

Heart Failure

In 2021, the first universal definition and classification of heart failure was published: "Heart failure is a clinical syndrome with symptoms and/or signs caused by a structural and/or functional cardiac abnormality and corroborated by elevated natriuretic peptide levels and/or objective evidence of pulmonary or systemic congestion."[133] Heart failure occurs when the heart is unable to generate an adequate cardiac output, causing inadequate perfusion of tissues, or when there is increased diastolic filling pressure of the left ventricle, or both, so that pulmonary capillary pressures are increased.

An estimated 6 million Americans over the age of 20 have heart failure, and the prevalence of heart failure has been predicted to increase by 46% by 2030. Heart failure results in 800,000 hospital admissions and 83,000 deaths per year in the United States.[12] Ischemic heart disease and hypertension are the most important predisposing risk factors. Another important risk factor is diabetes which has multiple effects on the myocardium (see Emerging Science Box: Diabetes and Heart Failure). Other risk factors include age, obesity, renal failure, valvular heart disease, cardiomyopathies, myocarditis, congenital heart disease, and excessive alcohol use. Numerous genetic polymorphisms have been linked to an increased risk for heart failure, including genes for cardiomyopathies, myocyte contractility, and neurohumoral receptors. Most heart failure results from dysfunction of the left ventricle (heart failure with reduced EF and heart failure with preserved EF). The right ventricle also may be dysfunctional, especially in pulmonary disease (right ventricular failure). Finally, some conditions cause inadequate perfusion despite normal or elevated cardiac output (high-output failure).

Emerging Science BoxDiabetes and Heart Failure

The prevalence of diabetes in individuals with heart failure ranges from 25% to 40%, and two thirds of those with metabolic syndrome will eventually develop HFrEF. In addition to being a risk factor for dyslipidemia, coronary artery disease, and hypertension, diabetes has direct toxicity to the myocardium (diabetic cardiomyopathy). Myocytes are impacted by insulin resistance resulting in decreased efficacy of intracellular calcium efflux and decreased contractility. The deposition of damaging by-products of insulin resistance (advanced glycation end products [AGEs]) contributes to hypertrophic and fibrotic remodeling of the myocardium. In addition to structural changes, insulin resistance in type 2 diabetes leads to impairment of ATP production, which shifts myocyte metabolism toward fatty acid oxidation. In the failing heart, increased demand for oxygen and energy is coupled with a decreased ability to use fatty acids as an energy source and lipids are deposited into the myocardium causing lipotoxicity. Diabetes also contributes to autonomic dysfunction and inflammation in the heart, further compromising myocyte function. In addition to blocking renal

reabsorption of glucose, the sodium-glucose cotransporter 2 (SLGT2) inhibitors increase renal sodium excretion and target many of the inflammatory, fibrotic, and neurohumoral mechanisms implicated in diabetes and heart failure. Clinical studies demonstrate improved cardiovascular outcomes for individuals with diabetes who are treated with these medications, and they are likely to become first-line medications for the treatment of diabetes and heart failure.

Data from Braunwald E. Diabetes, heart failure, and renal dysfunction: the vicious circles. *Progress in Cardiovascular Diseases*, 2019;62(4):298–302; Chen S, et al. Left Heart Failure (Congestive Heart Failure)

Left heart failure is categorized as heart failure with reduced EF (systolic heart failure) or heart failure with preserved EF (diastolic heart failure). It is possible for these two types of heart failure to occur simultaneously in one individual.

Heart failure with reduced ejection fraction

Heart failure with reduced ejection fraction (HFrEF), or systolic heart failure, is defined as heart failure with an ejection fraction of ≤40% and an inability of the heart to generate an adequate cardiac output to perfuse vital tissues. An ejection fraction (EF) of ≤40% means that 40% or less of the total amount of blood in the left ventricle at the end of diastole is pushed out with each systolic contraction (normal EF is 55% to 70%). This definition of HFrEF was affirmed in 2021, and two additional categories of HFrEF were proposed: (1) heart failure with mildly reduced EF (HFmrEF), which is defined as HF with an EF of 41% to 49%, and (2) heart failure with improved EF (HFimpEF) defined as a baseline EF of ≤40%, a ≥10-point increase from baseline EF, and a second measurement of EF > 40%.[133]

Cardiac output depends on the heart rate and stroke volume. Stroke volume is estimated by measuring the EF and is influenced by three major determinants: (1) contractility, (2) preload, and (3) afterload (see Chapter 31). Contractility is reduced by diseases that disrupt myocyte activity. MI is the most common primary cause of decreased contractility. Other primary causes include myocarditis and cardiomyopathies, especially dilated cardiomyopathy and hypertensive hypertrophic cardiomyopathy. Myocardial ischemia and increased myocardial workload contribute to inflammatory, immune, and neurohumoral changes (activation of the SNS and RAAS) that mediate a process called ventricular remodeling. Ventricular remodeling results in disruption of the normal myocardial extracellular structure and causes progressive myocyte contractile dysfunction over time (Fig. 32.24). When contractility is decreased, stroke volume falls and left ventricular end-diastolic volume (LVEDV) increases. This causes dilation of the heart and an increase in preload.

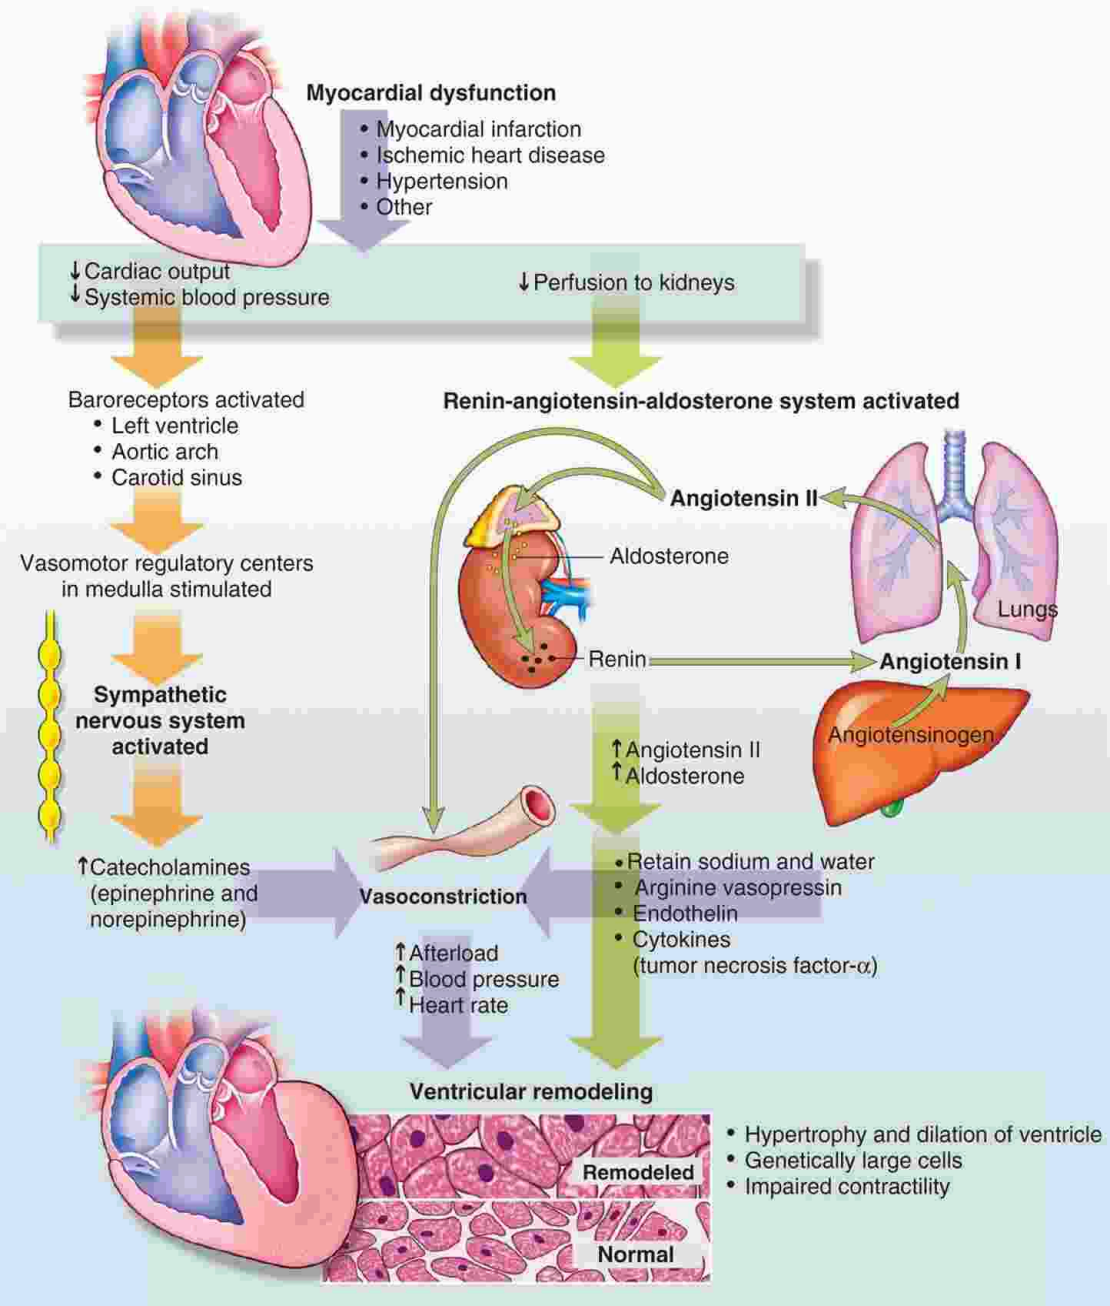

FIG. 32.24 Pathophysiology of Ventricular Remodeling.
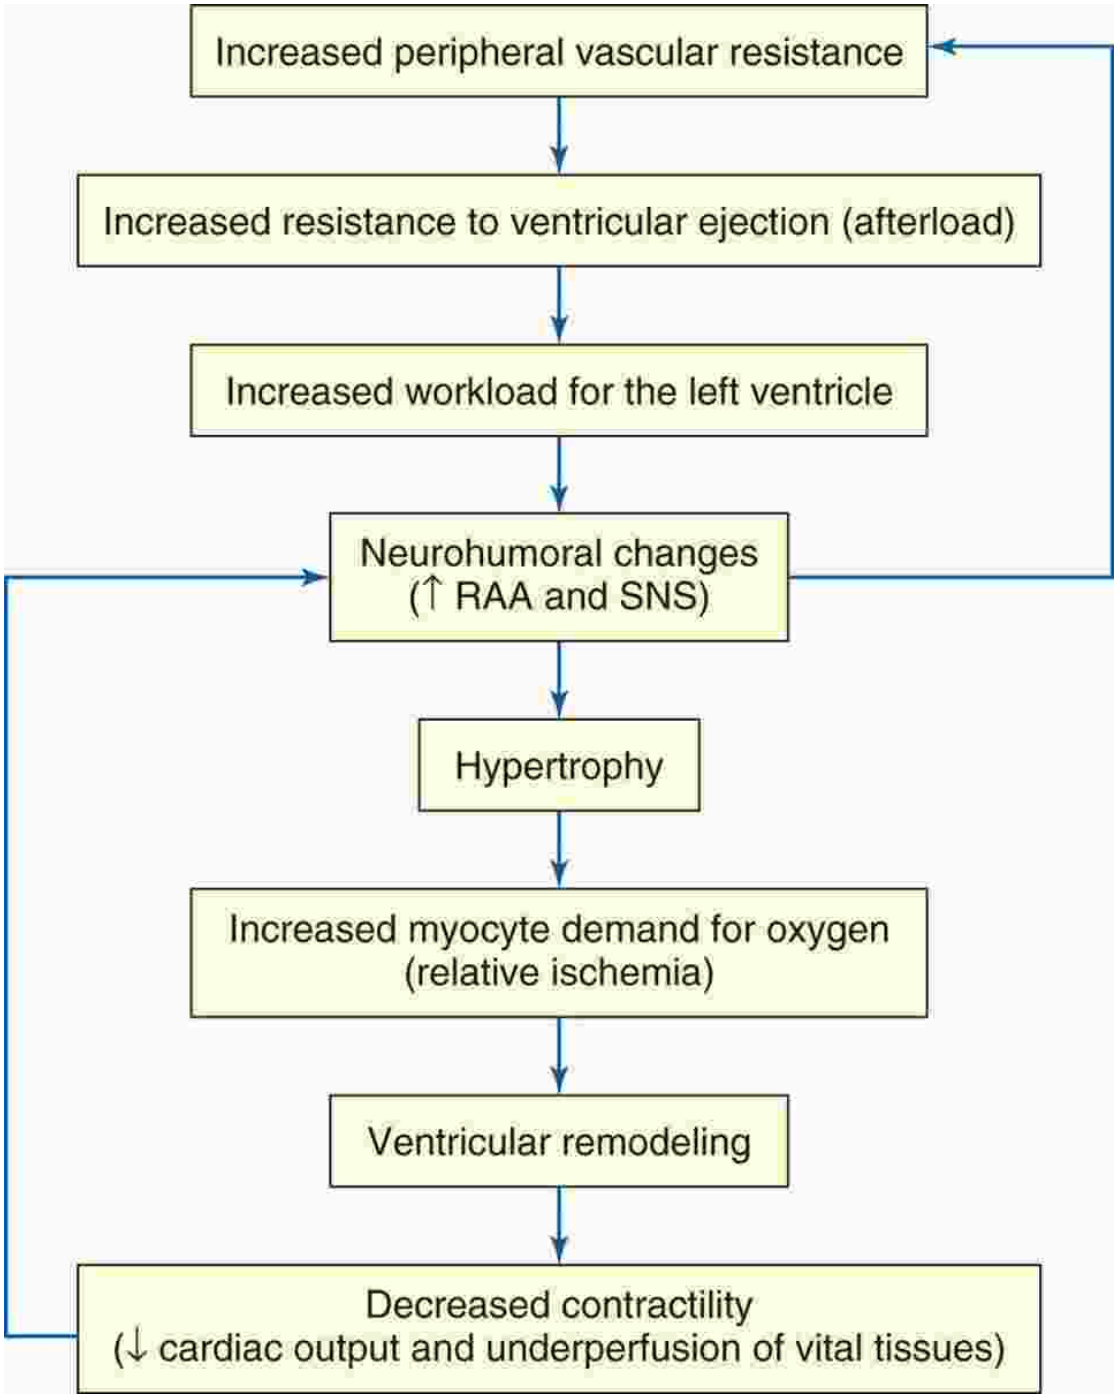
Myocardial dysfunction activates the renin-angiotensin-aldosterone and sympathetic nervous systems, releasing neurohormones (angiotensin II, aldosterone, catecholamines, and cytokines). These neurohormones contribute to ventricular remodeling. (Redrawn from Carelock J, Clark AP. Heart failure: Pathophysiologic mechanisms. *American Journal of Nursing*, 2001;101(12):27.)

An illustrated flowchart represents the pathophysiology of ventricular remodeling. The sequence of pathways in the flowchart are as follows. 1. Myocardial dysfunction: myocardial infraction; ischemic heart disease; hypertension; and other. An illustration shows the human heart. Leads to 2 and

3. 2. Decreased output and decreased systemic blood pressure. Leads to 4. 3. Decreased perfusion to kidneys. Leads to 10. 4. Baroreceptors activated: left ventricle; aortic arch; and carotid sinus. Leads to 5. 5. Vasomotor regulatory centers in medulla stimulated. Leads to 6. 6. Sympathetic nervous system activated. An illustration shows the nerve system. Leads to 7. 7. Increased catecholamines (epinephrine and norepinephrine). Leads to 8. 8. Vasoconstriction: increased afterload; increased blood pressure; and increased heart rate. Leads to 9. 9. Ventricular remodeling: hypertrophy and dilation of ventricle; genetically large cells; and impaired contractility. An illustration shows an inflamed heart. Accompanying magnified views of the ventricle show normal cells (small cells with nucleus) and remodeled cells (larger, overlapping cells with nucleus). 10. Renin-angiotensin-aldosterone system activated. A cyclic illustration shows the liver, the lungs, and the kidneys. Renin from the kidneys increases angiotensin 1 from the angiotensinogen in the liver. Angiotensin impacts the lungs, producing angiotensin 2. Angiotensin triggers the aldosterone in the kidney. Leads to 9 or 11. 11. Increased angiotensin 2 and increased aldosterone. Leads to 12. 12. Retain sodium and water; arginine vasopressin; endothelin; and cytokines (tumor necrosis factor-alpha). Leads to 9.

Preload, or LVEDV, increases with decreased contractility or an excess of plasma volume (intravenous fluid administration, renal failure, mitral valvular disease). Increases in LVEDV stretch the heart and can actually improve cardiac output up to a certain point, but as preload continues to rise, dilation of the myocardium eventually leads to dysfunction of the sarcomeres and decreased contractility. This relationship is described by the Frank-Starling law of the heart (see Fig. 31.15). Dilation of the heart also stretches the coronary arteries causing them to narrow, diminishing blood flow to the myocardium and further compromising contractility. Decreased contractility means less blood is ejected from the heart and therefore leads to further increases in preload.

Increased afterload is most commonly a result of increased PVR seen with hypertension. Although much less common, it also can be the result of aortic valvular disease. With increased afterload, there is resistance to ventricular emptying and more workload for the ventricle (Algorithm 32.9). Sustained afterload is associated with high levels of Ang II and catecholamines leading to remodeling and eventual hypertensive hypertrophic cardiomyopathy. This results in an increase in oxygen demand by the thickened myocardium. A state of relative ischemia develops that contributes to alteration of the cardiac extracellular matrix which can disrupt the integrity of the muscle, decrease contractility, and increase the likelihood that the ventricle will dilate and fail.[134]



ALGORITHM 32.9 Role of Increased Afterload in the Pathogenesis of Heart Failure.
RAA, Renin-angiotensin-aldosterone; *SNS*, sympathetic nervous system.

A flowchart shows the role of increased afterload in the pathogenesis of heart failure. 1. Increased peripheral vascular resistance. Leads to 2. 2. Increased resistance to ventricular ejection (afterload). Leads to 3. 3. Increased workload for the left ventricle. Leads to 4. 4. Neurohumoral changes (increased RAA and

SNS). Leads to 1 and 5. 5. Hypertrophy. Leads to 6. 6. Increased myocyte demand for oxygen (relative ischemia). Leads to 7. 7. Ventricular remodeling. Leads to 8. 8. Decreased contractility (decreased cardiac output and underperfusion of vital tissues). Leads to 4.

As cardiac output falls, renal perfusion diminishes and the RAAS is activated, which acts to increase PVR and plasma volume, thus further increasing afterload and preload. In addition, baroreceptors in the central circulation stimulate the SNS to cause yet more vasoconstriction and cause the hypothalamus to produce antidiuretic hormone. This vicious cycle of decreasing contractility, increasing preload, and increasing afterload causes progressive worsening of left heart failure (Fig. 32.25).

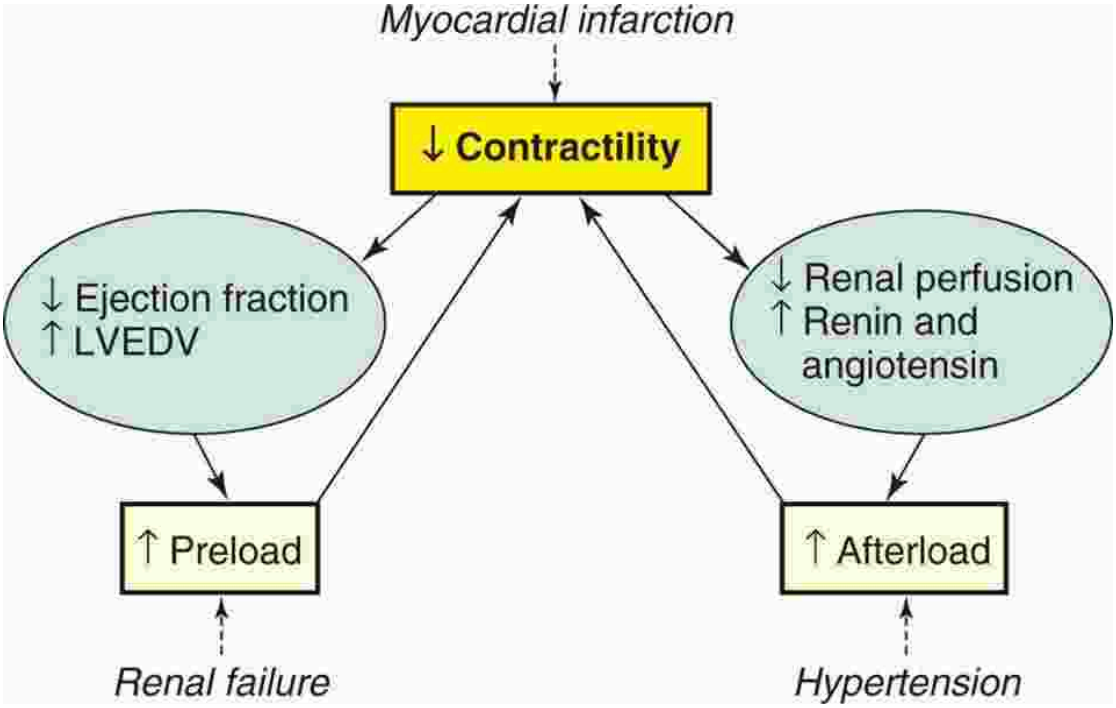


FIG. 32.25 Vicious Cycle of Heart Failure With Reduced Ejection Fraction. Although the initial insult may be one of primary decreased contractility (e.g., myocardial infarction), increased preload (e.g., renal failure), or increased afterload (e.g., hypertension), all three factors play a role in the progression of left heart failure. *LVEDV*, Left ventricular end-diastolic volume.

A cyclic diagram shows myocardial infarction leading to decreasing contractility, followed by decreased ejection fraction, increased L V E D V; decreased renal perfusion, increased renin and angiotensin. Ejection fraction, L V E D V and renal failure leads to increased preload. Decreased renal perfusion, increased renin and angiotensin, and hypertension leads to increased afterload.

In addition to these hemodynamic interactions, HFrEF is characterized by a complex constellation of neurohumoral, inflammatory, and metabolic processes. Natriuretic peptides, especially BNP, are released in an effort to improve renal salt and water excretion but are inadequate to compensate for

these neurohumoral perturbations. Ang II and aldosterone have direct toxicity to the myocardium, contributing to remodeling, myocyte death, and fibrosis. Arginine vasopressin (antidiuretic hormone [ADH]) contributes to vasoconstriction, renal fluid retention, and hyponatremia. Catecholamines released by the SNS are toxic to the myocardium and contribute to remodeling. Insulin resistance and diabetes not only contribute to heart failure but also are a complication of heart failure with changes in myocyte metabolism. Inflammatory cytokines, such as TNF-α, are released in heart failure, contributing to myocardial damage as well as systemic weight loss (cardiac cachexia). Finally, changes in the metabolic processes within the myocardium also are affected, with a decreased ability of the heart to produce energy and an increase in release of toxic metabolites. These neurohumoral, inflammatory, and metabolic aspects of left HFrEF have led to the routine use of combinations of medications that inhibit angiotensin, aldosterone, and catecholamines, and increase salt excretion in an effort to prevent long-term damage to the myocardium, as well as the exploration of new treatment modalities focused on reducing inflammation and improving myocardial metabolic function.

The clinical manifestations of left heart failure are the result of pulmonary vascular congestion and inadequate perfusion of the systemic circulation. Individuals experience dyspnea, orthopnea, cough of frothy sputum, fatigue, decreased urine output, and edema. Physical examination often reveals pulmonary edema (cyanosis, inspiratory crackles, pleural effusions), hypotension or hypertension, an S_3 gallop, and evidence of underlying CAD or hypertension. The diagnosis can be further confirmed with echocardiography showing decreased EF and cardiomegaly. The level of serum BNP is used to estimate the severity of heart failure. Genetic screening for underlying risk factors may be indicated in selected individuals.

Management of HFrEF is aimed at interrupting the worsening cycle of decreasing contractility, increasing preload, and increasing afterload. Current U.S. guidelines for management are based on the ACC/AHA staging system which uses risk, evidence of structural heart disease, symptoms, and response to treatment to guide therapeutic interventions.[135,136] A new staging system has been proposed that is very similar but adds biomarker measurement (serum BNP) to its criteria.[133]

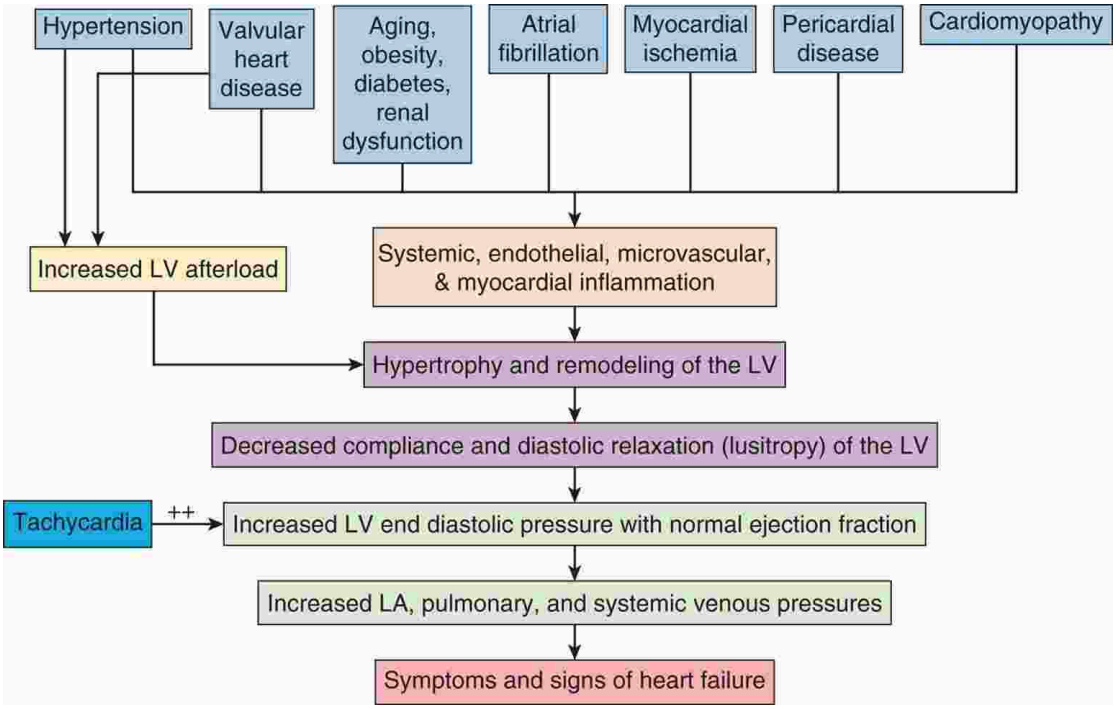
The acute onset of left heart failure is most often the result of acute myocardial ischemia and must be managed in conjunction with management of the underlying coronary disease. Oxygen, nitrate, and morphine administration improves myocardial oxygenation and helps relieve coronary spasm while lowering preload through systemic venodilation. Inotropic drugs, such as dopamine, dobutamine, and milrinone, increase contractility and can help raise the blood pressure in hypotensive individuals. Diuretics reduce preload. ACE inhibitors, ARBs, and aldosterone blockers reduce both preload and afterload by decreasing aldosterone levels and reducing PVR. Finally, individuals with severe HFrEF failure may benefit from acute coronary bypass or PCI. These people often are supported with the intra-aortic balloon pump (IABP) or left ventricular assist devices (LVADs) until surgery can be performed.[135]

Management of chronic left heart failure is based on current guidelines and clinical severity.[135,136] The overall goals are to reduce preload and afterload. Loop diuretics are effective in reducing preload. A combination of ACE inhibitors and aldosterone blockers are indicated, along with β-blockers.[135–137] In 2021, interim heart failure guidance issued by the American College of Cardiology added angiotensin receptor-neprilysin inhibitors (sacubitril/valsartan) and sodium-glucose cotransporter-2 (SGLT2) inhibitors (dapagliflozin, empagliflozin) to treatment algorithms for new-onset and chronic heart failure.[138] SGLT2 inhibitors have been shown to offer a significant reduction in mortality and heart failure hospitalizations, and improvement of quality of life when added to current standard drugs.[139] Inotropic drugs are used for those with refractory symptoms or to control atrial dysrhythmias. Recently, the selective myosin activator omecamtiv mecarbil was shown to improve cardiac function in individuals with HRrEF.[140] Additional interventions, such as implantable cardioverter-defibrillators, cardiac resynchronization, and LVADs, may be indicated in selected individuals.[135,136] For those individuals with CAD, coronary bypass surgery or PCI may improve perfusion to ischemic myocardium (hibernating myocardium) and improve cardiac output. Surgical interventions that improve ventricular geometry or heart transplantation may need to be considered.[141] Experimental therapies, including gene and stem cell therapies, are being explored.[142,143] Those with severe heart failure unresponsive to treatment and ineligible for transplantation should receive palliative care.

Heart failure with preserved ejection function

Heart failure with preserved ejection function (HFpEF) is a clinical syndrome in which individuals have symptoms and signs of HF with a left ventricular ejection fraction ≥50%.[135,136] It is associated with decreased compliance of the left ventricle. This results in the inability of the heart to achieve a normal cardiac output without the requirement for elevated cardiac filling pressures due to decreased diastolic relaxation. It is the cause of over half of all cases of left heart failure, affecting >70% of individuals with HF over the age of 65.[144,145] The major risk factors for HFpEF include hypertension, aging, obesity, diabetes, myocardial ischemia, valvular heart disease, atrial fibrillation, pericardial disease, and cardiomyopathies.

In the aging individual with risk factors for HFpEF, numerous pathological changes occur within the endothelium and myocardium of the left ventricle (Algorithm 32.10). In many individuals, a persistent increase in afterload due to hypertension or valvular disease results in hypertrophic remodeling of the left ventricle and deleterious changes to the extracellular matrix.[146] HFpEF is now considered to be a multisystem syndrome involving the heart, lungs, kidneys, skeletal muscle, adipose tissue, blood vessels, and inflammatory/immune activation.[144] Systemic chronic inflammation associated with aging, diabetes, obesity, ischemia, and primary disease of the pericardium and myocardium contributes to cellular damage and collagen deposition with scarring.[144,145,147] Endothelial microvascular and mitochondrial dysfunction compound these effects.[148] As a result, there is decreased compliance of the left ventricle and abnormal diastolic relaxation. With decreased compliance and inadequate relaxation, the ventricle lumen is smaller than normal during diastole and cannot accept filling with blood without causing an increase in wall tension. Thus a normal LVEDV results in an increased LVEDP. This pressure is reflected back into the left atrium, pulmonary vessels, and systemic venous circulation. Left atrial hypertrophy, pulmonary hypertension, and right ventricular hypertrophy may develop. If pulmonary pressures are high enough, pulmonary edema occurs. The increase in pressure is made worse by rapid ventricular filling, so symptoms are worse with tachycardia (e.g., with exercise).



ALGORITHM 32.10 Pathophysiology of Heart Failure with Preserved Ejection Fraction
LA, Left atrium; *LV*, Left ventricle.

A flowchart shows the pathophysiology of heart failure with preserved ejection fraction L A and L V. 1. Hypertension. Leads to 8 and 11. 2. Valvular heart disease. Leads to 8 and 11. 3. Aging, obesity, diabetes, renal dysfunction. Leads to 8. 4. Atrial fibrillation. Leads to 8. 5. Myocardial ischemia. Leads to 8. 6. Pericardial disease. Leads to 8. 7. Cardiomyopathy. Lead to 8. 8. Systemic, endothelial microvascular, and myocardial inflammation. Leads to 9. 9. Hypertrophy and remodeling of the L V. Leads to 10. 10. Decreased compliance and diastolic relaxation (lusitropy) of the L V. Leads to 11. 11. Increased L V end diastolic pressure with normal ejection fraction. Leads to 12. 12. Increased L A, pulmonary, and systemic venous pressures. Leads to 13. 13. Symptoms and signs of heart failure. 14. Increased L V afterload. Leads to 9. 15. Tachycardia (positive, positive). Leads to 11.

Individuals with early HFpEF present with dyspnea on exertion and fatigue. Evidence of pulmonary edema (inspiratory crackles on auscultation, pleural effusions) is usually not present in resting individuals without tachycardia but may develop over time. Late in diastole, atrial contraction with rapid ejection of blood into the noncompliant ventricle may give rise to an S_4 gallop. Other symptoms and signs in advanced disease include paroxysmal nocturnal dyspnea, jugular venous distension, and hepatomegaly. Electrocardiography often reveals evidence of left ventricular hypertrophy, and chest x-ray may show pulmonary congestion without cardiomegaly (Table 32.7). There also may be evidence of underlying coronary disease, hypertension, or valvular disease. Diagnosis is based on three factors: (1) signs and symptoms of heart failure, (2) normal left ventricular EF, and (3) evidence of diastolic dysfunction. The diagnosis is confirmed by clinical Doppler echocardiography, which demonstrates

poor ventricular filling with normal EFs. In some individuals, invasive hemodynamic exercise testing may be needed.[149] BNP levels are usually elevated in more severe cases.

Table 32.7

Comparison of Heart Failure With Reduced Ejection Fraction (HFrEF) and Heart Failure With Preserved Ejection Fraction (HFpEF)

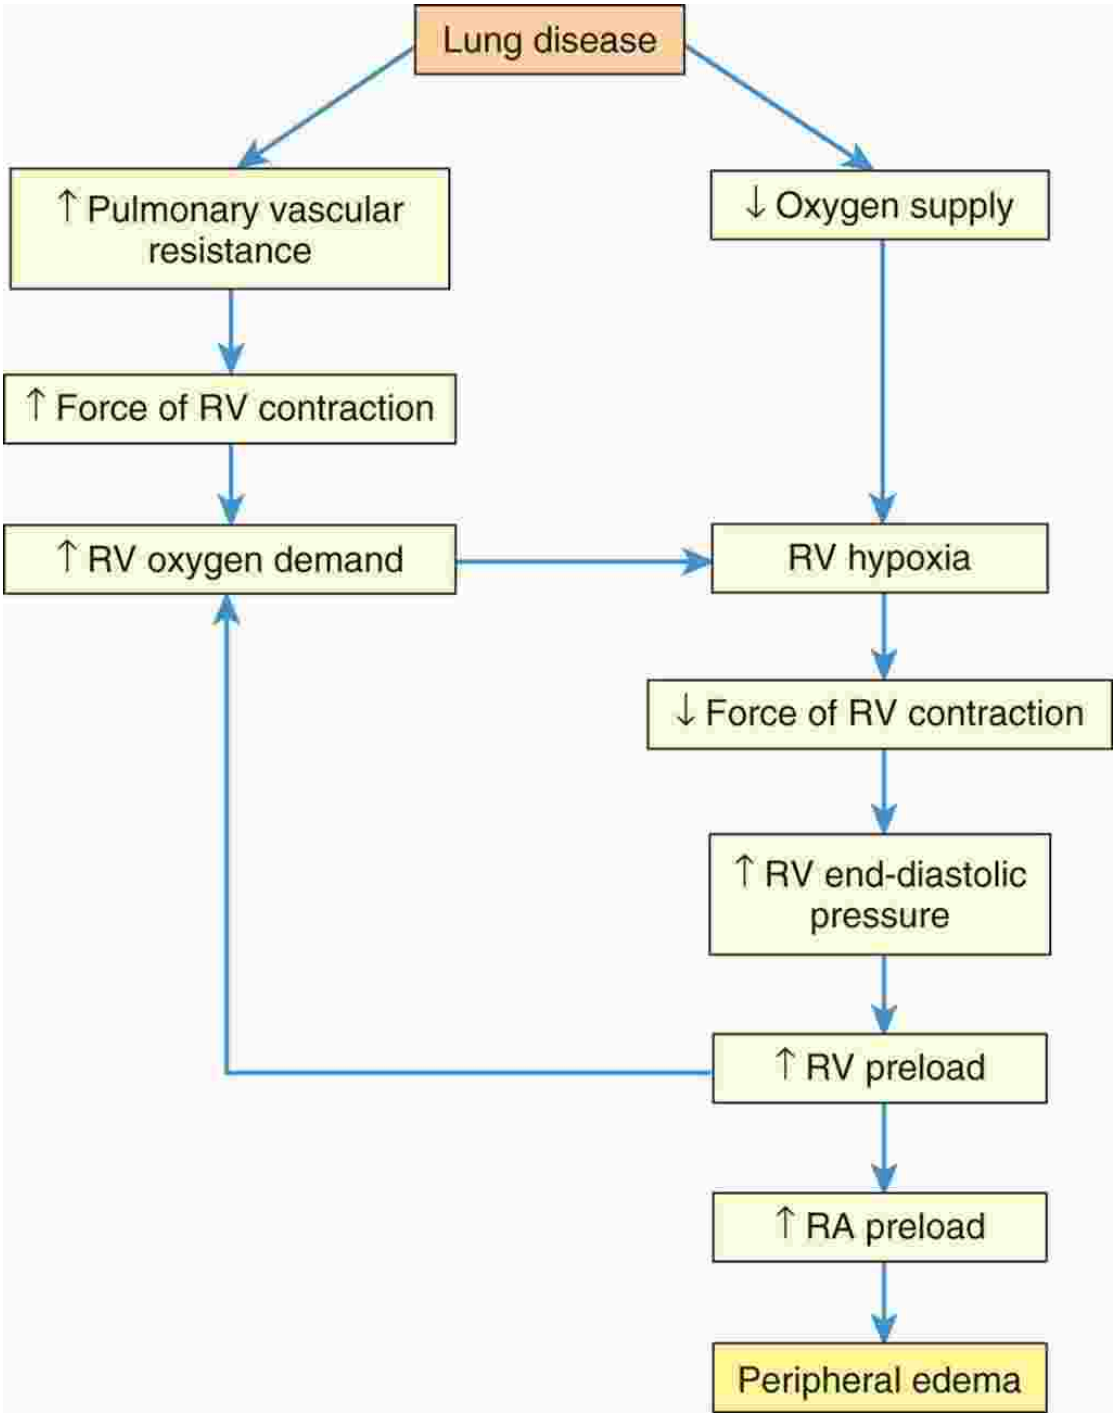
Characteristic	HFrEF	HFpEF
Sex	Male > female	Female > male
Left ventricular ejection fraction	Decreased	Normal
Left ventricular morphology	Remodeling with dominance of dilation	Remodeling with dominance of hypertrophy
Left ventricular chamber size	Increased	Decreased
Left ventricular end diastolic volume (LVEDV)	Increased	Normal
Left ventricular end diastolic pressure (LVEDP)	Increased	Increased
Chest radiography	Pulmonary congestion with cardiomegaly	Pulmonary congestion without cardiomegaly
Gallop	S_3	S_4

Management approaches for HFpEF are directed toward control of hypervolemia with thiazide or loop diuretics, the use of spironolactone and dual angiotensin-neprilysin inhibitors in selected individuals, exercise training, and management of associated comorbidities.[149] New therapies that target metabolic and immune signaling cascades are being developed.[144] Studies to evaluate the effectiveness of transcatheter interatrial shunts are underway.[150] Outcomes for individuals with HFpEF are as poor as those with HFrEF, and there has been little improvement in prognosis despite numerous new treatment trials.

Right Heart Failure

Right heart failure is defined as the inability of the right ventricle to provide adequate blood flow into the pulmonary circulation at a normal central venous pressure. It can result from left heart failure when an increase in left ventricular filling pressure is reflected back into the pulmonary circulation. As pressure in the pulmonary circulation rises, the resistance to right ventricular emptying increases. The right ventricle is poorly prepared to compensate for this increased afterload and will dilate and fail. When this happens, pressure will rise in the systemic venous circulation, resulting in peripheral edema and hepatosplenomegaly. Treatment relies on management of the left ventricular dysfunction as just outlined.

When right heart failure occurs in the absence of left heart failure, it is typically attributable to diffuse hypoxic pulmonary disease such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, and acute respiratory distress syndrome (ARDS). These disorders result in pulmonary vasoconstriction, pulmonary hypertension, and an increase in right ventricular afterload (Algorithm 32.11). The mechanisms for this type of right ventricular failure (cor pulmonale) are discussed in Chapter 35. Finally, MI, cardiomyopathies, and pulmonic valvular disease interfere with right ventricular contractility and can lead to right heart failure.



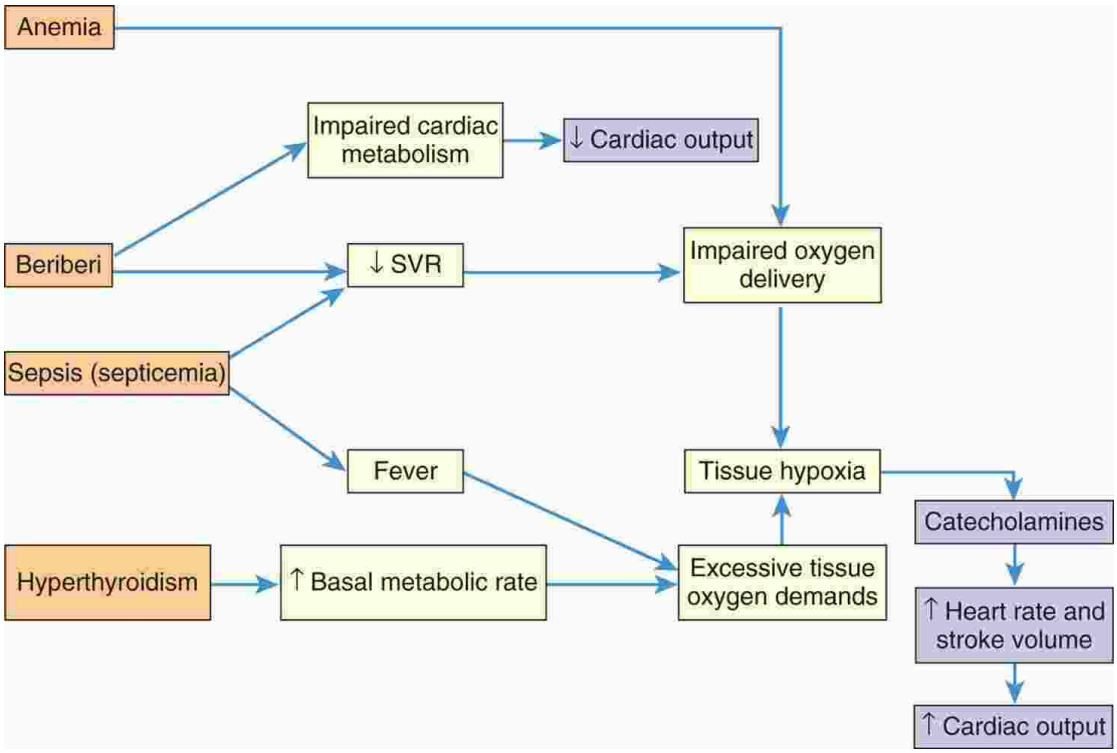
ALGORITHM 32.11 **Right Heart Failure Due to Lung Disease.**
RA, Right atrial; *RV*, right ventricular.

A flowchart represents the pathway to right heart failure. 1. Lung disease. Leads to 2 and 5. 2. Increased pulmonary vascular resistance. Leads to 3. 3. Increased force of R V contraction. Leads to 4. 4. Increased R V oxygen demand. Leads to 6. 5. Decreased oxygen supply. Leads to 6. 6. R V hypoxia. Leads to 7. 7. Decreased force of R V contraction. Leads to 8. 8. Increased R V end-diastolic

pressure. Leads to 9. 9. Increased R V preload. Leads to 4 and 10. 10. Increased R A preload. Leads to 11. 11. Peripheral edema.

High-Output Failure

High-output failure is the inability of the heart to adequately supply the body with blood-borne nutrients, despite adequate blood volume and normal or elevated myocardial contractility. In high-output failure, the heart increases its output, but the body's metabolic needs are still not met. Common causes of high-output failure are anemia, septicemia, hyperthyroidism, and beriberi (Algorithm 32.12).



ALGORITHM 32.12 High-Output Failure.
SVR, Systemic vascular resistance.

A flowchart represents the pathway to high-output failure. 1. Anemia. Leads to 10. 2. Beriberi. Leads to 5 and 6. 3. Sepsis (septicemia). Leads to 6 and 7. 4. Hyperthyroidism. Leads to 8. 5. Impaired cardiac metabolism. Leads to 9. 6. Decreased S V R. Leads to 10. 7. Fever. Leads to 12. 8. Increased basal metabolic rate. Leads to 12. 9. Decreased cardiac output. 10. Impaired oxygen delivery. Leads to 11. 11. Tissue hypoxia. Leads to 13. 12. Excessive tissue oxygen demands. Leads to 11. 13. Catecholamines. Leads to 14. 14. Increased heart rate and stroke volume. Leads to 15. 15. Increased cardiac output.

Anemia decreases the oxygen-carrying capacity of the blood. Metabolic acidosis occurs as the body's cells switch to anaerobic metabolism (see Chapter 3). In response to metabolic acidosis, heart rate and

stroke volume increase in an attempt to improve tissue perfusion. If anemia is severe, however, even maximum cardiac output does not supply the cells with enough oxygen for metabolism.

In septicemia, disturbed metabolism, bacterial toxins, and the inflammatory process cause systemic vasodilation and fever. Faced with a lowered systemic vascular resistance (SVR) and an elevated metabolic rate, cardiac output increases to maintain blood pressure and prevent metabolic acidosis. In overwhelming septicemia, however, the heart may not be able to raise its output enough to compensate for vasodilation. Body tissues show signs of inadequate blood supply despite a high cardiac output.

Hyperthyroidism accelerates cellular metabolism through the actions of elevated levels of thyroxine from the thyroid gland. This may occur chronically (thyrotoxicosis) or acutely (thyroid storm). Because the body's increased demand for oxygen threatens to cause metabolic acidosis, cardiac output increases. If blood levels of thyroxine are high and the metabolic response to thyroxine is vigorous, even an abnormally elevated cardiac output may be inadequate.

In the United States, beriberi (thiamine deficiency) usually is caused by malnutrition secondary to chronic alcoholism. Beriberi actually causes a mixed type of heart failure. Thiamine deficiency impairs cellular metabolism in all tissues, including the myocardium. In the heart, impaired cardiac metabolism leads to insufficient contractile strength. In blood vessels, thiamine deficiency leads to peripheral vasodilation, which decreases SVR. Heart failure ensues as decreased SVR triggers increased cardiac output, which the impaired myocardium is unable to deliver. The strain of demands for increased output in the face of impaired metabolism may deplete cardiac reserves until low-output failure begins.

Dysrhythmias

A dysrhythmia, or arrhythmia, is a disturbance of heart rhythm. Normal heart rhythms are generated by the SA node and travel through the heart's conduction system, causing the atrial and ventricular myocardium to contract and relax at a regular rate that is appropriate to maintain circulation at various levels of physical activity (see Chapter 31). There are many types of dysrhythmias that arise from disorders of impulse formation. These include those that are the result from dysfunction of the SA node, or from the development of abnormal electrical activity arising elsewhere in the conduction system or myocardium. Many other dysrhythmias arise from disorders of impulse conduction through the cardiac conducting system or heart tissue. There are multiple causes for disorders affecting conduction through the heart including inherited abnormalities, ischemia, infection, underlying diseases, medications, and iatrogenic injury from surgery or percutaneous interventions. For all arrhythmias, the primary clinical manifestations are the result of changes in the delivery of blood to the vital tissues due to changes in pulse rate, cardiac output, and blood pressure. These changes can range from asymptomatic to life-threatening. Diagnosis begins with documenting characteristic changes in the ECG along with evaluation for underlying causes. Management is aimed at supporting adequate cardiac output with medications or electrical stimulation (cardioversion, pacemaker insertion, cardiac resynchronization techniques) while attempting to reverse the underlying etiology.

While there are many ways to categorize dysrhythmias, national management guidelines focus on three primary areas: atrial dysrhythmias, ventricular dysrhythmias, and sinus node dysfunction and conduction disorders.[151–154] Table 32.8 provides an overview of some of the most common examples of these three types of dysrhythmias.

Table 32.8

Examples of Common Atrial and Ventricular Dysrhythmias and Cardiac Conduction Disorders

Pathophysiologic Type	Risk Factors	Clinical Manifestations	Acute Management
Atrial Dysrhythmias			
• Premature atrial contractions (PACs), • Atrial tachycardia, • Atrial flutter, • Atrial fibrillation, • Wolf-Parkinson White syndrome	Hypertension, ischemia, cardiomyopathy (e.g., hypertrophy), valvular heart disease, hyperthyroidism, alcohol/drugs, medications, inherited conduction abnormalities	Palpitations, lightheadedness, anxiety, dyspnea, chest pain, syncope, rapid or irregular pulse, hypotension, emboli (e.g., stroke)	Pharmacologic or electrical cardioversion, digoxin, calcium channel blockers, antiarrhythmics, pacemaker, catheter ablation, antithrombotics
Ventricular Dysrhythmias			
• Premature ventricular contractions (PVCs), • Ventricular flutter, • Ventricular tachycardia, • Torsades de pointes, • Ventricular fibrillation	Myocardial infarction, heart failure, electrolyte disorders, hypoxia, medications, hyperthyroidism, cardiomyopathy/myocarditis neuromuscular disorders, congenital heart disease, alcohol/drugs, underlying critical illness	Palpitations, lightheadedness, anxiety, dyspnea, chest pain, syncope, rapid, or irregular or absent pulse, hypotension	Cardioversion, antiarrhythmics, beta blockers, catheter ablation, pacing modalities
Sinus Node Dysfunction and Cardiac Conduction Disorders			
• Sinus node disease, • Atrioventricular block (first, second and third degree),	Medications (e.g., beta blockers, calcium channel blockers, digoxin), myocardial infarction, infection (e.g., Lyme carditis), infiltrative disease (e.g., cardiomyopathy), sleep	Fatigue, lightheadedness, syncope, coma, slow or irregular heart rate, hypotension	Vagolytics, sympathomimetics, theophylline, treatments specific for medication effects (e.g., intravenous calcium

Pathophysiologic Type	Risk Factors	Clinical Manifestations	Acute Management
• Atrioventricular disjunction, • Bundle branch block	apnea, hypothyroidism, iatrogenic (e.g., surgery)		for calcium channel blocker toxicity), pacemaker, cardiac resynchronization,

Data from Al-Khatib SM, Stevenson WG, Ackerman MJ, et al. 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Circulation*, 2018;138:e272–e391; January CT, Wann LS, Alpert JS, et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society in Collaboration with the Society of Thoracic Surgeons. *Circulation*, 2014;130:e199–e267; January CT, Wann LS, Calkins H, et al. 2019 AHA/ACC/HRS focused update of the 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society in Collaboration with the Society of Thoracic Surgeons. *Circulation*, 2019;140:e125– e151; Kusumoto FM, Schoenfeld MH, Barrett C, et al. 2018 ACC/AHA/HRS guideline on the evaluation and management of patients with bradycardia and cardiac conduction delay: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Circulation*, 2019;140:e382–e482.

Summary Review

Diseases of the Veins

1. Varicose veins are veins in which blood has pooled, usually in the saphenous veins of the leg. Varicose veins may be caused by damaged valves as a result of trauma to the valve or by chronic venous distention involving gravity and venous constriction.
2. Chronic venous insufficiency is inadequate venous return over a long period of time that causes pathologic ischemic changes in the vasculature, skin, and supporting tissues. Poor circulation makes tissues vulnerable to trauma and infection resulting in the formation of venous stasis ulcers.
3. A thrombus is a blood clot that remains attached to a vessel wall. Deep venous thrombosis results from stasis of blood flow, endothelial damage, or hypercoagulability. The most serious complication of deep venous thrombosis is pulmonary embolism.
4. Superior vena cava syndrome is a progressive occlusion of the superior vena cava that leads to venous distention in the upper extremities and head. Because this syndrome is usually caused by bronchogenic cancer, it is generally considered an oncologic emergency rather than a vascular emergency.

Diseases of Arteries

1. Hypertension is the elevation of systemic arterial blood pressure resulting from increases in cardiac output (blood volume), total peripheral vascular resistance, or both.
2. Hypertension can be primary, without a known cause, or secondary, caused by an underlying disease.
3. The risk factors for primary hypertension include a positive family history; male sex; advancing age; black race; obesity; high sodium intake; low magnesium, potassium, or calcium intake;

diabetes mellitus; cigarette smoking; and heavy alcohol consumption.

4. Primary hypertension is the result of a complicated interaction of genetics and the environment mediated by neurohumoral effects that influence intravascular volume and peripheral vascular resistance. Pathophysiologic mechanisms include overactivity of the sympathetic nervous system; overactivity of the renin-angiotensin-aldosterone system; sodium and water retention by the kidneys; hormonal inhibition of sodium-potassium transport across cell walls; and complex interactions involving insulin resistance, inflammation, and endothelial function.
5. Secondary hypertension is caused by a disease process or medication that raises peripheral vascular resistance or cardiac output.
6. As hypertension becomes more severe and chronic, tissue damage can occur in the blood vessels and tissues leading to target organ damage in the heart, kidney, brain, and eyes. Hypertensive crisis is an extremely high blood pressure that can lead to cardiac failure, stroke, or death, and is considered a medical emergency.
7. Clinical manifestations of hypertension result from damage of organs and tissues outside the vascular system. These include heart disease, renal insufficiency, central nervous system dysfunction, impaired vision, impaired mobility, vascular occlusion, and edema.
8. Hypertension is managed with both pharmacologic and nonpharmacologic methods that lower the blood volume and the total peripheral vascular resistance.
9. Orthostatic hypotension is a drop in blood pressure that occurs upon standing. The compensatory vasoconstriction response to standing is replaced by a marked vasodilation and blood pooling in the muscle vasculature.
10. The clinical manifestations of orthostatic hypotension include dizziness, blurring or loss of vision, and syncope or fainting.
11. An aneurysm is a localized dilation of a vessel wall; the aorta is particularly susceptible.
12. Arterial thrombi develop similarly to venous thrombi. They may grow large enough to occlude the artery, or they can dislodge and become a thromboembolus that may occlude flow into a distal systemic vascular bed.
13. An embolus is a mobile aggregate of a variety of substances that occludes the vasculature. Sources of emboli include clots, air, amniotic fluid, bacteria, fat, and foreign matter. These emboli cause ischemia and necrosis when a vessel is totally blocked.
14. The most common source of arterial thrombotic emboli is the left heart and they are associated with thrombus formation associated with myocardial infarction, valvular disease, left heart failure, endocarditis, and dysrhythmias.
15. Peripheral vascular diseases include thromboangiitis obliterans and Raynaud phenomenon.
16. Thromboangiitis obliterans is an autoimmune disease of the peripheral arteries characterized by the formation of thrombi filled with inflammatory and immune cells. It is strongly associated with smoking.
17. Raynaud phenomenon is characterized by vasospastic attacks in the small arteries and arterioles of the fingers and the toes triggered by brief exposure to cold, vibration, or emotional stress.
18. Atherosclerosis is a form of arteriosclerosis that is characterized by thickening and hardening of the vessel wall. It is the leading cause of peripheral artery disease, coronary artery disease, and cerebrovascular disease.
19. Atherosclerosis is an inflammatory disease that begins with endothelial injury.
20. Following injury, important steps in atherogenesis include inflammation, adherence of macrophages, release of inflammatory mediators, oxidation of LDL, formation of foam cells and fatty streaks, and development of fibrous plaque.
21. Once a plaque has formed, it can rupture, resulting in clot formation and instability and vasoconstriction, which lead to obstruction of the lumen and inadequate oxygen delivery to tissues.
22. Peripheral artery disease is the result of atherosclerotic plaque formation in the arteries that supply the extremities, and it causes pain, loss of pulse, and skin color changes in the affected limb.
23. Coronary artery disease (CAD) caused by atherosclerosis can diminish the myocardial blood supply until deprivation impairs myocardial metabolism enough to cause myocardial ischemia,

a local state in which the cells are temporarily deprived of blood supply.

24. Many risk factors contribute to the onset and escalation of CAD. Conventional (major) risk factors that are modifiable include dyslipidemia, smoking, hypertension, diabetes and insulin resistance, and obesity, sedentary lifestyle, and atherogenic diet. Conventional nonmodifiable risk factors include advanced age, male sex or women after menopause, and family history.
25. Nontraditional (novel) risk factors for CAD include markers of inflammation and ischemia, adipokines, chronic kidney disease, air pollution and ionizing radiation, medications, and the microbiome.
26. Myocardial ischemia develops if the flow or oxygen content of coronary blood is insufficient to meet the metabolic demands of myocardial cells. It is most commonly the result of coronary artery disease and the ensuing decrease in myocardial blood supply.
27. Atherosclerotic plaque progression can be gradual and cause stable angina pectoris, which is predictable chest pain caused by myocardial ischemia in response to increased demand (e.g., exercise) without infarction.
28. Prinzmetal angina, which results from coronary artery vasospasm, is chest pain attributable to transient ischemia of the myocardium that occurs unpredictably and often at rest.
29. Silent ischemia, myocardial ischemia that is asymptomatic, is an indicator of future serious cardiovascular events.
30. Sudden coronary obstruction because of thrombus formation on ruptured unstable atherosclerotic plaques causes the acute coronary syndromes. These include unstable angina and myocardial infarction.
31. Unstable angina results from rupture of an unstable plaque and subsequent thrombus formation with reversible myocardial ischemia.
32. Myocardial infarction is caused by rupture of an unstable plaque and thrombus formation leading to prolonged, unrelieved ischemia that interrupts blood supply to the myocardium. After about 20 minutes of myocardial ischemia, irreversible hypoxic injury causes cellular death and tissue necrosis.
33. Myocardial infarction is clinically classified as non-ST elevation myocardial infarction (non-STEMI) or ST elevation myocardial infarction (STEMI) based on electrocardiographic findings that suggest the extent of myocardial damage (subendocardial versus transmural).
34. An increase in plasma enzyme levels is used to diagnose the occurrence of myocardial infarction as well as indicate its severity. Elevations of the troponins are most predictive of a myocardial infarction.
35. Treatment of a myocardial infarction includes revascularization (thrombolytics or PCI) and administration of antithrombotics, ACE inhibitors, and beta-blockers. Pain relief and fluid management also are key components of care.

Disorders of the Heart Wall

1. Pericardial disease is a localized manifestation of another disorder, such as infection; trauma or surgery; neoplasm; or a metabolic, immunologic, or vascular disorder.
2. Acute pericarditis is acute inflammation of the pericardium. The pericardial membranes become inflamed and roughened, and a pericardial effusion may develop. Symptoms begin with sudden onset of severe chest pain that is worse with respirations or when lying down.
3. Pericardial effusion is the accumulation of fluid in the pericardial cavity. If the accumulation of fluid occurs rapidly, cardiac compression (tamponade) can occur.
4. In constrictive pericarditis, fibrous scarring with occasional calcification of the pericardium causes the pericardial layers to adhere. The fibrotic lesions encase the heart in a rigid shell which compresses the heart, reducing cardiac output.
5. Cardiomyopathies are a diverse group of diseases that affect the myocardium. The cardiomyopathies are categorized as dilated, hypertrophic, and restrictive. The size of the cardiac muscle walls and chambers may increase or decrease depending on the type of cardiomyopathy, thereby altering contractile activity.

6. Disorders of the endocardium damage the heart valves. Congenital or acquired disorders that result in stenosis (constricted or narrow valve), regurgitation (failure of valve to shut completely), or both can structurally alter the valves.
7. Characteristic heart sounds, cardiac murmurs, and systemic complaints assist in identification of an abnormal valve. If severely compromised function exists, a prosthetic heart valve may be surgically implanted to replace the faulty one.
8. Mitral valve prolapse (MVP) describes the condition in which the mitral valve leaflets do not position themselves properly during systole. MVP may be a completely asymptomatic condition or can result in unpredictable symptoms.
9. Rheumatic fever is an inflammatory disease that results from a delayed immune response to a streptococcal infection. Severe or untreated cases of rheumatic fever may progress to rheumatic heart disease, a potentially disabling cardiovascular disorder.
10. Infective endocarditis is a general term for infection and inflammation of the endocardium, especially the cardiac valves. Pathogenesis requires (1) endocardial damage, (2) adherence of blood-borne microorganisms to the damaged endocardial surface, and (3) formation of infective endocardial vegetations.

Manifestations of Heart Disease

1. Heart failure is when the heart is unable to generate an adequate cardiac output. Most causes of heart failure result from dysfunction of the left ventricle.
2. Left heart failure can be divided into heart failure with reduced ejection fraction (systolic) and heart failure with preserved ejection fraction (diastolic).
3. Heart failure with reduced ejection fraction (systolic heart failure) is caused by increased preload, decreased contractility, or increased afterload. These processes result in increased left ventricular end-diastolic volume and pressure that cause increased pulmonary venous pressures and pulmonary edema.
4. In addition to the hemodynamic changes of left ventricular failure, there is a neuroendocrine response that tends to exacerbate and perpetuate the condition.
5. The neuroendocrine mediators of heart failure include the sympathetic nervous system and the renin-angiotensin-aldosterone system; thus diuretics, beta-blockers, and angiotensin-converting enzyme (ACE) inhibitors are important components of the pharmacologic therapy.
6. Heart failure with preserved ejection fraction (diastolic heart failure) is a clinical syndrome characterized by the symptoms and signs of heart failure, a preserved ejection fraction, and abnormal diastolic function.
7. Heart failure with preserved ejection fraction means that the left ventricular end-diastolic pressure is increased, even if volume and cardiac output are normal.
8. Right heart failure is the inability of the right ventricle to provide adequate blood flow into the pulmonary circulation and can result from left heart failure or pulmonary disease.
9. High-output failure is the inability of the heart to adequately supply the body with blood-borne nutrients, despite adequate blood volume and normal or elevated myocardial contractility
10. A dysrhythmia (arrhythmia) is a disturbance of heart rhythm. Dysrhythmias range in severity from occasional missed beats or rapid beats to disturbances that impair myocardial contractility and are life-threatening.
11. Dysrhythmias can be categorized into atrial arrhythmias, ventricular arrhythmias, and sinus node dysfunction and conduction disorders.

Chapter Outline

OUTLINE

Congenital Heart Disease, 1109
- Classification of Congenital Heart Disease, 1109
- Defects With Increased Pulmonary Blood Flow, 1110
- Obstructive Defects, 1114
- Defects With Decreased Pulmonary Blood Flow, 1117
- Mixing Defects, 1119

Acquired Cardiovascular Disorders, 1122
- Heart Failure, 1123
- Kawasaki Disease, 1124
- Pediatric Hypertension, 1125

Cardiovascular disorders in children are classified as congenital or acquired. Congenital heart disease (CHD) is the most common. Early screening and improved surgical and perioperative care have resulted in improved outcomes. Acquired heart diseases such as Kawasaki disease and hypertension in children continue to present challenges to the practitioner. Although guidelines for diagnosing acquired diseases are available, work is still needed in developing standards of treatment and long-term follow-up protocols.

Congenital Heart Disease

Congenital heart disease(CHD) is a structural abnormality of the heart and (or) great vessels that is present at birth. Incidence varies

from 0.8% to 1.2% of live births worldwide. While several environmental and genetic risk factors have been linked to CHD, only 15% of cases can be attributed to a specific cause.[1] The relative lack of identifiable and modifiable environmental risks for most cases has limited the effectiveness of prevention measures for CHD. The environmental factors that have been linked to CHD are typically maternal and are listed with the associated congenital heart defect in Table 33.1.[2,3]

Table 33.1

Environmental Factors Associated With Congenital Heart Defects

Cause	Type of Congenital Heart Defect
Infection	
Intrauterine	PDA, PS, COA
Systemic viral	PDA, PS, COA
Rubella	PDA, PS, COA
Coxsackie B5	Endocardial fibroelastosis
Herpesvirus, cytomegalovirus	Can infect endothelial cells and vascular endothelium
Radiation	Studies of cancer survivors reveal radiation can cause atherosclerosis; myocardial, endocardial, and pericardial disease; conduction disturbances; and endothelial vessel disease
Metabolic Disorders	
Diabetes	VSD, cardiomegaly, transposition of the great vessels
Phenylketonuria	COA, PDA
Hypercalcemia	Supravalvular AS, PS; aortic hyperplasia
Drugs	
Alcohol	TOF, ASD, VSD
Lithium	Exact effect not known
Phenytoin	Embryonic dysrhythmia and valvular

Cause	Type of Congenital Heart Defect
	heart disease
Warfarin	ASD, PDA
Peripheral Conditions	
Increased maternal age	VSD, TOF (relationship unclear)
Antepartal bleeding	Various defects (relationship unclear)
Prematurity	PDA, VSD
High altitude	PDA, ASD (increased incidence)

Cause	Type of Congenital Heart Defect
Infection	
Intrauterine	PDA, PS, COA
Systemic viral	PDA, PS, COA
Rubella	PDA, PS, COA
Coxsackie B5	Endocardial fibroelastosis
Herpesvirus, cytomegalovirus	Can infect endothelial cells and vascular endothelium
Radiation	Studies of cancer survivors reveal radiation can cause atherosclerosis; myocardial, endocardial, and pericardial disease; conduction disturbances; and endothelial vessel disease

Antepartal bleeding	Various defects (relationship unclear)
Prematurity	PDA, VSD
High altitude	PDA, ASD (increased incidence)

AS, Aortic stenosis; *ASD*, atrial septal defect; *COA*, coarctation of the aorta; *PDA*, patent ductus arteriosus; *PS*, pulmonary stenosis; *TOF*, tetralogy of Fallot; *VSD*, ventricular septal defect.

Several specific chromosomal aberrations are associated with CHD, although the mechanism of causation is often unknown (Table 33.2). The incidence of CHD is three to four times higher in siblings of affected children, and chromosomal defects account for about 6% of all cases of CHD. Down syndrome (trisomy 21), trisomies 13 and 18, Turner syndrome, 22q11.2 deletion syndrome (DiGeorge/Velofacialcardio syndromes),[4] and cri du chat syndrome (chromosome 5p deletion syndrome) have been associated with a relatively high incidence of heart defects.

Table 33.2

Congenital Heart Disease in Selected Fetal Chromosomal Aberrations

Conditions	Incidence of CHD (%)	Common Defects (in Decreasing Order of Frequency)
5p (cri du chat syndrome)	25	VSD, PDA, ASD
Trisomy 13 syndrome	90	VSD, PDA, dextrocardia
Trisomy 18 syndrome	99	VSD, PDA, PS
Trisomy 21 (Down syndrome)	50	AVSD, VSD
Turner syndrome (XO)	35	COA, AS, ASD
Klinefelter variant (XXXXY)	15	PDA, ASD
22q11.2 deletion syndrome	75–80	TOF, PA + VSD, IAA, truncus arteriosus, VSD, Aortic arch anomalies

AS, Aortic stenosis; *ASD*, atrial septal defect; *AVSD*, atrioventricular septal defect; *COA*, coarctation of the aorta; *PDA*, patent ductus arteriosus; *PS*, pulmonary stenosis; *VSD*, ventricular septal defect; *TOF*, Tetralogy of Fallot; *PA*, pulmonary atresia; *IAA*, interrupted aortic arch.

From Park MK. *Pediatric cardiology for practitioners*, 6th edition. St. Louis: Mosby; 2014.

The diagnosis and management of CHD continues to improve with the use of fetal echocardiography for early detection, early interventional catheterization, neonatal pulse oximetry pre discharge screening,[5] and refined surgical repair. However, children who survive corrective surgery for their CHD continue to be at risk for long-term morbidity, including heart failure, obstructive pulmonary disease, neurologic diseases, and psychiatric illness.[6] For many types of CHD, endocarditis prophylaxis is recommended, especially after transcatheter or surgical intervention.

Classification of Congenital Heart Disease

Congenital heart diseases can be broadly categorized into those that are most commonly associated with normal oxygen delivery to tissues (acyanotic) and those that are most often associated with a decrease in oxygen delivery to tissues (cyanotic). This categorization is not absolute however, because severe cases of any type of cardiac defect may eventually lead to heart failure and cyanosis. There are four major subcategories based on whether they increase or decrease pulmonary blood flow, obstruct blood flow, or mix desaturated and saturated blood within the chambers or great arteries (Fig. 33.1). By classifying lesions into these categories, one can predict the clinical and physiological sequelae of the type of congenital heart defect based on its category.

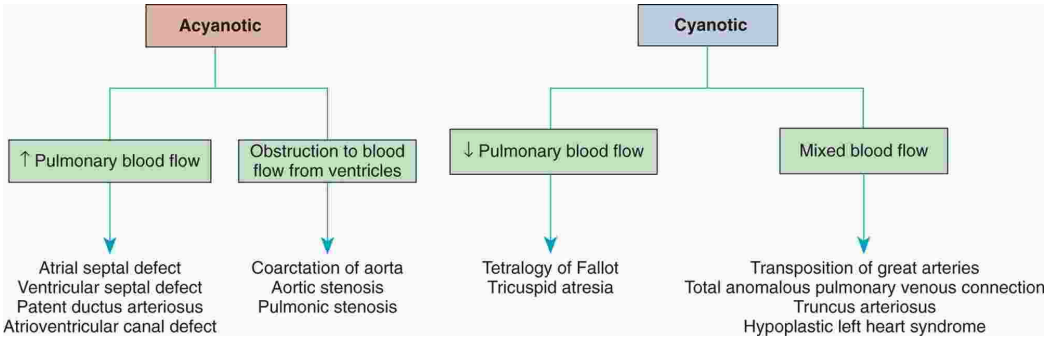

FIG. 33.1 Classification Systems for Congenital Heart Disease.
Individual diseases are discussed later in this chapter. (From Hockenberry MJ, Wilson D. *Wong's nursing care of infants and children*, 10th edition. St. Louis: Mosby; 2016.)

Two hierarchy diagrams show the classification systems for congenital heart disease. Left panel, acyanotic. Increased pulmonary blood flow results in the following: atrial septal defect, ventricular septal defect, patent ductus arteriosus, and atrioventricular canal defect. Obstruction to blood flow from ventricles results in the following: coarctation of aorta, aortic stenosis, and pulmonic stenosis. Right panel, cyanotic. Decreased pulmonary blood flow results in tetralogy of fallot and tricuspid atresia. Mixed blood flow results in transposition of great arteries, total anomalous pulmonary venous connection, truncus arteriosus, and hypoplastic left heart syndrome.

In normal cardiac physiology, the movement of blood through the right side of the heart and into the pulmonary system is separate from the blood flow through the left side of the heart into the systemic circulation (Fig. 33.2A). Abnormal movement from one side of the heart to the other is termed a **shunt**. A shunt typically occurs through a defect or hole between two chambers or blood vessels or through a patent ductus arteriosus (PDA). The direction of this shunt depends on multiple anatomic and physiologic factors, including pressure differences or the presence of any obstructions in the chambers or blood vessels distal to the defect.
